2. These reactions often have high explosive velocities, which means that it is usually necessary to work with amounts of the order of 10^{-3}–10^{-4} mole.

3. A characteristic feature of low-temperature reactions involving addition of halogens to olefins is that they are quantitative and specific. As a rule only one substance (addition product) is obtained in a yield close to 100%. This may be compared with reactions in gas and even in liquid phases at elevated temperatures[16] in which a large amount of substitution products is usually obtained.

4. Low-temperature reactions are highly selective. For example, it has been shown that chlorine adds readily to ethylene but not to acetylene. Nitrogen tetroxide adds readily to propene but not to ethylene. Hydrogen bromide adds to isobutene in the dark and to propene only under the action of ultraviolet light, etc.

5. At low temperatures each reaction usually has a definite characteristic (critical) temperature, as a rule associated with a phase transition (fusion, polymorphic

transformation, crystallisation). It is interesting that in the reaction of nitrogen tetroxide (N_2O_4) with olefins the reaction temperature depends on the conditions of heat exchange between the system and the surrounding medium[44]. Improvement of heat exchange displaces the onset of reaction towards higher temperatures and conversely, when heat exchange with the surrounding medium is poor, the reaction occurs at lower temperatures. This effect of heat exchange conditions on reaction rate is usually characteristic of reactions which proceed by a thermal explosion mechanism[16].

In an examination of the peculiarities of spontaneous low-temperature reactions it is necessary to consider the origin of reactions at low temperatures and their mechanism. The solution of these problems was facilitated by a comparative study of the addition reactions of halogens to olefins at low and normal temperatures. Let us consider as an example the bromination of cyclohexene in carbon tetrachloride solution[45]. Study of this reaction in the temperature range 263–313°K (Fig. 11) showed that it has a negative temperature coefficient and that the reaction rate follows the equation $W = k(Br_2)^2(C_6H_{10})$. These findings can be explained on the hypothesis that the reaction proceeds via a stage in which an intermediate molecular complex forms by the mechanism

$$(1)\ Br_2 + C_6H_{10} \underset{k_2}{\overset{k_1}{\rightleftarrows}} [Br_2 \cdot C_6H_{10}];\quad (2)\ [Br_2 \cdot C_6H_{10}] + Br_2 \rightarrow \text{reaction product}, \qquad (I)$$

$$(1')\ 2Br_2 + C_6H_{10} \underset{k_2}{\overset{k_1}{\rightleftarrows}} [C_6H_{10} \cdot 2Br_2];\quad (2')\ [C_6H_{10} \cdot 2Br_2] \overset{k_3}{\rightarrow} \text{reaction product}, \qquad (II)$$

where $[Br_2.C_6H_{10}]$ or $[C_6H_{10}.2Br_2]$ are unstable molecular compounds. Application of the steady-state method to both mechanisms results in the same expression for the rate of consumption of bromine:

$$(3)\ -\frac{d(Br_2)}{dt} = Kk_3(Br_2)^2(C_6H_{10}),$$

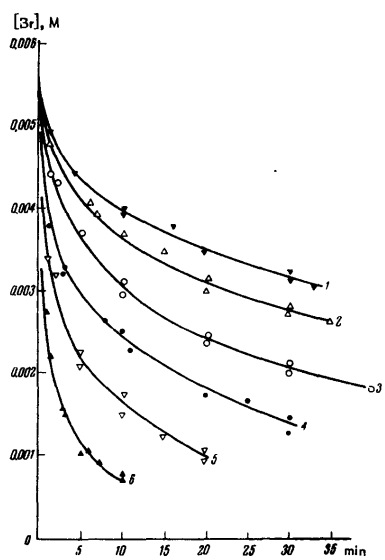

Fig. 11. Kinetic curves for the bromination of cyclohexane in carbon tetrachloride at different temperatures (°K):
1) 313; 2) 303; 3) 293; 4) 283; 5) 273; 6) 263.

where $K = k_1/k_2$ is the equilibrium constant for reactions (1) and (1'). This expression was obtained on the assumption that $K \ll 1$, and is consistent with the experimental order of reaction. Eqn. (3) shows that the experimental rate constant results from a combination of several constants:

$$k_{exp} = \frac{k_1k_3}{k_2} = \frac{k_1^0e^{-\frac{E_1}{RT}}k_3^0e^{-\frac{E_3}{RT}}}{k_2^0e^{-\frac{E_2}{RT}}} = k_0e^{-\frac{E_1-E_2}{RT}}e^{-\frac{E_3}{RT}} = k_0e^{\frac{\Delta H+E_3}{RT}},$$

where $\Delta H = E_1 - E_2$ is the heat of the complex-formation reaction. It may be assumed that over a small temperature range

$$\frac{\partial \ln k_{exp}}{\partial T} = \frac{\Delta H + E_3}{RT^2}.$$

The formation of molecular complexes occurs with evolution of heat ($\Delta H < 0$) and, when $E_3 < |\Delta H|$ and $E_3 + \Delta H < 0$, the rate of reaction falls with increase in temperature, i.e. there is a negative temperature coefficient.

The existence of a negative temperature coefficient is evidence that the reaction occurs in stages and shows that the heat of the rate-limiting stage, involving the formation of an intermediate, is higher than the activation energy for the conversion of the intermediate into the final reaction product. In a study of this reaction by differential thermal analysis (DTA) in a special vacuum reaction vessel it was shown that the reaction is nearly of first order. In the DTA method the observed temperature rise was mainly due to the heat of the rate-limiting stage. The result obtained is probably an indication that mechanism (II) is to be preferred for the bromination of cyclohexene.

The data on the kinetics of the bromination of cyclohexene in Fig. 11 show that the rate of reaction increases in accordance with the Arrhenius law as the temperature is reduced, but with, as it were, a negative activation energy $E = -12$ kcal mole^{-1}. This value is comparable to the heat of bromination of cyclohexene but exceeds the heat of formation of donor–acceptor complexes available in the literature, which are usually 1–5 kcal mole^{-1}.[13] This inconsistency suggests that in the halogenation reactions the intermediate molecular complex, whose structure is similar to that in the pre-reaction stage, is an aggregate (self-solvate) consisting of several bromine and cyclohexene molecules. As the temperature is reduced, the probability of the formation of such aggregates increases.

If the rate of halogenation of olefins is limited by the complex-formation stage, it follows in principle from the mechanism A + B $\rightleftharpoons$ (AB) $\rightarrow$ final product (A and B are the olefin and the halogen and AB is the intermediate complex) that conditions are possible in which the complex does not form and therefore the halogenation reaction cannot occur under the usual conditions. The bromination of tetrachloroethylene may be quoted as an example.

It has been demonstrated spectrophotometrically that at room temperature in the dark and in the absence of oxygen tetrachloroethylene does not react with bromine in carbon tetrachloride solution. When the mixture was kept at 253°K for 1.5 h, dibromotetrachloroethane was formed in 18% yield. This example clearly demonstrates the role of low temperature. In contrast to the usual postulates of classical chemical kinetics and our everyday experience, a reaction which does not take place in the liquid (condensed) phase begins to occur at a high rate when the temperature

is reduced. The occurrence of the bromination of tetrachloroethylene at low temperatures is evidence of the existence of highly active intermediate compounds responsible for the reaction and stable only at low temperatures. In the present author's view, such compounds are complexes of the donor–acceptor type.

On the other hand, it is also evident from the mechanism $A + B \rightleftharpoons (AB) \rightarrow$ final product that conditions may be found in which the relative rates of the individual reactions are such that the main effect is accumulation of the complex. When this is so, the use of low temperatures makes it possible to separate the complex-formation stage from the stage involving the conversion of the complex into final products. As an example, the results of a study of the bromine–propene system may be quoted[39].

Fig. 12 presents the results of the thermographic analysis of the bromine–propene mixture, with the components frozen into separate layers. The rapid reaction was preceded by two exothermic processes, one of which followed immediately after fusion of propene and occurred in the range between -185° and -156°C. It was shown that the evolution of heat in this temperature range is due to the dissolution of solid bromine in liquid propene and the formation of bromine–propene complexes, the heat of formation being about 5 kcal mole^{-1}. The second exothermic process occurred in the range between -156° and -125°C and preceded the reaction. This process may be associated with the segregation of the complexes into a separate phase and their association.

The use of low temperatures not only permits the separation of the stages involving the formation of the complex and the final product but also allows the accumulation of the intermediate complexes. For example, this can be done by repeated heating and cooling of the bromine–propene system in the temperature range between -196° and -156°C. The accumulation of complexes in this process is indicated by the fact that the amount of propene which may be evacuated from the bromine–propene system, for example at -145°C, decreases with the number of the above operations. The thermograms in Fig. 12 show that preliminary accumulation of complexes to a sufficiently high concentration results in the occurrence of rapid explosive reactions at -125°C. A relation between the complex-formation reaction and the bromination of propene is suggested by the fact that the magnitude of the exothermic peak at -125°C, corresponding to the reaction, depends on the number of heating and cooling cycles of the mixture in the temperature range between -196° and -156°C.

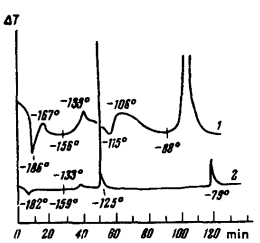

Fig. 12. Thermographic curves for bromine–propene mixtures:
1) specimens frozen in separate layers;
2) after preliminary mixing and accumulation of complex (temperatures in °C).

Additional proof of the participation of unstable molecular compounds in low-temperature halogenation of olefins was obtained with the aid of electronic absorption spectra, using bromination of propene as an example. In contrast to thermography, the spectroscopic method makes it possible to follow in greater detail the changes occurring in the initial molecules and in many cases helps elucidate the nature of the complexes formed[46].

The ultraviolet spectra of solid condensed films of bromine, propene, propane, and 1,2-dibromopropane were obtained with an SP-700 recording spectrophotometer. The test substances and their mixtures in various proportions were frozen in a vacuum cuvette on a quartz plate cooled with liquid nitrogen under conditions approximating to those in a molecular beam. The temperature of the film was measured with a thermocouple. At low temperatures propane is almost transparent up to 200 mμm. In the spectrum of solid propene there is a weak band in the region of 217–250 mμm. In the spectrum of solid bromine in amounts of 10^{-6} mole there is a band with an absorption maximum in the region of 280 mμm. When bromine is highly diluted with propane (1.8×10^{-7} mole of bromine and 4×10^{-4} mole of propane), the absorption in this region falls to an optical density of 0.01.

In the study of the bromine–propene system the initial components were frozen on to a cooled quartz plate in several successive layers. To ensure a more uniform distribution, bromine was diluted with propane in a number of experiments. The spectra of the bromine–propene system are presented in Fig. 13, which shows that in the spectrum of the mixture where the bromine was diluted with

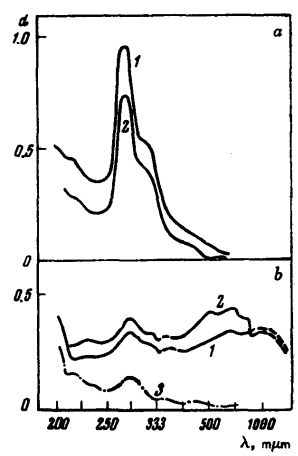

Fig. 13. Ultraviolet absorption spectra of the bromine (6×10^{-8} mole)–propene (9×10^{-4} mole) system:
a) spectra in the presence of added propane: 1) at 80°K; 2) mixture kept at 80°K for 1.5 h and then heated twice to 100°K [above m.p. of propene (83°K)], spectrum recorded at 73°K;
b) spectra of bromine–propene mixture (without propane): 1) at 80°K; 2) after 1.5 h at 80°K; 3) after heating to 100°K and recooling to 80°K, spectrum recorded at 80°K. The wavelength scale on the SP-700 spectrophotometer is expressed in cm^{-1}. In the Soviet chemical literature it is usual to express the wavelengths in the visible and ultraviolet spectra in millimicrons. The recalculation results in a non-linear scale.

propane there is an intense band in the region of 274 mμm. On the long-wavelength side of the band there is a distinct inflection in the region of 312.5 mμm. The absorption at the point of inflection is smaller at least by a factor of two than in the maximum of the band. When the temperature is raised, the band widens somewhat and its intensity falls irreversibly.

The spectrum of bromine–propene mixtures differs radically from that of the bromine–propane system. The much higher absorption intensity in the mixtures with propene indicates a pronounced donor–acceptor interaction between the bromine and propene. It may be supposed that in the bromine–propene system the bands in the region 274–312 mμm are due to 1:1 and 1:2 molecular charge-transfer complexes. The energy of an optical transition from the ground to an excited state in such donor–acceptor complexes is described by the approximate equation

$$h\nu = I - E - \frac{e^2}{r},$$

where I is the ionisation potential of the donor, E the electron affinity of the acceptor, and e^2/r the energy of the interaction of the components of the system, bearing opposite charges, at a distance r.[13,19] In binary complexes of bromine with various acceptors r varies in the range 3.6–4.5 Å, depending on the mutual disposition of the donor and acceptor molecules[22]. Adopting the average value of 4 Å for r and 1.2 eV for the electron affinity of bromine[22], the ionisation potential of propene was estimated as 9.3 eV from Eqn. (1) for the charge-transfer spectrum at $h\nu$ = 278 mμm. The satisfactory correlation of this value with $I_{C_3H_6}$ = 9.65 eV found for propene in the gas phase confirms the validity of the hypothesis that in the bromine–propene mixture molecular charge-transfer complexes are responsible for the absorption in the region 280–310 mμm. In the condensed phase the ionisation potential of the molecule should be lower than in the gas phase. This may be due to a certain energy gain resulting from the polarisation of the surrounding molecules by the positively charged ion and the free electron.

In the bromine–propene system undiluted by propane there are a number of new bands in addition to those at 278–312 mμm. The greatest interest attaches to a broad band in the region of 500–1000 mμm (Fig. 13, curve *1*). The intensity of this band is higher than that in the region of 278 mμm.

It is interesting that, on keeping the mixture at temperatures close to 77°K for a specified time, the intensity of the band in the region of 500–1000 mμm increases. On the other hand, if the mixture temperature is raised to 100°K (m.p. of propene is 88°K), the absorption in the range 500–1000 mμm vanishes irreversibly (Fig. 13*a*, curve *3*). The band in the region of 278 mμm persists to some extent. These results show that intermediate compounds which absorb between 500 and 1000 mμm are mainly responsible for the low-temperature bromination of propene.

The presence of the broad band between 500 and 1000 mμm in the spectrum of the bromine–propene mixture at low temperatures is evidence, in the author's view, that not binary complexes but strongly linked reactive aggregates of the type DADADADA, where D is the donor and A the acceptor, are responsible for the absorption. The existence of similar stable compounds with a chain structure at low temperatures has been described in the literature[47]. On energy grounds, at low temperatures such aggregates are more likely than binary compounds.

In associated compounds absorbing between 500 and 1000 mμm the molecular and intermolecular distances are markedly altered, with loosening of the double bond and its pronounced polarisation. Preliminary data from infrared spectra apparently confirm this conclusion because bands at lower frequencies have been detected in the spectra of frozen solid mixtures of bromine and propene in the region of double bond stretching vibrations (1632 cm^{-1}).

The formation of highly polarised associated molecular compounds of the donor–acceptor type in bromine–propene mixtures at low temperatures can probably facilitate electron transfer and the spontaneous appearance of ionised states. It is seen from the data in Fig. 13*b* that the energy of the non-equilibrium absorption of a light quantum (electron-transfer spectrum) at the long-wavelength edge of the absorption band of the aggregates at 2 μm is already as much as 0.5 eV. The energy of thermal excitation may be smaller than this and therefore it is reasonable to suppose that at low temperatures in strongly interacting complexes, formed during condensation with considerable evolution of heat, ions or radical-ions, facilitating the subsequent reaction, may form spontaneously.

The formation of molecular complexes with charge transfer probably plays a definite role also in liquid-phase halogenation of olefins at room temperature. This is indicated by the negative temperature coefficient characteristic of these reactions and the correlation between the rates of halogenation of olefins and their ionisation potentials I observed by the present author. As a rule, the lower the ionisation potential of the olefin, the higher is the rate of halogenation. For example the rates of bromination of various olefins increase in the series

ethylene	< propene	< but-1-ene	< isobutene	< trimethylethylene	< tetramethylethylene.
10.51	9.65	9.61	9.35	8.80	8.30 eV

A similar variation occurs also for olefin chlorination reactions. It was to be expected because a decrease of ionisation potential is accompanied by an increase in the concentration of complexes, in the degree of electron transfer, in dipole moment, etc. and ultimately the appearance of ionised states is facilitated. Definite correlations between olefin ionisation potentials, their polarity, and reaction temperatures obtain also in the low-temperature nitration of unsaturated compounds with nitrogen tetroxide.

It may be assumed that under the same conditions of heat exchange with the surrounding medium the reactivity of the olefin is higher the lower is the temperature of the onset of explosive reaction. The data in Table 6 suggest the following reactivity series for olefins in low-temperature nitration with nitrogen tetroxide

	isobutene	< but-1-ene	< propene,	hex-1-ene
Ionisation potential	9.35	9.61	9.65	9.59
Dipole moment	0.49	0.37	0.35	0.34

The higher is the polarity of the olefin, the lower is the temperature at which it can be nitrated. However, examination of more extensive experimental data shows

that the reactivity of olefins in relation to halogens and nitrogen tetroxide is not entirely determined by the dipole moment,

In the investigation of spontaneous low-temperature reactions it is important to obtain direct experimental proof of the formation of active centres when simple valence-saturated molecules interact in the absence of light. The author was able to demonstrate by the ESR method the formation of radicals in the interaction between tetranitromethane and cyclohexene, tetramethylethylene, and certain other olefins. The experiments were made in the dark at room temperature. Fig. 14 presents as an example the ESR spectrum obtained for mixtures of tetranitromethane with C_6H_{10}. It was shown spectrophotometrically that tetranitromethane can form charge-transfer complexes with olefins. The fact that an ESR signal can be obtained from such mixtures in the absence of light is an indication that, even in the absence of light, there is a complete electron transfer in the system, resulting in the formation of paramagnetic radical states. The ESR spectrum in Fig. 14 has a hyperfine structure consisting of five lines which probably indicates the interaction of the unpaired electron with the nuclei of two nitrogen atoms.

In conclusion it must be emphasised that the sum total of the experimental data, obtained mainly for halogenation and nitration of olefins, permits an examination of the mechanism of fast spontaneous low-temperature chemical reactions in the most general form. The first stage of the addition reaction occurs during the condensation of the starting materials and results mainly in the formation of molecular 1:1 or 1:2 compounds. In the halogenation of olefins the formation of such complexes constitutes only the initial stage of the reaction and cannot as a rule lead to the spontaneous occurrence of the reaction at low temperatures. The results of the spectroscopic study of the bromine–propene system show that at low temperatures not only molecular 1:1 or 1:2 compounds but also highly polar aggregates can form. The existence of such aggregates, which probably have a chain structure, is thermodynamically more favourable at low temperatures. Their formation should be accompanied by the evolution of considerable amounts of heat and may lead to the spontaneous appearance of active centres which initiate the addition reaction. The formation of final products usually occurs at higher temperatures at the instant of a phase transition. For this reaction to occur, it is probably necessary that a small activation barrier, associated with the elastic forces of the lattice, be overcome. The most favourable conditions for this occur in a phase transition, where molecules require a certain mobility. The presence of the previously formed chain structure at the instant of the phase transition retards molecular rotation and preserves their orientation which is favourable for the addition reaction. As a result, only one product is formed in quantitative yield. When the olefins and the halogen are frozen in separate layers, the stages involving the formation of the complexes and the final products may be separated. When the components are thoroughly mixed, for example on condensation under molecular beam conditions, all the stages merge and the halogenation reactions occur at temperatures close to that of liquid nitrogen. The occurrence of the reaction via a series of successive stages influences the activation energy for the overall process. The formation of unstable and probably strongly solvated exothermic molecular compounds decreases the effective activation energy by their heat of formation. When aggregates are formed, this effect is very considerable and may greatly facilitate low-temperature reactions.

Fig. 14. ESR spectrum of a mixture of tetranitromethane and cyclohexane at 293°K.

The results obtained suggest also a somewhat different mechanism for reactions in which there is donor–acceptor interaction at low temperatures. Apparently the role of molecular compounds and their aggregates does not consist solely in the facilitation of the initiation of the active centres, and their formation in all probability results in the conversion of the two-component system into a system of oriented molecules in which extensive electron transfer takes place and all the conditions required for reactions which proceed by the collective interaction mechanism, proposed earlier by Semenov to explain rapid low-temperature polymerisation reactions without activation energy[48], are thereby provided. In a polarised aggregate conditions are set up during the electron transfer process, as a result of the presence of markedly loosened and readily broken bonds, in which there is simultaneous dissociation of the double bonds and the bonds in the halogen molecules, new carbon–halogen bonds being formed. If the redistribution of electron density between the halogen and olefin molecules is insufficient for spontaneous propagation of the reaction by the above mechanism, then conversion of the chain, formed as a result of the intermolecular interaction, into the final product is possible by way of energy chains. The reactions examined are exothermic and are accompanied by the evolution of a considerable amount of heat. The energy evolved in the formation of the aggregate of the initial molecules can readily migrate at low temperatures along the chain of strongly interacting and favourably oriented molecules. As a result, neighbouring molecular complexes may be excited, and the entire chain may be converted into the final product virtually without activation energy.

Thus study of chemical reactions at low temperatures permits a closer approach to the solution of the principal problem in chemistry — the elucidation of the fundamental mechanism of the interaction of two species, and opens a route to fundamentally new chemical syntheses.

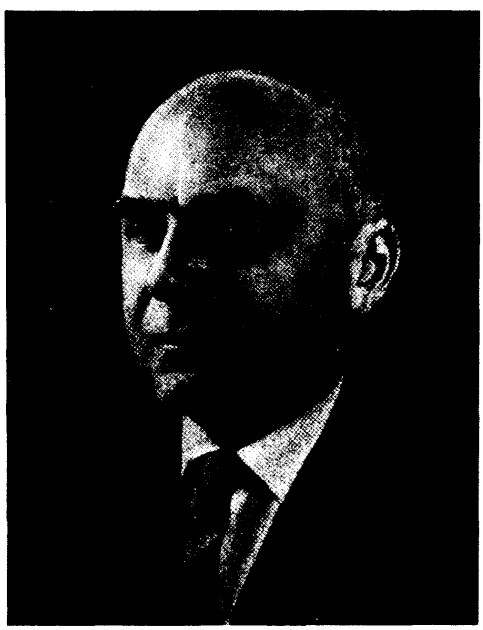
RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

May 1966



ALEKSANDR NIKOLAEVICH TERENIN

Deeply respected Aleksandr Nikolaevich!

The Editorial Board of the journal "Uspekhi Khimii" congratulates you heartily on your seventieth birthday. Your outstanding investigations in the field of physical chemistry have entered into the gold reserves of chemical science. The Editorial Board of "Uspekhi Khimii" is grateful to you for constant active assistance, and wishes you, dear Aleksandr Nikolaevich, good health and many years of life and creative work.

INTRODUCTION

Compounds of beryllium with other metals are of great scientific and practical interest, since many of them have high melting points, relatively low specific gravity, high hardness, and also specific nuclear characteristics, which are united in a series of beryllides with specified properties.

Several equilibrium diagrams of beryllium–metal systems have now been investigated, the crystal structures of many beryllide phases have been studied, some of their physical, chemical, and technological properties have been studied, and definite ideas are beginning to accumulate about their crystal chemistry, electronic structure, and chemical bonding, which makes it possible to sum up all these investigations and to survey the information about compounds of beryllium with metals which is scattered in the literature.

I. BERYLLIDES OF GROUP I METALS

A. BERYLLIDES OF THE ALKALI METALS

The reaction of beryllium with the alkali metals has been little investigated[1]. Beryllium is stable up to 600°† in molten lithium, sodium, and potassium, but starts to dissolve at higher temperatures, owing to oxidation by the oxygen present in these metals[2]. According to the data given in a review[1], with the alkali metals (other than lithium) the size factor is so unfavourable that the probability of alloys being formed with beryllium, and also the possibility of their being miscible in the liquid state, are very small. Nevertheless, there have been reports[1,3] of the existence of potassium beryllide Be_2K, having $MgCu_2$-type cubic structure and of its being apparently quite a stable compound. There is no information about alloys of beryllium with sodium, rubidium, or caesium[4–6].

B. BERYLLIDES OF THE METALS OF THE COPPER SUBGROUP

Beryllium–copper system. Alloys of beryllium and copper have been studied in detail in connection with their great practical value (the beryllium bronzes). The equilibrium diagram of the Be–Cu system, first described in detail by Hansen[7] in the region from 0 to 35% Be, was subsequently repeatedly investigated and refined[8–14], the results being surveyed in reviews[1,15,16]. Fig. 1 shows the diagram of this system after Vol[15]. There are three beryllide phases: CuBe in the region of the β phase, $CuBe_2$, and $CuBe_3$ in the region of the δ phase; the existence of the phase Cu_2Be reported by Oesterheld[17] has not been confirmed by subsequent investigations[1].

The diagram shown in Fig. 1 has been confirmed completely by studies of diffusion in the Be–Cu system[18]. It was shown that the greatest diffusion coefficients and the least activation energy correspond to phases γ and δ, that is, to the approximate region of the compound CuBe.

† Temperatures are in °C throughout this article, except when °K is specifically mentioned (Ed. of Translation).

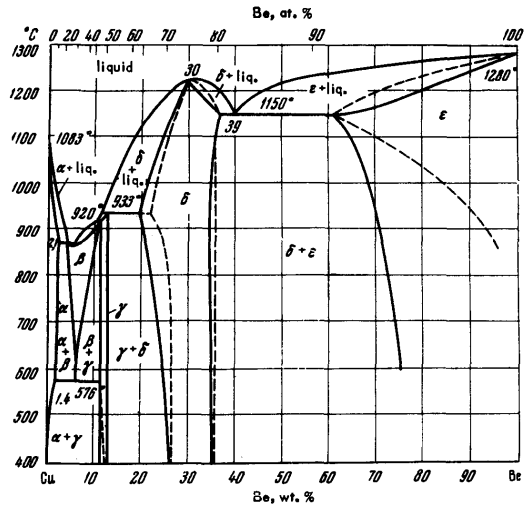

Fig. 1. Equilibrium diagram of the beryllium–copper system.

The physical and chemical properties of the copper beryllides (except for hardness) have hardly been studied (Table 1). The hardness of the quenched alloys whose compositions almost precisely correspond to beryllides[10], is relatively high and rises from CuBe to $CuBe_2$, then falls again slightly for $CuBe_3$. All the beryllides have a homogeneity region, the breadths of which have still not been found with sufficient accuracy. The properties (electrical resistivity, Hall constant, carrier current mobility) of copper–1.75 wt.% beryllium alloy, which is a mixture of the α and γ phases, have been studied in detail[19]. The resistivity of such alloys is ~7 $\mu\Omega$ cm.

It is difficult to prepare copper beryllides by melting the components together, owing to the great loss of beryllium at high temperatures; the best results are secured by making use of previously prepared copper–beryllium hardeners. The simplest method of making the beryllides is by powder metallurgy: by sintering copper and beryllium powders; according to Raub and Plate[20] the reaction between the compressed powders has begun even at 678°.

The beryllium–silver system has been studied[17,21,22]; Winkler[22] obtained the most reliable results, from which the diagram in Fig. 2 is constructed. There are two beryllides in the system: $AgBe_2$[23] and $AgBe_{12}$[24]. Both these phases are cubic, but $AgBe_2$ has a rather wider homogeneity region. Powder metallurgy is the most convenient method for obtaining silver beryllides, especially hot pressing of mixtures of the powders.

Beryllium–gold alloys were investigated by Winkler[22] and Chatterjee[25,26]; Fig. 3 shows the equilibrium diagram of the Au–Be system according to Winkler[22] and Fig. 4 the accurate phase diagram‡ of this system[26]. The following beryllide phases have been found in the system and identified by X-ray diffraction[1,26]: Au_3Be (β), Au_2Be (γ), AuBe (δ), $AuBe_3$ (ϵ), and $AuBe_5$ (η), and also, with great probability, phase $AuBe_{12}$, which is stabilised on replacing some of the Au atoms by W atoms[24]. At the same time the existence of the beryllide Au_4Be_3, stated by

‡ α is a solid solution of Be in Au, θ a solid solution of Au in Be.

TABLE 1. Properties of the beryllides of metals of the copper subgroup.

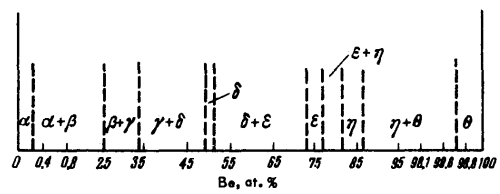

Fig. 4. Phase diagram of the gold–beryllium system.

Winkler, was not confirmed. The physical properties of the gold beryllides have not been studied much; it is known only that they exhibit great brittleness. Gold beryllides are usually prepared by powder metallurgical methods, particularly by hot pressing in a vacuum [31].

II. BERYLLIDES OF GROUP II METALS

A. BERYLLIDES OF MAGNESIUM AND THE ALKALINE EARTH METALS

Many attempts to alloy beryllium with magnesium [32,33] have failed, owing to the volatility of magnesium, and success was achieved [34,35] only by melting the metals in hydrogen under a pressure of ~ 100 atm. Later Baker and Williams [36] obtained $MgBe_{13}$, still the only compound of this system; it decomposes into the elements in a vacuum at 950°, and the authors showed that the eutectic between this compound and magnesium melts at a temperature very close to the melting point of magnesium [1,37]. Beryllium–magnesium alloys can be obtained by the methods of powder metallurgy [38] — either by impregnating a pressed blank of beryllium powder at 750° under argon, or by diffusion of magnesium from magnesium foil around a compact pressed from beryllium powder at 4.8 tf cm^2; the diffusion is also carried out at 750°.

Beryllium–calcium alloys have been obtained [32] heating solid beryllium with molten calcium; a beryllium–calcium compound $CaBe_{13}$ was observed. This compound

has been obtained[39] by the reduction of beryllium oxide with calcium and shown to be extremely stable.

Both the beryllides $MgBe_{13}$ and $CaBe_{13}$ are f.c.c., with parameters 10.166 and 10.312 Å respectively[36]. They are isomorphous with $NaZn_{13}$.[40]

There is no information about beryllides of strontium, barium, and radium.

B. BERYLLIDES OF METALS OF THE ZINC SUBGROUP

Beryllium–zinc alloys have not been obtained, owing to the high volatility of zinc, even in argon under pressure[11]. According to old information[41], beryllium does not dissolve in mercury and does not form an amalgam with it. It has been stated[42] that an amalgam was obtained at the mercury cathode on electrolysis of $BeCl_2$–NaCl mixtures; the possibility of the existence of the compound $BeHg_2$ is suggested in this work. It was established[43] that the solubility of beryllium in mercury rises from 1.10×10^{-6}% at 100° to 4.5×10^{-5}% at 800°. According to data given in a review[9], mercury had no action on a beryllium container in 330 h at 315°. There is no information about the interaction of beryllium and cadmium[44].

III. BERYLLIDES OF THE TRANSITION METALS

A. BERYLLIDES OF METALS OF SUBGROUP IIIa (THE RARE-EARTH ELEMENTS

In addition to lanthanum and the lanthanides, the rare-earth elements also include scandium and yttrium, which are close to the lanthanides as regards position in the Periodic System and physicochemical and geochemical features, although it is more correct to relate them to the *d* transition metals of the third and fourth periods.

Scandium beryllides. By sintering mixtures of fine scandium and beryllium (with 0.47% oxygen) powders at 1250° and then grinding the sinters and resintering, alloys of the Be–Sc system were obtained[45] in which from 0.5 at.% Sc onwards X-ray diffraction shows a phase with a structure of $NaZn_{13}$ type, isomorphous with the phases of analogous composition of yttrium and the lanthanides on the one hand, and of zirconium on the other. The melting point of $ScBe_{13}$ is above 1300°. Further investigation of the Be–Sc system[46,47] showed the presence of two more compounds; $ScBe_5$ and Sc_2Be_{17}, analogous to the corresponding beryllides of zirconium and hafnium.

Yttrium beryllides. In the Be–Y system, the diagram of which has been constructed by Lundin[48] (Fig. 5), there is one compound YBe_{13} with m.p. ~ 1920° and of $NaZn_{13}$-type structure[46,49]. Previously, the melting point of YBe_{13} had been taken as 1600° ± 300°.[50] The hardness of this compound is 870 kgf mm^{-2} (on the Knoop microhardness scale)[50,51], or 1240 kgf mm^{-2} from measurements[49] with a PMT-3 microhardness tester (100 g load). The compound is resistant to oxidation up to 1300°.[51]

Beryllides of the lanthanides. All the lanthanides form compounds MBe_{13} with beryllium[49,52,53]. Gladyshevskii and coworkers[53] obtained the beryllides MBe_{13} for all the lanthanides except Pm and Gd by melting

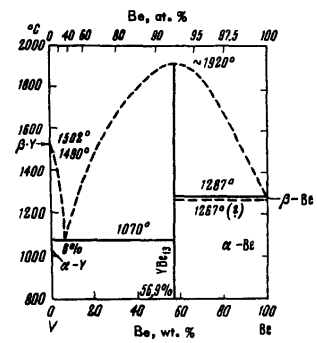

Fig. 5. Equilibrium diagram of the beryllium–yttrium system.

* Or Th_2Zn_{17}-type; and then the parameter is c = 11.25 Å (the two types are difficult to distinguish by X-rays).

distilled beryllium (99.8% purity) with metals of 95–99% purity in crucibles of BeO (or of Al_2O_3 lined with BeO) under argon in a Tammann furnace. An erbium beryllide of the same composition was obtained earlier[54]. Beryllides of a series of lanthanides were obtained[55] by reduction of the oxides with beryllium in a vacuum at 1300°:

$$M_2O_3 + 29Be = 2MBe_{13} + 3BeO.$$

Yttrium and lanthanum beryllides have been obtained[56] by sintering the metal powders with an excess of beryllium in tantalum crucibles at 1180° for 2 h in a vacuum of not below 5×10^{-6} mmHg followed by removal of the excess of beryllium by vacuum distillation at 1050° for 5 h.

In the same work the behaviour of YBe_{13} and $LaBe_{13}$ in a vacuum at temperatures up to 1550°K was investigated; it was found that the two compounds are appreciably dissociated above 1050° and equations were derived for the temperature dependence of the vapour pressure of beryllium over the beryllides during their thermal dissociation:

$$\text{for } YBe_{13}\text{: } \log P_{mm} = -\frac{16\,420}{T} + 8.30 \quad (1040\text{–}1290^\circ),$$

$$\text{for } LaBe_{13}\text{: } \log P_{mm} = -\frac{16\,600}{T} + 8.73 \quad (1080\text{–}1270^\circ).$$

Table 2 gives some information about the properties of beryllides of the rare-earth metals.

B. BERYLLIDES OF METALS OF SUBGROUP IVa

Titanium beryllides. Misch[23] obtained the compound $TiBe_2$ and showed that this beryllide crystallises in the $MgCu_2$ type. A systematic investigation of Be–Ti alloys was made by Erlich[62] on specimens obtained by sintering mixtures of titanium and beryllium powders, the sintering temperatures being: 1600° for alloys of empirical formula $TiBe_{0.4}$, 1300° for $TiBe_{0.5}$, and up to 1500° for $TiBe_{1.0}$ and alloys richer in beryllium. Erlich thinks that the composition $TiBe_{0.5}$ corresponds approximately to the eutectic of the system. X-Ray investigation of the alloys with empirical formulae from $TiBe_{0.1}$ to $TiBe_{10}$ showed that the solubility of beryllium in titanium is less than corresponds to the composition $TiBe_{0.1}$; the compounds have according to Erlich's results, the compositions TiBe, $TiBe_2$, $TiBe_4$, and $TiBe_{10}$, of which the first and the two last compounds have not been identified by X-ray diffraction. The compound TiBe evidently has a wide homogeneity region, since even the composition $TiBe_{0.75}$ gives an X-ray diagram identical with that of the alloy TiBe. The $TiBe_2$ phase has, according to Misch's data[23], a structure of $MgCu_2$ type with a parameter $a = 6.42_7$ Å, and this compound also has a certain region of homogeneity, since the determination of the lattice parameter of this phase in an alloy of conventional composition $TiBe_3$ gave a rather higher value, 6.45_6 Å. Later, $TiBe_{12}$[63] and Ti_2Be_{17}[58] were obtained directly from the elements; they are both hexagonal — the first of $ThMn_{12}$ type (sub-type $TiBe_{12}$ with 48 atoms in the unit cell) and the second of U_2Zn_{17} type. Later these phases were the subject of repeated investigations, which have been reviewed[64], and it is now accepted that $TiBe_{12}$ is not hexagonal but has a tetragonal structure of $ThMn_{12}$ type (analogous to the structures of VBe_{12} and $CrBe_{12}$), and that the Ti_2Be_{17} phase, which had been thought to be rhombohedral[65] or trigonal[66] is really hexagonal[64], with lattice parameters somewhat different from those found by Paine and Carrabine[58]. The $TiBe_{12}$ structure, as shown by Gillam and Rooksby[64] readily changes into the related Ti_2Be_{17} structure on loss of some of the beryllium atoms. The part of the diagram from Ti to $TiBe_2$ was studied[67] again in detail and the compounds TiBe and $TiBe_2$ were identified by X-ray diffraction; the general form of this part of the diagram was also confirmed. Hence the existence of at least four titanium beryllides, TiBe, $TiBe_2$, Ti_2Be_{17}, and $TiBe_{12}$, can now be considered established. Two of these are discounted in the hypothetical equilibrium diagram of the system constructed by the McQuillans[68] (Fig. 6), which now needs considerable modification.

Erlich[62] obtained titanium beryllides by sintering titanium and beryllium powders and also by arc melting in argon with a non-consumable tungsten electrode. According to Raub and Plate[20] the reaction between titanium and beryllium in powder mixtures starts at 800°. It is reported[69] that $TiBe_2$ is readily formed on heating briquettes, pressed from beryllium and titanium powders, in argon at 1200° for 1 h. $TiBe_2$ is also made by vacuum hot pressing[70] under a pressure of up to 100 kgf cm^{-2} in graphite dies coated with Al_2O_3.

Specimens of $TiBe_{12}$ with density 94%, obtained by vacuum hot pressing have high resistance to oxidation at 1260° for 100 h.[70] The high oxidation resistance of $TiBe_2$ and $TiBe_{12}$ has also been mentioned in a review[59].

Table 3 gives some information about the properties of titanium beryllides.

Zirconium beryllides. The first systematic investigation of beryllium–zirconium alloys was made by Hausner and Kalish[74] on specimens made by powder metallurgy. Lustman and Kerze[75] constructed the Be–Zr equilibrium diagram from the data of Hausner and Kalish[74], McGurty and coworkers[76], and others, but it was investigated again[77], from the results of which work Fig. 7 has been constructed. According to these results, the system contains the compounds $ZrBe_2$, $ZrBe_6$, and $ZrBe_9$, which are formed by peritectic reactions at 1235°, 1475°, and 1555° respectively, and $ZrBe_{13}$, which melts congruently at 1645°. Whereas the compositions of the beryllides $ZrBe_2$ [76-78] and $ZrBe_{13}$ [40,47] are accepted as the result of all the studies, the compositions of the beryllides with intermediate beryllium concentrations are at variance. Thus whereas some workers[76,77] take the composition of a beryllide as $ZrBe_6$ (evidently the most reliable), another[79] gives the composition as $ZrBe_5$. The beryllide of composition $ZrBe_9$, according to some[76,77] obviously corresponds to the most reliable composition Zr_2Be_{17}. Evidently, the composition $ZrBe_{16}$ given in one paper[76] is erroneous, and it obviously is the highest beryllide $ZrBe_{13}$ with beryllium impurity.

The zirconium beryllides Zr_2Be_{17} and $ZrBe_{13}$ — one of the most refractory of the transition metal beryllides (Table 4) — exhibit relatively high hardness; Fig. 8 shows the temperature dependence of the hardness of $ZrBe_{13}$.[59] There are marked differences in the hardness for $ZrBe_{13}$ obtained by different authors: 1650 kgf mm^{-2} according to Lewis[59], 790 kgf mm^{-2} according to Chubb and Dickerson[50], and 1130 kgf mm^{-2} according to Getz[79].

At high temperatures (~ 1400–1500°), Zr_2Be_{17} and $ZrBe_{13}$ show considerable resistance to oxidation[79,80], but over a certain temperature range they react rapidly with moisture, which leads to their rapid oxidation and disintegration into powder[81]. According to this work[81], hot-pressed $ZrBe_{13}$ showed this effect in the range 593–927°, but it is not observed below 538° nor above 982° in tests lasting 100 h. In this connection there have been several detailed investigations of the oxidation of $ZrBe_{13}$ in the medium-temperature range; they are cited in Getz' review[79]. In particular, it has been shown that the oxidation proceeds mainly inside the grain, although the oxidation products are partly liberated at the grain boundaries;

the stresses created by the formation of the oxides can bring about the destruction of the beryllides. That this takes place in the medium-temperature region is compared with the fact that at 984–1093° $ZrBe_{13}$ partly loses beryllium, being converted into Zr_2Br_{17} (a layer of which is situated between the $ZrBe_{13}$ and the oxide layer)[81], which has a thermal expansion coefficient quite different from that of $ZrBe_{13}$. The addition of 0.35–0.45 wt.% Al to $ZrBe_{13}$ brings about a sharp rise in its oxidation resistance in the middle-temperature region, both in dry and in moist (dew point 14°) air, at the cost of some deterioration in high-temperature strength, and a marked increase in room-temperature strength. It was shown in this work that aluminium is very slightly soluble in $ZrBe_{13}$ and much more soluble in Zr_2Be_{17}, with which is evidently also connected the beneficial effect of the additions of aluminium on the oxidation resistance of the beryllide $ZrBe_{13}$ in the middle-temperature region. The rate of oxidation of zirconium beryllides obeys a logarithmic law[59,81], which agrees with the protective nature of the oxide film.

According to Bookhand and others[82] the vapour pressure above Zr_2Be_{17} at 1200–1400° is relatively low, $\sim 10^{-3}$ mmHg.

Zirconium beryllides can be made by powder metallurgy methods, either by sintering previously compacted mixtures of beryllium and zirconium powders[74] in argon (the reaction between zirconium and beryllium is reported[20] to start at 685°) or by hot pressing[76] at 1600–1800°.

Beryllium–zirconium alloys have been made[77] by fusing the components in an argon arc furnace; a similar method has been described[51] for $ZrBe_{13}$.

The same work[51] describes various methods for making articles from $ZrBe_{13}$ and some other beryllides ($NbBe_{12}$, $MoBe_2$) — in particular, by vacuum (~ 0.1 mmHg) hot pressing of mixtures of powders (200 mesh), the temperature being raised to 1500° over a period of 2–3 h, and then held at 1550–1600° for 1–2 h (all the regimes are quoted for cylindrical articles with a diameter and height of ~ 50 mm). Good results are also obtained by using casting (induction heating) and extrusion at $\sim 1620°$.

Hafnium beryllides. The beryllium–hafnium system is quite similar to the beryllium–zirconium system; the existence of four compounds in it has also been established[58,65,86–88]: $HfBe_2$, $HfBe_5$, Hf_2Be_{17}, and $HfBe_{13}$. The beryllide $HfBe_2$ has a hexagonal lattice of the AlB_2 type; $HfBe_5$ also has a hexagonal lattice, of the $CaZn_5$ type; the Hf_2Be_{17} phase is reported[65] to have two modifications: α-Hf_2Be_{17}, rhombohedral ($a = 7.494$, $c = 10.93$ Å), and β-Hf_2Be_{17}, hexagonal ($a = 7.44$, $c = 7.38$ Å), but others state[86,87] that there is only a hexagonal type of Nb_2Be_{17} identical in type with U_2Zn_{17} or Th_2Zn_{17}. Finally, $HfBe_{13}$ has a cubic structure of $NaZn_{13}$ type[87]. This work[87] drew attention to the fact that the lattice parameters of the hafnium beryllides are less than those of the corresponding zirconium phases; this is connected with the atomic radius of hafnium (1.59 Å) being less than that of zirconium (1.60 Å). The main information on the properties of the hafnium beryllides is given in Table 5.

According to these data[87] as the proportion of beryllium in the compounds with hafnium is increased, the distance between its atoms diminishes ($HfBe_2$ 2.179, $HfBe_5$ 2.17, Hf_2Be_{17} 2.14, $HfBe_{13}$ 2.07 Å) but the distance between the hafnium atoms increases, which indicates an increase in the covalency of the bond between the beryllium atoms.

Hafnium beryllides can be obtained either by melting the components together under argon in a high-frequency (beryllium-rich) or arc (hafnium-rich) furnace[86,87] or by powder metallurgy methods, especially by hot pressing of mixtures of the powders[88] followed by annealing.

C. BERYLLIDES OF METALS OF SUBGROUP Va

Vanadium beryllides. Misch[23] found the existence of the beryllide VBe_2 with a hexagonal lattice of $MgZn_2$ type and parameters $a = 4.385$, $c = 7.130$ kX, $c/a = 1.639$, with four molecules in the unit cell. Further investigations of the compounds in this system[89–91] confirmed the existence of VBe_2 and its structure, and also showed the compound VBe_{12} with a tetragonal lattice of $ThMn_{12}$ type.

The icosahedral configuration of the beryllium atoms in this structure and also the decrease in the distance between the beryllium atoms on going from VBe_2 (2.25 kX) to VBe_{12} (2.19 kX) shows a considerable proportion of covalency in the bond between the beryllium atoms.

The existence of VBe_{12} was further confirmed by Batchelder and Raeuchle[92], who gave values of the lattice parameters for single crystals which were different from those quoted[89–91].

Vanadium beryllides are obtained by melting the components together in quartz containers in a resistance furnace under argon (Table 6).

Niobium beryllides. In the Be–Nb system the existence of a compound $NbBe_{12}$ with a face-centred tetragonal lattice was established[86,87,92] and then rhombohedral Nb_2Be_{17} was observed[93]. In addition there have been reports of the existence of $NbBe_2$,[91,94] Nb_3Be_2,[95] $NbBe_5$,[91,96] of which $NbBe_2$ and $NbBe_5$ were accepted in the construction of a tentative variant[96] of the Be–Nb equilibrium diagram (Fig. 9). This diagram, which has been described in detail[96,97] was confirmed by additional investigation[98] and it was shown that the solid solubility of niobium in beryllium is very small (considerably less than 0.7 wt.% Nb), eutectic crystallisation of α-Be + $NbBe_{12}$ from the melt takes place at 2.5 wt.% Nb, and the eutectic temperature is close to the melting point of pure beryllium. Furthermore, it is stated that the phase $NbBe_{12}$ may not be formed as a compound with an open maximum melting point but by a peritectic reaction between the melt and compound Nb_2Be_{17}, which obviously throws doubt on the part of the diagram in Fig. 9 between the phases Nb_2Be_{17} and $NbBe_{12}$; this part requires further, more detailed investigation.

In a thermal diffusion study of the beryllium–niobium system[96] the temperature dependence of the diffusion coefficients was determined approximately for "$NbBe_8$" (Nb_2Be_{17}) and $NbBe_{12}$:

$$D_{\text{«NbBe}_8\text{»}} = 5.7\times10^{-9}\exp(-14\,740/RT),$$

$$D_{NbBe_{12}} = 7.66\times10^{-4}\exp(-32\,000/RT)$$

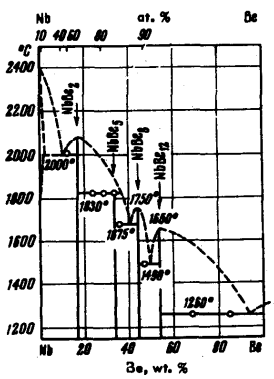

Fig. 9. Equilibrium diagram of the beryllium–niobium system.

A review of the data on the oxidation resistance of beryllium–niobium alloys has been given in a monograph[97]; that of the niobium beryllides proper has been investigated[59,79]. The moderate oxidation resistance of the beryllide $NbBe_2$ and its alloys with niobium was demonstrated[97]; the beryllides $NbBe_5$ and especially Nb_2Be_{17} and $NbBe_{12}$ are stable to oxidation, but the effect of a diminution in this stability in the middle temperature region noted for the higher beryllides of zirconium also occurs with the niobium beryllides, but is not so sharply expressed[79].

The niobium beryllides have relatively high hardness, which increases with the beryllium concentration[96–98]; Fig. 8 shows the temperature dependence of the hardness of $NbBe_{12}$ (data taken from Lewis[59]), the hardness minimum at 290° is still unexplained. The strength of the

niobium beryllides is of the same order as that of the beryllides of other transition metals but at high temperatures the strength is somewhat higher than that of other beryllides. The heats of formation of all the beryllides shown in Fig. 9 and the temperature dependence of the diffusion coefficients for Be in Nb with formation of beryllide phases have been determined[96]. Table 7 summarises the properties of the niobium beryllides.

The niobium beryllides can be made by the methods of powder metallurgy[59,91]. Cherkashin and coworkers[91] sintered mixtures of the powders at 1000° in a protective medium (molten sodium chloride) for 5–24 h, followed by long (10 days) annealing at 400°. However, it is more customary to obtain them by melting the components together, for example, under argon in a high-frequency furnace[98].

Tantalum beryllides. The investigation of alloys of beryllium and tantalum was started by Kaufmann and coworkers[11], and later Gladyshevskii and Kripyakevich[100] found the compound $TaBe_{12}$ with a tetragonal structure of $ThMn_{12}$ type (a = 7.322, c = 4.247 kX); simultaneously the same compound was established in another study[92]. Later, the compounds Ta_2Be, $TaBe_2$, Ta_3Be_2, $TaBe_3$, and Ta_2Be_{17} were reported[58,65,179]. The properties of the higher beryllides Ta_2Be_{17} and $TaBe_{12}$ have been studied best — they are refractory compounds with m.p. 1900–2000°, resistant to oxidation; unlike the zirconium and niobium beryllides, the tantalum beryllides are not subject to catastrophic oxidation in the middle-temperature region[79]. At high temperatures Ta_2Be_{17} has a vapour pressure of the same order as metallic beryllium[82]. Information about the properties of the lower tantalum beryllides is limited to what is known about their crystal structure[65]. $TaBe_2$ is cubic with lattice parameter a = 6.51 Å, Ta_3Be_2 is tetragonal with a = 6.5, c = 3.32 Å, $TaBe_3$ is rhombohedral with a = 4.53, c = 20.95 Å. The melting point of $TaBe_{12}$ is 1845° and its density 9.79 g cm^{-3}.[57] Table 8 gives the properties of the higher tantalum beryllides. The Be–Ta equilibrium diagram has not been studied.

Tantalum beryllides are obtained predominantly by powder metallurgy methods[59,100].

D. BERYLLIDES OF METALS OF SUBGROUP VIa

Chromium Beryllides. The diagram of the Be–Cr system was constructed by Edwards and Johnstone[101] up to 30 wt.% Be and shows the existence of a beryllide of composition $CrBe_2$ (Fig. 10), which had been found even earlier and identified by X-ray diffraction[23,102]. $CrBe_2$ is a phase of variable composition, homogeneous (according to Cherkashin and coworkers[91]) in a region extending at least from 70.9 to 77.5 at.% Be. A second compound has been established[90–92]: $CrBe_{12}$, which exists in a narrow concentration region at beryllium concentrations close to 92 at.%.[91] This compound is denoted by the symbol X in Fig. 10. Table 9 gives information about the properties of the chromium beryllides.

Chromium beryllides have been made by melting the components in pure argon[91,101]; they can also be obtained successfully by powder metallurgy[59].

Molybdenum beryllides. Only the molybdenum-rich part of the Be–Mo diagram (up to 7 wt.% Be) has been constructed [1]. The existence of two compounds in the system has been rather reliably established: $MoBe_2$ [23,103] and $MoBe_{12}$ [89,91,100,104]; in one work [103] the latter was given the composition $MoBe_{13}$, but this was later corrected by Raeuchle and Batchelder [104] and also by Gladyshevskii and Kripyakevich [100], who confirmed the composition $MoBe_{12}$. Furthermore, there is proof [58] of the compound Mo_3Be with a cubic structure of type O_h^3 with a = 4.89 Å and also a compound richer in beryllium $MoBe_{20}$ with structure $O_h^7(T_h^7)$ and a = 11.64 Å. A later investigation [105] confirmed the existence of this phase, but its composition was described by the formula $MoBe_{22}$ (instead of $MoBe_{20}$) with a structure of $ZrZn_{22}$ type, parameter a = 11.634 Å. The compounds Mo_3Be and $MoBe_{22}$ have hardly been studied, therefore Table 10 gives the properties for $MoBe_2$ and $MoBe_{12}$ alone.

Molybdenum beryllides can be made by melting the components in BeO crucibles under argon in a high-frequency furnace [100] and also by powder metallurgy [59]. The diffusion reaction of beryllium in molybdenum has been investigated [106] and it was shown that the phases $MoBe_2$, $MoBe_{12}$, and $MoBe_{22}$ are formed: $MoBe_2$ predominates up to 1000°, a mixture of $MoBe_2$ and $MoBe_{12}$ from 1000° to 1150°, and the phase $MoBe_{22}$ appears at higher temperatures. The layer on molybdenum consists successively of

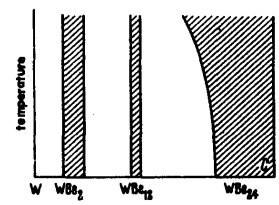

Fig. 11. Equilibrium diagram of the beryllium–tungsten system.

beryllide phases from the lowest beryllides to the highest; the diffusion proceeds preferentially through the beryllide layers.

Tungsten beryllides. In the beryllium–tungsten system, analogous to the beryllium–molybdenum system, the existence of the following beryllide phases has been established with sufficient reliability: WBe_2, [23,91,178] WBe_{12}, [91,62,100] and WBe_{22}, [58,105], the main properties of which are given in Table 11. Thermal diffusion has been investigated [107] in the Be–W system, the formation of three phases being established: WBe_2, WBe_{12}, and WBe_{24}; the last is evidently identical with the phase WBe_{22} which has been well identified by X-ray diffraction. According to the results, all three phases have homogeneity regions: the widest is the "WBe_{24}" phase, WBe_2 is narrower, and WBe_{12} is the narrowest (Fig. 11). The temperature dependence of diffusion coefficient in each phase has been determined approximately:

$$D_{WBe_2} = 1.10\times10^{-4}\exp(-3315/RT),$$
$$D_{WBe_{12}} = 2.36\exp(-66\,950/RT),$$
$$D_{\langle WBe_{24}\rangle} = 1.175\times10^{-3}\exp(-33\,800/RT).$$

It is reported [20] that on heating a compacted mixture of tungsten and beryllium powders, reaction between them to form intermetallic compounds begins at 880°; in the diffusion interaction of beryllium powder with the compact metal at 1100° for 4 h, all the beryllide phases are formed [107].

E. BERYLLIDES OF METALS OF SUBGROUP VIIa

Manganese beryllides. The solubility of beryllium in manganese is low [11,108]. According to some [23,93] there is a beryllide $MnBe_2$ of variable composition of $MgZn_2$ structure type; this structure type was also described by Hume-Rothery and Raynor [109]. A second compound [89,91]

TABLE 12. Properties of manganese beryllides.

has the composition $MnBe_8$ (at 400°) with a homogeneity region which broadens with temperature (at 1100° this region extends from $MnBe_8$ to $MnBe_{13}$); this beryllide has a cubic lattice of $MnCu_2$ type. Batchelder and Raeuchle [93] found the presence of a third beryllide $MnBe_{12}$.

It has been shown [20] that the reaction between compacted manganese and beryllium powders starts at 800°; the beryllides $MnBe_2$ and $MnBe_8$ have been obtained [91] by melting the components in a quartz container under argon. Table 12 gives information on the properties of manganese beryllides.

Technetium beryllides. There is no information about technetium beryllides.

Rhenium beryllides. According to Misch [23], the beryllium–rhenium system contains the compound $ReBe_2$; a beryllium-rich phase, which has been ascribed the composition $ReBe_{20}$, has been found [56]. It is evident that the true composition of this phase is $ReBe_{22}$, analogous to the corresponding phases of molybdenum and tungsten [105], with a cubic structure of the $ZrZn_{22}$ cubic type, lattice parameter [56] a = 11.64 Å.

The composition of the phase $ReBe_{22}$ has been established [110]; this beryllide is made by heating mixtures of rhenium and beryllium powders (in stoichiometric proportions) in BeO crucibles at 1650° for ~5 min under argon at a pressure of 0.5 atm. The lattice parameter is a = = 11.561 Å. In this beryllide the beryllium atoms form a complex skeletal polyhedron.

The beryllide $ReBe_2$ has a hexagonal lattice of $MgZn_2$ type with a = 4.354, c = 7.101 Å, c/a = 1.631. [23] $ReBe_2$ is prepared by heating pressed mixtures of the powders of the components under argon at 1200° and melts at a temperature above 2000°. The emissivity of $ReBe_2$ at 800–1600° (λ = 650 nm) is 0.80. [73]

F. BERYLLIDES OF METALS OF GROUP VIII

1. Beryllides of Metals of the Iron Group

Iron beryllides. The equilibrium diagram of the beryllium–iron system, constructed from published information [111,112] is shown in Fig. 12. Three beryllides exist in the system: $FeBe_2$, [113,114] $FeBe_8$, [113,114] and $FeBe_{12}$. [92,114] The beryllide $FeBe_2$ has high hardness and is ferromagnetic [112] with a Curie point at 643°.

The phases $FeBe_2$ and $FeBe_8$ have wide homogeneity regions [114], the $FeBe_{12}$ phase according to previous data [114] has the composition $FeBe_{12}$ and a hexagonal structure, although Batchelder and Raeuchle [92] conclusively confirmed its composition as $FeBe_{12}$ and a face-centred tetragonal structure.

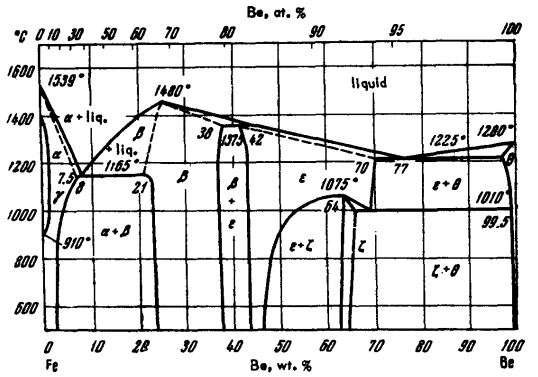

Fig. 12. Equilibrium diagram of the beryllium–iron system.

Table 13 gives the main information about the properties of the iron beryllides. The maximal solubility of Fe in Be is 0.0092 at.% (5.46 wt.%) at the eutectic temperature 1225°. [115]

Cobalt beryllides. After Köster and Schmid [116] who worked out the part of the Be–Co diagram up to 10 wt.% Be, Venturello and Burdese proposed the complete diagram of this system (Fig. 13). [117] In accordance with this diagram, the system contains the compounds CoBe [23,117,118] and Co_5Be_{21}, [117] however, according to Batchelder and Raeuchle [92] the lines of the X-ray diagram of this phase can

be ascribed to $CoBe_{12}$ and $CoBe_5$, analogous to the corresponding iron beryllides, which seems more probable. CoBe is reported [23] to have an ordered b.c.c. lattice and Co_5Be_{21} has been investigated repeatedly [1,15,16]; Jahn [119] has given its equilibrium diagram in the most complete form (Fig. 14). nents under inert gas in an electric resistance furnace. Table 14 gives the main properties of the cobalt beryllides.

On heating mixtures of beryllium and cobalt powders, reaction between them starts at 670°. [20]

Nickel beryllides. The beryllium–nickel system has been investigated repeatedly [1,15,16]; Jahn [119] has given its equilibrium diagram in the most complete form (Fig. 14). According to this diagram the system contains the compounds NiBe and Ni_5Be_{21}, which have not very wide homogeneity regions and melt congruently. The maximal solubility of nickel in beryllium is 4.93 at.% at the eutectoidal temperature, 1065°. [115] The existence of Ni_5Be_{21} is probably doubtful (as is the analogous compound in the Be–Co system) but there have been no investigations in this direction and a phase of this composition has to be accepted at present. The structures of NiBe and Ni_5Be_{21} were investigated by Misch [113] and by Losana and Goria [120] and the results of the latter workers are considered [1] to be the most reliable data on the lattice parameters. The NiBe

phase is responsible for the precipitation hardening during the aging of Be–Ni alloys [121]. Beryllium–nickel alloys are made by melting in an inert gas or under a flux layer in BeO or MgO crucibles [15]; reaction between nickel and beryllium powders is reported [20] to start at 732°. Table 15 gives the properties of nickel beryllides.

2. Beryllides of Metals of the Platinum Group

Ruthenium beryllides. The existence of $RuBe_2$ has been established [23], but the precise composition and structure of this compound have not been determined. The compound Ru_5Be_{17} has been observed [119] on heating a mixture of ruthenium and beryllium powders in a BeO crucible under argon at 1480°. It was found to be f.c.c. with a = 11.337 Å, and to be isomorphous with the corresponding osmium compound. Its melting point is ≃ 1635°. [122]

Rhodium beryllides. Misch [23] indicated the possibility of the existence of $RhBe_2$ or another compound with Rh : Be = 1 : 2; its X-ray diagram is analogous to that of $IrBe_2$.

Palladium beryllides. Fig. 15 shows the equilibrium diagram of the beryllium–palladium system after Winkler [22]. There is a large number of beryllides in this system: there are five between palladium and the compound PdBe and at least another two between PdBe and beryllium; $PdBe_5$ and $PdBe_{12}$. According to Misch [23], PdBe has the ordered CsCl type of structure with a = = 2.813 kX; these results were confirmed by Belov [123]. $PdBe_5$ has the $MgCu_2$ type f.c.c. structure (like $FeBe_5$ [23,24]) with a = 5.969 Å, [24] pyknometric density 4.56, X-ray density 4.62 g cm^{-3}. $PdBe_5$ does not exhibit superconductivity up to 0.30°K. Yet another phase has been reported [24],

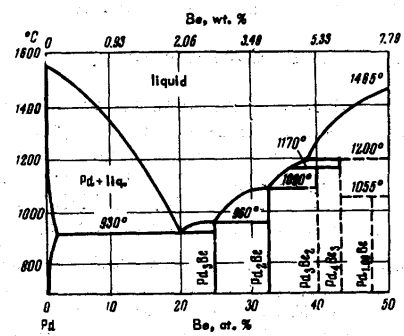

Fig. 15. Part of the equilibrium diagram of the beryllium–palladium system.

$PdBe_{12}$, isomorphous with $MoBe_{12}$, body-centred tetragonal, with a = 7.271 Å, c = 4.251 Å, c/a = 0.585, X-ray density 3.18 g cm^{-3}. The melting points are reported[22] to be: Pd_3Be 960°, Pd_2Be 1090°, Pd_3Be_2 1250°, Pd_4Be_3 1330°, $Pd_{13}Be_{12}$ 1450°, and PdBe 1465°.

Osmium beryllides. According to Misch[23], osmium forms the compound $OsBe_2$ with beryllium.

Iridium beryllides. According to the same author[23], there is the compound $IrBe_2$, the structure of which has not been established,

Platinum beryllides. Platinum and beryllium form the compounds $Pt_{15}Be$ and $PtBe_{12}$. $Pt_{15}Be$ was observed[124] and obtained by reducing a mixture of beryllium oxide and platinum powder at 1150°; it is hexagonal with a = 22.13, c = 27.12 Å. The compound $PtBe_{12}$ has[24] a face-centred tetragonal structure of $MoBe_{12}$ type with a = = 7.237, c = 4.252, c/a = 0.588, X-ray density 4.53 g cm^{-3}. Furthermore, in the same work[24] the possibility of there being a beryllide $PtBe_5$ was mentioned, f.c.c. with a = = 6.004 Å. According to older information[23] there is also a phase Pt_5Be_{21} with the structure of a deformed γ-brass (γ-Ni_5Zn_{21} type). However, the beryllides whose existence has been found most probably and reliably are $Pt_{15}Be$ and $PtBe_{12}$.

G. BERYLLIDES OF THE ACTINIDES

Thorium beryllides. The beryllium–thorium equilibrium diagram, earlier worked out only partially[1] has recently been supplemented considerably[125] (Fig. 16). This system contains the compound $ThBe_{13}$ (92.86 at.% Be) observed earlier by Baenziger and Rundle[40]. Babaeva and Kuznetsova[125] obtained it, like other alloys of the system, by melting 99.3% beryllium with 99.7% thorium in an arc furnace with a tungsten electrode and cooled copper hearth; the atmosphere was chemically pure argon. This compound is f.c.c. ($NaZn_{13}$ type) with a = 10.395 Å[40] (Babaeva and Kuznetsova[125] give a = 10.383 Å). The $ThBe_{13}$ structure has been confirmed[126]. $ThBe_{13}$ melts at ~ 1930°[125] and has good resistance to oxidation in a stream of dry air[79]. The microhardness of $ThBe_{13}$ is[125] ~ 950 kgf × × mm^{-2}. Reaction between compacted beryllium and thorium powders starts at 705°.[20]

Uranium beryllides. The equilibrium diagram of the beryllium–uranium system was developed mainly by Buzzard[127] and Hansen and Anderko's interpretation[16] is shown in Fig. 17. The system includes the compound UBe_{13} with an $NaZn_{13}$ type f.c.c. lattice. Reaction between uranium and beryllium in the form of compacted powders starts at 355°;[20] the compound UBe_{13} can be isolated from uranium-rich alloys by electrolytic dissolution in 10% chromic acid.

However, the main methods of obtaining UBe_{13} are powder metallurgy and vacuum induction melting[128]. In the former, uranium (or uranium hydride UH_3) and beryllium powders are used and the mixtures are sintered at 950–1050° (when beryllium and finely dispersed uranium powders are sintered in pure hydrogen the sintering temperature usually is 1300° and sometimes it reaches 1550°). Vacuum induction melting is done at 1130° (in a quartz container in argon at 1 atm) with subsequent addition of a 10% excess of beryllium (to compensate for the loss of beryllium by vaporisation) and brief homogenisation annealing at 1200–1300°.[128] For the preparation of compact articles of UBe_{13}, the products from sintering or melting are finely ground, pressed in a hydraulic press into blanks of the required shape, which are then sintered in argon at 1550° to give articles with a density > 97%.

Table 16 gives the principal physical properties of uranium beryllide; it must also be added that it exhibits marked brittleness[127]. The microhardness for the "UBe_{12}" phase is reported[59] to be 1300 kgf mm^{-2}.

In chemical respects UBe_{13} reacts with oxygen more slowly than do uranium carbides, nitrides, borides, and metallic uranium itself; it is especially resistant to oxidation at temperatures up to 500°. The oxidation at first follows a linear law and then slowly, by an exponential law, $k = 1.98 \times 10^8 \exp(-26\,200/RT)$ mg cm^{-2} s^{-1}. UBe_{13} behaves similarly with nitrogen, $k = 5.1 \times 10^4 \exp(-25\,800/RT)$, and with water vapour, $k = 5.46 \times 10^4 \exp(-25\,800/RT)$. The change in weight after treatment with water at 100° is 2.2 mg cm^{-2}, in addition to which water brings about rather marked intercrystalline corrosion of uranium beryllide.

Neptunium beryllides. In the reduction of neptunium fluoride by beryllium in a vacuum at 1100–1200°, the compound $NpBe_{13}$ (33.09% Be) was obtained [130]. This is isomorphous with the corresponding phases of thorium and uranium and is f.c.c. ($NaZn_{13}$ type) with a = 10.266 (on the beryllium side) to a = 10.256 Å (on the neptunium side), that is, there is some region of homogeneity. The melting point is above 1400°.

Plutonium beryllides. Plutonium also forms a compound with beryllium of composition $PuBe_{13}$ (32.63% Be) (Fig. 18) [131–133]; it is f.c.c. ($NaZn_{13}$) with a = 10.284 (on the beryllium side) to a = 10.278 Å (on the plutonium side) [130] in the limits of the homogeneity region; according to Konobeevskii [131] a = 10.274 Å. The microhardness of $PuBe_{13}$ [131] is 947 kgf mm^{-2}, the density [131,132] 4.35–4.36 g × × cm^{-3}. The compound is an active source of neutrons [131]. Its m.p. is 1600° and heat of formation 35.7 ± 3.3 kcal × × $mole^{-1}$. [134] $PuBe_{13}$ can be made by melting a mixture of pieces of metallic plutonium and beryllium powder in BeO crucibles under argon in a high-frequency furnace [135].

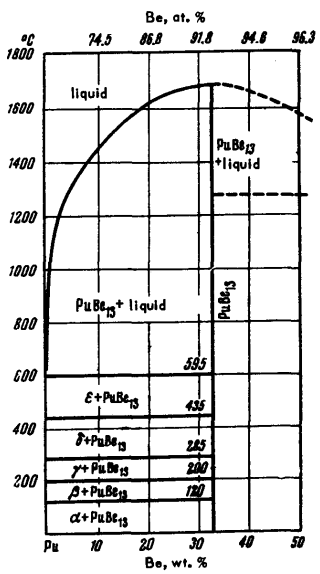

Fig. 18. Part of the equilibrium diagram of the beryllium–plutonium system.

The beryllide $PuBe_{13}$ corresponds to the maximal neutron emission in the Be–Pu system, 67 × 10^6 neutrons × × kg^{-1} s^{-1}. [136]

Americium beryllides. Runnals and Boucher [137] prepared a beryllide, $AmBe_{13}$, by reducing AmF_3 with beryllium in a vacuum (the reaction starts at 900° and proceeds rapidly at 1125°). Like the other beryllides of this composition, it is f.c.c.; a = 10.283 Å (on the beryllium side of the homogeneity region). Its m.p. is 1375°, density 4.376 g cm^{-3} (according to a review [138] 4.35 g cm^{-3}). It has mainly been studied as a source of neutrons [125].

IV. COMPLEX BERYLLIDES

In addition to two-component beryllides, several multicomponent complex beryllides have now been discovered and investigated; they are of considerable scientific and practical interest.

Nowotny and coworkers [88] discovered the ternary beryllides ZrBeSi and HfBeSi, with lattices of the nickel arsenide type ($B8_2$). The compound ZrBeSi has a certain region of homogeneity, within the limits of which the lattice parameters vary from a = 3.722, c = 7.232 Å (at the silicon-rich side) to a = 3.718, c = 7.217 Å (at the beryllium-rich side); for HfBeSi the lattice parameters are equal§: a = 3.693, c = 7.135 Å.

It has been found [139] that there is a continuous series of solid solutions between the compounds $ThBe_{13}$ and UBe_{13} in the Be–Th–U ternary system. An investigation of the physicochemical properties of the solid solution of composition $(Th_{0.9}U_{0.1})Be_{13}$ showed [140] that on oxidation in air at 482° the change in weight of specimens of this alloy is from 0.234 mg cm^{-2} (oxidation time 8 h) to 0.623 mg cm^{-2} (oxidation time 24 h). The physico-technical properties of alloys of (Th, U)Be_{13} with uranium have been described in detail [79].

A ternary compound of the idealised composition AlBeB has been observed [141] in the Al–B–Be system; it is a dark, finely crystalline substance, which crystallises with an antifluorite lattice, the sites of the metal atoms in which are occupied by ordered atoms of Be and Al.

The lattice parameters vary between 4.952 and 4.925 Å, owing to the partial formation by this ternary beryllide of solid solutions with Be_2B.

In the Be–Co–Mn system [142] a ternary phase of composition $MnCo_{0.8}Be_{1.2}$ is found, with the structure of a cubic Laves phase ($MgCu_2$ type) and a = 6.20 Å.

Several complex beryllide phases have been described in reviews [143,144]. In ternary systems with participation of binary beryllides the equilibrium has been described in the systems Be–Fe–P [145] (Fe_2P–$FeBe_2$ and Fe_3P–$FeBe_2$ sections); Be–C–U [146] (UC–Be_2C section); Al–Be–Zr [147] ($ZrBe_9$–Zr_4Al_3, $ZrBe_9$–$ZrAl_2$, $ZrBe_2$–$ZrAl_2$, $ZrBe_{13}$–$ZrAl_{13}$, $ZrBe_{13}$–Al, and $ZrAl_3$–Be sections); Be–Fe–Si [148] (compounds were found: FeSiBe, melting congruently at 1160° and $FeSiBe_3$, melting congruently at 1240°); Be–Cu–Mn [149,150] (Cu–$MnBe_2$); Be–Cu–Ti [150] (Cu–$TiBe_2$ section); Be–Co–Cu [150] (Cu–CoBe section); Cu–$CrBe_2$ [150]; Cu–$FeBe_2$ [150]; Al–Be–Cu [151]; and Be–Cu–Ni [152] (Cu–NiBe section).

§ Presumably on each side of the homogeneity region (Ed. of Translation).

V. STRUCTURE AND PHYSICOCHEMICAL NATURE OF THE BERYLLIDES

Hardly anything has been published about the principles governing the formation of alloys of beryllium and of its compounds with other elements, if one discounts the very general contributions dealing mainly with the possibility of the formation of solid solutions by beryllium [153].

Because the beryllium atom is larger than the boron atom Parthé [154] considers that the beryllides should not be so refractory as the corresponding borides: he thinks that the highest melting points should be expected from the compounds of beryllium with the metals of the sixth period, and bearing in mind the small number of valence electrons of beryllium, with the metals of Groups V and VI, that is, with tantalum and tungsten.

In considering the physicochemical nature of the beryllides it is of prime importance to allow for the peculiar electronic structure of the beryllium atom. The electronic configuration of the beryllium atom is $1s^2 2s^2$; in the formation of crystals, beryllium and compounds are characterised by a single-electron $s \rightarrow p$ promotion [155] with the formation of the electronic configuration $1s^2 2s 2p$. The presence of sp valence electrons brings about the formation of relatively strong covalent bonds between the beryllium atoms, both in the crystal lattice of the metal itself and in the lattices of its compounds with other elements, particularly with metals. In the last instance the tendency of the beryllium atoms to form a covalent bond with one another brings about a statistical diversion to this bond of electrons from the M–Be and M–M bonds, which leads to their corresponding weakening. Corresponding to the formation of a covalent bond between the beryllium atoms, the latter tend to associate in the crystal lattices of the beryllides into more or less intricate structural complexes.

Above all, the peculiarities of the electronic structure of the beryllium atom and its high capability for $s \rightarrow p$ promotion with the formation of a stable sp configuration of the electrons shows in the properties of beryllium itself. As the sp configuration is energetically somewhat more stable than s^2, then on thermal excitation the original $s^2 \rightleftharpoons sp$ equilibrium is shifted to the right and with the prevalence of statistical weight of the sp configuration the crystal structure of the beryllium can be changed, which is also observed in reality [156¶]. The fact that the temperature of this $\alpha \rightarrow \beta$ transformation is close to the melting point of beryllium shows that the sp configuration is not much more stable than the s^2 configuration; this requires a rather high temperature to create the prevailing statistical weight of the sp states and the corresponding modification transformation. Beryllium exhibits the highest heat of fusion among the metals, which is undoubtedly brought about by the presence in it of sp states; this explains the high electronic work function of beryllium, which is not characteristic for ordinary metals with s valence electrons. The tendency of the sp configurations already existing in beryllium to trap electrons and to the formation of the sp^2 and especially sp^3 configurations, which are more stable energetically, brings about both the exceptional tendency of beryllium to contamination by various impurities and the difficulty of removing them, and also the high brittleness of the contaminated beryllium, which in this state contains an electron configuration analogous in energetic state and type to the electron configurations in diamond, silicon, and germanium. The chemical properties of beryllium, which tends, for example, to form compounds of both basic and acidic type, are also evidence of the dual nature of this element, which possesses simultaneously the attributes of a metal (on account of the s electrons) and of a non-metal (on account of the known statistical weight of the sp states).

Just the presence of the sp states, which tend to be stabilised into the states of a higher energetic order sp^2, sp^3, determines the formation by the beryllium atoms of complex elements of structure in compounds, especially with partners, the atoms of which are donors of electrons.

Alkali metal beryllides have the composition MBe_2 ($MgCu_2$ type, characterised by there being in each octant a regular tetrahedron of beryllium atoms, so that their centroids are at the centres of the octants) [157]. Hence the stable tetrahedral configuration of beryllium atoms corresponding to the electronic configuration sp^3 is realised in this structure, for the creation of which the abstraction of electrons from an alkali metal is necessary. In turn the ability of alkali metals to transfer electrons to the Be–Be bond is determined by their ionisation potentials, which decrease from lithium (5.37 eV) to caesium (3.36 eV). Evidently therefore a beryllide has been observed first for potassium [11,158] which has a low ionisation potential (4.32 eV) among those alkali metals whose compounds have been longest and most carefully investigated (Li, Na, K). Possibly, lithium and sodium beryllides either are not formed at all, because of the high ionisation potentials of these metals, or are formed under conditions of strong excitation (high temperatures, strong electrostatic or magnetic fields, electrolysis); on the other hand, the formation of rubidium and caesium beryllides should proceed relatively easily and the fact that it has not yet been observed may be due to the compounds of these rare metals having been insufficiently studied.

On the other hand the possibility of the formation of alkali metal beryllides can be interpreted by assuming that in the formation of metallic crystals from alkali metal atoms s^2 configurations are formed from the valence electrons of the atoms, whereas for the formation of the beryllides the destruction of these configurations is necessary, which is especially easy to complete for the alkali metals starting with potassium owing to the partial promotion of s electrons to the completely vacant d states. Since this promotion increases with the principal quantum number of the d states it is obvious that the most favourable conditions for the formation of a beryllide is with potassium, for which this transition is sharply expressed for the excitation of the s^2 configuration but does not lead to preferential promotion of the s electrons into the d states, owing to the low principal quantum number of the latter; therefore the transfer of some of the s electrons to the beryllium atoms is possible.

The diversion of alkali metal electrons to the Be–Be bond and the formation of covalently bound complexes of beryllium atoms in the beryllide structures should confer on the alkali metal beryllides the character of ionic–covalent compounds with strong asymmetric distribution of the electron density — to sharp displacement of the electrons of the bonds in the direction of the complexes of beryllium atoms. Evidently this asymmetry should increase with a fall in the ionisation potential of the metal

¶ Here, in accordance with the high energetic stability of the sp configuration, the β modification of beryllium based upon it is cubic, whereas the α modification which is based upon the s^2 states is hexagonal, that is, has a lower symmetry.

and with a decrease in the statistical weight of the s^2 configurations; one should expect a parallel reduction in the thermal stability of the beryllides in their disproportionation with formation of groups of beryllium atoms in the vapour state, probably in this instance analogous to the groupings of carbon atoms in the disproportionation of some carbides. It can also be suggested that in these beryllides regions of homogeneity are almost absent or are very narrow.

Beryllides of the metals of the copper subgroup. In the formation of the beryllides of the metals of this subgroup there again appears a tendency for beryllium atoms to form *sp* electronic configurations and corresponding structural elements of beryllium atoms in the lattices of the beryllides; this tendency is combined with the existence of a free s^1 electron of the metal which is comparatively easily transferred to the beryllium atoms. In this connection, copper ($3d^{10}4s^1$, ionisation potential 7.67 eV) readily forms beryllides CuBe, $CuBe_2$, $CuBe_3$ with a growing bridge structure of beryllium atoms in the crystal lattices; in particular, whereas in the structure of CuBe (closely resembling FeSi) the beryllium atoms are isolated, in the $CuBe_2$ structure they form regular tetrahedra situated in the vacancies of the octants of the $MgCu_2$ structure, alternating with magnesium atoms, which are arranged in a diamond-type structure [157]. The greater ease of removal of electrons from the silver atom ($4d^{10}4f^05s^1$, ionisation potential 7.58 eV) facilitates the formation of covalent bonds between the beryllium atoms and shifts the concentration of beryllium in the corresponding beryllides towards higher values $AgBe_2$ and $AgBe_{12}$. Gold forms an even greater number of beryllide phases (Table 1).

In considering the number and nature of the beryllide phases formed by the metals of the copper subgroup, it must be borne in mind that whereas for copper the *s* electrons can be transferred to a partner without the destruction of the stable d^{10} configuration, with silver and gold the completely vacant corresponding *4f* and *5f* states appear, which can bring about partial abstraction of the electrons from the d^{10} configurations with destruction of the latter, and on going from silver to gold the probability of the transfer of the *d* electrons to the *f* states should increase owing to an increase in the energetic stability of the *f* states with rise in the principal quantum number [159]. However, the energetic stability of the d^{10} configuration rises simultaneously and to a greater extent, therefore metallic gold, in particular, has a melting point higher than that of silver, but lower than that of copper, for which (despite the low principal quantum number of the *d* electrons) the *d* electrons are not removed to the *f* states. In connection with the breakdown of the d^{10} configuration of silver and gold the loss of their stability due to the $d \rightarrow f$ transitions creates the possibility of both an increased transfer (compared with copper) of electrons of beryllium to form intricate structural complexes of them with high statistical weight of the sp^3 configurations, and also the possibility of covalent association of the silver or gold atoms with a tendency to the reduction of the destroyed d^{10} states, which brings about for gold the appearance of the lower beryllide phases Au_3Be and Au_2Be†. Analogously, it is to be expected that for silver also lower beryllide phases should be observed.

† On the contrary, in the higher beryllides of the $AuBe_{12}$ type the statistical weight of the d^5 configurations in the gold sublattice is probably very great.

Beryllides of magnesium and the alkaline earth metals. In accordance with the peculiarities of the structure of $NaZn_{13}$ type in which the only beryllium–magnesium compound ($MgBe_{13}$) crystallises, some of the beryllium atoms form icosahedra, the others are at the vertices, the centres of the faces, edges, and in the centre of the cell, and the magnesium atoms are isolated in the centres of the eight cubes into which the cell is divided. Hence in the $MgBe_{13}$ structure the structural motif of the beryllium atoms is particularly strongly expressed.

Beryllium, magnesium, and the alkaline earth metals (calcium, strontium, barium, and radium) have the s^2 configuration of the outer (valency) electrons, which is capable of being converted into the *sp* configuration by $s \rightarrow p$ promotion. As the stability of the *sp* states rises with fall in principal quantum number of the *sp* electrons, the probability of the $s \rightarrow p$ promotion with the formation of these states is much greater, as was shown above for beryllium. For magnesium, owing to the lower stability of the *sp* states the probability of the $s \rightarrow p$ promotion decreases, nevertheless magnesium also retains the feature of a certain dualism of properties, which leads to its separation from the group of alkaline earth metals proper. On passing further to calcium, this gradual fall in non-metallic properties is sharply accelerated with the appearance in calcium of completely vacant *3d* shells into which *s* electrons can be transferred.

Hence the electronic transitions acquire the general form expressed by the scheme $d \rightleftharpoons s^2 \rightleftharpoons sp$. Therefore the lowering of the statistical weight of the *sp* configurations at calcium is due not only to the increase in the principal quantum number of its *sp* electrons, but mainly to $s \rightarrow d$ promotion, which sharply lowers the probability of that of the $s \rightarrow p$. Since the stability of the electron configurations which are converted into the *d* states increases with increase in the principal quantum number of the *d* electrons, then on going from calcium to strontium, barium, and radium the equilibrium $d \rightleftharpoons s^2 \rightleftharpoons sp$ is sharply displaced in the direction of the formation of the configurations of *d* electrons with a diminution in the statistical weight of the *sp* states; the metallic properties of these elements rise correspondingly sharply.

Therefore in the compound $MgBe_{13}$ the "more metallic"‡ magnesium emerges as a donor of *s* electrons and beryllium as an acceptor with the formation of *sp* configurations. The difficulty of making magnesium beryllide described above (see p. 341) is probably explained not only and not so much by the volatility of magnesium and the difficulty of its concentration in the reaction space of the furnace, as by the relative similarity of the electronic structure and energetic states of the beryllium and magnesium, in particular, by the presence in both metals of the difficultly-excited *sp* electronic configurations. In this connection, the calcium beryllide $CaBe_{13}$ is formed much more easily when it is also taken into account that the stable pairs of s^2 electrons are destroyed in consequence of the $s \rightarrow d$ promotion. Therefore $CaBe_{13}$ is also more stable in thermal respects than magnesium beryllide.

It is possible that the absence of such phases for strontium and the other alkaline earth metals is due not only to their having been little investigated, but to the principal considerations that as a result of the $s \rightarrow d$ promotion there is a strong bonding of the electrons and increasing difficulty in their transfer to the beryllium atoms; this

‡ Obviously it would be even better to say "less non-metallic".

difficulty should increase with increase in the principal quantum number of the d electrons, that is, from strontium to radium.

It should be noted that Laube and Nowotny [45] connect the formation of the structural type $NaZn_{13}$ (AB_{13}) with the great difference in the atomic radii r_A and r_B, by showing that this explains the existence of the phases AB_{13} for the beryllides (A = Mg, Ca, Sc, Y, La, Ce, Zr, Hf, Th, U, Pu), zincides (A = Na, Sr, Ba), cadmides (A = K, Rb), and for the same reason such phases are unknown for the magnides, where component B would be magnesium. It is evident that this purely "geometrical" standpoint does not reveal the actual reasons for the formation of beryllide phases of the type AB_{13}.

Beryllides of metals of the zinc subgroup. The increase in the ionisation potentials (up to 9–10.5 eV) compared with the metals previously considered and also the existence of rather stable electronic configurations for the atoms of these metals (type $d^{10}s^2$) greatly hinders the transfer of electrons to beryllium, therefore it is evident that corresponding beryllides have still not been observed, if we rule out the indication of the possibility of the formation of an amalgam $BeHg_2$ on electrolysis, that is, under conditions when there is a rather strong excitation of the mercury atoms (mercury cathode). Under ordinary conditions of heating, the metals of the zinc subgroup are almost inert towards beryllium.

Hence the difficulty or even impossibility of forming beryllides of the metals of the zinc subgroup can most probably be explained by the presence in the crystals of these metals of a high statistical weight of the stable s^2 configurations, which should be destroyed for transfer of some of the s electrons to the beryllium atoms. Such a destruction is mainly possible on account of the $s \rightarrow f$ transitions with cadmium and mercury, which are also realised with sufficiently strong excitation of the atoms of the latter.

Beryllides of the rare-earth metals. It is evident that the picture of the nature of the chemical bond in the rare-earth beryllides is the same in principal as for the beryllides of the alkaline earth metals, owing to the high ionisation potentials (6–7 eV [160]) and the existence of paired outer s electrons for all the lanthanides. In this context, all the r.e.e. beryllides form beryllide phases of the same composition MBe_{13} with $NaZn_{13}$ structure (as do the alkaline earth metal beryllides), but scandium, as a typical d transition metal, forms (in addition to $ScBe_{13}$) also phases of composition Sc_2Be_{17} and $ScBe_5$, which are characteristic of zirconium and hafnium. However, the formation of beryllide phases by the r.e.e. proceeds more easily than that by the alkaline earth metals, apparently owing to the higher energetic position of the $6s^2$ electrons, and also the rather strong screening of the incomplete $4f$ electron shells of the lanthanides. Nevertheless, it must be suggested that their physical properties should differ rather appreciably, owing to a difference in ability to make $f \rightarrow d$ electron transitions and the possibility of the establishment of $5d$ states ($4f^n \rightarrow 4f^{n-1}\,5d^1$) [161,162], the probability of which should rise from gadolinium, on the one hand to lanthanum, and on the other to lutetium. The lattice parameters of the lanthanide beryllides MBe_{13} decrease almost monotonically with rise in atomic number [55] in accordance with the well-known lanthanide contraction. In this the usual breakdown of this monotonicity for europium and ytterbium is essentially not observed, for in the beryllides all the lanthanides behave as formally bivalent metals, and a high statistical weight of stable sp^3 electron configurations of beryllium atoms is formed.

Simultaneously, with increase in the number of electrons in the f shell of the isolated lanthanum atom there is a rise in the statistical weight of the stable f^7 (for elements with seven or less f electrons) or f^{14} (for elements with more than seven f electrons) configurations; correspondingly there should be a drop in the fraction of electrons changing into a delocalised state. Therefore for beryllides with a high statistical weight of f^7 and f^{14} states under the condition of simultaneous localisation of the beryllium valence electrons in stable sp configurations, the appearance of an energy gap and the corresponding semiconducting properties can be expected. The energetic isolation of configurations of electrons localised in the metal and beryllium atoms, with a corresponding decrease in the fraction of non-localised electrons leads to less breakdown of the lattice than would correspond with the relatively high melting points of the lanthanide beryllides, their high hardness, and also ability to disproportionate on melting or vaporisation, as all these features should increase with increase in the statistical weight of the stable f^7 or f^{14} configurations respectively of the atoms of the metal sub-lattice, as is actually observed (Table 2).

It has been noted [55] that the unit-cell volumes of the beryllides MBe_{13} are larger, which is associated with their high beryllium content (92.86 at.%), in which these volumes do not correspond with the rule of the additivity of the metal and beryllium volumes shown by Matyushenko [163] for the beryllides of all simple metals. In other words, since the MBe_{13} beryllides fit the additivity rule for the volumes of the components, then the volume of the beryllium atom should be decreased by ~ 0.23 Å^3 for most beryllides. This can be imagined to be the result of exceptional "close packing" (localisation) of the electrons of the skeletal beryllium atoms associated with the above-mentioned high statistical weight of stable sp electron configurations.

It must be noted that for $ScBe_{13}$ because of the high donor capability of the poorly filled d shell of the scandium atom the formation of the stable electronic configurations of the beryllium atom is accompanied by the appearance of a higher concentration of delocalised electrons, which should involve a lower melting point for this beryllide, more sharply expressed metallic properties, and a lower vapour pressure in thermal dissociation, owing to the greater fraction of electrons passing into the delocalised state and to the more symmetrical distribution of the electron density in the lattice.

Beryllides of the d transition metals. In considering the physicochemical nature and the electronic and crystal structures of the transition metal beryllides with incomplete d electron shells, we must consider the concept of the unimportant difference in distribution of the charge of the d electrons in a metal crystal from that in an isolated atom [164], the possibility of the formation of stable electron configurations of atoms of metals and non-metals [159], the possibility of electron promotion and transfer, and data on the distribution of electrons in the crystals of transition metals into covalently bound and delocalised [165–167]. The scheme of the bonds in the beryllides can be represented in the general form thus:

where M–Be is a predominantly metallic bond, effected by delocalised electrons, the bond Be : Be of predominantly covalent character, and the bond M+M mixed covalent--metallic. Evidently the fraction of the individual types of bonds in metal beryllides depends firstly on the ability of the d shells of these metals to accept or donate electrons with the formation of one or another configuration of localised electrons.

In accordance with ideas about the formation and breaking of stable electronic configurations which have been advanced [159,168,169,176] the stable states formed by the d electrons appear to be d^0, d^5, and d^{10}, the greatest stability being exhibited by the d^5 configuration, and the energetic stability of any configuration of the d electrons increases with increase in the principal quantum number of the d electrons.

For transition metals which possess in the state of isolated atoms the d^1s^2 configuration of valence electrons (scandium and yttrium) and also d^2s^2 (the metals of subgroup IVa) the most probable is the transfer of some of the valency electrons to partners with the formation of a high statistical weight of the d^0 state and a fall in the statistical weight of the d^5 state§. On passing to the metals of Groups V and VI (d^3s^2, d^4s^1, d^4s^2, d^5s^1) with a number of d electrons close to 5, the statistical weight of the d^5 configurations rises and there is a corresponding fall in the donor and rise in the acceptor ability of the atoms, directed to the completion and stabilisation of the d^5 configuration. For the transition metals with more than five electrons in the d shell (Group VIII) the presence of two stable configurations is characteristic: d^5 and d^{10}, the statistical weight of which changes to the benefit of the d^{10} states with rise in the number of electrons in the d shell of the isolated atom.

It must accordingly be expected that the transition metals of Groups III–IV will mainly tend to transfer valency electrons to beryllium atoms with the formation in the metallic sub-lattice of a high statistical weight of the d^0 state, and in the beryllium sub-lattice of covalent groups of beryllium atoms stabilised by valence electrons transferred by the metal atoms. With increase in the relative concentration of beryllium atoms there will be a greater transfer of metal electrons from the valence state in the beryllium atoms which are combined in stable configurations and there is an associated decrease in the concentration of delocalised free electrons, a corresponding decrease in the loosening of the lattice, and a rise in melting point, hardness, and electrical resistivity (Tables 4 and 5). It is noteworthy here that the melting points increase on going from the titanium to the zirconium beryllides, and then decrease for the hafnium beryllides; this is because on going from titanium to hafnium there is a simultaneous change in the stability and the statistical weight of the d^5 configuration and the probability of the promotion of part of the d electron density of zirconium and hafnium to the f state, whereas with zirconium there is evidently a known optimum — with the rise in stability and statistical weight of the d^5 state (leading to a fall is the concentration of the delocalised electrons) for zirconium the process of $d \rightarrow f$ promotion is still not strong enough, leading to a fall in the statistical weight of the d^5 state, to a rise in the weight of the d^0 state with a corresponding increase in the concentration of delocalised electrons, resulting in loosening of the lattice.

Similarly, for the metals of Group V the formation of beryllides should be connected with the breakdown of the electron configuration of beryllium and the transfer of the electrons to the transition metal atoms. However, owing to the tendency of beryllium to form stable electron configurations of type sp^3, it is evident that the same process of transfer of part of the valency electrons from the transition metal atoms to the beryllium occurs, but simultaneously strong covalent bonds are formed between the transition metal atoms [165–167], the more strongly the less they are destroyed by the transfer of electrons to the beryllium atoms. Therefore, for example, for the series of niobium beryllides (Table 6) the melting points of the corresponding phases do not decrease, but rise with increase in the relative proportion of metal, or with decrease in the relative proportion of beryllium. The same also occurs for the tantalum beryllides, and later in Group VI for the beryllides of molybdenum and apparently (judging by hardness)¶ — tungsten. It is interesting that tungsten and rhenium, which have quite stable and not readily excitable d^5 states (formed by d electrons which possess the highest principal quantum numbers, so that in tungsten these states are formed even in the metal crystal: $d^4s^2 \rightarrow d^5s^1$), form phases with the greatest relative amount of beryllium MBe_{22}, which is evidently connected with the considerable ease of transfer to beryllium of their s electrons of the stable d^5 states formed by the localised valence electrons.

For the transition metals having more than five electrons in the d shell of the isolated atom it is possible for both donor and acceptor properties to appear within wide limits, which gives rise to a wide variety of possible combinations of the bond functions and a correspondingly large number of compounds with beryllium, these being formed specially with the platinoids. Here, in those instances when the platinum metal is predominantly a donor, tending to give some of its electrons with a corresponding increase in the statistical weight of the d^5 configuration, phases with a high relative concentration of beryllium are formed predominantly (as for the transition metals of Groups IV–VI), for example, for ruthenium (d^7s^1), osmium (d^6s^2), and iridium (d^7s^2). When the metal is predominately an acceptor, tending to acquire electrons and increase the statistical weight of the d^{10} configurations, then phases with a high relative concentration of metal and a low relative concentration of beryllium are formed, which in this way is prevented from forming covalent groups because the metal atoms do not transfer to it the additional electrons. This occurs, for example, with palladium (d^{10}) and especially with platinum (d^9s^1), for which phases are formed with the lowest beryllium concentrations, right down to Be : M = 1 : 15. Nevertheless these metals, because they retain the probability of forming a type d^5 configuration, also form phases with a high relative concentration of beryllium.

X-Ray crystallographic studies of the beryllides TiBe, $TiBe_2$, Ti_2Be_{17}, and $TiBe_{12}$ have been made and they have

§ Using the results of the X-ray spectroscopic investigation of crystals of transition metals [165–167,177], the statistical weight of the d^5 configurations can be estimated for the metals (%): Sc 18, Y 22, La 23, Ti 43, Zr 52, Hf 55, V 63, Nb 76, Td 81, Cr 73, Mo 88, W 94.

¶ The more so, as hardness in these compounds of metallic type is determined by the concentration of delocalised electrons and by the degree of asymmetry of the electron density distribution, as in metals [170].

been compared with beryllium[66,171]. As a result it was found that for TiBe and $TiBe_2$ [171] the valence electrons of both atoms (titanium and beryllium) are delocalised, which ensures an essentially metallic type of bond with a small contribution from the donor–acceptor interaction of the 3*d* electrons of the titanium with the 2*p* electrons of the beryllium. In Ti_2Be_{17} [66] there is a marked weakening of the degree of overlap of the energy bands of the valence electrons of the components of the alloy and a substantial increase in the role of the interaction between the beryllium atoms, that is, apparently the appearance of strongly covalent Be–Be bonds, which the authors[66] designate as the difference in the "effective electronegativity" of beryllium from the electronegativity of titanium, instead of the practical equality of these quantities of the free atoms and their similar values for the phases containing less beryllium[171]. Hence the results of the X-ray studies of the titanium beryllides confirm well the nature of the change in the type of chemical bond with change in the relative concentration of beryllium atoms in the titanium beryllides.

Unfortunately, there has been no investigation of the superconducting properties of beryllium compounds which would permit several important conclusions about the electronic structure of these compounds to be drawn.

The dependence of the relative change in volume of beryllides of various compositions AB_x on atomic volumes of components A has been investigated[49,55] (Fig. 19). It is evident that the increase in the Be : M ratio leads to a decrease in the fraction of the volume associated with one atom of beryllium, that is, the significant growth in Be : Be covalent bonds and the corresponding packing of the structural complexes of beryllium atoms are again confirmed.

With increase in the Be : M ratio there is a corresponding increase in the coordination number of the M atoms: for the compounds MBe_2 (Laves phase type) the value 16 is characteristic; for the phases MBe_5 ($CaCu_5$ type), M_2Be_{17} (Th_2Zn_{17} type), and MBe_{12} ($ThMn_{12}$ type) 20; for the MBe_{13} phases ($NaZn_{13}$ type) 24. However, the coordination number of M for the MBe_{22} type phases is lower than in

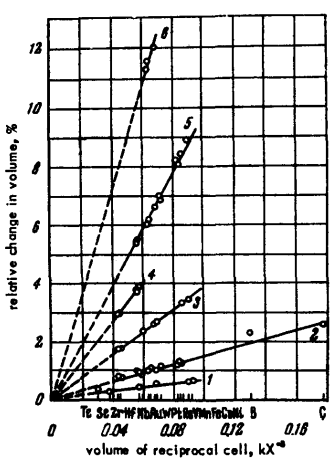

Fig. 19. Dependence of the relative change in the volume of the beryllides ABe_x on the atomic volumes of the components:
1) ABe; 2) ABe_2; 3) ABe_5; 4) $ABe_{8.5}$; 5) ABe_{12}; 6) ABe_{22}.

MBe_{12} and MBe_{13}, which agrees well with the formation here of the most complicated complexes from the beryllium atoms, which are structurally rather strongly isolated from the metal atoms (which in their turn, have a stable state with a high statistical weight of the d^5 configuration).

The electrophysical properties of the transition metal beryllides have hardly been studied at all, but the available data show that the beryllides of metals with a higher statistical weight of d^0 states and a correspondingly high concentration of delocalised electrons have the metallic type of conductivity with a temperature coefficient of resistivity which decreases with fall in the statistical weight of the d^0 state and increase in the weight of the d^5 state. The coefficients of thermal expansion of the beryllides tend to decrease, which is due to the great strength and rigidity of the bonds in their crystal lattices.

Hence the formation of covalent bonds, both between the transition metal atoms and also between the beryllium atoms, on simultaneous transfer of some of the valence electrons of the components into a delocalised state is characteristic of the transition metal beryllides. The transition metal beryllides then can be classified as covalent–metallic compounds with a wide variation in physical and chemical properties within these limits from being present in a predominantly covalent state (at a high statistical weight of stable electronic configurations of the metal and beryllium atoms) to metallic properties, determined by the lower statistical weight of the stable configurations and the large transfer of valence electrons of the components into a delocalised state.

VI. PROMISING FIELDS OF USE OF BERYLLIDES

The high strength of beryllides at high temperatures, especially of transition metal beryllides (Fig. 20), which is about ten times that of ceramics, in conjunction with high oxidation resistance and also high thermal conductivity (which is twice that of high-temperature materials based on oxides) suggests a promising use of beryllides as materials for heat-resistant and other high-temperature alloys with maximal operating temperatures up to 1700°.[172] The industrial use of beryllide heat-resistant materials has been described[80]. Thus, components of space vehicles and guided missiles made from such materials are capable of withstanding a temperature 1.5 times higher than the

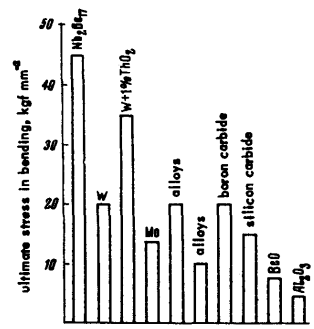

Fig. 20. Comparative strength of the beryllides and other refractory metals (at 1370°).

usual cobalt-, nickel-, and niobium-based alloys. The combination of high strength with low specific gravity (2.7 to 5–6) offers an especially promising use of beryllides in aviation and rocket technology. The resistance of beryllides to thermal shock at low rates of heat transfer and high-temperatures — which are higher than for most metal oxides, but lower than for graphite, fused silicon dioxide, and TiC-based cermets — is important for these fields of use; at high heat transfer rates the beryllides exhibit the same resistance to thermal shock as ThO_2, ZrO_2, and Al_2O_3.

The beryllides are of considerable practical interest for nuclear energy and energetics. Thus the beryllide UBe_{13} is liquid alkali metals is of interest as a nuclear fuel in heat liberating elements of the disperse type [173]. The Be–UBe_{13} dispersion systems have also been described [1,173]. The use of $NbBe_{12}$, YBe_{13}, and $ZrBe_{12}$ as moderators has been discussed [174]. The beryllide $PuBe_{13}$ is used as a neutron source, giving a stable yield of neutrons thanks to the long half-life of plutonium [131].

---o0o---

The peculiarity of the electronic structure of the beryllium atom, which enables it to form either a metallic bond by means of the valence *s* electrons, or covalent bonds, by means of the *sp* electronic configuration, determines both the dualism of the properties of beryllium itself, which acts simultaneously as a metal and as a non-metal, or as a semi-metal, and also the wide variety of compounds of beryllium with other metals — the beryllides — and their physicochemical properties.

In turn, the variety of properties ensures a wide potential field of use of this important and complex class of chemical compounds, especially in the various branches of high-temperature technology, nuclear physics, semiconductor technology, and in catalysis.

The investigation of the nature of the chemical bond is beryllides is of considerable importance for the development of the principles of contemporary metal chemistry [175] and the creation of new inorganic materials with previously specified physico-technical characteristics.

THE COLOUR OF DYES AND STERIC HINDRANCE IN THEIR MOLECULES

A. I. Kiprianov, G. G. Dyadyusha, and F. A. Mikhailenko

Steric hindrance in the molecules of organic dyes has a marked influence on their colour, ability to fluoresce, solubility, and many other physical and chemical properties. The presence of steric hindrance in the molecule quite often makes a dye unsuitable for practical application. With direct dyes the rule exists [1,2] that factors — including steric hindrance — which disturb bond conjugation weaken the affinity of the dye for the fibre, and may result in complete loss of this affinity. Moreover, steric hindrance lowers the intensity of absorption, so that dyes having non-planar molecules yield weaker colours [3]. Steric hindrance in the molecules of cyanine dyes sharply diminishes their ability to sensitise a silver halide emulsion [4]. Thus the problem of steric hindrance in the molecules of organic dyes is of great practical importance.

The chief method for detecting steric hindrance in dye molecules, as in other organic compounds, consists in examining their absorption in the visible or the ultraviolet region of the spectrum.

The absorption spectra of organic compounds depend to a considerable extent on the spatial arrangement of the atoms in their molecules, and sometimes this factor is dominant. The intense and longer-wavelength absorption bands typical of dyes (Burawoy's *K* bands [5]) are associated with $\pi-\pi^*$ electronic transitions, and are caused by the presence in the molecule of an extended system of conjugated double and single bonds, the chromophore [6]. Henceforward we shall confine our discussion to these bands.

Hückel [7] and Pauling [8] showed that the maximum conjugation of multiple bonds is achieved when the molecule has a planar structure, since the axes of the *p* orbitals are then parallel, and the orbitals overlap to the maximum extent. This theoretical conclusion was subsequently confirmed by the X-ray examination of a large number of compounds containing systems of conjugated bonds (*trans*-stilbene, phthalocyanines, cyanine dyes, etc.).

According to the conclusions of quantum-mechanical theory and the results of X-ray structural analysis, the principal structural features of an organic dye molecule are: (1) atoms forming part of the conjugated bond system lie in the same plane; (2) the angles between the bonds involving atoms in the conjugated chain are close to 120°; (3) double bonds in conjugated chains are usually arranged in *trans–trans*-positions; and (4) the lengths of bonds between directly linked atoms in the conjugated chain lie within the range 1.34–1.48 Å (the lengths of bonds between carbon atoms in buta-1,3-diene).

These rules may break down when bulky substituents are present in the conjugated system or adjacent to it. The departures from the normal geometry of the molecule are due to steric hindrance and the mutual repulsion of atoms which are not directly interlinked. If normal angles and a planar structure had been preserved in the molecule, these atoms would have been very close together.

Repulsive forces fall off very rapidly with increase in the interatomic distance. When the latter exceeds the sum of the van der Waals radii, repulsion between the atoms dies away. The van der Waals radii correspond to the minimum distances between atoms in various molecules and molecular crystals, and can be determined from X-ray data.

According to Kitaigorodskii [9] the van der Waals radii of atoms and radicals remain constant to within 0.01 Å on passing from the molecule of one substance to that of another. The van der Waals radii of several atoms and radicals, determined by the above method, are listed in Table 1. [10]

It must be remembered, however, that, as a result of some compression of the electron clouds, atoms can approach, without any considerable consumption of energy, to distances less than the sum of the van der Waals radii. Magat [11] introduced the concept of "effective" radii of atoms and radicals as a limit closer than which atoms could not approach. These effective radii or radii of action depend on the temperature in the sense that the higher the temperature the greater the energy of the colliding atoms, and the more strongly are they deformed on collision.

Although repulsive forces begin to act at distances equal to the sum of the van der Waals radii, the radii of action are in practice more suitable for detecting steric hindrance

TABLE 1.

* Half the thickness of an aromatic ring.

in a molecule. The radii of action of atoms and radicals are known only very roughly. In the case of atoms containing π electrons, they have different values parallel and perpendicular to the plane of the molecule. In view of the difficulty of determining radii of action, somewhat diminished van der Waals radii are often employed[12]. Some workers[13] use the relationship

$$R_{act} = R_{cov} + 0.8 \text{ Å}.$$

The presence or absence of steric hindrance in a planar conjugated molecule is established by drawing the molecule graphically to scale with the normal bond lengths and valency angles. Around each atom or radical is described a circle of radius corresponding to the radius of action. Steric hindrance is then detected from the overlapping of circles belonging to atoms or radicals which are not directly interlinked.

Table 2 gives bond lengths, bond angles, and radii of action for the most important atoms and radicals occurring in dye molecules†.

Fig. 1 shows as example a graphical representation of the cation of 2,2′,9-trimethylcarbocyanine (I).[15] It indicates that a coplanar conformation of this cation is impossible.

More accurate information on steric hindrance is provided by Stuart–Briegleb molecular models[16], which not only enable steric hindrance to be detected in a molecule but also permit the extent of breakdown of molecular coplanarity to be estimated. In these models interatomic

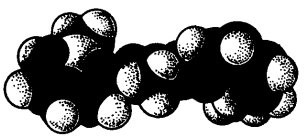

Fig. 2.

distances and angles are strictly fixed, while atoms are incompressible. The only variable parameters are provided by the angles of displacement about bonds. By constructing the model in such a way that atoms are located as close as possible to a single common plane, we can measure or calculate angles of displacement about individual bonds. Fig. 2 illustrates a Stuart–Briegleb model of the dye (II).

From simple geometrical considerations it may be supposed that steric hindrance changes the structure of a molecule in three ways — (1) by the stretching of bonds between atoms, (2) by the distortion of valency angles in a plane, and (3) by displacement about a bond, with one part of the molecule emerging from the plane of the remainder.

Actually, however, bond lengths remain almost unchanged, since the energy required to stretch C–C and C=C bonds is very large (3.25 and 7.05 kcal mole^{-1} respectively to lengthen these bonds by 0.01 Å[17]). Considerably less effort is necessary to distort valency angles in a plane. The energy of deformation of the  angle in the methane molecule and of the  angle in the ethylene molecule by 5.73° (0.1 radian) is respectively 0.39 and 0.26 kcal mole^{-1}.[17] However, displacement about a bond occurs most easily, as about an axis of rotation. The energy of displacement by 0.1 radian about an ethylenic (C=C) and an aromatic (C–C) bond is respectively 0.24 and 0.08 kcal mole^{-1}.[18] For a bond which approximates to a single bond, this energy is close to zero. It follows from these results that the primary effect of steric hindrance will generally be displacement about bonds, which will occur more readily the closer a given bond approximates to a single bond.

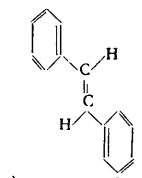
When considering the effect of steric hindrance on the absorption spectrum of a molecule containing a system of conjugated bonds, we must also bear in mind that the stretching of bonds and the distortion of valency angles have relatively little effect on the conjugation of π electrons[19], whereas rotation about a bond reflects the axes of p-electron orbitals from their parallel arrangement. The π-electron interaction energy varies with the square of the cosine of the angle of deflection[20-22]. On rotation through 90°, the atomic p orbitals cease to interact.

Let us now examine the changes in absorption spectrum resulting from steric hindrance and the breakdown of molecular coplanarity in the light-absorbing substance. These changes consist firstly in a displacement in the absorption band, which is usually characterised by the change in wavelength corresponding to maximum absorption (λ_{max}). Secondly a change, usually a decrease, occurs

in the intensity of absorption, which is characterised by the molecular extinction at the absorption maximum (ϵ_{max}).

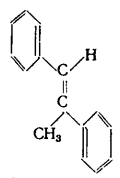
The decrease in absorption intensity is a direct consequence of the diminished mutual overlap of p orbitals in the conjugated system when its coplanarity breaks down. A fall in molecular extinction is therefore the first sign of the appearance of steric hindrance in the absorbing molecule.

The displacement of the absorption band is rather more complicated, since it may occur either towards longer or towards shorter wavelengths. Thus methyl-*trans*-stilbene (IV) absorbs at shorter wavelengths than does *trans*--stilbene (III)[23]:



λ_{max} 294 nm, logϵ 4.44

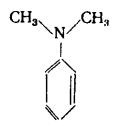
(III)



λ_{max} 272 nm, logϵ 4.30

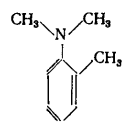
(IV)

NN-Dimethyl-*o*-toluidine (VI) absorbs at shorter wavelengths than does dimethylaniline (V)[24]:



λ_{max} 300 nm, ϵ 13.9 × 10³

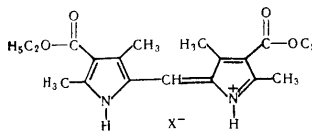
(V)



λ_{max} 277 nm, ϵ 6.0 × 10³

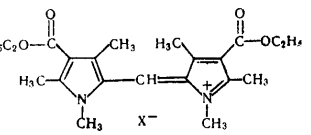
(VI)

In 1942 Brunings and Corwin[25] were the first to show that steric hindrance in the dipyrrylmethene (VIII) produces not a hypsochromic but a bathochromic shift:



λ_{max} 470 nm, ϵ 13.5 × 10⁴

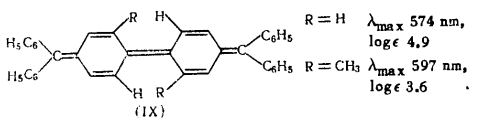
(VII)



λ_{max} 510 nm, ϵ 5.7 × 10⁴

(VIII)

A bathochromic shift has been observed to accompany steric hindrance in Chichibabin's hydrocarbon (IX)[26]:



R = H λ_{max} 574 nm, logϵ 4.9

R = CH₃ λ_{max} 597 nm, logϵ 3.6

(IX)

Absorption of light occurs in the visible and ultraviolet regions when the energy of the quanta of incident light coincide with that of the electronic transitions of the molecule from the ground state to an excited state. The frequency of the adsorbed light is determined by the difference in energy between ground and excited states according to the well--known Bohr formula

$$\nu = \frac{c}{\lambda} = \frac{E' - E_0}{h}.$$

Hence, in order to ascertain how the frequency (or wavelength) absorbed by the molecule changes under the influence of steric hindrance, we must know what changes are produced thereby in the energy of the ground and of the excited states (steric hindrance always increases the energy of a molecule in comparison with one that is free from steric hindrance).

If steric hindrance increases the energy of the excited state more than it does that of the ground state, the molecule will absorb light of higher frequency: i.e. the absorption band will shift to shorter wavelengths, and a hypsochromic shift in the absorption band will be observed. In the opposite case, when steric hindrance increases the energy of the ground state more than that of the excited state, the molecule will absorb light of lower frequency: the absorption band will be displaced to longer wavelengths (bathochromic shift).

Applying the LCAO approximation[27], we determine the order of the mobile (π-electron) bond p'_{rs} as the derivative of the energy E of the π electrons with respect to the exchange integral β_{rs} of the π-electron orbitals of the atoms r and s forming the given bond:

$$p_{rs} = \frac{1}{2}\frac{\partial E}{\partial \beta_{rs}}.$$

As we have seen, the influence of steric hindrance on absorption spectra is due to the disturbance of π-electron conjugation, represented by a decrease in the absolute magnitude of the exchange integral β_{rs}. If the change in the exchange integral is small, the corresponding change in the π-electron energy is[28]:

$$dE = \frac{\partial E}{\partial \beta_{rs}} d\beta_{rs} = 2p_{rs}\, d\beta_{rs}.$$

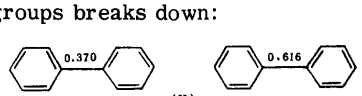
Since excitation involves no change in the relative positions of atoms, the change in exchange integral produced by steric hindrance is the same in ground and excited states. The difference in the change in energy of ground E_0 and excited E' states should depend on the difference in bond order between ground $p_{0,rs}$ and excited p'_{rs} states:

$$d(E' - E_0) = 2d\beta_{rs}(p'_{rs} - p_{0,rs}).$$

The exchange integral is a negative quantity. When it decreases in absolute magnitude, $d\beta_{rs}$ is positive. If, therefore, the bond order is greater in the excited than in the ground state, i.e. if $p'_{rs} - p_{0,rs} > 0$, the energy of the transition $E' - E_0$ increases, since $d(E' - E_0) > 0$, and we should observe a hypsochromic shift. When, on the other hand, $p'_{rs} - p_{0,rs} < 0$ and $d(E' - E_0) < 0$, a bathochromic shift should be observed. In the particular case in which $p'_{rs} - p_{0,rs} = 0$ and $d(E' - E_0) = 0$, steric hindrance does not affect the position of the absorption maximum, although it may influence the fine structure and the intensity of absorption.

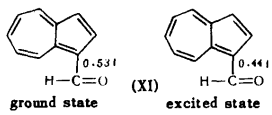
The bond order in the chain of conjugation in a molecule in its ground state can be determined[29] by X-ray examination of its length. Some information can be obtained from infrared and Raman spectra[30]. The experimental determination of bond orders in the excited state of a molecule is difficullt, but some information can be obtained from the vibrational structure of the absorption bands[31].

However, the order of the bonds in which we are interested (only the contribution of the π electrons to the bond order is taken into account), in both ground and excited states, can be calculated to a sufficiently close approximation by quantum-mechanical methods. Calculations by the molecular orbital method are most readily available. They show that the order of the central bond in biphenyl (X) increases on excitation. This is consistent with the observed hypsochromic shift when the coplanarity of the phenyl groups breaks down:

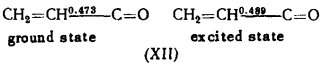


ground state (X) excited state

In just the same way calculation shows, in agreement with experiment, that the order of the bond between the cyclic system and the carbonyl group in azulene-1-aldehyde (XI) is lower in the excited state than in the ground state[28]:

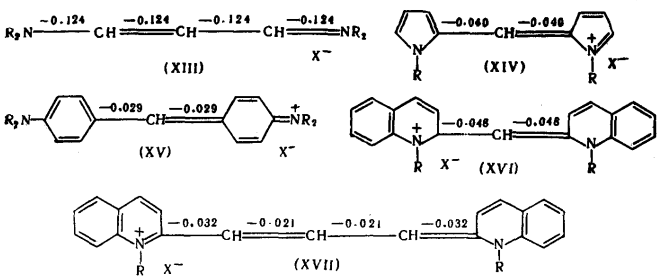


The comparatively small change in order of the similar bond in acryladehyde (XII) explains why no shift in its absorption maximum under the influence of steric hindrance is observed in its derivatives[28]:

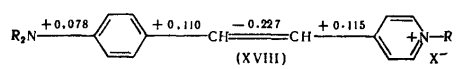


(XII)

Similar calculations (with the usual values for the parameters $\alpha_N = \alpha + \beta$ and $\beta_{CN} = \beta$[32]) show that the excitation of symmetrical polymethine dyes is accompanied by a decrease in order of all bonds in the polymethine chain, for example (with only the differences $p'_{rs} - p_{0,rs}$ indicated)



This rule does not extend to unsymmetrical dyes. For the 4-*p*-dimethylaminostyrylpyridinium cation (XVIII) calculation indicates that excitation will be accompanied by an increase in order of the "single" bonds and a decrease in that of the "double" bond:



Similar calculations have been made for bianthronyl[33], stilbene[34], and nitro-derivatives[35].

Quantum-chemical methods are also useful in enabling general tendencies and regularities to be detected in the changes in bond order accompanying excitation. It has been shown from symmetry considerations, for example, that the order of the central bond in compounds of general formula A–A increases on excitation if this bond is single when the formula is written in the usual way, and decreases if the bond is double or triple (except in the case of cumulenes)[36]. Similar principles have been formulated for the central bonds of symmetrical compounds of general formula Hal–X=Hal$^+$, i.e. for dyes[36].

If we have data on bond orders only in the ground state, we can guess the most probable direction of the change. In fact, if the bond about which deflection occurs is of low order in the ground state, cases in which this bond will have a still lower order should be more rarely met than cases in which it will be of a higher order in the excited state. If, one the other hand, the bond is of high order in the ground state, it is more likely to have a lower order in the excited state. It must be borne in mind here that, on the average, bond orders are lower in an excited state than in the ground state.

This follows from the fact that the energy of a molecule is an additive function of the bond energies, which are proportional to the bond orders. According to the definition of bond order which we have adopted, the coefficient of proportionality between the energy and the order of a bond should be double the exchange integral. Actually, if

$$E' = E_0 + 2\sum_{r<s} p_{rs}\beta_{rs},$$

we have

$$\frac{\partial E}{\partial \beta_{rs}} = 2p_{rs}.$$

The mean decrease in bond order on excitation depends on the transition energy and the number of bonds n involved in the absorption of light. Writing the mean values $\bar{p}$ and $\bar{\beta}$, we obtain

$$2\sum_{r<s} p_{rs}\beta_{rs} = 2n\bar{p}\bar{\beta};\ \bar{p}' - \bar{p}_0 = \frac{E' - E_0}{2n\bar{\beta}}.$$

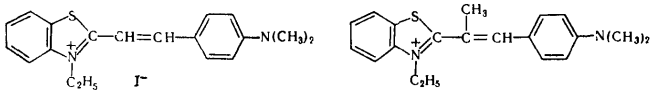
Substituting in this formula $\bar{\beta}$ = 73.2 kcal mole^{-1}[32], the transition energy, and n = 4 for the dye (XIII) (λ_{max} 409 nm), we obtain $\bar{p}' - \bar{p}_0 = -0.119$, in good agreement with the value of -0.124 calculated by the molecular orbital method. It follows from the relationship which has been obtained that the smaller the transition energy and the larger the number of bonds, the smaller is the difference in bond order between ground and excited states. This means that, as the molecule becomes more complicated and the colour of the substance deeper, steric hindrance exerts an ever diminishing effect on the transition energy (the displacement of the absorption band expressed in frequency units decreases). But this does not mean that the shift in the absorption maximum expressed in wavelength units should be smaller, under otherwise similar conditions, in more deeply coloured substances, since the sensitivity of the wavelengths of absorption maxima to changes in transition energy increases rapidly with increase in wavelength. In fact if follows from $\lambda_{max} = \nu_{max}^{-1}$ that $d\lambda_{max} = -\lambda^2_{max} d\nu_{max}$.

The conclusion that bond orders on the average decrease on excitation indicates a tendency of steric hindrance to cause bathochromic shifts. However, deflection about a bond which approaches a single bond in character requires less energy, and occurs first if there is a choice[37]. On the same principle sterically hindered compounds have a smaller energy content and are more stable the lower the order of the bond, rotation about which destroys the conjugation. Therefore we more often meet hypsochromic shifts.

Bond orders in ground and excited states can be estimated also by other quantum-chemical methods, e.g. the valence bond method. With this method it must be borne in mind that the "percentage double-bondedness" is ambiguous owing to a certain arbitrariness in the choice of canonical structures, and bond orders must be determined by Penney's method[38]. The inconvenience associated with this last method, as well as the necessity of taking into account ionic structures for the excited state, complicate application of the valence bond method in comparison with the molecular orbital method. Nevertheless, an empirical approximation of this method, known as the theory of resonance, enables the relative orders of difference bonds in the ground state, or the ratio of the orders of the same bond in ground and excited states, to be determined simply and clearly. The conclusions of this simple method do not usually differ qualitatively from those of the molecular orbital method. Thus the general conclusion that deflection about bonds of low order should result in hypsochromic

shifts, whereas deflection about bonds of high order should result in bathochromic shifts, was first obtained by Wheland [39] on the basis of this particular method.

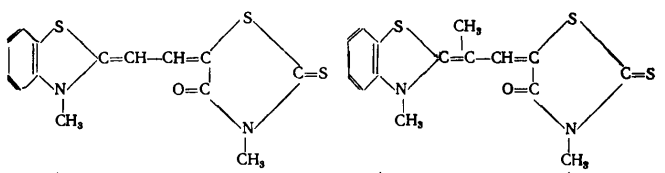
We can illustrate the application of resonance theory by an example [40]: the change from the styryl dye (XIX), having an unsubstituted chain, to its methyl derivative (XX) is accompanied by a diminished intensity of absorption and a marked displacement of the absorption band to shorter wavelengths:



λ_{max} 528 nm, ϵ 11.0×10^4 (XIX)

λ_{max} 481 nm, ϵ 6.2×10^4 (XX)

In the latter dye (XX) steric hindrance arises between the methyl group in the chain and the sulphur atom or the *N*-alkyl group. This interference forces the benzothiazole ring system to be deflected through a certain angle about its bond with the neighbouring carbon atom in the chain as axis, this bond being predominantly single in the ground state. On the other hand, the absorption maximum is displaced to longer wavelengths in merocyanine dyes, e.g. on passing from (XXI), whose chain is unsubstituted, to its methyl derivative (XXII):

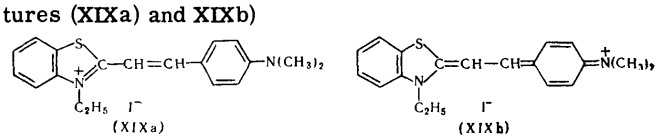


λ_{max} 521 nm, ϵ 9.13×10^4 (XXI)

λ_{max} 542 nm, ϵ 7.75×10^4 (XXII)

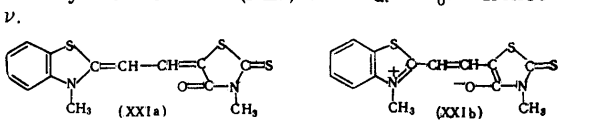
In contrast to (XX), the bond about which the ring system turns in the dye (XXII) in the ground state approximates to a double bond, not a single bond.

The structure of the molecule of (XIX) in both ground and excited states is intermediate between the structures (XIXa) and XIXb)



(XIXa) (XIXb)

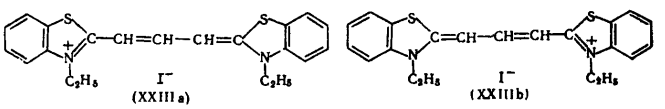
the former predominating in the ground state, and the latter in the excited state. A similar situation is found in the dye (XX). Denoting by E_0 the energy of compound (XIX) in the ground state and by E_0' that of compound (XX), and by E_{ex} and E_{ex}' the energies of these compounds in the excited state, we find that E_0' differs little from E_0, since deflection about a single bond requires no great consumption of energy. But E_{ex}' exceeds E_{ex}, since deflection about a double bond requires a considerable consumption of energy. Consequently the quantum of energy absorbed by the molecule (XX) $h\nu' = E_{ex}' - E_0'$ exceeds that absorbed by the molecule (XIX) $h\nu = E_{ex} - E_0$. Hence $\nu' > \nu$.



(XXIa) (XXIb)

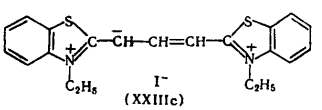
In the case of merocyanines in which a non-polar structure, e.g. (XXIa), predominates in the ground state, whereas a polarised structure (e.g. XXIb), predominates in the excited state, the energy relationships between ground and excited states are the reverse of those above, and $\nu' < \nu$.

In the case of symmetrical polymethine dyes, all carbon–carbon bonds in the polymethine chain have the same length of 1.40–1.41 Å, as has been shown for the thiacarbocyanine (XXIII) [41]



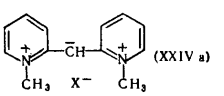
(XXIIIa) (XXIIIb)

The fact that steric hindrance in these dyes produces bathochromic shifts [42] is explained by the theory of resonance in terms of diminished interaction between the limiting structures — (XXIIIa) and (XXIIIb) [43] — resulting from the breakdown of conjugation. The same effect can be explained by a decrease in bond order in the excited state in comparison with the ground state owing to the great weight of bipolar structures of the type (XXIIIc) in the excited state [44].



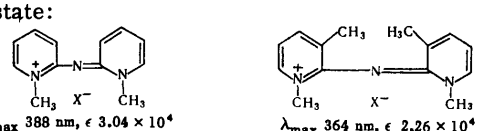
(XXIIIc)

These explanations do not contradict, but on the contrary supplement, one another. It is impossible to say in advance which of the effects should be the more important. This depends on the structure of the given dye. Contrary to Scheibe's original idea [44], it must be remembered that completely symmetrical structures, e.g. (XXIVa)



(XXIV a)

cannot be involved in an incompletely symmetrical excited state [45]. Therefore increase in the weight of such structures, as e.g. in the compounds (XXV) and (XXVI), results in a decrease in bond order not in the excited but in the ground state:



λ_{max} 388 nm, ϵ 3.04×10^4 (XXV)

λ_{max} 364 nm, ϵ 2.26×10^4 (XXVI)

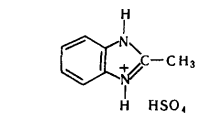
As a consequence, steric hindrance in these compounds produces hypsochromic shifts [46], instead of the bathochromic shifts which are usual for symmetrical dyes.

In the examination of experimental data, it is often difficult to assess the "pure" effect of steric hindrance, especially if it is caused by strong electron-donor or electron-acceptor substituents. In cases of this kind, steric and electronic effects are superposed, and are difficult to separate. In the investigation of steric effects, therefore, they are usually produced by introducing bulky alkyl groups, whose electronic effect is minimal [47].

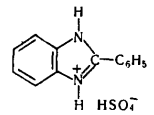
Data known to us on the effect of steric hindrance on the colour of dyes can be separated, to some extent arbitrarily, into two groups. The first group comprises cases in which steric hindrance prevents conjugation of a substituent with the main chromophore of the molecule. The second group consists of cases in which the coplanarity of parts of the chromophore itself is destroyed by steric hindrance.

The effect of steric hindrance on a substituent in a dye molecule is in general fairly simply revealed. The steric hindrance forces the substituent out of coplanarity with the chromophore, and thus diminishes or altogether eliminates

its effect on the absorption of light. An example is provided by replacing the methyl group in the 2-methylbenzimidazolium cation (XXVII) by phenyl, which produces a bathochromic effect[48]:

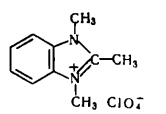


λ_{max} 275 nm, ϵ 0.096 × 10⁴ (XXVII)

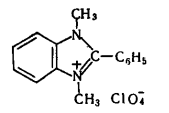


λ_{max} 300 nm, ϵ 2.76 × 10⁴ (XXVIII)

This effect almost disappears if methyl groups are attached to the nitrogen atoms, for they prevent the phenyl from lying in the plane of the heterocycle:

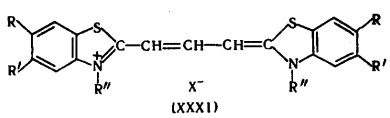


λ_{max} 277 nm, ϵ 0.84 × 10⁴ (XXIX)



λ_{max} 280 nm, ϵ 1.52 × 10⁴ (XXX)

Introduction of a substituent *ortho* to a dialkylamino- or a nitro-group in an aromatic ring produces a hypsochromic displacement of the absorption band owing to steric hindrance[49]. Let us examine in this connection the absorption of thiacarbocyanines of general formula



(XXXI)

which were investigated by Kiprianov and Zhmurova[50]. Comparison of dyes *4* and *1* in Table 3 shows that the introduction of two dimethylamino-groups into the thiacarbocyanine cation considerably deepens the colour and diminishes its intensity (the latter effect being associated with a broadening of the absorption band). If methyl radicals are introduced *ortho* to the dimethylamino-groups (dye *5*), some breakdown occurs in the coplanarity and conjugation of the dimethylamino-groups with the benzene rings, and their influence on the colour is somewhat weakened. In fact we see that the absorption maximum of dye *5* approaches that of dye *2*, and the intensity of absorption increases. The more bulky t-butyl groups force the dimethylamino-groups still further out of the plane of the benzene rings, and practically eliminate their effect on the colour. The narrow and intense absorption band of dye *6* almost coincides with that of dye *3*. In this case steric hindrance has a similar effect to protons binding unshared electron pairs in dimethylamino-groups (dye *7*).

Similar rules were observed by Levkoev et al.[51] on the introduction of halogen atoms *ortho* to dimethylamino--groups in thiacarbocyanines.

TABLE 3.

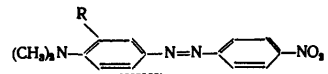
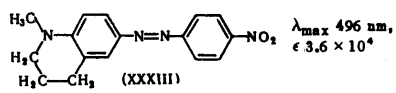
In azo dyes having the structure



(XXXII)

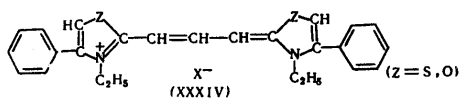
substituents R *ortho* to the dimethylamino-group diminish its auxochromic action and weaken the colour[52] (Table 4).

If the substituent forms a ring with the amino-group, fixing the latter in the plane of the benzene ring (dye XXXIII), it intensifies instead of weakening the colour:



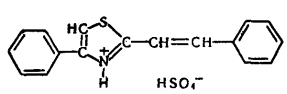
λ_{max} 496 nm, ϵ 3.6 × 10⁴ (XXXIII)

Aryl radicals in the 4,4′-positions of the cations of thiazolo- and oxazolo-cyanines have little effect on the absorption of light by these dyes, whereas the same aryls in the 5,5′-positions greatly deepen the colour[53–55]. It was suggested that, as a result of steric hindrance, aryl groups in the 4,4′-positions are not coplanar with the thiazole or oxazole rings:

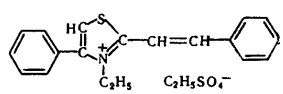


(XXXIV)

This hypothesis could be confirmed[56] by comparing the absorption curves of the sulphate (XXXV) and the ethyl sulphate (XXXVI) of 4-phenyl-2-styrylthiazoles:



λ_{max} 358 nm, ϵ 2.4 × 10⁴ (XXXV)



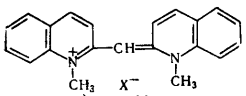
λ_{max} 355 nm, ϵ 1.82 × 10⁴ (XXXVI)

Steric hindrance was practically absent in the cation of the sulphate, and the phenyl group produced a bathochromic displacement of the absorption maximum.

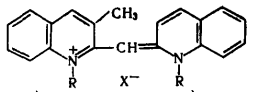
Experimental data on the effect of steric hindrance in the chromophores of dyes are far more varied. Cyanine dyes form the most convenient subject for investigations of this type. In them the length of the conjugated chain can be altered comparatively easily, as can substituents differing in bulk and electronic character be introduced into it, and hydrogen atoms substituted in the heterocyclic rings. Displacements of maxima resulting from the appearance of steric hindrance can be very conveniently observed in cyanine dyes, with their narrow and intense absorption bands.

The first systematic investigation in this field was undertaken by Scheibe[57]. He found that introduction of a methyl group into position 3 of the pseudocyanine dye (XXXVII), with the formation of (XXXVIII), produces no shift in the absorption maximum if methyl groups are

attached to the nitrogen atoms. Replacement of these methyl by ethyl groups produces a bathochromic shift:

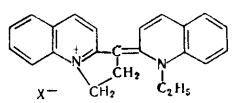


λ_{max} 522 nm
(XXXVII)

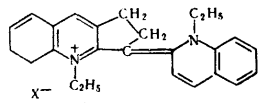


R = CH_3 λ_{max} 523 R = C_2H_5 λ_{max} 535 nm
(XXXVIII)

The substantial change in the absorption maximum on passing from methyl to ethyl groups attached to the nitrogen atoms in itself shows that steric hindrance is involved here. Passing from (XXXVII) to the dyes (XXXIX) and (XL) will give an increase in steric hindrance and a sharp increase in the bathochromic shift:

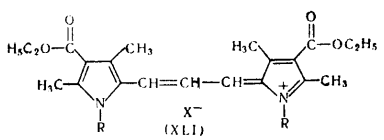


λ_{max} 575 nm
(XXXIX)



λ_{max} 583 nm
(XL)

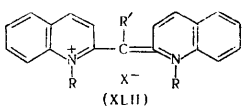
Brooker et al.[43] showed that the previously mentioned Brunings–Corwin effect was associated with a loss of coplanarity, not with the electronic character of the methyl group. In the vinylogue (XLI) of dipyrrylmethane, replacement by methyl groups of the hydrogen atoms attached to the nitrogen atoms produces merely a slight hypsochromic shift, since the coplanarity of the molecule is not thereby disturbed:



(XLI)

R = H λ_{max} 595 nm
R = CH_3 λ_{max} 581 nm

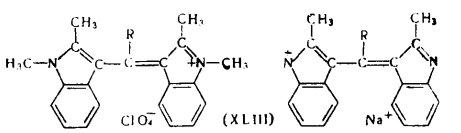
Brooker found an effect, similar to that described for dyes (XXXVII) and (XXXVIII), on introducing an alkyl radical into the methine group of pseudocyanines:



(XLII)

R	R′	λ_{max} nm
CH_3	H	520
CH_3	CH_3	574.5
C_2H_5	H	522.5
C_2H_5	C_2H_5	584

Similar facts had been observed even before Brooker's work. They had either remained unnoticed, as occurred, for example, with the indocyanines

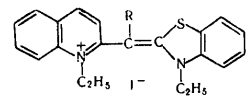


(XLIII)

R = H λ_{max} 482 nm
R = C_6H_5 λ_{max} 518 nm

R = H λ_{max} 482 nm
R = C_6H_5 λ_{max} 526 nm

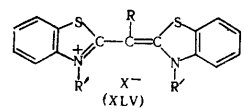
synthesised by König[58] in 1925, or were puzzling. Thus Götze[59] in 1936 was the first to prepare *meso*-methylthia--2-quinocyanine (XLIV, R = CH_3), but he thought that he was dealing with a more complicated substance, since its violet colour differed sharply from the orange colour of the unsubstituted dye‡:



R = H λ_{max} 486 nm; R = CH_3 λ_{max} 545 nm[60]
(XLIV)

Bathochromic shifts accompanying the introduction of bulky alkyl substituents into the methine groups of monomethinecyanines were observed by Kiprianov and Ushenko[42] and by Fry and Kendall[62] in thiacyanines, by Jeffreys and Knott[63] in pyrrolocyanines, and by Hamer[60] in unsymmetrical cyanines.

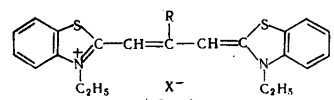
Kiprianov et al.[64] showed that this effect is actually associated with steric hindrance. Studying the monomethinecyanines (XLV), they found that replacement of the methine hydrogen atom by a methyl group produces no steric hindrance if hydrogen atoms are attached to the nitrogen atoms. Such replacement results in a loss of coplanarity and a bathochromic shift only when alkyl groups are attached to the nitrogen atoms:



(XLV)

R	R′	λ_{max} nm
H	H	425
CH_3	H	425
H	CH_3	425
CH_3	CH_3	465

A *meso*-methyl group does not give rise to steric hindrance in the thiacarbocyanines (XLVI, R = CH_3)[4]. The slight hypsochromic shift without appreciable decrease in intensity is explained by its electronic effect[65]. In the dye (XLVI, R = C_6H_5) the phenyl group, because of steric hindrance, lies in a plane perpendicular to the rest of the molecule. Conjugation of the phenyl group with the chromophore of the dye disappears, and the group has no significant effect on the colour[66]:



(XLVI)

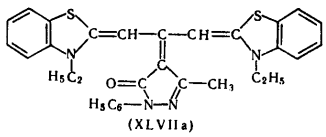
R = H λ_{max} 558 nm, R = CH_3 λ_{max} 543 nm,[67] R = C_6H_5 λ_{max} 560 nm

Even the introduction of polar substituents — $N(CH_3)_2$, OH, O^- — into the *para* position of this phenyl group does not significantly affect the absorption maximum[68].

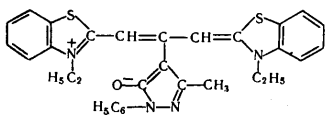
Brooker observed an interesting phenomenon, which he termed allopolar isomerism[69], in some trinuclear dyes. The dye (XLVII) can be represented by three limiting structures, a non-polar form (XLVIIa) and two bipolar

‡ The non-planar structure of this dye was confirmed in 1960 by X-ray examination, the angle between the planes of the quinoline and the benzothiazole rings being 60°.[61]

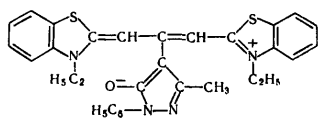
structures — (XLVIIb) and (XLVIIc) — having the same energy:



(XLVIIa)



(XLVIIb)

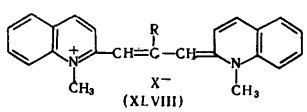


(XLVIIc)

As can be seen from Fig. 3, it is not possible for all three ring systems in the dye (XLVII) to lie in the same plane: at least one of them must be perpendicular to the other two.

In a polar solvent (methanol) this dye gives an absorption curve (Fig. 4*B*) which is typical of thiacarbocyanines. Hence the molecule is polarised in methanolic solution, the two benzothiazole systems lying in one plane, while the pyrazolone ring, with a negative charge on the carbonyl oxygen atom, is deflected from this plane as a result of rotation about the single bond, as in structures (XLVIIb) and (XLVIIc) (Fig. 3*B*). In a non-polar solvent (lutidine) the absorption curve (Fig. 4*C*) is quite different in shape, resembling that of a merocyanine based on a benzothiazole and a pyrazolone ring. It is obvious that in lutidine solution the benzothiazole and pyrazolone systems lie in the same plane, while the second benzothiazole ring system is deflected out of this plane — structures (XLVIIa) and (XLVIIb) (Fig. 3*C*).

Introduction of a methyl group into the *meso* position of the 2,2′-carbocyanine (XLVIII) now causes steric hindrance[70], which is eliminated by deflection of the quinoline rings about the bonds of the polymethine chain. The consequence is a bathochromic shift:



(XLVIII)

R = H λ_{max} 607 nm,[71]
R = CH_3 λ_{max} 649 nm,[7]
R = C_6H_5 λ_{max} 648 nm,[71]

In the dye (XLVIII) with R = C_6H_5 the phenyl group lies in a plane perpendicular to that of the chromophore, but even in this position it, like the methyl group, causes steric hindrance.

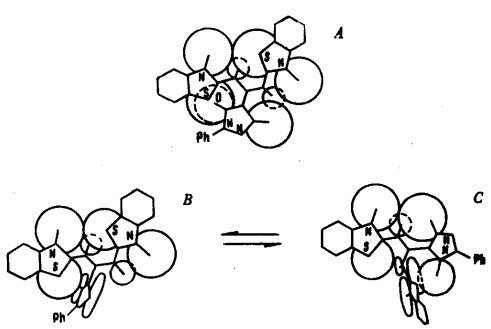


Fig. 3.

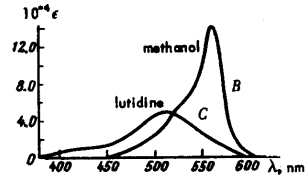

Fig. 4.

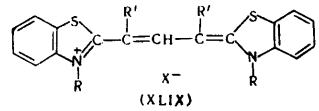
Kiprianov and his coworkers have shown that alkyl or aryl groups in the $\alpha\gamma$ positions of the polymethine chain of thiacarbocyanines (XLIX) cause steric hindrance[42,72]:

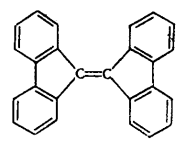


(XLIX)

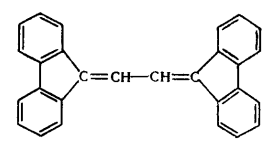
R	R′	λ_{max} nm
CH_3	H	559
CH_3	CH_3	577
CH_3	C_2H_5	571
CH_3	iso-C_3H_7	576
CH_3	C_6H_5	580
C_6H_5	H	565
C_6H_5	CH_3	602

Deflection of the benzothiazole ring systems about the bonds of the polymethine chain results in a bathochromic shift, which is especially marked if phenyl radicals are attached to the nitrogen atoms.

An interesting case occurs when steric hindrance present in a lower vinylogue because of the large volume of the ring systems of the dye disappears when the polymethine chain is lengthened. For example, 9,9′-bifluorenylidene (L) is more deeply coloured than is its vinylogue (LI)[73]. In the non-coplanar dye (L) the ring systems have been deflected about a bond which approximates to a double bond. This has led to a bathochromic shift in the absorption maximum exceeding the vinylene shift in the maximum on passing from (L) to (LI).

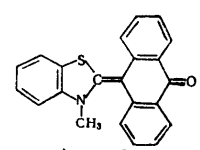


λ_{max} 458 nm
(L)

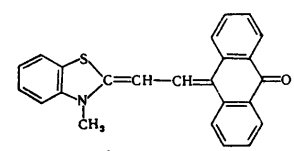


λ_{max} 444 nm
(LI)

A similar phenomenon is observed in the quinone methides (LII) and (LIII)[74].

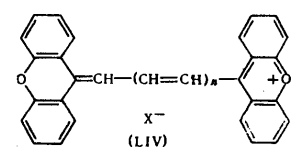


λ_{max} 551 nm
(LII)



λ_{max} 537 nm
(LIII)

In xanthocyanine (LIV, n = 0) the bathochromic shift due to breakdown of coplanarity is detected from the decrease in the vinylene shift on passing from n = 0 to n = 1:[75]

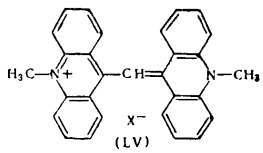


(LIV)

		$\Delta\lambda_{max}$
n = 0	λ_{max} 648 nm	
		57 nm
n = 1	λ_{max} 705 nm	
		80 nm
n = 2	λ_{max} 785 nm	
		80 nm
n = 3	λ_{max} 865 nm	

The considerable breakdown in coplanarity in acridinomethinecyanine (LV) is detected from the very low extinction

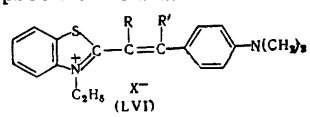
of this dye and the wide absorption band without any distinct maximum[43]:



(LV)

In dyes having a high degree of electronic asymmetry the effect of steric hindrance will depend on the order of the bond about which the ring systems of the dye have been deflected.

In styryls (LVI) with substituents in the β or α position, deflection of the benzothiazole and benzene ring systems occurs about bonds of diminished order, resulting in a hypsochromic shift[76]:

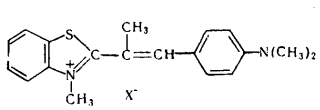


(LVI)

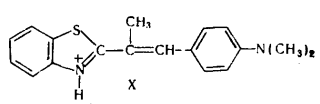
R=H R′=H λ_{max} 530 nm
R=CH_3 R′=H λ_{max} 481 nm
R=H R′=CH_3 λ_{max} 518 nm

Similar results were obtained by Brooker[43] and by Hamer[60].

The presence of steric hindrance in the styryl dye (LVII) has been confirmed by Kiprianov and Tolmachev, who showed that its analogue (LVIII), in which steric hindrance should not be present, absorbs at considerably longer wavelengths[77]:

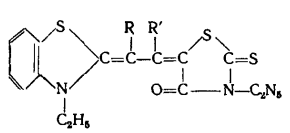


λ_{max} 478 nm
(LVII)



λ_{max} 496 nm
(LVIII)

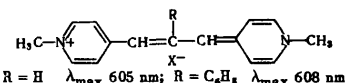
The bonds between the heterocyclic systems and the neighbouring methine groups in merocyanines (LIX) are of high order, and deflection of the rings about these bonds results in bathochromic shifts[78]:



(LIX)

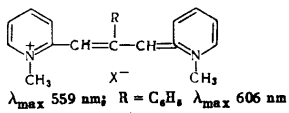
R	R′	λ_{max} nm
H	H	524
CH_3	H	540
C_6H_5	H	536
H	CH_3	532
H	C_6H_5	542

Kiprianov and Dyadusha[15] made a spectroscopic study of steric hindrance in symmetrical and unsymmetrical *meso*-phenylcarbocyanines. They showed that in the 4,4′-pyridocarbocyanines (LX) a *meso*-phenyl group produces no change in the absorption maximum, as in the case of the thiacarbocyanines discussed earlier:



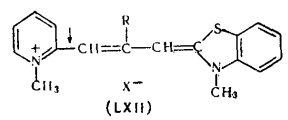
R = H λ_{max} 605 nm; R = C_6H_5 λ_{max} 608 nm
(LX)

A phenyl group in the same position in 2,2′-pyridocarbocyanines (LXI) results in appreciable steric hindrance, as in the dye (XLVIII, R = C_6H_5). Deflection of the rings about bonds in the polymethine chain produces a bathochromic shift:



R = H λ_{max} 559 nm; R = C_6H_5 λ_{max} 606 nm
(LXI)

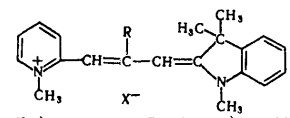
In unsymmetrical dyes (LXII) bonds of higher and lower order alternate in the chain. The degree of non-equivalence of the bonds is measured by the deviation[79,80] (the displacement, towards shorter wavelengths, of the absorption maximum of the unsymmetrical dye from the arithmetic mean of the absorption maxima of the corresponding symmetrical dyes):



(LXII)

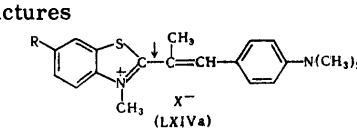
R=H λ_{max} 536 nm
deviation 22.5 nm
R=C_6H_5 λ_{max} 544 nm
deviation 39 nm

In the dye (LXII) with R = C_6H_5 steric hindrance between the pyridine ring and the phenyl group is removed by rotation about a bond (shown by the arrow in the formula) of rather diminished order. This results in a smaller bathochromic shift on passing from the dye (LXII) with R = H to the corresponding dye with R = C_6H_5 compared with the similar bathochromic shift in the dye (LXI). Deflection of the pyridine ring about a bond of diminished order results in a still greater decrease in the order of this bond, and hence in an increase in the deviation. With a sufficiently large difference in basic character between the ring systems, as e.g. in the dye (LXIII), the bathochromic shift is replaced by a hypsochromic shift:

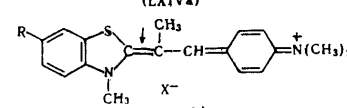


R = H λ_{max} 509 nm; R = C_6H_5 λ_{max} 460 nm
(LXIII)

Kiprianov and Mikhailenko have investigated, on polymethine dyes of several types, how displacement of the absorption maximum changes with variation in the order of the bond about which the ring systems of the dye are deflected. In styryl dyes (LXIV)[40] the first of the two limiting structures



(LXIVa)



(LXIVb)

predominates in the ground state, and deflection of the benzothiazole ring system caused by interference with the methyl group takes place about a bond which approaches a single bond in character. The consequence of this is a hypsochromic shift in the absorption maximum on passing from the dye with an unsubstituted chain to its methyl derivative. However, the order of this bond — marked by an arrow in formula (LXIVa) — can be to some extent varied by introducing various polar substituents into the benzothiazole system. The electron-donor dimethylamino-group, where R = $N(CH_3)_2$, by increasing the basic strength of the benzothiazole moiety still further stabilises structure (LXIVa), lowers the order of the bond shown by the arrow, and increases the hypsochromic displacement of the maximum to 80 nm. The electron-acceptor nitro-group (R = NO_2) will give the opposite effect (hypsochromic shift decreases to 50 nm) (Table 5).

In the unsymmetrical carbocyanine (LXV) having an unsubstituted chain (R = R′ = H) the cationic charge is located predominantly on the more basic ring system (with the dimethylamino-group in position 6), and the bond ***a*** is

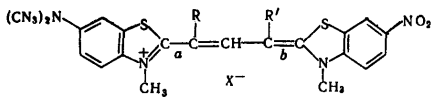
TABLE 5.

R	$\Delta\lambda_{max}(H \rightarrow CH_3)$, nm
$N(CH_3)_2$	80
H	61
NO_2	50

TABLE 6.

Solvent	$\Delta\lambda_{max}(H \rightarrow CH_3)$, nm	Solvent	$\Delta\lambda_{max}(H \rightarrow CH_3)$, nm
Water	—65	Acetone	+ 4
Methanol	—57	Chloroform	+12

closer to a single bond, while bond *b* is closer to a double bond (deviation 15 nm)[81]:

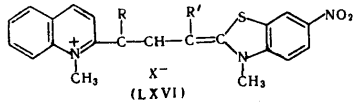


R=H R′=H λ_{max} 586 nm, deviation 15 nm,
R=CH_3 R′=H λ_{max} 556 nm, deviation 44.5 nm,
R=H R′=CH_3 λ_{max} 601 nm, deviation 7 nm.

(LXV)

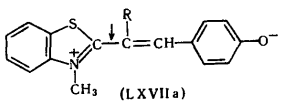
Replacement by methyl of the methine hydrogen adjacent to the bond *a* — dye (**LXV**) with R = CH_3 and R′ = H — shifts the absorption maximum to shorter wavelengths, whereas similar substitution in the methine group adjacent to bond *b* (R = H and R′ = CH_3) displaces the absorption maximum to longer wavelengths, compared with the dye having an unsubstituted chain, although the steric hindrance is the same in the two dyes. In dye (**LXV**) with R = CH_3 and R′ = H, as also in dye (LXII) with R = C_6H_5, deflection of the left-hand benzothiazole system about a bond of lower order increases the deviation to 44.5 nm. Deflection of the right-hand ring system about bond *b* in dye (**LXV**) with R = H and R′ = CH_3 lowers the order of this bond. The electronic asymmetry of the dye is diminished, as is evident from the decrease in the deviation to 7 nm.

Similar phenomena are observed in unsymmetrical carbocyanines (LXVI) made up of quinoline ring system (the more basic) and a 6-nitrobenzothiazole system (the less basic).

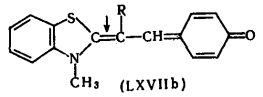


(LXVI)

In the zwitterionic anhydro-bases of the *p*-hydroxystyrenes



(LXVIIa)



(LXVIIb)

the order of individual bonds in the conjugated chain can be varied as desired by dissolving the dye in solvents of different polarities. This is the explanation of the solvatochromism of zwitterionic dyes[82]. The bond marked by the arrow in formulae (LXVIIa) and (LXVIIb) is closer to a single bond in polar solvents, and closer to a double bond in non-polar solvents. In conformity with this, substitution of methyl for hydrogen as the radical R in the dye (LXVII) will give different displacements of the absorption maximum depending on the solvent, as can be seen from Table 6.[74]

If the zwitterionic dyes — (LXVII), R = H and R = CH_3 — are dissolved not in pure solvents but in mixtures of the weakly polar pyridine and the strongly polar water, smooth curves are obtained showing how the displacement (H → CH_3) in the absorption maximum varies

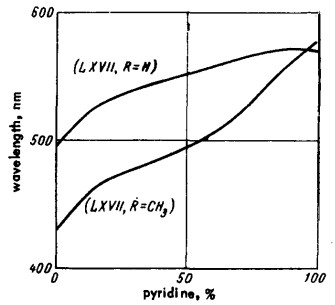


Fig. 5.

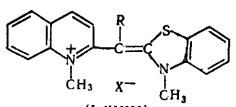
with the percentage of pyridine in the water. It is seen from Fig. 5 that, as the pyridine content increases (the polarity decreases), the colour of the anhydro-bases deepens, the order of the bond marked by an arrow increases, and the curve of the dye with R = CH_3 approaches the curve for the anhydro-base having an unsubstituted chain (the hypsochromic shift decreases). With a mixture containing 90% of pyridine, the bonds in the chromophore of the anhydro-base level out (the colour being the deepest), and in this region the hypsochromic shift changes to a bathochromic shift.

Bulky polar substituents may have two effects — steric and electronic — and it is often difficult to determine the proportion of each. The introduction of phenyl and *p*-nitrophenyl radicals into the methine group of a monomethinecyanine (**LXVIII**, R = H) causes a bathochromic shift. These radicals undoubtedly lie in a plane perpendicular to that of the heterocyclic ring systems, and the observed bathochromic shifts are due, as in the case of the methyl group, solely to steric effects[60]:

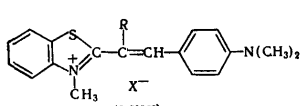


(LXVIII)

R	λ_{max} nm
H	486
CH_3	545
C_6H_5	552
p-$C_6H_4NO_2$	548
$COOC_2H_5$	474

When, however, the hydrogen atom is substituted by an ethoxycarbonyl group, a hypsochromic instead of a bathochromic shift is observed, owing to the predominating electronic effect of the ethoxycarbonyl group. It is known that negative substituents in the α position of a chain should give a hypsochromic displacement of the absorption band[83,84].

In the styryls (**LXIX**), the two effects act in the same direction, which explains the comparatively large hypsochromic shift when R = $COOC_2H_5$:

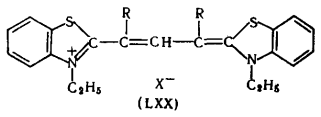


(LXIX)

R=H λ_{max} 525 nm
R=CH_3 λ_{max} 460 nm
R=$COOC_2H_5$ λ_{max} 418 nm

The effect of polar substituents in the *meso* position of thiacarbocyanines is determined solely by the electronic effect: electron-donor substituents produce a hypsochromic shift[85], whereas electron-acceptor substituents produce a bathochromic shift[86,87].

Alkoxy- and aroxy-groups in the $\alpha\gamma$ positions of the thiacarbocyanine (LXX) cause a bathochromic shift[72,88,89], the magnitude of which is little affected by the nature of the aryl:

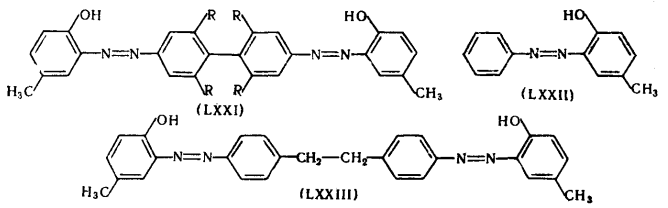


(LXX)

R	λ_{max}, nm
H	558
OCH_3	586
OC_6H_5	589
p-OC_6H_4Cl	585
p-$OC_6H_4OCH_3$	590
OH	565

The slight decrease in intensity compared with the dye having an unsubstituted chain and the fact that the dye with $R = C_6H_5$ is a good sensitiser[4] indicate that the electronic effect predominates in this case.

The effect of steric hindrance on the colour of dyes of other classes has been far less studied than in the case of polymethine dyes.



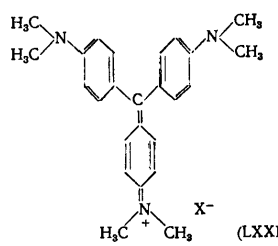
(LXXI)

(LXXII)

(LXXIII)

Brode and his coworkers[90,91] studied the effect of steric hindrance in bisazo dyes which are derivatives of biphenyl. They found that the absorption curve of the dye (LXXI) with $R = CH_3$ resembles that of the dyes (LXXII) and (LXXIII): i.e. there is no conjugation between the biphenyl rings in the first of these three dyes. Similar results have been reported in a series of papers by Krasovitskii[92].

Di- and tri-arylmethane dyes having a symmetrical distribution of the electron cloud resemble symmetrical polymethine dyes. In Crystal Violet



(LXXIV)

only the nitrogen and the central carbon atom lie in the same plane, owing to steric interference (of the *ortho*-hydrogen atoms). The benzene rings have been turned relative to one another in such a way that the structure of the dye resembles a three-bladed propeller. Calculation shows that each benzene ring should turn through 18°.[93]

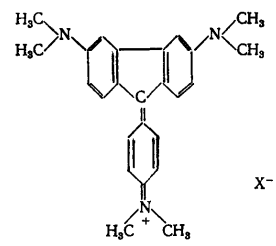
The introduction of methyl groups *ortho* to the central carbon atom results in further deflection of the rings about bonds of enhanced order, which leads to an increase in the bathochromic shift (Table 7)[94]. The uniform displacement of the absorption maximum with increasing number of *o*-methyl groups suggests that all three rings have been deflected to the same extent (in the 2,2′,2″-trimethyl derivative the angle of deflection should be about 34°). But the 2,6-dimethyl derivative gives a larger shift per methyl group. It is possible that in this case the xylidine

TABLE 7.

Methylated Crystal Violets	λ_{max}, nm	Methylated Crystal Violets	λ_{max}, nm
Crystal Violet (LXXIV)	589	2,2′,2″-Trimethyl	614
2-Methyl	597	2,6-Dimethyl	614.5
2,2″-Dimethyl	605		

ring has been greatly rotated, and the charge is concentrated on the two dimethylaniline rings, as in Malachite Green. Similar results have been obtained for Michler's Hydrol Blue.

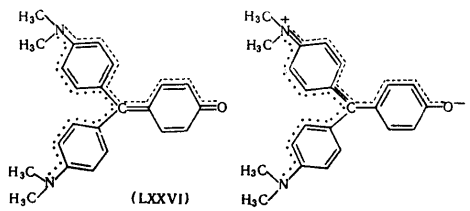
Barker[95] fixed two rings of Crystal Violet in a plane by means of an additional valency bond, but obtained an unexpected result: the dye (LXXV) proved to be more deeply coloured than Crystal Violet. This result was subsequently explained by formation of the new C–C bond and the greater possibility of conjugation of the rings[96,97].



(LXXV)

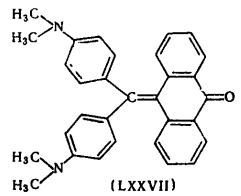
X^- λ_{max} 647 nm

A phenomenon analogous to Brooker's allopolar isomerism was observed by Hünig[98] in sterically hindered triphenylmethane dyes. Of the two possible systems of conjugation in tetramethyldiaminofuchsone (LXXVI) — the dimethylaminofuchsone system (broken line in the formula) and the Malachite Green system (dotted line in the formula) — only the former is developed. The dye has one absorption maximum, which migrates with change in the polarity of the solvent:

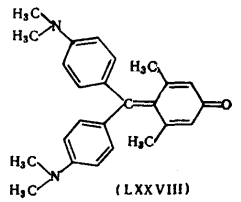


(LXXVI)

In the dyes (LXXVII) and (LXXVIII), which exhibit great steric hindrance, the quinone ring is turned relative to the rest of the molecule, and partly emerges from conjugation:



(LXXVII)

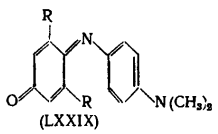


(LXXVIII)

The spectra of these dyes now reveal two systems of conjugation (the dyes each have two absorption maxima, one of which migrates with change in the polarity of the medium). When acid is added to solutions of the dyes, only the absorption maximum remains which does not vary with

change in the solvent, and this undoubtedly belongs to the conjugation system of Malachite Green.

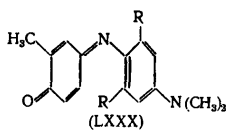
In the indaniline dye (LXXIX, R = H) the C⁄N\C angle is less than 180°, and a value of 120° has been assumed[99] by analogy with *cis*-azobenzene:



(LXXIX)

R = H λ_{max} 634 nm
R = CH_3 λ_{max} 653 nm

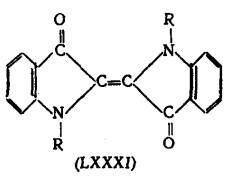
Steric hindrance in the dye (LXXIX, R = CH_3) between one of the *o*-methyl groups and the dimethylaniline ring is eliminated only by turning the quinone ring about the double bond, which causes a bathochromic shift. Rotation of the dimethylaniline ring about the single bond does not eliminate steric hindrance, which remains between one of the methyl groups and the plane of the benzene ring of the dimethylaniline[100]. In the dye (LXXX, R = CH_3), on the other hand, the dimethylaniline ring turns about a bond which is close to a single bond, with a hypsochromic shift as a consequence[101]:



(LXXX)

R = H λ_{max} 630 nm
R = CH_3 λ_{max} 610 nm

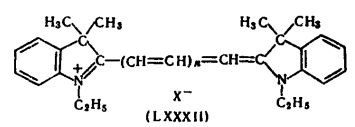
Although the order of the central bond in indigo (0.628)[102] is less than that of an aromatic bond (0.667), it should decrease on excitation, as has been shown by Dyadyusha[36]. This explains the bathochromic shift on passing from indigo (LXXXI, R = H) to dimethylindigo (LXXXI, R = CH_3), in which Weinstein and Wyman assume the presence of steric hindrance[103]:



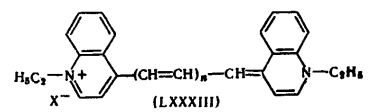
(LXXXI)

R = H λ_{max} 591 nm
R = CH_3 λ_{max} 644.5 nm

Hofer et al.[12] showed that steric hindrance inhibits the fluorescence of cyanine dyes. Indocyanines (LXXXII) and 4-quinocyanines (LXXXIII) fluoresce only when $n = 2$ or above. This observation was confirmed by Kiprianov and Ushenko[104], who also observed that sterically hindered dyes show practically no fluorescence.

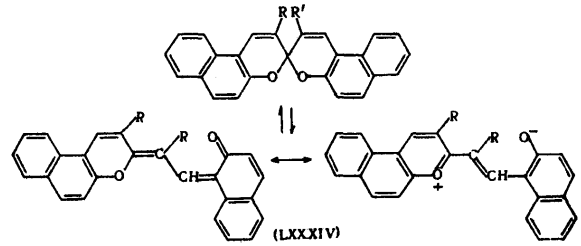


(LXXXII)



(LXXXIII)

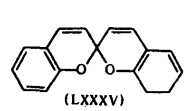
Finally, the effect of steric hindrance on the thermochromism of spiropyrans (LXXXIV), which has been studied by Koelsch[105], must be noted. The thermochromism of colourless spiropyrans (LXXXIV, R = H) is due to their conversion with ring-opening into a coloured form:



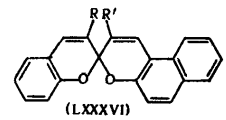
(LXXXIV)

In the spiropyran (LXXXIV) with R = CH_3, the form with opened rings exhibits greater steric hindrance than the spiro-form, in which the rings are mutually perpendicular: therefore ring-opening does not occur, and thermochromism is not observed.

Dibenzospiropyran (LXXXV) is non-thermochromic, since conversion into the form with open rings involves the formation of an unstable *o*-benzoquinone ring. Benzonaphthospiropyran (LXXXVI, R = R′ = H) exhibits thermochromism, probably with the formation of a naphthaquinone ring.



(LXXXV)



(LXXXVI)

In this connection, the difference between the spiropyrans (LXXXVI, R = CH_3 and R′ = H) and (LXXXVI, R = H and R′ = CH_3) is interesting. The former is thermochromic, since formation of the modification with open rings occurs without strain. The latter compound does not exhibit thermochromism, since formation of the modification with open rings involves steric hindrance.

THE MECHANISM OF HALOGENATION OF ALKENES WITH A QUATERNARY CARBON ATOM AT THE DOUBLE BOND

I. V. Bodrikov and Z. S. Smolyan

CONTENTS

I. Introduction 374

II. Early views on the mechanism of anomalous chlorination 374

III. Homolytic mechanism of chlorination 374

IV. Heterolytic mechanism of halogenation 375

V. Reaction of alkenes containing a quaternary carbon atom with hypohalogen acids 379

VI. Reactions of alkenes branched at the double bond with bromine and interhalogen compounds 381

I. INTRODUCTION

Millions of tons of various halogen derivatives of hydrocarbons are produced every year over the whole world and used in many branches of industry, agriculture, and everyday life [1].

This review deals with information on the mechanism of the very interesting reactions that occur in the halogenation of unsaturated hydrocarbons with a quaternary carbon atom at the double bond (with 2-methylpropene as a particular example). Up to now there have been different views on the mechanism of these reactions, and we kept this in mind in compiling the review.

It seemed that a critical analysis of the available publications together with a presentation of experimental results obtained by the authors of the review would bring a certain amount of clarity to this problem.

II. EARLY VIEWS ON THE MECHANISM OF ANOMALOUS CHLORINATION

In 1884 Sheshukov found that when chlorine acts on 2-methylpropene, instead of the expected saturated dichloro-derivatives, the main products of the reaction were monochlorides of the allyl and vinyl types [2].

Later L'vov and his students showed [3-8] that trimethylethylene [2-methylbut-2-ene], tetramethylethylene [2,3-dimethylbut-2-ene], and unsymmetrical ethylmethylethylene [pent-2-ene] also react with chlorine in an unusual manner. Subsequently, reactions of this type, which were termed anomalous, were the object of thorough study.

A number of schemes were proposed to explain the formation of allyl and vinyl monochlorides, and also saturated dichlorides, when alkenes are chlorinated.

L'vov and coworkers considered that chlorination reactions of unsaturated hydrocarbons proceed through two successive steps [9-11]:

$$C_nH_{2n} + Cl_2 \rightarrow C_nH_{2n}Cl_2;$$
$$C_nH_{2n}Cl_2 \rightarrow C_nH_{2n-1}Cl + HCl.$$

It was supposed that an unstable dichloride is first formed, which decomposes into hydrogen chloride and an unsaturated monochloride with displacement of the double bond.

This view has been shown to be untenable by thermodynamic [12] and kinetic [13] results on the decomposition of dichlorides, and also by a comparison of the results of dehydrochlorination of saturated dichlorides with unbranched and branched hydrocarbon skeletons.

It is well known that the low-temperature chlorination of ethylene leads to the formation of dichloroethane, and only an insignificant amount of vinyl chloride is obtained as a by-product [14-16]. Under comparable conditions the reaction of chlorine with 2-methylpropene gives mainly unsaturated monochlorides, although the dichlorides of both alkenes are about equally stable.

As one of us has shown [12], the dehydrochlorination of 1,2-dichloroethane with a conversion of 80% is achieved at 400° when the reaction is initiated with molecular chlorine (1%). In the absence of initiators, the analogous conversion of 1,2-dichloroethane into vinyl chloride requires a temperature of 480–500°. [17] According to Striegler [18], 1,2-dichloro-2-methylpropane is also dehydrochlorinated at 500° with 77.5% conversion into 2-methylallyl chloride and dimethylvinyl chloride, which are present in the reaction mixture in the constant ratio of 75 : 25. Moreover, Tishchenko [19] checked the doubtful results of Pauly and Lieck [20], who only obtained an addition product at the carbon–carbon double bond by the action of chlorine on mesityl oxide, and found that when one mole of chlorine acts on two moles of 2-methylpent-2-en-4-one, 60–70% of 3-chloro-2-methylpent-1-en-4-one is obtained. The 2,3-dichloro-2-methylpentan-4-one obtained together with the unsaturated monochloride in this reaction decomposes by the Wagner–Saytzeff rule with liberation of hydrogen chloride to form a mixture of 3-chloro-2-methylpent-1-en-4-one and 3-chloro-2-methylpent-2-en-4-one.

The scheme proposed by Ostromyslenskii [21] for the chlorination of alkenes with a quaternary carbon atom at the double bond has not brought clarity into this field and has the same disadvantages as L'vov's scheme. By the action of chlorine on 2-methylbut-2-ene, the author obtained almost equal amounts of t-pentyl chloride and the unsaturated chloromethylbutene, and explained this by the elimination of a molecule of hydrogen chloride from the saturated dichloride produced. The liberated hydrogen chloride then combines with 2-methylbut-2-ene to give a saturated monochloride, that is, it is assumed that there is an unusual transfer of the elements of hydrogen chloride from the dichloride molecule to the ethylene bond of the initial alkene:

$$C_5H_{10} + Cl_2 \rightarrow C_5H_{10}Cl_2;$$
$$C_5H_{10}Cl_2 + C_5H_{10} \rightarrow C_5H_9Cl + C_5H_{11}Cl.$$

III. HOMOLYTIC MECHANISM OF CHLORINATION

For a long time due attention was not given in world literature to the work of Russian chemists mentioned above, and it was only in the 40's that these investigations

were continued. Deanesly [22] found that the addition of chlorine to alkenes is initiated by the reaction in which hydrogen is replaced by chlorine in alkanes present at the same time. Since that time, American workers have continued the study of the chlorination of alkenes with the object of preparing unsaturated chloro-derivatives [23-27].

Solodar' and Markin [28] have analysed the work of this school (see also Refs. 29 and 30). Furthermore, Smolyan and coworkers [31] have reviewed the mechanism of substituting chlorination, dealing with examples of the halogenation of saturated hydrocarbons under different conditions (initiated, photochemical, thermal, etc.).

American workers who studied the high-temperature and low-temperature chlorination of alkenes used a radical scheme for chlorination by substitution. Thus, Burgin and coworkers [32] proposed a scheme for the chlorination of 2-methylpropene at low temperatures according to which 2-methylallyl chloride is formed by the migration of a hydrogen atom from one of the methyl groups. The formation of unsaturated monochlorides in the non-photochemical chlorination of ethylene [15,16,33,34] at room temperature, and of pent-2-ene [35] in carbon tetrachloride solution was also explained by the direct replacement of hydrogen. Stewart and Weidenbaum attempted to associate a three-atom chlorine molecule with the formation of unsaturated monohalo-derivatives [36]. They suggested that in chlorination, a chlorine radical formed by thermal chain generation reacts by two competing routes.

$$Cl^{\cdot} + Cl_2 \rightarrow Cl_3,$$
$$\text{or } Cl^{\cdot} + C_2H_4 \rightarrow C_2H_4Cl.$$

It was assumed that the active three-atom chlorine molecule reacts preferentially by the addition route.

Groll and Hearne [24], who studied the reaction of alkenes with chlorine at different temperatures, showed that there are certain critical temperatures above which monochlorides are formed preferentially:

	°C
2-Methylpropene	< -40
Pent-2-ene	125 — 200
But-2-ene	150 — 225
Propene	200 — 350
Ethylene	250 — 350

This temperature "threshold" was found to be lowest for hydrocarbons with a quaternary carbon atom at the double bond. A "threshold" was not established for 2-methylpropene, and this caused the authors to have doubts about the existence of a critical temperature for this hydrocarbon. Only recently, Lishnevskii and Sergeev succeeded in obtaining the addition product (1,2-dichloro-2-methylpropane) in 87% yield by the reaction of frozen layers of 2-methylpropene with chlorine [37]. It was also previously reported [38] that when chlorine is passed through a mixture of pentenes cooled to -17°, the reaction proceeds without the formation of hydrogen chloride, but a slight increase in temperature promoted elimination of the latter. The proportions of the reagents, as well as the temperature, affect the direction of the reaction. A deficiency of chlorine in the reaction zone increases the yield of unsaturated monochlorides [27]. For example, in the chlorination of butenes at 380–390°, the optimal ratio of alkene to chlorine is 3.5 : 1, [39] and for 2-methylpropene the ratio is 1.5–2.0 : 1. [18] The mechanism of substituting chlorination proposed by American workers cannot explain why unsaturated monochlorides of the allyl type are formed and why chlorine does not replace hydrogen in all possible positions.

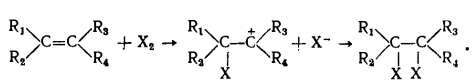
The active state postulated by Hass [40] for hydrogen atoms linked with carbon atoms in the α-position to the double bond also does not explain these contradictions. Indeed, in substituting chlorination, the probability of replacement of hydrogen by chlorine is the same for any position [41-43].

The formation of unsaturated monochloro-derivatives in high-temperature halogenation may occur partly by L'vov's scheme. Thus, a study of the chlorination of ethylene in a reactor with a moving heat carrier at 400–500° showed that vinyl chloride is partly formed through 1,2-dichloroethane with subsequent dehydrochlorination [44]. Moreover, as Reeve and coworkers have shown [45,46], in the gas-phase chlorination of 2-methylpropene containing the tracer carbon isotope ^{14}C (2-methyl-[1-^{14}C]prop-1-ene) at 0°, it is the extreme carbon atom linked to the double bond that is chlorinated, and not the methyl groups. The formation of unsaturated monochloro-derivatives in the low-temperature chlorination of alkenes is accompanied by the displacement of the double bond; according to Azinger, this indicates a heterolytic halogenation process at low temperatures [47]. On the other hand, it is highly probable that the high-temperature chlorination of alkenes in the absence of a thin film [48] proceeds by a homolytic mechanism [49,50]. A proof of this is the reduction of the temperature of gas-phase chlorination in the presence of additives that promote the formation of free radicals [25]. Semenov [51], who examined two competing radical reactions in the chlorination of ethylene — substitution and addition of chlorine with reference to energy factors — established a relation between the rate of substitution and the temperature of the process.

It should be mentioned that the main defect in the interpretation by American workers of the mechanism of chlorination of alkenes with a quaternary atom at the double bond is the unfounded extension of the principles of high-temperature and initiated halogenation to low-temperature chlorination under non-photochemical conditions.

IV. HETEROLYTIC MECHANISM OF HALOGENATION

The action of chlorine on alkenes with a quaternary carbon atom at the double bond is dealt with in greatest detail in the papers of Tishchenko and coworkers [52-56]. A heterolytic mechanism proposed for the halogenation of straight-chain alkenes was used to interpret the experimental results. Francis [57] studied the halogenation of ethylene in dilute aqueous solutions of various salts and observed the formation of mixed addition compounds. The reaction of bromine with ethylene in solutions of sodium chloride or nitrate gives 2-bromo-1-chloroethane or 2-bromoethyl nitrate respectively as the main product; with iodine in sodium chloride solution the main product is 1-chloro-2-iodoethane. The author explained the production of mixed products by the intermediate formation of a carbonium ion of the type $[R-\underset{|}{C}Br-\underset{|}{C}R]^{+}$ in the bromination. Ingold [58] and Robinson [59] proposed the following scheme for the mechanism of halogenation of alkenes:



The authors consider that this reaction is electrophilic; the molecule taking part in the addition is first polarised,

and this is followed by attack on the substrate by the positive halide ion, which leads to the formation of an organic cation. The halide anion reacts with the latter to give the final addition product. Ingold used the addition of iodine monochloride to propene to illustrate this scheme [60]. The distribution of electron density in the ICl molecule corresponds [61] to the formula I^+-Cl^-; on the other hand, the electron density of the π bond of propene is displaced because of the positive inductive effect of the CH_3-group [62] (from a calculation of the limiting electron density for divinyl and isoprene molecules carried out by Hayashi), which permits the scheme for this reaction to be represented as follows:

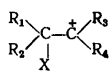
$$H_3C\rightarrow CH=\overset{\delta-}{C}H_2 + Cl-I^+ \longrightarrow CH_3-\overset{+}{C}H-CH_2I + Cl^- \longrightarrow CH_3-CHCl-CH_2I.$$

This mechanism is similar to that proposed by Nenitzescu for the iodination of alkenes [63].

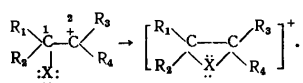
Other workers have also pointed out that an organic cation is formed in the first stage of the reaction of molecular halogens with the ethylene bond [64,65].

Moreover, the existence of various carbonium ions is confirmed by numerous investigations in which NMR spectra [66], ultraviolet spectra [67-74], cryoscopy [75-77], and chemical methods [76,78-80] have been used.

However, the question of the structure of the carbonium ion is still debatable [81]. Thus, it has been noted that the structure of the organic ion proposed by Ingold and Robinson is not in accord with the stereospecificity of the addition [82]. In the hypothetical ion



free rotation is possible round the single C–C bond, which should lead to the formation of *cis*- and *trans*-adducts in equal amounts. Nevertheless, *trans*-products are mainly formed in a number of instances [83]. Since a halogen atom with an unshared pair of electrons in *p*-orbitals is close to the positively charged carbon atom in the intermediate carbonium ion, Roberts and Kimball have suggested that interaction leading to the formation of a bond is possible between the centre of the carbonium ion and halogen atoms [84]. The structure of the intermediate carbonium ion would then be close to a three-membered ring:



The preparation of stable cyclic onium compounds in the aromatic series has confirmed this hypothesis [65].

An analysis of published results made by Bethell and Gold [81] is also in favour of the cyclic cation of Roberts and Kimball.

We shall see below that this hypothesis provides a fairly good interpretation of addition to a multiple bond, although it is subject to the criticism that considerable bond strain is required for the formation of a three-membered ring [86].

However, the formation of *cis*- and *trans*-adducts in additions, at least to the ethylene bond, cannot be unambiguously related to the structure of the intermediate complex.

It is well known that the internal rotation of groups of molecules relative to one another has several potential energy minima for a complete rotation round a single bond. It has been shown by various physical methods that for molecules of the general formulae XH_2C-CH_2X and XH_2C-CH_2Y (X and Y = Cl, Br, I, CH_3, OH, etc.) the *trans*-configuration is the most stable [87-89].

Less stable forms, which have been found together with the *trans*-isomer in a study of the liquid and gaseous states of 1,2-dihaloethanes, are gauche conformations, obtained from the *trans*-form by rotation of one of the CH_2X-groups of the molecule through an angle of $\pm 120°$. [90,91]

The *cis*-form of the rotational isomers is the least stable of known conformations [91]. The stability of *trans*-isomers may be the main reason for the preferential formation of *trans*-adducts in the addition of halogens to alkenes.

Later a new interpretation was put forward for the structure of the intermediate addition complex, which Dewar termed a π complex [92,93]. With both aromatic compounds [94-96] and unsaturated aliphatic compounds [97], the formation of complexes by halogen molecules, which are electron donors, is due to the presence of low antibonding orbitals in iodine, bromine, and chlorine molecules [98] and their considerable polarisability [96]. Freed and Sancier [97] studied the spectra of frozen solutions of iodine in alkenes and their solutions in propane at temperatures from -196° to -43°; the authors assumed that cooling to a low temperature would reduce the rate of addition of halogen to alkenes and increase the concentration of pre-reaction complexes. This assumption was recently confirmed by a thermographic investigation of the propene–bromine system, in which it was shown by the use of low temperatures and special freezing-out procedures that the complex-formation and final-product stages could be separated, and the intermediate complex could be accumulated [99]. In propane, iodine gives only a visible band at 520 nm, with no bands right down to 210 nm. The addition of propene displaces the visible band and produces an intense band with a maximum at 280 nm, similar to that observed in aromatic complexes.

Analysis of published data [100,101] indicates that the new ultraviolet absorption band is due to a complex formed by donor–acceptor interaction between halogen molecules and unsaturated compounds, which is also called a charge-transfer complex [101].

The heats of formation of complexes of iodine with aromatic compounds are estimated at 1 kcal $mole^{-1}$. [102] For alkenes this value is somewhat less than 1 kcal $mole^{-1}$, with the exception of the 2-methylpropene complex, the heat of formation of which is somewhat higher [100].

In spite of such low intermolecular bond energies in associations of halogens with unsaturated hydrocarbons, a review of published information shows that these are not associations of a purely cohesion type. This is indicated by the results of a thermographic investigation of the propene–bromine system [99], evaluation of which showed that the heat of formation of the propene–bromine complex is not less than 5 kcal $mole^{-1}$.

A study [96] of the infrared absorption spectra of the cyclohexene–iodine system showed a reduction in the vibrational frequency of the C=C bond from 1650 to 1524 cm^{-1}, which was considered to be due to the formation of a cyclohexene–iodine π complex.

A reduction of the vibrational frequency of chlorine dissolved in benzene and its derivatives has also been observed; the reduction in frequency increases with increasing electron density in the ring.

According to Mulliken [98,103], the most probable structure for the complex is that in which the halogen molecule is symmetrically arranged in a plane parallel to the benzene ring, because this ensures maximum overlap of selected orbitals [98,103].

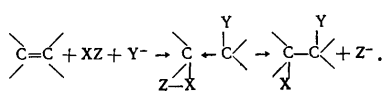
If the molecule of alkene or aromatic compound is unsymmetrical, then the electron density of the bond between the donor and acceptor in the π complex does not have a plane of symmetry perpendicular to the C–C bond. The positively charged halogen atom in such a π complex is situated closest to the carbon atom with the highest electron density [104].

Terenin [100], developing the intermolecular-complex hypothesis, concluded that in the formation of the complex its components are partially ionised, for example, $C_6^{+\delta}H_6.I_2^{-\delta}$, that is, part of the charge is transferred to the iodine molecule, which becomes negatively charged.

Later it was shown [101] that the degree of electron transfer from the donor to the acceptor may vary from zero to complete transfer; in the latter instance, neutral molecules are converted into ion-radicals.

According to Reutov [104], in the course of chemical reaction the π complex can assume the structure of Roberts and Kimball's carbonium ion [84].

Shilov and coworkers [86,105-110] showed that the π complex hypothesis is in good agreement with the kinetics of heterolytic addition reactions; in particular, it explains the emergence of termolecular kinetic equations. If the reaction is of the ionic type, a termolecular addition mechanism operates:



The molecule XZ behaves as an electron acceptor and Y^- behaves as a donor.

Shilov called this a termolecular acceptor–donor mechanism [106]. In the general case a termolecular heterolytic mechanism leads to a termolecular kinetic equation

$$v = k[A][XZ][Y^-],$$

where [A] is the concentration of unsaturated compound. This form of kinetic equation has been established for many addition reactions [111-113].

It is assumed that in electrophilic addition the unsaturated molecule A forms a complex with the electron acceptor XZ in the equilibrium state (constant R), which then reacts with the donor Y^- (nucleophilic reagent).

The reaction rate is then given by the equation

$$v = RC_{AXZ}C_Y = RkC_AC_{XZ}C_Y.$$

A number of reactions are also known in which halogenation of unsaturated hydrocarbons in solvents with a certain polarity, particularly acetic acid, is a second-order reaction [114-118]:

$$v = k[A][Hal_2].$$

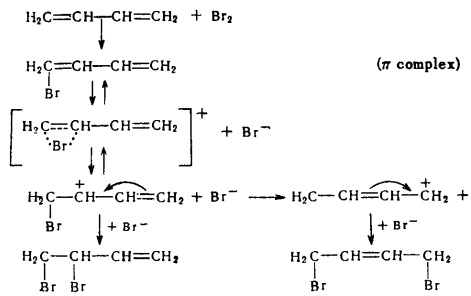
However, the addition of bromine to alkenes in solvents that are no more polar than acetic acid, or in acetic acid over a certain concentration range (0.025 M), is third-order [119-122]:

$$v = k[A][Hal_2]^2.$$

Dilution, increase in temperature, or addition of water reduces the order of reaction from third to second.

The results of these kinetic investigations show that the agent attacking the double bond is a halogen molecule, which acts on alkenes as an electrophilic reagent [123].

Petrov adduces sufficiently convincing facts in favour of the two-stage mechanism for electrophilic 1,2- and 1,4--addition to 1,3-diene compounds [124]. He considers the π complex to be the first combination with the diene; this complex is then converted into a carbonium ion:



The idea of association of the halogen with the π bond of the alkene, and of the charge-transfer complex [100,101], and the results of a thermographic study [99] are in agreement with this scheme.

In explaining the mechanism of chlorination of alkenes with a quaternary carbon atom at the double bond, Tishchenko [52-56] considered that the process is initiated by the addition of the positive end of the halogen molecule, as in all electrophilic additions to the carbon atom with the maximal electron density. The polarisation of the multiple bond in asymmetrical disubstituted and trisubstituted ethylenes is achieved by the positive inductive effect of alkyl groups [62,125].

Because of the displacement of four electron pairs to the double bond, symmetrical tetrasubstituted ethylenes have a large inductomeric effect, which is brought into play under the influence of approaching ions or polar molecules at the moment of reaction. This statement is confirmed by the increase in the relative rates of bromine addition to ethylene and its methylated derivatives [126]:

Alkene	$CH_2=CH_2$	$CH_3CH=CH_2$	$(CH_3)_2C=CH_2$	$C(CH_3)_3=CHCH_3$	$(CH_3)_2C=C(CH_3)_2$.
Rate of addition	1.0	2.0	5.5	10.4	14.0

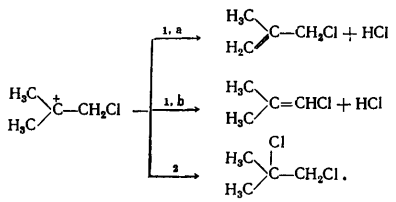
The ionisation potentials decrease in parallel [127,128]:

Alkene	$CH_2=CH_2$	$CH_3CH=CH_2$	$(CH_3)_2C=CH_2$	$CH_3CH=C(CH_3)_2$	$(CH_3)_2C=C(CH_3)_2$.
Ionisation potential	10.62	9.84	9.35	8.85	8.45

For 2-methylpropene, the first stage of chlorination may be represented by the following scheme:

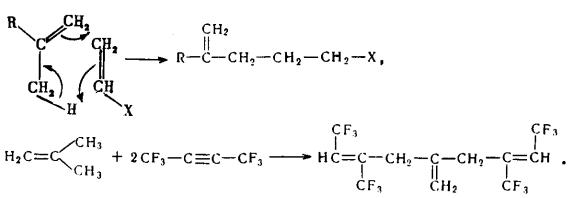
The intermediate carbonium ion is then stabilised in two main ways: (1) by elimination of a proton from adjacent alkyl groups with the formation of unsaturated monochlorides and the separation of a molecule of hydrogen chloride;

(2) by addition of a negative chloride ion to the positive centre of the carbonium ion with the formation of a saturated dichloride



Stabilisation of the carbonium ion in the first way is energetically less favoured by about 8 kcal mole^{-1}.[30] However, when there is a quaternary carbon atom at the double bond, this is the predominating route; according to Tishchenko, the approach of the Cl^- ion to the centre of the carbonium ion is sterically hindered, and this reduces the probability of stabilisation of the organic ion by the second route. In addition to an unsaturated monochloride of the allyl type, the reaction mixture always contains a small quantity of monochloride of the vinyl type. Tishchenko ascribes the preferential formation of the former to the high "proton-likeness" of the primary hydrogen of the methyl group.

This hypothesis was later confirmed experimentally by Morton and coworkers[129], who proposed a method for determining the relative acidity of unsaturated hydrocarbons and of the most "proton-like" hydrogen atom in the alkene. Moreover, the mobility of the allyl hydrogen has been confirmed by reactions in which monoalkenes are added to various activated unsaturated compounds[130-133].



A study of the microwave spectrum of 2-methylpropene[134] showed that the ordinary C–C bond in the latter is appreciably shortened in comparison with saturated compounds, which also indicates the acidity of the allyl hydrogen.

As a result of thorough investigations, Tishchenko[52-56] established that the presence of a quaternary carbon atom and polarisation of the double bond by substituents are necessary conditions for the anomalous chlorination of alkenes at low temperatures; using the reaction of phosphorus(V) chloride with ketones as an example, he confirmed these conclusions[53].

With the object of eliminating side-reactions due to the liberated hydrogen chloride (addition to the initial and final products[56]), a method of chlorination in the presence of sodium hydrogen carbonate, which readily reacts with hydrogen chloride, has been proposed[54,56]. Aschan's hypothesis[135] that sodium hydrogen carbonate catalytically promotes the elimination of hydrogen chloride from the initial dichloride has been disproved[56]. For example, 2,3-dichloro-2-methylbutane does not react with the hydrogen carbonate even at 135°. The mechanism of low-temperature chlorination proposed by Tishchenko was later accepted also by advocates of "substituting" chlorination[136]. The work of Tishchenko and coworkers on the chlorination of terpenes[30,137-140], many of which contain a quaternary carbon atom at a double bond, provided convincing proof of the views he developed on the mechanism of anomalous chlorination of alkenes.

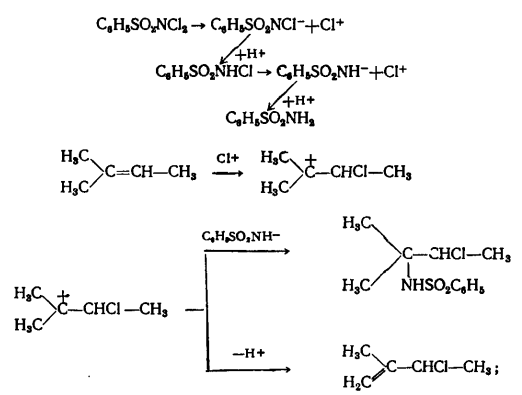
Other papers also show that schemes based on the heterolytic mechanism are widely applicable[141].

Some workers have expressed doubts about the Ingold–Tishchenko mechanism for the chlorination of alkenes[142,143], at least as applied to the chlorination of alkenes in non-polar media, where it was considered there were no grounds for assuming the existence of carbonium ions and ions of the halogenating agent.

The results of mass-spectrometric determinations of ionisation potentials of various compounds in solutions and gases show that this criticism is not valid[144]. Moreover, the heterolytic mechanism does not require that the addend should be ionised before the reaction[145].

Tishchenko's hypothesis that there is steric hindrance to the approach of the chloride anion to the centre of the carbonium ion has been denied without proof by Esafov[142]. Results of later investigations in this field[37] have shown that this criticism is not valid; the rapid addition of chlorine to alkenes (ethylene, propene, 2-methylpropene, styrene, and cyclohexene) at low temperatures in a condensed phase was explained by a reduction in steric hindrance.

Impressive arguments in favour of the steric-hindrance hypothesis in anomalous halogenation reactions have also been put forward by Isagulyants and Balashova[146-148], who studied the chlorination of alkenes with a quaternary carbon atom at the double bond by molecular chlorine and *NN*-dichlorobenzenesulphonamide. They showed that the yield of the anomalous chlorination product depends on the size of the halogenating-agent anion. Thus, in the chlorination of 2-methylbut-2-ene with *NN*-dichlorobenzenesulphonamide[147], the mechanism may be represented as follows:

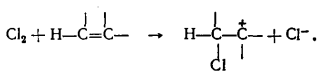


the main reaction product is the unsaturated 2-chloro-3-methylbut-2-ene. Because of the large bulk of the anion of the chloroamide compared with the chloride anion, only 1% of the 2-methylbut-2-ene reacts to form an addition product with the chloroamide, that is, 10–15 times less than with molecular chlorine[42]. Under the same conditions, the action of *NN*-dichlorobenzenesulphonamide on normal pentenes leads mainly to addition products[147].

The results of the chlorination of 3-chloro-2-methylbut-1-ene with *NN*-dichlorobenzenesulphonamide in a mixture

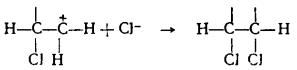
of methyl and ethyl alcohols are also satisfactorily interpreted by the steric-hindrance hypothesis [147].

Taft [145] presents a somewhat different scheme for the heterolytic mechanism in the anomalous chlorination of alkenes. According to Taft, the first stage, which determines the reaction rate, is electrophilic attack on the alkene with the formation of a carbonium cation and a chloride anion as in the Ingold–Tishchenko scheme,

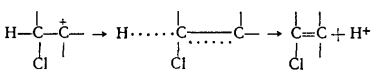


The intermediate carbonium ion reacts by two routes:

a. with the addition of a chloride anion



b. with elimination of a proton



The ratio of the amount of addition products to the amount of unsaturated monochlorides is determined by factors that affect the rates of addition and substitution. This ratio depends on the structure of the intermediate carbonium ion, and also on the reaction medium and the temperature.

Using published experimental results on the chlorination of various alkenes, Taft [145] established a relationship between the yield of unsaturated chloro-derivatives and the number of hydrogen atoms attached to carbon atoms in the α-position to the centre of the carbonium ion (Table 1).

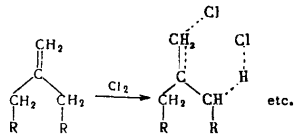
According to Taft, the dependence of the ratio of addition products to substitution products on the number of hydrogen atoms results from a hyperconjugation type of resonance [149,150]. The greater number of possible resonance structure in the chlorination of 2-methylpropene compared with ethylene means that the carbonium ion formed from 2-methylpropene may be more effectively transformed into a stable state than the ion obtained from ethylene. By analogy [151], this should reduce the ratio of the rates of addition and substitution, that is, at low temperatures the chlorination of 2-methylpropene leads to the formation of large amounts of unsaturated monochloride but ethylene mainly reacts to add on chlorine. This hypothesis of Taft on anomalous reactions is not confirmed by the general principles of electrophilic addition to alkenes.

Ingold [152], in analysing a communication of Robertson, concluded that in additions to alkenes the inductive effect of alkyl groups, and not the Baker–Nathan effect with participation of hydrogen, has the greatest influence on the reaction rate. Moreover, results have been published that do not generally favour the hyperconjugation effect [153–156].

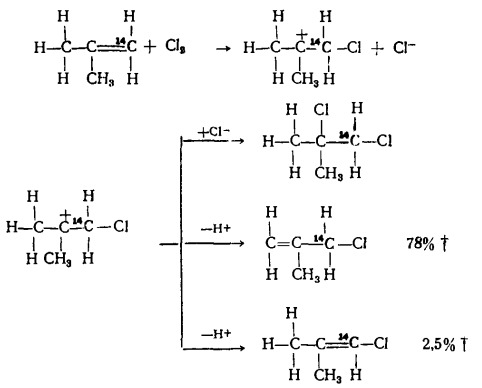
TABLE 1.

No. of hydrogen atoms	Substitution, %	Addition, %
2—3	0—35	60—100
4—5	10—60	40—90
6—7	70—85	10—30
8	93	7

In addition to the mechanisms given above for the chlorination of alkenes with a quaternary carbon atom at the double bond, synchronous cyclic and non-cyclic type mechanisms have been proposed, in which attack on the alkene molecule by a positively charged chlorine atom is accompanied simultaneously by reaction of a negatively charged chlorine atom with a protonated hydrogen atom [157,158]:



The papers of Reeve and coworkers mentioned above are of great interest for the elucidation of the mechanism of anomalous chlorination [45,46]. Their experimental results lead to a mechanism for the chlorination of 2-methylpropene similar to Tishchenko's mechanism:



The results of kinetic studies of the low-temperature chlorination of individual branched and straight-chain alkenes and their mixtures also indicate that these reactions are heterolytic [158–160].

Analysis of the kinetic results shows that substitution and addition reactions of chlorine with alkenes are parallel reactions of the same order and with the same common polar intermediate complex.

V. REACTION OF ALKENES CONTAINING A QUATERNARY CARBON ATOM WITH HYPOHALOGEN ACIDS

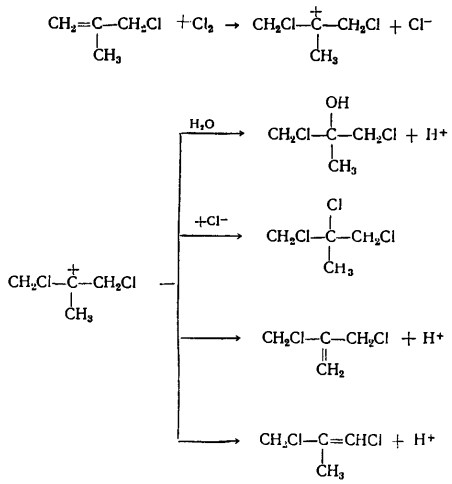
The addition of hypochlorous acid to unsaturated hydrocarbons was first studied by Markovnikov, who established the rule that bears his name [161]. Saytzeff [162], who studied the reaction of hypochlorous acid with butene, also found that the halogen adds to the carbon atom with the greatest number of hydrogen atoms, and the hydroxy-group to the carbon atom with the least number. On the other hand, Henry found that hypochlorous acid adds to propene and 2-methylpropene in the reverse manner [163]. Butlerov [164], who assumed that the product of the reaction of 2-methylpropene with hypochlorous acid was 2-chloro-2-methylpropan-1-ol, confirmed Henry's results, which were later shown to be erroneous.

Michael [165] repeated Henry's experiments and showed that the product of the reaction of hypochlorous acid with propene is 1-chloro-propan-2-ol, thus confirming the

† Yield based on chlorine.

validity of Markovnikov's rule. This conclusion was confirmed by Krasuskii [166,167], who showed that propene chlorhydrin contains ~ 68% of 1-chloropropen-2-ol, and 2-methylpropene chlorhydrin, not less than 78% of 1-chloro-2-methylpropan-2-ol. Quantitatively, these results differ somewhat from those reported by other workers for the addition of hypochlorous acid to propene [168] and 2-methylpropene [169-172].

Later papers are mainly devoted to a study of the mechanism of these reactions. Burgin and coworkers [136], who studied the action of chlorine water on 2-methylallyl chloride, explained the composition of the final products by the initial formation of a positively charged carbonium ion complex, which is then stabilised in several ways:



At 30° the yield of 1,3-dichloro-2-methylpropan-2-ol is 70%, and 10% of allyl and vinyl substitution products is formed. Other nucleophilic solvents may be used as the "active" medium instead of water. Thus, the action of chlorine [173] and bromine [174] on ethylene hydrocarbons in the presence of ethylene oxide leads mainly to the formation of $\beta\beta'$-dichloro- and $\beta\beta'$-dibromo-substituted ethers [173,174]. Besides these ethers, other products are obtained which indicate that the mechanism of this reaction is in principle similar to the mechanism for the chlorination of alkenes in an aqueous medium.

By means of the reaction of aromatic compounds with hypobromous acid, it has been shown that a bromine cation participates in brominations in aqueous solutions [175-177]; the rate of these reactions is proportional to the concentration of hydronium ions [108].

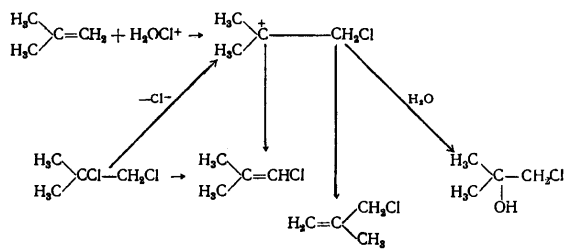
$$\frac{d[\mathrm{BrOH}]}{dt} = k[\mathrm{A}][\mathrm{BrOH}][\mathrm{H_3O^+}],$$

where [A] is the concentration of the organic compound. The concentration of the bromine cation is related to [BrOH] by the equation:

$$k_p[\mathrm{BrOH}][\mathrm{H_3O}] = [\mathrm{BrOH_2^+}].$$

The existence of a bromine cation was deduced from kinetic results obtained in the chlorination with hypochlorous acid of organic compounds [178,179]. Later, the experimental results on which the hypothesis of a chlorine cation is based were subjected to criticism [180].

Using an isotope dilution method at 45°, de la Mare and coworkers [181] separated 11.9% of 3-chloro-2-methylprop-1-ene and 0.4% of 1-chloro-2-methylprop-1-ene from the reaction products obtained by the action of hypochlorous acid on 2-methylpropene. A somewhat larger total of unsaturated monochloro-derivatives (16%) was obtained by the hydrolysis of 1,2-dichloro-2-methylpropane under comparable conditions. From these results the authors conclude that identical carbonium ions are formed as intermediates when hypochlorous acid acts on 2-methylpropene and in the hydrolysis of 1,2-dichloro-2-methylpropane:



on hydrolysis	6%	10%	84%
on addition	0.4%	12%	87.6%

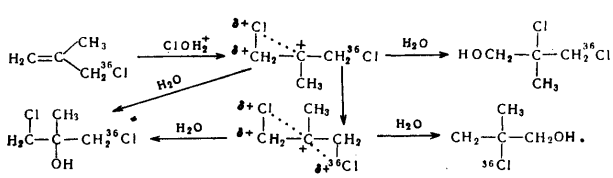
This hypothesis is in good agreement with the results of spectrographic [74,182] and cryoscopic studies [75] on solutions of tertiary alcohols and the corresponding alkenes in sulphuric acid. Thus, Gold and coworkers [74,75,183] showed that when $\alpha\alpha$-diphenylethylene is dissolved in sulphuric acid, a carbonium ion is formed identical with that obtained by similar treatment of 1,1-diphenylethanol:

$$(C_6H_5)_2C{=}CH_2 + H_2SO_4 \rightarrow (C_6H_5)_2CH_3C^+ + HSO_4^-,$$
$$(C_6H_5)_2CH_2COH + 2H_2SO_4 \rightarrow (C_6H_5)_2CH_3C^+ + H_3O^+ + 2HSO_4^-.$$

Later, the trimethylmethylium ion was obtained from 2-methylpropene and t-butyl alcohol by analogous methods [182]:

$$(CH_3)_2C{=}CH_2 \xrightarrow{+H^+} (CH_3)_3C^+ \xleftarrow[(-H_2O)]{+H^+} (CH_3)_3COH.$$

The preferential formation of unsaturated chloro-derivatives of the allyl type in comparison with vinyl derivatives (30 : 1) by the action of hypochlorous acid is explained [184] by internal interaction between the centre of the carbonium ion and the chlorine atom, as described by Roberts and Kimball [84]. Ballinger and de la Mare [185] studied the addition of hypochlorous acid to 2-methylallyl chloride containing the labelled atom ^{36}Cl and confirmed the hypothesis that the centre of the carbonium ion interacts with the halogen on the adjacent carbon atom by the partial displacement of ^{36}Cl from position 3 to position 2:



A similar migration of the chlorine atom was also observed in the reaction of hypochlorous acid with allyl chloride [186]. However, in the chlorination of allyl alcohol with molecular chlorine, the assumed interaction of the hydroxyl group with the positively charged carbon atom was not accomplished by migration of the hydroxyl group

to the centre of the carbonium ion [187], although that such a migration is possible in principle has been shown by the rearrangement of 1-phenylallyl alcohol to 3-phenylallyl alcohol in a mixture of dioxan and water (60:40 vol.%) in the presence of perchloric acid at 0°. [188]

The observations of de la Mare and coworkers [189] are important in considering the reasons for the elimination of a proton from alkyl groups adjacent to the centre of the carbonium ion with the formation of anomalous products; these workers found that treatment of [3-^{36}Cl]-2,3-dichloroprop-1-ene with hypochlorous acid leads to the formation of substitution products (3.7% of *cis*- and 4.3% of *trans*-1,2,3-trichloropropene). These results are in agreement with an earlier statement [53] that anomalous products are formed in chlorination not only by alkenes with a quaternary carbon atom at the double bond, but also by unsaturated compounds in which only one of the carbon atoms at the double bond does not have a hydrogen atom.

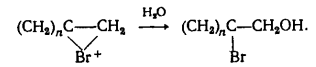
This analogy indicates the similarity between the mechanisms of chlorination and hypochlorination of alkenes, at least in the first stage when a carbonium ion is formed. This has been confirmed by other examples [47,191,192]. It is well known that normal alkenes react with chlorine at ordinary or slightly increased temperature to form only addition products. The action of hypochlorous acid on but-2-ene [190] and 2-methylpent-3-ene [191] also leads to addition at the double bond, but under similar conditions 2,4-dimethylpent-2-ene and diisobutylene give unsaturated monochlorides as the main products [191]. Umnova [191] explained the mechanism of the formation of substitution products in these reactions by L'vov's scheme, which includes initial additions of hypochlorous acid to the double bond followed by elimination of a molecule of water. We have dealt with the defects of this scheme in the section above on the chlorination of alkenes.

The action of hypobromous acid on acyclic unsaturated hydrocarbons leads to the formation of bromhydrins; the order of addition is mainly the same as that in hypochlorination. For example, the reaction of hypobromous acid with 2-methylpropene gave an addition product in 77% yield containing not less than 97% of 1-bromo-2-methylpropan-2-ol and 3% of the isomer, 2-bromo-2-methylpropan-1-ol [192,193].

A comparative study of the reaction of hypochlorous acid with allyl bromide and the reaction of hypobromous acid with allyl chloride [194] in a water–dioxan mixture showed that the solvent materially affects the composition of the products of the reaction, in which a halogen atom of the starting alkene migrates to the central carbon atom. The change in the composition of the reaction products can be explained fairly satisfactorily by a mechanism based on the formation of an intermediate carbonium ion.

Bodot and Jullien give an interesting theoretical explanation of orientation in the addition of electrophilic agents to alkenes [195]; using the method of Smith and coworkers [196], they calculated the relative stability of possible carbonium ions and showed, for example, that in the reaction of hypochlorous acid with 2-methylpropene the carbonium ion structure $(CH_3)_2\overset{+}{C}CH_2Cl$ is energetically more favoured than the structure $(CH_3)_2CClCH_2$.

However, in the hypohalogenation of cycloalkenes the order of addition is, as a rule, not so rigid as in the electrophilic addition of HOX to acyclic unsaturated compounds. Thus, in the hypobromination of methylenecycloalkenes the order of addition is reversed [192,193]. Traynham and Pascual [193] attempted to explain this orientation in the addition of hypobromous acid to methylenecycloalkenes by the formation of a bromonium ion with subsequent attack of a water molecule on the secondary carbon atom:



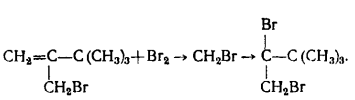
VI. REACTIONS OF ALKENES BRANCHED AT THE DOUBLE BOND WITH BROMINE AND INTERHALOGEN COMPOUNDS

The action of bromine, iodine, and interhalogen compounds on alkene compounds has mainly been studied with reference to normal compounds [113-122,197-202].

In a review [203], Dombrovskii lists the substitution reactions that occur in the halogenation, sulphonation, nitration, alkylation, acylation, and azo-coupling of both alkenes and aromatic compounds. In this review, the reactions of bromine and interhalogen compounds with unsaturated compounds having a quaternary carbon atom at the double bond are compared with the corresponding chlorination reactions.

As early as 1879, Butlerov observed the liberation of hydrogen bromide, and therefore the formation of substitution products, in the bromination of triisobutylene [204].

Hydrolysis of the products of the reaction of bromine with 2-methylbut-2-ene also showed the presence of unsaturated monobromides in the reaction mixture [205,206]. Later, Favorskii [207] established that the reaction mixture obtained by the bromination of isopentene contains t-pentyl bromide, with dibromo- and tribromo-derivatives of 2-methylbut-2-ene. With increase of bromination temperature, unsaturated bromo-derivatives of methylbutene were formed [208]. The dibromo- and tribromo-derivatives were the main products of the action of bromine on 2,3,3-trimethylbut-1-ene, when the reagents were cooled with an ice–salt mixture [207]. However, a mixture of saturated and unsaturated monobromides were separated from the low-boiling fractions. The formation of unsaturated monobromides was explained by L'vov's scheme for anomalous chlorination [9-11]. The formation of tribromo-derivatives was considered to be due to the reaction of bromine with the unsaturated monobromide which is partly formed:



It was also noted that *unsym*-dineopentylethylene [4,4-dimethyl-2-neopentylpent-1-ene] reacts with bromine with liberation of hydrogen bromide [209].

Esafov [210] observed considerable liberation of hydrogen bromide in the determination of the bromine numbers of di- and tri-isobutylene, and also of diene hydrocarbons with branching at the double bond. A thorough analysis of the bromination products of 2-methylpropene at 0° was first carried out by Pogorzhel'skii [211]. The main reaction product was 1,2-dibromo-2-methylpropane, that is, the addition product; t-butyl bromide and polybromo-derivatives of 2-methylpropene were also separated. Saponification of the fraction boiling below 100° failed to convert 0.3 g of bromo-derivatives (out of 4.4 g) into alcohols, and this

portion was assumed to consist of unsaturated monobromide. In later papers on the bromination of 2-methylpropene to obtain dibromo-derivatives, the formation of unsaturated monobromides is not mentioned[212,213]. However, since t-butyl bromide is formed, it may be assumed that the bromination of 2-methylpropene[210] is accompanied by the formation of 2-methylallyl bromide or dimethylvinyl bromide and hydrogen bromide. The latter further reacts with the starting 2-methylpropene.

The liberation of hydrogen bromide has also been noted in the bromination of 2-methylpropene in the presence of calcium halide, which catalyses additions to alkenes[214].

It was later shown[215] that bromination of an excess of liquid 2-methylpropene at -10°, either directly or in the presence of a non-polar solvent, is accompanied by the formation of up to 20% of allyl and vinyl substitution products. The yield of unsaturated monobromides falls to 5.5–6% if the experiment is carried out with stoichiometric quantities of the reagents.

If this reaction is carried out at a very low temperature (-154°), as in the chlorination of 2-methylpropene in a condensed phase[37], only addition products are formed[216].

In the gas-phase bromination of 2-methylpropene at 300–350° in an atmosphere of nitrogen, up to 50% of 2-methylallyl bromide and 20% of dimethylvinyl bromide are formed[18]; the remaining products are t-butyl bromide (7%) and polybromides (20%).[18] Under these conditions the reaction is probably of the free-radical type, and a sharp increase in the yield of 2-methylallyl bromide and dimethylvinyl bromide is probably due to replacement of hydrogen atoms according to Semenov[51]. It is well known, for example, that in the halogenation of alkenes with *N*-bromosuccinimide[217] and *N*-bromoacetamide[218,219], hydrogen in methyl and methylene groups is readily replaced by bromine. These reactions are accelerated by heat and by ultraviolet light[220], and also by the addition of peroxides[221]; the presence of peroxides promotes the formation of unsaturated monobromo-derivatives, while 4-t-butylpyrocatechol, an inhibitor of radical reactions, increases the yield of addition products.

Although the halogenation of alkenes by *N*-bromoacetamide is carried out in the presence of hydrobromic acid, like low-temperature bromination, the reaction is heterolytic, since here the double bond of the alkene is attacked by molecular bromine[219]:

$$AcNHBr + HBr \rightleftarrows AcNH_2Br^+ + Br^-;$$
$$AcNH_2Br^+ + Br^- \rightleftarrows AcNH_2 + Br_2.$$

Novikov and coworkers[222] examined published information on the halogenating properties of organic compounds containing positive halogen and concluded that *N*-bromosuccinimide can react with alkenes both by an ionic and by a homolytic mechanism.

Tishchenko and Yarzhemskaya[223] studied the bromination of 2-methylbut-2-ene and 3-chloro-2-methylbut-2-ene at low temperatures in the presence of sodium hydrogen carbonate; they showed that, in contrast to chlorinations[41], only a small part of the bromine reacts to form unsaturated monobromides.

Comparison of published information on low-temperature chlorination[42,46] and bromination[215,223] of alkenes with branching at the double bond shows that while chlorination leads mainly to the formation of anomalous products, in bromination the predominating reaction is addition (Table 2).

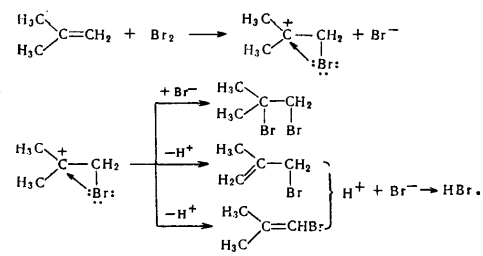
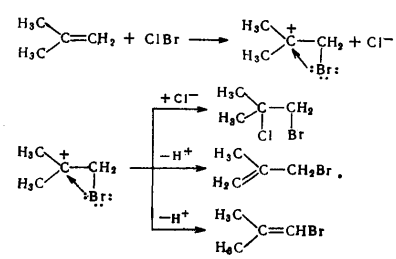
H_3C H_3C $C=CH_2$	chlorination	82.4	17.6	46
	bromination	20	60	215

The mechanism of the reaction of bromine with alkenes containing a quaternary carbon atom may be represented by the Ingold–Tishchenko scheme, a halogen atom reacting internally with a carbonium centre:



According to Temnikova[224], the composition of the reaction products of halogens with alkenes having a quaternary carbon atom is determined by the nature of the nucleophilic component of the halogenating agent. However, the results of low-temperature bromination and chlorobromination of liquid 2-methylpropene have shown that the nucleophilic properties of the halogen have no appreciable effect on the yield of anomalous chlorination products[215].

Published information[225–229] shows that bromine chloride adds to unsaturated compounds by an ionic mechanism; Br^+ attacks the double bond of alkenes to form an intermediate carbonium ion. The mechanism of chlorobromination may thus be represented by the following scheme:



Comparison of the scheme for the mechanism of bromination of 2-methylpropene with this scheme for chlorobromination shows that both reactions proceed through an identical intermediate carbonium ion. If it is assumed that the nucleophilic centre of the halogen plays a predominating part in anomalous halogenation reactions, then the yield of monobromides should be higher in chlorobromination than in bromination. However, experimental results show that in both the yield of unsaturated monobromo-derivatives is ~ 20%.

In the gas-phase chlorobromination of 2-methylpropene at 150° in a flow-through system[230], the yield of 2-methylallyl bromide is 41.5%, that is, somewhat lower than in the

gas-phase bromination of 2-methylpropene at 300°.[18] From this it follows that the anionic centre of the halogen has no appreciable effect on the composition of the products of halogenation of alkenes with a quaternary carbon atom at the double bond.

The authors of the present review[231] have put forward the hypothesis that the main reason for the elimination of a proton from alkyl groups in the α-position to the carbonium ion centre, and therefore for the formation of anomalous halogenation products, is the high degree of localisation of the positive charge at the centre of the organic cation formed as a result of electrophilic attack on the alkene[231]. On the other hand, delocalisation of the positive charge, due to the high polarisability of the electrophilic part of the reagent attached to the carbon atom in the α-position to the centre of the organic cation, hinders the elimination of a proton; as a result, the carbonium ion is stabilised by the addition of a halide ion to the positively charged carbon, and dihalo-derivatives are formed as final adducts. Here the reaction rate also depends on the nucleophilic properties of the halide anion[115].

Interaction of the centre of the carbonium ion with the added halogen probably occurs not in a chain-like manner but spatially, according to Roberts and Kimball[84], or de la Mare and coworkers[184,185]. This hypothesis was checked experimentally by introducing atoms of different inductomeric polarisability into the α-position of the alkene being chlorinated. Results obtained in the chlorination of 2-methylallyl chloride, 2-methylallyl bromide and 2-methylallyl iodide confirm the hypothesis; as the inductomeric polarisability of the halogen atom at the carbon atom in the α-position to the carbonium ion increased, the yield of anomalous chlorination products fell from 50% to 0%[231] (see Table 3).

Internal interaction between a positively charged centre and electronegative or strongly polarised groups at the α-carbon atom may lead to the formation of a new bond. On the basis of the foregoing hypothesis, the formation of halo-lactones when bromine or chlorine acts on the sodium salt of dimethylmaleic or dimethylfumaric acid may be represented by the following scheme[232]:

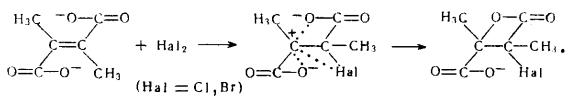


TABLE 3. Results of the low-temperature chlorination of unsaturated monohalo-derivatives of 2-methylpropene.

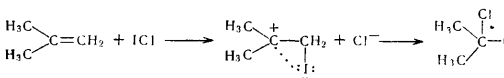
* The total isomers of unsaturated halo-derivatives are arbitrarily denoted by a single formula.

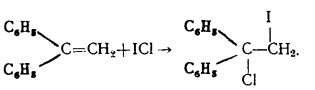
In the first example, because of its greater inductomeric polarisability, the added bromine atom probably partially delocalises the charge on the intermediate organic cation, which further stabilises the latter and thereby prevents the formation of a new lactone bond between the carbon atom and the carboxyl group.

A number of other results are also in good agreement with interpretations that take account of the effect of the polarisability of the electrophilic centre of the reagent.

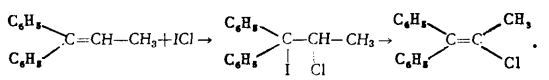
Thus, in the reaction of 2-methylpropene with iodine chloride, the positive charge on the carbon atom is delocalised by the added iodine atom; for this reason, 2-methylallyl iodide was not formed and 2-chloro-1-iodo-2-methylpropane was the sole reaction product[233]:



The addition of iodine chloride to propene[60,234], allyl alcohol and its esters[235], styrene[236], and 1,1-diphenylethylene[237] confirmed the validity of this order of orientation of the iodine chloride molecule, for example:



However, as Temnikova and coworkers have shown, this order may be changed by other substituents[237]. Thus, the production of 2-chloro-1,1-diphenylprop-1-ene when iodine chloride reacts with 1,1-diphenylprop-1-ene was explained by the initial formation of 2-chloro-1-iodo-1,1-diphenylpropane, which eliminates hydrogen chloride at the moment of reaction:



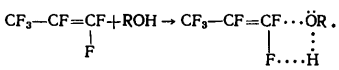
Recently, the effect of the magnitude of the charge on the positively charged carbon atom on the stabilisation route of the carbonium ion was studied in the low-temperature bromination of liquid 2-methylpropene in the following solvents of varying polarity: 2-methylpropene, chloroform, 1,1-dichloroethane, 1,2-dichloroethane, t-butyl chloride, and nitroethane[238]. It was shown that the total yield of 2-methylallyl bromide and dimethylvinyl bromide, and therefore the rate of elimination of a proton from the alkyl groups of the carbonium ion, decreases in proportion to the increasing dipole moment of the solvent; the yield of unsaturated monobromides decreases from 24% with 2-methylpropene to zero with nitromethane in the solvent order given above.

A study of the effect of solvent : alkene ratio on the composition of the products of the low-temperature halogenation of alkenes with a quaternary carbon atom at the double bond showed that a reduction in the concentration of alkene in the solvent leads to a decrease in the yield of allyl and vinyl substitution products[238].

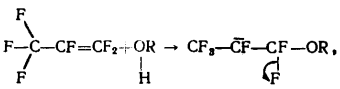
These results show that the ionic charge due to a strongly polar solvent may be reduced by increasing the quantity of less polar solvent while other reaction conditions are kept constant.

An interesting analogy is observed in reactions of alkenes with electrophilic reagents and of fluoroalkenes with nucleophilic compounds[239]. In reactions of perfluoroalkenes with nucleophilic reagents, the difluoromethylene group, which has an induced partial positive charge, is the object of nucleophilic attack; perfluoro-2-methylpropene reacts more readily with nucleophilic agents than perfluoropropene.

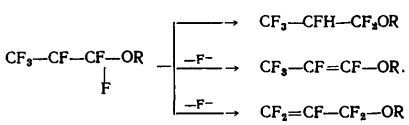
On the other hand, because of the positive inductive effect of alkyl groups, the methylene group of alkenes has excess electron density and is the object of electrophilic attack; the activity of alkenes in reactions with electrophilic reagents increases with the number of methyl groups at the double bond[126]. There is another interesting analogy between the reactions of alkenes and fluoroalkenes. When perfluoroalkenes are subjected to nucleophilic attack, replacement of fluorine atoms in the vinyl, and frequently the allyl, position is observed as well as addition at the double bond[240-245]. It has been suggested[243] that the nucleophilic reagent is linked with the electrophilic perfluoroalkene molecule in a four-membered transition state, which is stabilised by the intramolecular formation of a hydrogen bond[243]:



A somewhat different explanation of the mechanism of these reactions has also been put forward: the initial step in the reaction is considered to be attack by an anion; this leads to the formation of an intermediate carbanion,



which is then stabilised by the addition of a proton or the elimination of a fluoride anion:



Under the same conditions, the relationship between addition, allyl substitution, and vinyl substitution depends on the structure of the perfluoroalkene and on the mobility of the unshared pair of the nucleophilic agent[239].

The main conditions that determine the stabilisation route of the carbonium ion, and therefore the composition of the products, in the electrophilic low-temperature halogenation of alkenes, are also, as pointed out above[52-56], the structure of the alkene and the mobility of the unshared pair of the attacking electrophilic agent[215,231]. Additions to fluoroalkenes and to alkenes are therefore similar.

A change in the mobility of the electron pairs of atoms at the carbon atom in the α-position to the centre of the carbonium ion, should also affect the composition of the final products in fragmentation reactions, in which the intermediate carbonium ion formed by displacement of some substituent from the organic compound may be stabilised in several ways[246-248]:

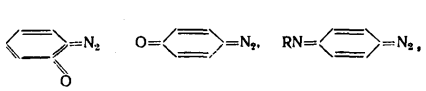
C. Structure of *p*-iminoquinone diazides (*p*-imido-quinone diazides) 402

I. INTRODUCTION

para-Substituted and *para*- and *ortho*-hydroxy-substituted diazonium salts have characteristic properties; when treated with alkaline agents they form compounds of the type:



although most diazonium salts form diazoates. The following names are used in the literature for these compounds: diazoanhydrides, diazoquinones, diazo-oxides, and quinone diazides for the oxo-derivatives, and *p*--diazoimines (*p*-diazoimides if R is an acyl group), *p*-iminodiazoquinones, and *p*-iminoquinone diazides (or *p*-imidoquinone diazides) for the imino-derivatives. We shall call these compounds quinone diazides and *p*-iminoquinone diazides (or *p*-imidoquinone diazides)†.

Because of their unusual properties, these compounds occupy a special place in the chemistry of the diazo-compounds. *p*-Iminoquinone diazides and quinone diazides are theoretically interesting, as they may be regarded as occupying an intermediate position between aliphatic diazo-compounds and aromatic diazonium salts. Moreover, these compounds are widely used industrially for the synthesis of photosensitive dyes. In the laboratory, many compounds otherwise difficult to obtain are synthesised from *p*-iminoquinone diazides and quinone diazides.

Although good reviews have been published on the structures and properties of diazonium salts [1,2] and of aliphatic diazo-compounds [3-5], there is no review on the present state of the chemistry of *p*-iminoquinone diazides and quinone diazides. Since a large number of papers has appeared, particularly in recent years, on the reactions and structures of these compounds, it seemed useful to systematise the extensive information that has accumulated. A review of the literature on the synthesis, properties, and structure of quinone diazides and *p*-iminoquinone diazides (*p*-imidoquinone diazides) is given below.

II. PREPARATION OF *o*- AND *p*-QUINONE DIAZIDES AND *p*-IMINOQUINONE DIAZIDES

A. Preparation of Quinone Diazides

Methods used for the preparation of diazo-ketones and methods for synthesising diazonium salts may both be used for the synthesis of quinone diazides.

The following are five different methods of synthesis: (1) diazotisation of aminophenols; (2) diazotisation of aromatic amines not containing hydroxyl groups, with subsequent introduction of a hydroxyl group into the diazonium salt; (3) from phenols by introduction of a diazo-group; (4) from quinones, through *p*-toluenesulphonylhydrazones; (5) by the introduction of new substituents into a quinone diazide already synthesised.

It should be mentioned that each of these methods requires an acid medium at one stage, and therefore the synthesis of quinone diazides reduces to the preparation of the corresponding hydroxyaryl-diazonium salt with subsequent elimination of a molecule of acid from this salt.

A solid quinone diazide is readily formed by elimination of a molecule of acid from the diazonium salt, if the aryl group consists of a system of condensed benzene rings [6] or has negative substituents [7,8]; the solid quinone diazide is then precipitated when the diazo-solution is diluted with water. Sometimes the solution must be strongly cooled, or it must be neutralised [9-11]. If the diazide is poorly soluble in water, it may be extracted with benzene [12]. If the diazides are very soluble in water, special methods are used for their separation. Thus, Anderson and Roedel [13] obtained *p*-benzoquinone diazide in low yield by

† The second of these alternatives is usually favoured in the Russian text but the first has been employed in the translation (Ed. of Translation).

treating the diazonium chloride with silver oxide in alcohol, and cooling the solution to -70° after the addition of ether; *o*-benzoquinone diazide was first obtained by Anderson and Le Fevre, using the same procedure [14]. Stille and coworkers used an analogous method for the preparation of some *p*-benzoquinone diazides [15]. Later, *o*-benzoquinone diazide was obtained in high yield by treating dry *o*-hydroxyphenyldiazonium chloride with anhydrous sodium carbonate, the diazide being subsequently extracted by boiling ether or hexane [11].

1. Synthesis of quinone diazides by diazotisation of *o*- or *p*-aminophenols. Difficulties are encountered in the diazotisation of aminophenols by the usual methods, because of the readiness with which these compounds are oxidised, or because of their low solubility. For this reason, the diazotisation of aminophenols is often carried out under special conditions. The diazotisation proceeds most smoothly in organic solvents. Schmidt and Glitz were the first to diazotise the simplest aminophenols with nitrogen oxides in ether [16]. Hantzsch and Davidson later used this reaction for the diazotisation of unsubstituted aminophenols [10].

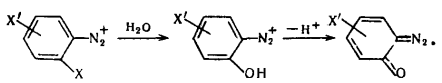
Diazotisation of aminophenols with sodium nitrite in a medium of concentrated organic acids proved to be a very convenient method, solutions of the corresponding diazonium salts being obtained in high yield [17-20]. The yield of the salt increases with the strength of the organic acid used as solvent [17,18]. In the diazotisation of some highly condensed or heterocyclic hydroxy-amines, good results are obtained with the use of dimethylformamide or glycol methyl ether as solvent [7].

When aminophenols are diazotised in the usual way with nitrite in hydrochloric acid solution, large amounts of oxidation products are obtained. Thus, diazotisation of aminonaphthols in aqueous acid gives the corresponding quinones and azo-dyes [21,22]. Aminophenols with positive substituents in the nucleus, for example, aminoresorcinol, are very strongly oxidised [23]. However, it has been shown that in dilute sulphuric acid the diazotisation of unsubstituted *o*- and *p*-aminophenols proceeds without complications [11]. Using this method, Ershov and Nikiforov [12] obtained a number of crystalline *p*-quinone diazides with alkyl substituents in positions 2 and 6.

The presence of electronegative substituents in the nucleus gives rise to a difficulty of another kind: diazotisation does not occur because of the poor solubility of these aminophenols in weakly acid solution. Although monohalo- and mononitroso-substituted aminophenols can be diazotised in the usual way [7,9,24], the introduction of additional negative substituents into the nucleus makes diazotisation impossible under ordinary conditions.

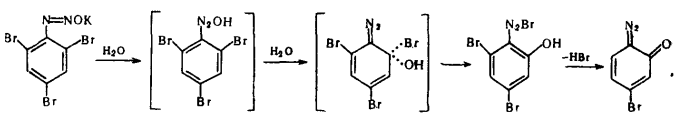
To overcome these difficulties, it has been proposed that oxidisable aminophenols should be diazotised with sodium nitrite in an aqueous solution not containing mineral acids but containing salts of heavy metals, $CuSO_4$,[6,25] $SnCl_2$,[26] etc.[1] Aminophenols with negative substituents are smoothly diazotised by nitrosylsulphuric acid in concentrated sulphuric acid [20,27]. Hodgson and Birtwell [20] showed that substituted aminophenols that cannot be diazotised by other methods because of oxidation, are readily diazotised in concentrated sulphuric acid without the addition of nitrite. In this way a diazonium salt was obtained from 1-amino-4-diazonaphth-2-ol, and the diazotisation of this amine was equally smooth in glacial acetic acid [20].

2. Synthesis from amines containing no hydroxy-groups. If the diazonium salt has a substituent in the *ortho*- or *para*-position to the diazonium group, under certain conditions (dilution of the diazo-solution with water or addition of bases) this substituent is readily exchanged for a hydroxyl group, and the hydroxyaryldiazonium salt formed is converted into the corresponding quinone diazide by the loss of a molecule of acid:



A nitro-group, halogen, sulpho-, or methoxyl group may be replaced by a hydroxyl group [1]. Orton, who was the first to make a systematic study of replacement of halogens by the hydroxyl group, found [28] that the reaction rate greatly depends on the structure of the diazonium compounds (Table 1).

The accumulation of negative substituents on the nucleus facilitates replacement. In the naphthalene series, replacement occurs much more readily than in the benzene series. Since potassium tribromophenyldiazoate is stable under the reaction conditions, Orton suggested that the diazohydroxide, and not the diazoate, takes part in the reaction [28]. According to Orton, an intermediate quinonoid transition state is formed:



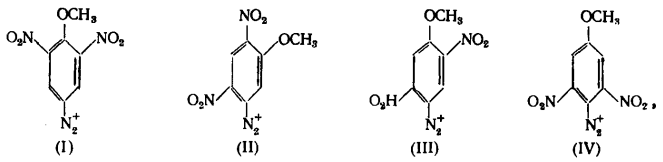
Much later, Mills noted that substitution occurs in the diazonium cation [29].

Meldola and coworkers made a detailed study of the replacement of substituents by hydroxyl groups and observed a number of special features in this exchange [30-35]. Meldola and Eyre showed that the nitro-group and halogens are eliminated as the corresponding anions [34]. For example, in the elimination of the nitro-group nitrous acid is formed in solution, and this can diazotise the starting amine [34]. This is the first description of what is called auto-diazotisation. These workers also showed that in concentrated hydrochloric acid the substituent is exchanged not for a hydroxyl group but for a chlorine atom [34]. In sulphuric or nitric acid, the acid anion is never exchanged for a substituent in the diazonium salt. Meldola and coworkers established [33,35] that two conditions are necessary for the replacement of a substituent by the hydroxyl group: the group replaced must be in the *o*- or *p*-position to the diazonium group and it must be activated by a nitro-group

TABLE 1.

Diazo-compound from	Chlorine eliminated in 24 hours, %	Diazo-compound from	Chlorine eliminated in 24 hours, %
2,4-Dibromo-1-naphthylamine	97	2,3,4,6-Tetrabromoaniline	74
2,4,6-Tribromo-3-nitroaniline	93	2,4,6-Tribromoaniline	64
2,4-Dibromo-5-nitroaniline	80	2,4,6-Trichloroaniline	63
1-Chloro-2-naphthylamine	76	2,6-Dibromoaniline	24
		2,4-Dichloroaniline	traces

in the *ortho*-position to it[35]. Thus, of the compounds I to IV:



(I) (II) (III) (IV)

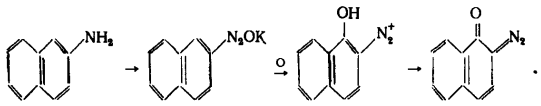
only I and III, which satisfy these conditions, are capable of exchanging a nitro-group or a methoxyl group for a hydroxyl group and undergoing conversion into quinone diazides. If the nitro-group and the alkoxyl group are in positions equally favourable for replacement, the nitro-group is replaced[35]. Continuing this work, Morgan and Evens showed that the nitro-group in the diazonium salt obtained from 2,4-dinitroaniline can also be replaced[36]. If conditions are equally favourable for the replacement of a halogen atom or an alkoxyl group by a hydroxyl group, the alkoxyl group is replaced[37]. If conditions are equally favourable for the replacement of an *o*- and a *p*-nitro-group, the *ortho*-group is preferentially replaced[36,38]. The tendency for the formation of *o*-quinone diazides is so great that in the diazotised 2,6-dichloro-4-nitroaniline molecule a chlorine atom and not a nitro-group is replaced by a hydroxyl group[39].

Hodgson and Birtwell showed[27] that if a substituted naphthylamine is diazotised in sulphuric acid containing the minimal quantity of water, the diazonium sulphates corresponding to the initial amine are formed[27]. However, if the diazo-solution is diluted, or if the diazotisation is carried out in acetic acid, or in a mixture of acetic and sulphuric acids, the corresponding substituent is replaced and diazides are formed[27]. These workers recommend that the diazotisation should be carried out with sodium nitrite in a mixture of sulphuric and acetic acids, or in glacial acetic acid, and that the diazide should be separated by diluting the solution with water or by neutralising it with ammonia or copper carbonate.

The formation of quinone diazides following the replacement of electronegative groups in the diazonium cation by a hydroxyl group is sometimes undesirable, for example, in Sandmeyer's reaction with diazonium salts obtained from 2,4-*x*-trinitro-1-naphthylamine (x = 3, 5, 7, 8)[40]. In order to avoid the formation of quinone diazide as a by-product, it has been proposed that Sandmeyer's reaction should be carried out in non-aqueous media with, for example, acetic acid saturated with hydrogen halide as solvent[41].

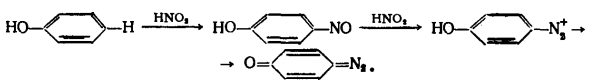
This reaction in which substituents are exchanged is of great importance in the azo-dye industry, since on coupling the hydroxyaryl-diazonium (*ortho*-isomers) salts formed are converted into hydroxyazo-dyes, which are capable of forming lakes with heavy metal cations. The synthesis of hydroxyazo-dyes incorporating a stage in which various groups are replaced by a hydroxyl group is described in many patents. The hydroxyaryldiazonium salts are then formed in solution only as intermediate products and the corresponding diazides are never separated. Detailed information on these patents is given in the monograph of Saunders[1].

The oxidation reaction, in which a hydrogen atom is replaced by a hydroxyl group, is a special case of the introduction of a hydroxyl group into the molecule of a diazonium compound. Bamberger[42-44] proposed this method of synthesising diazides; he oxidised diazoates obtained from 1- or 2-naphthylamines with potassium hexacyanoferrate(II) in alkaline solution:



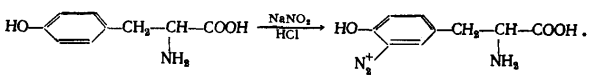
1,2- and 2,1-naphthoquinone diazides were obtained in high yield.

3. Synthesis of quinone diazides from phenols. In this method phenols or nitrosophenols are treated with nitrous acid in aqueous solution. Hydroxyaryldiazonium salts are first formed, and these are then converted to quinone diazides:



Although this method has been little studied, it is very promising, because it permits the preparation of quinone diazides directly from phenols, and it obviates the synthesis of aminophenols, which are not always accessible and are sometimes difficult to diazotise. This applies particularly to phenols with positive substituents.

The method is based on a reaction discovered by Weselsky[45], who treated phenol with nitrogen oxides and obtained hydroxyphenyldiazonium nitrate. The same salt was obtained in a similar way from nitrosophenol[46]. Morel and Sisley carried out the following reaction[47]:



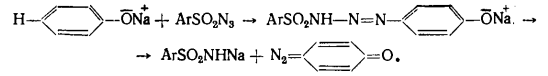
It was shown by azo-coupling that the yield of the diazo-compound is 80%. Phenols containing sulpho-groups[48] or chlorine[49] were also treated with nitrogen oxides, and the corresponding diazophenols were found in the reaction mixture. Nesmeyanov and Ioffe[50] showed that the presence of substituents of the first kind in the nitrosophenol nucleus promotes the formation of a quinone oxime structure and thereby prevents diazotisation. Nitrosonaphthols, which exist as naphthoquinone oximes, do not react with nitrogen oxides. From the results obtained it was concluded that nitroso-compounds react with nitrogen oxides in the benzenoid and not in the quinonoid form.

Nemodruk showed that when nitrous acid acts on salicylic acid carbon dioxide is liberated and diazophenol is formed in the solution in good yield[51]. If cyclic metal salts of salicylic acid are introduced into the reaction, the diazo-group enters the *para*-position to the hydroxyl group, and salts of 5-diazosalicylic acid are formed in nearly quantitative yield[52].

In recent years Tedder and Theaker developed a method for the preparation of hydroxyphenyldiazonium salts from phenols[53]. They showed that the greatest yield of diazo-compound is obtained when the reaction is carried out in aqueous solution with a molar ratio of starting materials (phenol: HCl: $NaNO_2$) of 1 : 4 : 14.5. The mixture is maintained at 0° for 20–40 h, and the yield of the diazo-compound is determined by azo-coupling. The yield largely depends on the nature of the phenol: the greater the acidity of the starting phenol, the lower the yield of the diazo-compound. It is assumed that nitrosophenols are formed as intermediates. Naphthols do not form diazo-compounds, as they are converted into quinoneoximes. If

the position *para* to the hydroxyl group is free in the phenol, the corresponding *p*-hydroxyphenyldiazonium compound is formed.

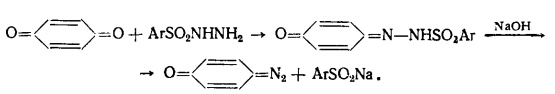
Tedder and Webster treated various phenoxides with *p*-toluenesulphonyl azide and obtained mixtures of azo--dyes[54]. They proposed the following scheme for the process:



The quinone azide couples with an excess of phenoxide to form the dye. If the diazide obtained couples slowly, it may be separated. This reaction provides a convenient method for the introduction of a diazo-group into phenols containing negative substituents which do not react with nitrogen oxides in acid solution.

The preparation of quinone diazides by treatment of compounds with nitrogen oxides has been used in industry. The preparation of 1,4-didiazo-anthra-9,10-quinone by treating anthraquinone with nitrosylsulphuric acid has been described in a patent[55].

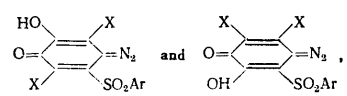
4. Synthesis of quinone diazides from quinones. Börche and Frank showed that treatment of quinones with aromatic sulphonyl hydrazides gives arylsulphonylazophenols $HO.C_6H_4N_2SO_2Ar$, which are also obtained from quinone azides and arylsulphonic acids[56-59]. When treated with mineral acids or alkalis, the arylsulphonylazophenols are decomposed into arylsulphinic acids and hydroxyphenyldiazonium salts (or the corresponding diazoates, according to Börche and Frank[56]). Later this reaction was used for the synthesis of aliphatic diazo--cations[59], and then Cava and coworkers[60] used it for the synthesis of cyclic diazo-ketones, including some quinone diazides. The reactions proceed according to the following scheme:



Using the method they had developed, Cava and coworkers[60] were the first to obtain the diazides corresponding to isatin and 9,10-phenanthraquinone; a previous attempt to obtain this compound by diazotisation of aminohydroxyphenanthrene was not successful[61].

The method of synthesising diazides from quinones became particularly valuable after Horner and Dürckheimer had proposed[62] a simple procedure for the preparation of *o*-quinones by the oxidation of aromatic diazo--compounds with chloroaniline or bromoaniline.

Reid and Dietrich made a detailed study of the synthesis of quinones through *p*-toluenesulphonyl hydrazones. They showed[63] that the hydrazones of aliphatic ketones decompose only in alkaline solutions, but quinone hydrazones decompose in both acid and alkaline solutions. The colour of the hydrazone is a rough indication of its stability: the more intense the colour, the lower the stability. It was also noted that if the oxidation potential of the quinone is sufficiently high, side-reactions occur in the preparation of the diazides. For example, compounds of the following type were obtained from halo-anils:



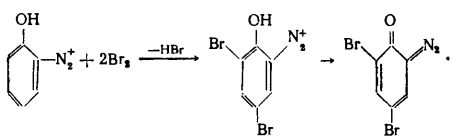
where X is a halogen atoms.

Reid and Dietrich[64] showed that the compounds obtained do not result from the secondary reaction of quinone diazides with arylsulphinic acid, but replacement of chlorine by an arylsulphinic acid residue occurs with the formation of a diazide from quinone *p*-toluenesulphonylhydrazones[64].

Horner and Dürckheimer studied[65] the reaction of various *o*-quinones of the benzene series with *p*-toluenesulphonyl hydrazide in order to determine which of the two non-equivalent quinone carbonyl groups takes part in the reaction. The results showed that in 4- or 5-substituted *o*-quinones the C=O group not conjugated with the substituent reacts with the hydrazide, but in 3- and 3,5-substituted quinones the reactive group is the carbonyl remote from the substituent in position 3. In these instances steric factors predominate over electronic factors.

The synthesis of quinone diazides has permitted the preparation of a large number of diazides with electropositive substituents[65].

5. Preparation of substituted quinone diazides. Only a few examples are known of the preparation of diazides by the introduction of new substituents into a previously synthesised diazide. In 1881 Bohmer[66] showed that when treated with bromine water, *o*- and *p*-benzoquinone diazides give 2-diazo-4,6-dibromo-*o*-benzoquinone and 4-diazo-2,6-dibromo-*p*-benzoquinone. The mechanism of these reactions has not been studied, but the author assumes that a diazonium cation takes part:



The reaction with hydroxyphenyldiazonium nitrate and hydrobromic acid proceeds in the same way; a nitrate ion formed in the first stage of the process oxidises the acid to bromine, which then brominates the diazide.

The halogen atom may replace other groups besides the hydrogen atom. Kollrepp[67] established that when bromine water acts on 3-chloro-5-diazo-2-oxocyclohexa-3,4-dienesulphonic acid, sulphurous acid is eliminated and 6-bromo-2-chlorobenzoquinone diazide [6-bromo-2--chloro-4-diazocyclohexa-2,5-dien-1-one] is formed[67].

It has been reported[68] that 6-bromo-4-sulphonaphtho--1,2-quinone 1-diazide is formed from 4-sulphonaphtho--1,2-quinone 1-diazide by the action of bromine in chlorosulphonic acid or sulphuric acid. However, in the naphthalene series this reaction sometimes leads to the oxidation of the diazide with elimination of diazoate. Thus, the action of bromine on 4-bromonaptho-1,2--quinone 2-diazide gives dibromonaphtho-1,2-quinone[69]; sometimes brominated naphthols are formed[70].

According to patent information[71-73], 1-diazo-2-naphthol--4-sulphonic acid can be nitrated and sulphonated. According to Ruggli and coworkers[68-72], the nitro-group (and probably also the sulpho-group) enters position 6 in the naphthalene ring.

All the reactions mentioned above are carried out in strongly acid solution, and there is reason to suppose that it is the diazonium, and not the diazide, form of the compounds that takes part in the replacement reaction.

Another example of substitution in the quinone-diazide ring is the conversion of diazides of the naphthalene series containing sulpho-groups; when these diazides are treated with sulphuryl chloride or chlorosulphonic acid, sulphonyl chlorides are formed, which give sulphonamides on treatment with amines [7,8,74-82].

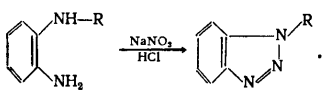
In recent years various examples of this reaction have been published in patents [74-82]. These sulphonamide derivatives of quinone diazides are of interest because they are widely used in the production of photosensitive materials.

Reid and Dietrich have succeeded in acylating a hydroxyl group in quinone diazides [64].

B. Preparation of *p*-Iminoquinone Diazides

Only *para*-substituted diazonium salts form imino-quinone diazides (imidoquinone diazides). When treated with even weak alkaline agents (sodium acetate) *meta*--substituted diazonium salts lose the diazo-nitrogen and are converted into phenol derivatives, which immediately condense with another diazonium molecule [83].

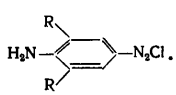
In contrast to *o*-quinone diazides, *o*-iminoquinone diazides cannot be prepared, because diazotisation of *o*-phenylenediamines gives, instead of the diazonium salt, a precipitate of a colourless internal condensation product (benzotriazole derivative) [83]:



p-Iminoquinone diazides are much less stable compounds than quinone diazides, and there are therefore much fewer methods of preparing them. *p*-Iminoquinone diazides are mainly prepared by the action of alkaline agents on solutions of amino-substituted diazonium salts.

p-Iminoquinone diazides are formed only from *N*-substituted *p*-aminophenyldiazonium salts:

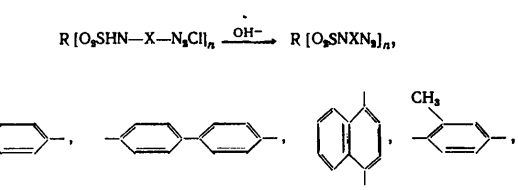
or from nuclear-substituted diazonium salts:



NaOH, NH_4OH, Na_2CO_3, $NaHCO_3$, or CH_3COONa may be used as the alkaline agent, according to the nature of the substituent R; sometimes the *p*-iminoquinone diazides may be separated by simply diluting the diazo-solution with water.

p-Iminoquinone diazide was first obtained by Ykuta [84], who prepared it in an impure state by treating the corresponding diazonium sulphate with ammonium hydroxide. Hantzsch investigated and described the compound [85]. Morgan and coworkers then found that *p*-iminoquinone diazides are formed by the action of a saturated solution of sodium acetate (or other alkaline agents) on diazotised *N*-substituted *p*-phenylenediamines, in which the substituent is an alkylsulphonyl [83], arylsulphonyl [86,87], or a mixed arylalkylsulphonyl group [88].

The reaction may be represented by the following general scheme [89]:



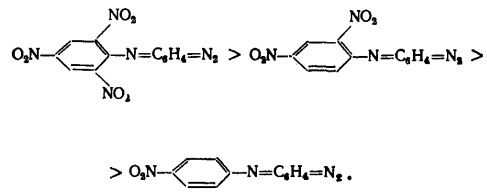
and *n* is the valency of the radical linked to the sulphonyl group; when $n = 1$, R = CH_3, C_6H_5, p-$CH_3C_6H_4$; when $n = 2$, R = $-CH_2-$, 1,3-phenylene; when $n = 3$,

p-Iminoquinone diazides with substituents in the *ortho*- or *meta*-position to the diazo-group are formed without the addition of alkaline agents by simply diluting the diazo--solution with water [90].

p-Iminoquinone diazides are also formed fairly readily from nitro-derivatives of diazotised *p*-aminodiphenylamine [91]:

where $n = 0, 1, 2, 3$.

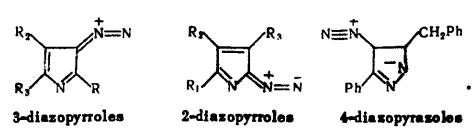
Morgan notes that the reaction rate and the stability of the *p*-iminoquinone diazide formed increase with increasing acidity of the substituent on the amino-nitrogen [91]:



Thus, trinitro-derivatives are obtained by adding sodium acetate to a hydrochloric acid solution, but the separation of a dinitro-derivative requires the addition of a more alkaline agent, such as potassium hydrogen carbonate, to the diazo-solution, and mononitro-derivatives are obtained from the diazo-solution only by adding ammonium hydroxide.

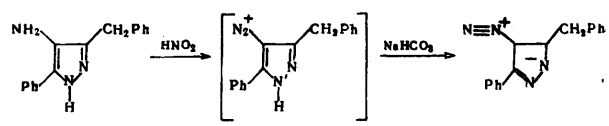
p-Iminoquinone diazides are also obtained from carbazole-3-diazonium chloride [92].

The following heterocyclic diazo-compounds may also be regarded as diazo-imines [93-95]:

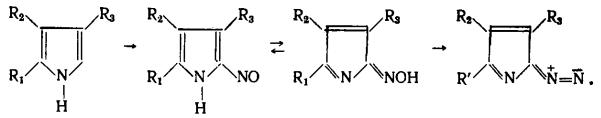


3-diazopyrroles 2-diazopyrroles 4-diazopyrazoles

These compounds may be prepared by the usual diazotisation of the corresponding amine and neutralisation of the solution obtained [93,96]:



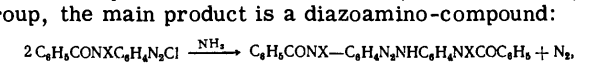
Tedder's method may also be used: in this the diazo-group is introduced into the ring with the aid of nitrous acid[94,95]:



For a long time attempts to prepare *p*-iminoquinone diazides from *N*-formyl-, *N*-acetyl-, and *N*-benzoyl--amino-substituted diazonium salts were not successful. Morgan and coworkers showed that in these instances the use of ordinary alkaline agents leads to some unexpected results[97]. When the diazo-solutions of *N*-benzoyl-1,4--phenylenediamine and *N*-benzoyl-1,4-naphthylenediamine are treated with sodium acetate no precipitate is formed, but treatment with cold concentrated solutions of potassium hydrogen carbonate and sodium nitrite gives yellow crystalline precipitates, which Morgan regarded as aryldiazonium hydrogen carbonate and nitrite[97]. The action of alkali on *p*-*N*-benzoylaminophenyldiazonium chloride gives a different result: Morgan considers the main reaction product to be a diazo-oxide[98]:

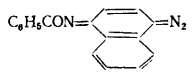
where X = H, CH_3, C_2H_5.

According to Morgan and coworkers, the action of ammonia depends on the substituent X; if X is an alkyl group, the main product is a diazoamino-compound:



if X = H, a mixture of diazo-oxide and diazoamino-compound is obtained. It has been shown that the action of a cold concentrated solution of potassium hydrogen carbonate, a cold solution of ammonium hydroxide, or a 0.1 *N* solution of sodium hydroxide on an aqueous solution of *p*-*N*-benzoylaminophenyldiazonium chloride at 0–4° leads to the formation of a yellow precipitate consisting of a mixture of diazonium chloride and the corresponding *p*-iminoquinone diazide, but the pure *p*-iminoquinone diazide *p*-$C_6H_5CONC_6H_4N_2$ could not be obtained in this way[99].

The action of alkali on the diazo-solution of *p*-*N*-benzo-amino-1,4-naphthylenediamine leads to the separation of a yellowish brown product, which Morgan regarded as the nitrosoamine $C_6H_5CONHC_{10}H_6NHNO$.[100] Later Dimrot and coworkers[101] showed that the *p*-iminoquinone diazide



is in fact formed, and not the nitrosoamine.

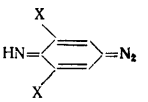
The preparation of *p*-iminoquinone diazides from *p*-*N*-acetyl and *p*-*N*-formyl-aminophenyldiazonium chlorides is still more difficult. Morgan and coworkers tried the effect of various alkaline agents ($KHCO_3$, $NaNO_2$, CH_3COONa, NH_4OH) on these diazonium chlorides[97]. No precipitate was obtained with potassium hydrogen carbonate or sodium nitrite; with sodium acetate the diazoamino--compound $R'CONHC_6H_4N_2NHC_6H_4NHCOR'$ was precipitated; and with ammonium hydroxide a compound was formed the analysis of which indicated that it was most likely a nitrosoamine.

Thus, the *p*-iminoquinone diazides $RNC_6H_4N_2$ (where R = HC(=O)–, CH_3C(=O)–, or C_6H_5C(=O)–) cannot be prepared by the usual method, that is, by the action of various alkaline agents on diazonium chlorides.

Morgan and coworkers[89,102] proposed another method of preparing *p*-iminoquinone diazides, consisting in the direct diazotisation of the amine $R'CONHC_6H_4NH_2$, where R' = H, CH_3, C_6H_5, with dinitrogen trioxide in a solution of dry acetone. The *p*-iminoquinone diazides obtained in this way are described as unstable compounds that cannot be purified, because they become more contaminated on recrystallisation; they are pale yellow, while all quinone diazides and *p*-iminoquinone diazides have a bright yellow, orange, or red colour.

Later it was shown[99] that the action of dinitrogen trioxide on *p*-*N*-acetyl- and *p*-*N*-benzoyl-*p*-phenylenediamines leads to the formation of the corresponding aryldiazonium nitrate and not to iminoquinone diazides.

The unsubstituted *p*-iminoquinone diazide $HNC_6H_4N_2$ could not be obtained at all. The ring-substituted *p*-iminoquinone diazides

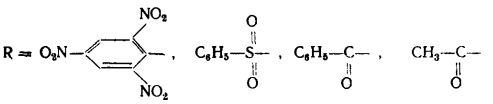


were obtained by the diazotisation of the corresponding amines with dinitrogen trioxide[102]. However, this work requires confirmation.

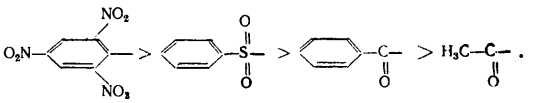
Thus, iminoquinone diazides (imidoquinone diazides) are only formed from *N*-substituted *p*-aminophenyldiazonium salts $RNHC_6H_4N_2^+X^-$; the reaction proceeds more readily as the electronegativity of the substituent R increases, and the ease of formation increases with the molecular weight of the *p*-iminoquinone diazide. The stability of the *p*-iminoquinone diazides increases in the same order. This explains why the *p*-iminoquinone diazides $RCON{:}C_6H_4{:}N_2$, where R = CH_3, C_6H_5, could not be obtained for a long time and why *p*-iminoquinone diazide itself

has not been prepared.

Ultraviolet and infrared spectroscopy have been used successfully to investigate the conversion of the diazonium chlorides $RNHC_6H_4N_2Cl$, where



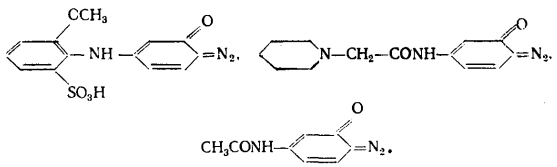
into the corresponding *p*-iminoquinone diazides in buffered solutions[99]. The two latter *p*-iminoquinone diazides decompose very rapidly in light at ordinary temperature. It has been shown that this conversion is an acid–diazo-cation dissociation. The strength of the acid $RNHC_6H_4N_2^+$ decreases in the following order according to the substituent R:



Thus, *p*-*N*-picrylaminophenyldiazonium chloride is instantly converted into the *p*-iminoquinone diazide even by dissolution in water, but an appreciable quantity of *p*-iminoquinone diazide is formed from *p*-*N*-acetylamino-phenyldiazonium chloride only in alkaline solutions of pH 9 or higher.

Para- and *ortho*-hydroxyphenyldiazonium chlorides are stronger acids, and they therefore form quinone diazides

more readily; this is due to the greater acidity of the hydroxyl group. Thus, diazonium salts with both OH– and RNH– groups in the ring form quinone azides [103,104], but not *p*-iminoquinone diazides, for example:



The special properties of hydroxy- or amino-substituted diazonium salts whereby they form quinone diazides and *p*-iminoquinone diazides when treated with alkaline agents is due, on the one hand, to the presence in the molecule of the hydroxy- or amino-group, which can eliminate a proton under certain conditions, and, on the other hand, to the presence of an extremely strong electronegative diazonium group, which confers acidity on the hydroxy- or amino-group in the *ortho*- or *para*-position. In the diazonium chloride

an electron-acceptor substituent R is also needed to ensure the elimination of a proton from the amino-group.

III. PROPERTIES OF QUINONE DIAZIDES AND *p*-IMINOQUINONE DIAZIDES

A. Physical Properties

Quinone diazides and *p*-iminoquinone diazides are coloured crystalline compounds, with colours varying from yellow to red.

Their behaviour with solvents greatly depends on their structure. Thus, *o*-quinone diazides are always more soluble than the *para*-isomers. Unsubstituted *o*- and *p*-benzoquinone diazides, their methyl and methoxy--derivatives, *p*-*N*-acet- and *p*-*N*-benziminoquinone diazides are very soluble. Arylsulphonyliminoquinone diazides are moderately or even poorly soluble in organic solvents and water. Some *p*-iminoquinone diazides are readily soluble in *p*-toluidine [86], but depression of the freezing point indicates that they form addition products with the solvent. The presence of a large number of condensed benzene rings in quinone diazides and *p*-iminoquinone diazides reduces the solubility of these compounds in water and increases the solubility in organic solvents. Thus, 1,2- and 2,1-naphthoquinone diazides are easily crystallised from aqueous solution [7,13], but are readily soluble in organic solvents. The introduction of negative substituents into quinone diazides reduces their solubility in both polar and non-polar solvents.

Some diazides contain water of crystallisation [10,24,105]. Hantzsch and Davidson studied a number of simple quinone diazides by the cryoscopic method and showed that they are not associated in solution [10].

All quinone diazides and *p*-iminoquinone diazides are sensitive to heat, and nitro-derivatives explode when heated in the dry state. The decomposition temperature largely depends on the rate of heating [106]. The thermal stability increases with the number of negative substituents in the nucleus.

Photosensitivity is a specific property of quinone diazides and *p*-iminoquinone diazides, the latter being the more sensitive to light. The use of these compounds in the printing industry is based on this property. *o*-Quinone diazides are more photosensitive than the *para*-isomers, and naphthalene derivatives are more sensitive than benzene derivatives.

A large amount of information on the use of diazides for the preparation of photosensitive compositions has been published in the patent literature [74-82] and has been reviewed by Saunders [1] and Dinaburg [107].

De Jonge and coworkers [108] determined quantum yields for the photolytic decomposition of quinone diazides irradiated in aqueous solution with light of wavelength 3500–4000 Å. They found that the quantum yield varies between 0.20 and 0.40, and they noted that, although the quantum yields are similar for all the compounds, variations in the photosensitivity of quinone diazides are due to differences in light-absorbing capacity. The more highly absorbing quinone diazides are more photosensitive. This also accounts for the higher photosensitivity of quinone diazides compared with diazonium salts; absorption curves of quinone diazides are displaced towards the long-wave side compared with the curves of diazonium salts.

The higher photosensitivity of *o*-quinone diazides compared with *para*-isomers may be explained in the same way.

Different physicochemical characteristics (spectra, dipole moments) are closely related to the structures of these compounds; for this reason, the relevant published information is considered in the section dealing with the structure of quinone diazides and iminoquinone diazides.

B. Chemical Properties

1. Diazide–diazonium acid–base equilibrium. It is characteristic of quinone diazides and *p*-iminoquinone diazides that they are converted into diazonium salts by the action of acids. Using ultraviolet spectroscopy, Kazitsyna and coworkers [99,109,110] made a detailed study of this transition as applied to unsubstituted, bromo-substituted and nitro-substituted *ortho*- and *para*--benzoquinone diazides, and the *p*-iminoquinone diazides $RNC_6H_4N_2$, where R = C_6H_5CO, CH_3CO, $C_6H_5SO_2$, or $(NO_2)_3C_6H_2$. The absorption curves obtained for *o*-benzoquinone diazides and *p*-benzenesulphonyliminoquinone diazides (Figs. 1 and 2) in various acidity regions have isobestic points, which indicates that only two forms (diazonium and diazide) occur in solution [110,111]. A similar picture is observed with substituted quinone diazides [110,112]. Therefore, the diazonium-cation–quinone diazide (*p*-iminoquinone diazide) change is an acid–base equilibrium.

Thus, quinone diazides and *p*-iminoquinone diazides are bases. These bases may differ greatly in strength. The *p*-iminoquinone diazides *p*-$CH_3CONC_6H_4N_2$ and *p*-C_6H_5-$.CONC_6H_4N_2$ are fairly strong bases; they are protonated, that is, converted into the corresponding diazonium cations, even in neutral or weakly alkaline solution [99]. Unsubstituted *para*- and *ortho*-quinone diazides and the *p*-iminoquinone diazides *p*-$C_6H_5SO_2NC_6H_4N_2$ are weak bases, and are protonated in acid solution, but within the limits of the pH acidity scale [109-111]. Bromo- and nitro-derivatives of quinone diazides, as weak bases, are only protonated in

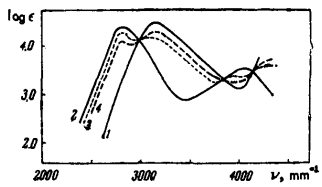


Fig. 1. Electronic absorption spectra of *p*-hydroxyphenyldiazonium chloride: 1) in 0.1 *N* HCl; 2) in water; 3) in 4×10^{-4} *N* HCl; 5) in 5×10^{-4} *N* HCl.

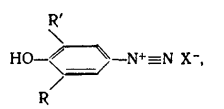
concentrated acids[66,110]. Ershov and Nikiforov made a spectrophotometric study of the conversion of *p*-quinone diazides with alkyl substituents in the *ortho*-position to the oxygen atom into the corresponding hydroxyphenyldiazonium salts[112]:



where R = R′ = H; R = R′ = CH_3; R = R′ = $CH(CH_3)_2$; R = = R′ = $C(CH_3)_3$; R = CH_3 and R′ = $C(CH_3)_3$, and found values for the logarithms of the equilibrium constants for this reaction. Their results show that quinone diazides with more branched alkyl substituents are weaker bases. The stability of the quinone diazide or *p*-iminoquinone diazide is inversely proportional to its basic strength.

Since diazides exist in aqueous solutions of different acidity in equilibrium with the diazonium form, it is sometimes difficult to decide whether the diazide or the diazonium form take part in the reaction. Authors of various papers on quinone diazides do not generally consider this aspect of the problem; for this reason, where possible, the form taking part in the reaction will be noted in the discussion on chemical properties.

2. Reactions in which nitrogen is retained. Both atoms are retained in many reactions of diazides and diazonium salts. Thus, with cyanides or sulphites quinone diazides form hydroxyaryl-diazocyanides or -diazosulphonates[10,43,66]. Like sulphurous acid, arylsulphonic acids react with quinone diazides to form sulphoazophenols[57,58]. As mentioned above, the same compounds are obtained by the action of arylsulphonyl hydrazides on quinones[56].

It has been reported that quinone diazides and their corresponding diazonium salts do not form perhalogen compounds[10,66].

Concentrated sulphuric acid sulphonates diazides of the naphthalene series[72], nitric acid nitrates them[72], and bromine brominates them[68]; in these reactions the substituent enters the 6-position. Diazides of the benzene series are brominated by bromine water[66].

In acid solutions of metal chlorides, quinone diazides form double salts, metal hydroxyaryldiazonium halides[10,66,113].

Hantzsch and Davidson[10], showed that, in the absence of acid, *p*-hydroxyphenyldiazonium salts form compounds of the type $HOC_6H_4N_2X.OC_6H_4N_2.MN_n$ with $CdCl_2$, CdI_2, and $HgCl_2$, but the action of cadmium iodide on quinone diazide leads to the formation of the compound $C_6H_4N_2O.CdI_2$. They put forward no hypotheses as to the structure of these compounds.

Kazitsyna and coworkers[113] made a detailed study of the reaction of *o*- and *p*-benzoquinone diazides with $ZnCl_2$, $CoCl_2$, $HgCl_2$, and $NaBF_4$. In aqueous and methanol solutions, finely crystalline, coloured compounds are formed, for which the following formula was proposed on the basis of elemental and infrared analysis:

$$[(HOC_6H_4N_2)_m\ OC_6H_4N_2]^{+m}\ [MCl_{n+m}]^{-m},$$
(II)

$m = 1$ with BF_4^-; $m = 2$ with $ZnCl_4^{2-}$, $CoCl_4^{2-}$.

The infrared spectra (ν_{CN_2} frequencies) indicates that there is some interaction between the quinone diazide molecule and the hydroxyphenyldiazonium cation.

A study of the reaction conditions showed that a weakly acid medium produced by partial hydrolysis of the salt is necessary for the formation of salts of this kind; the presence of this medium leads to quinone diazide–diazonium--cation equilibrium. Because of this property of quinone diazides, compounds of type (I) are obtained by the action of metal halides on both hydroxyphenyldiazonium salts and quinone diazides. When the acidity of the medium is increased, quinone diazides react with the metal halides to form ordinary hydroxyphenyldiazonium metal-halide salts.

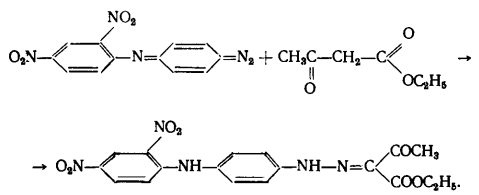
Mercury(II) chloride reacts with *o*- and *p*-benzoquinone diazides to form simple addition products of the composition $OC_6H_4N_2.HgCl_2$; Hantzsch found that mercury(II) iodide reacts in the same way.

The azo-coupling reaction of quinone diazides is of great importance, being widely used in industry for the synthesis of hydroxyazo-dyes, which form stable lakes with metal cations. Azo-coupling is also often used for the quantitative determination or identification of quinone diazides[51-54]. Diazides may be coupled in weakly acid or alkaline solution. The reaction conditions and characteristics determined with different compounds indicate that the compounds are capable of coupling in the diazide as well as in the diazonium form. The azo-coupling of diazides in acid solution is described in many patents[1]. In industry, hydroxyaryldiazonium salts are not separated in the dry state, but azo-coupling is carried out directly in solutions obtained after diazotisation, an alkaline solution of the azo-component being added.

Although no quantitative study has been made of the relation between the rate of azo-coupling and the nature of the substituent in quinone diazides, a number of rules governing the reaction may be noted. When the molecule contains a large number of condensed benzene rings, the tendency to form diazides increases, and these compounds couple less readily than simpler compounds, which are

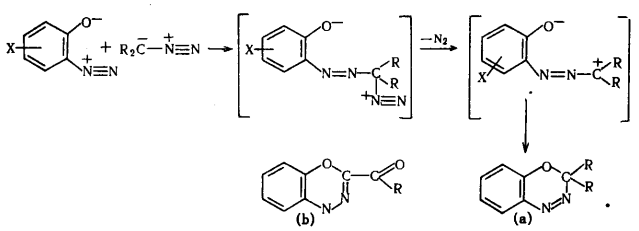
capable of being more easily converted into hydroxyaryldiazonium salts. *o*-Quinone diazides, which are formed more easily than *para*-compounds, also couple less readily than the *para*-isomers [36,38,54]. The introduction of negative substituents into the diazide nucleus leads to an increase in the positive charge on the diazo-group and significantly increases the tendency of the diazides to undergo azo-coupling [114]. Thus, Bamberger showed that unsubstituted 1,2- and 2,1-naphthoquinone diazides in alkaline solutions couple very slowly and only with active components [43,44]. Introduction of bromine or the cyano-group into the nucleus leads to more active coupling [20,68].

p-Iminoquinone diazides are also capable of undergoing the azo-coupling reaction. These compounds couple best with phenols, 2-naphthol, and resorcinol in dry pyridine [86]. Coupling occurs only with the most reactive amines: aniline and its homologues do not couple, but the reaction is quantitative with naphthylamines and toluene-2,4-diamine [86,115]. As Simonov showed [116], *p*-iminoquinone diazides couple with aliphatic and heterocyclic enols (ethyl acetoacetate, phenylmethylpyrazolone, etc.). The reaction proceeds readily at 20–30° in acetone solution:



The products are identical with those formed by the reaction of diazonium salts with enols.

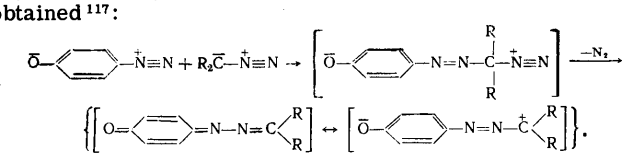
Huisgen and coworkers discovered the azo-coupling reaction of diazonium salts with aliphatic diazo-compounds [117]. These workers also coupled aliphatic diazo--compounds with quinone diazides [114]:



They noted that diazides have a much lower tendency to couple than ordinary aromatic diazonium salts; the introduction of negative substituents into diazides facilitates this reaction. The final products of coupling are derivatives of benzohydrooxadiazines (a). 1,2- and 2,1--naphthoquinone diazides do not undergo the coupling reaction.

If *o*-quinone diazides are coupled with diazo-carbonyl compounds, cyclic azoketones (b) are obtained as final products.

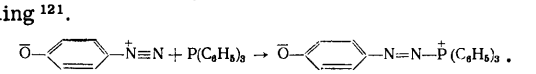
p-Quinone diazides may also react with aliphatic diazo--hydrocarbons, but substituted quinone azines are then obtained [117]:



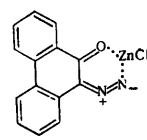
p-Quinone diazides do not react with diazo-carbonyl compounds.

Karlinskaya and Khromov-Borisov found that diazides of the pyrimidine series with a methyl group adjacent to the diazo-group are capable of intramolecular azo-coupling with the formation of indazole derivatives [118]. This reaction, of course, also occurs with diazonium compounds of the benzene series, while *o*-toluenediazonium salts form benzindazole derivatives [119].

Quinone diazides may also react with other nucleophilic compounds. Staudinger and Lüscher showed that quinone diazides, like aliphatic diazo-ketones, couple with triphenylphosphine to form quinonetriphenylphosphazines [120]. Reid and Appel made a detailed study of this reaction, and they noted that it is subject to the same rules as azo--coupling [121].



The *para*-compounds give a higher yield of phosphazines than the *ortho*-compounds, and the reaction is promoted by substituents that increase the positive charge of the diazo--group. Unsubstituted quinone diazides with condensed benzene rings undergo this reaction with difficulty. These compounds react more readily if a solution of quinone diazide and a Lewis acid are used. The authors consider that an intermediate complex of type (II) is formed, in which the Lewis acid increases the positive charge on the diazo-group:

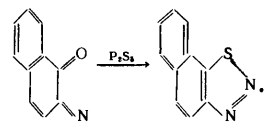


(II).

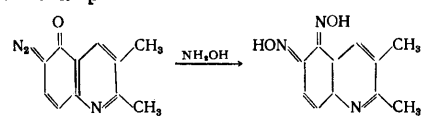
An increase in the positive charge on the diazo-group increases the tendency of quinone diazides to react with triphenylphosphine and it also increases the frequency of the stretching vibrations of the CN_2 group in the infrared absorption spectra of the diazides. It is therefore thought that the value of ν_{CN_2} may give an indication of the reactivity of a quinone diazide.

The reactions mentioned above occur with both diazides and diazonium salts, but some reactions have been described that are characteristic of diazides only.

Bamberger showed that when naphthoquinone diazide is treated with phosphorus pentasulphide, oxygen is replaced by sulphur and thiadiazole derivatives are formed by ring closure [43]:



It has been found that quinone diazides of the heterocyclic series react with hydroxylamine to give quinone dioximes as final products [122]:



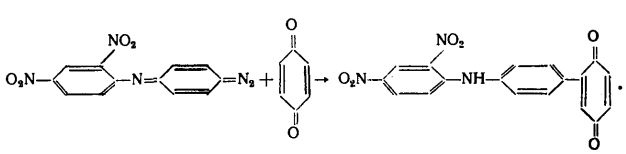
This reaction has not been further studied, but it may be supposed that it is applicable to many diazides, and might probably be a convenient method for synthesising otherwise inaccessible quinone dioximes.

3. Reactions in which nitrogen is eliminated. In acid solutions diazides undergo all the reactions that are observed with solutions of diazonium salts

in general. Thus, in acid solutions of copper(I) chloride quinone diazides undergo the Sandmeyer reaction with the liberation of nitrogen and the formation of the corresponding chlorophenol derivative[24,34,123]. When quinone diazides are treated with potassium iodide or hydriodic acid, nitrogen is also liberated and iodophenols are formed[35,123]. When diazides are boiled in acid aqueous solution, the diazo-group is replaced by a hydroxyl group, but strong oxidation occurs and azo-dyes are also formed[43,66,124]. Reduction of the diazides with tin and hydrochloric acid gives the corresponding aminophenols with the liberation of ammonia[66]. Milder reducing agents, such as tin(I) chloride in hydrochloric or acetic acid, lead to the formation of hydroxyarylhydrazines[66,114,125]. When quinone diazides are boiled in alcoholic solution, the diazo-group is replaced by hydrogen, and the corresponding phenols are formed[30,31,126]; sometimes the reaction is carried out in the presence of alkalis or with the addition of metal powders[20,70]. This reaction was first studied in detail by Cameron[126], who established that replacement of the diazo-group by an alkoxyl group competes with replacement by hydrogen, and with alcohols higher than methanol the second reaction begins to predominate. Negative substituents in the nucleus facilitate the replacement of the diazo-group by hydrogen, and replacement occurs more readily in *ortho*- than in *para*-isomers. Hodgson and Bartwell[127] noted that negative substituents also accelerate the azo-coupling side-reaction, and the yield of reduction product therefore decreases in the order: $NO_2 < Cl < Br < I < SO_3H$. For the reduction, these workers used tin(I) chloride, or powders of aluminium, zinc, iron, or Devarda's alloy[70,126]. Horner and Dürckheimer successfully used hypophosphorous acid as a reducing agent in the presence of hydrochloric acid[65]. Replacement of the diazo-group by hydrogen is a reaction characteristic not only of quinone diazides, but also of various diazonium salts. Kornblum has published a review of the literature on this subject[128].

p-Iminoquinone diazides are reduced by sodium ethoxide, the diazo-group being replaced by hydrogen[86]:

When *p*-iminoquinone diazides are heated with alkalis, resins are formed[83]. Like diazonium salts, *p*-iminoquinone diazides arylate quinones[116]:

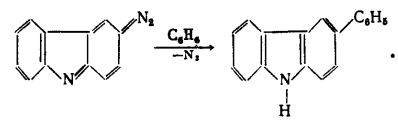


4. Photolytic and thermal decomposition of quinone diazides and *p*-iminoquinone diazides. Since many quinone diazides and *p*-iminoquinone diazides are used as photosensitive and explosive materials, the photochemical and thermal decomposition of these compounds has been intensively studied in recent years. It has long been known that hydroxydiazonium and *p*-aminophenyldiazonium compounds are more photosensitive than other diazonium salts[129]. However, the mechanism of the action of light on diazides has only been elucidated quite recently. Süs[130] and de Jonge and coworkers[131] began to study this question at the same time.

The study of the photochemical and thermal decomposition of these compounds led to the discovery of new methods of synthesising many compounds of different types that were difficult to obtain.

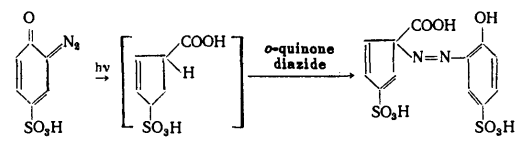
When *p*-quinone diazides and *p*-iminoquinone diazides are irradiated in alcoholic solution, monoalkyl ethers of aromatic *p*-dihydroxy-derivatives and *p*-aminophenols are obtained[8]:

The photochemical decomposition of *p*-quinone diazides and *p*-iminoquinone diazides dissolved in aromatic hydrocarbons is used preparatively as a method of arylation and for the preparation of hydroxy- and amino-derivatives of these hydrocarbons, and also for the preparation of various heterocyclic compounds[8]:

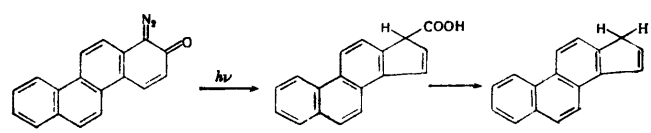


The photodecomposition or thermal decomposition of *p*-iminoquinone diazides and *p*-quinone diazides in the absence of water and polar organic solvents leads to the formation of thermostable polymers[8,132]:

Under the action of ultraviolet light the decomposition of *o*-quinone diazides proceeds quite differently. Süs who made a detailed study of this reaction, established that photolysis of *o*-quinone diazides is accompanied by ring contraction. Süs showed[130] that irradiation results in the formation of either a derivative of cyclopentadienecarboxylic acid, or the product of azo-coupling of this acid with the starting quinone diazide, the product depending on the structure of the latter:



Later, Süs and other workers studied the photolysis of *o*-quinone diazides of the naphthalene series[7,134], *o*-quinone diazides with condensed aromatic rings[7,10], and *o*-quinone diazides of the heterocyclic series[7,133,134]. In reviewing his papers on this subject, Süs[135,136] put forward some general rules governing the photolysis of *o*-quinone diazides and showed that this reaction can be used for the synthesis of new cyclic systems. For example, irradiation of chrysene-1,2-quinone 1-diazide enabled a compound with a steroid skeleton to be synthesised[7]:

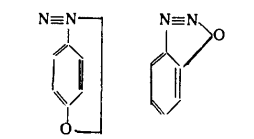


While the manuscript of this review was being prepared for the press, Dinaburg's monograph on photosensitive diazo-compounds and their applications appeared[107]; this gives a review of the literature on the photolytic decomposition of *p*- and *o*-quinone diazides and *o*-iminoquinone diazides. For this reason, we shall not consider these interesting reactions in detail here.

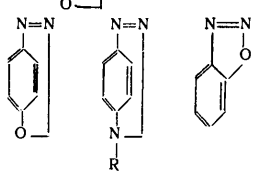
IV. STRUCTURE OF QUINONE DIAZIDES AND *p*-IMINOQUINONE DIAZIDES

The diazides are one of the classes of organic compounds the structure of which cannot be definitely established by chemical methods alone. The main conclusions as to the structure of these compounds have been drawn from the results of physicochemical investigations. We shall briefly consider this problem below and we shall analyse its present status in more detail. We shall first consider the structure of simple diazides, and then the structure of substituted diazides. We shall primarily consider material on the structure of the quinone diazides.

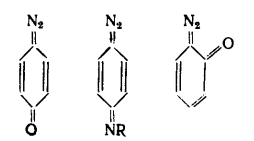
The following formulae have been proposed at different times for quinone diazides and *p*-iminoquinone diazides:



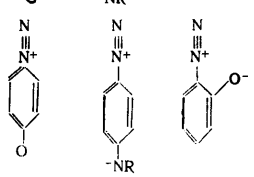
(I)



(II)



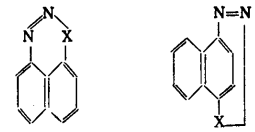
(III)



(IV)

Formula (I), containing quinquecovalent nitrogen, which was proposed by Bamberger [137], is incorrect according to modern interpretations. This formula was last used by Klemenc [124]. If Zsollinger's view [2] is accepted and the bridge bond is considered to be ionic, then this structure reduces to formula (IV).

For a long time a selection could not be made between the cyclic (II) and the quinoid (III) formulae to describe the structure of the quinone diazides and *p*-iminoquinone diazides. After the work of Morgan and coworkers [138,139], the cyclic formula (II), which had also been proposed by Bamberger [137], was considered almost up to the 1950's. Although there are now convincing proofs for the rejection of this formula, [9,13,14] some workers use it for *o*-diazides even today.[118] This is because the following facts favour the cyclic structure: (1) the yellow colour, which may be explained by the presence of the –N=N– group, as in coloured azo-compounds; (2) many properties, such as stability, azo-coupling, etc., have been associated with the presence of an easily cleaved oxydiazole ring; (3) finally, Morgan and coworkers reported (obviously in error) that diazo-oxides and diazoimides with similar properties are obtained from *peri*- and *para*-aminonaphthols and *peri*- and *para*-naphthylenediamines [138,139]. But since *peri*-derivatives cannot have a quinoid structure, both diazo-oxides and both diazoimides must have a cyclic structure:



(where X = O or RN).

Using the analogy of the cyclic configuration of 1,4-diazoiminonaphthalene, Morgan proposed the cyclic formula (II) for the whole series of *p*-diazoimides, although he did not definitely reject the quinoid formula (III).

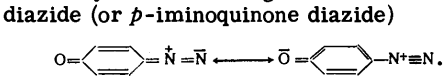
The following facts favour the quinoid structure for diazoimides and diazo-oxides: (1) colour and photosensitivity; (2) negative experiments on the preparation of *p*-diazoimides and *o*-diazo-oxides [74]; (3) differences in physical and chemical properties between *p*-diazoimides and *o*-diazoimides (the latter in fact have a cyclic structure); (4) it is difficult to suppose that the formation of *p*-diazo-oxides and *p*-diazoimides, which occurs readily (and sometimes instantaneously) in the cold, is associated with the closure of a seven-membered ring; (5) the ultraviolet and infrared spectra of the quinone diazides, which will be discussed below; (6) finally, Anderson and Roedel reported [13] that when they repeated Morgan's synthesis [140] they were unable to obtain the cyclic diazo-oxides he described from *peri*-aminonaphthol [13].

It will be seen that there is much more evidence in favour of the quinoid structure (III) and it has therefore been given preference over the others.

The quinoid structure, which is generally ascribed to Wolff [140], was first put forward without proofs by Bamberger [141] as one of the possible formulae of the quinone diazides; it could not be written unambiguously, because the structure of the diazonium group was not known. Later, following Wolff, this structure was accepted by Hantzsch [76,142] and other workers [9,13]. Bamberger [141] and Hantzsch [142] considered that the structure (IIIa) was the correct one. Bamberger [143] also proposed the formula (IIIb), which Angeli accepted [144]. In accordance with modern interpretations, the quinoid formula of the diazides is written in the form (IIIc):

(IIIa) (IIIb) (IIIc)

However, even the quinoid formula cannot exactly describe the structure of the quinone diazides and *p*-iminoquinone diazides. Recently, there has been an increasing tendency to accept the intra-ionic formula (IV), not as an independent formula, but as one of the extreme structures in a resonance hybrid describing the structure of the quinone diazide (or *p*-iminoquinone diazide)



(IV)

Sidgwick and coworkers were the first to put forward the idea of mesomerism of this type [145], and Modling and Burger represented quinone diazides in the same way [122]. Simonov [116] proposed mesomerism of ionic and quinonoid structures for iminoquinone diazides. Later, the mesomerism of these structures was used repeatedly to explain the properties of diazides [1,94,127].

It was characteristic of Hantzsch that as early as 1890 he noted that one formula alone was not sufficient to describe the properties of the diazides, and he thought that oscillation between the structures (I) and (III) was possible [10].

A. Structure and Physicochemical Properties of Quinone Diazides

As mentioned above, more precise determination of the structure of diazonium compounds became possible only with the development of physicochemical methods of investigation.

In 1945 Anderson and coworkers began the publication of papers in which they reported studies on the ultraviolet spectra and dipole moments of some quinone diazides of the benzene and naphthalene series; they compared their results with corresponding data for quinones and compounds containing triazole or thiodiazole rings [13,14]. They noted that the *o*- and *p*-quinone diazides have similar properties and their spectra are similar to the spectra of the corresponding quinones. However, the quinone diazides and cyclic thiodiazoles did not show similarities in their dipole moments and spectra. These workers concluded that the cyclic structure for quinone diazides is entirely ruled out, and they assigned a quinonoid structure to these compounds.

The results of dipole-moment measurements on six quinone diazides published by Anderson and coworkers (see Table 2) show that the *o*-quinone diazides are more "quinonoid" than the *para*-compounds [14]. The introduction of a nitro-group into the molecule increases the dipole moment.

Vaughan and Phillips studied the thermal stability of unsubstituted and nitro-substituted *o*- and *p*-quinone diazides, and showed that the *o*-quinone diazides are thermally no less stable than the *para*-isomers [106]. A nitro-group in the *ortho*- or *para*-position to the hydroxyl group stabilises the molecule, two nitro-groups have a greater effect, and a nitro-group in the *meta*-position has no effect. The results were regarded as being in agreement with the hypothesis that quinone diazides have a structure intermediate between the quinonoid and ionic structures.

TABLE 2. Dipole moments of quinone diazides

Compound	μ_H	μ_X	μ_I^*
3,5-Dibromobenzo-1,2-quinone 2-diazide	2.9	2.5	13.1
Naphtho-1,2-quinone 1-diazide	4.0	3.9	13.7
Naphtho-1,2-quinone 2-diazide	3.5	3.9	13.7
4-Nitronaphtho-1,2-quinone 1-diazide	4.6	2.8	16.2
1,4-Naphthoquinone diazide	4.2	1.6	27.4
p-Benzoquinone diazide	5.0	1.6	27.4

* μ_H dipole moment found experimentally; μ_X dipole moment calculated for the quinonoid form; μ_I dipole moment calculated for the ionic form.

On the bases of differences between ultraviolet absorption spectra of solutions of hydroxyphenyldiazonium sulphate in 5 *N* sulphuric acid, De Jonge and coworkers [146] concluded that the structure of *o*-benzoquinone diazides was intermediate between the quinonoid and ionic forms; they consider that in acid solutions the structure is close to that of benzene, since under these conditions, the quinonoid structure is energetically less favoured. In aqueous solutions the structure of the compound is close to the quinonoid form. These workers explain the different behaviour of *o*-hydroxyphenyldiazonium sulphate in neutral and acid aqueous solutions, and particularly the difference in ultraviolet absorption spectra and the different course of the photodecomposition reaction, by the hypotheses mentioned above. However, as mentioned above (see Section III.B.1), this is not a question of the quinonoid and benzenoid structure of *o*-benzoquinone diazide, but of the existence of an *o*-hydroxyphenyldiazonium cation in acid solutions and of *o*-benzoquinone diazide in aqueous solutions.

In recent years a large number of papers have appeared on the infrared absorption spectra of various quinone diazides. Intense absorption bands were always observed in the region of stretching vibrations of a triple bond and in the region of vibrations of the carbonyl group, which confirms the quinonoid structure, or in the opinion of a number of workers, the "mesomeric" structure of diazides. In the first paper of this type, published in 1954, the infrared spectra of seven quinone diazides were studied; the results are shown in Table 3.[147]

These results were compared with the frequency of the stretching vibrations of the CN_2(ν_{CN_2}) bond of phenyldiazonium tetrafluoroborate (ν_{CN_2} = 2296 cm^{-1}) and with the frequency of the stretching vibrations of the N–N ($\nu_{-N=N-}$) bond of benzo-1-thia-2,3-diazole ($\nu_{N=N}$ = 1542 cm^{-1}) and it was concluded that in quinone diazides the bond between the nitrogen atoms is intermediate between double and triple, and that the carbonyl group has the C=O structure.

Whetsel and coworkers [9] studied the infrared spectra of a number of diazonium salts, including diazonium compounds obtained from some aminophenols. They found the absorption bands in the region of diazo-group vibrations shown in Table 4.

To explain the lower values of ν_{CN_2} of quinone diazides compared with diazonium salts, the authors suggested that in the solid state the structure of quinone diazides is intermediate between the ionic and quinonoid forms.

TABLE 3. Infrared spectra of quinone diazides.

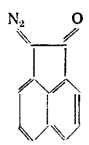
m-Aminophenol tetrafluoroborate	2288
p-Aminophenol chloride	2237
p-Aminophenol diazide	2107
4-Nitro-2-aminophenol diazide	2183

In recent papers that contain information on the infrared spectra of quinone diazides, the authors either do not consider the relationship between spectra and structure at all[60,65,104,148,149], or they attempt to find if quinone diazide has a quinonoid, benzenoid, or mesomeric structure[150,151].

Reid and Appel[121] relate ν_{CN_2} with the reactivity of quinone diazides; they consider that the higher the value of ν_{CN_2}, the more vigorously the compound couples with triphenylphosphine. Thus, if $\nu_{CN_2} = 2125$ cm^{-1}, the compound does not undergo this reaction; if the value of ν_{CN_2} is 2125–2200 cm^{-1}, the compound couples very readily, and when $\nu_{CN_2} > 2200$ cm^{-1}, an anomalously fast reaction is observed. It is of interest that, on the basis of results obtained, these workers concluded that the quinone diazide (V) obtained from acenaphthoquinone is more an aliphatic diazoketone than a quinone diazide. This is in agreement with the conclusion based on a study of the infrared spectra of acenaphthoquinone.



(V)

All that has been said above on the structure of quinone diazides corresponding to aromatic hydrocarbons is also valid for diazides of the heterocyclic series. The spectra of these compounds show C=N̊=N̄ (or C–N̊≡N) and C=O stretching vibration bands[60,63], but the chemical properties of the compounds are the same as those of diazides of the aromatic series. Thus the similarity between the heterocyclic and aromatic diazides clearly shows that the former do not contain the oxydiazole ring[118], but have either a quinonoid structure[151], or, like uracil derivatives, the structure of a hydroxydiazonium compound[152].

Table 5 gives information on the stretching vibrations of C=N̊=N̄ and C=O bonds of diazides. Not all results are of the same value, since they were obtained under different conditions and with different degrees of precision (NaCl, LiF prisms, differences in degree of purity of the compounds, etc.). This is the reason why some frequencies given by different workers for the same compounds do not coincide. Another reason for the discordance probably resides in peculiarities in the structure of the diazides — peculiarities that have not yet been studied. Diazides obtained under different conditions may have different crystal structures, or their crystals may sometimes contain solvent molecules. The results of elemental analyses are not always given for diazides. This probably explains why the same compound may show one ν_{CN_2} band, or this band may sometimes be split into two or more components. Nevertheless, for the sake of completeness, we included a large proportion of the published results in Table 5.

The spectra of quinone diazides have a number of characteristic features. An increase in the number of condensed benzene rings in the quinone diazide molecule reduces ν_{CN_2} and increases $\nu_{C=O}$ at the same time. The value of $\nu_{C=O}$ for diazides varies within the limits 1630–1570 cm^{-1}; the results obtained by Glowiak form the only exception to this rule[150]. The values of ν_{CN_2} vary within the limits 2200–2000 cm^{-1}; higher values are observed only with carboxylic acids; these diazides containing the carboxyl or sulpho-group will be considered below. The stretching vibration band of the C=N̊=N̄ bond in *o*-diazides is nearly always split into two components, but no splitting occurs with the *para*-isomer. This interesting phenomenon has not been explained, and no research worker has even considered it. As a rule, the value of ν_{CN_2} for diazides is increased by electronegative substituents and diminished by electropositive substituents. However, this relationship, on the basis of which a number of workers have drawn conclusions about the structure and reactivity of the quinone diazides, is not very pronounced, and examples may be found in Table 5 in which substituents have the opposite effect. No such relationship is observed with regard to the effect of substituents on the

value of $\nu_{C=O}$; the frequency varies very little and substituents of the same type may increase it or reduce it. The value of ν_{CN_2} is always higher for *ortho*-isomers than for the corresponding *para*-compounds. The integral intensity of the absorption band of the CN_2 bond in *o*-benzoquinone diazide is half that of the band for the bond in the *para*-isomers [153].

B. Structure of Substituted Quinone Diazides

The study of infrared spectra, especially in the 2000–2300 cm^{-1} region, that is, in the absorption region of $C=\overset{+}{N}=\bar{N}$ and $C-\overset{+}{N}\equiv N$ groups, is very useful in the determination of the structure of quinone diazides. But when this method is used, other physical and chemical properties of the quinone diazides and the corresponding diazonium salts must be taken into account.

In examination of the structure of the quinone diazides, it is generally assumed that diazides with high values ν_{CN_2} have a structure closer to the benzenoid form, and those with low values have a structure closer to the quinonoid form. However, examination of the data in Table 5 shows that one value of ν_{CN_2} alone is not sufficient to enable a decision to be made as to whether a compound is more or less benzenoid (or quinonoid). For example, Table 5 shows that the value of ν_{CN_2} is higher for *o*-diazides than for *p*-diazides, but chemical properties and dipole-moment measurements show that *o*-quinone diazides are more quinonoid than *p*-diazides [14]. Moreover, workers studying the structure of quinone diazides have not compared values of ν_{CN_2} obtained for quinone diazides with values for the corresponding hydroxyaryldiazonium salts (known to have a benzenoid structure), but have limited themselves to comparisons within the diazides. But experimental results show that for each quinone diazide there is a corresponding hydroxyaryldiazonium salt; the values of ν_{CN_2} in the spectra of the diazonium salts are higher than the values for the corresponding quinone diazides by 100–150 cm^{-1} (Table 6).

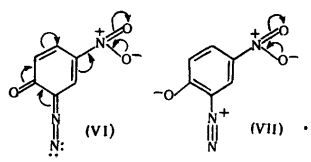
Thus, those diazides with high values of ν_{CN_2}, which are considered by many workers to exist in the benzene form, must have corresponding diazonium salts with known benzene structures and with still higher values of ν_{CN_2}. For example, ν_{CN_2} = 2190 cm^{-1} for 4,6-dinitrobenzo-1,2-quinone 2-diazide [150]. The corresponding hydroxyphenyldiazonium cation containing two nitro-groups, if it exists, must have a ν_{CN_2} of about 2300 cm^{-1}.[154] Therefore, higher values of ν_{CN_2} for substituted quinone diazides do not indicate that these compounds have a more benzenoid structure, since the corresponding benzene form (hydroxyphenyldiazonium salt) has a still higher value of ν_{CN_2} compared with these quinone diazides.

TABLE 6*.

Compound	ν_{CN_2} of quinone diazide			ν_{CN_2} of diazonium chloride*
p-Benzoquinone diazide	2107 s.	—	2278 w.	2251 m.
4,6-Dibromobenzo-1,2-quinone 2-diazide	2122 s.	2144 s.	2260 w.	2248 m.
o-Quinone diazide	2107 s.	2132 s.	2063—2169s.	2247 m.
1-Diazo-2-hydroxy naphthalene 4-sulphonic acid	2089 s. (potassium salt)	2109 s.	2230 w.t	2229 (internal salt)

* s. strong band; m. band of moderate intensity; w. weak band.

The increase in ν_{CN_2} observed when negative substituents are introduced into the quinone diazide occurs, because these substituents, acting on the diazo-group through the ring, withdraw electrons from this group, in the same way as the presence of a nitro-group in the ring of the nitrophenyldiazonium cation leads to a reduction in the electron density of the diazonium group. Although the diazo-group of the quinone diazide is somewhat similar in type to the diazonium group, the effect of substituted nitro-groups is to decrease the electron density of the oxygen of the C=O group, and not to increase it, as would be required for the intra-ionic benzene structure (VII)

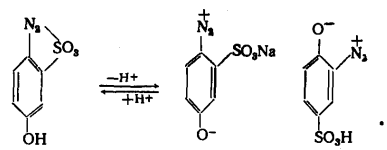


(VI) (VII)

Thus, quinone diazides with electronegative substituents, in contrast to the corresponding diazonium cations, do not have a benzenoid structure but the structure (VI), which is characteristic of unsubstituted quinone diazides; in this structure electrons are somewhat displaced towards the electronegative substituent.

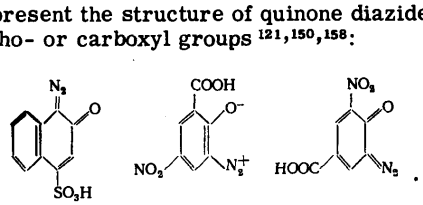
Compounds containing a carboxylic or sulphonic group occupy a special place in the hydroxyaryldiazonium series. In these compounds the diazonium group may interact with the acid group to form an internal diazosulphonate, and with the hydroxyl group to form a quinone diazide. Although the structure of these compounds has been under discussion for 50 years, the question has still not been finally cleared up.

Morgan and Tomlins [155], Battegay and Schmidt [156], and Schmidt and Maier [157] have discussed the structure of hydroxyaryldiazosulphonic acids. Some information on this question has been systematised in the book by Saunders, in which the literature up to 1949 is examined [1]. Saunders noted that in acid solutions these compounds are colourless and appear to be internal diazosulphonates (VIII), but in alkaline solutions they are yellow and probably have the structure (IX). Saunders ascribed the structure (X) to some quinone diazides that are coloured in acid solution, for example, 4-sulphobenzo-1,2-quinone 2-diazide:



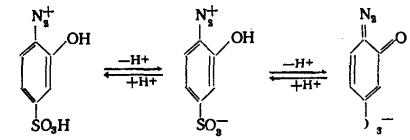
(VIII) (IX) (X)

At present a number of workers use formulae (XI)–(XIII) to represent the structure of quinone diazides containing sulpho- or carboxyl groups [121,150,158]:



(XI) (XII) (XIII)

In any examination of the structure of these compounds, it should be noted that hydroxyphenyldiazonium cations containing sulpho- or carboxyl groups are dibasic acids:



(XIV) (XV) (XVI)

The first acidity constant, corresponding to dissociation of the sulpho-group, is much greater than the second constant, corresponding to the dissociation of the hydroxyl group (it is well known that sulphonic and carboxylic acids are more acidic than phenols). Therefore, in acid solutions, in which dissociation of the hydroxyl group is suppressed, these compounds exist as the internal diazonium salt (XV). In neutral and weakly acid solutions, in which dissociation of the hydroxyl group is possible, the compound must exist as an equilibrium mixture of form (XV) and the diazide form (XVI). Finally, in alkaline solutions these compounds have the quinonoid structure (XVI). Thus, the solid compound obtained from acid solutions is the internal diazonium salt (XV). From neutral solutions that form separates which has the lowest solubility under the given conditions. Obviously, this will be form (XV), since it is known that internal diazonium salts of sulphonic acids are poorly soluble in water, but quinone diazides with an ionised sulpho-group should be much more soluble. From alkaline solutions the quinonoid form of the compounds will separate as the metallic salt of the acid, for example:

$$O{=}C_6H_3{=}N_2\ (SO_3Na)$$

(XVII).

Thus, these compounds never exist in the form of quinone diazide with an un-ionised sulphonic of carboxylic group — structures (X), (XI), and (XIII).

C. Structure of *p*-Iminoquinone Diazides (*p*-Imidoquinone Diazides)

As early as 1940, Simonov [116], who examined the chemical properties of *p*-iminoquinone diazides, rejected the cyclic formula proposed by Morgan [139] and proposed that the structure of these compounds cannot be generally represented by a single formula, but rather by the superposition of ionic and quinonoid structures:

He emphasised that these structures were in a mesomeric and not a tautomeric relationship.

The state of the compound will be determined by the predominance of one structure or the other, according to the strength of the competing effects of the diazonium group and the substituent R. If the substituent is a weak electron acceptor (R = $CH_3-\overset{O}{\overset{\|}{C}}-$, $C_6H_5-\overset{O}{\overset{\|}{C}}-$, C_6H_5-), equilibrium is displaced towards the formation of the quinonoid structure, but if the substituent is a strong electron acceptor, as when R = $ArSO_2-$, $(NO_2)_3C_6H_2-$, etc., then the dipolar-ion structure predominates; in other words, the *p*-diazoimine (*p*-diazoimide) structure is regarded as the internal diazonium salt.

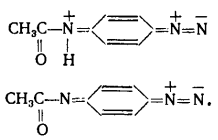
								2090		

The hypotheses and conclusions of Simonov were not confirmed by studies of the physicochemical properties of *p*-iminoquinone diazides. Anderson and coworkers used ultraviolet and visible absorption spectra to establish the structure of the *p*-diazoimines [160,161]. According to their results, the ultraviolet spectra of solutions of *p*-diazoimines are identical with those of the corresponding diazonium chlorides. These workers were not surprised at this finding, because they considered that both the diazonium cation and the *p*-iminoquinone diazide have the quinonoid structure:

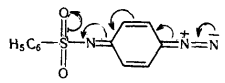


But the properties of the *p*-iminoquinone diazides differ from those of the corresponding diazonium chlorides. The former are much more photosensitive, and more strongly coloured; for these reasons, it is unlikely that these compounds have the same ultraviolet spectrum and therefore the same structure. In the analogous case of *p*-hydroxyphenyldiazonium chloride and *p*-quinone diazide, the compounds have different ultraviolet spectra and structures [109].

A recent study of the ultraviolet spectra of *p*-amino-substituted salts and of their conversion into *p*-iminoquinone diazides [99,111] showed that the latter absorb in a more longwave region of the spectrum than the corresponding *p*-amino-substituted diazonium salts (Table 7).

The ultraviolet spectra obtained by Anderson and coworkers are characteristic only of *p*-amino-substituted diazonium cations [160,161]. Anderson and coworkers did not succeed in obtaining the ultraviolet spectra of *p*-iminoquinone diazides, with the exception of the spectrum of one compound, because they did not sufficiently closely observe the conditions under which these compounds exist. When these conditions were observed (the diazo-solution was adjusted to pH 11.8 with NH_4OH), Anderson and Steedly found [160] that the spectrum of the diazonium salts *p*-$C_6H_5NHC_6H_4N_2HSO_4$ differed from that of the *p*-iminoquinone diazide *p*-$C_6H_5NC_6H_4N_2$, the latter absorbing in the more longwave region.

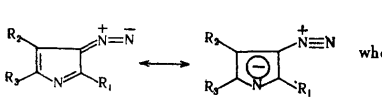
The values of ν_{CN_2} in the infrared spectra of *p*-iminoquinone diazides are close to the value for the cumulated C=N=N bond, and the values for *p*-amino-substituted diazonium salts are close to the value for the triple C−N≡N bond (see Table 7), but lower than the values for other aryldiazonium salts [99]. These results show that the structure of *p*-amino-substituted diazonium cations is close to the benzenoid form, but the structure of the *p*-iminoquinone diazides is close to the quinonoid form. But the ordinary formulae do not accurately reflect the structures of these compounds. Although the structure of *p*-iminoquinone diazides is closer to the quinonoid form in comparison with the initial *p*-amino-substituted diazo-compounds, this structure has a greater or lesser tendency to approach the benzenoid form, according to the electron-acceptor properties of the substituent:



This is reflected in an increase in the values of ν_{CN_2} in the infrared spectra and in a displacement of the ultraviolet absorption band towards the shortwave side (see Table 7).

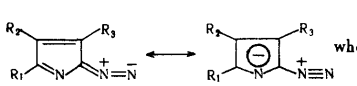
Little information has been published on the physicochemical properties and structure of *p*-iminoquinone diazides, and they have generally been much less studied than the more accessible quinone diazides. However, the study of these compounds is of undoubted practical and theoretical interest.

According to Tedder and Webster, the structure of heterocyclic diazo-imines is represented by a resonance hybrid [94,95].



where

R_1	R_2	R_3	ν_{CN_2}, cm^{-1}
Ph	NO_2	Ph	2150
Ph	H	Ph	2095
Ph	H	CH_3	2062



where

R_1	R_2	R_3	ν_{CN_2}, cm^{-1}
Ph	H	Ph	2138
Ph	NO_2	Ph	2172

Values of ν_{CN_2} have not been compared with those of the corresponding diazonium salts, although these salts have been separated in some instances [94].

Farnum and Yates [93] consider that the diazo-pyrazoles have structures close to the intra-ionic form, because the ν_{CN_2} values for these compounds are higher than those for the diazo-ketones, and close to those for the diazonium salts; however, they do not deny the possibility of resonance of two structures.

I. INTRODUCTION

The study of bulk polymerisation at high extents of reaction is of both theoretical and practical interest. Although polymerisation to high conversions is often encountered in daily practice, relatively little systematic work has been done on this problem, in contrast to the initial stages of the polymerisation reaction, mainly because of the complexity of the quantitative interpretation of the results.

Nowadays there are semiquantitative theories which explain, on the whole satisfactorily, the characteristic features of polymerisation at advanced stages of the reaction. However, many problems still remain unsolved, which, for example, makes it impossible to control the "gel effect" in the polymerisation of important vinyl monomers such as methyl methacrylate, butyl methacrylate, etc.

The present review deals with the polymerisation of vinyl compounds not accompanied by the appearance of a new phase. Problems concerning the appearance of a new phase in ω-polymerisation, polymerisation of monomers whose polymers are insoluble, etc. are not included. The literature on these problems can be found in a number of monographs [1-3].

II. GENERAL THEORY OF THE "GEL EFFECT"

At the end of the 1930's it was observed that bulk polymerisation of certain vinyl monomers involves a sharp increase of reaction rate on attainment of certain degrees of conversion of the monomer into the polymer [1-18]. This phenomenon was called the "gel effect" or the "Trommsdorff effect". In the polymerisation of methyl methacrylate the acceleration usually occurs on attainment of about 15–25% conversion. In the polymerisation of substances whose polymers are insoluble in the monomers the reaction rate increases immediately after the formation of appreciable amounts of the polymer. The shape of the kinetic curves for polymerisation with self-acceleration is determined by the nature of the monomer, the concentration of the initiator, and the reaction conditions.

Initially it was believed that the increase in reaction rate is due to the process being non-isothermal [2,16]. It was suggested that the heat evolved during polymerisation raises the temperature of the reaction mass. However, this view soon had to be rejected [13,17]. Firstly, it was shown that polymerisation under strictly isothermal conditions also involves considerable self-acceleration. Secondly, it was established that in the acceleration stage the molecular weight of the polymers formed increases, whereas according to the equation

$$\frac{d\ln P}{dT} = \left(E_r - \frac{1}{2}E_0 - \frac{1}{2}E_{in}\right)/RT^2 \qquad (1)$$

the increase in polymerisation temperature in a chemically initiated reaction should in fact lower the molecular weight.

Norrish and Smith [17] suggested that the reason for the self-acceleration is the decrease of the rate constant k_t for the chain termination reaction. They showed that an increase of the initiator concentration or temperature in the polymerisation of methyl methacrylate displaces the onset of self-acceleration towards higher degrees of conversion. Since an increase of temperature and initiator concentration results in a lowering of the molecular weight of the polymer and hence of the viscosity of the medium, it is evident that the change in k_t is associated with an increase in viscosity.

To confirm these findings, Norrish and Smith [17] studied the polymerisation of methyl methacrylate in the presence of various solvents and established that systems of low viscosity exhibit the smallest self-acceleration. As suggested, the molecular weight of the polymers increased with the viscosity of the medium. Similar ideas about the possibility of a decrease of the rate constant for chain termination were put forward by Medvedev and coworkers [18], who studied the polymerisation of chloroprene.

Somewhat later Schulz and Harborth [19] made a detailed study of the polymerisation of methyl methacrylate in the presence of benzoyl peroxide and established that the rate of reaction in the later stages can exceed the initial rate of polymerisation by several tens. By varying the concentration of the peroxide, they showed that the maximum rate of polymerisation at the self-acceleration stage is directly proportional to the initial rate. Their explanation of the phenomenon of self-acceleration was the same as that of Norrish and Smith [17].

Trommsdorff and coworkers [15] established that introduction of poly(methyl methacrylate) into the monomer causes self-acceleration at the very beginning of the polymerisation reaction. Furthermore, they showed that if the system is cooled sharply to -20° at the self-acceleration stage and then reheated to the previous temperature a long time afterwards, the rate of reaction is the same as before the freezing. These data also confirm the general theory of the "gel effect".

On the other hand, the rate of polymerisation is determined by the rate of chain growth which can also vary with the viscosity of the medium. However, if allowance is made for the fact that the molecular size of the monomer is small compared with that of the macroradicals whose interaction leads to chain termination, it may be assumed that the variation of k_p during polymerisation is slight when the degree of reaction is low. An appreciable change of k_p at a degree of reaction of the order of 50–70% might be expected. Schulz and Harborth [19], who noted a sharp decrease in the rate of polymerisation at degrees of conversion exceeding 70–80%, arrived at this conclusion.

Thus a quantitative theory of the "gel effect" was developed at the end of the 1930's and the beginning of the 1940's of the present century. A quantitative test of the theory became possible only after the development of methods for the determination of the rate constants for the fundamental reaction steps.

III. QUANTITATIVE DATA

After the rotating sector and thermometric methods began to be used to determine the ratio k_p/k_t in chain polymerisation, papers dealing with the variation of k_p and k_t with the degree of conversion appeared. Matheson and coworkers [20-22] were the first to make reliable measurements (rotating sector method) and confirmed quantitatively the treatment of the "gel effect" proposed by Norrish, Smith, Schulz, and others. The study of the polymerisation of methyl methacrylate [22] showed that at 33% conversion the chain propagation rate constant remains virtually unchanged, whereas the chain termination constant decreases by a factor of more than a hundred. On the other hand, in the study of the photopolymerisation of

methyl acrylate in the presence of diacetyl and azobisisobutyronitrile, Matheson and coworkers[22] found that the rate of polymerisation increases continuously from the very beginning of the reaction. By comparing their results with the data of other investigators, they confirmed the theory of Norrish, Smith, and coworkers. Similar results were also obtained in the polymerisation of styrene, but the change in the ratio k_p/k_t was much smaller than for methyl methacrylate. This is due to the almost complete absence of the "gel effect" in the polymerisation of styrene. The percentage conversion at which self-acceleration begins is determined by the molecular weight of the polymer formed, and hence by the viscosity of the medium. The ratios $k_p(35\%)/k_p(0\%)$ and $k_t(35\%)/k_t(0\%)$ obtained by Matheson and coworkers[22] are given in Table 1.

Naylor and Billmeyer[23] obtained interesting data on the variation of the molecular weight of poly(methyl methacrylate) with the degree of reaction in photopolymerisation. They emphasised that the observed increase in the degree of polymerisation is associated with a decrease in the rate of termination of the polymeric chain and should be accompanied by a variation of the molecular weight distribution as the monomer is converted into polymers. Examination of the "percentage conversion–(time)(intensity)$^{1/2}$" relation clearly showed that, as the intensity of irradiation increases, the onset of self-acceleration becomes more distinct and is observed at increasing degrees of conversion. At high irradiation intensities the molecular weight of the polymer is lower than at low intensities. Hence it follows that for the same degree of conversion the viscosity of the medium is smaller in the former case and the acceleration should occur at higher degrees of conversion. These authors concluded that the use of light filters makes it possible to control the "gel effect". Somewhat later Pravednikov[24,25] confirmed the theory of Norrish, Smith, and others and noted that the interpretation of the self-acceleration phenomenon as a consequence of the formation of a three-dimensional polymeric network[26] is incorrect.

Melville[27] and Bengough[28] showed, using the thermocouple method, that in the polymerisation of vinyl acetate k_t decreases by a factor of three at 50% conversion, whereas k_p remains virtually unchanged (Table 2).

TABLE 1. "Gel effect" in the polymerisation of certain monomers.

Monomer	Temperature, °C	Conversion corresponding to onset of self-acceleration, %	$\frac{k_p(35\%)}{k_p(0\%)}$	$\frac{k_t(35\%)}{k_t(0\%)}$	Degree of polymerisation, P_{limit}
Vinyl acetate	25	>40	—	—	2400
Styrene	50	30	0.67	0.075	4000
Methyl methacrylate	30	15	1.12	0.0066	5000
Methyl acrylate	30	0	—	—	10000

TABLE 2. Photopolymerisation of vinyl acetate at 25° in the presence of the dinitrile of 1,1-azodicyclohexylcarbonic acid.

Conversion, %	k_p, litre mole^{-1} s^{-1}	$10^{-6}k_p$ litre mole^{-1} s^{-1}	E_p, kcal mole^{-1}	E_p kcal mole^{-1}
4	860	240	4.2	1

65	30	1.15	11.4	13.0
73	—	—	14.4	15.4

TABLE 3. Polymerisation of butyl acrylate at 25° (rate of initiation 2.1 × × 10^{-8} mole litre^{-1} s^{-1}).

Conversion, %	$10^{-6}k_p$	$10^{-8}k_t$
1	2.93	4.8
20	0.76	0.38
40	0.46	0.115
60	0.26	0.43
70	0.0044	0.0073

There is an analogous variation of the activation energy for the chain propagation and termination reactions. Similar results were obtained for butyl acrylate and methyl methacrylate. In the polymerisation of butyl acrylate it was established that the reaction rate increases slightly with the degree of conversion, the fall in rate beginning at 20–30% conversion. Table 3 presents data on the variation of k_p and k_t and shows that the decrease of k_t is accompanied by a sharp decrease of k_p. In the authors' view this fact is associated with the structure of the polymer which is responsible for the "gel effect" at degrees of conversion much smaller than 20%. In the polymerisation of methyl methacrylate it was found[27] that k_t begins to decrease at about 20% conversion, whereas the decrease of k_p does not begin until the degree of conversion is about 50%.

Later Bengough and Melville[29] showed that, for the polymerisation of methyl methacrylate, the exponent n in the equation

$$V = kI^n[M] \qquad (2)$$

(I is the intensity of irradiation or the concentration of the sensitiser) decreases from 0.5 at 0–15% conversion to about 0.3 at 15–25% conversion, and then increases again and reaches 1 when the degree of conversion is of the order of 40%. It was also found that increase of conversion from 0 to 35% (at 32°) results in an increase of $10^5k_p/k_t$ from 1.9 to 110, whereas k_t decreases from 5.7×10^6 to 8.8×10^4 (litre mole^{-1} s^{-1}). Recently Hayden and Melville[30] confirmed these data. They found that at 10–40% conversion n decreases to 0.25, the activation energy for chain termination increases appreciably, while k_p and E_p remain constant. At a conversion in excess of 50% n increases, k_t and k_p decrease, and E_t and E_p increase.

Fujii[31,32] made a novel study of the polymerisation of styrene and methyl methacrylate at high extents of reaction and demonstrated that the lifetime of free radicals in viscous media can be conveniently calculated from the photochemical after-effect. He used the equation

$$\ln\left(\frac{V_p+V_\alpha}{V_p-V_\alpha}\right) = \ln\left(\frac{V_{pL}+V_\alpha}{V_{pL}-V_\alpha}\right) + 2\frac{V_\alpha}{V_{pL}}\frac{t}{\tau}, \qquad (3)$$

derived on the hypothesis that after irradiation ceases radicals are destroyed according to the law

$$-\frac{d[R\cdot]}{dt} = k_t[R\cdot]^2 - k_i[M]^2, \qquad (4)$$

where V_α is the steady-state rate of thermal polymerisation, V_p the rate of polymerisation at the instant t after irradiation is switched off, V_{pL} the steady-state rate of photopolymerisation, and the other symbols have the usual significance.

It follows from Eqn. (3) that the plot of

$$\frac{V_{pL}}{2V_\alpha}\ln\left(\frac{V_p+V_\alpha}{V_p-V_\alpha}\right)$$

against t makes it possible to determine $1/\tau$ and hence the lifetime of free radicals and the ratio k_p/k_t. The results are presented in Table 4.

Fujii also showed that the order of the chain-termination reaction decreases from 1.9–2.1 to 1.4–1.6 when the conversion increases from about 0 to 68%. These results are consistent with the data of Melville and coworkers[29,30]. Similar results were obtained in the polymerisation of methyl methacrylate[32] (Table 5). The order of the chain termination reaction for this monomer decreases from 1.9–2.1 to 1.65–1.8 when the conversion rises from 0 to 60%. In the polymerisation of styrene[31] and methyl methacrylate[32] the apparent activation energy decreases with percentage conversion.

Miyama[33-36] used a thermistor method to determine the variation of k_p/k_t with percentage conversion in the polymerisation of vinyl monomers. Fujii and Tanaka[37] obtained interesting results by measuring the lifetime of free radicals in the photopolymerisation of styrene in the presence of carbon tetrachloride. The addition of carbon tetrachloride tends to increase the initial rate of polymerisation but at high degrees of conversion it reduces the lifetime of macroradicals.

In order to reconcile the data on the variation of k_t and k_p with the degree of polymerisation and the molecular weights obtained, Robertson[38], who studied the kinetics of the polymerisation of styrene and methyl methacrylate, assumed that the effectiveness of initiation f varies with the degree of reaction. It was shown that, as polymerisation proceeds, f for many of the initiators investigated (benzoyl peroxide, azobisisobutyronitrile, t-butyl peroxide, and lauroyl peroxide) falls sharply and becomes very small when the percentage conversion is more than 50–60%.

TABLE 4. Photopolymerisation of styrene*.

Conversion, %	Temperature, °C	k_p/k_t	$k_{t(x\%)}/k_{t(0\%)}$
0	20	$0.55\cdot10^{-6}$	
38±1	30	$2.36\cdot10^{-6}$	1
43±2	30	$6.36\cdot10^{-4}$	$3.75\cdot10^{-3}$
	30	$2.56\cdot10^{-3}$	$9.22\cdot10^{-4}$
60±2	30	$1.30\cdot10^{-2}$	$1.81\cdot10^{-4}$
70±2	30	$1.37\cdot10^{-2}$	$1.71\cdot10^{-4}$

* Intensity of irradiation 4×10^{-8} einstein s^{-1}.

TABLE 5. Photopolymerisation of methyl methacrylate*

Conversion, %	Temp., °C	k_p/k_t	$k_{t(x\%)}/k_{t(0\%)}$
0≃1	30	$1.93\cdot10^{-5}$	1
	40	$2.47\cdot10^{-5}$	
47±2	30	$9.20\cdot10^{-3}$	$2.10\cdot10^{-3}$

	40	$9.48\cdot10^{-3}$	
	50	$9.86\cdot10^{-3}$	
72±3	30	$2.96\cdot10^{-2}$	$6.52\cdot10^{-4}$

* Intensity of irradiation 4×10^{-8} einstein s^{-1}.

Calculations of f in the polymerisation of styrene in the presence of azobisisobutyronitrile were also made by Nishimura[39], who used the equation

$$\bar{P}_n = \frac{[M]_0}{f[c]_0}\times\frac{x}{1-\exp(-k_d t)}, \qquad (5)$$

where $\bar{P}_n$ is the cumulative degree of polymerisation, $[c]$ the initiator concentration, k_d the initiator breakdown rate constant, and x the extent of reaction. A similar calculation was also made with allowance for the change in volume with the extent of reaction. However, Nishimura believes that the variation of f is only apparent.

After many data had accumulated on the effect of the extent of reaction of vinyl monomers on the kinetic constants of the fundamental reaction steps, it became necessary to relate quantitatively the changes in these parameters to the viscosity of the medium. The first serious attempts in this field were made by Vaughan[40] and Schulz[41,42]. Schulz examined Smoluchowski's equation and showed[41] that the rate of chain termination by reaction between radicals may be determined by diffusion even in media of relatively low viscosity. The rate of chain growth should be limited by diffusion only in media of very high viscosity. The results of Schulz's theoretical study were subsequently used by a number of investigators. Fujii[31] noted that the decrease of the overall activation energy with the extent of reaction is associated with the increase of the activation energy for chain termination:

$$E = E_p - \tfrac{1}{2}E_0 + \tfrac{1}{2}E_i.$$

Using the equation proposed by Spencer and Williams[43],

$$\eta = 3.63\times10^{-10}\exp\{0.0572\sqrt{M} + \sqrt{W_2}(22.54-0.045\sqrt{M}+5000/T)\} \qquad (6)$$

(where η is the viscosity of the styrene–polystyrene system in centipoises, M the molecular weight determined by the Staudinger method, and W_2 the weight fraction of the polymer), Fujii estimated the activation energy for the diffusion of polymeric polystyrene radicals for 38 and 60% conversion. He obtained 6.1 and 7.7 kcal $mole^{-1}$ respectively, which in his view is in good agreement with experiment and confirms the conclusion that the rate of the chain termination reaction is determined by diffusion. Fujii[32] also estimated the activation energy for chain termination in the polymerisation of methyl methacrylate (5.8 kcal × × $mole^{-1}$) for 52% conversion. This value is in good agreement with the data of Spencer and Williams[43] and the activation energy for viscous flow of fused polyesters, which according to Flory[44] is about 8 kcal $mole^{-1}$.

Miyama[36] made a detailed study of the effect of the viscosity of the medium on the kinetic constants for vinyl polymerisation. He expressed doubt about the correctness of the equation derived by Vaughan[40] on the basis of the theoretical study of Rabinowitch[45]. Miyama showed that the use of Smoluchowski's equation[46] for the number of collisions in solution makes it possible to obtain an expression relating the second-order rate constant to the viscosity of the medium. Comparison of the experimental values of k_p/k_t with η of the medium yields the following expressions:

$$(k_t)_{0\%}/k_t = 0.76 + 0.24\,[(\eta/\eta_0)^{0.30}\times10^{-8}(\eta/\eta_0)^{1.50}] \qquad (7)$$

(for vinyl acetate)

$$(k_t)_{0\%}/k_t = 0.83 + 0.17\,(\eta/\eta_0)^{28} \qquad (8)$$

(for methyl methacrylate)

The following formula is valid for the values of $(k_p)_{0\%}/k_p$ in the polymerisation of vinyl acetate[36]:

$$(k_p)_{0\%}/k_p = 1 + 0.65 \times 10^{-6}(\eta/\eta_0) \quad (9)$$

In Eqns. (7)–(9) the subscript 0% refers to zero percentage conversion. Miyama noted that the analysis of his data on the basis of the Rabinowitch equation gives unsatisfactory results. Starting in 1959, North and others published a series of papers in which they described a thorough investigation of the effect of the medium on the rate constants for vinyl polymerisation and in which they make a comprehensive examination of the mechanism of the chain termination process whose rate is determined by diffusion[47-52]. These studies led to important conclusions.

In order to eliminate the effects of branching and cross-linking, in their attempts to elucidate the effect of viscosity on polymerisation processes Benson and North[47] studied the relevant reactions in solvents of high viscosity. The ratio k_p/k_t was determined by the photochemical after-effect method. Later they calculated the ratio k_t/k_p^2 and hence k_t and k_p on the basis of a study of the dependence of the degree of polymerisation on the rate of reaction. The earlier postulate that the viscosity of the medium affects only k_t and not k_p (in media with a viscosity exceeding by a factor of several hundred the viscosity of the monomer) was confirmed. The study showed that in the range of η values from 0.400 to 1000 cP (methyl methacrylate) there is a linear relation between k_t and the viscosity of the medium. A relation of this kind was not observed for n-butyl acrylate. Thus the rate of chain termination in the polymerisation of methyl methacrylate is determined by diffusion even in a medium of low viscosity, comparable with the viscosity of the monomer, whereas in the polymerisation of n-butyl acrylate in media of relatively low viscosity k_t is independent of the viscosity and the reaction occurs in the "kinetic" region (k_t is then the rate constant of a chemical step). Only in media with viscosities in excess of about 10 cP is the rate of chain termination determined by diffusion.

The authors examined the results obtained within the framework of a three-step mechanism of radical reaction which they proposed[47]. It was shown that this mechanism leads to the equation

$$\frac{1}{k_t} = \frac{\eta}{k_{d'}} + \frac{1}{k_{c'}} \quad \text{or} \quad k_t = k_{c'} - \frac{k_{c'}}{k_{d'}}(k_t\eta), \quad (10)$$

where $k_{d'}$ and $k_{c'}$ are constants evaluated in the derivation of the relation between k_t and $k_t\eta$. Three possible models of bimolecular reactions are examined in the same study[47]. Later North and Reed[48] confirmed the earlier data showing that the rate of the chain termination reaction in the polymerisation of certain vinyl monomers is determined by diffusion even in media of low viscosity, comparable with the viscosity of the monomer[47,53,54]. In the polymerisation of methyl methacrylate the opposite relation between k_t and the viscosity of the medium was observed[48]. This effect is not due to the chemical nature of the solvent and the shape of its molecules. The results can be explained in terms of a two-stage diffusion-dependent chain termination process. Comparison of the diffusion-dependent chain termination rate constants and the diffusion coefficients of poly(methyl methacrylate) as a function of the concentration of the latter showed that the rate-determining stage of the process is segmental diffusion of the ends of the polymeric radicals and not translational diffusion (diffusion of the centres of gravity) of the macroradicals. It was also established that the chain termination process is influenced by the molecular weight and the concentration of the polymer in solution.

The studies of North and coworkers led to the paradoxical conclusion[48] that the rate of chain termination is determined by diffusion even when the conversion is only 0%, whereas self-acceleration becomes appreciable for conversions of the order of several per cent or even several tens per cent (styrene). However, North and Reed[48] showed that this apparent paradox is caused by inadequate allowance for the viscosity of the "segment–solvent" microregions.

Recently Benson and North[49] demonstrated that the rate constant for diffusion-dependent chain termination is a function of the chain length of the reacting radicals. They examined two models of segmental diffusion. The first leads to reasonable termination rate constants but is inconsistent with kinetic data. In the examination of the second model it was assumed that segmental diffusion depends on chain length until the latter exceeds a certain characteristic value N_L. After that segmental diffusion no longer depends on the chain length. If N_L is smaller than the average length of the kinetic chain, then

$$k_t = (4P_{AB}kT/3\eta)(R_E/x_0N_L^{1/2}), \quad (11)$$

where P_{AB} is a multiplier equal to 1/8, R_E is the effective distance between the ends of the chains in the transition state, and x_0 is a proportionality constant of the order of 2.2 Å. It follows from Eqn. (11) that the chain termination rate constant is a function of T/η, i.e.

$$k_t = f(T/\eta). \quad (12)$$

Calculations by Eqn. (11) are in satisfactory agreement with experiment. For example, for a monomer of the type of styrene η = 0.5 cP (R_E/x_0 = 1.4, N_L = 100). Hence at 300°K $k_t = 1.1 \times 10^8$ litre mole^{-1} s^{-1}. If the chain length is small and ν (the kinetic chain length) $< N_L$, the polymerisation kinetics cannot be described by the usual equations.

Later North and Reed[50] yet again confirmed their theoretical findings. They showed that in the polymerisation of methyl, n-butyl, isobutyl, and 3,5,5-trimethylhexyl methacrylate in solvents of different viscosity the rate of chain termination is determined for all alkyl methacrylates by the segmental diffusion of the ends of the macroradical chains. In media with viscosities between 0.42 and 5.72 cP k_t/k_p for the polymerisation of the above monomers is proportional to η^{-n}, where n = 1 for methyl methacrylate and $n < 1$ for the other alkyl methacrylates.

Allen and Patrick[55] examined the effect of diffusion on chain propagation and chain transfer reactions for high degrees of conversion. Using the previously published data[56] they showed that the usual hypothesis according to which the rate of chain propagation (transfer) at high extents of reaction is determined by diffusion is inconsistent with the diffusion coefficients of small molecules in polymers. Indeed it is known[56] that the diffusion coefficient D of small molecules (monomer) in a polymeric network is of the order of 10^{-7} cm^2 s^{-1}, whereas a much lower value is necessary for the rate of chain propagation ($k_p < 10^3$) to be determined by diffusion.

Guzman and Tratou[57] analysed the self-acceleration in the photopolymerisation of vinyl acetate in terms of the

Rabinowitch and Smoluchowski equations and derived the following relation on the basis of experimental data:

$$\frac{k_t}{k_t^*} = 0.97 + 0.03(\eta/\eta_0)^{0.41}, \quad (13)$$

where k_t is the chain termination rate constant without allowance for diffusion and k_t^* the value of k_t found experimentally. They state that the diffusion of macroradicals becomes rate-limiting in the process when the extent of reaction is of the order of 2%.

Guertin[58] obtained kinetic equations taking into account the effect of viscosity on the chain-termination reactions in free-radical polymerisation. He also showed that chain transfer results in a decrease of the "gel effect" because the former is independent of the viscosity of the medium, like the chain termination reaction.

Ryabov and others[59,60] showed that the rate of copolymerisation of methyl methacrylate with methacrylic acid begins to increase appreciably when the viscosity of the medium is 100–500 P which in their view is evidence of a considerable decrease of the rate of diffusion of macroradicals[60]. They believe that the onset of self-acceleration is determined solely by the viscosity of the medium and is independent of the nature and concentration of the initiator.

IV. CHAIN TRANSFER REACTIONS

The general theory of the "gel effect" does not take into account the effect of the chain transfer reactions on the polymerisation at high degrees of conversion. Relatively little work has been done on this problem[23,61,62]; among the papers dealing with this question, the excellent review of Pyrkov and Frenkel'[61] may be mentioned.

As the degree of conversion of the monomer into the polymer increases, the role of the chain transfer reactions via the polymer molecules increases too. Evidently this phenomenon is associated with the increase in the concentration of the polymer in the system. Furthermore, it may be that the rate constant for chain transfer via the polymer depends on the degree of polymerisation which increases with the degree of conversion. Schulz and others[3,63,64] showed that in the polymerisation of methyl methacrylate the rate constant for chain transfer via the polymer varies significantly with the molecular weight of the polymer, decreasing as the latter increases. This phenomenon is due to the fact that chain transfer occurs mainly via the terminal groups formed in chain termination by disproportionation and not via groups containing the initiator fragment. One of the proofs of the validity of this hypothesis is that the rate constant for chain transfer via the polymer is independent of the nature of the initiator (benzoyl peroxide, azobisisobutyronitrile). The rate constants for chain transfer via inner and terminal groups may be expressed by the equations

$$\left(\frac{k_{tr}}{k_p}\right)_{\text{inner}} = 2.2 \times 10^{-4},$$

$$\left(\frac{k_{tr}}{k_p}\right)_{\text{terminal}} = 0.10.$$

We may note that the results of Schulz and others do not exclude the possibility that the initiator affects the structure of the polymers synthesised. In their study of the polymerisation of styrene, Henrici-Olivé and Olivé[65-69] noted that the degree of polymerisation is higher at high extents of reaction than would be expected from the reaction rate. This phenomenon may be explained if it is assumed that the relative contribution of the chain transfer reaction in the reaction between primary radicals and macromolecules increases with the degree of conversion:

$$R_{per}^{\cdot} + P \rightarrow RH + P^{\cdot}$$
$$P^{\cdot} + n\mathrm{M} \rightarrow \text{branched polymer.}$$

Thus in the polymerisation of styrene in the presence of azobisisobutyronitrile at 50° the average number of initiator fragments per polymer molecule increases from 2.03 to 2.48 when the degree of conversion rises from 0.05 to 0.93. The chain transfer reactions can result in an apparent change of the effectiveness of initiation (calculated from the molecular weight of the polymer) with the degree of conversion. Chain transfer via the polymer results in an anomalous increase of the molecular weight of the latter and the value of f calculated from Eqn. (5) may be too low.

V. NEW THEORETICAL POSTULATES

Examination of the quantitative data obtained by Norrish, Smith, and Schulz shows that the problem of setting up a rigorously quantitative theory of the "gel effect" is extremely complex. Nevertheless, a number of investigators attempted to develop other semiquantitative theories[70-74]. The first serious attempt was made by Burnett and coworkers. They suggested[70] that the phenomenon of self-acceleration may be explained from the standpoint of a change in the concentration of the growing radicals in the polymerisation. Burnett and coworkers[70,71] demonstrated that the rate of polymerisation of methyl methacrylate is a linear function of percentage conversion when the latter is in the range 20–60%. The overall activation energy for the process falls initially as polymerisation proceeds and then increases sharply:

Conversion, %	0	19	30	36	41	50	57	62	67	71
E, kcal mole^{-1} (25–60°)	5.2	4.7	3.4	2.7	2.0	1.7	3.1	4.1	5.0	8.4

The exponent n in the rate equation for the reaction is initially 0.5 and then falls, it passes through a minimum at about 20% conversion, and increases again to 0.8 at about 60% conversion. These results are consistent with the data of Bengough and Melville[29] and show that chain termination is not a second-order reaction. Hence it follows that the old interpretation of the results of studies on bulk polymerisation lacks reliable justification, since the kinetic expressions used presuppose that chains are destroyed as a result of their interaction. The explanation of the "gel effect" must be sought in the change of the concentration of macroradicals during polymerisation and not only in the possible change of the rate constants for the fundamental reaction steps. Polymerisation results in an increase of the viscosity of the medium and macroradicals can no longer react with one another. At not too high extents of reaction the monomer molecules diffuse towards macroradicals and react with them. Thus the overall rate of reaction increases because of the lowering of the rate of chain termination and the increase of the rate of chain propagation. As already pointed out, the latter is more likely to be due to a change in the radical concentration than to a change in the rate constants for the fundamental reaction steps. Burnett and coworkers assumed that, starting with a certain degree of conversion, the rate of increase of the number of radicals is proportional to the

concentration of the polymer formed. Hence it follows that

$$d[R\cdot]/dx = k_1(x - x_1), \quad (14)$$

where $[R^{\cdot}]$ is the radical concentration, k_1 a constant, x the specific degree of conversion of the monomer into the polymer, and x_1 the critical degree of conversion, which depends on the molecular weight of the polymer formed in the initial stages.

Integration of Eqn. (14) gives

$$[R\cdot] - [R\cdot]_0 = \tfrac{1}{2}k_1(x - x_1)^2, \quad (15)$$

where $[R^{\cdot}]_0$ is the value of $[R^{\cdot}]$ where $x = x_1$. Eqn. (15) can be rewritten in the form

$$\frac{[R\cdot]}{[R\cdot]_0} = 1 + K_1(x - x_1)^2, \quad (16)$$

where $K_1 = \frac{1}{2}k_1(k_t/V_i)^{1/2}$ is a constant and V_i is the rate of initiation ($V_i = k_t[R^{\cdot}]^2$). Assuming that the concentration of the monomer near the growing radicals is constant, the following expression can be obtained instead of Eqn. (16):

$$(V_x/V_0 - 1)^{1/2} = K_1^{1/2}(x - x_1), \quad (17)$$

where V_x is the rate of polymerisation for a degree of conversion x and V_0 the initial rate of polymerisation.

It follows from Eqn. (17) that in the self-acceleration stage there should be a linear relation between $[(V_x/V_0) - 1]^{1/2}$ and x; the intercept made by the straight line on the abscissa should be equal to x_1 and its slope should be $K_1^{1/2}$. Eqn. (17) holds satisfactorily over a limited range of percentage conversions. At higher percentage conversions (about 50–60%) macroradicals become inaccessible to monomer molecules and the following equation then holds:

$$\frac{[R\cdot]}{[R\cdot]_0} = 1 + K_1(x - x_1)^2 - K_2(x - x_2)^2, \quad (18)$$

where x_2 is the second critical degree of conversion. Eqn. (18) can be written thus

$$[1 + K_1(x - x_1)^2 - V_x/V_0]^2 = K_2^{1/2}(x - x_2). \quad (19)$$

Hence it follows that there should be a linear relation between $[1 + K_1(x - x_1)^2 - V_x/V_0]^2$ and x. Burnett and Duncan[71] showed that this relation holds in the polymerisation of methyl methacrylate.

Similar results were obtained in the photopolymerisation of n-propyl and n-butyl methacrylates[72]. However, the polymerisation of methyl methacrylate[73] can be described by the above method only when allowance is made for additional factors characterising the possibility of the formation of branched and cross-linked structures.

The validity of the general postulates of Burnett and coworkers is evident. Clearly at high degrees of conversion a considerable increase in the lifetime of the polymeric radicals and hence an increase in their concentration may be expected. The electron spin resonance method made it possible to determine directly the concentration of radicals in viscous media. Many measurements of this kind were made[75–78]. For example, Bresler and coworkers[79], who made an ESR study of the photopolymerisation of methyl methacrylate, established that at high degrees of conversion the concentration of radicals exceeds 10^{-3} M. It should be noted that not all the radicals detected in the polymer–monomer system by the ESR method are equally stable. After irradiation ceases most of them vanish over a period of several minutes. The remaining radicals are stable and persist in the specimen at room temperature over a fairly long period.

Sawada[74] attempted to interpret quantitatively the results obtained in the study of the block polymerisation of methyl methacrylate. He started with the hypothesis that, if the radicals in a highly viscous medium become immobile and cannot disappear as a result of interaction with one another, their concentration should increase continuously as polymerisation proceeds. At a certain critical degree of conversion, the macroradicals are so firmly "stuck" in the polymer that they cannot react with the monomer.

If it is assumed that the concentration of radicals is proportional to the amount of monomer consumed since the onset of self-acceleration, the following expression holds:

$$[R\cdot] = K(x - b), \quad (20)$$

where K is a constant, x the degree of conversion of the monomer, and b the degree of conversion at which self-acceleration begins. On expressing the concentration of the monomer in terms of the critical degree of conversion a, i.e. putting

$$[M] = (a - x), \ (x < a) \quad (21)$$

and substituting the values of $[R^{\cdot}]$ and [M] from Eqns. (20) and (21) in the rate equation for the reaction, we obtain the equation

$$dx/dt = k_pK(x - b)(a - x). \quad (22)$$

Integration of Eqn. (22) yields

$$[1/(a - b)]\ln[(x - b)/(a - x)] = k_pKt + C, \quad (23)$$

where C is a constant. It follows from Eqn. (23) that $[2.3/(a - b)]\log[(x - b)/(a - x)]$ should vary linearly with time, which according to Sawada's data is borne out by experiment.

Allen and Patrick[75] examined the role of the so called "geminate chain recombination" in the kinetics of the polymerisation at high conversions.

Thus the explanation of the "gel effect" given by Norrish, Schulz, and other investigators presupposes the existence of a steady state throughout the bulk polymerisation process. However, the variation of the exponent n of the irradiation intensity in Eqn. (2) during polymerisation contradicts this hypothesis. It follows from the theory of Schulz and others that a higher value of k_t for a monomer should involve a more pronounced "gel effect". However, this is not in fact observed. Thus for styrene $(k_t)_{30\%} = 5.0 \times 10^7$ and for methyl methacrylate the corresponding value is 2.4×10^7. Nevertheless the "gel effect" in the polymerisation of methyl methacrylate is much more pronounced than in the polymerisation of styrene. The theory of Burnett and Duncan is more satisfactory. However, it is only qualitative and is based on purely empirical postulates. Although at the present time it is probably impossible to set up a rigorously quantitative theory because of the large number of factors involved in block polymerisation, a number of additional postulates must nevertheless be taken into account. Thus the majority of investigators do not consider the effect of the nature of the initiator on the polymerisation kinetics at high conversions. Also, frequently allowance is not made for the change in volume during polymerisation[80], the possible change in the rate of initiation associated with the increasing viscosity of the medium, and other factors.

At first sight it may appear that both in the initial stages and at high conversions the nature of the initiator is fairly

completely characterised by the rate constant k_d for the breakdown of the given initiator and the effectiveness of initiation f. In fact these quantities are never adequate for the description of the polymerisation process at high conversions[81]. It is well known that the following expression holds for catalysed polymerisation[1-8]:

$$-\frac{d[M]}{dt} = \frac{k_p}{k_0^{1/2}}(2k_d f)^{1/2}[c]^{1/2}[M], \quad (24)$$

where $[c]$ is the concentration of the initiator.

If the breakdown of the initiator is a first-order reaction, then obviously

$$-\frac{d[c]}{dt} = k_d[c]. \quad (25)$$

Furthermore,

$$[c] = [c]_0 e^{-k_d t}, \quad (26)$$

where $[c]_0$ is the initial concentration of the initiator. On substituting Eqn. (26) in Eqn. (24), we have

$$-\frac{d[M]}{dt} = \frac{k_p}{k_0^{1/2}}(2k_d f)^{1/2}[c]_0^{1/2}e^{-k_d t/2}[M]. \quad (27)$$

There is no doubt about the applicability of Eqn. (27) to polymerisation in many systems, both in the solid state and in solution, at low conversions[82,83]. However, Eqn. (27) no longer holds for polymerisation in viscous media. As polymerisation proceeds, the rate of initiation and the value of f in Eqn. (27) begin to vary. For example, Breitenbach and Frittum[84] showed that the rate of decomposition of the peroxide $(p\text{-}ClC_6H_4CO)_2O_2$ in polystyrene is lower than in solvents. Similar data were obtained by Haas[85-87]. Abdul-Said[2] showed that, when the viscosity of the solution is increased by a factor or ten, the rate of initiation falls by a factor of two. Dolgoplosk and coworkers[88] observed an increase in the yield of the recombination products of primary radicals in the decomposition of asymmetric diazo-compounds in viscous media. If the "gel effect" theory of Schulz and others is adopted, i.e. if allowance is made for the variation of the rate constants for the fundamental reaction steps with increasing viscosity and appropriate corrections to f are made, Eqn. (27) still need not always hold. The reason is that all the theories described above fail to take into account a number of factors. Thus allowance is not made for the possibility of chain termination when chains interact with primary radicals and for the chain transfer reaction. The possibility of chain termination by primary radicals during polymerisation has been pointed out in a number of papers[61,81,89-95]. The kinetic equations obtained with allowance for these processes differ considerably from the equations which follow from the usual theory[94,95]. Chain transfer reactions with participation of primary radicals at high conversions were studied by Henrici-Olivé and Olivé[65-69,101] and also other workers[58].

Theoretical examination shows that an increase in the viscosity of the medium lowers the rate of reactions in which large species participate (chain termination in the reaction of macroradicals) and has almost no effect (at least at 50–70% conversion) on the rate of processes involving small species (chain propagation, chain termination by primary radicals, chain transfer via initiator and low-molecular-weight inhibitor molecules, chain transfer with participation of primary radicals, etc.). Hence it follows that, as polymerisation proceeds, the relative role of processes involving the participation of small molecules should increase, which may lead to a decrease of the "gel effect"[81]. The reactivity of primary radicals will of course determine the nature of the "gel effect" on a par with other factors. However, for reasons stated above, account must also be taken of purely geometrical factors, namely the size of primary radicals which affects the diffusion coefficients.

In relatively non-viscous media the size of primary radicals has little effect on the capacity to participate in chain termination (transfer) reactions. This also applies to the value of f, which is associated with the possibility of recombination of primary radicals (cage effect). At high conversions the size of primary radicals determines both the possibility of their participation in the chain termination (transfer) reaction and the value of f. The relation between the effect of primary radical recombination and the viscosity of the medium is well known. For example, in his study of the decomposition of benzoyl peroxide in polymeric media, Haas[85-87] confirmed the postulates of the theory of primary recombination. On the other hand, it is evident that radicals such as $CH_3^{\cdot}$, $C_2H_5^{\cdot}$, ..., C_nH_{2n+1} may participate in chain termination and transfer reactions to different extents because the diffusion coefficients may vary markedly with the size of the species[96].

It follows from the above considerations that the nature of self-acceleration at high conversions should be determined not only by the monomer but also by the initiator. Furthermore, the magnitude of the "gel effect" is determined by the concentration of the initiator and the experimental conditions. The "gel effect" may vary from one initiator to another[81]. Thus it has been established that bulk polymerisation of methyl methacrylate in the presence of peroxydicarbonates involves a smaller "gel effect"[97,98] compared with polymerisation in the presence of benzoyl peroxide, azobisisobutyronitrile, and other initiators. Similar results were obtained in a study of the polymerisation of methyl methacrylate activated by partial oxidation during exposure to ionising radiation[99], ultraviolet light[100], and visible light in the presence of sensitisers[101,102]. As already mentioned, such differences may be associated not only with different values of k_d and f for the given initiators but also with the different nature of the initiators themselves and the primary radicals which may participate in the chain termination and transfer reactions. The decrease of the "gel effect" at high conversions of the photo-activated monomer[100] is due to an increase of the effect of inhibitors and peroxide decomposition products formed during oxidation of the monomer. The differences in the nature of the "gel effect" during polymerisation in the presence of benzoyl peroxide, azobisisobutyronitrile, percarbonates, and hydrogen peroxide is due to the chain transfer and chain termination effects with participation of primary radicals. These conclusions were arrived at[81] by comparing the kinetic curves for polymerisation in the presence of the initiators enumerated above. Fig. 1 shows curves characterising the self-acceleration of the polymerisation of methyl methacrylate in the presence of the various initiators.

The data presented were obtained for equal concentrations of the initiators compared and therefore the differences are due to different values of k_d for the initiators and processes which are not usually taken into account by the theory. In order to eliminate the effect of k_d on the "gel effect", it is desirable to make the comparison for the same rate of initiation. Such data are presented in Fig. 2, which shows that the nature of the initiator has a significant effect on the magnitude of the "gel effect".

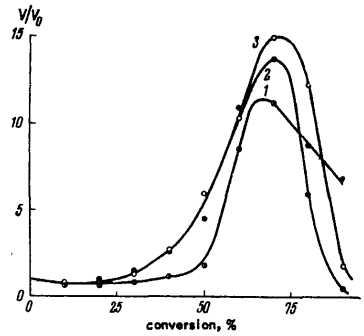

Fig. 1. Self-acceleration in the polymerisation of methyl methacrylate in the presence of various initiators at 60° and a constant initiator concentration (0.45 mole %):
1) dicyclohexyl peroxydicarbonate; 2) azobisisobutyronitrile; 3) benzoyl peroxide.

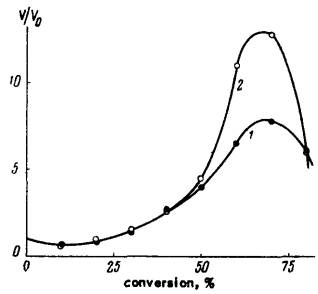

Fig. 2. Self-acceleration in the polymerisation of methyl methacrylate at 60° and constant initial rates of initiation:
1) dicyclohexyl peroxydicarbonate (0.045 mole %); 2) azobisisobutyronitrile (0.45 mole %).

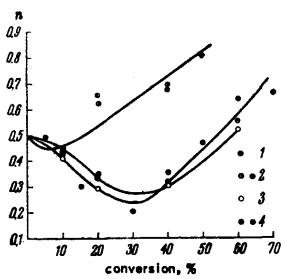

Fig. 3. Variation with the extent of conversion at 60° of the exponent n of the initiator concentration in the kinetic rate equation for the reaction, initiator — benzoyl peroxide:
1) n calculated for the initiator concentration range 0.0045–0.00045 mole %; 2) different series of experiments; 3) 0.045–0.0045 mole %; 4) 0.45–0.045 mole %.

It is difficult to allow for this effect quantitatively, but information about the chain transfer reaction may be obtained from a study of the molecular weight and polymer structure at different conversions. The possibility of chain termination by primary radicals can be assessed indirectly from the value of the exponent n of the initiator concentration (or irradiation intensity) in Eqn. (2)†. The variation of n with percentage conversion is determined by the nature of the initiator and its concentration (Fig. 3). These findings are in good agreement with the theory.

VI. OTHER STUDIES

There have been a number of investigations whose results confirm qualitatively the general theory of the "gel effect". Arbuzova and others [103] studied the photopolymerisation of acrylamide, methacrylamide, and hydroxymethylmethacrylamide in aqueous and glycerol solutions ($\lambda \simeq 3000$ Å). It was found that acrylamide and methacrylamide are polymerised only in glycerol. The rate of polymerisation of hydroxymethylmethacrylamide in glycerol is much higher than in aqueous solution. The authors explained these results on the hypothesis that the viscosity of the medium affects the rate constants for the termination of the polymeric chains. Later a similar phenomenon was observed in the polymerisation of acrylonitrile and other monomers but here initiation was effected at the interface between two phases [104]. Guzman and Delgado [105] studied the kinetics of the polymerisation of vinyl acetate at high conversions. The data obtained are consistent with the usual theory.

A number of investigators observed self-acceleration in the polymerisation of styrene [106–109]. A sharp increase in the molecular weight of the polymer was noted between 20 and 25% conversion [107,108]. The acceleration of the reaction in the case of methyl methacrylate and other acrylic esters was described by a number of investigators [106,110–115]. Burnett and coworkers [110] and also Matyska et al. [111] studied the polymerisation of n-butyl methacrylate. They established that self-acceleration occurs only after the attainment of about 40% conversion. A similar phenomenon was observed also for n-propyl methacrylate [112]. In their study of the copolymerisation of methyl methacrylate with methacrylic acid, Tarakanov et al. [113] showed that, as the methacrylic acid content of the system increases, the rate of polymerisation also rises; there is a corresponding increase in the maximum rate.

The general theory of the "gel effect" was also used in the treatment of the mechanism of three-dimensional polymerisation. Melville [27] and Melville and Hayden [30] were the first to study the effect of a three-dimensional polymer on self-acceleration at high conversions. It was shown that in the copolymerisation of methyl methacrylate with ethylene glycol dimethacrylate increase of the concentration of the latter results in onset of self-acceleration at lower conversions, while the rate of the chain termination reaction is determined by diffusion at zero conversion. Later Korolev and Berlin and coworkers made a detailed study of the three-dimensional polymerisation of a number of oligomers [116–122]; their results fully confirmed the validity of the general theory of polymerisation at high conversions. In addition, new data were obtained on the

† It should be noted that the variation of n with percentage conversion is also associated with the variation of the diffusion coefficient of macroradicals as the conversion changes [48].

characteristic features of three-dimensional polymerisation.

Thus it may be regarded as demonstrated[71,98] that the characteristic features of polymerisation at high conversions are not associated only with changes in the chain termination rate constant but with other kinetic parameters, namely the chain propagation rate constant, the rate of initiation, and the concentration of macroradicals. Furthermore, it was established that chain termination in the polymerisation of monomers such as methyl methacrylate, styrene, and others is diffusion-dependent even in the initial stages of the reaction[47,50].

At the same time the studies made in recent years show that the hypotheses described above are inadequate for the construction of a rigorously quantitative theory. For example, the available data are clearly inadequate for the interpretation of the absence of self-acceleration in the initial stages of the polymerisation of methyl methacrylate and other monomers[48]. The "paradox" considered above[48] may be explained if account is taken of the fact that in media of low viscosity not only the chain termination rate constant but also the effectiveness of initiation and the initiator breakdown rate constants vary[98,123]. The last two factors are also responsible for differences in the nature of acceleration during polymerisation in the presence of various initiators[98].

There are interesting possibilities in the study of many fundamental processes at high conversions. Thus it has been shown[124] that the study of inhibition processes in media of high viscosity permits a direct quantitative estimate of the reactivity of compounds which are relatively unreactive in radicals reactions. This cannot be done by other available methods. It is possible that further study of polymerisation at high conversions will lead not only to improved control methods for processes in which high conversions are attained[125] but also to some revision of the available data on polymerisation at low conversions[126].

RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

June 1966

IVAN LYUDVIGOVICH KNUNYANTS

Dear Ivan Lyudvigovich,

Your collaborators, numerous pupils, and the Editorial Board of the Journal "Uspekhi Khimii" wish to convey to you their heartfelt greetings on the occasion of your 60th birthday. Your encyclopaedic knowledge, inexhaustible energy, brilliant talent for research work, and constant endeavour to investigate the unknown have made you one of the greatest organic chemists, whose work in a great variety of fields of organic chemistry has received world recognition. You have pioneered the youngest and most vigorously developing scientific field, the chemistry of organic compounds of fluorine, and have become the head of the Soviet school of organic fluoro-chemistry. Your work on the study of the synthesis of physiologically active substances and the study of the relation between their structure and biological action is also widely known.

Throughout your activities you have always conducted an active struggle in defence of scientific truth which earned you deep respect and recognition by the scientific community.

We wish you, dear Ivan Lyudvigovich, good health and new creative successes.

U.D.C. 547.321

ELECTROPHILIC ADDITION REACTIONS OF FLUORO-OLEFINS

B.L.Dyatkin, E.P.Mochalina, and I.L.Knunyants

CONTENTS

Introduction 417

I. Addition of halogens 417

II. Addition of hydrogen halides 419

III. Addition of other inorganic acids 420

IV. Addition of sulphur trioxide 420

V. Mercuration 420
VI. Alkylation 421
VII. Acylation 421
VIII. Condensation with formaldehyde 421
IX. Nitration 423
X. Nitrosation 423

INTRODUCTION

The specific properties of fluoro-olefins, revealed in the unusual ease of their reaction with nucleophilic reagents (alcohols, amines, mercaptans, organomagnesium compounds, and others), are now well known and are no longer surprising; they find a natural explanation in the electron--acceptor effect of the fluorine atoms and the perfluoroalkyl groups, which is due both to the inductive effect and the conjugation effect. On the other hand, the electrophilic addition reactions, which are typical also for unsubstituted olefins, are hindered in the case of fluoro-olefins and for this reason they have been little investigated for a long time. However, in the course of development of organic fluoro-chemistry interest in reactions of fluoro-olefins with electrophilic reagents increased continuously. They attracted the attention of chemists both in connection with the theoretical study of the nature of the π bond of fluoro--olefins and for practical reasons, in connection with possible ways of synthesising new classes of organic fluoro-compounds. Numerous investigations carried out in recent years showed that the π bond in fluoro-olefins retains to a certain extent the nucleophilic properties characteristic of double-bonded carbon atoms, and fluoro--olefins are capable of reacting with various electrophilic reagents. As a rule, these reactions take place under comparatively severe conditions and require the application of effective catalysts; only when the electrophilicity of the reagent is very high can they occur under mild conditions and in the absence of catalysts.

However, it should be borne in mind that fluoro-olefins enter fairly readily into homolytic reactions and their interaction with certain electrophilic reagents, which can easily undergo fission into radicals, takes place predominantly by a radical mechanism. On the other hand, fluoro--olefins with pronounced electron-acceptor properties sometimes react by a nucleophilic addition mechanism even with substances which usually behave as electrophilic reagents. There is a fairly large number of examples of such "reversal of mechanism" and they are of special interest.

I. ADDITION OF HALOGENS

The addition of halogens to the double bond of fluoro--olefins occurs in most cases by a radical mechanism — as a result of a photochemical or thermal process. There are few examples of reactions whose conditions indicate an ionic mechanism (low temperature, the use of appropriate catalysts, etc.) and these involve mainly hydrogen-containing fluoro-olefins which have not yet lost their similarity to unsubstituted olefins.

Thus 1-chloro-1,2-difluoroethylene combines with bromine at -25°.[1] The addition of chlorine to trifluoroethylene at 100° in the presence of ferric chloride has been described[2]. Apparently the reaction did not really require such severe conditions, since it has been shown that bromine adds readily to trifluoroethylene at 20° in the dark without catalyst[3]. Vinylidene fluoride and tetrafluoroethylene are readily brominated at -10°.[4] 2-Trifluoromethylpropene and 1-chlorotrifluoromethylpropene combine quantitatively with chlorine in the dark in the presence of traces of ferric chloride[5].

The addition of halogens to perfluorovinyl ethers[6,7] and perfluorovinyl amines[6,8], where the electron density at the double bond is extremely high due to conjugation with the unshared electron pair of oxygen or nitrogen, is undoubtedly an electrophilic reaction:

$$CF_3-\overset{\curvearrowleft}{CF}=CF-\overset{\curvearrowleft}{O}-CH_3+Br_2 \xrightarrow{0^\circ} CF_3CFBrCFBrOCH_3,$$

$$CF_3-\overset{\curvearrowleft}{CF}=CF-\overset{\curvearrowleft}{N}(C_2H_5)_2+Br_2 \xrightarrow{0^\circ} CF_3CFBrCFBrN(C_2H_5)_2.$$

An ionic mechanism can be definitely invoked for the addition of mixed halogens, IF, BrF, ICl, and IBr, to fluoro-olefins†. These compounds are polar due to the different electron affinities of the halogens, which favours their heterolytic breakdown:

$$\overset{\delta+}{I} \rightarrow \overset{\delta-}{Cl} \rightarrow I^+ + Cl^-.$$

Indeed the greater the differen e in the electronegativities of the halogens the easier is the addition of the mixed halogens to fluoro-olefins. The addition of IF to the fluoro-olefins $CF_3CH=CF_2$,[9] $CF_2=CHF$,[10] $CF_2=CH_2$, perfluorocyclobutene[11], perfluorocyclohexene[11], and CFCl=CHF [1] proceeds in accordance with the polarisation of the reagents and in each case a single addition product is obtained in high yield. The ease of addition of iodine monochloride to fluoro-olefins decreases in the series[11]:

$$CF_2=CH_2 \; CF_2=CFCl \; \begin{array}{l} CF_2-CF \\ \| \quad | \\ CF_2-CF \end{array} \; \begin{array}{ccc} & CF_2 & \\ CF_2 & & CF \\ \| & & | \\ CF_2 & & CF \\ & CF_2 & \end{array} \; CF_3CF=CFCF_3.$$

The addition of IBr to $CF_2=CH_2$ [12] is also consistent with the polarity, a single product, CF_2BrCH_2I being obtained, while according to modern concepts concerning the stability of intermediate radicals the homolytic reaction should have given CF_2ICH_2Br. The addition of IF [13-15] and BrF [13] to fluoro-olefins occurs similarly, for example:

$$CF_3-CF=CF_2+IF \rightarrow CF_3CFICF_3.$$

More complex reactions take place in the addition of mixed halogens to chlorotrifluoroethylene $CF_2=CFCl$. The double bond of chlorotrifluoroethylene is polarised in such a way that a partial positive charge is concentrated at the difluoromethylene group, since, in consequence of the smaller length of the C–F bond compared with the C–Cl bond, the free electron pair of fluorine is involved in conjugation with the π electrons of the double bond to a greater extent than the free electron pair of chlorine.

According to the initial communications[16,17], the addition of iodine chloride to chlorotrifluoroethylene yields a single product, 1,2-dichlorotrifluoroiodoethane $CF_2ClCFClI$, whose formation is consistent with the polarity of the

† The stoichiometric mixtures $BrF_3 + Br_2$ and $IF_5 + I_2$ are used as the monofluorides of bromine and iodine.

reagents. However, a number of investigators subsequently showed[13,18-20] that as a rule both possible isomers are formed in proportions which depend on the temperature, the material of the reaction vessel, etc.

$$CF_2=CFCl+ICl \rightarrow CF_2ClCFClI+CF_2ICFCl_2.$$

These two modes of reaction were interpreted by one of the authors[18] as proof of a radical mechanism in the addition of ICl to $CF_2=CFCl$. Indeed, the addition of ICl to $CF_2=CFCl$ under the conditions of the homolytic reaction, in the gas phase under ultraviolet irradiation, gives a mixture of both isomers[21]. Nevertheless the two modes of reaction in liquid-phase processes are probably due to purely steric factors which permit electrophilic addition in a manner opposed to that dictated by the polarisation of the double bond[13]. Below it will be shown that the same reasons are responsible for two pathways in the condensation of chlorotrifluoroethylene with formaldehyde which is undoubtedly ionic.

The change in the mode of reaction when the mechanism is altered is clearly seen in the reaction of iodine chloride with trifluoroethylene, where in contrast to chlorotrifluoroethylene, the addition by ionic and radical mechanisms should lead to different isomers:

$$CF_2=CHF \xrightarrow{I^+} {}^+CF_2CHFI \xrightarrow{Cl^-} ClCF_2CHFI, \quad (I)$$

$$CF_2=CHF \xrightarrow{Cl\cdot} \cdot CF_2CHFCl \xrightarrow{I\cdot} ICF_2CHFCl. \quad (II)$$

In fact in the liquid-phase reaction compound (I) is formed almost exclusively whereas under ultraviolet irradiation the amount of compound (II) increases to 26–36%.[22]

A mixture of both possible isomers is formed when IF and BrF react with chlorotrifluoroethylene[13,14] and IF with the asymmetric dichlorodifluoroethylene $CF_2=CCl_2$.[23] The reasons for this phenomenon are probably the same as for the two modes of reaction of ICl with $CF_2=CFCl$.

Fluoro-olefins can enter into coupled addition reactions with halogens. Hydrogen-containing fluoro-olefins such as $CF_3CH=CH_2$, $CF_2=CHF$, and $CF_2=CH_2$ react with bromine in acetic acid in the presence of mercuric acetate or sulphate with formation of the acetates of the corresponding bromohydrins or their reaction products[24]:

$$CF_3CH=CH_2+Br_2+CH_3COOH \xrightarrow{Hg(OAc)_2} CF_3CHBrCH_2OCOCH_3,$$

$$CF_2=CFH+Br_2+CH_3COOH \xrightarrow{Hg(OAc)_2} CFHBrCF_2OCOCH_3,$$

$$CF_2=CH_2+Br_2+CH_3COOH \xrightarrow{Hg(OAc)_2} CH_2BrCF_2OCOCH_3.$$

The reaction in the presence of CCl_3COOH, CF_3COOH, and CHF_2COOH proceeds similarly[25]. The mechanism of the addition is undoubtedly the same as the mechanism of the familiar halogenation reactions of olefins in water, alcohol, or acetic acid, where the principal products are the halogenohydrins or their esters[26]:

The coupled addition of chlorine and fluorine to vinylidene fluoride occurs under the action of hexachloromelamine in anhydrous hydrogen fluoride[27]:

$$[-N=C(-NCl_2)-]_3+3HF \rightleftarrows [-N=C(-NH_2)-]_3+3Cl^++3F^-,$$

$$CF_2=CH_2 \xrightarrow{Cl^+} {}^+CF_2CH_2Cl \xrightarrow{F^-} CF_2CH_2Cl.$$

Recently it has also been shown that coupled addition of halogens to fluoro-olefins by a nucleophilic mechanism occurs under the action of potassium fluoride and iodine in an autoclave[28]:

$$>C=C< \xrightarrow{F^-} >C(F)-C^-< \xrightarrow{I_2} >C(F)-C(I)<.$$

Fluoro-olefins such as tetrafluoroethylene, hexafluoropropene, higher α-perfluoro-olefins, and perfluorocyclobutene enter into this reaction:

$$CF_2=CF_2 \rightarrow CF_3CF_2I,$$

$$CF_2=CF-CF_3 \rightarrow CF_3CFICF_3,$$

$$\begin{matrix} CF_2-CF \\ \| \\ CF_2-CF \end{matrix} \rightarrow \begin{matrix} CF_2-CF-I \\ | \quad | \\ CF_2-CF_2 \end{matrix}.$$

Perfluoroisobutene gives an 86% yield of perfluoro-t-butyl iodide under the action of potassium fluoride and iodine in nitrobenzene at 170°:[29]

$$(CF_3)_2C=CF_2 \rightarrow (CF_3)_3C-I.$$

Thus this method can be used for the coupled halogenation of fluoro-olefins which do not react with halogens under the conditions of the electrophilic reaction or react with difficulty.

II. ADDITION OF HYDROGEN HALIDES

There is a fairly large number of examples of the addition of hydrogen halides to fluoro-olefins by an electrophilic mechanism. In the first place this applies to hydrogen-containing fluoro-olefins. Thus 1,1-difluorobut-1-ene[30] and 1,1,3,3,3-pentafluoropropene[31] combine with hydrogen fluoride on heating without catalysts, in conformity with the polarisation of the reagents:

$$CH_3CH_2CH=CF_2+HF \xrightarrow{40^\circ} CH_3CH_2CH_2CF_3,$$

$$CF_3CH=CF_2+HF \xrightarrow{100^\circ} CF_3CH_2CF_3.$$

Hydrogen halides also add in a non-catalytic reaction to vinylidene fluoride[32].

In many cases Lewis acids are used as catalysts. For example, hydrogen fluoride adds to $CF_2=CH_2$ and $CF_2=CHCl$ when the reagents are passed through a nickel tube with aluminium trifluoride at 300°.[33] Boron trifluoride has also been successfully used as a catalyst[34]:

$$\begin{matrix} CF_2=CCl_2 \\ CFCl=CFCl \\ CFCl=CCl_2 \\ CHCl=CF_2 \\ CF_3CH=CFCl \end{matrix} \xrightarrow{+HF/BF_3} \begin{matrix} CF_3CHCl_2 \\ CF_3ClCHFCl \\ CF_2ClCHCl_2 \\ CH_2ClCF_3 \\ CF_3CH_2CF_2Cl \end{matrix}$$

1,1-Difluoropropene combines with hydrogen chloride in the presence of aluminium trichloride[35]:

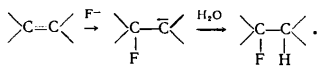
$$CH_3CH=CF_2+HCl \xrightarrow{150^\circ,\ 12\ h} CH_3CH_2CF_2Cl.$$

The addition of hydrogen bromide to hexafluoropropene is catalysed similarly by aluminium tribromide[36].

The addition reactions of hydrogen halides to fluoro-olefins at a high temperature (100–300°) in the presence of activated charcoal impregnated with alkaline earth metal sulphates as catalysts constitute a fairly large group.

Under these conditions hydrogen halides add to perfluoro--olefins in only one way, in conformity with the polarisation of the reactants [37-40]. In all probability the mechanism of these reactions is ionic and it is evident that it can be both electrophilic and nucleophilic. The relative ease of addition to perfluoroisobutene compared with perfluoropropene indicates a nucleophilic mechanism, while an electrophilic mechanism is more likely for fluoro-derivatives of ethylene.

Fluoro-olefins readily combine with hydrogen fluoride under the action of water in the presence of alkali metal fluorides, i.e. by a nucleophilic mechanism [41]:



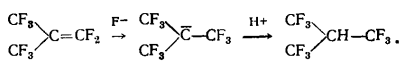
Hydrogen fluoride adds in the same way to trifluoromethyl perfluorovinyl ether [42]:

$$CF_3OCF=CF_2 \xrightarrow{KF} CF_3O\bar{C}FCF_3 \xrightarrow{H_2O} CF_3OCHFCF_3,$$

and to perfluoroallene [43,44]:

$$CF_2=C=CF_2 \xrightarrow{CsF} CF_3\bar{C}=CF_2 \xrightarrow{H_2O} CF_3CH=CF_2.$$

Under nucleophilic reaction conditions the addition of hydrogen fluoride to perfluoroisobutene takes place particularly easily [45,46]:



III. ADDITION OF OTHER INORGANIC ACIDS

Fluorosulphonic acid adds to trifluoroethylene at atmospheric pressure at 20–30° [47]:

$$CFH=CF_2+HOSO_2F \rightarrow CFH_2CF_2O-SO_2F.$$

The adducts of fluorosulphonic acid and vinylidene fluoride and 2-chloro-1,1-difluoroethylene have been obtained under similar conditions [48,49]:

$$CH_2=CF_2+HOSO_2F \rightarrow CH_2CF_2OSO_2F,$$
$$CHCl=CF_2+HOSO_2F \rightarrow CH_2ClCF_2OSO_2F.$$

Perfluoro-olefins require more severe conditions. Thus the addition of fluorosulphonic acid to tetrafluoroethylene, hexafluoropropene, 4-hydroperfluorobut-1-ene, perfluorohept-1-ene, and 8-hydroperfluoro-oct-1-ene requires heating in an autoclave at 150–200° for several hours:

$$R-CF=CF_2+HOSO_2F \rightarrow RCFHCF_2OSO_2F,$$

where R = F, CF_3, $H(CF_2)_2$, $CF_3(CF_2)_4$, and $H(CF_2)_6$.

The addition of sulphuric acid to perfluoropropene requires heating at 350°, which is due to the lower electrophilicity of sulphuric acid compared with fluorosulphonic acid:

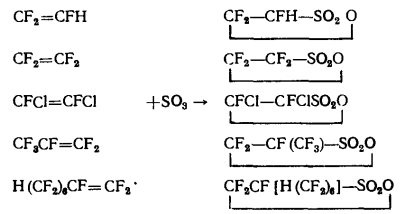
$$CF_3-CF=CF_2+H_2SO_4 \rightarrow CF_3CFHCF_2OSO_3H.$$

In all cases the mode of addition is consistent with the polarisation of the double bond [50,51].

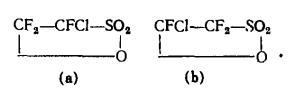
IV. ADDITION OF SULPHUR TRIOXIDE

As already mentioned, fluoro-olefins behave as electron-donor compounds in relation to reagents whose electrophilicity is particularly high. The reaction of fluoro--olefins with sulphur trioxide is a process where this property is particularly marked.

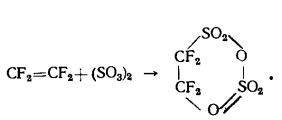
A number of investigators have shown [52-57] that fluoro--olefins readily combine with sulphur trioxide with formation of cyclo-adducts — β-sultones. The initial reaction step is undoubtedly attack on the double bond by the positively charged sulphur atom of sulphur trioxide:



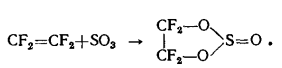
The above examples show that in reactions of asymmetric fluoro-olefins the addition of sulphur trioxide occurs in conformity with the polarisation of the double bond. Contradictory data have been published concerning chlorotrifluoroethylene. Dmitriev et al. [53,55] obtained only one isomer of the addition product, α-chlorotrifluoro-β-sultone (a), formed in conformity with the polarity of the reactants, whereas according to the data of England et al. [56,57] the adduct is a mixture of both possible isomers, (a) and (b):



The experimental conditions of the reactions differed somewhat in the two cases. β-Sultones are the sole reaction products only when freshly-distilled sulphur trioxide (α-form, monomer) is used. The dimer of sulphur trioxide yields pyrosultones:



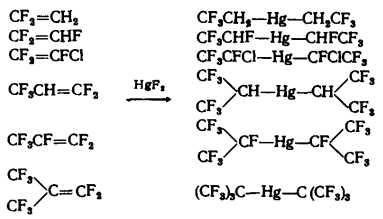
The formation of tetrafluoroethylene sulphite has also been noted [57]:



V. MERCURATION

The fluoro-derivatives of ethylene and higher fluoro--olefins with a terminal double bond combine with mercuric fluoride in solution in arsenic trifluoride or anhydrous hydrogen fluoride (in the latter case mercuric oxide can be used instead of mercuric fluoride). The addition occurs on heating in an autoclave at 50–100° and results in the formation of bis-perfluoroalkyl derivatives of mercury [58-63].

The following series of examples demonstrates the fairly wide range of application of this reaction:

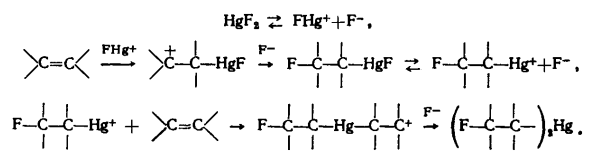


The addition of mercuric fluoride to chlorotrifluoroethylene and tetrafluoroethylene at 100° in an autoclave without solvent leads to small yields of the corresponding perfluoroalkylmercury fluorides[64]:

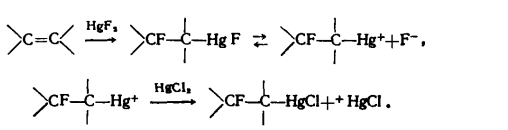
$$CF_2=CFX+HgF_2 \rightarrow CF_2CFX-HgF,$$

where X = F, Cl.

Fluoro-olefins with a non-terminal double bond, such as perfluorocyclobutene and 2,3-dichloro-octafluorobut-2-ene do not combine with mercuric fluoride[65]. There is no doubt that the mechanism of the addition is electrophilic:



This mechanism is confirmed by the fact that undissociated mercuric chloride does not add to fluoro-olefins, while a 1:1 mixture of mercuric fluoride and chloride yields perfluoroalkyl mercury chlorides[62]:

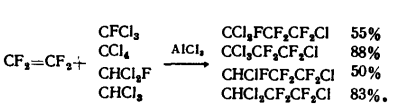


The nucleophilic mechanism of the addition of mercuric fluoride suggested by Goldwhite et al.[64] seems unlikely.

It should be noted that the reaction with mercuric fluoride is the only known example of electrophilic addition to the double bond of perfluoroisobutene. In contrast to other fluoro-olefins, the interaction of $(CF_3)_2C=CF_2$ with mercuric fluoride occurs at 180–200°.[60]

VI. ALKYLATION

In the presence of aluminium chloride, tetrafluoroethylene condenses with chlorotrifluoromethane, carbon tetrachloride, chlorodifluoromethane, and chloroform[66-68]:



The alkylation of asymmetric fluoro-olefins occurs in conformity with the polarity of the double bond. The communication[69] that CCl_3F, CCl_4, $CHFCl_2$, and $CHCl_3$ add to chlorotrifluoroethylene in the presence of aluminium chloride in a manner contrary to the polarity proved to be erroneous[70]. It has been shown that the addition of CCl_4 and $CHCl_3$ to $CF_2=CFCl$ [71,72] also occurs in conformity with the polarisation of the double bond:

$$CF_2=CFCl+CCl_3X \rightarrow CF_2ClCFClCCl_2X,$$

where X = Cl, H. The addition of isopropyl chloride to chlorotrifluoroethylene and the asymmetric dichlorodifluoroethylene in the presence of aluminium chloride has also been described[73]:

$$CF_2=CXCl+(CH_3)_2CHCl \xrightarrow{AlCl_3} CF_2Cl-CXCl-CH(CH_3)_2,$$

where X = F, Cl.

The substitution of fluorine by chlorine and disproportionation are side-processes which usually accompany the reactions of fluoro-olefins in which aluminium chloride participates.

VII. ACYLATION

The addition of the chlorides of carboxylic acids by an electrophilic mechanism in the presence of aluminium chloride (by Kondakov's reaction) was achieved only in the case of vinylidene fluoride and trifluoroethylene[74]. The mode of addition is consistent with the polarity of the starting materials:

$$R-COCl+CF_2=CHX \xrightarrow{AlCl_3} R-CO-CHX-CF_2Cl,$$

where X = H and F and R = CH_3, C_2H_5, and n-C_3H_7.

At the same time there is complete or partial substitution of fluorine by chlorine and products of further condensation are formed. The acylation of perfluoro-olefins can be achieved only by a nucleophilic mechanism. In the presence of alkali metal fluorides, difluorophosgene adds to perfluoro-olefins, yielding the fluorides of perfluoro-carboxylic acids. The fluorides of perfluoro-carboxylic acids react similarly with formation of perfluoro-ketones[75-77]:

$$CF_2=CF_2 \xrightarrow{F^-} CF_3CF_2^- \xrightarrow{COF_2} CF_3-CF_2-COF+F^-,$$
$$CF_3CF_2COF+CF_2=CF_2 \rightarrow CF_3CF_2-CO-CF_2CF_3.$$

VIII. CONDENSATION WITH FORMALDEHYDE

Condensation reactions with formaldehyde in the presence of acid catalysts are characteristic of olefins, and are known to result in the formation of either unsaturated alcohols, or 1,3-glycols or their derivatives — *m*-dioxans. Halogeno-olefins yield β-hydroxy-acids or their derivatives, for example[78]:

$$CCl_2=CCl_2+CH_2O+H_2O \xrightarrow{H^+} [HOCH_2CCl_2CCl_2OH] \xrightarrow{H_2O} HOCH_2CCl_2COOH.$$

The reaction of tetrafluoroethylene with paraformaldehyde in the presence of 80% sulphuric acid in an autoclave at 80°, resulting in a small yield of αα-difluorohydracrylic acid, was described in 1949:[79-81]

$$CF_2=CF_2+CH_2O \rightarrow HOCH_2CF_2COOH.$$

Among other fluoro-olefins only trifluoroethylene reacts with formaldehyde in the presence of 90% sulphuric acid[82]. The product is α-fluorohydracrylic acid:

$$CF_2=CHF+CH_2O \rightarrow HOCH_2CHFCOOH.$$

Catalysts of this reaction which are much more effective than sulphuric acid are chlorosulphonic and fluorosulphonic

acids, in whose presence formaldehyde can be condensed with tetrafluoroethylene, chlorotrifluoroethylene, 1,2-dichloro-1,2-difluoroethylene, and hexafluoropropene[83,84]. In all the cases investigated the following hydracrylic acids were obtained in satisfactory yields:

$CF_2=CF_2$	$HOCH_2CF_2COOH$	62.6%
$CF_3CF=CF_2$	$HOCH_2CFCOOH$ (CF$_3$)	41.3%
$CFCl=CFCl + CH_2O + ClSO_3H \rightarrow$	$HOCH_2CFClCOOH$	50%
$CF_2=CFCl$	$HOCH_2CFClCOOH$	19.8%
	$HOCH_2CF_2COOH$	30.5%

Trifluoroethylene and hexafluoropropene gave respectively α-fluorohydracrylic and α-fluoro-α-trifluoromethylhydracrylic acids which is consistent with the polarity of the double bond in fluoro-olefins. It was to be expected that the condensation of chlorotrifluoroethylene with formaldehyde would give α-chloro-α-fluorohydracrylic acid. This acid was indeed isolated (as the ethyl ester) in 19.8% yield, but the mixture of products also contained 30.5% of the ethyl ester of $\alpha\alpha$-difluorohydracrylic acid whose formation can only be conceived as a result of electrophilic attack on the CF_2 group, i.e. on the carbon atom bearing a positive charge relative to the carbon atom of the CFCl group.

The occurrence of two modes of reaction was also noted for certain other addition reactions of fluoro-olefins, including chlorotrifluoroethylene. However, in this case addition contrary to the polarity is observed for a process about whose ionic character there can not be even the slightest doubt. Apparently this phenomenon can be explained by a competition of steric and polar factors. The effective radius of fluorine is 1.25 Å and of chlorine 1.58 Å; thus the mode of reaction in conformity with the polarisation of the double bond encounters considerable steric hindrance. In nucleophilic addition reactions of chlorotrifluoroethylene the effects of the polar and steric factors reinforce each other and therefore there is strictly only one mode of reaction in such processes.

The condensation of fluoro-olefins with formaldehyde in the presence of fluorosulphonic and chlorosulphonic acids can be represented as follows:

$$ClSO_2{-}OH + CH_2O \rightarrow ClSO_2{-}O{-}CH_2OH \overset{H^+}{\rightleftarrows} ClSO_2OCH_2^+ + H_2O,$$

$$CF_2=CF_2 + ClSO_2OCH_2^+ \rightarrow [ClSO_2OCH_2CF_2CF_2^+] \xrightarrow{ClSO_2O^-}$$
$$\rightarrow ClSO_2OCH_2CF_2CF_2{-}O{-}SO_2Cl \xrightarrow{H_2O} HOCH_2CF_2COOH.$$

The intermediate halogenosulphonates exhibit a high capacity for alkylation, and can therefore be used in the preparation of the corresponding β-halogeno-carboxylic acids[82,83]:

$$FSO_2OCH_2CFClCFCl{-}O{-}SO_2F \xrightarrow{KX,\ H_2O} X{-}CH_2CFClCOOH,$$

where X = Cl and Br.

The study of the condensation of formaldehyde with fluoro-olefins in solution in anhydrous hydrogen fluoride yielded interesting results. Vinylidene fluoride and trifluoroethylene enter into this reaction even at 0°, the products being fluorinated ethers[85-87]:

$$CF_2=CH_2 + CH_2O + HF \rightarrow CF_3CH_2CH_2{-}O{-}CH_2CH_2CF_3,$$

$$CF_2=CHF + CH_2O + HF \rightarrow CF_3CHFCH_2{-}O{-}CH_2CHFCF_3.$$

The condensation in the presence of alcohols gives the corresponding mixed ethers[88,89] and in the presence of acetic acid the products are fluoroalkyl acetates[89]:

$$CF_2=CH_2 + CH_2O + HF + ROH \rightarrow CF_3CH_2CH_2{-}O{-}R,$$

$$CF_2=CH_2 + CH_2O + HF + CH_3COOH \rightarrow CH_3COOCH_2CH_2CF_3.$$

In the reaction with trifluoroethylene, the alcohol CF_3CFHCH_2OH is formed together with the ether $(CF_3CFHCH_2)_2O$. Alcohols or their fluoromethyl ethers are the main products of the condensation of the aldehyde with the perfluoro-olefins tetrafluoroethylene and hexafluoropropene[87,90,91]:

$$RCF=CF_2 + CH_2O + HF \rightarrow RCF_2CF_2CH_2OH + RCF_2CF_2CH_2{-}O{-}CH_2F,$$

where R = F and CF_3.

There are data[87] showing that a solution of paraformaldehyde in anhydrous hydrogen fluoride is an equilibrium mixture consisting of 25–30% of fluoromethanol and 70–75% of fluoromethyl ether:

$$CH_2=O + HF \rightleftarrows FCH_2OH + FCH_2{-}O{-}CH_2F.$$

The formation of all the products of the formaldehyde condensations of fluoro-olefins in solution in hydrogen fluoride can be satisfactorily explained by postulating dissociation of these compounds at the C–F bond:

$$FCH_2OH \rightleftarrows {}^+CH_2OH + F^-,$$

$$FCH_2OCH_2F \rightleftarrows FCH_2OCH_2^+ + F^-,$$

$$CF_2=CFH \xrightarrow{HOCH_2^+} [{}^+CF_2CFHCH_2OH] \xrightarrow{F^-} CF_3CHFCH_2OH,$$
$$\downarrow FCH_2OCH_2^+$$
$$[{}^+CF_2{-}CFH{-}CH_2OCH_2F] \xrightarrow{F^-} CF_3CFHCH_2OCH_2F \xrightarrow{-F^-}$$
$$\rightarrow [CF_3CFHCH_2OCH_2^+] \xrightarrow{CF_2=CFH} [CF_3CFHCH_2OCH_2CFHCF_2^+] \xrightarrow{F^-} (CF_3CFHCH_2)_2O$$

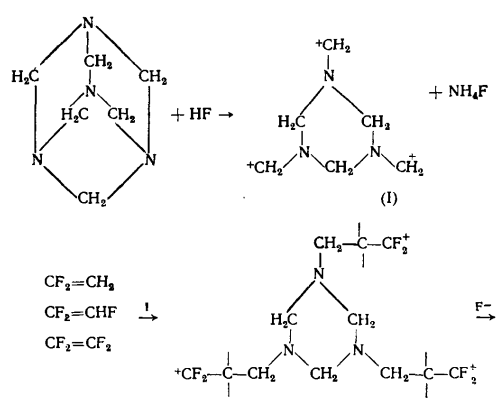
The participation of fluoromethyl ether in these reactions is not essential; under the action of the hydroxymethyl cation alone the same results are obtained:

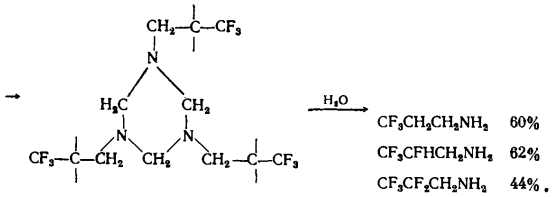
$$CF_2=CFH \xrightarrow{HOCH_2^+} CF_3CFHCH_2OH \xrightarrow{CH_2O} [CF_3CFHCH_2OCH_2OH] \xrightarrow{H^+}$$
$$\rightarrow [CF_3CFHCH_2OCH_2^+] \xrightarrow{CF_2=CFH} [CF_3CFHCH_2OCH_2CFHCF_2^+] \xrightarrow{F^-}$$
$$\rightarrow CF_3CFHCH_2OCH_2CFHCF_3, \text{ etc.}$$

It is interesting that a cyclodimer has also been isolated from the products of the reaction of tetrafluoroethylene with formaldehyde in hydrogen fluoride[87]:

$$\begin{matrix} CF_2=CF_2 \\ CH_2=O \end{matrix} \rightarrow \begin{matrix} CF_2{-}CF_2 \\ | \quad | \\ CH_2{-}O \end{matrix}.$$

In the reaction of fluoro-olefins with a solution of hexamethylenetetramine in hydrogen fluoride aminomethylation takes place[92]:





IX. NITRATION

The nitration of fluoro-olefins can be achieved both by radical and ionic mechanisms. In the radical process, the nitrating agent is the monomer of nitrogen dioxide, the reaction products being vicinal dinitro-compounds and nitro-nitrites whose hydrolysis leads to fluorine-containing nitro-acids, nitro-ketones, or nitro-alcohols[93-100]. On the other hand, in ionic processes various nitrating agents are used, forming the nitronium cation under the reaction conditions. One of the best investigated reactions of this type is the nitrofluorination of fluoro-olefins with a mixture of nitric acid and anhydrous hydrogen fluoride:

$$HNO_3 + HF \rightleftarrows O_2N^+ + 2F^- + H_3O^+$$

$$>C=C< + O_2N^+ \rightarrow \left[>C-\overset{+}{C}<\right] \xrightarrow{F^-} >C-C<$$
$$\qquad\qquad\qquad\quad NO_2 \qquad\qquad NO_2\ F$$

In the fluoro-olefin series this reaction was first achieved for tetrafluoroethylene[101]:

$$CF_2=CF_2 + HNO_3 + HF \rightarrow CF_3CF_2NO_2.$$

The study of the nitrofluorination of asymmetric fluoro-olefins[102,103] showed that the mode of addition is determined by the polarity of the double bond:

$CF_2=CH_2$	$CF_3CH_2NO_2$	59%
$CF_2=CHF$	CF_3CFHNO_2	86%
$CF_2=CFCl$ + HNO_3/HF →	$CF_3CFClNO_2$	88%
$CF_2=CFCF_3$	$(CF_3)_2CFNO_2$	75%.

The hydrogen-containing fluoro-olefins vinylidene fluoride and trifluoroethylene are most readily nitrofluorinated. They react when bubbled through a mixture of anhydrous hydrogen fluoride and nitric acid at -60°. Tetrafluoroethylene and chlorotrifluoroethylene react at 10–20°[102] and hexafluoropropene on heating in an autoclave at 60°.[103]

The nitration of fluoro-olefins with a mixture of nitric and sulphuric acids has also been investigated. The products are fluoronitro-carboxylic acids or their chlorides[104]. The reaction mechanism is ionic, involving attack by the nitronium cation on the double bond. Thus the action of sulphuric and nitric acids on tetrafluoroethylene and chlorotrifluoroethylene results in the formation of difluoronitroacetic acid[105]:

$$\begin{matrix}CF_2=CF_2\\CF_2=CFCl\end{matrix} + HNO_3/H_2SO_4 \rightarrow CF_2NO_2COOH.$$

Similarly symmetrical dichlorodifluoroethylene gives chlorofluoronitroacetic acid[106]:

$$CFCl=CFCl \rightarrow CFClNO_2COOH,$$

and 2,2-dichloro-1-fluoroethylene gives the chloride of fluoronitroacetic acid[107]:

$$CCl_2=CHF \rightarrow CHFNO_2COCl.$$

The perhalogenopropenes $(CF_2Cl)CCl=CCl_2$ and $CF_3CCl=CCl_2$ yield the acid chlorides $(CF_3Cl)CClNO_2COCl$ and CF_3CClNO_2COCl respectively[108].

The possibility of using nitryl fluoride as the nitrating agent has been almost not investigated. However, it has been shown that NO_2F adds to the double bonds of alkyl perfluorovinyl ethers with the formation of fluorinated nitro-ethers which can be converted into esters of perfluoronitro-carboxylic acids[109]. The esters of tetrafluoro--α-nitropropionic and hexafluoro-α-nitroisobutyric acids were obtained in this way:

$$CF_3-C(R)=CF-OR' + FNO_2 \rightarrow CF_3-C(R)(NO_2)-CF_2-OR' \xrightarrow{AlCl_3}$$
$$\rightarrow CF_3-C(R)(NO_2)-C(=O)X \xrightarrow{R'OH} CF_3-C(R)(NO_2)-COOR',$$

where R = F and CF_3, X = F or Cl, and R′ = alkyl.

X. NITROSATION

The nitrosation of fluoro-olefins, i.e. the addition of various nitrosating agents to the double bond, for example nitrosyl halides or nitrogen oxides, is of considerable interest as a possible general pathway for the synthesis of fluoronitroso-alkanes and fluoronitroso-compounds with different functional groups. These reactions can be divided into two groups. The first group comprises the homolytic processes

$$>C=C< \xrightarrow{X^\cdot} X-C-\underset{A}{C}\cdot \xrightarrow{NO} X-C-C-NO.$$

The radical X′ attacks the double bond of the fluoro-olefins, the intermediate radical A being stabilised by the addition of the radical-like molecule of nitric oxide. Dinitrogen trioxide[110] and nitrosyl chloride[111,112] add to fluoro-olefins in this way. The second group of reactions includes processes for which a heterolytic mechanism has been demonstrated or is at least likely. These reactions are discussed regardless of whether they yield nitroso-compounds or products of further reactions of the latter.

Nitrosyl chloride reacts with tetrafluoroethylene, chlorotrifluoroethylene, and asymmetric dichlorodifluoroethylene when the mixture is passed through a heated Pyrex tube, the products being nitro-compounds[113]:

$$CF_2=CF_2 \xrightarrow{50^\circ} CF_2ClCF_2NO_2, \qquad 63\%$$
$$CF_2=CFCl + NOCl \xrightarrow{100^\circ} CF_2ClCFClNO_2, \qquad 67\%$$
$$CF_2=CCl_2 \xrightarrow{100^\circ} CF_2ClCCl_2NO_2. \qquad 57\%$$

Similar results are obtained when the reaction is carried out in sealed tubes[114,115] or in an autoclave[116] at room temperature; thus $CF_2=CFCl$ forms a nitro-compound and 1,2,2-trichloro-1,1,2-trifluoroethane:

$$CF_2=CFCl + NOCl \rightarrow CF_2ClCFClNO_2 + {}^1/_2\,Cl_2 + {}^1/_2\,N_2.$$
$$\xrightarrow{Cl_2} CF_2ClCFCl_2$$

When the initially formed nitroso-compound contains a hydrogen atom in the α position, it is stabilised by the nitroso-oxime rearrangement, for example[114,115]:

$$CHF=CHCl + NOCl \rightarrow [CHFClCHClNO] \rightarrow CHFCl-CCl=NOH.$$

It is readily seen that in all the cases quoted above the addition of nitrosyl chloride occurs in conformity with the

polarisation of the double bond. Nitrosyl bromide and tetrafluoroethylene react in an autoclave at 55° to give $O_2NCF_2CF_2Br$.[113] The intermediate formation of nitroso--compounds is confirmed by the fact that in the reaction of nitrosyl chloride with an excess of $CF_2=CF_2$ in an autoclave at 100° the principal product is oxazetidine[116]:

$$CF_2=CF_2 + ClNO \rightarrow ClCF_2-CF_2-N=O \xrightarrow{CF_2=CF_2} CF_2ClCF_2-N(-O)-CF_2-CF_2 .$$

It has been established that the addition of nitrosyl chloride to tetrafluoroethylene in the liquid phase can occur by an ionic electrophilic mechanism. The reaction occurs smoothly on bubbling $CF_2=CF_2$ through a solution of aluminium trichloride in nitrosyl chloride at -78°.[117] When nitrosyl chloride was added to $CF_2=CF_2$ and $CF_2=CFCl$ in a tube over ferric chloride at 45°, nitroso-compounds, dichlorides, and chloronitro- and dinitro-compounds were isolated[118], the yield of the nitroso-compounds being of the order of 80%. Similar results were obtained when nitric oxide was used instead of nitrosyl chloride[119]. The authors of these studies believe that in the latter case the first reaction step is the formation of nitrosyl chloride from nitric oxide and ferric chloride:

$$NO + FeCl_3 \rightleftarrows NOFeCl_3,$$
$$NOFeCl_4 + NO \rightarrow NOFeCl_2 + NOCl,$$
$$NOCl + FeCl_3 \rightarrow NOFeCl_4,$$
$$NOFeCl_4 + 2\,NO \rightarrow NOFeCl_2 + 2\,NOCl,$$

although usually these processes occur at a higher temperature than the one at which the NO + $FeCl_3$ mixture interacts with fluoro-olefins.

The authors believe that the addition of nitrosyl chloride to fluoro-olefins over ferric chloride takes place by a radical mechanism. They base this view on the idea, prevalent until recently, that fluoro-olefins are incapable of undergoing electrophilic addition reactions. However, as already mentioned, numerous studies in recent years showed that fluoro-olefins have by no means lost the electron-donor properties characteristic of olefins and under certain conditions enter into electrophilic reactions. Comparison with the results obtained by Titov[117] suggests that the mechanism of these reactions is similar and can be represented as follows:

$$NOCl + MCl_3 \rightleftarrows NO^+ + MCl_4^-$$
$$CF_2=CF_2 + {}^+NO \rightarrow [CF_2(NO)-CF_2^+] \xrightarrow{MCl_4^-} CF_2(NO)-CF_2Cl + MCl_3$$

where M = Al, and Fe.

There is no doubt that the addition of nitrosyl chloride to alkyl perfluorovinyl ethers has an electrophilic mechanism[120]:

$$\begin{matrix} CF_2=CF-OR \\ ClCF=CF-OR \\ CF_3CF=CFOR \end{matrix} + NOCl \xrightarrow{-78°} \begin{matrix} ON-CF_2CFClOR \\ ON-CFClCFClOR, \\ CF_2CFCFClOR \\ | \\ NO \end{matrix}$$

where R = CH_3, and C_2H_5.

As mentioned in Section IX, nitrogen dioxide reacts with fluoro-olefins by a radical mechanism with formation of dinitro-compounds and nitro-nitrites. The interaction of nitrogen dioxide with alkyl perfluorovinyl ethers[121], resulting after hydrolysis in the formation of fluoro-α--nitroso-carboxylic acid esters, is of a quite different type:

$$X-CF=CFOR + N_2O_4 \xrightarrow{-78°} [XCF(NO)-CF(ONO_2)-OR] \xrightarrow{H_2O} XCF(NO)-COOR,$$

where X = F, Cl, and CF_3 and R = CH_3 and C_2H_5.

The esters of difluoronitrosoacetic acid $ONCF_2COOR$, chlorofluoronitrosoacetic acid ONCFClCOOR, and tetrafluoro-α-nitrosopropionic acid $CF_3CF(NO)COOR$ have been prepared in this way. The dimer of nitrogen dioxide enters into this reaction as nitrosonium nitrate:

$$N_2O_4 \rightleftarrows {}^+NO + {}^-ONO_2.$$

The conjugation with the unshared electron pair of the oxygen atoms makes the double bond of the alkyl perfluorovinyl ethers sufficiently nucleophilic for reaction with dinitrogen tetroxide by an ionic mechanism.

The addition of nitrosyl fluoride to fluoro-olefins was first achieved by Knunyants et al.[122], who studied the interaction of nitrosyl fluoride with $CH_2=CF_2$, $CHF=CF_2$, $CF_2=CF_2$, $CF_2=CFCF_3$, and $CF_2=C(CF_3)_2$. It was found that the addition of nitrosyl fluoride to perfluoroisobutene proceeds smoothly at room temperature in an autoclave in the presence of a small amount of potassium fluoride with formation of nonafluoronitroso-t-butane:

$$(CF_3)_2C=CF_2 + NOF \rightarrow (CF_3)_3CNO.$$

Perfluoropropene reacts with nitrosyl fluoride on heating at 150° in the presence of calcium sulphate on activated charcoal as the catalyst. Heptafluoro-2-nitrosopropane $(CF_3)_2CFNO$ is obtained in a small yield; the main products are substances formed as a result of its further reaction — hexafluoroisopropyl nitrite $(CF_3)_2CF(ONO)$ and hexafluoroacetone CF_3COCF_3 — and also as a result of side--processes of a radical type — hexafluoronitronitrosopropane $CF_3CF(NO)CF_2NO_2$, the hydrate of pentafluoronitroacetone $CF_3C(OH)_2CF_2NO_2$, etc. In the absence of a catalyst products of the radical nitration of $CF_3CF=CF_2$ are formed exclusively. In the presence of $CaSO_4/C$ tetrafluoroethylene reacts with nitrosyl fluoride at 70–80°, the main product being the corresponding oxazetidine:

$$CF_2=CF_2 + NOF \rightarrow CF_3CF_2-N=O \xrightarrow{CF_2=CF_2} CF_3CF_2-N(-O)-CF_2-CF_2 .$$

Trifluoroethylene and vinylidene fluoride react with nitrosyl fluoride very readily at room temperature without catalyst in an inert solvent. Reaction with $CF_2=CFH$ gave CF_3CF_2NO,

$$CF_2=CFH + NOF \rightarrow [CF_2(NO)CFHF] \rightarrow [CF_2=CF(NO)H] \xrightarrow{HF} \rightarrow [CF_2(NO)CF_2H(OH)] \xrightarrow{[O]} CF_3CF_2NO.$$

and reaction with $CF_2=CH_2$ gave a compound to which the following structure was attributed:

$$CF_3CF_2N(-O)-CF_2-CH(-OH)-N-.$$

The results of Knunyants and coworkers were subsequently confirmed by Andreades[123], who showed that the addition of nitrosyl fluoride to $CF_2=C(CF_3)_2$ occurs readily even without catalyst. Perfluorobut-2-ene, an olefin with a central double bond, proved to be incapable of combining with nitrosyl fluoride even at a high temperature (200°),

yielding only degradation products — CF_3COF, $CF_3CF_2NO_2$, CF_3NO_2, CF_3CF_2COF, etc.[123]

The addition of nitrosyl fluoride to alkyl perfluorovinyl ethers proceeds exceptionally easily (at -78°)[120]:

$$\begin{matrix} CF_2{=}CF{-}OR \\ CFCl{=}CFOR \\ CF_3CF{=}CFOR \end{matrix} + NOF \rightarrow \begin{matrix} ONCF_2CF_2OR \\ ONCFClCF_2OR \\ CF_3CF(NO)CF_2OR \end{matrix},$$

where R = CH_3 or C_2H_5. However, the addition of nitrosyl fluoride to ethyl perfluoroisobutenyl ether occurs only at room temperature:

$$\begin{matrix} CF_3 \\ CF_3 \end{matrix}\!\!>\!C{=}CF{-}OC_2H_5 \xrightarrow{NOF} \begin{matrix} CF_3 \\ CF_3 \end{matrix}\!\!>\!C(NO){-}CF_2OC_2H_5.$$

Nitrosyl fluoride adds very readily to the fluoride of perfluoromethacrylic acid $CF_2{=}C(CF_3)COF$ and di(trifluoromethyl)keten $(CF_3)_2C{=}C{=}O$ [124] which are distinguished by exceptionally high electrophilicity. An examination of the above addition reactions of nitrosyl fluoride at the double bond readily reveals an interesting peculiarity consisting of the fact that the addition takes place easily to vinyl ethers and hydrogen-containing fluoroethylenes ($CH_2{=}CF_2$ and $CHF{=}CF_2$), becomes more difficult with $CF_2{=}CF_2$ and $CF_2{=}CF{-}CF_3$, and then again becomes very much easier with $(CF_3)_2C{=}CF_2$. This behaviour has the following logical explanation. The addition to vinyl ethers and the first members of the fluoro-olefin series involves an electrophilic mechanism and begins with attack by the nitrosonium cation; while in the addition of perfluoroisobutene, nitrosyl fluoride behaves as a nucleophilic agent and the first reaction step is attack on the double bond by the fluoride anion:

$$NOF \rightleftarrows F^- + \overset{+}{N}O,$$

$$CF_2{=}CF{-}OR \xrightarrow{+NO} [ON{-}CF_2{-}\overset{+}{C}FOR] \xrightarrow{F^-} ONCF_2CF_2OR,$$

$$F_3C{\equiv}C{-}C{=}C_2 \xrightarrow{F^-} [(CF_3)_3C^-] \xrightarrow{+NO} (CF_3)_3C{-}NO.$$

The nucleophilic mechanism of the addition of nitrosyl fluoride to higher fluoro-olefins was confirmed by the experimental finding[125] that alkali metal fluorides are effective catalysts of the addition reaction, particularly in strongly ionising solvents. Thus interaction of nitrosyl fluoride with perfluoropropene and perfluorocyclobutene in sulpholane in the presence of potassium fluoride and caesium fluoride gives the corresponding nitroso-compounds in yields of the order of 70%:

$$\begin{matrix} CF_3CF{=}CF_2 \\ CF_2{-}CF \\ CF_2{-}CF \end{matrix} + NOF \rightarrow \begin{matrix} CF_3CF(NO)CF_3 \\ CF_2{-}CF{-}NO \\ CF_2{-}CF_2 \end{matrix}.$$

Potassium and caesium fluorides do not catalyse the reaction of nitrosyl fluoride with $CF_2{=}CF_2$ and $CF_2{=}CFCl$ in sulpholane; on the other hand, in the presence of Lewis acids, for example boron trifluoride, in sulpholane, the reaction mixture reacts under mild conditions, and in the case of $CF_2{=}CFCl$ it is possible to isolate in 30% yield α-chlorotetrafluoronitrosoethane $CF_3CFClNO$, whose formation is consistent with the polarity of the reactants[126]. In addition to the nitroso-alkane, a non-distillable oil is formed, probably a copolymer of $CF_3CFClNO$ and $CF_2{=}CFCl$. Only traces of $CF_3{-}CF_2NO$ can be obtained from $CF_2{=}CF_2$, the main reaction product being the copolymer of the two compounds.

Thus there is a reversal of the mechanism of the addition of nitrosyl fluoride in the following series: $CF_2{=}CF{-}O{-}R$; $CF_2{=}CH_2$; $CF_2{=}CHF$; $CF_2{=}CFCl$; $CF_2{=}CF_2$; $CF_2{=}CFCF_3$; $(CF_3)_2C{=}CF_2$; $CF_2{=}C(CF_3)COF$; $(CF_3)_2C{=}C{=}O$. The addition of nitrosyl fluoride to first members of this series, including tetrafluoroethylene, proceeds by an eletrophilic mechanism, and, starting with perfluoropropene, by a nucleophilic mechanism. The present review shows that a similar reversal of mechanism occurs also for a number of other reactions of fluoro-olefins but the present case is particularly interesting, since here we are dealing with the reversal of the mechanism of the addition of the same reagent.

A complete analogy can be drawn with the addition of hydrogen fluoride to fluoro-olefins discussed in Section II:

$$HF \rightleftarrows H^+ + F^-,$$

$$CF_2{=}CH_2 \xrightarrow{H^+} [CH_3CF_2^+] \xrightarrow{F^-} CH_3CF_3,$$

$$\begin{matrix} CF_3 \\ CF_3 \end{matrix}\!\!>\!C{=}CF_2 \xrightarrow{F^+} \left[\begin{matrix} CF_3 \\ CF_3 \end{matrix}\!\!>\!\overset{-}{C}{-}CF_3\right] \xrightarrow{H^+} (CF_3)_3CH.$$

THE PART PLAYED BY STRUCTURAL PHENOMENA IN DETERMINING THE PROPERTIES OF POLYMERS†

V.A.Kargin

We have all been accustomed to relating the properties of polymers in the first place to the chemical composition, structure, and dimensions of their molecules. The detection of structural formations in a wide variety of polymers, however, is making it necessary to devote increasing attention not only to the actual molecules of the polymers but also to their mutual arrangement and packing. The part played by these structural formations in determining the properties of polymers is often as great as in the case of metals, silicates, and other solids.

Despite the very great variety of morphological forms, it is now possible to distinguish the chief types of structural formation in polymers, in both crystalline and amorphous states.

The simplest type consists of the globular structures, formed by one or many polymer molecules, coiled up into spherical particles. This type of structure is characteristic of amorphous polymers in the vitreous state, although almost any polymer can be obtained in the form of amorphous globules. The formation of globules is accompanied by the loss of an appreciable number of the properties characteristic of linear molecules, and globular polymers are generally brittle and are broken by mechanical shock. Globular structures may also be present, infrequently, in elastic polymers. In this case the globules uncoil on deformation, and the polymers exhibit elastic properties, but have a reduced strength. Thus this type of structure does not favour good mechanical properties. Typical globular structures for polyacrylic acid, polyvinyl chloride, and fluorocarbon rubber are shown in Fig.1. The mechanism of formation of these structures

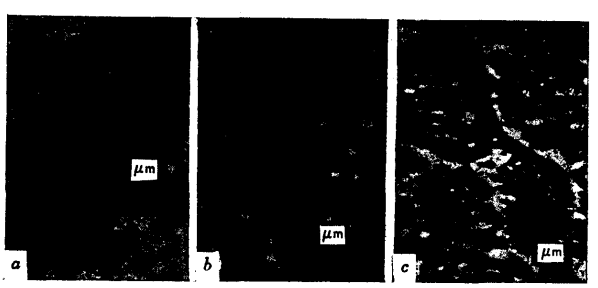

Fig.1. Globular structures: *a*) polyacrylic acid; *b*) polyvinyl chloride; *c*) SKF-26 fluorocarbon rubber.

† Paper presented at the International Symposium on the Chemistry of Macromolecules, Prague, 1965.

was the subject of a paper presented at the Symposium on Polymers in Wiesbaden and has been described in a number of papers[1-7].

Increased rigidity of the molecular chains or decreased intramolecular interaction produces a type of structure consisting of straight chains, which are, however, aggregated into bundles. These structural formations consist of tens or hundreds of chains and are the simplest structural units from which all subsequent types of structure are formed. In amorphous glasses, long thin bundles of chains may be formed, and these, as a result of subsequent aggregation, may form dendrites with regular shapes and very large dimensions of several hundred microns. This type of linear amorphous structure is illustrated in Fig. 2, which shows the sodium salt of polyacrylic acid and the bundles and dendrites of the copolymer formed by acrylic acid and diethyl vinylphosphonate[2,8].

In the elastic state in amorphous polymers, another very typical type of structure is produced — banded structures consisting of formations which now have much greater dimensions. These structures are characteristic of almost any polymer in the elastic state, but because of experimental difficulties they were detected only comparatively recently. Fig. 3 gives as examples the structures of natural rubber in the amorphous state, the copolymer of butadiene and styrene, and vinyl octanoate[9-11]. These banded structures are apparently secondary formations. When specimens are prepared for electron-microscope study at very low temperatures or in the initial stages of crystallisation, it is also possible to see the formation of the simplest fibrillar structures in rubbers (Fig. 4).

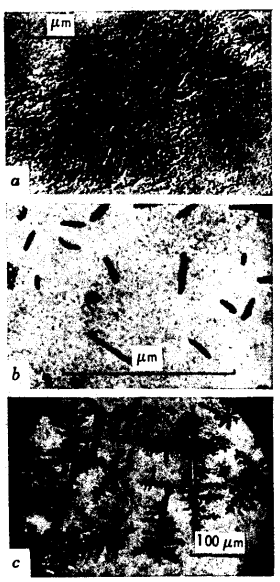

Fig. 2. Fibrillar structures of amorphous polymers:

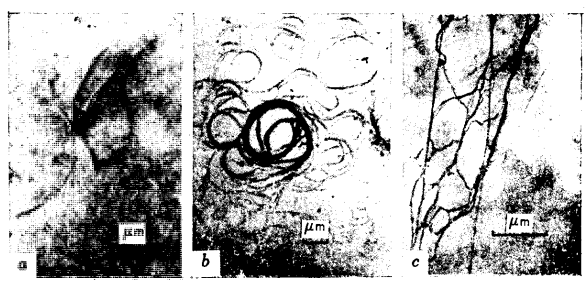

Fig. 5. Bundle-like structures in crystalline polymers:
a) polypropylene; *b*) polyamide copolymer; *c*) polyethylene.

As in amorphous polymers, the simplest structural formations in crystalline polymers are bundles of chains. Fig. 5 gives examples of such formations in polypropylene and a polyamide–polyethylene copolymer[12]. Further combination to give more complex formations may take place by two different mechanisms: the formations may combine by the familiar mechanism first discovered by Keller[13], to give planes which form spherulites and single crystals, or they may combine to give larger linear formations or fibrils which undergo further aggregation, again with the formation of spherulites and single crystals. Fig. 6 shows typical spherulites and crystals of lamellar type formed by isotactic polystyrene[14]. Formations of this type given by polystyrene have been well studied. Typical fibrillar formations are also illustrated in Fig. 7, which shows spherulites and crystals of polypropylene[15].

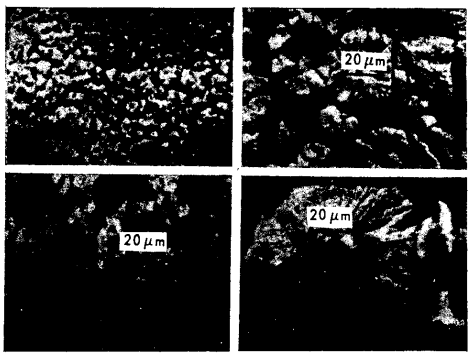

Fig. 9. Spherulitic structures of various dimensions in gutta-percha.

Thus among the great variety of structural forms in polymers, it is possible to distinguish clearly four basic types of structure: globular structures, usually produced in amorphous polymers obtained by polycondensation; banded structures, typical of all polymers in the elastic state (rubbers); fibrillar structures, characteristic of extensively ordered amorphous addition polymers and the initial stages of crystallisation; and finally the large structural formations in crystalline polymers — spherulites and crystals. The four characteristic types of polymer structure are illustrated in Fig. 8.[16]

It can now be confidently stated that the formation of globular and coarsely-crystalline structures has an unfavourable influence on the production of satisfactory mechanical properties. The coiling of linear chains into globules usually leads to the loss of elastic properties, and the mechanical heterogeneity of coarsely-crystalline polymers leads to the ready formation of cracks and to premature breakdown. The formation of simple fibrillar structures is always favourable. Banded structures have as yet been little studied, but they apparently occupy an intermediate position. Thus decrease in the dimensions of coarsely-crystalline formations and uncoiling of globules with conversion into linear formations should lead to an improvement in mechanical properties. The influence of the dimensions of the crystalline formations can be illustrated for the case of gutta-percha. The dimensions of the spherulites produced can be readily altered by altering the thermal conditions of crystallisation. Fig. 9 shows photomicrographs for gutta-percha specimens with spherulites of different dimensions, and Fig. 10 shows stress–tensile strain plots for the same specimens. It can be seen that merely by decreasing the dimensions of the spherulites it is possible to increase the tensile strength and elongation on rupture several times over[17-20].

By altering the conditions of the preparation, Slonimskii[21] was able to convert the globular form of the polyester of isophthalic acid and phenolphthalein into a fibrillar form, with a corresponding marked change in the mechanical properties. Fig. 11 and the Table give respectively

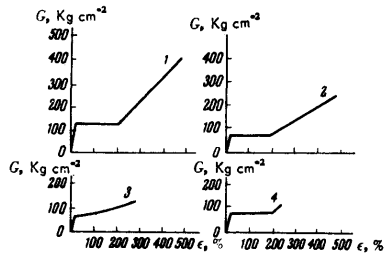

Fig. 10. Stress–tensile strain relations for the gutta-percha specimens whose structures are shown in Fig. 9.

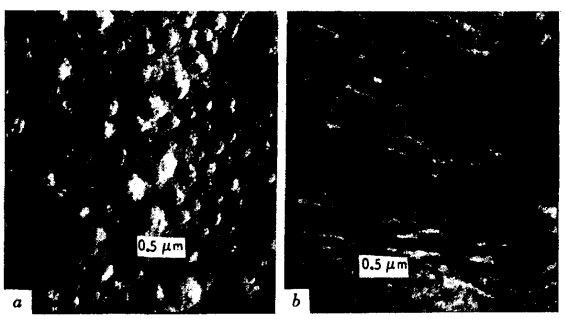

Fig. 11. Globular (*a*) and fibrillar (*b*) structures of the polyester formed by isophthalic acid and phenolphthalein.

TABLE. Properties of the polyester formed by isophthalic acid and phenolphthalein, with globular and fibrillar structures.

Property	Globular	Fibrillar	Property	Globular	Fibrillar
Molecular weight	28 000	28 000	Elongation at rupture, %	10—20	50—80
Softening temperature, °C	270	290	Specific impact strength,		
Tensile strength, Kg cm^{-2}	640	740	Kg cm cm^{-2}	2—3	6—10

photomicrographs of the structures and the mechanical characteristics of the linear and globular polyesters. These examples show that structure may have a considerable influence on mechanical properties and that it is important to be able to control the structure[17-21].

The simplest problem in this field is possibly the control of the dimensions of the coarsely-crystalline formations or spherulites. Spherulitic structures are typical of most readily-crystallising polymers, and there are now several examples of control of this type. Firstly, we have the introduction of synthetic crystallisation nuclei, which act as centres for the formation of spherulites. The greater the quantity of such centres introduced, the smaller will be the dimensions of each spherulite. The dimensions of the spherulites can also be altered by thermal treatment of melts to alter the number of natural nuclei. In this case, however, recrystallisation phenomena with consequent aging of the polymer material are possible. Synthetic nuclei make it possible not only to alter the dimensions of structural formations, but also to preserve them, with a consequent increase in the stability of the material[22-25].

As an example of the action of synthetic nuclei, Figs. 12 and 13 give respectively the structures and deformation curves for pure isotactic polystyrene and for polystyrene containing indigo particles to act as nuclei. Analogous behaviour is shown by many and possibly all crystallising polymers capable of forming structures having large dimensions[24].

It is also possible to alter the dimensions of the structural formations, and hence the properties, by introducing low-molecular compounds, which act as surface-active

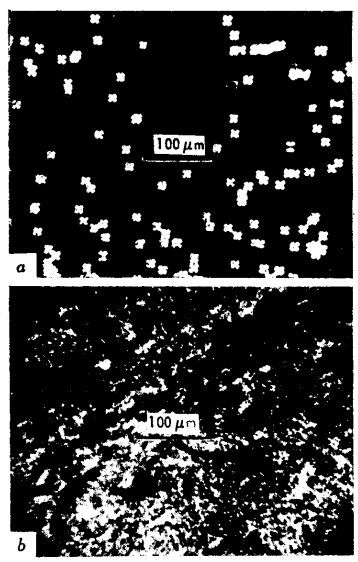

Fig. 12. Structure of specimens of isotactic polystyrene: *a*) pure; *b*) containing indigo.

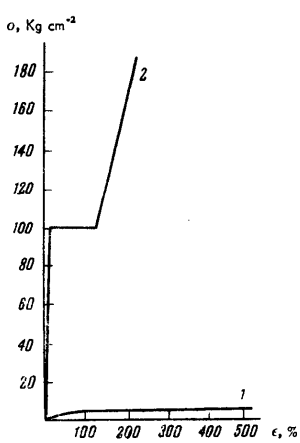

Fig. 13. Deformation curves for the elongation of specimens at 110°:
1) pure isotactic polystyrene; 2) isotactic polystyrene containing indigo.

substances. These are sorbed on the surface of the structural formations, and the dimensions and shapes of the latter are altered in a fashion analogous to that familiar for crystals of low-molecular substances. Fig. 14 gives photographs of the spherulites for nylon 66 with and without the addition of 1,4-dimesidinoanthraquinone. We see again the sharp change in structure, again accompanied by a change in properties[26]. It must be remembered, however, that low-molecular substances introduced into crystalline polymers may produce a quite different effect, particularly when added in comparatively large quantities. By distributing themselves over the interfaces between the simplest structural formations, for example bundles of chains or fibrils, they increase the mobility of the latter and lead to the development of brittle structures. Fig. 15 shows photographs of the structures of pure isotactic polystyrene and polystyrene containing 20 vol.% of cetyl chloride.

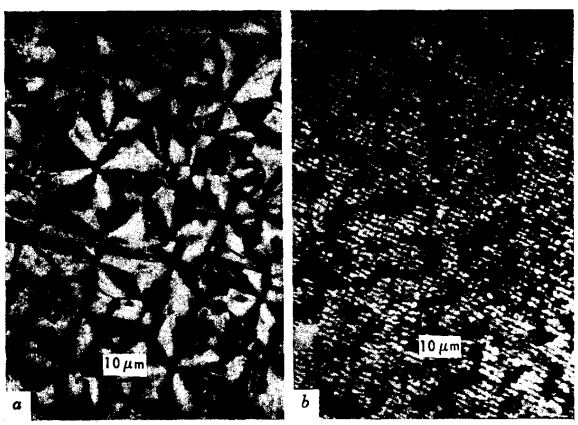

Fig. 14. Structure of nylon 66: *a*) pure; *b*) containing 1,4-dimesidinoanthraquinone.

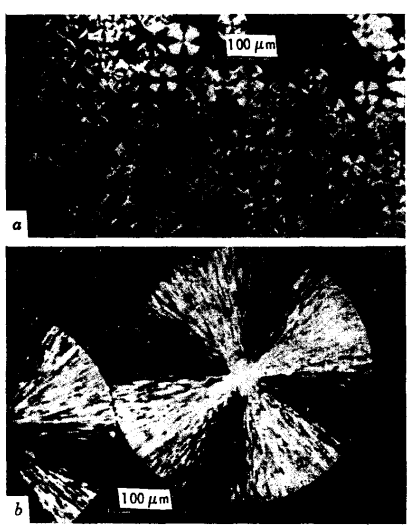

Fig. 15. Structure of isotactic polystyrene: *a*) pure; *b*) containing cetyl chloride.

Brittle spherulites are produced and the specimen becomes weak and brittle. This is why attempts to plasticise crystalline polymers by means of the usual plasticising agents often leads to the opposite of the expected results — the production of brittleness in the specimens being plasticised[27].

Mention may be made of the grafting of polymers as a means of controlling structures; this was described at the previous symposium in Paris[28]. The grafting of any other polymer generally hinders the formation of higher structures, whereas it does not prevent the development of simpler structures, more favourable for the production of the required mechanical properties. We shall not consider this question in more detail.

Up to the present we have dealt only with physical methods for influencing structure formation processes. Complete change from the most disordered structures to the most perfect structures can of course be achieved by changing the structure of the actual polymer chains, and this subject will be considered later in this paper.

Up to the present we have been discussing isotropic structures. In nature and technology, however, a very important part is played by anisotropic polymeric formations — fibres and fibrous materials. Most synthetic fibres are obtained by elongating originally isotropic or almost isotropic fibres. To trace the origin of oriented structures, it is extremely important to know whether relationships exist between the structure, and hence the properties, of oriented fibres and the structure of the original material from which the fibre is prepared by elongation. Orientation, particularly in crystalline polymers, usually takes place abruptly, with the production of so-called "necks". It was observed at an early date[29] that this process occurs as a phase transformation. It might be suggested that the production of a "neck" is accompanied by complete breakdown of the structures which existed in the isotropic polymer and the production of completely new structures in an oriented state. It was recently shown, however, that a direct relationship exists between the original structure and the structure produced on orientation. When a film of crystalline polymer exhibiting a spherulitic structure (for example polypropylene) is extended, the abrupt formation of an oriented polymer is readily observed. If observations are made of individual spherulites, it can be seen that they are preserved in the extended film. They are usually difficult to observe in fibres, since after elongation they become very long and fine, but they can sometimes be readily seen. Fig. 16 shows the conversion of a polypropylene spherulite into the oriented state[30]. It can be clearly seen that the spherulite is preserved after orientation. It can be shown that these elongated spherulites are only pseudomorphs; the interface between the spherulites is preserved, but not their internal structure. If, however, this oriented film is very carefully heated to a temperature several degrees below the melting point of the crystalline polymer, it contracts and returns almost completely to its original dimensions. In the process, the original spherulites are also restored. Thus the elongation of the spherulites, even when it takes place with the formation of a "neck", may be a reversible process. This phenomenon of the reversible deformation of large crystalline formations has been demonstrated for a number of materials and is apparently fairly common[17,31]. From this it follows that the simpler structural elements making up the spherulites or crystals remain unchanged during orientation and that, moreover, they may preserve

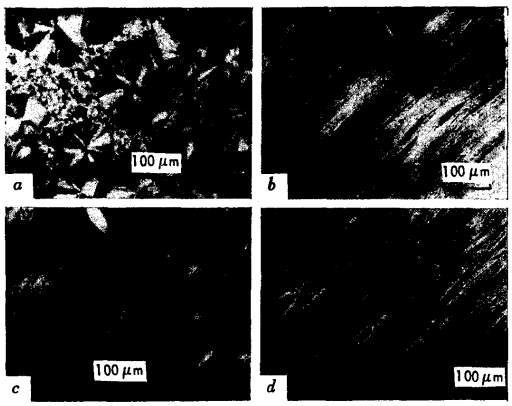

Fig. 16. Change in the structure of polypropylene during extension: *a*) original specimen; *b*)–*d*) extended films.

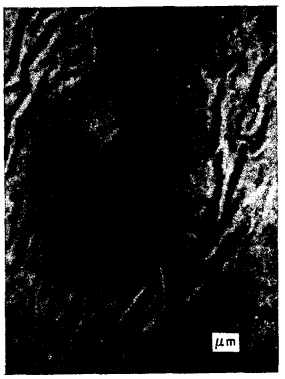

Fig. 17. Conversion of banded structures into crystalline fibrils in polychloroprene.

their mutual arrangement. This phenomenon indicates essentially that large reversible deformations may take place in crystalline polymers without fusion, merely as a result of mutual displacement of the bundles of chains or fibrils.

This phenomenon shows that a close relationship exists between the structures of fibres and the original isotropic materials, and that the structure of fibres begins to be formed even before their orientation. The influence of the structure of fibres on their mechanical properties has been studied for many years, but always on the assumption that the actual orientation process determines the complete structure of the oriented polymer. It is found that the structure of fibres begins to be formed much earlier, even in the isotropic state, and possibly even earlier in melts or solutions, or directly in the polymerisation process! The fact that the structure of oriented fibres influences their properties is generally accepted, and need not be mentioned further.

Thus the development of the properties of solid polymers is closely related to structure formation. This naturally leads to the question of the extent to which the phenomena of structure formation are encountered in elastic polymers and finally the question of where and how the structures begin to be formed — whether they are produced only in the solid state or begin to be produced in the melts or solutions or possibly directly in the processes of polymerisation and polycondensation.

Mention has already been made of the discovery of banded structures in typical rubbers. Similar structures have also been found to be typical of other polymers in the elastic state. The most perfect structural forms in elastomers can be observed only at low temperatures. In crystallising rubbers, however, it is possible to observe the complete change from banded structures to crystalline fibrils and large crystalline formations — spherulites and single crystals. This change has already been described for polybutylene[28]. The conversion of bands into crystalline fibrils is typical, and examples of this change are given in Fig. 17 for polychloroprene. It can be seen that crystallisation is not the original source of order in polymers, but that, on the contrary, ordering in the amorphous state is a necessary prerequisite for crystallisation, which is the last stage in the ordering process. We are thus faced with the question of how the properties of an elastomer change on going from the simplest banded structures to crystalline fibrils and then to spherulites and single crystals.

We are accustomed to the idea that crystallisation always leads to a decrease in elastic properties and to a decrease in elongation. Combined study of properties and structure shows, however, that the earliest stages in crystallisation do not always lead to a decrease in elongation. The production of well-formed fibrils apparently always leads to an increase in strength, and, for a small change in the modulus of elasticity, to an increase in elongation at rupture. We have the effect of "self-reinforcement" which is found in rigid polymers and was first observed clearly for polycarbonates[32,33]. The elastic properties are lost not when the crystalline fibrils are produced but only when the coarsely-crystalline structures — primarily spherulites — are formed. An example of the change from amorphous to crystalline structures is provided by the series of copolymers of ethylene with vinyl acetate. Pure polyethylene has a clearly defined spherulitic structure. The copolymer containing more than 25% of vinyl acetate is a typical amorphous elastomer with a banded structure. With increase in the concentration of vinyl acetate, the crystallinity of the copolymer decreases and the elongation increases, but the strength passes through a maximum. This maximum corresponds to a stage where the crystallinity of the copolymer is still high (Fig. 18). The structures of pure polyethylene and the completely amorphous copolymer, and the structure of the copolymer with maximum elongation, are shown in Fig. 19. The copolymer with maximum elongation shows a clearly defined fibrillar structure and is a transparent typical resilient elastomer.

So far these transitions have been little studied, but even now it can be stated that a definite degree of ordering is necessary for the production of effective mechanical properties in elastomers. The degree of ordering produced in amorphous banded structures is inadequate and a fundamental problem in the production of structures in rubbers is to increase the degree of ordering until well-defined fibrils are formed, both by the use of fillers and by stereospecific polymerisation and copolymerisation. Extremely characteristic phenomena are observed in thin polymer films. Fig. 20 shows the structure of isotactic

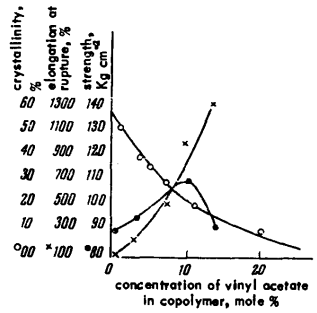

Fig. 18. Composition dependence of the properties of the copolymer of ethylene and vinyl acetate.

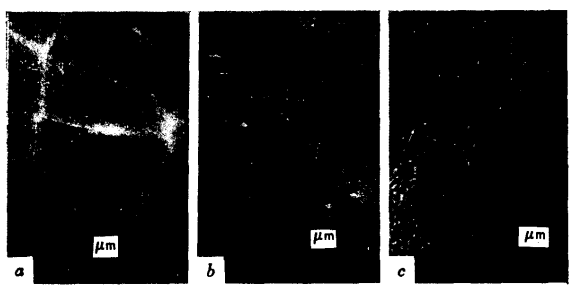

Fig. 19. Structures of pure polyethylene (*a*), the copolymer of ethylene and vinyl acetate at maximum elongation (*b*), and the amorphous copolymer of ethylene and vinly acetate (*c*).

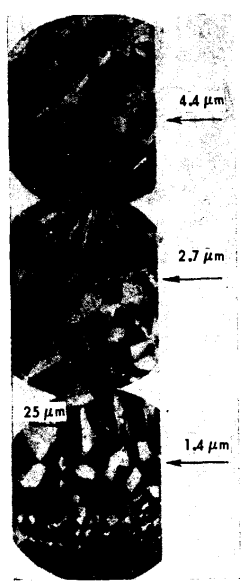

Fig. 20. Change in the structure of isotactic polypropylene with change in film thickness from 1.4 μm to 4.4 μm.

polypropylene in a layer of adhesive whose thickness is varied from several tenths of a micron to one micron. It can be seen that, with decrease in the thickness of the film, the dimensions of the spherulites at first increase, after which, when a definite critical thickness has been reached, they disappear and are replaced by fibrillar structures. Thus for a number of crystalline polymers at least[34], there exists a definite limit of thickness below which large crystalline formations cannot be produced. Thus in the thin polymer layers (produced on surfaces), with thicknesses of several microns, in foams, in reinforced systems, and in systems with high concentrations of fillers, either large or fibrillar structures may be produced depending on the thickness with corresponding consequences for the development of mechanical properties.

Thus detailed study has shown that structure formation is not exceptional but is a common phenomenon for all types of rigid and elastic polymers. It has also been shown that the influence of structures on mechanical properties is important and must always be taken into account.

Where does the formation of structures begin, however? In very dilute solutions polymers are probably present in the form of individual molecules. Similarly it may be confidently assumed that in melts at sufficiently high temperatures all the structures disappear and the polymer is converted into a system of disordered entangled molecules. The change from these infinitely dilute or molten systems to rigid structured polymers, however, may take place over a fairly wide range of temperatures and concentrations. Thus for each polymer it is necessary to estimate the concentrations or temperatures at which structures begin to be produced, since the start of structure formation corresponds to the start of the development of properties.

The fact that very rapid crystallisation takes place in a number of polymers indicates the existence of a fairly high degree of order in the melt. Papers presented at the previous Symposium in Prague gave information on the state of polymers in melts, based on electron diffraction studies[35,37] which showed the existence of a high degree of order in the arrangement of the polymer molecules. The existence of ordered structures in melts is also indicated by the adsorption properties[36] and by the fluidity of the melts[38,39]. Possibly the most graphic demonstration of the existence of structures in the melts is obtained by heating a coarsely-crystalline polymer above its melting point under the microscope and then cooling the melt. In this experiment the microscopic structure of the specimen being studied is very often completely restored. Photographs of polypropylene before and after fusion (with heating to a temperature 20 deg above the melting point) (Fig. 21) are almost indistinguishable. The same spherulites are produced at the same crystallisation centres. This "memory" is preserved in molten polypropylene on heating to a temperature 20–25 deg above its melting point. If the specimen is heated to higher temperatures, however, the number of nuclei gradually begins to decrease and the number of spherulites decreases, with a corresponding increase in their dimensions. Finally, after a definite temperature has been reached (for polypropylene this temperature lies 150–200 deg above the melting point) all traces of the original structures preserved in the melt disappear and the entire crystallisation picture changes sharply. The same polypropylene specimen, after being heated to 350°, has a finer spherulitic structure (Fig. 22). It can be seen how the foundations for the structures are

Fig. 21. Structure of polypropylene film before (*a*) and after (*b*) fusion.

Fig. 22. Structure of polypropylene film after fusion at 350°.

created in the melt and how the temperature conditions in the melt determine the structure and hence the properties of the polypropylene specimen. There is thus no doubt that structures exist in molten polymers although up to the present no one has been able to observe these structures directly.

Quite recently, however, it has been possible to observe directly the formation of structures in solutions. By using as solvents substances which show absolutely no tendency to crystallise and which form glasses on cooling, it is possible to obtain solutions of polymers in the vitreous state. It is highly probable that, when a solution is converted into a glass, it retains the structure which it had in the liquid state. By breaking the glass and taking a replica from the surface of the fracture, it is possible to study the structure of the solutions. The electron-microscope photographs of replicas obtained from 0.1% and 0.5% solutions of poly-α-butylene in vitreous rosin (Fig. 23) show the start of structure formation at a concentration of 0.1% and clearly defined structures at 0.5%.[40]

These results were confirmed by a different method. By dissolving a polymer in a solvent with a low critical point and heating the solution above the critical temperature, we

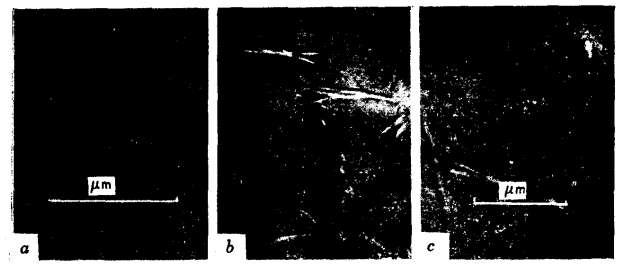

Fig. 23. Replicas from solutions of poly-α-butylene in vitreous rosin at concentrations of 0% (*a*), 0.5% (*b*), and 0.1% (*c*).

obtained a solution in a gas, with the same density as the original liquid. In this case also it may be assumed that the structure of the solution will not change significantly. If we break a heated ampoule containing such a solution in a vacuum, we expand the gas without the production of an interface and scatter the species present in the solution throughout the entire volume of the vessel. If we place at the foot of this vessel pieces of gauze with the thin carrier films usually employed in electron microscopy, we can collect these particles and examine them in the electron microscope. An example is provided by a solution of polybutylene in propane, heated to 115°. This experiment gave results completely analogous to those described above for vitreous solutions[41].

In the same way it is possible to follow the formation of globular structures in solutions. As noted above, almost any polymer can be obtained in the globular state from extremely dilute solutions. With increase in the concentration of solutions containing coiled molecules, however, aggregation of the molecules also begins. In the case of globular formations this leads to an increase in the dimensions of the globules, since the aggregating globules combine together to form larger globules containing not one but an appreciable number of polymer molecules. Rearrangement of the globules into linear structures may take place only at comparatively high concentrations. Fig. 24 shows photographs obtained for solutions of isotactic polyacrylic acid in liquid ammonia with a small quantity of water above the critical temperature. At a concentration of 0.05% each globule contains 1–4 polymer molecules, with increase in the concentration to 0.5% the number of molecules in each globule increases to between 9 and 70, and at a concentration of 1% the number of molecules in each globule increases to 120 and rearrangement to a linear structure begins.

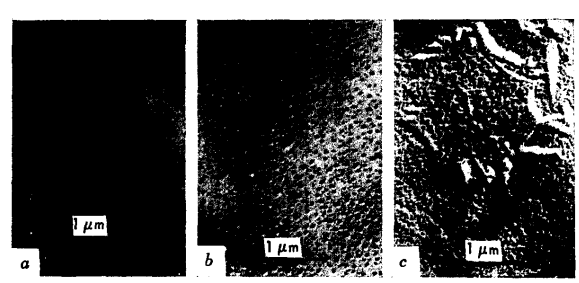

Fig. 24. Structure of isotactic polyacrylic acid in liquid ammonia solution at concentrations of 0.05% (*a*), 0.5% (*b*), and 1% (*c*).

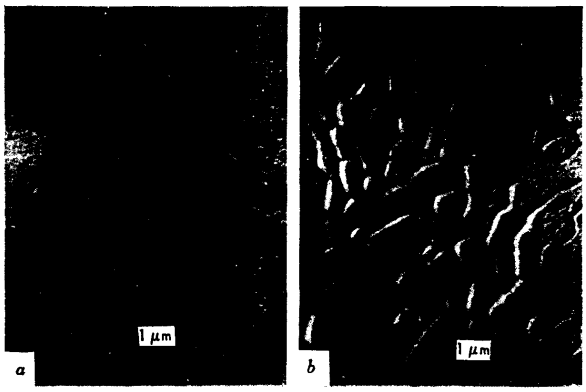

Fig. 25. Structure of polystyrenesulphonic acid in liquid ammonia solution at concentrations of 0.2% (*a*) and 1% (*b*).

Fig. 25 shows analogous photographs for polystyrenesulphonic acid; in 0.2% solution each globule contains between one and twenty molecules, whereas at a concentration of 1% the structure is completely fibrillar.

Thus these few results show that structures are produced in solutions at low concentrations and that concentrated solutions naturally contain structures which are extremely similar to the simplest types of structure found in solid polymers. Nucleation of the structures and hence the start of the development of properties takes place even in comparatively dilute solutions and hot melts.

It is also possible to make the more far-reaching assumption that structures may be produced directly in the polymerisation process. Several years ago the production of coarse fibrous structures was observed on the surface of heterogeneous catalysts during the polymerisation of ethylene and propene[42,43] and the polymerisation of a number of solid monomers[44]. When the temperature of the experiment exceeds the glass temperature of the polymer, however, there is always a danger of molecular rearrangement and the formation of structures as a result of secondary processes. The only polymerisation experiment free from criticism is one in which the monomer and polymer are solid and are at a temperature lower than the glass temperature. Such experiments were carried out recently by polymerising solid monomers directly in the electron microscope, where the electron beam itself initiated the polymerisation. The materials studied were phenylmethacrylamide, *p*-biphenylylmethacrylamide, and sodium acrylate. Fig. 26 shows electron-microscope photographs of polyphenylmethacrylamide and polybiphenylylmethacrylamide obtained by polymerising the solid monomers, and Fig. 27 shows an electron-microscope photograph of sodium polyacrylate obtained under the same conditions.

It can be seen that, instead of the continuous thin film which should have been obtained for regular polymerisation throughout the entire volume of the monomer, typical bundle-like structures are in fact produced, accompanied by a small number of globules. The actual polymerisation process is readily observed under the electron microscope and provides an example of the direct production of structures in the polymerisation process. It is as yet difficult to say anything regarding the extent of such phenomena, but it is now known that they are possible. If, however,

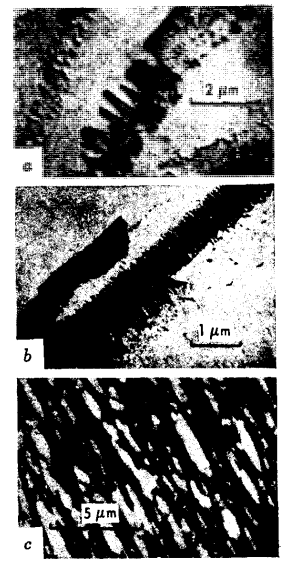

Fig. 26. Structures of polybiphenylylmethacrylamide (*a*) and polyphenylmethacrylamide (*b* and *c*) obtained by polymerisation of the solid monomers.

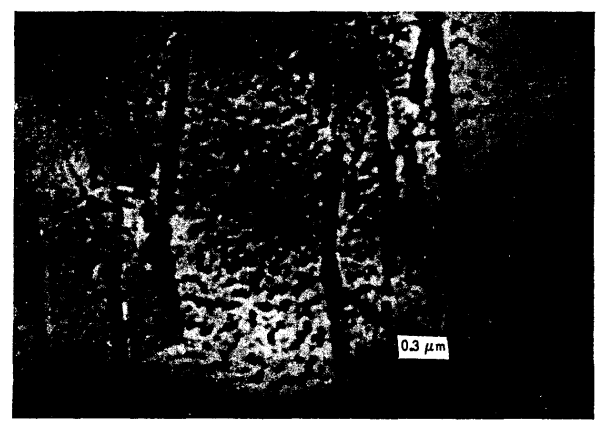

Fig. 27. Structure of sodium polyacrylate obtained by polymerisation of the solid monomer.

structures can be formed directly in the polymerisation process, this can and must influence the polymerisation process itself, particularly the free energy changes during polymerisation. The total free energy change is always equal to the sum of the free energies of conversion of the monomer into the polymeric molecules and the formation of structures from individual polymeric molecules. In most cases, when the heats of polymerisation are large and the polymerisation–depolymerisation equilibria are displaced towards very high temperatures, the free energy changes in structure formation are unimportant. When the heats of polymerisation are small, however, as for example in the polymerisation of rings, structure formation may play an important part and there may even be cases

where polymerisation becomes possible only when structure formation takes place. Several cases are known where polymerisation takes place only when the resulting polymer crystallises and does not take place when the polymer cannot crystallise (α-methylstyrene, α-pyrrolidone, and α-piperidone[45-47]. Crystallisation is most favourable for displacement of polymerisation–degradation equilibria towards polymerisation, but it may be assumed that very strong interaction between the chains and the formation of amorphous structures may be sufficient. Processes such as the polymerisation of nitriles may be possible only as a result of structure formation by the polymeric chains with conjugated double bonds[48].

We cannot deal in detail here with the part played by all structural phenomena in polymerisation and we would merely mention that structure formation also influences the kinetics of polymerisation, leading to the characteristic phenomena of autocatalysis[49], that phase transformations in solid monomers are responsible for very rapid polymerisation in the solid phase[50-54], and that polymerisation in complexes makes it possible to carry out a number of polymerisation processes which are not undergone by the pure monomers[55-59]. An equally important factor is the influence of the state of aggregation of the monomer on the structure of the resulting polymeric molecule. Thus in the polymerisation of diketen, initiated by metallic magnesium, two different isomeric forms of the polymer may be obtained, depending on the state of aggregation of the monomer. Polymerisation of solid monomer obtained by the joint condensation of the vapours of the monomer and metallic magnesium at a temperature several degrees below the melting point gives a polyether. Polymerisation at or above the melting point, however, gives a different isomer — a poly-β-diketone[60]. Similarly, acetaldehyde polymerised in the solid state in the presence of metallic magnesium, introduced into the monomer by joint condensation of the vapours, gives polyacetal. When the same system is polymerised above the melting point, polyvinyl alcohol is formed[61]. In both cases the difference between the polymerisation temperatures above and below the melting point amounts to only a few degrees. The formation of the different polymeric isomers is undoubtedly determined entirely by the state of aggregation of the monomer. Thus it is also necessary to make allowance for the part played by structural phenomena in the polymerisation stage, particularly in the case of polymerisation in the solid state and in those cases where structures are produced directly in the polymerisation process. The most general conclusion to be reached from the foregoing is that structures are extremely common in polymers of all types and that structures are produced at very early stages in the formation of solid polymers in solutions, in melts, and in the polymerisation process. If this is correct, polymers in most cases cannot be regarded as homogeneous systems like ordinary liquids. The occurrence of structure formation implies the existence of interfaces, differences in densities, and irregular distribution of mechanical stresses. This is related to the influence of the structures on mechanical properties. The heterogeneity of polymers should also influence their other properties, and particularly chemical reactions involving the polymers and the processes involved in the swelling and plasticising of polymers.

In fact, low-molecular substances introduced into a polymer may be distributed in different ways. The most usual result is regular distribution of the substance throughout the entire bulk of the polymer, corresponding to true dissolution of the low-molecular substance in the polymer. This leads to corresponding changes in mechanical properties and particularly to a decrease in the glass temperature, proportional to the mole fraction[62] or volume fraction[63] of the added plasticiser.

In polymers showing structure formation, however, another possibility arises. If the low-molecular substance (plasticiser) is insoluble in the polymer but wets it, it may be distributed along the interfaces between the structures, acting as a lubricant between them and thus increasing the mutual mobility of the individual elements of the structure. Very small quantities of plasticiser may then produce very marked effects, but at the same time saturation should take place rapidly and addition of excess plasticiser will not be accompanied by a further decrease in the glass temperature or modulus of the polymer. These phenomena, described as inter-bundle or inter-structural plasticising, have been detected particularly in cellulose esters[64-68]. Fig. 28 shows the dependence of the glass temperature of nitrocellulose on the concentration of various plasticising agents, introduced via the solution. For dibutyl phthalate, which shows unlimited solubility in nitrocellulose, the glass temperature decreases continuously with increase in concentration. Castor oil is insoluble in nitrocellulose, and its addition in very small quantities (see the upper right hand section of Fig. 28) leads to a sharp decrease of the glass temperature, but its effect rapidly reaches a limit beyond which no further change takes place (curve *2* in Fig. 28). We thus see two different types of plasticising — that by a soluble plasticising agent and that by an insoluble plasticising agent, which is distributed only at the interfaces between the structures. The effect of the insoluble plasticising agent is unusually pronounced — the addition of 0.1% produces the same effect as the addition of 10% of the soluble plasticising agent, but saturation takes place equally rapidly. An analogous situation is observed in the plasticising of acetylcellulose. Curve *1* in Fig. 29 illustrates the effect of the soluble plasticising agent 2-methyl-1-nitropropan-2-ol, and curve *3* illustrates the effect of the insoluble plasticising agent butyl stearate, which acts between the bundles. We can see the same typical effect of unusually small quantities of the inter-bundle plasticising agent, with rapid attainment of the limit at a concentration of only 0.05%. The sparingly soluble plasticising agent trimonochloroethyl phosphate occupies an intermediate position.

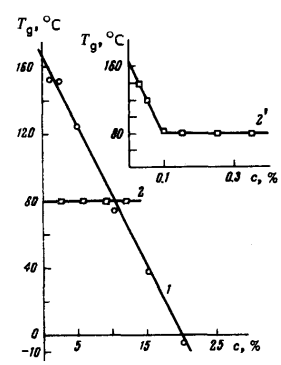

Fig. 28. Dependence of the glass temperature of nitrocellulose on the concentration of plasticiser added via the solution: 1) butyl phthalate; 2) and 2′) castor oil.

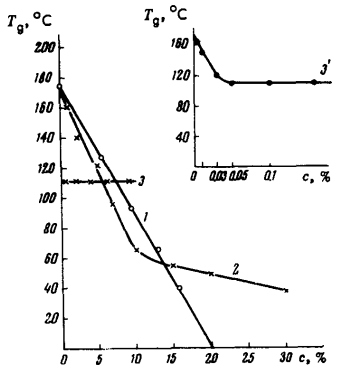

Fig. 29. Dependence of the glass temperature of cellulose triacetate on the concentration of the plasticiser:
1) 2-methyl-1-nitropropan-2-ol; 2) trimonochloroethyl phosphate; 3) and 3′) butyl stearate.

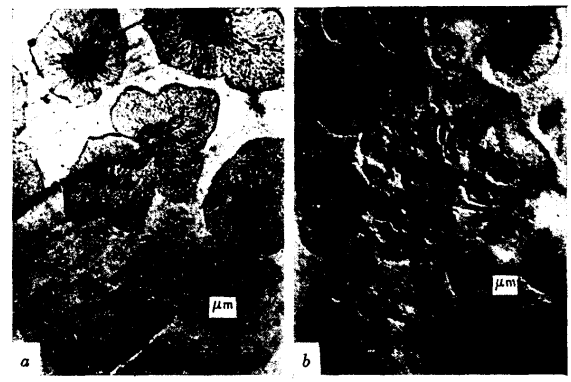

Fig. 30. Successive stages of structure formation in polychloroprene rubber vulcanisates broken down mechanically by rolling (*a* and *b*).

Analogous phenomena have recently been observed for other polymers[69-71].

We must not forget other effects associated with inter-structural plasticising. A small quantity of a low-molecular substance present at the interfaces increases the mobility of the structural formations and facilitates the production of higher supermolecular structures. This is not dangerous in the case of amorphous polymers, but in crystalline polymers it may lead to a sharp increase in the rate of recrystallisation with the formation of brittle structures, so that the result is not plasticising but the production of brittleness[72].

Chemical reactions in polymers also often take place similarly as in heterogeneous systems. A paper presented at the Symposium in Paris described structural phenomena observed in the production of graft polymers. The general conclusion was that the grafting process usually takes place not in the entire bulk of the polymer but only at the interfaces between the structural formations, and that the resulting graft polymers usually show the phenomena of "micro-layer formation", that is a change to heterogeneity[73].

Another example of a chemical process which takes place in polymers similarly as in heterogeneous systems is vulcanisation. It has for long been known that vulcanised rubbers from crystallisable raw rubbers retain the ability to undergo crystallisation. The explanation given was that crystallisation takes place only in small sections of the chains. It has recently been possible to show that rubbers vulcanised in the normal way retain not only their ability to undergo crystallisation but also their abilitiy to form higher structures, as far as the formation of single crystals. Fig. 30 shows the various successive stages of the ordering and crystallisation of polychloroprene, vulcanised by Tonox to a vulcanisation network frequency corresponding to the average production of one bond per 300 carbon atoms. The vulcanised specimens were rolled until the soluble state was attained, after which specimens for electron-microscope study were obtained from solution in carbon tetrachloride. It is obvious that even after vulcanisation the rubber still contained a sufficiently large number of unbranched chains and linear structural formations, without which the formation of large

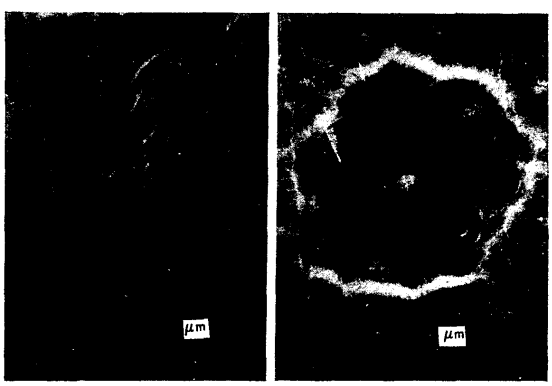

Fig. 31. Structures produced in polychloroprene rubber thermovulcanisates.

structures and single crystals is impossible. This takes place only when the vulcanisation bonds are distributed irregularly in the rubber, which is possible only in heterogeneous systems.

Fig. 31 illustrates analogous structure formation in polychloroprene heat-vulcanisates. Thus thermochemical decomposition also takes place irregularly throughout the entire bulk of the rubber[74,75].

A curious feature is that it is also possible to detect phenomena associated with the presence of structural formations in solutions in the study of chemical reactions involving polymers. In the chlorination of high-density polyethylene in carbon tetrachloride solution in the concentration range 0.1–0.5% at 115–125°, the chlorination product is divided into two fractions immediately after the solution is cooled — fractions soluble and insoluble in cold carbon tetrachloride. The concentrations of chlorine in these fractions differ by a factor of 2–3, the total chlorine concentrations being 14–22% for the soluble fraction and 4–8% for the insoluble fraction. This phenomenon persists up to 130°, after which a homogeneous product is formed, soluble or insoluble in chlorobenzene, depending on its chlorine content. A curious feature is that this

temperature is extremely close to the melting point of polyethylene crystals and evidently corresponds to complete breakdown of the structural formations in solution. The experiments were carried out by rapidly mixing solutions of polyethylene and a solution of chlorine in chlorobenzene, to avoid possible non-uniformity in the chlorination by the gas[76]. Analogous phenomena are observed in the chlorination of gutta-percha[18].

In this paper an attempt has been made to present basic data on the formation of structures in polymeric substances in all their states, on their nucleation, and on the part which they play in polymerisation processes, the development of mechanical properties, and their influence on the chemical behaviour of polymers. Structural phenomena must not now be regarded as exceptional but as an integral part of all processes leading to the development of the most important properties of polymers.

I. INTRODUCTION

Recently there has been extensive development of new polycondensation processes leading to the preparation of a number of hetero-chain polymers which include many compounds of great practical interest since these are substances with high thermal stability, interesting electrophysical properties, biological activity, etc. Among these processes mention must be made in particular of interfacial polycondensation, dehydropolycondensation, and especially oxidative dehydropolycondensation, and also the polyrecombination reaction, the polycyclisation reaction, and certain others.

For clarity we shall adopt the conventional definition of polycondensation as a process involving the formation of high-molecular-weight compounds in which in addition to the polymer a low-molecular-weight product is formed, most often water, hydrogen chloride, and similar substances. Because of this the elementary composition of the polymer formed differs from that of the initial monomer or the initial mixture of monomers.

In the general case the polycondensation reaction of two starting materials can be represented by the following equation:

$$x\text{a}-\text{A}-\text{a}+x\text{b}-\text{B}-\text{b}\rightarrow\text{a}-(-\text{AB}-)_x-\text{b}+2(x-1)\text{ab}$$

and in the case where both functional groups enter into the composition of the same initial molecule, the reaction equation is

$$x\text{a}-\text{A}-\text{b}\rightarrow\text{a}-(-\text{A}-)_x-\text{b}+(x-1)\text{ab}.$$

II. TYPES OF POLYCONDENSATION

We now know that, depending on the structure of the starting materials and the method of carrying out the reactions, polycondensation can be achieved in two different ways, namely: (1) as equilibrium polycondensation and (2) as non-equilibrium polycondensation. In addition there are probably certain reactions which exhibit the features of both types of polycondensation. Unfortunately reactions of this intermediate type have so far been little investigated.

A characteristic feature of equilibrium polycondensation is a low equilibrium constant. Very many examples of equilibrium polycondensation are known. Examples which have been particularly thoroughly investigated are the formation of polyamides or polyesters in the reactions, on heating, between dicarboxylic acids and diamines or glycols.

Equilibrium polycondensation constitutes a classical method of synthesising polymers which has been known for a long time. It has been studied thoroughly in many instances and its principal features have been established in a large number of investigations and have been described in reviews and monographs[1-9].

On the other hand, non-equilibrium polycondensation is a new process which was discovered relatively recently

and therefore it has so far been little investigated and its principal features are still the subject of study.

The present review represents a first attempt to examine the results obtained in the study of non-equilibrium processes and to elucidate the specific features of such reactions.

1. Non-Equilibrium Polycondensation

At the present time there are comparatively few cases of non-equilibrium polycondensation which have been investigated in detail. However, it is now possible to divide such reactions into two groups. The first group includes reactions which occur at a high rate under mild conditions, at low temperatures, where exchange interactions cannot occur. An example is the formation of polyamides or polyesters from the chlorides of dicarboxylic acids and diamines or dihydric phenols, which takes place very rapidly under conditions of interfacial polycondensation or in solutions.

The second group of non-equilibrium reactions includes cases of polycondensation which, although taking place fairly slowly at high temperatures, can nevertheless be classified as non-equilibrium polycondensation reactions because the polymers formed are very stable under the reaction conditions and are incapable of hydrolysis and other degradative conversions, such as, for example, interaction with the starting materials or the growing macromolecules. As a result of this stability of the macromolecules formed, degradative and other exchange processes are absent during the reaction, and this results in the irreversibility and the non-equilibrium nature of the process as a whole. Examples of such reactions are the formation of various polymers in dehydropolycondensation, polyrecombination, polycyclisation, and certain other processes, which will be examined below.

The chemical characteristics of the non-equilibrium polycondensation reactions enumerated above will be considered first.

2. Interfacial Polycondensation

Interfacial polycondensation, which was developed by Morgan[10], is carried out by mixing the reactants dissolved in two immiscible solvents, for example in water and in a hydrocarbon, hence its name: polycondensation at the interface between phases‡.

Interfacial polycondensation opens up new possibilities for the synthesis of many polymers, polyamides, polyesters, and many others and for this reason has greatly attracted the attention of investigators. In the synthesis of polyamides the reaction between the initial acid dichloride and the diamine proceeds according to the equation

$$x\mathrm{ClCOR'COCl} + x\mathrm{H_2NRNH_2} \rightarrow [\mathrm{—COR'CONHRNH—}]_x + 2x\mathrm{HCl}.$$

Interfacial polycondensation is based on the acylation of diamines or bisphenols with acyl or aryl chlorides in the presence of aqueous alkali. The principal feature of this reaction is the use of reactive starting materials such as the chlorides of dicarboxylic acids, which ensures a high reaction rate.

Interfacial polycondensation was studied in detail and reviewed by Frunze et al.[11]. Polymers are synthesised in this way in practice. Polycarbonates, polyamides, polyurethanes, polyarylates, and certain other high-molecular-weight compounds are obtained in this way.

When gaseous acid chlorides are used, there arises a new modification of this process, "gaseous polycondensation", which, as shown by Sokolov et al.[12], exhibits somewhat different features.

3. Polycondensation in Solution

A second variety of polycondensation processes which take place when the chlorides of dicarboxylic acid are used is polycondensation in solution which may be carried out both at low and elevated temperatures. The polycondensation of bisphenols with the chlorides of dicarboxylic acids in solution (with heating) was used successfully by Korshak and Vinogradova[13] for the synthesis of polyarylates (polyphenylene esters of aromatic dicarboxylic acids). High-boiling solvents are used (Dinile, ditolymethane, Sovol, α-chloronaphthalene, and others), which made it possible to lower the viscosity of the reaction mass and to obtain high-molecular-weight polyesters[14]. Kwolek and Morgan[15] showed that in low-temperature polycondensation in solution in chloroform and other organic solvents it is possible to obtain polyamides, polysulphonamides, polyesters, and polyurethanes, tertiary amines being sometimes used. In solution in dimethylacetamide, hexamethylphosphoramide, hexamethylphosphoramide etc. polypyromellitimides, polyoxadiazoles, and other polymers are obtained[41,43].

4. Dehydration Polycondensation

Homofunctional dehydration polycondensation of silanediols and silanetriols, leading to the formation of organosilicon polymers[16], is also a non-equilibrium reaction, which can be represented by the equation

$$\gtrless\mathrm{Si—OH} + \mathrm{HOSi}\lessgtr \longrightarrow \gtrless\mathrm{Si—O—Si}\lessgtr + \mathrm{H_2O}.$$

It goes to completion even in the presence of an excess of water, since the reverse reaction, involving the hydrolysis of siloxane bonds, does not take place at low temperatures[17]. Since this reaction is the main stage in the synthesis of polyorganosiloxanes by hydrolytic polycondensation, the entire process may be regarded as a non-equilibrium one. This is particularly so because in most cases the first stage is the non-equilibrium hydrolysis of the chlorine atom or other groups linked with the silicon atom.

The formation of polyethers or glycols, according to the equation

$$x\mathrm{HO—R—OH} \rightarrow (\mathrm{—OR—})_x + x\mathrm{H_2O},$$

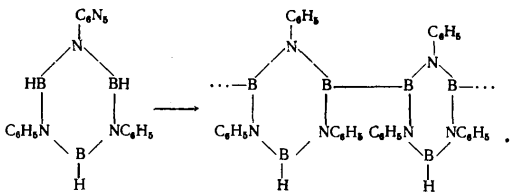
is also a case of non-equilibrium polycondensation.

5. Dehydropolycondensation

Yet another example of non-equilibrium polycondensation is dehydropolycondensation which has been used for the synthesis of high polymers only recently. Korshak

‡ The Russian author calls this type of polycondensation interphase polycondensation and refers to interfacial polycondensation as a second name for this process (Ed. of Translation).

et al.[18] showed that it may involve simple removal of hydrogen, as, for example, in the synthesis of organoboron polymers by heating *N*-triphenylborazole:



The most interesting example of reactions of this type is oxidative dehydropolycondensation which is based on the oxidation of hydrocarbons or their derivatives by oxygen or other oxidising agents and takes place with removal of hydrogen by the oxidising agent.

By oxidative dehydropolycondensation of acetylene in the presence of copper salts,

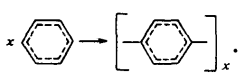
$$x\mathrm{HC{\equiv}CH} \longrightarrow [-\mathrm{C{\equiv}C}-]_x + x\mathrm{H_2O},$$

the present author obtained a new carbon polymer — "carbene".[9] The application of this reaction to diacetylene compounds of the type HC≡C–R–C≡CH enabled several investigators[20–23] to obtain a large number of linear polymers of a new type having the general formula

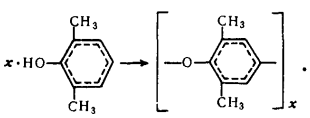
$$[-\mathrm{C{\equiv}C{-}R{-}C{\equiv}C}-]_x,$$

containing triple bonds in the chain together with phenyl and other groups.

Another example is the synthesis of polyphenylene by the oxidation of benzene in the presence of aluminium chloride and cuprous chloride, discovered by Kovacic and Kyriakis[24], which takes place as follows:



Fox and coworkers[25] showed that the oxidation of 2,6-dimethylphenol by atmospheric oxygen in the presence of a pyridine-copper complex involves a reaction leading to the formation of polyphenylene ethers:

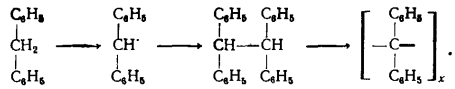


The polyethers obtained in this way are chemically stable and are of practical interest.

6. Polyrecombination

Another new example of non-equilibrium polycondensation reactions is polyrecombination. Recently increasing attention has been paid to the problem of synthesising polymers from substances which are not monomers in the strict sense of this term, i.e. they do not contain double bonds, rings, or other functional groups capable of entering into polymerisation or polycondensation reactions. One of the possible approaches to the solution of this problem involves the use of the polyrecombination reaction, discovered by Korshak et al.[26], as a result of which polymers can be obtained from a wide variety of classes of organic substances, such as saturated hydrocarbons, ethers, ketones, amines, phenols, nitriles, aldehydes, alcohols, "organoelemental" compounds, and many other substances incapable of being polymerised in the usual way[20,26–29].

Polyrecombination is a method of synthesising polymers, which in the case of diphenylmethane can be represented by the equation



The fundamental processes in polyrecombination are the formation and recombination of free radicals produced in the decomposition of t-butyl, benzoyl, and other acyl peroxides. A characteristic feature of the monomers used in polyrecombination is the presence of a labile hydrogen atom which can be readily removed by free radicals. If the monomers have two reactive hydrogen atoms, soluble products are obtained, and when there are three and more such atoms the products are insoluble three-dimensional polymers[27].

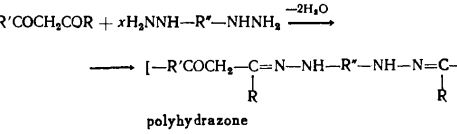
7. Polycyclisation

Polycyclisation is an extremely interesting new example of non-equilibrium polycondensation. It is a new type of reaction leading to the formation of polymers with a ring-chain structure which are interesting because they include a number of substances with exceptionally high thermal stability. Unfortunately at present there are as yet few data concerning the mechanism of the polycyclisation reaction, but those that are available suggest certain generalisations and make it possible to put forward a mechanism in a general, schematic form for these reactions, which appear to be two-stage processes.

The first stage is often an equilibrium reaction of the usual type, which takes place on heating of the reaction mixture and leads to the formation of polyamides, polyesters, polyhydrazones, and similar compounds, depending on the structure of the starting material. The features of this stage do not differ in general from those known for similar reactions. However, in many cases the first stage of this process can also be carried out in a non-equilibrium manner by interfacial polycondensation or reaction in solution.

The second stage involves the cyclisation itself, i.e. the closure of the heterocycle which is characteristic of this reaction. In most cases this stage constitutes true non-equilibrium polycondensation because it involves irreversible formation of stable aromatic rings.

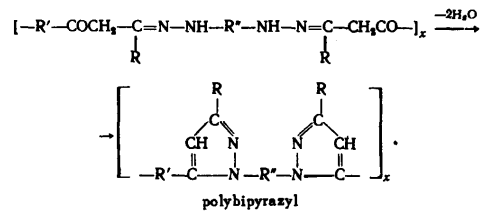
Thus in synthesis of polypyrazoles, obtained for the first time by Korshak et al.[30,31], the intermediate is a polyhydrazone formed in the reaction between bisdiketones and dihydrazines or dihydrazides which can be represented as follows:



polyhydrazone

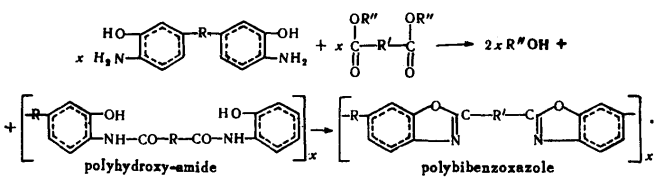
This stage is probably reversible, since condensation of dicarbonyl compounds with dihydrazines is known to be an

equilibrium process[32]. In the second stage the polyhydrazone is converted into a polypyrazole by the following reaction:



polybipyrazyl

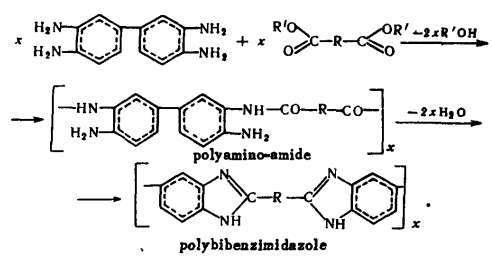
The same picture was established also in the synthesis of polybenzoxazoles obtained by a number of investigators[33-36,58]. The reaction involves the intermediate formation of polyhydroxy-amides formed from dihydroxy--diamines and dicarboxylic acid esters:



polyhydroxy-amide polybibenzoxazole

The polyhydroxy-amide formed in the first stage is unconverted by cyclisation into polybibenzoxazole. Both in this and the preceding case the reaction can be carried out with isolation of the intermediate product or can be taken at once to completion with preparation of the ring-chain polymer.

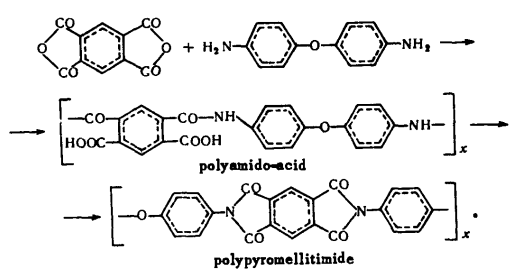
The formation of polybenzimidazoles, which has been investigated in detail by Marvel[37] and other investigators[36,38-40], probably involves the intermediate formation of a polyamino-amide:



polyamino-amide

polybibenzimidazole

The formation of polypyromellitimides takes place in the same way[41]:



polyamido-acid

polypyromellitimide

The polycyclisation process has undergone extensive development as a result of the work of Marvel[37] and other investigators and has led to the preparation of a large number of polymers incorporating in the chain heterocycles such as triazole[42], imidazole[36,37-40], pyrazole[30,31], oxadiazole[43-45], oxazole[33-36], triazine[46], thiazole[45], pyromellitimide[41], quinoxaline[47], and others.

Having examined the most important examples of non--equilibrium polycondensation, we shall now consider certain data concerning reactions of this type. The most important characteristics of equilibrium and non-equilibrium polycondensation are the presence of exchange reactions in the first case and their absence in the second, the effect of the excess of the reactants, and finally the fractional composition of the polymers formed. The available literature data on these problems will be examined below in the sequence indicated.

III. EXCHANGE REACTIONS

The significant difference between equilibrium and non--equilibrium polycondensation consists in the fact that in the first case exchange reactions take place between the growing polymer macromolecules and also between the latter and the starting materials or low-molecular-weight reaction products (water and others). For this reason, the macromolecules formed in the equilibrium process change during its course, which is reflected in the first place in the fractional composition (polydispersity) of the polymer, while in a non-equilibrium reaction exchange processes do not occur and therefore the distribution of the polymers formed with respect to molecular weight is different.

At temperatures normally used for equilibrium polycondensation, exchange reactions between individual macromolecules play a considerable role. This has been demonstrated in a number of cases. Thus on heating of two specimens of different polyamides there is a gradual change in melting point; for example, Fig. 1 shows the change in melting point when a mixture of polyhexamethyleneadipamide and polyhexamethyleneisophthalamide is heated[48].

The melting point of the mixture falls until the melting point of the corresponding copolymer, a mixed polyamide is reached. The mixture of the two homopolymers is converted into the copolymer via a block-copolymer stage which exists for a limited period. Fig. 2 shows the variation of the content of these three products in the reaction medium in the course of the process[49].

These reactions also take place when mixtures of polymers as different as polyamides and polyesters are heated.

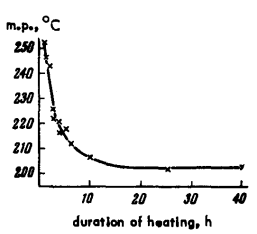


Fig. 1. Variation of the melting point of a mixture of polyhexamethyleneadipamide and polyhexamethyleneisophthalamide as a function of the duration of heating.

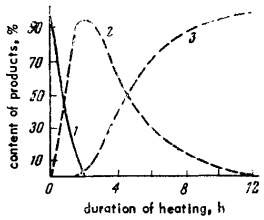

Fig.2. Variation of the content of the homopolymer (curve 1), block-copolymer (curve 2), and mixed polyamide (curve 3) with the duration of heating of a mixture of homopolyamides.

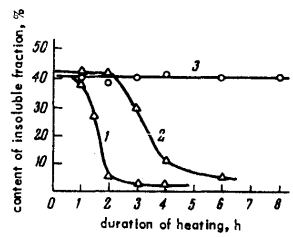

Fig.3. Variation of the content of the benzene--insoluble fraction with the duration of heating of a mixture of polyhexamethylenesebacamide and polyhexamethylenesebacate at various temperatures: 1) 290°; 2) 280°; 3) 260°.

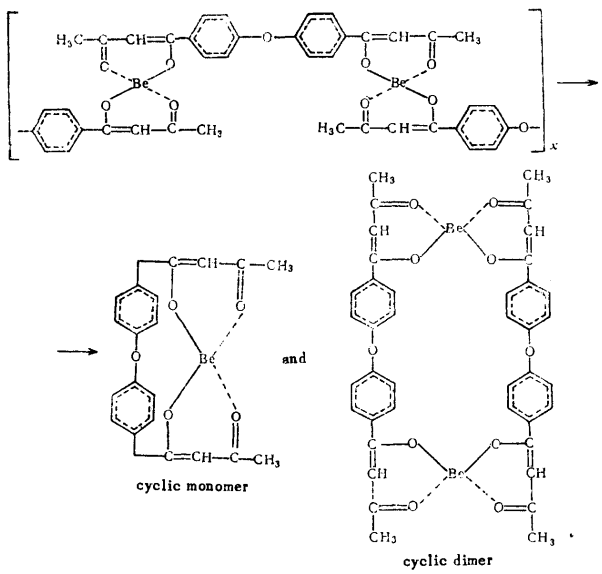
At a temperature in excess of 280°, and in the presence of catalysts even at 260°, a mixture of polyamide and polyester is converted into the copolymer, polyamido-ester, the process being accompanied by a change in melting point and solubility of the mixture of the starting polymers[50].

Fig.3 shows the variation of the content of the benzene--insoluble fraction when a mixture of polyhexamethylenesebacamide and polyhexamethylenesebacate is heated at various temperatures. It is seen that at 280° and above vigorous exchange reactions take place and result in the formation of benzene-soluble polyamido-ester and the disappearance of the insoluble polyhexamethylenesebacamide.

Exchange reactions take place particularly readily in coordination polymers of the chelate type. When a mixture of two coordination polymers of different molecular weights is heated, exchange takes place and results in the molecular weight being averaged out[51]. These polymers have been found to undergo an unusual exchange reaction — exchange of one metal for another. Thus when copper acetylacetonate acts upon the chelate polymer of beryllium, the latter metal is displaced and a chelate polymer of copper is formed[49]. Exchange reactions can occur very readily in chelate polymers, particularly in dilute solutions.

Korshak et al.[51,52] found that only brief heating of a dilute solution of the polymer is sufficient for complete degradation, resulting in the conversion of the polymer into cyclo-oligomers:



When these cyclic oligomers are heated in more concentrated solutions, they are reconverted into the initial polymer. Thus here we encounter for the first time an example of a reaction involving total reversibility of the ring–polymer conversion, the equilibrium position of which depends on the concentration of the solution. The examples of exchange reactions quoted for various polymers clearly demonstrate this feature of the equilibrium polycondensation process.

On the other hand, the products formed in a non-equilibrium polycondensation reaction, under conditions ensuring their formation, are quite incapable of undergoing exchange processes. This applies both to synthesis of polymers under the mild conditions of interfacial polycondensation and to the synthesis of polymers at high temperatures under severe conditions in the case of the polycyclisation and polyrecombination reactions.

Thus on heating a mixture of products obtained by polycyclisation, exchange reactions do not occur. Korshak et al.[42] showed that, after heating for 20 h at 270° a mixture of two poly-4-amino-1,2,4-triazoles, obtained by the polycondensation of hydrazine with adipic acid in one case and with sebacic acid in the other, it is possible to isolate unchanged the initial polymers, which indicates the absence of exchange reactions between their macromolecules. Mixed poly-4-amino-1,2,4-triazoles could be obtained only by the polycondensation of the initial monomer, i.e. hydrazine, with a mixture of the two dicarboxylic acids[42].

IV. THE RULE OF THE NON-EQUIVALENCE OF FUNCTIONAL GROUPS

The molecular weight of polymers obtained by polycondensation is determined in the first place by the relative proportions of the starting materials when the reaction takes place between two different components. In this case the *"rule of the non-equivalence of functional groups"* operates, according to which the excess of one of the starting materials, provided that it is not removed

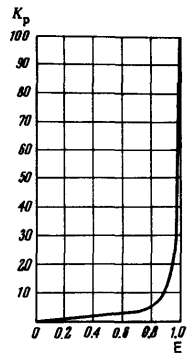


Fig. 4. Variation of the polymerisation coefficient (K_p) with the equivalence coefficient (E).

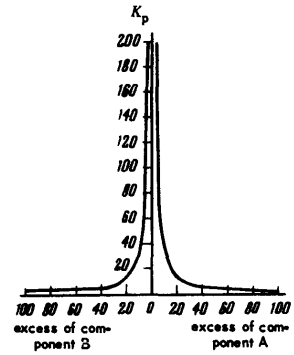

Fig. 5. Variation of the limiting value of the polymerisation coefficient (K_p) with the excess of one of the starting materials (mole %).

during the reaction, lowers the molecular weight to an extent proportional to the degree of this excess.

If the reaction is represented in the general form

$$xa - A - a + (x+1)b - B - b \rightarrow b - B - [-A - B -]_x b + 2xab$$

the equivalence coefficient, characterising this relation, can be expressed as follows[53]:

$$E = \frac{x}{x+1}$$

Fig. 4 shows graphically the relation between the equivalence coefficient and the polymerisation coefficient for the polymer being formed. It is readily seen that the closer are the relative amounts of the starting materials to equivalent proportions the higher is the polymerisation coefficient of the polymer.

The existence of a definite relation between the excess of one of the starting materials and the size of the molecule of the polymer formed leads to the following expression[54]:

$$K_p = \frac{100}{q},$$

where K_p is the polymerisation coefficient and q the excess of one of the substances expressed in mole per cent. We may note that this excess plays an additional role in equilibrium polycondensation. It causes the degradation of the growing chains and influences the polydispersity of the polymer, decreasing it.

This relation between the polymerisation coefficient and the amount of the excess component is represented graphically by two branches of a hyperbola (Fig. 5).

The validity of this relation for all the cases of equilibrium polycondensation investigated has been demonstrated for a large number of examples[55]. This relation holds also in non-equilibrium polycondensation, as can be seen from Fig. 6, where the results obtained in the synthesis of poly-2,2′-(octamethylene)-5,5′-dibenzimidazole in the presence of an excess of one of the initial substances[40], are plotted. Here the presence of an excess of each of the starting materials, i.e. both tetramine and the dicarboxylic acid ester, also results in a lowering of the molecular weight of the polymer obtained.

In practice a cessation of the growth of the molecular weight is observed at comparatively early polycondensation

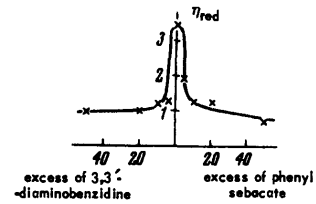

Fig. 6. Variation of the reduced viscosity of a solution of polybenzimidazole with the ratio of the starting materials (mole %).

stages, which leads to a departure of the curve from the theoretical form shown in Fig. 5. This can be explained by the presence of a number of side-reactions and also by the fact that usually all the functional groups are not completely utilised in polycondensation. For this reason, the relation between the molecular weight and the excess of the starting materials observed in practice has the form shown in Fig. 7.[55]

The presence in the reaction mass of monofunctional compounds of a similar chemical type exhibits the same effect as the excess of the starting materials. This behaviour was observed earlier for a large number of examples of equilibrium polycondensation reactions and has been found also in non-equilibrium polycondensation. Fig. 8

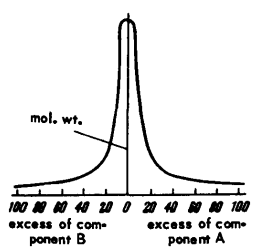

Fig. 7. A schematic representation of the experimentally observed relation between the molecular weight and the excess of the starting material (mole %).

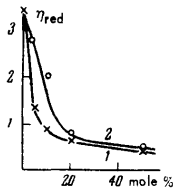

Fig. 8. Variation of the reduced viscosity of polybenzimidazole with the amount of added monofunctional reagent:
1) stearic acid; 2) α-naphthylamine.

shows the effect of added monocarboxylic acid or monoamine on the molecular weight of the polybenzimidazole formed[40].

A similar relation holds also in other cases. For example, in interfacial polycondensation of hexamethylenediamine with the chloride of adipic acid the molecular weight of the polyamide formed decreases in proportion to the amount of added butyryl chloride[11] (Fig. 9).

The same effect is observed when butylamine is introduced into this reaction, as shown in Fig. 10.

In the polycondensation of dian§ with the chloride of isophthalic acid the addition of benzoyl chloride or phenol also causes a corresponding decrease of the molecular weight[11]. This is shown in Figs. 11 and 12.

The present author observed a relation between the molecular weight of the polymer formed and the amount of peroxide used in a polyrecombination reaction[27]. Fig. 13

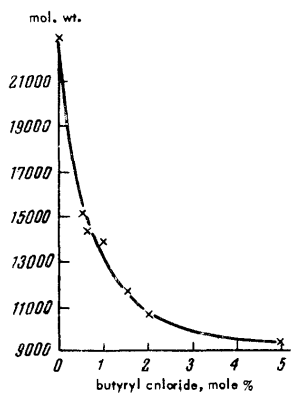

Fig. 9. Variation of the molecular weight of polyamide with the amount of added butyryl chloride.

§ Bis-(p-hydroxyphenyl)dimethylmethane (Ed. of Translation).

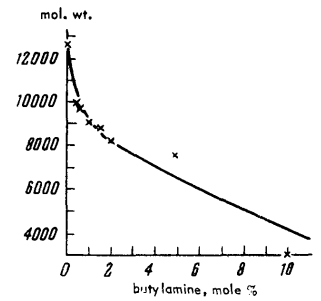

Fig. 10. Variation of the molecular weight of polyamide with the amount of added n-butylamine.

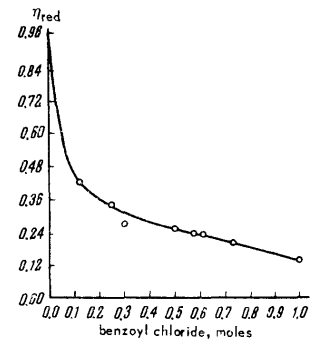

Fig. 11. Variation of the reduced viscosity of polyarylate with the amount of added benzoyl chloride.

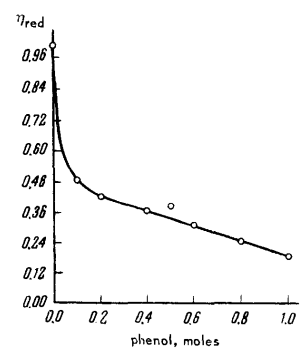

Fig. 12. Variation of the reduced viscosity of polyarylate with the amount of added phenol.

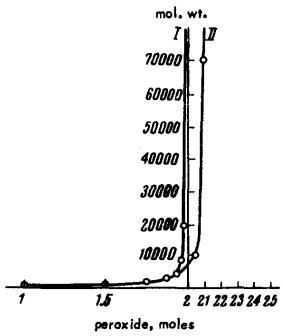

Fig. 13. Variation of the molecular weight of polydiphenylmethylene with the peroxide : : hydrocarbon ratio.

shows the calculated and observed relations between the molecular weight of polydiphenylmethylene and the amount of peroxide used for the polyrecombination. It is seen that the maximum molecular weight is attained when about two moles of peroxide are consumed per mole of the initial hydrocarbon.

V. MOLECULAR WEIGHT DISTRIBUTION OF POLYMERS

Polymers synthesised by non-equilibrium polycondensation exhibit a wider molecular weight distribution than polymers obtained by equilibrium methods. Thus in the case of polyarylates prepared by interfacial polycondensation or reactions in solution at an elevated temperature it was found that the former show a wider distribution than the latter. To account for this difference, it may be pointed out that the polydispersity coefficient M_w/M_n for the former is about 1.5 and for the latter about 2.0. The Table presents data obtained in a study of the molecular weight distribution of polyarylate specimens prepared by the polycondensation of isophthalic acid chloride with two bisphenols under different conditions[56].

We may point out here that polycondensation at an elevated temperature is probably of an intermediate type, since in this case there is no reverse degradative reaction between the polymer and hydrogen chloride but there is a degradative reaction between the polymer formed and the initial bisphenol. Polyesters formed in equilibrium polycondensation show a smaller polydispersity.

The Table shows that the molecular weight distribution of the polyarylates prepared by interfacial polycondensation approaches that predicted by the theory put forward by Flory[1]. Polyamides were found to show a considerable difference in the polydispersity of the products obtained by interfacial condensation and at high temperatures.

Fig. 14 shows curves characterising the fractional composition of polyhexamethylenesebacamide obtained by the interfacial process and poly-ϵ-caproamide obtained in the melt[57]. The much wider molecular weight distribution of the interfacial polycondensation products is clearly evident.

Study of the polymers prepared by polyrecombination showed that they are distinguished by an even greater degree of polydispersity.

TABLE. The polydispersity coefficients of the polyarylates obtained by various methods from isophthalic acid and diols.

Polyarylate based on	Polycondensation in solution		Interfacial polycondensation	
	M_w/M_n from fractionation	degree of completion of reaction	M_w/M_n from fractionation	degree of completion of reaction
bis-(4-Hydroxyphenyl)methane	1.52	0.9795	2.03	0.9934
2,2-bis-(4-Hydroxyphenyl)-propane	1.68	0.9845	2.06	0.9810
ditto	1.60	0.9818	2.03	0.9855

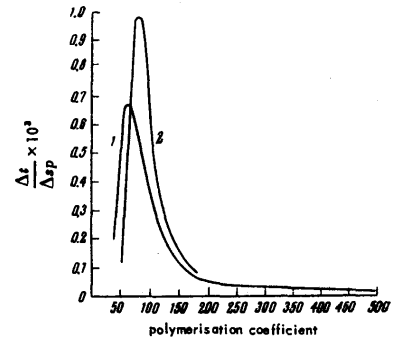

Fig. 14. Fractional composition of polyhexamethylenesebacamide (curve 1), obtained by interfacial polycondensation, and poly-ϵ-caproamide (curve 2).

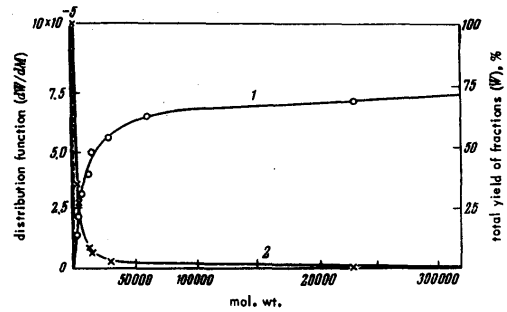

Fig. 15. Molecular weight distribution of polydiphenylmethylene: 1) integral curve; 2) differential curve.

Fig. 15 shows that the molecular weight distribution of polydiphenylmethylene is very wide[29]. The polydispersity coefficient calculated for this polymer proved to be 43. Hence it resembles in this respect high-pressure polyethylene which exhibits a very wide molecular weight distribution.

In conclusion, we may note that examination of the available data makes it possible to elucidate a number of specific features distinguishing non-equilibrium polycondensation. On the basis of the results discussed, we may

conclude that a new field of polycondensation reactions, non-equilibrium polycondensation, has arisen, whose further development and study will permit an even more extensive application of this new method of synthesis of polymers.

ALKYLATION OF CYCLOALKANES, OXACYCLOALKANES, AND ARALKANES

N.I.Shuikin and B.L.Lebedev

CONTENTS

1. Introduction 448

2. Alkylation of cycloalkanes in the presence of acid catalysts 448

3. Alkylation of aralkanes in the presence of basic catalysts 450

4. Thermal and initiated alkylation of cycloalkanes, oxacycloalkanes, and aralkanes 451

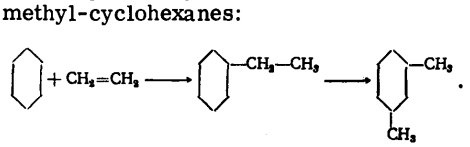
1. INTRODUCTION

Advances in the chemistry of fuel are closely connected with the development of studies in the field of alkylation. Beginning with the middle of the nineteenth century, work on the alkylation of aromatic hydrocarbons became widely known. The search for new methods of synthesis of high-octane components led to the discovery of alkane alkylation reactions. The extensive experimental data in this field have been described systematically in a number of reviews.

Comparatively recently new fields of application of the alkylation reaction have been discovered. This reaction has been extended to the alkylation of cycloalkanes, cyclic ethers (oxacycloalkanes), and the side-chain of aliphatic-aromatic hydrocarbons (aralkanes).

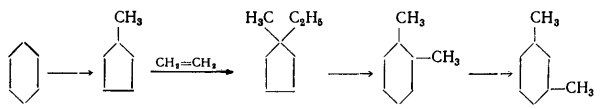
2. ALKYLATION OF CYCLOALKANES IN THE PRESENCE OF ACID CATALYSTS

In the presence of acid catalysts the composition of the alkylation products depends on the structure of the cycloalkane and the nature of the catalyst. When cyclohexane is alkylated with ethylene in the presence of aluminium chloride at 50–75°, a mixture containing 1,3-dimethylcyclohexane, tetramethylcyclohexane, and hexaethylbenzene was obtained[1] instead of the expected ethylcyclohexane. In Ipatieff's view, the absence of the direct alkylation products, ethylcyclohexane and diethylcyclohexane, can be explained by their isomerisation to dimethyl- and tetramethyl-cyclohexanes:



This hypothesis is consistent with the data of Grignard[2], who showed that in the presence of aluminium chloride, ethylcyclohexane indeed isomerises to dimethylcyclohexane. The presence of hexaethylbenzene in the catalytic reaction mixture proves the intermediate formation of hexaethylcyclohexane, which is then dehydrogenated under the reaction conditions[3].

Schmerling[4] holds a different view. He believes that the alkylation process is preceded by the isomerisation of cyclohexane to methylcyclopentane after which the alkene adds to the tertiary carbon atom:



This mechanism is supported by the fact that, in the presence of boron trifluoride, cyclohexane does not react with ethylene, since, unlike aluminium chloride, boron trifluoride does not cause the isomerisation of cyclohexane to methylcyclopentane under the alkylation conditions. The formation of hexaethylbenzene is explained by the dehydrogenation of cyclohexane and subsequent alkylation of benzene.

In the alkylation of cyclohexane with propene[5] in the presence of aluminium chloride at 10–45° polymethylated cyclohexane, dicyclohexyl, alkylated dicyclohexyl, and 2,6-dimethyldecalin are formed in the catalytic reaction mixture[6]. The propylcyclohexane formed in the alkylation of cyclohexane isomerises to polymethylated cyclohexane. The alkylation of cyclohexane with isobutene proceeds with more difficulty, since under the reaction conditions the latter tends to polymerise[5]. In the reaction between cyclohexane and di-isobutene in the presence of aluminium chloride, alkylated cyclohexanes boiling in the range 170–250° were obtained[7].

After passing a mixture of cyclohexane and ethylene over Ni/Al_2O_3 at 300°, 5% of toluene was isolated from the reaction mixture[8]. According to Komarewsky, cyclic hydrocarbons are not alkylated under the conditions described. The formation of toluene is explained by the dehydrogenation of cyclohexane to benzene[9], the alkylation of the latter with ethylene to ethylbenzene, and the decomposition of ethylbenzene with formation of toluene and methane[10].

When an equimolar mixture of cyclohexane and ethylene is passed over Cr_2O_3/Al_2O_3 at 475°, ethylbenzene is formed[11].

In the presence of sulphuric acid, neither cyclopentane nor cyclohexane react with alkenes[12,13].

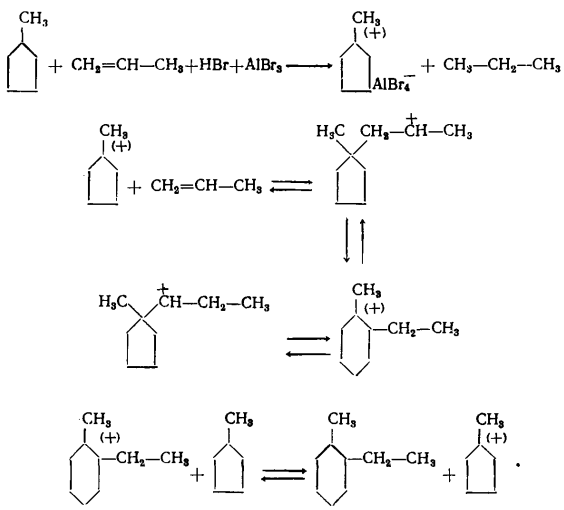
A number of patents[14-16] describe the alkylation of cycloalkanes with alkenes in the presence of mercaptans and a small amount of oxygen. The process is carried out at 300–450° and a pressure of 150–175 atm. The effects of pressure, component ratio, and various promoting agents have been investigated. Under optimum conditions the degree of reaction of the alkenes reaches 79%.

It is also recommended that cycloalkanes be alkylated in the presence of phosphoric acid on carriers[17] and catalysts based on hydrofluoric acid and alkali metal fluorides[18,19]. Ipatieff and Grosse[20] patented a method of alkylating three- and four-membered cycloalkanes with propene and butene in the presence of sulphuric and phosphoric acids, zirconium chloride, boron trifluoride, and activated clay. According to Levitt's data, the reaction of cyclopropane with t-butyl chloride in the presence of aluminium chloride results in the formation of a mixture of products having the composition $C_7H_{15}Cl$.[21,22]

In the presence of acid catalysts six-membered alkylcycloalkanes react with alkenes more readily than the unsubstituted compounds, forming the corresponding dialkylcycloalkanes. In the alkylation of alkylcyclopentanes the ring isomerises to a six-membered ring, and products of direct alkylation are not observed in the alkylation mixture.

According to the data of Ipatieff et al.[23], ethylene reacts with methylcyclohexane and methylisopropylcyclohexane in the presence of aluminium chloride (70°, 15 atm) and also with methylcyclohexane and methylcyclopentane in the presence of boron trifluoride (30°, 15 atm).

The alkylation of methylcyclopentane with propene in the presence of aluminium bromide at -42° was studied by Pines and Ipatieff[24]. Alkylated cyclohexane with the composition C_9H_{18} and other hydrocarbons with the composition $C_{12}H_{22}$ were isolated. The hydrocarbon C_9H_{18} proved to be 1-ethyl-2-methylcyclohexane, which is formed by the following mechanism:



The structures of 1-cyclohexyl-3-methylcyclopentane and 1-cyclohexyl-2-methylcyclopentane were attributed to the hydrocarbons with the composition $C_{12}H_{22}$. However, in later studies it was shown that these hydrocarbons consist of a mixture of 2,3- and 2,6-dimethyldecalins[25,26].

In 1944 Pines and Ipatieff patented a method of alkylating methylcyclopentane with propene in the presence of phosphoric acid at 100–400°[27] or boron trifluoride promoted by hydrofluoric acid at 30–50°.[28]

In the alkylation of methylcyclopentane with butenes, pentenes, and octenes in the presence of sulphuric and hydrofluoric acids, direct alkylation products could not be detected in the catalytic reaction mixture[29-31]. The authors of these studies explained their results by postulating that the main reaction is accompanied by a number of side-processes, such as the expansion of five-membered rings, dehydrogenation of cycloalkanes and hydrogenation of alkenes, isomerisation of alkenes with subsequent hydrogenation to isoalkanes, depolymerisation and dealkylation, and dehydrogenation of cycloalkanes with formation of polycyclic hydrocarbons.

The main product of the alkylation of methylcyclopentane with butene in the presence of sulphuric acid at 10–17° is a mixture of 1-ethyl-3,5-dimethyl- and 1-ethyl-3,4-dimethyl-cyclohexanes (83%). In the alkylation of methylcyclopentane with isobutene under the same conditions 10% of alkylated cyclohexane and 31% of polycyclic compounds were obtained. In the alkylation of methylcyclopentane with di-isobutene 4% of alkylcyclohexane and 60% of di- and poly-cyclic hydrocarbons were formed. Pent-2-ene enters into the reaction with greater difficulty than but-1-ene. Alkylated cycloalkanes, isopentane, decanes, and polycyclic hydrocarbons were obtained in the alkylation of methylcyclopentane with 3-methylbut-1-ene.

In the presence of hydrofluoric acid at 10° methylcyclopentane almost does not react with but-1-ene. When the reaction temperature was raised to 60°, alkanes, 1-ethyl-2,4-dimethylcyclohexane, and dicyclic hydrocarbons were isolated.

Schneider[32] alkylated methylcyclopentane, dissolved in isobutane or isopentane, with propene and isobutene in the presence of hydrofluoric acid. The main reaction product was tetramethylcyclohexane. Under similar conditions methylcyclohexane does not react either with isobutene or but-2-ene. The main product of the alkylation of methylcyclohexane with propene in the presence of aluminium chloride was a mixture of 1-methyl-3-propyl- and 1-methyl-4-propyl-cyclohexanes; polymethylated cyclohexanes were not detected.

Chernevskaya[33] showed that in the alkylation of methylcyclohexane with octyl chloride over a period of 6 h at 90° in the presence of aluminium chloride *gem*-methyloctylcyclohexane forms in 30% yield. Schmidl's patent[34] deals with the preparation of synthetic lubricating oils by the reaction of cycloalkanes with olefins in the presence of aluminium chloride.

Aluminium chloride has been suggested as the catalyst for the alkylation of methylcyclohexane with alkyl halides at 20–80°. A small amount of chlorocyclohexane forms together with alkylcyclohexanes[35]. Ethylmethylcyclohexane was obtained in the alkylation of methylcyclohexane with ethylene over a period of 6 h at 160–195° and a pressure of 65 atm. Mixtures of thorium oxide, aluminium chloride, and a metal (magnesium, sodium, or aluminium) have been recommended as catalysts for the process[36].

In the reaction between methylcyclohexane and ethylene in the presence of a mixture of stannous chloride and aluminium chloride a mixture of ethylmethylcyclohexane, trimethylcyclohexanes, and tetramethylcyclopentanes is formed. In the absence of aluminium, there is virtually no alkylation[37]. For the alkylation of methylcyclohexane with propene, Appell[38] proposed a mixed catalyst consisting of aluminium chloride and aluminium with added iron, cobalt, nickel, or tin. 1-t-Butyl-4-methylcyclohexane was obtained in the reaction between methylcyclohexane and isobutene at 0–25° in the presence of sulphuric acid[39]. McAllister and Bullard[40] alkylated alkylcycloalkanes with cyclopentene and cyclohexene in the presence of sulphuric acid promoted with benzenesulphonic acid or a mixture of sulphuric and phosphoric acids. In a study of the alkylation of methylcyclohexane with propene in the presence of sulphuric acid, Mamedaliev and Kuliev[41] showed that, in contrast to paraffinic hydrocarbons, the hydrogen of the tertiary carbon atom of methylcyclohexane is not substituted by an alkyl group: the catalytic reaction mixture does not contain *gem*-disubstituted cycloalkanes. In the alkylation of methylcyclohexane, ethylcyclohexane, and isopropylcyclohexane with propene and isobutene in the

presence of sulphuric acid at 0–60° up to 20–30% of dialkylcyclohexanes is formed, mainly 1,4-isomers, and 15% of polyalkylcyclohexanes[12,13]. Thus in the reaction between methylcyclohexane and propene 1-isopropyl-4--methylcyclohexane was obtained.

Unlike the other substituted cyclohexanes investigated, t-butylcyclohexane is not alkylated by alkenes in the presence of sulphuric acid, which may be due to steric hindrance caused by the t-butyl group.

In the alkylation of methyldecalin with propene in the presence of sulphuric acid[42,43], it was found that under the optimum conditions (30° and molar ratios sulphuric acid : methyldecalin : propene = 2 : 1 : 1) the alkylation mixture contains 20% of isopropylmethyldecalin. In the reaction between decalin and ethylene in the presence of aluminium chloride[44], a reaction mixture of complex composition was obtained from which it proved possible to isolate only a small amount of 2-ethyldecalin.

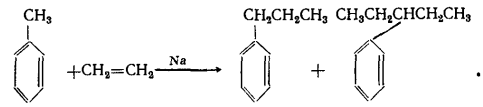
Chernevskaya[33] studied the alkylation of decalin with alkyl halides in the presence of aluminium chloride at 100°. A study was made of the effect of temperature, duration of the reaction, amount of catalyst, and the proportions of the reactants. As the amount of catalyst was increased, there was an increase in the yield of the reaction products but the content of the desired product fell. With the increase in the decalin : alkyl halide ratio from 1 : 1 to 10 : 1, the yield of alkyl derivatives increased to 30%. The maximum yield of the alkylation products was obtained in the presence of 2% of catalyst. The main products of the reaction are disubstituted derivatives.

The alkylation of aromatic compounds in the presence of acid catalysts is well known[45,46]. In the presence of acid catalysts, aralkanes are alkylated in the ring. A study has been made of the ethylation of toluene in the presence of mixed catalysts. Only traces of *p*-propylbenzene and 3-phenylpentane are formed at 300° on an aluminium–chromium catalyst. In the presence of an aluminium–molybdenum or an aluminium–cobalt–molybdenum catalyst the ring is alkylated. Both types of alkylation are observed to a small extent in the presence of an aluminium–platinum catalyst. In all cases the ethylene was also polymerised[47].

Much work has been done on the alkylation of tetralin, which, as regards its properties, can also be classified as an aralkane. The catalysts used in these reactions were phosphoric[48], hydrofluoric[49], and sulphuric[50] acids, aluminium[51], aluminosilicate[52], aluminium chloride[50], zinc chloride[52], etc. It has been established that in the presence of acid catalysts only the aromatic ring is alkylated.

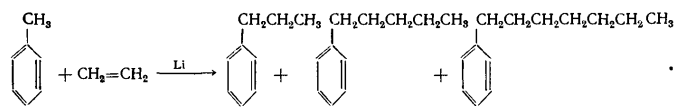
3. ALKYLATION OF ARALKANES IN THE PRESENCE OF BASIC CATALYSTS

In 1928 Hofmann and Michael[53] showed that aliphatic aromatic hydrocarbons can be alkylated by diolefins in the presence of alkali metals and their alloys. The alkylation of toluene and tetralin with butadiene in the presence of sodium was described as an example. Later Whitman[54] showed that aliphatic-aromatic hydrocarbons (toluene, cumene, tetralin) and unsaturated cyclic compounds (cyclohexene, cyclopentadiene) can be alkylated at 150–450° and a pressure of 50–3000 atm in the presence of 0.1–2% of an alkali metal. Thus in the alkylation of toluene with ethylene over a period of 17 h at 225° in the presence of sodium, n-propylbenzene and 3-phenylpentane were obtained:



The alkylation of ethylbenzene with styrene in the presence of sodium[57] gave 1,3-diphenylbutane as the main product. It has been established[55,56] that the yield of the monoalkylated derivative increases on addition of powdered iron. Pieper and Wegler[58,59] extended this reaction to nitrogen--containing heterocycles (picoline, quinaldine, 2-methylbenzothiazole). In the reaction of 370 g of picoline with 200 g of butadiene in the presence of 7 g of sodium over a period of 1 h at 100–120° 160 g of the monoalkenyl derivative and 100 g of the dialkenyl derivative was obtained.

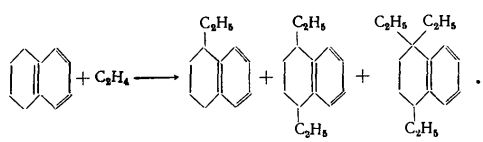
Fotis[60] showed that in the presence of lithium alkylation takes place at the terminal carbon atom of the side-chain of aliphatic-aromatic hydrocarbons. For example, in the alkylation of toluene (0.47 mole) with ethylene (68 atm) in the presence of lithium (0.075 mole) for 25 h at 250° 40% of n-propylbenzene, 13.4% of 1-phenylpentane, 13.4% of 1-phenylheptane, and 33.2% of a residue was obtained:



Later it was shown that the alkylation of the side chain of aliphatic-aromatic hydrocarbons can be carried out in the presence of organic alkali metal compounds. Little[61] alkylated toluene, tetralin, and cyclohexene in the presence of pentylsodium and phenylsodium.

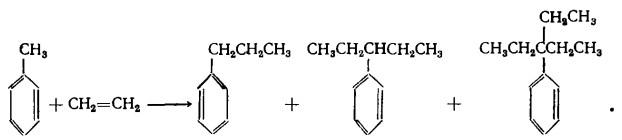
Pines and Ipatieff showed that the side chain of alkylbenzenes can be alkylated with alkenes in the presence of alkali metal acetylides[62], a mixture of an alkali metal and a nitrogen-containing compound[63], a mixture of alkali metals and an organic peroxide, and a mixture of an alkali metal and an organic compound of the general formula RX, where R = alkyl, alkenyl, cyclohexyl, and alkylphenyl, and X = OH, COOH, OR, NO_2, Cl, and CN[64–67]. Sodioanthracene proved to be the best catalyst.

Glosson et al.[68–72] alkylated cyclohexene, tetralin, toluene, and alkylheterocycles with alkenes in the presence of benzylsodium and sodiotetralin. Thus in the alkylation of cyclohexene with ethylene for 2.5 h at 125° in the presence of benzylsodium, 9.6% of 3-ethylcyclohexene was obtained. Under similar conditions isobutylbenzene was prepared from toluene and propene. The alkylation of tetralin was carried out in the presence of sodiotetralin at 140° and an ethylene pressure of 100 atm. The reaction yielded 21% of 1-ethyltetralin, 41% of 1,4-diethyltetralin, and 8% of 1,1,4-triethyltetralin:



Pines et al.[73] alkylated toluene, ethylbenzene, propylbenzene, indane, and cyclohexylbenzene with ethylene in

the presence of sodioanthracene at 200–225° and a pressure of 30 atm. The alkylation of toluene gave *p*-propylbenzene, 3-phenylpentane, and 3-ethyl-3-phenylpentane:



Ethylbenzene reacts with ethylene to form s-butylbenzene (75%) and a small amount of 3-methyl-3-phenylpentane. The reaction of isopropylbenzene with ethylene gives t-pentylbenzene (78%). t-Butylbenzene does not react with ethylene. In the alkylation of cyclohexylbenzene, 1-ethylphenylcyclohexane was obtained (50%) while the alkylation of indane yielded 1-ethylindane (26%). It has been found that the reactivity of xylenes in the alkylation reaction decreases in the series *o*-xylene > *m*-xylene > *p*-xylene. The reaction with ethylene gives between 66 and 80% of the corresponding n-propyltoluenes. Cymene gives 62% of the monoalkylated derivatives which contain 72% of *p*-t-pentyltoluene. The alkylation of mesitylene gave 79% of 1,3-dimethyl-5-n-propylbenzene.

It has been shown, using the alkylation of toluene with ethylene as an example, that compounds which readily react with sodium, for example anthracene, fluorene, *o*-chlorotoluene, *o*-bromotoluene, and peroxides are satisfactory promoting agents.

According to a number of investigators, the mechanism of the alkylation of aliphatic-aromatic hydrocarbons, for example toluene, can be represented as follows (RX = molecule of promoting agent, X = halogen):

$$RX + 2Na \rightarrow RNa + NaX, \quad (1)$$

$$C_6H_5CH_3 + RNa \rightarrow C_6H_5CH_2Na + RH, \quad (2)$$

$$C_6H_5CH_2Na + CH_2{=}CH_2 \rightarrow C_6H_5CH_2CH_2CH_2Na, \quad (3)$$

$$C_6H_5CH_2CH_2CH_2Na + C_6H_5CH_3 \rightarrow C_6H_5CH_2CH_2CH_3 + C_6H_5CH_2Na, \quad (4)$$

$$C_6H_5CH_2Na + C_6H_5CH_2CH_2CH_3 \rightarrow C_6H_5CH_3 + C_6H_5CH(Na)CH_2CH_3, \quad (5)$$

$$C_6H_5CH(Na)CH_2CH_3 + CH_2{=}CH_2 \rightarrow C_6H_5CH\langle{}^{CH_2CH_3}_{CH_2CH_2Na}, \quad (6)$$

$$C_6H_5CH\langle{}^{CH_2CH_3}_{CH_2CH_2Na} + C_6H_5CH_3 \rightarrow C_6H_5CH(C_2H_5)_2 + C_6H_5CH_2Na. \quad (7)$$

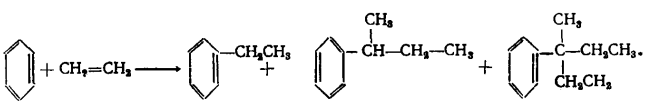
The reaction of promoting agents with sodium gives organosodium compounds which metallate the side-chain of the aliphatic-aromatic hydrocarbon. The resulting organosodium compound adds to ethylene with formation of a new organosodium compound which then metallates the initial hydrocarbon or the ethylated alkylbenzene, forming the monoalkylation product.

Later Pines and Mark[74] studied the reaction of aliphatic-aromatic hydrocarbons with various olefins in the presence of organosodium compounds at 300°. They showed that the reaction of but-1-ene and oct-1-ene gives 2-benzylbutane and 2-benzyloctane in up to 10% yields. Similarly the reaction of propene with toluene, ethylbenzene, isopropylbenzene, and diphenylmethane results in the formation of isobutylbenzene (10%), 3-methyl-2-phenylbutane (16.7%), 2,3-dimethyl-2-phenylbutane (7.8%), and 2-methyl-1,1-diphenylpropane (51%) respectively. 1,3-Diphenylpropane (21%), 1,3-diphenylbutane (12%), 1,3,5-triphenylpentane (29%), and 1,3,5-triphenylhexane (16%) are formed in the alkylation of toluene and ethylbenzene with styrene[75] in the presence of sodium at 110–125°. The yield of monosubstituted derivatives increases in the presence of promoting agents: benzylsodium, sodioanthracene, and sodium isopropoxide. For example, in the case of benzene the yield of monoalkyl derivatives increases from 21 to 40%. In the presence of promoting agents isopropylbenzene reacts with styrene, forming 9% of monoalkylated and 29% of dialkylated derivatives; in the absence of promoting agents polymers are formed.

Schaap and Pines[76] studied the alkylation of toluene, ethylbenzene, cumene, and cyclohexylbenzene with ethylene in the presence of the potassioanthracene catalyst. Cyclisation products were found in the catalytic reaction mixture together with monoalkyl derivatives. The yield of cyclisation products ranges from 2% for toluene to 43% for cumene. Addition of sodium to potassioanthracene increases the yield of alkylation products.

The reaction of isopropylbenzene with ethylene in the presence of metallic potassium gives only the alkylation product[77]. It is interesting that a mixture of potassium hydride and butyl-lithium is an active catalyst for both alkylation and cyclisation of the side-chain of aliphatic-aromatic compounds[78].

Podall and Foster[79] state that the toluene side-chain may be alkylated in the presence of graphite–potassium alloy. According to the data of Esmay et al.[80], in the presence of alkali metals on carriers benzene is alkylated with subsequent further alkylation of the side chains. Thus in the reaction of benzene with ethylene in the presence of Na/Al_2O_3 the products obtained were 10% of ethylbenzene, 40% of s-butylbenzene, and 30% of 3-methyl-3-phenylpentane:



Other catalysts which may be used are Na/C and Li/C and also potassium, sodium, lead, and caesium on MgO, ZnO, BaO, and CdO.[81] The alkylation does not take place in the presence of Na/NaCl and Na/TiO_2.

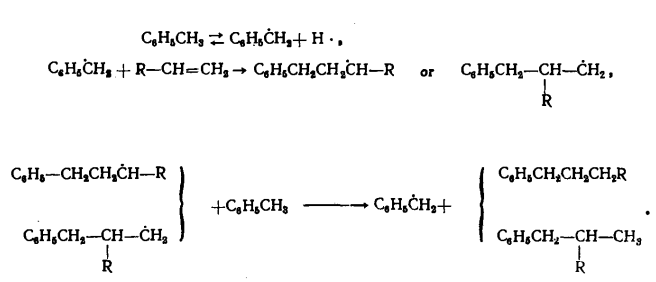
In many cases the alkylation of aliphatic-aromatic and unsaturated cyclic hydrocarbons can be achieved in the presence of alkali metal hydrides[82,83]. Thus Voltz[47] showed that the reaction of toluene with ethylene in the presence of sodium and lithium hydrides at 300° gives alkylation and polymerisation products. In the presence of calcium, strontium, and barium hydrides there is no alkylation. The hydrides of titanium and tantalum are ineffective in the alkylation of toluene at 300°. In the presence of zirconium hydride there is both alkylation of toluene and polymerisation of the alkene.

4. THERMAL AND INITIATED ALKYLATION OF CYCLOALKANES, OXACYCLOALKANES, AND ARALKANES

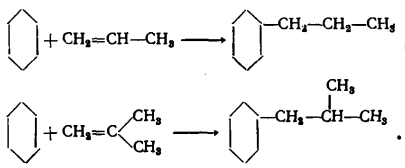
The side-chains of aliphatic-aromatic compounds are known to resemble in their chemical properties alkanes and therefore it might have been expected that it would prove possible to alkylate the side-chains of such hydrocarbons without involving their aromatic rings. Acid catalysts are unsuitable for this purpose, since in their presence the aromatic ring is in fact alkylated. By analogy with the behaviour of alkanes, Ipatieff et al.[84] attempted to

alkylate the side-chain of alkylbenzenes at a high temperature and pressure. It was shown that the alkylation of toluene with ethylene gives n-propylbenzene.

Subsequently this reaction was studied by Pines and coworkers[85-87]. The thermal alkylation of toluene (I), ethylbenzene (II), and cumene (III) was studied in a flow system at a pressure of 420 atm and 400–500° using a brief contact time and a molar ratio alkylbenzene : alkene of 5 : 1. As was expected, an asymmetric alkene gives two products, corresponding to addition to two different carbon atoms of the double bond. One of the products is formed in a greater amount, as happens in the alkylation of alkanes. The authors introduced the concept of "selectivity", i.e. the ratio of the yield of the product of addition to the more stable radical and the yield of the product of addition to the less stable radical. It was shown that the selectivity of addition of alkylphenyl groups to asymmetric alkenes decreases with decrease in the stability of the corresponding free radical. As in the thermal alkylation of alkanes, the reactivity of alkenes decreases in the series propene > > isobutene > 2-methylbut-2-ene, but-1-ene > but-2-ene. A free-radical mechanism, similar to that for the thermal alkylation of alkanes, was proposed for the formation of the monoalkylation products:



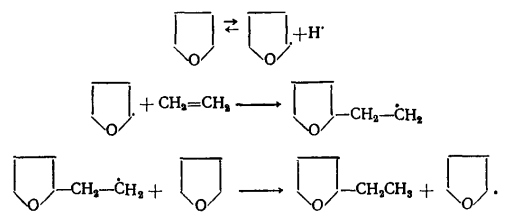
Recently the alkylation of cyclohexane[88] and cyclopentane[89] with alkenes was achieved at 450° at a pressure of 200 atm. Ethylcyclohexane, propylcyclohexane, and isobutylcyclohexane were isolated in the alkylation of cyclohexane with ethylene, propene, and isobutene respectively. It was found that at an elevated temperature cyclohexane adds to the most unsaturated carbon atom of the alkene:



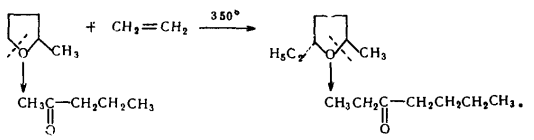
Study of the alkylation of methylcyclohexane with alkenes[90] at 350° and 50 atm showed that the main product of the reaction of methylcyclohexane with ethylene is a mixture of ethylmethylcyclohexanes. The reaction with propene proceeds with greater difficulty. Since it is known that a tertiary radical forms more readily than a secondary radical, it might have been expected that the alkylation of methylcyclohexane with ethylene would give 1-ethyl-1-methylcyclohexane. However, a mixture of 1-ethyl-3-methyl- and 1-ethyl-4-methyl-cyclohexanes was obtained instead.

In contrast to benzene, cyclohexane reacts with alkenes albeit at an elevated temperature and pressure. The different behaviour of cyclohexane and benzene in the alkylation process is shown clearly in the alkylation of tetralin. It might have been supposed[91] that under similar conditions tetralin should be selectively alkylated by olefins in the cycloparaffin ring, and this was confirmed experimentally. 1-Ethyltetralin and 1,4-diethyltetralin were isolated after alkylation of tetralin with ethylene at 450° and 200 atm; the alkylation with propene proceeds with greater difficulty.

In their study of the reaction of oxacycloalkanes (tetrahydrofuran, tetrahydrosilvan, tetrahydropyran) with various olefins at an elevated temperature, Shuikin and Lebedev[92] found that alkylation occurs in the temperature range 300–400°; below 300° there is virtually no reaction and above 400° decomposition processes predominate. A study was made of the effect of temperature, the duration of the reaction, and ethylene pressure on the degree of conversion of the oxacycloalkanes and the yield of monoalkyl derivatives. It is interesting that introduction of a methyl group into the tetrahydrofuran ring lowers the yield of the monoalkyl derivative. Apparently thermal alkylation of oxacycloalkanes, for example tetrahydrofuran, takes place by a free-radical mechanism, like the thermal alkylation of alkanes:



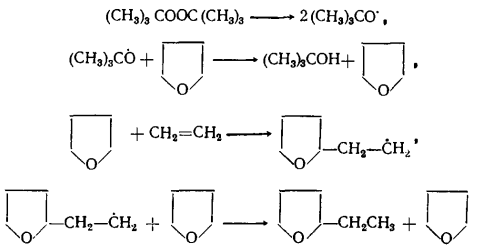
In their oxacycloalkane alkylation experiments, Shuikin and Lebedev[93] were the first to observe the thermal isomerisation of alkyl tetrahydrofurans. 2-Pentanone (the product of the isomerisation of the initial tetrahydrosilvan) and 3-heptanone (the product of the isomerisation of the 2-ethyl-5-methyltetrahydrofuran formed) were detected in the products of the alkylation of tetrahydrosilvan with ethylene at an elevated temperature:



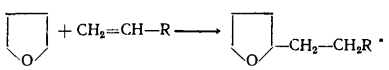
Ethylene is known to undergo polymerisation in the presence of peroxides[94], the rate of polymerisation increasing appreciably in the presence of ethers[95]. A number of patents describe the formation of polymerisation products in the reaction of cyclic ethers with unsaturated compounds. For example, the formation of heavy waxes in the telomerisation of ethylene with dioxan, tetrahydrofuran, dioxolane, and ethyl ether at 50–300° and a pressure of 400–1000 atm has been described[96].

According to the data of Hanford and Roland[97], the reaction of oxygen-containing compounds with ethylene in the presence of radical-forming initiators gave polymerisation products with the formula $R(CH_2CH_2)_nH$, where n is between 22 and 54. In particular, the reaction of dioxan with ethylene resulted in the formation of a product having the formula $C_4H_8O_2(CH_2CH_2)_{54}H$. The telomerisation of dioxolane with ethylene (600–900 atm) for 18 h at 100° in the presence of benzoyl peroxide yielded a wax having the composition $C_3H_6O_2(CH_2CH_2)_{44.5}H$.[98] The products of the reaction of dioxan with decene in the presence of benzoyl peroxide are used as lubricating oils[99].

Shuikin and Lebedev[100] showed that in the presence of di-t-butyl peroxide the reaction of oxacycloalkanes with unsaturated compounds occurs at a much lower temperature (150°). The radical mechanism of the alkylation and the initiating activity of peroxides is confirmed by the presence in the reaction products of t-butanol, which is formed as follows:



Using the alkylation of tetrahydrofuran and tetrahydropyran with hex-1-ene as an example, it was shown that a decrease of the concentration of the alkene results in an increase of the yield of the monoalkyloxacycloalkane. Thus when the tetrahydrofuran : hex-1-ene ratio is increased from 10 : 5 to 10 : 0.5, the yield of 2-hexylhydrofuran increases from 13.2 to 79.2%.[101,102] An increase of the length of the hydrocarbon chain of the alkene lowers somewhat the yield of the 2-alkyloxacycloalkane. The corresponding 2-ethyloxacycloalkanes were obtained in the alkylation of tetrahydrofuran, tetrahydropyran, and dioxan with ethylene in the presence of peroxide at 150°. In the presence of peroxide the alkene adds to oxacycloalkanes via its most unsaturated carbon atom. Thus in the alkylation of tetrahydrofuran with propene, hex-1-ene, hept-1-ene, and oct-1-ene in the presence of peroxide the corresponding 2-alkyltetrahydrofurans with a straight side-chain were obtained:



A similar situation is observed in the alkylation of tetrahydropyran with hex-1-ene and hept-1-ene.

According to Schmerling's data[103], in the presence of organic peroxides cycloalkanes interact with ethylene and form polymers. For example a polymer having the composition $C_6H_{11}(CH_2-CH_2)_nH$ was obtained in the reaction between cyclohexane and ethylene. It has been stated[104] that ethylene enters into a telomerisation reaction with toluene at 200° and a pressure of 140 atm when the process is initiated with cumenyl hydroperoxide.

Nikishin et al.[105] established that toluene, ethylbenzene, cumene, *p*-xylene, and α-methylnaphthalene are capable of adding to alkenes at 150–160° in the presence of t-butyl peroxide. The yield of the monoalkylation products is 10–15%. In the presence of tetraethyl-lead alkylbenzenes are alkylated by ethylene at the α-carbon atom of the side-chain[106].

Eidus and Ershov[107,108] showed that when mixed with carbon monoxide and hydrogen cyclohexene is methylated to the extent of 7–10% by CH_2 radicals formed on reduction of the carbon monoxide with hydrogen, and is converted into mono- and 1,2-di-methyl derivatives. Methylcyclohexene was also obtained in the alkylation of cyclohexene by methylene radicals formed by the hydrocracking of isobutene at 190° on a cobalt–clay catalyst[109].

The review of the literature dealing with the alkylation of saturated cycloalkanes shows that, in the presence of acid catalysts, the composition of the alkylation products depends on the structure of the cycloalkane and the nature of the catalyst. Thus in the presence of aluminium chloride, unsubstituted cyclohexane forms a mixture of polymethylated cyclohexanes. In the presence of sulphuric acid neither cyclopentane nor cyclohexane reacts with alkanes.

In the alkylation of alkylcyclopentanes in the presence of aluminium chloride or boron trifluoride expansion to a six-membered ring takes place; direct alkylation products have not been detected in the alkylation mixture. In the presence of sulphuric acid six-membered alkylcycloalkanes form the corresponding 1,4-dialkylcyclohexanes. In the alkylation of tetralin in the presence of acid catalysts the alkylating agent adds to the aromatic ring; under these conditions the cycloparaffin ring is not alkylated.

The study of the alkylation of saturated systems entered a new phase when it was found that the alkylation of cycloalkanes and the side-chain of aliphatic-aromatic compounds can be carried out in the presence of basic catalysts: sodium, sodioanthracene, benzylsodium, potassium, lithium, etc. Thus in the alkylation of toluene with ethylene in the presence of sodium propylbenzene is obtained and in the alkylation of tetralin in the presence of sodiotetralin ethylene adds to the cycloparaffin ring.

The need to obtain motor fuels with a higher octane number led investigators to attempt the thermal alkylation of alkanes. An industrial method has been developed for the preparation of neohexane by the thermal alkylation of isobutene with ethylene. Subsequently, assuming an analogy with the behaviour of alkanes, a study was made of the thermal alkylation of the side-chains of aliphatic-aromatic hydrocarbons, cycloalkanes, and oxacycloalkanes. The alkylation of the side-chains of aliphatic-aromatic hydrocarbons and oxacycloalkanes occurs under milder conditions in the presence of initiating substances. Chloroform, benzyl chloride, dichloropropane, and organic peroxides have been suggested as initiators.

OUTER-SPHERE INTERACTION IN AQUEOUS SOLUTIONS OF COMPLEX COMPOUNDS

V.E.Mironov

CONTENTS

1. Introduction 455
2. Standardisation of conditions for studying outer-sphere association in aqueous solutions of complex compounds 456
3. Procedure for calculating the outer-sphere association constants for labile complexes 457
4. The most widely used methods for determining outer-sphere association constants 459
5. Outer-sphere association and the law of mass action 459
6. Some rules of outer-sphere association 461
7. Prediction of constants for the association of anionic complexes with alkali metal cations 465
8. Comparison of outer-sphere and inner-sphere association constants 465
9. Complex formation with allowance for associative interaction with the ions of the salt medium 466

1. INTRODUCTION

The majority of chemical processes in nature and technology take place in aqueous solutions. These processes are closely linked with complex formation.

Ions in water are present as simple aquo-ions or mixed complexes: hydroxoaquo-, oxoaquo-, halogenoaquo-, and similar compounds. Complex formation in solutions involves the replacement of ligands in the inner sphere of the so called "free" central ion. This replacement may take place with or without change in the geometric configuration of the inner sphere[1,2].

Complex compounds in solution are defined as any associated species whose components are joined by a direct bond[3], whose energy of formation is greater than, or at least only slightly less than, the kinetic energy of the solvent molecules[4]. Associated species in which there is no direct bond between the ions are called outer-sphere complexes or associated species of the ion-pair type[5].

The results of many studies[3] show that complex formation in solutions is not restricted to the Werner[6] coordination sphere. Complex ions which according to Werner's theory are coordinatively saturated may still combine with ions with opposite sign[3] and polar molecules[7].

In a number of complexes the stability of the inner-sphere bonds is comparable to and even slightly less than the stability of the outer-sphere bonds[3,8,9]. This situation is often encountered in complex formation in concentrated ($> 1\ N$) aqueous solutions of inert salts, but is sometimes also found in dilute aqueous solutions of complex compounds[10,11].

Data have been published on outer-sphere interaction in aqueous solutions of complex compounds in the presence and absence of inert salts, but there are no reviews or monographs on this subject. Moreover, technologists and many research workers, following Bjerrum[12], consider that the influence of outer-sphere ions on complex formation in aqueous solutions is non-existent or negligibly small relative to the effect of inner-sphere interaction, although there are not always sufficient grounds for this.

The present paper is an attempt to examine critically published data on outer-sphere interaction in aqueous solutions of complex compounds. The problem of standardising conditions for the study of outer-sphere association is discussed, a procedure for calculating outer-sphere association constants for labile[13] and relatively unstable ionic

complexes is described, it is shown that outer-sphere association obeys the law of mass action, and the chief methods for studying outer-sphere interaction are described. In addition, a number of new regular features of outer-sphere association are formulated, the stabilities of outer-sphere and inner-sphere bonds in various complexes are compared, the possibility of predicting outer-sphere association constants in certain systems which have not been studied is demonstrated, and complex formation with allowance for associative interaction of the ions with the salt medium is discussed.

2. STANDARDISATION OF CONDITIONS FOR STUDYING OUTER-SPHERE ASSOCIATION IN AQUEOUS SOLUTIONS OF COMPLEX COMPOUNDS

Outer-sphere association in aqueous solutions of complex compounds is studied under the same standard conditions as the inner-sphere interaction[14,15]. The chief standard state for the study of complex formation in solutions is a hypothetical molal solution exhibiting the properties of an infinitely dilute solution[16]. In addition, in the past twenty years the state of solutions with high and constant ionic strength has been taken as standard state[15-18].

The low stability of outer-sphere complexes makes it impossible to obtain accurate values for their thermodynamic functions relating to an infinitely dilute solution, due to the difficulty of graphical or analytical extrapolation of the low values of the thermodynamic functions from real concentrated solutions to solutions with zero ionic strength[14].

Vasil'ev's work[19,20] improved the procedure for extrapolating the stability constants of ionic complexes to zero ionic strength. Vasil'ev replaced the two [adjustable ? (Ed. of Translation)] constants in the Debye–Hückel equation[21] by a single constant (the ion parameter a) and assumed that this constant has the value 4.9 Å in all systems. This assumption is hardly justified for all types of outer-sphere complexes, for which the ion parameter a may vary over a wider range than for ionic complexes.

The most convenient standard state for the study of outer-sphere association in labile and relatively unstable (first stability constant less than 100) ionic complexes is that of solutions with high and constant ionic strength[15] maintained with inert salts. The use of lithium perchlorate as an inert salt is recommended[3], since the ClO_4^- anion and Li^+ cation form the least stable associated species with the majority of singly-, doubly-, and triply-charged ionic complexes[22]. Ions with a lower tendency to undergo association than for example the ClO_4^- anion are known[23] but they are unfortunately unstable in aqueous solutions.

The Li^+ cation cannot be used as an inert ion in systems with anionic complexes whose charge exceeds three. On association, highly-charged ionic complexes break down the hydration sheath of the Li^+ cation and form more stable associated species with this cation than with the cations of the other alkali metals. Large cations of the type NR_4^+, where R = CH_3, C_2H_5, etc.[24,25], are inert with respect to highly-charged anionic complexes. The majority of salts with NR_4^+ cations are sparingly soluble in water, so that the outer-sphere association of highly-charged ionic complexes is usually studied[22] in dilute solutions with variable or constant ionic strengths and the thermodynamic functions are calculated for solutions with zero ionic strength. The hypothetical molal solution exhibiting the properties of an infinitely dilute solution can be used as a standard state for the study of the outer-sphere association of highly-charged ionic complexes, since the latter form extremely stable outer-sphere complexes.

If lithium perchlorate is used as an inert salt to establish the ionic strength, outer-sphere association is studied[3] in solutions with ionic strengths equal to three or four, since the low stability of the outer-sphere complexes necessitates high concentrations of outer-sphere ions for their formation, and in solutions with low ionic strengths this leads to a change in the activity coefficients of the reacting components. Studies in lithium perchlorate solutions with concentrations greater than 4 M are impossible, since the solubility of lithium perchlorate in water at 20° is 4.2 M.

The replacement of water by aqueous solutions of inert salts does not alter the significance of the laws of thermodynamics[18], so that solutions with high and constant ionic strengths and the hypothetical molal solution exhibiting the properties of an infinitely dilute solution can equally justifiably be regarded as standard states. Change from one standard state to the other changes the conditions under which the activity coefficients are equated to unity. Change in the conditions changes the composition of the associated species which include both "free" ions and ionic complexes[17].

In dilute aqueous solutions the concentration of free ions M (here and subsequently the charges of most ions are omitted for simplicity) is understood to be the concentration the species $\sum_{n=0}^{n=N} M(H_2O)_n$, where N is the maximum number of water molecules joined to M. X-Ray study of aqueous solutions[26], study of exchange with water containing the isotope ^{18}O,[27] magnetic and spectroscopic data[28], and their interpretation[29] from the viewpoint of ligand field theory show that in dilute aqueous solutions of most completely dissociated salts, N is the maximum coordination number of Werner's theory.

In concentrated solutions of inert salts, for example in lithium perchlorate solutions, the concentration of free M ions is understood to be the total concentration of associated species:

$$\sum_{x=0}^{x=X}\sum_{y=0}^{y=Y}\sum_{z=0}^{z=Z} M(H_2O)_x(ClO_4)_yLi_z, \qquad (1)$$

and the concentration of ionic complexes ML_n, where L is the ligand, is understood to be the concentration of the species

$$\sum_{n=0}^{n=N}\sum_{x=0}^{x=X}\sum_{y=0}^{y=Y}\sum_{z=0}^{z=Z} ML_n(H_2O)_x(ClO_4)_yLi_x \qquad (2)$$

where n lies in the range $1-N$. There is at present no information on the values of X, Y, and Z in species of types (1) and (2).

Outer-sphere associated species made up of ionic complexes of low stability have been studied chiefly in 3 M and 4 M $Li(ClO_4, L)$ and (Li, B)L solutions[3,8,9,30-46], where B represents the outer-sphere ions. The concentration of ligand in $Li(ClO_4, L)$ solutions was varied in a number of systems in the range 0–3 M and 0–4 M.

The replacement of any quantity of perchlorate or other inert anions by ligand anions leads unavoidably to a change in the activity coefficients of the reactant and product ions

in solutions with high and constant ionic strength[47]. However, the activity coefficients of M, L, and ML_n are assumed[15,17,35,36,48] to be constant in 1–4 M Li(ClO_4, L) and Na(ClO_4, L) solutions for replacement of less than 10–15% of the perchlorate ions by singly-charged ligand anions, since the low accuracy of present experimental methods does not permit a change in activity coefficients to be observed under the above conditions. The replacement of more than 20% of the perchlorate anions by ligand anions produces a significant change in the activity coefficients of the reacting ions in the great majority of systems studied in 1–4 M Li(ClO_4, L) and Na(ClO_4, L) solutions, the logarithms of the activity coefficients being directly proportional to the logarithms of the ligand anion concentrations[3,49,50].

The extent of the change in the activity coefficients of M and L in solutions with high (greater than 0.1 M) and constant ionic strength is influenced markedly by the nature of the reacting ions[3,15,48]. The extent of this change is often determined[15,35,36,48] from the deviation from constant values shown by $a_M j+[L^-]^j$ or $[M^{j+}]a_{L^-}$ (a is the activity†) for sparingly soluble salts containing M and L, in solutions saturated with such salts. These data indicate that increase in the charge of M or in the differences between the electrostatic characteristics of L and the inert anion leads to an increase in the deviations of the activity coefficients of M and L from constant values. For example, the complete replacement of perchlorate anions by chloride, bromide, thiocyanate, and iodide anions in 4 M Na(ClO_4, L) solutions at 25° alters the value of $a_{Tl^+}[L^-]$, which changes in the same sense as the activity coefficients of M and L, by 36, 12, 9, and 3% respectively[48]. $a_{Tl^+}[L^-]$ changes to almost the same extent when ClO_4^- is replaced by L in 4 M Li(ClO_4, L) solutions[3,15]. The values of $a_{Pb^{2+}}[L^-]^2$ in 3 M and 4 M Li(ClO_4, L) and Na(ClO_4, L) solutions change by 74% and 35% on complete replacement of perchlorate anions by chloride and bromide ions respectively[3,35].

The nature of the alkali and alkaline earth metal cations has little influence on the values of $a_M j+[L^-]^j$ in 3 M and 4 M (Li, B)L solutions, where B represents alkali and alkaline earth metal cations[15,35,36]. It may be assumed[3] that the replacement of Li^+ cations by B cations alters the values of $[M^{j+}]a_{L^-}$, but there is no published information on these quantities.

One of the main disadvantages of both standard states (the hypothetical molal solution and solutions with high and constant ionic strength) used in the study of the stability of ionic and outer-sphere complexes is the change in the activity coefficients of the reacting ions with change in the salt composition of the medium being studied. In solutions with high and constant ionic strength the activity coefficients are more nearly constant than in solutions with varying ionic strengths. It is, however, easier at present to make allowance for the change in the activity coefficients in dilute (< 0.2 N) solutions with varying ionic strength than in solutions with high and constant ionic strength. The values of the thermodynamic functions for relatively unstable associated species cannot be determined with high accuracy whatever method is used to allow for activity coefficients[3].

The advantages and disadvantages of the standard states for studying equilibria in aqueous solutions have been discussed many times[3,5,15,17,18]. The great majority of accurate studies of equilibria in solutions have been made in the past twenty years[22] by the constant ionic strength method[51] and the self-medium method[52]. Where possible, equilibria should be studied in solutions at several constant ionic strength values, after which various methods should be used to calculate the values of the thermodynamic functions for solutions with zero ionic strength. This applies equally to the thermodynamic functions of ionic[20] and outer-sphere complexes[20]. An unambiguous comparison of the thermodynamic functions of standardised solutions with the same high and constant ionic strength can be made only when the same inert salt is used.

3. PROCEDURE FOR CALCULATING THE OUTER-SPHERE ASSOCIATION CONSTANTS FOR LABILE COMPLEXES

To determine the composition and calculate the outer-sphere association constants for any labile complexes, data from three series of experiments are required[3]. In the first series of experiments complex formation by the central atom M with the ligand L should be studied in the presence of the most inert anions and cations, in the second series of experiments the reaction of the outer-sphere ion with the ligand or with the central ion should be studied, and in the third series of experiments the influence of the outer-sphere ions on the degree of complex formation by the central ion should be studied. The second series of experiments becomes unnecessary if almost no interaction between the outer-sphere ions and the central ion and ligands takes place due to specific features or because of the conditions used.

A procedure has been described[28,33,37] for calculating the association constants for relatively unstable anionic complexes with alkali and alkaline earth metal cations. In this procedure no allowance is made for the interaction of the outer-sphere cations with the ligand, but this simplification is unimportant. When interaction between the outer-sphere ions and the ligand takes place, the calculations by this procedure must be carried out with the equilibrium concentrations of outer-sphere ions B and ligands L. The values of [B] and [L] can be determined experimentally[3] or calculated using the formation constants of BL_n or $B(H_2O)_xL$.

The procedure for calculating outer-sphere association constants given in papers by Mironov and others[3,28,33,37,39] is suitable for calculating the constants for the association of anionic complexes with outer-sphere cations and of cationic complexes with outer-sphere anions. The chief assumption of this procedure is that the activity coefficients of the reacting ions and resulting complexes remain constant in all experiments whose results are used in the calculations.

Complex formation in the absence of outer-sphere association, that is in a medium of the most inert anions and cations, is represented in simplest form by the equilibrium

$$M + nL \rightleftarrows ML_n \qquad (3)$$

and is characterised by the stability constants of the ions ML_n:

$$\beta_n = [ML_n] \cdot [M]^{-1} \cdot [L]^{-n}, \qquad (4)$$

where $n = 1, 2, \ldots N$, and N is the maximum coordination number of M with respect to L under the conditions of the experiment.

† Calculated on the assumption that $a_{L^-} = [L^-]$ or $a_{M^{j+}} = [M^{j+}]$.

Outer-sphere association is represented[3] in simple form by the equilibrium

$$yB + ML_n \rightleftarrows B_yML_n \quad (5)$$

and is characterised by the outer-sphere association constants

$$\gamma_{n,y} = [B_yML_n]\cdot[B]^{-y}\cdot[ML_n]^{-1}, \quad (6)$$

where $y = 1, 2, \ldots Y$, and Y is the maximum number of outer-sphere ions attached to ML_n.

When ionic complexes ML_n are formed, the total concentration of the central ion M (C_M) is defined by the equation

$$C_M = \sum_{n=0}^{n=N} [ML_n]. \quad (7)$$

With allowance for outer-sphere complexes, C_M is given[3,30,32,37] by the equation

$$C_M = \sum_{n=0}^{n=N} [ML_n] + \sum_{y=1}^{y=Y}\sum_{n=1}^{n=N} [B_yML_n]. \quad (8)$$

By expressing the concentrations of ionic and outer-sphere complexes in terms of the stability constants and dividing the right-hand and left-hand sides of Eqns. (7) and (8) by the equilibrium concentration of the central ion, we obtain the equations

$$C_M[M]^{-1} = \Phi = 1 + \sum_{n=1}^{n=N} \beta_n [L]^n \quad (9)$$

and

$$C_M[M]^{-1} = \Phi^{total} = 1 + \sum_{n=1}^{n=N} \beta_n [L]^n + \sum_{n=1}^{n=N}\sum_{Y=1}^{y=Y} \beta_n\gamma_{n,y}[B]^y[L]^n, \quad (10)$$

where Φ is the degree of complex formation by M with L to give ML_n, and Φ^{total} the degree of complex formation by M with L and B to give ML_n and B_yML_n.

Subtraction of Eqn. (9) from Eqn. (10) gives

$$\Delta\Phi = \Phi^{total} - \Phi = \sum_{n=1}^{n=N}\sum_{y=1}^{y=Y} \beta_n\gamma_{n,y}[B]^y[L]^n, \quad (11)$$

where $\Delta\Phi$ is the change in the degree of complex formation by M resulting from the outer-sphere association of ML_n with B.

The unknown quantities in Eqn. (11) are the values of y and $\gamma_{n,y}$, for the values of β_n and n are determined by familiar methods[14] from Φ–[L] data by solving Eqn. (9). To find the numerical values of y and $\gamma_{n,y}$, it is sufficient to measure the dependence of $\Delta\Phi$ on the concentration of outer-sphere ions at several ligand concentrations and then to compile and solve a system of several equations of the same type as Eqn. (11).

Outer-sphere association constants in different systems are calculated[3,8,9,30–34,36,37] using particular forms of Eqn. (11). In practice, the most frequently encountered systems are those in which one complex ion ML_N reacts with one outer-sphere ion[9,53] or in which, of two complex ions ML_N and ML_{N-1} present, the first reacts with two outer-sphere ions and the second with one outer-sphere ion[37,38]. When only BML_N is formed, Eqn. (11) acquires the simpler form

$$\Delta\Phi = \gamma_{N,1}[B]\beta_N[L]^N \quad (12)$$

and when BML_N, BML_{N-1}, and B_2ML_N are formed Eqn. (11) becomes

$$\Delta\Phi = \gamma_{N,1}[B]\beta_N[L]^N + \gamma_{N-1,1}\beta_{N-1}[B][L]^{N-1} + \gamma_{N,2}\beta_N[B]^2[L]^N. \quad (13)$$

A complete analysis of the characteristic features and methods of solution for Eqn. (11) has been published[3,39]. In practice up to the present no studies have been made of systems in which the outer-sphere interaction is described by a more complex form of Eqn. (11) than Eqn. (13). The latter is conveniently solved by a graphical method similar to Leden's method[14,54].

The first stage in the solution of Eqn. (13) involves the construction of the graphical dependence of the function F_1 on the concentration of B ions. The function F_1 is defined by the equation

$$F_1 = \Delta\Phi[B]^{-1}[L]^{-N}\beta_N^{-1} = \gamma_{N,1} + \gamma_{N-1,1}\beta_{N-1}\beta_N^{-1}[L]^{-1} + \gamma_{N,2}[B]. \quad (14)$$

Graphical extrapolation is used to find $\lim F_1$ as $[B] \to 0$

$$\lim_{[B]\to 0} F_1 = \gamma_{N,1} + \gamma_{-N1,1}\beta_{N-1}\beta_N^{-1}[L]^{-1}. \quad (15)$$

In a number of systems studied[3]

$$\gamma_{N,1} \gg \gamma_{N-1,1}\beta_{N-1}\beta_N^{-1}[L]^{-1} \quad (16)$$

and in these cases $\lim F_{1[B]\to 0} = \gamma_{N,1}$. If the two terms on the right-hand side of Eqn. (15) are commensurate, it is necessary in the determination of the values of $\gamma_{N,1}$ and $\gamma_{N-1,1}$ to determine F_1 at not less than two ligand concentrations and then to compile and solve a system of two equations of the same type as Eqn. (15). The solution of this system gives the values of $\gamma_{N,1}$ and $\gamma_{N-1,1}$. It is often impossible to measure the values of the function F_1 at several ligand concentrations even in cases where the two terms on the right-hand side of Eqn. (15) are commensurate. This was the situation, for example, in a study of the outer-sphere associated species formed by bromo-complexes of zinc[37,40] or chloro-complexes of lead(II) with heavy alkali metal cations[38,39]. These complexes were also studied in 4 M $Li(ClO_4$, L) solutions but it was necessary to study the outer-sphere association in 4 M (Li, B)L solutions, since the simultaneous presence of K^+, Rb^+, or Cs^+ cations and perchlorate anions in 4 M (Li, B)(ClO_4, L) solutions is impossible due to the low solubility of the perchlorates of the heavy alkali metals. In these cases[3,37–40] the values of F_1 were determined for 3 M and 4 M (Li, B)L solutions. The values of F_1 for 3.1 M and 3.9 M (Li, B)L solutions were found by making use of the linear dependence of F_1 on the ionic strength of the solution[55,56]. Systems of two equations of type (15) were then compiled. One system was compiled from data for 3.0 M and 3.1 M (Li, B)L solutions and the other from data for 3.9 M and 4.0 M (Li, B)L solutions. Solution of these systems gave the values of γ_N and γ_{N-1} for 3.0 M and 4.0 M (Li, B)L solutions. This method of finding γ_N and γ_{N-1} is based on the assumption that the outer-sphere association constants remain constant when the ionic strength of the solutions is changed from 3.0 to 3.1 and from 4.0 to 4.1. Experimental data confirmed that it is possible to make this assumption[3].

After the determination of $\lim F_1$ as $[B] \to 0$, Eqn. (11) is transformed to

$$F_2 = (\Delta\Phi - \lim_{[B]\to 0} F_1)[B]^{-1} = \gamma_{N,2} \quad (17)$$

and the values of $\gamma_{N,2}$ are calculated. In a number of systems studied with this method of calculating $\gamma_{N,2}$ it was found[3] that the values of the function F_2 depend on the

concentration of B; in this case $\lim F_2$ as $[B] \to 0$ was determined and $\gamma_{N,2}$ was calculated in the same way as $\gamma_{N,1}$.

4. THE MOST WIDELY-USED METHODS FOR DETERMINING OUTER-SPHERE ASSOCIATION CONSTANTS

In recent years a large amount of information has been published[8,9,30-34,37-46] on constants for the association of labile anionic complexes with alkali and alkaline earth metal cations. Most of these data were obtained potentiometrically. Measurements are usually made of the e.m.f. of cells of the type

$$M(Hg)\,|\,S_{LiClO_4}\,|\,3 \quad \text{or} \quad 4\ M\ LiClO_4\,|\,S_x\,|\,M(Hg), \tag{18}$$

$$M(Hg)\,|\,S_{LiL}\,|\,3 \quad \text{or} \quad 4\ M\ LiL\,|\,S_y\,|\,M(Hg), \tag{19}$$

where M represents thallium, lead, bismuth, zinc, cadmium, etc., and L represents chloride, bromide, thiocyanate, iodide, nitrate, or other anions. The solutions S_{LiClO_4} consisted of 0.0001–0.05 M perchlorate of the cation M in 3 M or 4 M lithium perchlorate and the solutions S_{LiL} consisted of 0.0001–0.05 M L_j in 3 M or 4 M LiL. The solutions S_x were prepared by mixing the solutions S_{LiClO_4} and S_{LiL}, and the solutions S_y by mixing the solutions S_{LiL} and S_{BL}. The latter contained 0.0001–0.05 M L_j in 3 M or 4 M BL solution. To suppress the hydrolysis of M, all the solutions studied had a constant acidity, which varied in the range 0.001–1.0 g-ion H^+ litre^{-1}, depending on the stability of the hydroxo-complexes of M.

Other versions of the potentiometric method for determining outer-sphere association constants have been described[3,30] but they are comparatively little used.

Outer-sphere association constants have been determined by polarographic methods[3,30], based on the study of the dependence of the displacements of the half-wave potential of the central M ion on the concentration of L in solutions with compositions analogous to that of solution S_x in cell (18) and also the dependence of these displacements on the concentration of B cations in solutions with compositions analogous to that of solution S_y in cell (19).

The chief disadvantage of these versions of the potentiometric and polarographic methods for studying the interaction in S_x and S_y solutions is that they involve the measurement of the total e.m.f. or displacements of the half-wave potential due to association and diffusion. Thermodynamics does not make it possible to separate the effect of diffusion (the diffusion potential) from the effect of change in the activity coefficients[57]. In practice measurements are made of nominal diffusion potentials, including diffusion and change in the activity coefficients[51].

To increase the accuracy of the potentiometric and polarographic methods for studying association in cells (18) and (19), the diffusion potentials have been determined[3,58] by the flowing junction method[59-61,122].

The solubility of salts of the type ML_j or B_yML_n makes it possible to determine outer-sphere association constants from data obtained by the solubility method[39,62-65].

A large number of papers describe measurements of the solubilities of the halides and thiocyanates of thallium(I)[9,35,66-68], lead(II)[36,39,69], and silver[70], and other sparingly soluble salts with various compositions[40,64,65], usually in solutions with constant ionic strengths. These data have been used to calculate outer-sphere association contants[9,32,36,39,40,53,66,67,70].

Accurate values for the solubility products of sparingly soluble compounds are necessary for calculating the stability constants of ionic complexes and outer-sphere association constants from data obtained by the solubility method[14,16]. In most systems where outer-sphere association constants have been calculated from data obtained by the solubility method, the solubility products were determined potentiometrically[35,36,39,69].

A method has been described[44,45] for calculating the outer-sphere association constants for the anions Br_3^- and $Fe(SCN)_n^{3-n}$, where $n = 4-6$, from the distribution of Br_2 or $H[Fe(SCN)_4]$ between carbon tetrachloride or ethyl ether and 3 M (Li, H, B)L solutions. The extraction method for determining outer-sphere association constants is based on measurement of the distribution constants of Br_2 and Fe^{3+} at different concentrations of the outer-sphere cations[40,44,45].

The spectrophotometric method cannot be used to study relatively unstable outer-sphere complexes, since the latter are ion pairs, whose formation is not accompanied by a significant change in the absorption spectra of the simple ions or ionic complexes[3,40,44,71]. The spectrophotometric and electrical-conductivity methods are the most widely used procedures for studying stable outer-sphere associated species formed by highly-charged, extremely stable, or extremely inert ionic complexes[22].

The spectrophotometric method has been used many times to study the association of cationic complexes with outer-sphere anions, since their interaction is usually accompanied by a change in the spectrum of ML_n.[72-76]

The study of outer-sphere association by an ion-exchange method using cation and anion exchange resins has been described[77].

Data obtained by direct calorimetric measurements[3,40] and the temperature dependence of outer-sphere association constants[9,30,39,41] have been used to calculate enthalpy changes during outer-sphere interaction.

5. OUTER-SPHERE ASSOCIATION AND THE LAW OF MASS ACTION

The change in the stability constants of ionic complexes on going from one salt medium to another is attributed[14,16] to the change in the activity coefficients of M, L, and ML_n, since

$$\beta_n^0 = \beta_n \cdot f_{ML_n} \cdot f_M^{-1} \cdot f_L^{-n} \tag{20}$$

where β_n^0 represents the stability constants relating to the solution with zero ionic strength, β_n the stability constants relating to the solution with a definite salt medium, and f with different subscripts represents the activity coefficients of the species denoted by the subscripts. This explanation of the influence of the salt medium on complex formation in solutions is purely formal, however, since it neglects the fact that any significant changes in activity coefficients are unavoidably associated with definite chemical processes.

The activity coefficients of ions are influenced little by ions of the same sign but are influenced appreciably by ions of the opposite sign[51]. This is explained by the structure of electrolyte solutions[57], in which each ion is surrounded by an atmosphere of ions of the opposite sign. Any ions with charges of different sign naturally attract one another in accordance with Coulomb's law, to form associated species of different types. The formation of any associated species, usually described in the case of strong

electrolyte solutions by the activity coefficients, can be characterised by the constants of the law of mass action[3], if the type of species formed is known and the influence of side processes is excluded. Izmailov[78] emphasised that "the properties of any electrolyte in non-aqueous and even in aqueous solutions must be described on the basis of a process obeying the law of mass action".

It is often possible to isolate the contribution of a definite association process to the influence of the ionic medium on complex formation in solutions[3,30]. The behaviour of certain systems[79] has been described by some workers in terms of formal values of the activity coefficients and by other workers in terms of the constants of the law of mass action.

Before the publication of papers by Mironov and co-workers[32,33], the influence of the salt medium on the stability constants of relatively unstable ionic complexes was always characterised by the changes in the activity coefficients. Experiments and calculations[3,30,32,39] showed that the values of the outer-sphere association constants, calculated from data on the influence of the salt medium on complex formation in solutions in accordance with the procedure described above and measured by various methods, remain almost constant when the concentration of the reacting components is changed by factors of several hundred. This is confirmed by the data in Table 1.

Various methods (Table 1) have been used to determine outer-sphere association constants in systems which might be expected to show a maximum change in these constants[3], for example as a result of a change in the activity coefficients, as a result of the very low stability of ionic complexes, or as a result of the influence of various side-processes. The errors of the determination of the outer-sphere association constants given in Table 1 amount to not less than ±5–40%.[3] In all the systems studied (with the exception of the Na^+–$PbBr_4^{2-}$ system), change in the concentration of ML_n by a factor of 10–500 changed the values of the constants by not more than 10%. The scatter in the values of the constants found by the potentiometric and polarographic methods and by solubility measurements rarely exceeds ±10%.

The values obtained are independent of the method of determination and the concentrations of the reacting substances only for the constants for the association of ionic complexes with the first ion of the outer-sphere. In calculations of the second and third outer-sphere association constants, change in the concentration of ML_n and, more particularly, change in the method of measuring $\Delta\Phi$ changed $\gamma_{n,y}$ by more than 20–80%.[3]

TABLE 1. Outer-sphere association constants for ML_n in 4 M (Li, B)L solutions at 25°.

Outer-sphere cations	Anionic complexes	Outer-sphere association constants, calculated from data obtained by			References
		potentiometric method	polarographic method	solubility method	
Na^+	$TlCl_2^-$	0.10	—	0.08	32
K^+	$TlCl_2^-$	0.14	0.15	0.15	30,32
Cs^+	$TlCl_2^-$	0.22	—	0.25	3,32
Na^+	$PbCl_4^{2-}$	0.73	0.73	0.52*	3,36
Na^+	$PbBr_4^{2-}$	0.11	0.15	0.16	3,30
Na^+	$CdCl_4^{2-}$	0.50	0.51	—	3,33
Na^+	$Pb(NO_3)_4^{2-}$	0.47	0.51	—	3,8
K^+	$PbCl_4^{2-}$	2.1	1.9	2.0	3,30
K^+	$Tl(SCN)_4^{3-}$	0.70	0.70	0.80	3,63
K^+	$PbBr_4^{2-}$	1.0	—	0.95	3,32

* This figure relates to 3 M (Li, B)Cl solutions.

Different methods for studying complex formation in solutions are sensitive to different extents to changes in the activity coefficients of the reactant and product ions[48], so that for the calculation of outer-sphere association constants [according to Eqn. (11) or modifications of this equation] the degree of complex formation by M with L and the degree of complex formation by M with L and B must be measured by the same method. This rule must be obeyed in the study of the stability of outer-sphere complex ion associated species with $\beta_1 < 100$, since in these systems it is necessary to replace more than 20% of the inert ions by ligands[39]. In the calculation of outer-sphere association constants, use is made of the stability constants of the most extensively coordinated ionic complexes, that is, the constants for ML_N, ML_{N-1}, etc. The value of β_N shows its maximum dependence on the changes in the activity coefficients when the composition of an ionic medium with constant ionic strength is varied[39,69,80]. Thus the values of the stability constants of $PbCl_n^{2-n}$ with $n = 1-3$ remain constant in 3 M solutions of a mixture of lithium perchlorate and chloride, but the stability constant of $PbCl_4^{2-}$ is 52 ± 12 according to solubility data[36] and 11 ± 2 according to potentiometric data[80]. This is due to the fact that the $PbCl_4^{2-}$ ion is formed in 3 M Li(ClO_4, Cl) solutions at a chloride ion concentration greater than 0.6 M, that is, in the range of chloride ion concentrations in which the replacement of ClO_4^- by Cl^- changes the activity coefficient of the doubly-charged lead cation[36]. Thus the stability constant of $PbCl_4^{2-}$ ions, determined for 3 M Li(ClO_4, Cl) solutions, includes both the effect of the interaction of the lead cation with four chloride ions and the change in the activity coefficients. If the effect of change in the latter is not to influence the value of the outer-sphere association constants for $PbCl_4^{2-}$, it must be eliminated by using the values of β_N calculated from data obtained using the same method as in the determination of $\Delta\Phi$.

An interesting feature is that the potentiometric and polarographic methods for determining the stability constants of ionic complexes in 3 M and 4 M Li(ClO_4, L) solutions apparently reflect to equal extents the changes in the activity coefficients resulting from the change in the composition of an ionic medium with constant ionic strength[3].

The values of the second outer-sphere association constants calculated using Eqn. (13) are determined by the slope of the linear plot of F_1 against [B]. The replacement of more than 20% of the lithium cations by the cations of other metals in 3–4 M (Li, B)L solutions may lead to a change in the activity coefficients of the reaction ions[35,39]. Thus the slope of the linear plot of F_1 against [B] and hence $\gamma_{n,2}$ may change with change in the method of measuring $\Delta\Phi$ and with change in the concentration of ML_n.

At high concentrations of B in (Li, B)L solutions, an appreciable quantity of BML_n complexes is formed. The statistical mean charge of ML_n is greater than the charge of BML_n, so that the complex BML_n has a greater tendency to add on an additional ligand ion than the free ML_n ion. It may be assumed[3] that the greater part of the change in the activity coefficients of M, L, and ML_n in 3–4 M (Li, B)L solutions with [B] greater than 0.5–2.0 M is due to the conversion of BML_n into BML_{n+1}. The correctness of this explanation is confirmed by a large quantity of

published data[3] which indicate an increase of n in ML_n with increase in the ability of the outer-sphere ions to undergo association with ionic complexes.

6. SOME RULES OF OUTER-SPHERE ASSOCIATION

In the formulation of the rules of outer-sphere association, only the first association constants are used[3], since the values of $\gamma_{n,y}$ for $y > 1$ are arbitrary[14].

The first constants for the outer-sphere association of anionic complexes with alkali and alkaline earth metal cations depend on the dimensions of the outer-sphere cations, being related to the radii of the latter by the equation

$$\gamma_{n,1} = A(r_B - C) \qquad (21)$$

where A and C are constants whose values change with change in M, L, or the charge of ML_n, and r_B the Goldschmidt radii of the outer-sphere cations (in Å). The correctness of Eqn. (21) and of the postulates of the present section is confirmed by the data in Tables 2–4.

The outer-sphere association constants for most labile, relatively unstable chloro-complexes vary according to Eqn. (21) with $C = 0.78$, which is numerically equal to the crystallographic radius of the Li^+ cation. The association constants of bromo-, nitrato-, thiocyanato-, and certain other types of anionic complexes[3,40] are characterised by Eqn. (21) with values of C in the range 0.7–1.1 (Table 2).

The constants for the outer-sphere association of cyanoferrate(III) and other inert highly stable anionic complexes with alkali and alkaline earth metal cations are given by the equation

$$\log \gamma_{n,1} = Ar_B - C, \qquad (22)$$

although within the limits of error of their determination the constants are also described by Eqn. (21) [40,65] (Table 3).

The constants for the outer-sphere association of anionic complexes of low stability with caesium cations (Table 2) are sometimes found to be greater or less than those calculated from Eqn. (21). High values of $\gamma_{n,1}$ are attributed[34] to the inclusion, in the value of the constant, of the increase in the degree of complex formation by M resulting from the increase of n in $CsML_n$. This is apparently the case for the constants for the outer-sphere association of the $ZnCl_3^-$ ion with the Cs^+ cation (Table 2). In general, the possibility that the effect of inner-sphere interaction is included in the value of the first outer-sphere association constant increases with decrease in the stability of the M–L bonds and with increase in the stability of the B–ML_n bonds[3]. From this, it is to be expected that at very low values of β_n and high values of $\gamma_{n,1}$ the values of the latter will depend on the concentration of ML_n and on the method used to determine the outer-sphere association constants.

Low values of $\gamma_{n,1}$ relative to those calculated from Eqn. (21) are attributed to a significant difference between the total and equilibrium concentrations of ligand when C_L is used in the calculations. In the series of alkali metal cations, the stability of the ion pairs $B(H_2O)_xL$ increases from lithium to caesium[82] for $L = Cl^-$, Br^-, I^-, NO_3^-, SCN^-, etc., with the exception of OH^-, CH_3COO^-, etc.[32] Thus the maximum differences between C_L and [L] in the systems whose characteristics are given in Table 2 might be observed for $B = Cs^+$.

** Calculated from solubility data.

*** Calculations carried out using the stability constants of the TlI_4^{3-} ion found for 4 M $Na(ClO_4, I)$ solutions and not for 4 M $Li(ClO_4, I)$ solutions.

**** The constants relate to a solution with zero ionic strength and were calculated using the Fuoss–Onsager equation[82]. The same method[82] gave for the stability constants of $Na^+(H_2O)_xBr^-$, $K^+(H_2O)_xBr^-$, $Na^+(H_2O)_xI^-$, and $K^+(H_2O)_xI^-$ the values 0.2, 0.4, 0, and 0.3 respectively.

Decrease in the charge and decrease in the dimensions of hydrated anionic complexes leads to a decrease in the outer-sphere association constants (Table 2). In the series of anionic complexes $TlCl_2^-$, $PbCl_4^{2-}$, $BiCl_6^{3-}$, $ZnBr_3^-$, $ZnBr_4^{2-}$, $PbCl_3^-$, and $PbCl_4^{2-}$,[3,40] the outer-sphere association constants change according to the equation

$$\gamma_{n,1} = \gamma \cdot Z^2 \qquad (23)$$

where Z is the charge of the anionic complex, and γ without subscript denotes the outer-sphere association constant for the singly-charged anionic complex. In some systems[44,46] this equation has been used to calculate γ_N

and γ_{N-1} from $\lim F_1$ as [B] → 0 [see Eqn. (15)]. For example, this method was used to calculate the constants for the outer-sphere association of $Fe(SCN)_n^{3-n}$ ions (n = = 4–6) with alkali metal and ammonium cations[44] (Table 2).

Eqn. (23) is applicable to outer-sphere association constants relating to the same standard state. This equation is not applicable to the outer-sphere association constants found for $PbCl_4^{2-}$ ions in 3 M (Li, B)Cl solutions or to the outer-sphere association constants found for $BiCl_6^{3-}$ anions in 3 M (Li, H, B)Cl solutions with $[H^+]$ = 1 M (Table 2), since an appreciable proportion of the $BiCl_6^{3-}$ ions in solutions with $[H^+]$ = 1 M are bound in $[HBiCl_6]^{2-}$ complexes, which also associate with alkali metal cations. $TiCl_2^-$ anions undergo almost no association with H^+, so that the constants for the formation of the outer-sphere complexes $BTlCl_2$ are little influenced by the replacement of Li^+ by H^+ in 4 M (Li, B)Cl solutions[3] or by the change from 4 M to 3 M (Li, B)Cl solutions.

In the series of anionic complexes $ZnCl_4^{2-}$, $CdCl_4^{2-}$, $HgCl_4^{2-}$, and $PbCl_4^{2-}$, the constants for association with alkali metal cations (Table 2) are inversely proportional to the crystallographic radii of the central ions[3]. The tendency to undergo hydration increases in the opposite sequence of central ions but the dimensions of the hydrated MCl_4^{2-} anions apparently decreases in the sequence given above.

The nature of the central ion has no influence on the outer-sphere association constants for singly-charged anionic complexes (Table 2). The anionic complexes $ZnCl_3^-$, $PbCl_3^-$, and $SnCl_3^-$ have identical constants for association with Na^+, K^+, and Rb^+ cations. The values of the outer-sphere association constants for the singly-charged $TlCl_2^-$ anions differ from those for MCl_3^- ions. This is due to the difference in the dimensions of the hydrated $TlCl_2^-$ and MCl_3^- anions and possibly to a number of other factors[3].

The outer-sphere association constants for MBr_4^{2-} anions decrease in the sequence Zn, Pb, Cd (Table 2); this distinguishes the dependence of the outer-sphere association constants for bromo-complexes on the nature of the central ion from the analogous dependence for the chloro--complexes MCl_4^{2-}. The high values of the outer-sphere association constants for $B^+ZnBr_n^{2-n}$ have been attributed[40] to the low stability of $ZnBr_n^{2-n}$ and the contribution to the value of $\gamma_{n,1}$ due to the increase of n in $ZnBr_n^{2-n}$. This explanation is not convincing, however[3]. Unfortunately, the outer-sphere association constants for $ZnBr_4^{2-}$ anions were determined only by the potentiometric method[40].

The stability of the outer-sphere associated species formed by anionic complexes ML_n^- and ML_n^{2-} decreases with increase in the dimensions of the ligand (Table 2). For example, the constants for the formation of outer--sphere complexes $BPbL_4$, where B represents Na^+ and K^+ cations and L represents chloride, bromide, and nitrate anions, and also the constants for the formation of complexes $BZnL_3$, where L represents chloride, bromide, and iodide anions, decrease in direct proportion to the crystallographic radii of the ligands[40]. The values of $\gamma_{n,1}$ apparently always decrease in the same sense as the dimensions of the ligand, if the values of the outer-sphere association constants are determined with a sufficient degree of reliability[3].

The outer-sphere association constants of thiocyanato--complexes are very low compared with those for halogeno--complexes (Table 2). It may be suggested[3] that the ion pairs $B^+(H_2O)_x(SCN)^-$ are more stable than the analogous compounds with chloride and bromide anions, so that in the calculation of the outer-sphere association constants for thiocyanato-complexes in 3–4 M (Li, B)SCN solutions it is necessary to make allowance for the difference between the total and equilibrium concentrations of thiocyanate ions, since this difference is much larger than in systems containing halogeno-complexes.

The ionic strength of the solutions has little influence on the outer-sphere association constants in the ionic strength range three to four (Table 2).[3] Change in the ionic strength of the solutions from zero to four leads to an appreciable decrease in outer-sphere association constants[40], as in the case of the constants for inner-sphere interaction[3]. A noteworthy feature (Table 3) is that the decrease in the constants for the outer-sphere association of anionic complexes with alkali metal cations on going from solutions with zero ionic strength to solutions with an ionic strength equal to three is much less than that for the analogous characteristics for alkaline earth metal cations. In solutions with an ionic strength equal to three, the constants for outer-sphere association, for example of cyanoferrate(III) anions with alkali and alkaline earth metal cations, are almost identical, but in solutions with zero ionic strength the constants for the attachment of alkaline earth metal cations are several dozen times greater than the constants for the attachment of alkali metal cations (Table 3).

The decrease in the differences between the constants for the attachment of alkali and alkaline earth metal cations on going from solutions with zero ionic strength to solutions with an ionic strength equal to three is attributed[3] (Table 3) to the increase in the interaction of the alkaline earth metal cations with the ligand anions or anions of the salt medium with increase in the ionic strength of the solution[84]. Alkali metal cations also undergo association with ligands or anions of the salt medium, like the alkaline earth metal cations, but this interaction does not have a significant influence on the outer-sphere association constants, if $[ML_n] \ll [B]$. In solutions with equal ratios $[ML_n]/[B]$ and $[L]/[B]$, the $B(H_2O)_xL$‡ complexes are more

‡ The stability constants of $B^+(H_2O)_xCl^-$ in 3–4 M (Li, B)Cl solutions for B = Na^+, K^+, Rb^+, and Cs^+ are 0.4, 0.8, 1.2, and 1.6 respectively[86] if the change from solutions with I = 0 to solutions with I = 3–4 doubles the stability constants.

stable than the $B(H_2O)_xML_n$ complexes, if the charges of L and ML_n are equal. The correctness of this last statement is confirmed by study of electrical conductivity in 3 *N* solutions of mixtures of cadmium chloride with alkali metal chlorides at equal concentrations of $CdCl_2$ and BCl [3,85] and also by potentiometric studies of the stability of the chloro-complexes of cadmium at C_{Cd} = 0.001–0.01 M and high concentrations (up to 5 M) of alkali metal chlorides [41,87]. Data obtained by the electrical conductivity method indicate that the degree of complex formation by cadmium increases in the sequence caesium chloride–lithium chloride, but potentiometric data indicate that the degree of complex formation by cadmium increases in the sequence lithium chloride–caesium chloride. Thus [32] in solutions with equal concentrations of cadmium and alkali metal chlorides the behaviour of the system is determined by the formation of $B^+(H_2O)_xCl^-$ while in solutions with low cadmium concentrations it is determined by the formation of $B^+(H_2O)_xCdCl_3^-$, since the stability of the complexes of both types increases from lithium to caesium.

The stability of the outer-sphere complexes of ML_n with alkali and alkaline earth metal cations increases in inverse or direct proportion to the dimensions of the latter [3]. For association without breakdown of the hydration sheaths of the alkali and alkaline earth metal cations, the stability of the outer-sphere complexes increases in the sequences lithium–caesium and magnesium–barium, but for interaction with breakdown of the hydration sheaths the stability increases in the opposite sequences. From this, it follows that all the complexes whose stability constants are given in Tables 2 and 3 are formed without complete breakdown of the hydration sheaths of the outer-sphere cations; however, the outer-sphere association constants are linear functions of the crystallographic radii of the outer-sphere ions. Under the conditions studied (3–4 M solutions of inert salts) the radii of the hydrated alkali metal cations are apparently inversely proportional to the crystallographic radii of these cations [3]; this explains why the outer-sphere association constants are given by Eqns. (21) and (22).

The enthalpy and entropy changes accompanying outer-sphere association have been determined [3,9,31,32,40,41,81]. The numerical data in Table 4, collected from various papers, show that the interaction of singly-, doubly-, and triply-charged anionic complexes with alkali and alkaline earth metal cations is accompanied by appreciable enthalpy and entropy changes. The decrease in entropy again indicates interaction without complete breakdown of the hydration sheaths of the alkali metal cations [88].

The outer-sphere interaction of quadruply-, quintuply-, and some triply-charged anions is accompanied by an increase in entropy [24], as is the interaction of singly-, doubly-, and triply-charged anionic complexes with outer-sphere cations with low degree of hydration or high charge (greater than three) [89–91].

Increase in the charge or decrease in the dimensions of the anionic complex or outer-sphere cation leads to a smaller decrease in entropy during outer-sphere association (Table 4). The identical decrease in entropy for the association of $PbCl_4^{2-}$ and $BiCl_6^{3-}$ anions with alkali metal cations is attributed to the high acidity of the solutions§ in

TABLE 4. Entropy change accompanying the formation of BML_n at 25°.

which the outer-sphere associated species of the chloro-complexes of bismuth were studied (Table 4). In the presence of hydrogen ions even the doubly-charged $PbCl_4^{2-}$ anions react according to the equation

$$H^+ + PbCl_4^{2-} \rightleftarrows HPbCl_4^- \qquad (25)$$

with equilibrium constant equal to five.[3]

The entropy change accompanying the outer-sphere association of one anionic complex with various alkali metal cations is described by the equation [9,31,39,41]

$$\Delta S = 0.1Q_B + A \qquad (26)$$

where Q_B is the heat of hydration of the alkali metal cations and *A* is a constant. The low accuracy of the determination of the entropy change, however, makes necessary repeated verification of the correctness of this statement [3]. These doubts are also raised by the fact that an equation of type (26) characterises the entropy change in substitution processes but not in addition processes [16].

A direct calorimetric method was recently used to measure the enthalpy changes accompanying the association of alkali and alkaline earth metal cations with cyanoferrate(III) anions [40,65]. This increased the accuracy of the determination of the entropy changes. The accurate data [65] showed that the association of $Fe(CN)_6^{3-}$ ions with sodium, potassium, magnesium, and barium cations in 3 *N* solutions of mixtures of lithium chloride with the chlorides of the metals studied is accompanied by a decrease in entropy by 15–17 e.u., the value of ΔS being apparently independent of the nature of the outer-sphere cation.

Association with a decrease in the number of species by unity is accompanied by an entropy decrease of ~17 e.u. [20,92]. This quantity is almost independent of the nature of the interacting species. This result, together with experimental data [40,65], shows that the association of cyanoferrate(III) ions with alkali and alkaline earth metal cations takes place without breakdown of the hydration sheaths of the interacting ions. Spectrophotometric study [65] confirms this conclusion but indicates breakdown of the hydration sheaths in the association of K^+ with $Fe(CN)_6^{4-}$ in 3 M (Li, K)Cl solutions.

The interaction of anionic complexes with highly charged cations ($Z > 2$), weakly hydrated cations, or cations with a tendency to form covalent bonds is usually accompanied by an increase in entropy and a change in the ultraviolet range of the spectrum of ML_n and B. [22,87,89,90] These facts indicate the formation of direct bonds (without the presence of intervening solvent species along the $B–ML_n$ link) between the anionic complexes and outer-sphere cations of these types.

§ In strongly acidic solutions the $BiCl_6^{3-}$ ion is converted into $HBiCl_6^{2-}$, which reacts to form $B^+(H_2O)_xHBiCl_6^{2-}$ with higher positive values of ΔS than $BiCl_6^{3-}$.

Nitrate, sulphate, phosphate, and similar ions are complex anions which do not dissociate in aqueous solutions. The association of these anions with various cations may involve complex formation or outer-sphere association, depending on the nature of the interacting ions. For example, in 3 N $Li(ClO_4, L)$ solutions, Tl^+ forms only ion pairs $Tl^+(H_2O)_xNO_3^-$ with nitrate ions but gives typical complexes with pyrophosphate anions[15]. An intermediate position is occupied by associated species comprising sulphate and thallium[93]. Highly charged cations and cations with a tendency to form stable hybrid bonds form typical ionic complexes with pyrophosphate and sulphate anions and also with nitrate anions[22]. The clearly-defined stepwise nature of their formation distinguishes inner-sphere complexes from outer-sphere complexes. The rules governing the interaction of undissociated complex anions with cations have been examined repeatedly[5,16].

There is as yet no information about the association of labile and relatively unstable cationic complexes with outer-sphere anions, but the outer-sphere association of inert and stable cationic complexes has been studied by many workers[22]. The outer-sphere complexes of the $Co(NH_3)_6^{3+}$ ion have been studied most completely and most frequently, but the data on the stability constants of these complexes are extremely contradictory[3] and are the subject of discussion[62,74]. The values obtained by various workers for the formation constant of the complex $Co(NH_3)_6^{3+}.Cl^-$ lie in the range 0.2–390.[63] Verification of the values of this constant[3] showed that the results of all earlier work[22,74] are correct and that the values of the constants for the formation of the luteochloride complex depend to a marked extent on the concentration and composition of the salt medium in which the studies are carried out[63]. Change in the composition of the salt medium changes the thermodynamic characteristics of the luteochloride complex by factors of several hundred and even changes their sign. Thus the complexes with composition $Co(NH_3)_6^{3+}.Cl^-$ at 25° are formed with $\gamma_{6,1} = 15.3$, $\Delta H = -5.8$ kcal mole^{-1}, and $\Delta S = -11$ e.u. in 0.1–0.5 M sodium chloride solutions but with $\gamma_{6,1} = 0.49$, $\Delta H = 5.6$ kcal × × mole^{-1}, and $\Delta S = 18$ e.u. in a 1 M solution of a mixture of sodium perchlorate and chloride[62]. This sharp change in the thermodynamic characteristics of the luteochloride complex is attributed to a change in the type of association on going from one salt medium to the other. In 0.1–0.5 M NaCl solutions the association of the $Co(NH_3)_6^{3+}$ and Cl^- ions takes place with the formation of a direct bond between the ionic complex and the outer-sphere ion. This is indicated by the decrease in entropy and by the agreement between the values of the outer-sphere association constant determined by solubility and spectrophotometric methods[3]. In 1 M sodium perchlorate solution the luteo-ion forms $\{[Co(NH_3)_6^{3+}].(ClO_4)_x\}^{3-x}$ complexes which are less stable than the complexes with other anions. The replacement of perchlorate ions by chloride ions in 1 M $NaClO_4$ solution leads to conversion of the luteoperchlorate complexes into luteochloride complexes; this process is accompanied by a bathochromic displacement of the absorption band of the luteo-ion in the ultraviolet range of the spectrum and is characterised by an increase in entropy, like the usual process of complex formation in aqueous solutions[5].

The marked influence of the composition and concentration of the salt medium on the thermodynamic characteristics of the ion pairs formed by cationic complexes makes it difficult to compare these characteristics and to recalculate them for solutions with zero ionic strength. Semi-quantitative comparison of a large amount of published data[22] shows that the $Co(NH_3)_6^{3+}$ ion and apparently the ions $Coen_3^{3+}$, $Copn_3^{3+}$, $Pten_3^{4+}$, $Cuen_2^{2+}$, etc., where en represents ethylenediamine and pn propylenediamine, form outer-sphere complexes with various anions, the stability of these complexes (with composition $ML_n.B$) increasing in the order

$$SCN^-, OH^-, I^-, N_3^-, Br^-, Cl^-, S_2O_3^{2-}, SO_4^{2-}, P_3O_9^{3-}, P_4O_{12}^{4-} \quad (27)$$

Increase in the dimensions of the cationic complex decreases the outer-sphere association constants; for example, the stability of the outer-sphere complexes formed by $Co(NH_3)_6^{3+}$, $Coen_3^{3+}$, and $Copn_3^{3+}$ with chloride, sulphate, and other anions decreases with increase in the molecular weight of the amine in the inner sphere[22].

According to modern theories, the stability of the outer-sphere complexes is determined by the charges and dimensions of the ionic complex and outer-sphere ion[94], but the values of the outer-sphere association constants are influenced by the structure of the ionic complex and also, apparently, by the structure of the outer-sphere ion. The *cis*-isomer of $CoCl_2en_2^+$ forms outer-sphere complexes with chloride and acetate anions in aqueous alcohol solutions but the analogous *trans*-isomer does not[49,95]. This can be attributed to the presence of a dipole moment in the *cis*-isomer and its absence in the *trans*-isomer.

The $Cr(H_2O)_6^{3+}$ ion forms less stable outer-sphere complexes with outer-sphere anions than the $Co(NH_3)_6^{3+}$ ion[22]. This difference has been related[94,96] to the higher positive charge of the $Co(NH_3)_6^{3+}$ ion, which has six protons more than the $Cr(H_2O)_6^{3+}$ ion. Increase in the number of protons in cationic complexes of the type $M(RH_n)_6^{3+}$, where RH_n represents molecules containing protons, increases the positive character of the peripheral charge of these complexes[94].

Most ion pairs of cationic complexes are formed by endothermic reactions involving an appreciable increase in entropy[3] and a change in the charge-transfer spectra[72,97]. Linhard[97] showed that the ultraviolet absorption spectrum of the luteo-ion exhibits a bathochromic shift when halide ions are added to a solution of the luteoperchlorate. The magnitude of the bathochromic shift changes in the same sense as the dimensions of the halide ion[72]. The charge transfer in the process

$$[Co(NH_3)_6]^{3+} + I^- \xrightarrow{h\nu} [Co(NH_3)_6]^{2+}.I^0$$

is responsible for the bathochromic shift in the spectrum of the luteo-ion when iodide ions are added to the solution[97].

The outer-sphere association of cationic complexes whose charge exceeds two usually takes place with breakdown of the hydration sheaths of the interacting ions and is accompanied by the formation of direct bonds between the ionic complexes and outer-sphere ions[3] but the nature of this bond has been little studied.

CN^- ions are joined to central cations via the carbon atom[97]. From this, it may be assumed that interaction takes place via the nitrogen atom in the outer-sphere complexes $B[Fe(CN)_6]$. The structures of outer-sphere complexes of the Prussian Blue type are apparently analogous to those of organo-derivatives of gold cyanide. The same is approximately true of the bonds in thiocyanato super-complexes[3¶].

¶ The term "super-complex compound" is synonymous with the term "outer-sphere complex".

The stability of the bond formed by the first halide anions with the luteo-cation increases with decrease in the atomic weight of the outer-sphere ion, but the stability of the anionic super-complexes $\{[Co(NH_3)_6].Hal_x\}^{-x+3}$, where Hal represents halide anions, changes in the opposite sense. This is indicated by chromatographic studies[77] and by study of the solubility of the luteoperchlorate in aqueous solutions of lithium and sodium chlorides and bromides. The increase in the stability of the anionic super-complexes $\{[Co(NH_3)_6].Hal_x\}^{-x+3}$ with increase in the atomic weight of the outer-sphere ion is attributed[77] to the formation of a covalent bond by $Co(NH_3)_6^{3+}$ with halide ions as a result of the donor properties of the latter. This explanation is confirmed[3] by the fact that the values of the stability constants of the luteohalide outer-sphere complexes, calculated from solubility and spectrophotometric data, are identical.

Outer-sphere association has a significant influence on the kinetics of chemical reactions[93,99-101] since outer-sphere complexes of the ion-pair type are more reactive than the free ionic complexes. It cannot be assumed that this is applicable to all systems[3] but up to the present no systems are known[94] in which outer-sphere interaction leads to a significant decrease in the rate of chemical reactions.

The catalysis of a number of redox processes is based on the formation of outer-sphere complexes[99], the catalytic effect increasing in the same sense as the stability of the outer-sphere complexes.

7. PREDICTION OF THE CONSTANTS FOR THE ASSOCIATION OF ANIONIC COMPLEXES WITH ALKALI METAL CATIONS

The results of studies which have been partly summarised in Table 2 and a number of other papers[3,39,40] show that the dependence of $\gamma_{N,1}$ on r_B, r_M, r_L, and Z^2 is linear for most systems studied. These relationships can be used to predict association constants in systems which have not been studied or have been little studied. Experimental verification has confirmed that such prediction is possible[3]. Some predicted outer-sphere association constants[3,40] are given in Table 5. The verification of the numerical data in this Table is of interest.

The dependence of the e.m.f. of cell (19) on the concentration of Na^+ in S_y solutions is linear for all systems studied[3,39], so that for the calculation of the constant for the outer-sphere association of ML_n with Na^+ it is sufficient to measure the e.m.f. of cell (19) at a single Na^+ concentration in the S_y solution. The constants for the association of ML_n with the other alkali metal cations are then most conveniently determined from the plot of $\gamma_{N,1}$ against r_B or the plot of $\log \gamma_{N,1}$ against r_B, knowing that the value of r_B at which $\gamma_{N,1} = 0$ is determined by the nature of the ligand[3] (see section 6).

8. COMPARISON OF OUTER-SPHERE AND INNER-SPHERE ASSOCIATION CONSTANTS

There is a large amount of published information[22] on the composition and stability constants of acido-complexes, determined without allowance for the association of anionic complexes with outer-sphere cations. As a result of such studies, it was found[35,66,67,102-104] that a given central ion forms, for example, a smaller number of ionic complexes and less stable ionic complexes with the halides of light alkali metals than with the halides of heavy alkali metals. An analogous result was observed in the study of nitrato-,[105] thiocyanato-,[68] and other[3] complexes. On the other hand, in a study of hydroxo-complexes[106] it was found that the degree of complex formation by central ions with hydroxide ions increases in the sequence CsOH–LiOH. Calculations of the composition and stability constants of ML_n from data obtained by different methods showed that the values of n and β_n depend on the method of determination[35] and also led to anomalously low or anomalously high values for stepwise stability constants and to the detection of ionic complexes which in fact do not exist in solution[3]. All this was observed when no allowance was made for outer-sphere interaction[3], but these contradictions disappeared in many systems formed by ionic complexes when allowance was made for the formation of outer-sphere complexes, and the constants for the formation of the latter did not depend on the method of determination or the concentration of the reacting substances[32,39].

The need to make allowance for outer-sphere interactions can be seen by comparing the data in Tables 2 and 6, which show that the constants for the attachment of the N-th ligands to ML_{N-1} are less than the constants for the outer-sphere association of ML_N with alkali metal cations for the chloro-complexes of thallium(I), lead(II), zinc, cadmium, and even bismuth(III).[31]

In the formation of nitrato-complexes of lead(II), only the first nitrate anion is joined to Pb^{2+} by a more stable bond than that joining the K^+ cation to the $Pb(NO_3)_4^{2-}$ anion.

TABLE 5. Predicted[3] values of the stability constants of the ion pairs $B(H_2O)_xML_n$ at 25° in 4 M (Li, B)L solutions.

Anionic complexes	Constants for outer-sphere association with the cations of			
	sodium	potassium	rubidium	caesium
$PtCl_4^{2-}$	0.5	1.2	1.6	1.8
$CuCl_2^-$	0.1	0.2	—	—
$AgCl_2^-$	0.1	0.2	—	—
$AgBr_2^-$	—	0.03	0.06	0.08
$SnCl_4^{2-}$	0.6	1.9	2.6	3.0

TABLE 6. Stability constants of ML_n ions in 4 M $Li(ClO_4$, L) solutions at 25°, calculated from potentiometric data.

M	L	Stepwise stability constants of ML_n with n equal to				References
		1	2	3	4	
Tl^+	Cl^-	0.80	0.14	—	—	35
Pb^{2+}	Cl^-	17	3.1	2.3	0.18	80
Zn^{2+}	Cl^-	2.0	0.50	10	0.01	34
Zn^{2+}	Br^-	1.16	0.13	12.7	0.18	37
Zn^{2+}	I^-	0.34	0.03	18	0.31	40
Cd^{2+}	Cl^-	58	6.9	3.7	0.29	33
Pb^{2+}	NO_3^-	3.0	1.2	0.37	0.19	3

Heavy alkali metal cations are joined by a more stable bond to $PbCl_3^-$ and $ZnCl_3^-$ anions than to the four-coordinated chloro-anions. This explains the fact that when Na, K, Rb, or Cs chlorides are added to a solution containing Pb^{2+}, Zn^{2+}, and, apparently, Cd^{2+} cations, the formation of MCl_3^- ions is followed by the formation of $BMCl_3$ outer-sphere complexes, to which the fourth chloride ion is attached. The alkali metal cations are joined to the MCl_3^- anions via a layer of water molecules, but the fourth chloride ion is joined by a direct bond to the central metal ion[3]. This indicates that the outer-sphere interaction without direct bonding between MCl_3^- and alkali metal cations leads to an increase in the coordination sphere of the central ion or, more accurately, increases the probability of the replacement of water in the inner sphere of $[MCl_3(H_2O)]^-$ by a Cl^- anion.

The data in Tables 2 and 6 show that in many systems which have been studied repeatedly the effect of outer-sphere interaction is much greater than the effect of attachment of the last ligands in ML_N, so that the data on the composition and stability constants obtained for these ionic complexes without allowance for outer-sphere interaction[22] require correction†.

9. COMPLEX FORMATION WITH ALLOWANCE FOR ASSOCIATIVE INTERACTION WITH THE IONS OF THE SALT MEDIUM

The composition of the medium, that is the nature and concentration of the solvent and any ions present in the solution, influences complex-formation equilibria. The salt medium may produce either an increase or a decrease in the degree of complex formation by the central ion[3]. A decrease in the degree of complex formation by M with L often takes place when these components form new structural units[15] with the influencing ions, and an increase in the degree of complex formation is observed when outer-sphere complexes are formed by the ionic complexes with the influencing ions. The decrease in the degree of complex formation by M with L under the influence of ions which form new structural units with M or L has been used many times[14] to study complex formation in solution. The increase in the degree of complex formation under the influence of the ions of the salt medium was first taken into account after a series of studies had been carried out in solutions with high and constant ionic strengths, maintained using inert salts[17], but up to the present the allowance made for this effect has been purely qualitative. It is often considered[107] that secondary reasons for the influence of the ions of the salt medium, involving a change in the activity of the solvent, a change in the activity coefficients of the reactant and product ions, a change in the structure of the solution, etc. exert an influence which cannot be distinguished from chemical interaction in systems with labile and relatively unstable complexes. The contents of the preceding sections of the present review refute this suggestion. At present, however, there is little information on outer-sphere interaction or on the dissociation of the alkali and alkaline earth metal salts whose anions are used as ligands in the study of complex formation in aqueous solutions with high and constant ionic strengths.

† The coordination number of the super-Werner sphere is equal to 12; less frequently it amounts to 6 for octahedral complexes and 4 for tetrahedral complexes. The centres of the edges or faces of the tetrahedra and octahedra are used in super-Werner coordination[123].

The replacement of water by aqueous solutions of inert salts smoothes out the difference in the extents to which the dissociation of strong and weak electrolytes obeys the law of mass action[108], so that the interaction of a central ion with ligands and the ions of a salt medium, like the dissociation of all alkali and alkaline earth metal salts, can be characterised by the constants for the formation of definite complexes[3].

Formulae (1) and (2) characterise the composition of the simple ions and ionic complexes formed in concentrated solutions of inert salts. The replacement of any ions of the salt medium influences the composition and structure of the complexes (1) and (2). Increase in the tendency of the ions of the inert salt to react with the central ion decreases the experimentally measured degree of complex formation with the ligand. Thus in the study of the formation of bromo-complexes of lead in solutions with constant ionic strengths, maintained with sodium perchlorate, nitrate, and chloride, it was found[55] that the degree of complex formation of Pb^{2+} in solutions with equal bromide ion concentrations decreases with change in the ions of the salt medium in the sequence ClO_4^-, NO_3^-, Cl^-. This is attributed to the fact that these anions themselves form complexes with the bivalent lead cation, and complex formation with bromide ions involves the replacement, by bromide ions, of the above anions in the inner sphere of the lead cation. The stabilities of the Pb^{2+} complexes increase in the sequence $Pb(ClO_4)_n^{2-n}$, $Pb(NO_3)_n^{2-n}$, $PbCl_n^{2-n}$.[56]

The Li^+ cation forms the least stable outer-sphere complexes with the great majority of anionic complexes with charges less than three[3]. Perchlorate anions rarely form anionic complexes with central ions[22,109] and, more particularly, do not form anionic complexes with charges exceeding three. Thus the stability of complexes of type (1) will be smaller in the presence of Li^+ than in the presence of other cations which do not form stable compounds with the ligand. This explains why, in the interaction of central ions with alkali and alkaline earth metal salts, the highest degree of complex formation by the central ion is observed in a medium containing of lithium salts[110]. This result is not affected by the increase in the stability of the outer-sphere complexes B_yML_n in the sequence lithium–caesium and magnesium–barium[3], since the relative increase in the degree of complex formation by M as a result of the outer-sphere interaction increases with decrease in the stability of the M–L or $M–ClO_4^-$ bonds[103,117].

The stability of the ion pairs $B(H_2O)_xL$, the outer-sphere complexes B_yML_n, and the complexes

$$\sum_{n=0}^{n=N}\sum_{x=0}^{x=X}\sum_{y=0}^{y=Y}\sum_{z=0}^{z=Z} ML_n(H_2O)_xA_yB_z, \qquad (28)$$

by which we mean[14,15,17,54] ionic complexes ML_n in concentrated solutions of inert salts with cation B and anion A, increases from lithium to caesium and from magnesium to barium for different A and L = Cl^-, Br^-, I^-, NO_3^-, SCN^-, SO_4^{2-}, etc.[35,102,103,111], but changes in the opposite sequence for L = OH^-, CH_3COO^-, etc.[3,106] Usually, the stability of the B–ML_n and $B(H_2O)_x$–L bonds changes in the same sequence of cations B, and increase in the strength of these bonds leads to an increase in the degree to which M is bound in complex (28). The anions A, like the cations B, increase the extent to which M is bound in complex (28) with increase in the stability of the M–A bond[3]. Some published data[55,56] contradict this result, due to the fact that the salt medium

was regarded as an inert solvent for M, L, and ML_n, and not as a component of the equilibrium for the dissociation of complex (28).

The cations of the salt medium have little influence on the stability constants of cationic complexes and neutral molecules[63,102,112] if complexes BL_n are not formed. The influence of alkali and alkaline earth metal cations involves chiefly a change in the structure of the cationic complexes, and hence a change in ΔH and ΔS for formation of the latter[20]. The replacement of alkali metal cations in the sequence lithium, sodium, and potassium[113] displaces the equilibrium

$$CdNO_3^+ + xH_2O \rightleftarrows Cd^{2+}(H_2O)_xNO_3^- \quad (29)$$

to the right, since the tendency of these cations to bring about the dehydration of the Cd^{2+} cation decreases in the above sequence.

The influence of the cations of inert salts on the formation of neutral molecules, for example of the type ML_2, is due to their influence[39,43,46,110] on the equilibria

$$2ML_2 \rightleftarrows ML^+ + ML_3^- \quad (30)$$

and

$$3ML_2 \rightleftarrows 2ML^+ + ML_4^{2-} \quad (31)$$

which are often established in stepwise complex formation[3], but which have unfortunately been little studied as yet.

Increase in the tendency of the cations of the salt medium to form outer-sphere complexes with ML_3^- and ML_4^{2-} anions displaces equilibria (30) and (31) to the right and leads to a decrease in the stability constants of ML_2.[43]

The most direct method for investigating complex formation in solutions is by studying the Raman spectra[17,109]. Data obtained by this method are influenced to the minimum extent by the effect of the medium on complex formation and give information about the concentration of individual ionic complexes and also about the nature of the bonds M–L, B–ML_n, and ML–A.[114]

The intensity of the characteristic bands of the Raman spectra is proportional to the concentration of the complex formed and can be used as the chief parameter for the quantitative representation of processes taking place in solutions[114]. Clear-cut measurement of the intensity of the characteristic bands in Raman spectra is possible, however, only for the ionic complexes predominating in the ML, $ML_2 \ldots ML_n \ldots ML_N$ system[115]. The predominating ions are usually ML and ML_N.

Raman spectra are extremely useful for demonstrating the differences between outer-sphere and inner-sphere complexes[109]. The formation of outer-sphere complexes is not reflected in the Raman spectra[116].

The low sensitivity of present-day apparatus unfortunately makes it impossible to use Raman spectra to study complex formation in solutions with reactant concentrations less than 0.5 M.[3] Increase in the sensitivity of the apparatus by several orders of magnitude may make this method the most suitable for studying various types of complex in solution in any salt medium[17].

Despite the low sensitivity of the method, the use of Raman spectra has proved the existence of inner-sphere nitrato-complexes of Ca^{2+}, Ce^{4+}, Th^{4+}, Cu^{2+}, Ag^+, Zn^{2+}, Hg^{2+}, Al^{3+}, and In^{3+} [117,118] and has completely refuted, for almost all elements of the Periodic System, the suggestion that perchlorato-complexes are inner-sphere complexes[109].

The influence of the salt medium on complex formation in solutions often involves the formation of various types of ionic molecules[78] for which allowance is not made in the interpretation of the experimental data[3]. The low energies of formation of ionic molecules points to the possibility of detecting these complexes by means of the vibrational and rotational spectra.

Unfortunately, there is almost no published information on the use of infrared spectra to study the association of ions and the influence of the salt medium on complex formation.

Water absorbs over a wide range of the infrared spectrum. Only the use of thin-layer (5–10 μm) cells or surface reflectance spectra makes it possible to study association in aqueous solutions by infrared spectroscopy and even then only for a limited number of anions.

The sulphato-,[119] thiocyanato-,[120] and cyano-complexes[121] of various metals in aqueous solutions have been studied by infrared spectroscopy. The separate detection of outer-sphere complex formation, usually attributed to the influence of the nature of the salt medium, and inner-sphere interaction showed[119] that the tendency to form inner-sphere monosulphato-complexes decreases in the sequence $Cd^{2+} \simeq Cu^{2+} > Ni^{2+} > Co^{2+} \simeq Zn^{2+} > Mn^{2+}$. The change from the monosulphato- to the disulphato-complexes decreases the contribution made by outer-sphere complex formation[119].

Mathematical treatment of the experimental infrared spectroscopic data sometimes makes it possible to estimate the constants for both inner-sphere and outer-sphere interaction[120].

Increase in the sensitivity and the more extensive use of physical methods for studying association in aqueous solutions should extend our knowledge in this field.

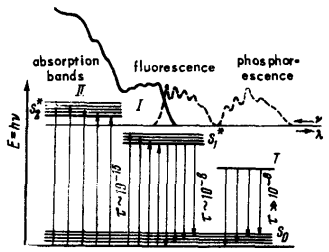
1. ELECTRONIC STATES AND VIBRONIC SPECTRA OF POLYATOMIC MOLECULES

The complete electronic spectrum of a molecule arises from changes in electronic, vibrational, and rotational energy[1-7]. The energy of rotational quanta in polyatomic



molecules is relatively small (the wave numbers corresponding to rotational quanta, which are proportional to their energy, are of the order of $\bar{\nu}_{rot} \simeq 1$ cm^{-1}), and the shape of an electronic band is largely determined by the superposition of the effect of vibrational sub-levels on that of the electronic transition (see Figure). The electronic states of molecules are classified on the basis of the total spin of the electron[1-3,5,6]. As in the case of atoms, a state in which the spins are compensated is called a singlet (S), a state with unit spin is called a triplet (T), and so on. Optical transitions between electronic states in a molecule are controlled by selection rules, according to which transitions between states of the same multiplicity are permitted and transitions between states of different multiplicity are forbidden. Molecular states are further classified on the basis of considerations of the symmetry of the potential field surrounding the nuclear skeleton of the molecule. The symmetry of the wave functions describing particular states of the molecule may not coincide with the symmetry of the skeleton.

In symmetry operations the electronic and the vibrational wave functions undergo similar transformations: hence, classification of these functions and of the states which they describe is possible. We should note that symmetry descriptions are the only precise statements which can be made regarding the wave functions of molecules, since it is impossible, in practice, to obtain the wave functions describing a molecular state in an explicit form. The most convenient classification of states from the point of view of their symmetry is achieved by applying the theory of point groups[1-4,6-9]. Every molecule can be assigned to a definite symmetry group by considering the characteristic symmetry elements of the molecule and symmetry operations. The properties of the transformations of the wave functions stem directly from the concepts of groups. They can be obtained for all groups with which known molecules can be identified. A definite energy state of a molecule with fixed symmetry is called an energy level. The classification of electronic and vibrational states allows us to establish selection rules for optical electronic transitions between energy levels. The probability of a dipolar transition between two states is given by the square of the integral

$$\int \psi^* \hat{\mathbf{M}} \psi^0 \, dv, \qquad (1)$$

where ψ^* is the wave function of the state to which the transition occurs, ψ^0 is the wave function of the initial state, $\hat{\mathbf{M}}$ is the operator of the dipole moment of the transition.

The integral (1) will be non-vanishing if the function within the integral sign (or one of its terms, if the function is in the form of a sum) is fully symmetrical, i.e. if its symmetry properties are identical to those of the molecular skeleton. The function within the integral sign can be fully symmetrical if the product of the terms of the functions under the integral sign ($\psi^* \hat{\mathbf{M}} \psi^0$) gives a fully symmetrical term.

According to the Jahn-Teller theorem[1,2,7], the ground state of a non-linear polyatomic molecule must be non-degenerate and, therefore, fully symmetrical. Hence, a fully symmetrical term will be obtained for the integrand of (1) if the state to which the molecule undergoes a transition from its ground state belongs to the same symmetry type as one of the components of the vector $\mathbf{M}$ (M_x, M_y, M_z in a Cartesian system of coordinates). The selection rules for vibrational-electronic transitions are obtained from formula (1) by putting the wave functions in the form $\psi = \psi_{el}\psi_{vibr}$ (assuming that the rotational state remains unchanged):

$$\int \psi^*_{el} \, \psi^*_{vibr} \, \hat{\mathbf{M}} (\psi^0_{el} \, \psi^0_{vibr}) \, dv. \qquad (2)$$

A purely electronic transition takes place without change in the vibrational state, i.e. $\psi^0_{vibr} = \psi^*_{vibr}$. Multiplication of the vibrational term by itself gives a fully symmetrical term. Therefore, the electronic transition will be allowed if the symmetry of the term ψ^*_{el} coincides with that of one of the components of $\mathbf{M}$ (and the transition will be polarised along the corresponding axis). When an electronic transition is allowed on symmetry grounds, transitions to vibrational sublevels with fully symmetrical terms are also allowed. Vibrations can be active also if they alter the symmetry of the state in such a way that the symmetry of the function $\psi^*_{el}\psi^*_{vibr}$ coincides with the symmetry of one of the other two components of the vector $\mathbf{M}$, the polarisation of the transition changing at the same time by 90°.

If an electronic transition is forbidden on symmetry grounds (so that the purely electronic band is weak, or altogether absent from the spectrum), a vibration of a given symmetry may cause it to become allowed. This requires that the product of the electronic and the vibrational term should belong to the system which describes the transformation of one of the components of $\mathbf{M}$, i.e. should coincide with the symmetry of one of these components. It is evident from formula (2) that strong progressions can occur only with fully symmetrical vibrations, because they do not alter the term in the function within the integral sign even in the overtones. Consider as an example the symmetry group D_{2h}, to which many of the molecules discussed in this review belong. The group D_{2h} includes seven symmetry elements [three mutually perpendicular planes $\sigma(x, y)$, $\sigma(x, z)$, and $\sigma(y, z)$, three second-order symmetry axes c_2^z, c_2^y, c_2^x, and a centre of symmetry], three of which can be independent. Accordingly, eight different types of symmetry are possible, i.e. as many as the number of possible combinations of the signs + and - taken three at a time. Table 1 shows the behaviour of the possible terms of the molecule with respect to symmetry operations.

In the last column of Table 1 the translations T_x, T_y, T_z and the rotations R_x, R_y, R_z are assigned to the symmetry types of pseudo-vibrations. The components of the dipole moment operator $\hat{\mathbf{M}}$ coincide with the components of the vector $\mathbf{T}$. Table 1 shows that the following transitions are allowed for molecules of D_{2h} symmetry: transitions to the state B_{1u} (polarisation along the z axis), to B_{2u} (along the y axis), and to B_{3u} (along the x axis). The products of the various terms can be found from Table 2, which lists the products for the symmetry group.

According to Table 2, in an allowed electronic transition such as A_{1g}–B_{3u} (with polarisation along the x axis)

TABLE 1.

D_{2h}	σ_{xy}	σ_{xz}	σ_{yz}	i	c_2^z	c_2^y	c_2^x	
A_g	+	+	+	+	+	+	+	
A_u	−	−	−	−	+	+	+	
B_{1g}	+	−	−	+	+	−	−	R_z
B_{1u}	−	+	−	−	+	−	−	T_z
B_{2g}	−	+	−	+	−	+	−	R_y
B_{2u}	+	−	+	−	−	+	−	T_y
B_{3g}	−	−	+	+	−	−	+	R_x
B_{3u}	+	+	−	−	−	−	+	T_x

TABLE 2*.

A_{1g}	A_{1u}	B_{1g}	B_{1u}	B_{2g}	B_{2u}	B_{3g}	B_{3u}	
A_{1g}	A_{1u}	B_{1g}	B_{1u}	B_{2g}	B_{2u}	B_{3g}	B_{3u}	A_{1g}
	A_{1g}	B_{1u}	B_{1g}	B_{2u}	B_{2g}	B_{3u}	B_{3g}	A_{1u}
		A_{1g}	A_{1u}	B_{3g}	B_{3u}	B_{2g}	B_{2u}	B_{1g}
			A_{1g}	B_{3u}	B_{3g}	B_{2u}	B_{2g}	B_{1u}
				A_{1g}	A_{1u}	B_{1g}	B_{1u}	B_{2g}
					A_{1g}	B_{1u}	B_{1g}	B_{2u}
						A_{1g}	A_{1u}	B_{3g}
							A_{1g}	B_{3u}

* Taken from Sponer and Teller[7].

we may find, in addition to fully symmetrical vibrations, vibrations of B_{1g} and B_{2g} symmetry, which can alter the polarisation of the band: $B_{3u}B_{1g} = B_{2u}$ (along the y axis) and $B_{3u}B_{2g} = B_{1u}$ (along the z axis).

Sponer and Teller have analysed the electronic–vibrational spectra of many polyatomic molecules on the basis of their symmetry properties, and have tabulated the characteristics and products of various symmetry point groups[7].

Lastly, another important effect of the motion and position of the nuclei on the optical transitions in a molecule is expressed by the Franck–Condon principle: neither the relative position nor the velocity of the nuclei can change appreciably during the transition of a molecule from one electronic state to another, because the transition takes place in a time (10^{-15} s) which is short compared to the vibration period of molecules (10^{-12} s). One consequence of this principle is that molecules can undergo only vertical transitions in the potential energy diagram of the electronic states. Since the molecule spends most of the time at the extreme points (of its vibrations), vertical transitions between points on the potential energy curves are the most probable. If the equilibrium distance r is the same for the ground state and the excited state, bands similar to the purely electronic band will show up most strongly in the spectrum. When r changes appreciably, the purely electronic band becomes weak, even for an allowed transition.

It follows from the Franck–Condon principle, which was formulated in terms of classical physics by simultaneously considering the configurations and velocities of the nuclei, that only fully symmetrical vibrations can be active in electronic–vibrational spectra. Tavger's quantum-mechanical analysis of the Franck–Condon principle[10] has led to the conclusion that active frequencies may include some vibrations which are not fully symmetrical. Obviously the number of active, not fully symmetrical, vibrations must be limited by the selection rules according to the symmetry and structural peculiarities of the molecules.

Absorption and Emission Spectra

Under normal conditions (at room temperature) practically all the molecules remain in the electronic ground state of minimum electron energy. The Boltzmann factor kT is of the order of 200 cm^{-1} for T = 20°C (293°K). Therefore, most of the molecules reside in the zeroth vibrational sublevel of the ground state. For the overwhelming majority of known molecules the ground state is a singlet (S_0). As a consequence of the selection rule, S_i–S_k (i.e. singlet–singlet) transitions have the highest probability. Experiment shows that an excited molecule can remain in the lowest excited S_1^* state for a time $\tau \simeq 10^{-8}$ s, and for even shorter times in higher electronic levels. Hence, no appreciable concentration of molecules in excited states will arise during absorption of light by a system of molecules, and under normal conditions transitions of the type $S_{i>0} \rightarrow S_k^*$ will not occur during absorption, but only transitions from the ground state to excited states: $S_0 \rightarrow S_i^*$. The vibrational structure of an absorption band will be determined mainly by the vibrational sublevels of the excited state (see Figure).

A metastable triplet state may arise in the molecule as a result of non-optical and, to a certain extent, of optical transitions (details of the T-state in the molecule are given below). If a molecule is previously excited to a T-level, it is possible to measure absorption bands for $T \rightarrow T_i^*$ transitions (see Karyakin and Duzhenkov's review[11]). The weak bands of forbidden $S_0 \rightarrow T$ transitions are very much harder to observe.

The frequencies of normal vibrations depend on the electronic state of the molecule. Therefore, the vibrational differences obtained from absorption spectra can be expected to differ from the values for the same vibrations as observed in the vibrational spectra.

The lifetime of a molecule in the excited state and its ability to radiate the excitation energy depend essentially on radiationless deactivation processes. These are strongly dependent on the medium, the temperature, the structure of the molecule, and other factors. Light emission by a molecule is possible if the molecule resides in the excited state for a time $\geqslant 10^{-10}$ s. Experiment shows that a molecule can remain for this length of time only in the lowest S_1^* excited state and in its zeroth (vibrationless) vibrational level. Higher excited S_1^* states and vibrational sublevels undergo radiationless deactivation in shorter time intervals, and light emission from the molecule occurs only from the lowest excited S_1^* state (mainly from a vibrationless level) and from a T-state. Radiation caused by an S_1^*–S_0 transition is termed fluorescence. The structure of the fluorescence spectrum is determined by the active vibrations of the molecules in the ground state; therefore, the frequency values should be close to the frequencies of the same vibrations active in the Raman and infrared absorption spectra. The first, purely electronic fluorescence band, if present, should adjoin the long-wavelength edge of the absorption spectrum (partly overlapping the longest-wavelength absorption band), and the whole of the emission spectrum is located in a longer-wavelength region of the spectrum than the corresponding absorption (Stokes displacement of the emission bands, p. 470). The fluorescence yield is not directly related to the intensity of the long wavelength and other absorption bands. When the radiationless transitions are very weak the excited molecule can remain in a metastable T-state for a longer time (more than 10^{-8} s). The triplet nature

of the metastable state was first pointed out by Terenin[5,12], and subsequently by Lewis[13]. It can be demonstrated experimentally by measuring the magnetic susceptibility of the metastable state of a number of molecules[14,15]; more recently it has been demonstrated by electron spin resonance measurements on molecules of aromatic polycyclic hydrocarbons, and some others[16-18].

Under favourable conditions it is possible to observe an emission band due to a $T \rightarrow S_0$ transition accompanied by radiation and known as phosphorescence. The phosphorescence time can amount to several seconds, since the $T \rightarrow S_0$ transition is forbidden by the selection rule. The transition becomes allowed as a result of spin–orbital interaction. Emission spectra can be observed with opaque, scattering specimens, and, what is even more important, at very low concentrations (in some cases as low as 10^{-12} M). Emission spectra have one limitation: not all molecules can luminesce. An important problem in the field of molecular emission spectroscopy is to identify the conditions which favour the appearance of luminescence. It has been found that with many compounds radiationless deactivation is minimised by working with a solid phase and at low temperatures, thus enhancing the luminescence of the molecules.

Influence of the Medium on the Spectra. Quasi-Linear Structure

In practice one observes the spectra not of a single isolated molecule but of a large assembly of molecules, subjected to various external influences. The spectra of vapours may be thought to be those most closely resembling the spectrum of an individual molecule. However, the spectra of polyatomic molecules are usually diffuse owing to the high temperatures involved (which enhance intramolecular interactions, leading to diffuseness of the bands). Without considering in detail the causes of diffuseness in the spectra of vapours, we shall only point out an obvious cause of "diffuseness" in a vibrational sublevel: the quasi-continuous system of rotational sublevels. This, together with other factors, gives a gaseous system of molecules a spectrum whose structure cannot be properly resolved even with a high-resolution instrument. It should be noted, also, that many compounds are not stable in the vapour state. It is easy to see, therefore, why so few data have been published on well resolved absorption and luminescence spectra of complex molecular vapours, especially of polycyclic aromatic hydrocarbons.

Studies of the spectra of aromatic compounds in a condensed phase are more numerous: liquid and solid solutions, pure and mixed crystals. Under these conditions the spectra are significantly affected by intermolecular interactions, which also cause some diffuseness in the structure of the spectra. The most satisfactory resolution of spectral structure in a condensed phase is obtained at low temperatures for pure or mixed crystals and in neutral, very dilute crystalline solutions. In the latter case we are dealing, figuratively speaking, with a "frozen gas". The spectra of these solutions are either indistinguishable from or slightly shifted towards long wavelengths as compared with vapour spectra. In a condensed phase the molecules are closely spaced, and this hinders or altogether prevents molecular rotations. The earliest studies of quasi-linear electronic–vibrational spectra in crystals are due to Obreimov and Prikhot'ko[19,20]. Spectroscopic studies of pure or mixed single crystals having a crystal lattice of known structure, using polarised light, allow the direction of the moments of electronic transitions to be determined with respect to the axes of the molecule. For aromatic hydrocarbons, investigations of this type have been made by McClure (naphthalene in durene[21], phenanthrene[22]), Sidman (anthracene[23], anthracene in naphthalene and phenanthrene[24], naphthacene in naphthalene[25]), Pesteil and coworkers (see review article[26]), and others.

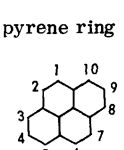
The observation of emission spectra of many aromatic hydrocarbon crystals showing a structure is limited by the photodimerisation effect, involving an excited and a non-excited molecule (excimer formation): the molecular emission band, with a structure, is converted into a structureless emission band at a longer wavelength. This phenomenon has been discussed in detail, for example, in a paper by Stevens[27], but the nature of the phenomenon was made clear by the work of Förster and coworkers[28-31], who studied it in concentrated solutions. Excimer formation from aromatic hydrocarbon molecules in solutions at concentrations above 10^{-3} M suggests the presence of strong interactions involving fluorescing molecules. Therefore, only the spectra of dilute solutions are similar to the spectra of undisturbed molecules. Polarisation measurements on the spectra, enabling the relative polarisation of the various electronic transitions to be determined, are also possible in the case of solutions.

In a series of investigations[32-38], Zimmerman and Yoop have examined the polarisation of the absorption and fluorescence spectra of alcoholic solutions of benzene, naphthalene, anthracene, naphthacene, phenanthrene, 1,2-benzanthracene, chrysene, pyrene, perylene, triphenylene, coronene, and azulene at -180°C. In every case they were able to show that the singlet–singlet bands are polarised in the plane of the molecule. Dörr and coworkers[39-41] showed that the moment of the T–S_0 transition for a series of aromatic hydrocarbons is polarised along a direction normal to the plane of the molecule.

There is no general method for obtaining spectra with an optimum degree of resolution of the vibrational structure, and the problem has to be approached empirically for each individual compound. Shpol'skii and coworkers made an important contribution in this field when they obtained, in 1952, quasi-linear fluorescence spectra for coronene and 3,4-benzopyrene† [42] in crystalline solutions at 77°K. They observed a splitting of the bands into multiplets which has since become known as the Shpol'skii effect. We shall not dwell on the specific features and on the nature of band multiplicity: interested readers are referred to existing review articles[43].

The n-hydrocarbon class of inert solvents has been very useful for resolving the structure of the spectra of many compounds: the study of spectral structure in n-hydrocarbons at low temperatures (77°, 20°, and 4°K) is called the Shpol'skii method. Shpol'skii and his school studied the quasi-linear spectra of many aromatic hydrocarbons[44-66]; their results are used in the present review. In a series of papers[67-69] Sponer, Kanda, and their coworkers showed

† The numbering of the pyrene ring system used by the author is evidently



which is contrary to that adopted by IUPAC and the Chemical Society (Ed. of Translation).

The abbreviations specify the spectra from which the electronic transition frequencies were determined and the solvent used: abs. — absorption spectrum; fl. — fluorescence spectrum; hex. — hexane; PE — petroleum ether; EPA — ether–isopentane–alcohol; oct. — octane; hept. — heptane; pent. — pentane; non. — nonane; cycl. — cyclohexane; alc. — alcohol.

that frozen cyclohexane is a good matrix for resolving the structure of the phosphorescence spectra of various compounds. The present writer has shown, for the case of pyrene in polyisobutylene[62,63], that quasi-linear structure can be obtained also in a polymeric matrix. Bowen and Brocklehurst[70], and also Pesteil and Rabaud[71], have used Shpol'skii's method to obtain quasi-linear spectra for a series of aromatic hydrocarbons.

Among organic compounds which absorb in the visible and near ultraviolet region of the spectrum, aromatic hydrocarbons are the simplest in the sense that their electronic bands in that region are associated with a single type of transition ($\pi-\pi^*$). The problem of establishing the relationship between structure and spectra amounts to formulating the influence of conjugation type (including the geometry of the conjugated system of π-electrons) upon the electronic bands. Polycyclic, fused hydrocarbons have a rigid planar structure which favours the appearance of a vibrational band substructure. The vibrational structure of bands of this class of compounds arises primarily from fully symmetrical vibrations of the carbon skeleton of the molecule (ν_{C-C}). In these cases we can apply a classification in terms of the symmetry of the energy states and establish selection rules for the particular molecule. Practically all known hydrocarbons exhibit fluorescence, and many also phosphorescence (under certain conditions). There is published information both on the absorption and on the luminescence spectra of this class of compounds. Inspection of the relation between the spectra and the structure of the molecules has shown a tendency for the absorption and fluorescence bands in aromatic hydrocarbons to be shifted towards longer wavelengths as the number of benzene rings and of conjugated double bonds in the skeleton of the molecule increases. When the arrangement of benzene nuclei is non-linear the wavelength displacement rule for the electronic bands becomes more complicated. Clar has described the absorption spectra and classified the absorption bands of aromatic hydrocarbons empirically on the basis of intensity differences, differences in the degree of the bathochromic shift with increase in the size of the π-electron system of the molecule, and differences in band shift on going from vapours to solutions[72-77].

α-Bands have a small extinction coefficient ($\log\epsilon \simeq 2.3-3.3$) and appear at the longest wavelengths for many hydrocarbons. On increasing the length of the linear chain of benzene rings, the α-band is usually obscured by a stronger p-band. p-Bands of average intensity ($\log\epsilon \simeq 3.6-4.1$) move rapidly towards longer wavelengths on increasing the linear condensation of nuclei. β-Bands of high intensity ($\log\epsilon \simeq 4.5-5.2$) undergo shifts similar to those of the α-bands as the number of benzene nuclei is increased.

Clar and Zander[78] have collected and discussed the data on phosphorescence spectra for a series of polycyclic hydrocarbons. They point out that the frequency differences between p-bands and the triplet level (of the order of $10-12\times10^3$ cm^{-1}) are approximately constant; T-level positions are listed in other papers[79,80].

Many theoretical discussions of the electronic states and spectra of aromatic hydrocarbons are available: these rely on concepts of the covalent bond, molecular orbitals, and the free electron model. Platt has proposed a perimetric model of the free electron for *ortho*-fused hydrocarbons; with this model, he has calculated the polarisation energies and classified the electronic transitions of many hydrocarbons[81,82]. Platt's band designations ^1L_b, ^1L_a, ^1B_b, ^1B_a, where the subscripts a and b denote polarisation along a particular axis of the molecule, are adopted in the present article. Platt[83] calculated the molecular orbitals by the simple one-electron LCAO method, and also considered[84] the transitions in *peri*-fused hydrocarbons. Ham and Ruedenberg[85] calculated the electronic states of aromatic hydrocarbons on the basis of antisymmetric products of free-electron molecular orbitals. This led to a slight modification of Platt's band classification: their values are shown in brackets in the present article.

There are also theoretical calculations by Pariser[86] and Moffit[87]. An unusual evaluation of transition energies in aromatic hydrocarbons, based on calculated resonance energies of structures in an excited state, has recently been carried out[88].

Table 3 lists the data on the energy of $S_1^*-S_0$ and $T-S_0$ transitions for a number of hydrocarbons.

2. BENZENE AND POLYACENES

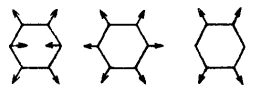
From the point of view of electronic spectra, the polyacene series should be regarded as beginning with naphthalene rather than benzene, because all polyacene molecules (except benzene) belong to the same symmetry group D_{2h}.

The benzene molecule (I)‡ has the D_{6h} symmetry.

In absorption, benzene shows three bands in the region of 2600, 2000, and 1800 Å. The band at 1800 Å ($\log\epsilon \simeq 4.6$) is ascribed to the $A_{1g}-E_{1u}$ transition. The transition is allowed by symmetry and is polarised in the plane of the molecule[89]. The second band at 2000 Å ($\log\epsilon \simeq 3.6$) is resolved into diffuse bands and is associated with the $A_{1g}-B_{1g}$ transition, forbidden by symmetry. The symmetry properties of the B_{1g} state correspond to an alternating distribution of electron density. The symmetry bar

‡ Here and elsewhere in this article, molecules are numbered as in Table 3.

is removed by a vibration of the e_g^+ type. Vibrational series of 160 and 965 cm^{-1} have been identified[89,90]. The weak long-wavelength band of benzene at 2600 Å has been the object of many investigations (see, for example, the review by Jones and Spinner[106]), and has been assigned to the $A_{1g}-B_{2u}$ transition, forbidden by symmetry. In the vapour phase this band is found to split into many narrow bands. A detailed vibrational analysis of this band has been made[7,91], and the vibrations have been assigned to symmetry types It has been shown that the symmetry bar is removed by a vibration of the e_g^+ type, having a frequency of 520 cm^{-1} in the S_1^* state. The fundamental series in the spectrum is determined by fully symmetrical vibrations of frequency 923 cm^{-1}, and begins at the frequency $\nu = \nu_{00} + \nu_{e_g^+} = 38089 + 520$ cm^{-1} (for the vapour). The 923 cm^{-1} vibration corresponds to a "breathing" vibration of the ring



520 + 923 = 1443 (in the S_1^* state); 606 + 992 = 1600 cm^{-1} (in the S_0 state).

The frequency 1600 cm^{-1} is often very active in the spectra of compounds containing benzene rings. The weak fluorescence band of benzene, in the region of 2700–3100 Å, is associated with the same $B_{2u}-A_{1g}$ transition, forbidden by symmetry. In emission the transition becomes allowed as a result of the e_g^+ vibration of frequency 606 cm^{-1}, but the fundamental series is associated with a vibration at 992 cm^{-1}. The structure of the fluorescence spectrum of benzene is well resolved at 77°K in cyclohexane solution. According to Braude[90], in hexane the ν_{00} frequency of the $S_1^*-S_0$ transition is 37800 cm^{-1}. A phosphorescence spectrum with a structure has been obtained[92] in a matrix of cyclohexane at 77°K (and also[67] at 77° and 4.2°K). The $T-S_0$ spectrum has been interpreted by Sponer and coworkers[67] starting with the doublet at 29501/29442 cm^{-1}, referred to the 00 band, with the help of the e_g^+ vibration frequencies 607, 1178, 1590/1607 cm^{-1}, of the b_{2g} vibration frequencies 698, 988, 1458 cm^{-1}, and of the series of fully symmetrical vibrations (frequency 992 cm^{-1}). A vibrational analysis of $T-S_0$ spectra has also been given by Shull[93] and by Dikun and Sveshnikov[94].

The frequency difference $\nu_{S_1^*-T}$ in benzene amounts to 8300 cm^{-1}.

Naphthalene (II). Symmetry D_{2h}. Three electronic bands can be distinguished in the absorption spectrum[73]: ^1L_b (31750), ^1L_a (34500), ^1B_b. The most intense short-wavelength band at 220 nm is practically structureless, and is associated with the $A_{1g}-B_{3u}$ transition, polarised along the long axis of the molecule[21,32]. The broad ^1L_a band in the region of 2900–2300 A, with a weakly developed vibrational structure, is associated with the $A_{1g}-B_{3u}$ transition, polarised along the x axis, as shown by McClure[21] in his study of the absorption spectrum in polarised light of a mixed naphthalene–durene single crystal, and by Zimmerman and Yoop[32] on the basis of polarisation absorption and luminescence spectra of solutions at -180°C. The weakest long-wavelength absorption band (3300–2900 Å) has a sharp vibrational structure in many solutions at low temperatures, and is ascribed to an $A_{1g}-B_{2u}$ transition. McClure[21] separated two series of bands in the vibrational structure: a series of weak bands, beginning from the purely electronic band, polarised along the y axis, and a stronger series of bands, whose origin lies 509 units higher (on the cm^{-1} scale) than the 00 band. The 3300 Å fluorescence band of naphthalene, associated with the same $B_{2u}-A_{1g}$ electronic transition as the long-wavelength absorption, also has a well developed vibrational structure. Bolotnikova[51] has described the quasi-linear structure of the fluorescence band in pentane solution at 77°K. McClure distinguished two systems, having mutually perpendicular polarisations, in the fluorescence spectrum. Similar results were obtained by Bolotnikova in her vibrational analysis of fluorescence in pentane. She identified the most active frequencies (517, 772, 1033, 1386, 1465, and 1579 cm^{-1}) and assigned them to fully symmetrical skeletal vibrations. The 500 cm^{-1} interval by which the origin of the second series is separated from the 00 band (ν_{00} = 31731 cm^{-1}) was assigned to a vibration of b_{1g} symmetry. Papers on the long-wavelength absorption[95] and emission[96-98] bands of naphthalene vapour give a detailed vibrational analysis of the electronic bands. The results for vapour spectra agree with the analysis of solution spectra: two series of bands, with a 506 cm^{-1} difference in relative position, can be distinguished also in the spectra of the vapour. (In the vapour, ν_{00} for the long-wavelength transition is 32017 cm^{-1}). The vibration frequencies obtained from an analysis of the vibronic spectra are in good agreement with the frequencies obtained from the vibrational spectra of naphthalene[99] and also with the theoretically calculated values[100,101].

The phosphorescence spectrum in a propyl ether–isopentane solution at -190°C begins with a strong band ($\nu_{00} \simeq$ $\simeq$ 21300 cm^{-1}) and can be resolved into 20 bands, interpreted[102,103] in terms of the frequencies 512, 1146, 1380, and 1575 cm^{-1}.

Anthracene (III). The absorption spectrum is characterised by three electronic bands with a sharply resolved vibrational structure: ^1L_a (26000), ^1B_b (40400), $^1C_b(^1B_a)$ (45000 cm^{-1}).[73]

Sidman[24] measured the absorption bands in polarised light for anthracene–naphthalene and anthracene–phenanthrene crystals, and showed that the transitions ^1L_a and $^1C_b(^1B_a)$ are polarised along the x axis, whereas the ^1B_b transitions are polarised along the y axis. These results were confirmed[32] by measurements of the absorption and fluorescence polarisation spectra of solutions, and also[104] by measuring the dichroism of the absorption bands in stretched films. Polarisation of a similar type was observed also for pure single crystals of anthracene[23,105]. Jones and Spinner[106] give an analysis of the structure of the absorption bands in pentane solution at -100°.

p-band: $\nu(26570 + 390n_1 + 790n_2 + 1440n_3)$ cm^{-1} ($n_1 =$ $= n_2 = 0,1$; $n_3 = 0-5$).

β-band: $\nu(39460 + 300n_1 + 1070n_2 + 1370n_3)$ cm^{-1} ($n_1 = n_3 = 0,1$).

A detailed analysis of the long-wavelength band, associated with the $A_{1g}-B_{3u}$ transition, was published by Sidman[24] for a mixed crystal at 4°K and by Bolotnikova[52] for a heptane solution at 77°K. The structure is determined mainly by a 1400 cm^{-1} series, assigned to a fully symmetrical vibration.

The blue fluorescence band of anthracene lies almost entirely in the visible region of the spectrum. The best resolution of this structure was obtained[52] in solution at

77°K, when the purely electronic band (26241 cm^{-1}) was separated from the vibrational frequencies (390, 1037, 1165, 1407, 1565, 1645 cm^{-1}), assigned to fully symmetrical vibrations. Sidman[24] gave an analysis of the fluorescence band of anthracene in a mixed crystal. It is interesting to note that the 403 and 1416 cm^{-1} frequencies in the spectrum of the mixed crystal are reduced to 390 and 1407 cm^{-1} in the spectrum of the heptane solution. Intense series in the fluorescence band are associated with the frequency 1407 cm^{-1}.

Zimmerman and Yoop[32] analysed the structure of the band in absorption and in emission on the basis of polarisation spectra of the solution at -180°C. They resolved two series of bands, polarised in mutually perpendicular directions. The main series, with its origin in the 00 band, is polarised along the x axis: $\nu_N = \nu_{00} \pm n_1\nu_1 \pm n_2\nu_2$ (ν_{00} = = 26000 cm^{-1}, $\nu_1 = 1400$, $n_1 = 0, 1, 2$; $\nu_2 = 500$, $n_2 = 0, 1$), and the subsidiary series has $\nu_N = \nu_{00} \pm 900 \pm n_1\nu_1 \pm n_2\nu_2$, polarised along the y axis (the + sign refers to the absorption bands, the - sign to the emission bands). As in the case of naphthalene, the difference of 900 cm^{-1} must be assigned to a vibrational frequency of b_{1g} symmetry. The same authors[32] point out certain minima in the polarisation absorption spectra at 28500 and 30000 cm^{-1}, which they tentatively ascribe to a ^1L_b transition in absorption, since according to theory the weak ^1L_b band should be hidden by the ^1L_a band.

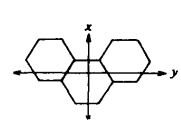
Anthracene has a phosphorescence band in the infrared region. The structure of the T–S_0 spectrum has been described[107] in terms of an initial band at 14928 cm^{-1} and vibrational frequencies of 410, 1137, 1266, 1414, and 1573 cm^{-1}. The transition is interpreted as $^3B_{2u}$–$^1A_{1g}$, and the frequencies are assigned to fully symmetrical vibrations.

Naphthacene (IV). ^1L_b and ^1L_a bands have been identified[73] in the absorption spectrum. According to theory, the weak $^1L_b(\alpha)$ band is concealed by the ^1L_a band. Studies of the polarisation of the spectra of naphthacene in naphthalene have shown[25] that the ^1L_a band is polarised along the short x axis, whereas the ^1L_b and ^1B_b bands are polarised along the y axis. Sidman gives a detailed analysis of the structure of the long-wavelength absorption and fluorescence bands of a mixed crystal. Bolotnikova[52] analysed the vibrational structure of the given fluorescence spectrum of naphthacene in nonane at 77°K, and found a structure identical to that of the fluorescence in naphthalene. She isolated the frequencies at 321, 462, 615, 1165, 1473, and 1380 cm^{-1}. The intense series of the last frequency determines the form of the fluorescence spectrum. The data on the polarisation of the electronic transitions were confirmed by Zimmerman and Yoop[32]. The weak minima at 25000 and 26400 cm^{-1} in the polarisation absorption spectra are ascribed to a ^1L_b transition. The same authors also describe[32] the vibrational structure of the polarisation fluorescence spectrum. The initial band at 20000 cm^{-1} consists of two superimposed bands with mutually perpendicular polarisation, from which two series of bands with a 1400 cm^{-1} period originate. Only a calculated value (~10500 cm^{-1}) of the energy of the T–S_0 transition appears to be known[80]. The quoted value[79] ν_{phos} = 19600 must be ascribed to impurity phosphorescence. Clar and Zander[78] have shown that the phosphorescence bands disappear upon careful purification of naphthacene. It has been suggested[60] that the impurity is naphthacenequinone.

The long-wavelength band of pentacene (V) extends over the whole of the visible region 6000–4000 Å (the T-level[80] is in the region of 8000 cm^{-1}). The last of the polyacenes which have been prepared, hexacene (VI), absorbs[73] in the region 7000–5500 Å ($\nu_{S_1^*-S_0} \simeq 14430$ cm^{-1}). Polyacenes with a larger number of rings are unstable. The long-wavelength absorption band and the fluorescence spectrum of anthracene, naphthacene, and pentacene show a similarity in their vibrational structure, which is determined mainly by a vibrational difference of 1400 cm^{-1}. In the polyacene series (benzene, naphthalene, anthracene, naphthacene, pentacene, and hexacene) the energy of the S_1^*–S_0 and T–S_0 transitions decreases as the number of benzene rings increases by the following amounts respectively: 6300 (8000 for T–S_0), 7000 (6600), 5000 (4000), 4000 (2500), 3000 cm^{-1} (see Table 3). The drop in energy becomes gradually smaller as the number of rings increases. At the same time, the energy difference between the S_1^* and the T states retains its value (10000 cm^{-1}) practically unchanged, with only a slight decrease.

3. ANGULAR *ortho*-FUSED HYDROCARBONS

Phenanthrene, of C_{2v} symmetry, the simplest angular hydrocarbon, is an isomer of anthracene. It was originally suggested that its spectroscopic characteristics should be similar to those of anthracene. In practice, its spectra are much more complicated, and quite different from those of anthracene. The bands of four electronic transitions can be distinguished in the absorption spectrum: ^1L_b, ^1L_a, ^1B_b, and $^1C_b(^1B_b)$. Calculation predicts that the ^1L_b and $^1C_b(^1B_b)$ transitions should be polarised along the x axis, whilst the ^1L_a and $^1B_b(^1B_a)$ transitions are polarised along the y axis. McClure studied the spectrum of the ^1L_b absorption band of a crystal at 20°K in polarised light, and showed[22] that the band of the 00 transition (28660 cm^{-1}) is polarised along the x axis. It follows from measurements of the polarisation absorption spectra in ethanol solution at -180°C that the 00 band of the ^1L_b transition is polarised at right angles to the bands of the ^1L_a (3400 cm^{-1}) and ^1B_b (39300 cm^{-1}) 00 transitions. Zimmerman and Yoop[35] report that weak bands at 34900 and 38200 cm^{-1}, polarised along the x axis, are also present in the spectrum. The ^1L_b band has a clearly defined vibrational structure in the polarisation spectrum, due to the presence of two series of bands polarised in mutually perpendicular directions. The main series begins at the 00 band: ν_N = 28900 cm^{-1} + $+ n_1\nu_1$(ν_1 = 1400 cm^{-1}; n_1 = 0, 1, 2). The origin of the secondary series differs by 700 cm^{-1}: ν_N = 28900 + 700 + $+ n_1\nu_1$. Popov[104] studied the dichroism of absorption bands in stretched films and showed that the ^1L_b transition is polarised along the x axis, whilst the ^1L_a and ^1B_b transitions are polarised along the y axis. He also discovered in the dichroism curve a structure within the ^1L_b band, which he associated with the appearance of a not fully symmetrical vibration at 670 cm^{-1}.



Later workers obtained a better resolution of the vibrational structure of this band, and showed that it arises from the large number of frequencies which are active in the vibrational spectrum. McClure published an analysis

of the structure of the absorption band of crystalline phenanthrene[22]. Kharitonova[108] examined the structure of the absorption bands of the vapour, and distinguished the frequencies ν_{00} = 29 120 cm^{-1} and ν_{vibr} = 680 and 1420 cm^{-1} in the ^1L band. In the second band, with $\nu_{00} \simeq$ 35 200 cm^{-1}, she found ν_{vibr} = 360, 470, 680, 960, and 1400 cm^{-1}.

The fluorescence spectrum, investigated under a variety of conditions, shows a well resolved vibrational structure. The polarisation structure of the fluorescence spectrum[35] indicates the presence of two series of bands, polarised at right angles to each other. The main series begins at the 00 band, and the origin of the second series is separated from it by the frequency of a vibration of b_2 symmetry whose value could not be accurately determined.

Pesteil and Rabaud[71] obtained an extensive quasi-linear structure in the fluorescence band of a pentane solution at 20°K. The spectrum, with a band head at 28 818 cm^{-1}, was interpreted with the help of more than 30 frequencies, some of a_1 symmetry, and some apparently b_2 symmetry. The authors[71] also made a detailed analysis of the phosphorescence spectrum under the same conditions, found in a region of lower frequencies (~7020 cm^{-1}). Kanda and Shimada[109] analysed the T–S_0 spectrum in ether–isopentane–alcohol and in petroleum ether media at 90°K. In solution in polypropyl ether–isopentane the phosphorescence band splits into 16 bands at 77°K: $\nu_{00} \simeq$ 21 730, $\nu_{vibr} \simeq$ 406, 1417, 1608 cm^{-1}. According to Cropper and Dörr[39], the T–S_0 transition is polarised at right angles to the plane of the molecule, and some not fully symmetrical vibrations are active in the T–S_0 spectrum in addition to the fully symmetrical vibrations. As regards phosphorescence, phenanthrene shows some further differences from anthracene. The initial band of its bluish-green phosphorescence lies at even higher frequencies than the green phosphorescence band of naphthalene. These facts suggest that Clar's hypothesis[74], according to which the π-electron cloud of phenanthrene can be regarded as the π-electron cloud of biphenyl plus an ethylene group (for the ground state of the molecule), is not applicable to these spectra. The long-wavelength transitions of biphenyl and phenanthracene are polarised at right angles to each other, but the energy of the transition is higher in biphenyl than in naphthalene, whilst it is lower in phenanthrene. We should note that the spectroscopic characteristics of phenanthrene are, perhaps, closer to those of naphthalene than to those of anthracene. This similarity between the spectra of 1,2-benzopolyacenes and those of the parent polyacenes becomes even more apparent with longer polyacene units.

1,2-Benzanthracene (tetraphene) (VIII). Four absorption systems have been distinguished in the absorption spectrum: ^1L_b, ^1L_a, ^1B_b, and $^1C_b(^1B_a)$. The 00 bands for these transitions in alcohol solution at -180°C occur[47] at 26 000 cm^{-1} for ^1L_b, 27 300 cm^{-1} for ^1L_a, 34 400 cm^{-1} for ^1B_b, and 43 500 cm^{-1} for ^1C_b. Experimental data on the polarisation of the electronic bands are in approximate agreement with theory[100], but they give somewhat different values for the angles between the polarisation vectors[35]. The regions of the different mutually overlapping electronic bands have been identified[110] from the temperature dependence of the spectra. The results[100], given in Table 4, do not agree entirely with the analysis of the bands[35].

Sandorfy and Jones[111] have analysed the absorption spectra in pentane at -100°C in the region 26 000–33 000 cm^{-1}, and have distinguished two series of bands with a spacing of 1400 cm^{-1}.

TABLE 4.

Band region (cm^{-1})	Type (after Zhirnov[100])	Type (after Craig et al.[98])
26 000–31 000	^1L_b	α
27 000–33 000	^1L_a	p
33 000–35 000 (Possibly 37000)	^1B_b	
33 000–38 000	^1B_a	β
	Three other electronic band systems were not interpreted	

The fluorescence spectrum[111,112] of a solution at room temperature consists of wide bands with ν_{00} = 26 000 cm^{-1} and an interband spacing ν_{vibr} = 1400 cm^{-1}. The first phosphorescence band has a frequency about 9500 cm^{-1} lower than the fluorescence band[102,113]. In solution in isopentane–methylcyclohexane (1 : 4) at 77°K the phosphorescence spectrum shows three maxima: at 6060 (15 500 cm^{-1}, 6570, and 7250 Å. In a propyl ether–isopentane solution the phosphorescence band splits into 6 bands in the region of 16 700 (ν_{00})–11 200 cm^{-1}; their frequencies are given by the series $\nu = (\nu_{00} - 400n_1 - 1350n_2)$ cm^{-1}.

The T level in 1,2-benzanthracene is found to be somewhat higher than in anthracene (just as it is higher in phenanthrene than in naphthalene). Angular fusion of a benzene ring in the 1,2-position in polyacenes is accompanied by an increase in the relative height of the T level, or by a decrease in the difference $\nu_{S_1^*-T}$. For the longer polyacenes [1,2-benzonaphthacene (IX), 1,2-benzopentacene], only the absorption spectra are known. The long-wavelength bands are fairly similar in position and vibrational structure to those of the parent polyacenes. We shall now consider angular molecules formed by a centro-symmetrical combination of benzene rings.

Chrysene (X). Symmetry C_{2h}. The absorption spectrum contains four electronic bands: ^1L_b, ^1L_a, ^1B_b, $^1C_b(^1B_a)$.

An analysis of the polarisation absorption and fluorescence spectra gave approximate agreement with theory, with slightly different values of the angles[35]. The following values are reported[35] for the 00 band frequencies: 27 800 cm^{-1} for ^1L_b, 30 900 cm^{-1} for ^1L_a, 37 000 cm^{-1} for ^1B_b, and 44 100 cm^{-1} for $^1C_b(^1B_a)$. Although the chrysene molecule contains four benzene rings, the long-wavelength transition in this molecule has an energy intermediate between those of phenanthrene and anthracene. The vibrational structure of the ^1L_b absorption band has been analysed[64] as for the crystalline state.

The structured band spectrum of the deep blue fluorescence[13,114] in solution in ether-isopentane–alcohol at -190°C begins with a band having $\nu_{00} \simeq$ 27 800 cm^{-1}. The difference ν_{vibr} = 1370 cm^{-1} has been identified[115] in the fluorescence spectrum of the crystals. Nurmukhametov and coworkers[64] have analysed the vibrational structure of the quasi-linear fluorescence spectrum in octane solution at 77°K, and have identified the vibrational frequecies 295, 875, 1180, and 1395 cm^{-1}, the last being the most characteristic of the spectrum. Two series of bands, polarised at right angles to each other, have been detected[35] in the polarisation fluorescence spectra of an alcohol solution at 90°K: $\nu_N = \nu_{00} - n_1\nu_1$ (ν_{00} = 27 900, ν_1 = 1400) cm^{-1}, n_1 = = 0, 1–3; $\nu_N = \nu_{00} = 800 - n_1\nu_1$. Dörr and Cropper[40]

have demonstrated the presence of two subsidiary series with identical polarisation: $\nu_{N'} = \nu_{00} - 300 - n_1\nu_1$ and $\nu_{N''} = \nu_{00} - 800 - n_1\nu_1$ (where $\nu_{00} = 27\,800$, $\nu_1 = 1400$ cm^{-1}, $n_1 = 0,1-4$).

The T level in chrysene is lower than the S_1^* level by 7500 cm^{-1}, i.e. approximately by the same amount as in phenanthrene. The vibrational structure of the phosphorescence band in octane solution has been analysed[35] in terms of the frequencies ν_{vibr} = 300, 646, 1230, 1375, and 1617 cm^{-1} ($\nu_{00} = 20\,000$ cm^{-1}). The phosphorescence in ether–isopentane–alcohol at -190°C has been described. Measurements of the polarisation phosphorescence spectra[40] have shown that the $T-S_0$ transition is polarised at right angles to the plane of the molecule, and in alcohol solution has the frequency $\nu_{00} \simeq 19\,800$ cm^{-1}. The phosphorescence spectrum shows a definite similarity to the phosphorescence spectrum of phenanthrene. The frequencies 300 and 375 must be assigned to not fully symmetrical vibrations, the remainder to fully symmetrical vibrations.

1,2; 5,6-Dibenzanthracene (XI). Symmetry C_{2h}. Clar distinguished three electronic bands in the absorption spectrum of its benzene solution: α (with maxima at 3950, 3850, 3730 Å), p (3510, 3365, 3220 Å), and β (3000, 2900, 2770 Å).

Bolotnikova[53] analysed the vibrational structure of the long-wavelength absorption band in pentane at 77°K, assigned the 25 441 cm^{-1} band to a 00 transition, and identified the differences 488, 605, 691, 748, 1355, 1445, and 1586 cm^{-1}. The fluorescence band of the solution at room temperature consists of three maxima[117] (25 400, 24 000, and 22 500 cm^{-1}); at 77°K the band splits, in hydrocarbon or alcoholic solutions, into 13 bands[118], and in pentane–octance solutions it splits into a large number of bands with initial $\nu_{00} \simeq 25\,442$ cm^{-1}. In the vibrational structure the following differences have been identified: 220, 320, 453, 495, 544, 588, 620, 721, 880, 1153, 1296, 1343, 1590, and 1765 cm^{-1}.

Butlar and Grebenshchikov[120] report the values 25 300 and 18 300 cm^{-1} for the $\nu_{S_1^*-S_0}$ and the ν_{T-S_0} transition frequencies respectively.

It should be noted that the S_1^* level is only 550 cm^{-1} lower, and the T level is actually 1500 cm^{-1} higher, than the corresponding levels in benzanthracene. Therefore, angular fusion of one additional ring leads to even closer approach of the energies of the S_1^* and T levels. The great similarity between the absorption curves of benzanthracene and dibenzanthracene is also noteworthy.

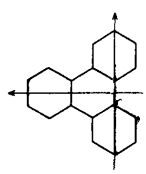
1,2; 7,8-Dibenzonaphthacene (XII). Symmetry C_{2h}. Clar isolated p and β bands, having a coarse vibrational structure at room temperature, in the absorption spectrum of a benzene solution of this compound. The average interval is ν_{vibr} = 1400 cm^{-1} for the p band. The structure of this band is very similar to those of naphthacene, benzonaphthacene, and dibenzonaphthacene. The initial ν_{00} band is quite strong (22 851 cm^{-1}), and has a higher frequency than the corresponding bands in naphthacene and benzonaphthacene. The fluorescence band[117] has three maxima: 23 000, 21 500, and 20 100 cm^{-1}. The T level is located at 18 000 cm^{-1}, i.e. 7300 cm^{-1} below the S_1^* level.

The absorption spectrum of 1,2; 8,9-dibenzopentacene in methylnaphthalene is reminiscent of the spectra of pentacene and benzopentacene, but this spectrum too occurs at shorter wavelengths than those of the last named hydrocarbons. The corresponding seven-ring linear polyacene is quite unstable. Less is known about the spectra of hydrocarbons having two benzene rings fused angularly to the polyacene chain symmetrically with respect to the short axis of the polyacene.

3,4-Benzophenanthrene (XIII) has a very unusual absorption spectrum with a 00 long-wavelength transition band (26 874 cm^{-1}) somewhat lower than in chrysene. The T level[119] is at 20 200 cm^{-1}, i.e. $\nu_{S_1^*-T} = 6700$ cm^{-1}.

The absorption spectrum of 1,2; 7,8-dibenzanthracene (XIV) has a very complex structure, beginning approximately at the same frequency ($\nu_{00} = 25\,309$) as that of 1,2; 5,6-dibenzanthracene. The energy[80] of the $T-S_0$ transition is approximately 17 900 cm^{-1}. The first phosphorescence band[78] is at 18 500 cm^{-1}, i.e. the T level lies 680 cm^{-1} below the S_1^* level (as in the case of 1,2;5,6-dibenzanthracene).

The absorption spectrum of 1,2; 9,10-dibenzonaphthacene (XV) has not been analysed in the literature. It consists of a large number of peaks; the long-wavelength peaks are similar to the absorption band of naphthacene; the first band is at 23 115 cm^{-1}, i.e. approximately at the same frequency as the absorption edge of 1,2;7,8-dibenzanthracene.



Triphenylene (XXXVI). Symmetry D_{3h}. Because of the presence of a third-order symmetry axis the electronic spectra of triphenylene show some specific features. The absorption spectrum has three bands: ^1L_b, ^1L_a, and ^1B_a (the ^1B_a and ^1B_b states are mixtures, as in benzene and coronene[85]). The electronic transitions ^1L_b and ^1L_a are forbidden by symmetry.

Butlar and Grebenshchikov[120] have recently obtained a quasi-linear structure for the $S_1^*-S_0$ and $T-S_0$ spectra in hexane and heptane solutions at 77°K. The 00 transition band at 29 138 cm^{-1}, coinciding in absorption and emission by resonance, was found to be very weak, in accordance with expectations that this band should be forbidden by symmetry. In the long-wavelength absorption spectrum the following vibrational differences were identified: 260, 606, 740, 1026, 1160, 1336, and 1416 cm^{-1}, of which the 1336 frequency is the one most frequently found in combination with other frequencies. The fluorescence spectrum contains more than 50 narrow bands, interpreted in terms of the fundamental frequencies 253, 616, 688, 749, 1048, 1185, 1341, 1430, and 1472 cm^{-1}.

The most characteristic frequency difference is 1341 cm^{-1}. The phosphorescence spectrum begins with a weak band ($\nu_{00} = 23\,587$ cm^{-1}), and has a very complicated structure. Only the differences 735, 1341, and 1430 cm^{-1} can be reliably identified. The polarisation phosphorescence spectrum has a vibrational structure[36].

1,2;3,4-Dibenzanthracene. Symmetry C_{2h}. The absorption spectrum in benzene begins with a weak α band at 3750 Å (26 660 cm^{-1}), which occurs at a shorter

wavelength than in the corresponding 1,2; 7,8- and 1,2; 5,6-isomers. The lower $S_1^*-S_0$ transition is close in energy to that of anthracene but the type of excitation of the electrons may be similar to that in chrysene and 1,2; 5,6- and 1,2; 7,8-dibenzanthracenes. The phosphorescence band has three maxima[78] at 17770, 16330, and 16180 cm^{-1}.

1,2;3,4-Dibenzonapthacene. As the polyacene part of the molecule becomes longer, the electronic bands characteristic of the appropriate polyacene stand out more sharply. The long-wavelength absorption band of 1,2;3,4-dibenzonaphthacene is very similar in structure to the band in naphthacene. The same is true of the spectrum of 1,2;3,4-dibenzopentacene.

The fusion of four benzene nuclei to a polyacene produces a spectrum with a more complicated system of bands.

4. *peri*-FUSED HYDROCARBONS

In some cases it is more reasonable to regard *peri*-fused hydrocarbons as the result of the condensation not of simple benzene rings but of more complicated aromatic nuclei.

Pyrene (XVIII). Symmetry D_{2h}. This hydrocarbon can be regarded as the condensation product of two naphthalene rings. The absorption spectrum has four electronic bands: ^1L_b (ν_{00} = 26900 cm^{-1}), ^1L_a (29500 cm^{-1}), ^1B_b (36400 cm^{-1}), and ^1B_a (41300 cm^{-1}). Theoretical considerations predict polarisation of the ^1L_b and ^1B_b bands along the x axis, and polarisation of the ^1L_a and ^1B_a bands along the y axis. Measurements of polarised fluorescence by Williams[121] revealed that the polarisation is the same for the ^1L_b, ^1L_a, and ^1B_b bands. However, the polarisation spectra obtained by Zimmerman and Yoop[36] confirmed the theoretical predictions. The papers by Shpol'skii and his coworkers[44,45,55,118] describe studies of the structure of the electronic bands. Klimova[55] distinguished three systems of bands in absorption: a system of diffuse bands in the region 2800–2500 Å, a system of second electronic transition bands in the region 3400–3800 Å, and a system of $S_1^*-S_0$ transition bands in the region 3700–3400 Å.

Table 5, compiled from Ref. 55, illustrates the good agreement between the frequencies which are active in vibronic bands and the frequencies obtained from vibrational spectra (infrared and Raman). The possibility of interpreting the vibrational frequencies of the excited states of a molecule is also evident from Table 5.

The activity of vibration frequencies of type b_{1g} has been confirmed experimentally. Zimmerman and Yoop[36] distinguished two series of bands, polarised in mutually perpendicular directions, in the polarisation fluorescence spectrum of an alcoholic solution at -180°C. The main series began with a 00 band at ~26900 cm^{-1}, and the origin of the second series was displaced towards lower frequencies by about 900 cm^{-1}. This difference is close to the frequency of the b_{1g} vibration ($\nu_{b_{1g}} \simeq$ 1106 cm^{-1}); the discrepancy between the observed frequencies arises from the inadequate resolution of the spectral structure in the alcohol solution.

The spectrum of the orange-red phosphorescence of the solutions is found in the region 16900–15250 cm^{-1}. The structure of the phosphorescence spectrum, interpreted using the frequencies 404, 1232, and 1406 cm^{-1}, is most sharply resolved at low temperatures in hexane solution[44,45,55]. The triplet level in the pyrene molecule lies 10000 cm^{-1} below the S_1^* level ($\nu_{S_1^*-S_0} \simeq$ 26837 cm^{-1}), so that the difference in the $\nu_{S_1^*-T}$ frequencies in pyrene is of the same order of magnitude as in the polyacenes. This fact provides evidence in favour of our suggestion regarding the condensation of naphthalene rings. Another surprising fact should be noted: the frequencies of the ^1L_b and ^1L_a 00 bands in the pyrene spectrum are lower than those of the corresponding bands in the naphthalene spectrum by approximately the same amount ($\Delta\nu\,^1L_b$ = 31750 - 26837 = = 4913 cm^{-1} and $\Delta\nu\,^1L_a$ = 34500 - 29500 = 5000 cm^{-1}). A decrease in the frequency of the ν_{00} bands of comparable magnitude is observed when the length of the polyacene chain is increased.

TABLE 5. Fundamental vibrational frequencies (cm^{-1}) of the pyrene molecule[55].

1,2-Benzopyrene (XIX). Symmetry C_{2v}. The absorption spectrum is fairly similar to that of pyrene in shape and position. Solutions have a violet fluorescence, with a band extending from 3750 to 4500 Å. At 77°K the fluorescence spectrum in alcohol splits into 10 bands, and the spectrum in hexane splits into ~100 bands. The relatively weak, first fluorescence band (ν_{00} = 26570 cm^{-1}) is shifted towards the red by only 300 cm^{-1} as compared with the corresponding band of pyrene. Shpol'skii and coworkers[46] have given a detailed analysis of the fluorescence and phosphorescence spectra in hexane at 77° and 4°K. They identified 32 frequencies in the fluorescence bands, the most active of which are 1254, 1339, 1415, and 1444 cm^{-1}, assigned to fully symmetrical vibrations, and also 772 and 780 cm^{-1}, assigned to not fully symmetrical vibrations. The first four frequencies are intense only in

combination with the last two. The first phosphorescence band ν_{00} = 18 630 cm^{-1} is strong, and is separated from the ν_{00} fluorescence band by 7940 cm^{-1} (on the low-frequency side). Thus, the $\nu_{S_1^*-T}$ difference in 1,2-benzopyrene is lower than in pyrene. In the phosphorescence band, which extends over the region 5330–6700 Å, the following vibrational frequencies have been identified: 343, 383, 456, 649, 1090, 1150, 1255, 1262, 1339, 1415, and 1444 cm^{-1}. The absorption spectra of hydrocarbons consisting of a polyacene group fused to the pyrene nucleus in the 1,2-position can be treated as the sum of the absorption curves of pyrene and the corresponding polyacene. Thus, the long-wavelength absorption band of naphtho(2′, 3′-1,2)--pyrene is very similar in position and vibrational structure to the *P* band of anthracene. A second, very strong band, coincides with the strong β band of pyrene, and the third strong band coincides with the β band of anthracene. In a similar way, the absorption spectrum of 5,6; 15,16--dibenzohexacene can be described by superimposing the bands of naphthacene and pyrene.

3,4-Benzopyrene (XX). Symmetry C_{1h}. The fusion of a benzene ring to pyrene in the 3,4-position produces a more substantial change in the absorption spectrum than with 1,2-benzopyrene. The absorption spectrum begins with a stronger band, at a longer wavelength (4030 Å).

The bright fluorescence spectrum in alcohol and liquid paraffin solutions consists[122] of broad bands, spaced 1390 cm^{-1} apart. In hexane–octane solutions at 77°K these bands split into narrow-band multiplets[44]. Shpol'skii and Klimova[47] made a detailed analysis of the structure of the fluorescence band in heptance and other n-paraffins at 20° and 4°K. The strong component of the purely electronic multiplet is at 4023 Å (24 847 cm^{-1}); the following frequencies are active in the vibrational spectrum: 218, 335, 455, 613, 635, 853, 1111, 1163, 1237, 1345, 1389, 1417, 1586, and 1636 cm^{-1}. Frequency progressions by 1389 cm^{-1} are the most active, and give a characteristic periodicity to the spectrum. This is obviously associated with the same type of skeletal vibration as the 1406 cm^{-1} frequency in pyrene. The phosphorescence spectrum, which begins with a ν_{00} band at 14 670 cm^{-1}, has been described by Muel and Hubert-Habart[119], who report vibrational frequencies of 335 and 1237 cm^{-1}. Addition of a benzene ring to pyrene in the 3,4-position lowers the energies corresponding to $\nu_{S_1^*-S_0}$ and ν_{T-S_0} by the same amount (2000 cm^{-1}). It is surprising that the frequencies of these transitions in 3,4-benzopyrene are the same as in anthracene, despite the fact that the former has two additional benzene rings.

1,2; 4,5- or 3,4; 6,7-Dibenzopyrne (XXI). Symmetry C_{1h}. The absorption spectrum begins with a band at 4280 Å, and is similar to the spectrum of 3,4-benzopyrene, differing from it by a large number of weak, long--wavelength α bands. Although it is generally believed that the absorption spectrum begins at a longer wavelength than that of 3,4-benzopyrene, in fact, the purely electronic fluorescence bands show that the two spectra begin in the same region. A quasi-linear fluorescence spectrum (3900–4300 Å) in n-paraffins at 77°, 20°, and 4°K was obtained and analysed by Shpol'skii and Klimova[49,56]. The strongest component of the purely electronic multiplet in octane is at 25 250 cm^{-1}. 16 frequencies have been identified in the vibrational structure. Most of the fundamental frequencies coincide with those found to be active in the fluorescence spectrum of 3,4-benzopyrene: this follows, in part, from symmetry considerations (the two molecules have the same symmetry type). Fusion of a 6,7-ring to 3,4-benzopyrene produces an increase of ~400 cm^{-1} in the $\nu_{S_1^*-S_0}$ frequency. Unfortunately, there are no data on the position of the triplet level of this molecule. In the writer's opinion, the $\nu_{S_1^*-T}$ difference should decrease in the same way as on going from pyrene to 1,2-benzopyrene; the *T* level can be expected to lie in the region of 17 000 cm^{-1}.

3-Methyl-4,5-ethylene-3,4; 6,7-dibenzopyrene (XXII). The above hypothesis is confirmed by considering the spectra of 3-methyl-4,5-ethylene-3,4;6,7--dibenzopyrene (XXII), an alkyl derivative of the previous hydrocarbon. The structure of the long-wavelength absorption band and of the luminescence bands at 77°K in octane solution has been examined by Khesina[59,60]. Not surprisingly, the saturated five-membered ring and the methyl group produce a small bathochromic shift of the 00 band ($\nu_{S_1^*-S_0}$ 3988 Å, 25 065 cm^{-1}) as compared with 3,4; 6,7-dibenzopyrene. The following vibrational frequencies have been identified in the absorption band: 245, 270, 385, 440, 600, 635, 850, 1236, and 1415 cm^{-1}.

The fluorescence band contains the following frequencies: 251 (s.), 312 (m.), 410 (m.), 445 (s.), **602** (s.), 635 (s.), 854 (s.), 1236 (s.), **1354** (s.), 1415 (s.), and **1633** (s.). (These frequencies have similar values to the strong frequencies of 3,4; 6,7-dibenzopyrene.) The phosphorescence spectrum is shifted by 8600 cm^{-1} towards lower frequencies. It begins with a strong band at 6081 Å (16 450 cm^{-1}), and contains the differences 312 and 602 cm^{-1}, i.e. it occurs in the region which we have suggested for the phosphorescence of 3,4; 6,7-dibenzopyrene. Similar spectroscopic characteristics are to be expected also in another derivative of pyrene 1,2; 3,4-dibenzopyrene (XXIII), a close isomer of 3,4; 6,7-dibenzopyrene.

3,4-Naphtho-6,7-benzopyrene (XXV). Replacement of the benzene ring in the 3,4-position of 3,4; 6,7-dibenzopyrene by a naphthalene ring produces a decrease (to 23 900 cm^{-1}) in the frequency of the lower $S_1^*-S_0$ transition. Khesina[60] described the banded absorption, fluorescence, and phosphorescence spectra of a hexane solution of the compound at 77°K. The absorption spectrum was analysed from the ν_{00} band (23 917 cm^{-1}) in terms of the frequencies 190, 315, 471, 540, 745, 770, 990, 1370, 1430, and 1580 cm^{-1}, and the fluorescence spectrum in terms of the frequencies 205, **280**, **315**, **460**, **635**, 745, 785, 1340, 1440, and 1624 cm^{-1}. (These frequencies are active also in the phosphorescence spectrum.)

3,4,5,6,7-Tribenzopyrene. The frequencies of the $S_1^*-S_0$ and $T-S_0$ transitions in this molecule are not very different from the corresponding frequencies in 3-methyl-4,5-ethylene-3,4; 6,7-dibenzopyrene. The fluorescence band, located in the region 3950–5000 Å, splits (in octane solutions at 77°K) into a large number of narrow bands[60], interpreted in terms of the frequencies **286**, **387**, 415, 500, 690, 1267, 1311, 1410, and 1634 cm^{-1}. (These frequencies are active in the phosphorescence spectrum.) The first phosphorescence band (16 386 cm^{-1}) is separated from the first fluorescence band (25 258 cm^{-1}) by 8872 cm^{-1}. The frequencies 283, 385, 411, 620, and 645 cm^{-1} have been identified[59] in the long-wavelength absorption spectrum.

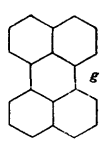
3,4; 8,9-Dibenzopyrne (XXVI). Symmetry C_{2h}. The absorption spectrum of a solution of this compound

begins with a 4510 Å band of medium intensity (a p band according to Clar); the second system extends from 3135 to 2400 Å. Shpol'skii and Klimova[49,56] analysed the structure of these bands in solutions of n-paraffins at 20° and 4°K. Six broad bands (3160–2900 Å) were detected in the region of the second transition. The long-wavelength absorption band with ν_{00} = 22 465 cm^{-1} was interpreted in terms of 17 frequencies, identical in value to frequencies which are active in the fluorescence spectrum. The fluorescence spectrum was interpreted in terms of 19 frequencies: 265 (v.s.), 419 (w.), 508 (w.), 647 (m.), 783 (v.w.), 1096 (w.), 1162 (m.), 1198 (s.), 1241 (v.s.), 1276 (s.), 1332 (w.), 1341 (w.), 1359 (v.w.), 1386 (s.), 1436 (s.), 1567 (m.), and 1632 (w.). The phosphorescence spectrum is shifted 10 425 cm^{-1} towards lower frequencies with respect to the fluorescence spectrum. According to Muel and Hubert-Habart[119] the 00 phosphorescence band is at 12 040 cm^{-1} in toluene, and there are vibrational differences of 280, 1400, and 2610 cm^{-1}. The 3,4; 8,9-dibenzopyrene molecule, like the anthanthrene molecule, can be regarded as the condensation product of two anthracene rings. The large energy difference between the S and T levels is retained, and the frequencies of the S_1^*–S_0 and T–S_0 transitions are close to the corresponding values for anthracene; $\nu_{S_1^*-S_0}$ is lower by about 3800 cm^{-1} than in anthracene and by about 2400 cm^{-1} than in 3,4-benzopyrene.

The absorption spectra of the other pyrene derivatives described in a series of papers by Clar[74–77] vary in a complicated manner with the number and positions of fused benzene rings.

Anthanthrene (XXVII). Symmetry C_{2h}. This molecule can be regarded as the result of the linear cyclisation of naphthalene or anthracene nuclei. The absorption spectrum contains three intense systems of bands: p, β, and β', according to Clar, beginning at 4330 Å (23 100 cm^{-1}). At room temperature[117] the fluorescence band has two maxima: 23 250 and 21 900 cm^{-1} ($\Delta\nu$ = 1350). In the phosphorescence spectrum, 5 bands have been identified. The first is at 11 850 cm^{-1}, the others are separated from it by 360, 740, 1430, and 1650 cm^{-1} respectively[119]. The difference in energies and levels is 11 400 cm^{-1}, i.e. of the same order as in the polyacenes.

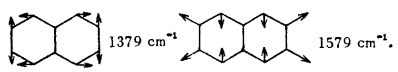
A different mode of condensation of aromatic rings is found in the perylene series.



Perylene. Symmetry D_{2h}. Perylene is readily prepared from naphthalene[73] by *peri*-condensation of naphthalene nuclei. The nuclei retain the π-electron conjugation of naphthalene, because the g bonds are not very different in length from single bonds. However, the absorption properties are vastly different. The frequency of the S_1^*–S_0 transition in perylene is lower than in naphthalene by 9000 cm^{-1}: this shift is greater than for the change from naphthalene to pyrene. The absorption spectrum is characterised by four bands: p, α, α', and β, according to Clar, with 00 transitions at the frequencies 22 700, 29 500, 34 300, and 39 600 cm^{-1} for an alcoholic solution[36] at -180°C (Clar gives[73] 22 800, 29 600, 34 300, and 39 000 cm^{-1}). Platt[84] made a theoretical study of the electronic states of perylene. His calculations gave transition energies different from the experimental values, with identical polarisations for the first three transitions.

The polarisation measurements of Williams[121], and Zimmerman and Yoop[36] showed that the 22 800 and 39 900 cm^{-1} transitions are polarised in mutually perpendicular directions. Hochstrasser[123] concluded that the long-wavelength transition is polarised along the long axis. The quasi-linear structure of the long-wavelength absorption and fluorescence bands (associated with an A_{1g}–B_{2u} transition) in hexane solution at 77°K has been described by Shpol'skii and Personov[48,58]. (The fluorescence spectrum under those same conditions was obtained earlier by Bowen and Brocklehurst[70].)

The strongest component of the multiplet of the purely electronic fluorescence band is at 4454 Å (22 445 cm^{-1}). The absorption bands have been analysed in terms of the frequencies 356, 420, 548, 1290, 1402, and 1604 cm^{-1}, and the fluorescence bands in terms of the frequencies 358, 430, 550, 1298, 1375, and 1578 cm^{-1}. In his analysis of these spectra, Personov[48,57] pointed out the identity of the frequencies of fully symmetrical vibrations which are active in the fluorescence spectra of naphthalene and perylene: 1379 and 1579 cm^{-1}. In the case of naphthalene these frequencies are associated with skeletal vibrations:



According to a calculation[80], the triplet level, or more accurately the frequency of the T–S_0 transition, lies in the region of 12 600 cm^{-1}. The difference between $\nu_{S_1^*-S_0}$ and ν_{T-S_0} amounts to 10 100 cm^{-1}, and is thus comparable in magnitude to the value for linear polyacenes. This is in keeping with the view that perylene is the result of *peri*-fusion of two naphthalene rings.

1,12-Benzoperylene (XXXIV). Symmetry C_{2v}. Since its structure is intermediate between those of perylene and coronene, 1,12-benzoperylene shows significant differences in spectral characteristics from these hydrocarbons. It would seem that addition of a benzene ring to perylene should induce, most probably, a bathochromic shift of the p band. However, although the absorption spectrum begins at λ_{00} = 4065 Å, i.e. at a longer wavelength than in perylene, this absorption is associated[73] with a weak α band ($\log\epsilon$ = 2.7). The stronger p band ($\log\epsilon$ = 4–4.5) lies in the region 3900–3300 Å, and lastly the strongest β band lies in the region of 3000 Å. Ganguly and Mukherjee[124] measured the polarisation of the absorption bands for a single crystal, and showed that the p band is polarised along the long, y axis of the molecule. For the α band, they obtained the ratio I_b/I_a = 1.04, whereas a ratio of 0.015 is expected theoretically for polarisation along the axis. Nevertheless, the electronic transition of the long-wavelength band appears to be polarised along the x axis, and the discrepancy is due to the fact that the band structure is not resolved and contains overlapping vibrational bands polarised at right angles to each other, as in the absorption spectrum of phenanthrene[71] which has the same symmetry as that of 1,12-benzoperylene. Personov[58] was able to resolve and to interpret partly the complex vibrational structure of the long-wavelength absorption, fluorescence, and phosphorescence spectrum in paraffin solutions at 77°K. The 00 fluorescence band in hexane at 4060 Å (24 625 cm^{-1}) is fairly strong. The short-wavelength doublet at 16 258/16 228 cm^{-1} in the phosphorescence

spectrum is separated from the ν_{00} fluorescence band by 8400 cm^{-1}. The decrease in $\nu_{S_1^*-T}$ as compared with perylene and the occurrence of the long-wavelength α band are additional evidence of the similarity of the spectral properties of 1,12-benzoperylene and phenanthrene: 1,12-benzoperylene can be regarded as a dimer of phenanthrene. The dimerisation is accompanied by a decrease in the frequencies of the $S_1^*-S_0$ and $T-S_0$ transitions by 4200 and 5350 cm^{-1} respectively.

Comparison of 1,12-benzoperylene with phenanthrene allows us to understand the difference between its spectra and those of perylene, whose electronic states have peculiarities similar to those of the polyacenes.

Terrylene (XXIX). Symmetry D_{2h}. The *peri*--fusion of three naphthalene nuclei shifts the origin of the absorption spectrum towards longer wavelengths. The first band (5300 Å, 18 860 cm^{-1}) is 4000 cm^{-1} below that of perylene.

1,2-Benzoperylene. The absorption curve is similar to that of perylene, but shifted towards the long--wavelength region (first band at 5140 Å). A similar state of affairs is found with 1,2; 7,8-dibenzoperylene. The origin of the absorption spectrum lies at still longer wavelengths (λ_{00} = 5460 Å). The spectrum of 1,2; 11,12-dibenzoperylene is characterised by an even larger shift. The first absorption band is at 5580 Å (17 920 cm^{-1}).

In *meso*-naphthodianthrene (XXX) two anthracene nuclei are joined by three bonds in the *peri*-position. The long-wavelength absorption band is at 6625 Å (15 090 cm^{-1}). The frequency of the $S_1^*-S_0$ transition is 10 000 cm^{-1} lower than in anthracene, i.e. of the same order as on going from naphthalene to perylene.

1,14-bisanthene (XXXV). In this compound the initial λ_{00} band is at 6350 Å (15 740 cm^{-1}), 700 cm^{-1} higher than in *meso*-naphthodianthrene. The increase in the $\nu_{S_1^*-S_0}$ frequency is similar to that found in the spectra of the perylene–1,12-benzopyrene pair.

Coronene (XXXVII). This molecule has the same D_{6h} symmetry as the benzene molecule. This predetermines many of its general spectral properties. Three bands are distinguished in the absorption spectrum: ^1L_b, ^1L_a, and $^1B_{ab}$. Calculation showed that the $^1A-^1L_b$ and $^1A-^1L_a$ transitions are forbidden by symmetry, whereas the $^1A-^1B_{ab}$ transition is allowed. Mentzel and Zimmerman[38] gave a vibrational analysis of the absorption and luminescence bands of a solution of coronene in a mixture of tetrahydrofuran, alcohol, and ether (11 : 14 : 1) at 90°K. The structure of the $^1B_{ab}$ band (λ_{00} = 32 900 cm^{-1}) was analysed in terms of the differences 500, 1400, and 1700 cm^{-1}, the second frequency giving rise to the main series. The differences 500, 1000, 1200, 1350, and 1500 cm^{-1} were identified in the ^1L_a band, which extends from 28 850 to 32 400 cm^{-1}. The last two give rise to series. The ^1L_b band (ν_{00} = 23 500 cm^{-1}) was interpreted in terms of the frequencies 350, 650, 1250, 1350, 1450, and 1600 cm^{-1}. The series are determined by the frequencies 1350 and 1600 cm^{-1}. It has also been shown that the absorption bands of 1,12-benzoperylene, which is usually present as an impurity in coronene, appear in the spectrum. Bowen and Brocklehurst obtained a quasi--linear structure from the luminescence spectra of coronene in hexane at 77°K, and also noted the presence of the fluorescence bands of 1,12-benzoperylene, present as an impurity[70]. Shpol'skii and coworkers[44] published a detailed vibrational analysis of the fluorescence spectrum of coronene, which consists, in hexane at 77°K, of sharp doublets beginning at 23 543/23 456 cm^{-1}. These workers pointed out the active status of the "breathing" frequency of the benzene ring (992 cm^{-1}) and of the symmetrical stretching vibration of the C–H bonds (3070 cm^{-1}). Sidman[125] analysed the fluorescence spectrum in hexane at -180°C and assigned the 320 and 1400 cm^{-1} frequencies to vibrations of e_g^+ symmetry. Mentzel and Zimmerman[38] interpreted the fluorescence spectrum, consisting of 24 bands with an initial band at 23 500 cm^{-1}, in terms of the frequencies 350, 650, 1000, 1250, 1450, and 1600 cm^{-1}. They observed a constant polarisation along the entire fluorescence spectrum.

The phosphorescence spectrum of the compound in the crystalline state was studied at 77°K by Clar and Zander[78], in a mixture of propyl ether and isopentane at 90°K (ν_{00} = = 19 410 cm^{-1}) by Czekalla and Mager[103], in hexane and heptane at 77°K (ν_{00} = 19 375) by Shpol'skii and Klimova[50], and in alcohol at 90°K (ν_{00} = 19 400) by Dörr and Cropper[40]. A detailed analysis of the structure, using the best spectral resolution[50], led to the identification of the fundamental frequencies 120, 365, 850, 1157, 1226, 1350, 1405, 1435, 1618, and 1630 cm^{-1}. The polarisation phosphorescence spectrum shows a large change of polarisation along the spectrum[40]; this indicates the occurrence of not fully symmetrical vibrations whose frequencies, however, were not identified. It should be noted that in a mixed crystal with perhydrocoronene, delayed fluorescence (due to the return of the molecule from the T to the S_1^* state followed by $S_1^*-S_0$ radiation) is observed for coronene in addition to phosphorescence[23,126]. Zander[127] found that, on increasing the temperature, the relative intensity of the $T-S_0$ emission decreases, whilst the delayed fluorescence increases. So far coronene is the only hydrocarbon for which this type of delayed fluorescence has been observed. This is because the energy difference between the S_1^* and the T states is least in coronene: $\nu_{S_1^*-T}$ = 4100 cm^{-1}. Such a large drop in $\nu_{S_1^*-T}$ arises because in this molecule the angular cyclisation of benzene rings proceeds to a complete cycle.

The spectral features of fused polycyclic hydrocarbons containing a five-membered ring are discussed below using fluorene and fluoranthene as examples

Fluorene (XXXIX). Symmetry C_{2v}. The molecule has the π-electron system of the biphenyl nucleus, the $-CH_2-$ bridge affecting the energy of electronic transitions like an alkyl substituent. The long-wavelength $S_1^*-S_0$ transition is polarised, as in the biphenyl molecule, along the C–C bond linking the benzene rings[128]. There are papers giving an analysis of the vibrational structure of the long-wavelength absorption band of fluorene in the crystalline state[61,128] and in frozen solutions[61]. The resonance band in absorption and fluorescence is at 33 160 cm^{-1} (in heptane). The fluorescence band spectrum of the crystals has also been described; it has been shown[128] that the frequencies 404 and 564 cm^{-1} give rise to strong series of bands for fully symmetrical vibrations, polarised along the short axis of the molecule. Nurmukhametov and Gobov[61] described also the fluorescence and phosphorescence band spectrum of a heptane solution at 77°K. The structure of the phosphorescence band of a cyclohexane solution of this compound has been described[69]. The purely electronic

phosphorescence band (23 786 cm^{-1}) lies 9374 cm^{-1} below the first fluorescence band.

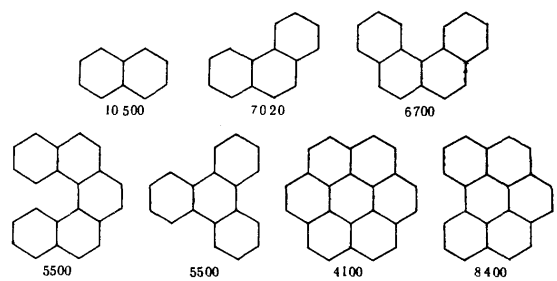
Fluoranthene (XXXVIII). Quasi-linear luminescence spectra have been obtained by Val'dman and Sheremet'ev[129] at 77°K in heptane. The vibrational frequencies 226, 343, 556, 792, 908, and 1614 cm^{-1} in the blue fluorescence band were identified with ν_{00} = 24 521 cm^{-1}. The orange-red phosphorescence spectrum begins with a band at 18 416 cm^{-1} and contains the frequencies 343, 556, 792, 1175, 1310, 1420, and 1614 cm^{-1}. The difference between the S_1^* and the T levels is 6105 cm^{-1}; cyclisation of benzene rings around a five-membered ring lowers this difference, just as it does in the case of cyclisation around a benzene ring (triphenylene, coronene). Lastly, we shall consider the work on the structure of the spectrum of azulene, which consists of two condensed rings (one five- -membered and one seven-membered).

The hydrocarbon azulene has unusual properties: being coloured, it shows ultraviolet fluorescence[130-133]. It has been shown that the fluorescence is due to emission from the second excited singlet level, whereas excitation in the first absorption band does not cause luminescence[130]. Ruzevich[133] obtained a well resolved vibrational structure of the fluorescence band in hexane solution at 77°K.

---o0o---

We shall now consider the correlations which have been established empirically between the position and the structure of the electronic bands. An increase in the length of the π-electron system in the polyacene series (naphthalene, anthracene, naphthacene, pentacene, hexacene) causes a monotonic decrease in the energy of the long-wavelength $S_1^*-S_0$ and $T-S_0$ transitions by the following amounts: 5500 (6370 for ν_{T-S_0}), 5080 (4430), 4000 (2500), and 3000 cm^{-1}. As will be clear from the subsequent discussion, the decrement in $\nu_{S_1^*-S_0}$ and ν_{T-S_0} frequencies per benzene ring is largest in the polyacenes, with an average value of 5000 cm^{-1} for the first few members. All the polyacenes, beginning with anthracene, have a "*p* band", with a very similar coarse vibrational structure. This similarity arises because one of the frequencies in the region 1400 cm^{-1} is predominant. The difference in position between the S_1^* and T levels, amounting to some 10 000 cm^{-1}, is hardly affected by an increase in the number of condensed rings in the polyacene series (see Table 3). Molecules which can be regarded as formed by the condensation of more complicated aromatic nuclei also show this type of spectral peculiarity. Thus, the pyrene molecule is obtained by the linear condensation of two naphthalene nuclei, the molecule of anthanthrene can be derived from two anthracene or three naphthalene nuclei, and the molecule of 1,12-benzoperylene from two phenanthrene molecules. The energies of the $S_1^*-S_0$ and $T-S_0$ transitions in the spectra of the pairs of compounds naphthalene–pyrene, anthanthrene–anthracene, and 1,12-benzopyrene–phenanthrene differ by the following amounts respectively: 4900 (4400 for $T-S_0$), 3000 (3000), and 4200 (5550) cm^{-1}. Thus, fusion of the more complicated aromatic nuclei lowers the frequency of the electronic bands by about the same amount as in the polyacenes, despite the fact that the number of benzene rings in the molecule is increased by more than unity. The difference between the frequencies $\nu_{S_1^*-S_0}$ and ν_{T-S_0} also stays practically constant in condensation of this type: in pyrene and anthanthrene $\nu_{S_1^*-T}$ equals 9900 and 11 400 cm^{-1} respectively. *Peri*-condensation of naphthalene and anthracene nuclei (as in perylene) lowers the frequencies of the long-wavelength bands more significantly than in the pyrenes. However, this decrease is less than in the polyacenes when calculated for a single ring. Again, the frequency difference between $\nu_{S_1^*-S_0}$ and ν_{T-S_0} is found to be constant (in perylene $\nu_{S_1^*-T}$ = 10 000 cm^{-1}). When π-electron groups are conjugated in an open chain, as in the polyphenyls and diphenylpolyenes, the decrease in $\nu_{S_1^*-S_0}$ frequency per unit of the conjugated system is smaller than in the polyacenes by about a factor of two. In these classes of compounds, phosphorescence has been observed only for biphenyl, in the spectrum of which the $\nu_{S_1^*-T}$ difference amounts to 10 000 cm^{-1}.

A different type of spectral changes is observed for angularly condensed hydrocarbons. Fusion of a benzene ring to a polyacene molecule in the 1,2-position causes a much smaller shift of the long-wavelength origin of the absorption spectrum. The α bands are more affected than the p bands, which keep their position unchanged in the benzopolyacene series. As a result, the α band becomes the long-wavelength band in some benzopolyacenes instead of the p band (the long-wavelength band in the corresponding polyacenes). In benzopolyacenes with a long polyacene chain the shift is insufficient, and the p band retains the long-wavelength position and is very similar to the p band of the polyacene. Also, angular condensation decreases the difference between the S_1^* and T levels: in phenanthrene this difference drops to 7080 cm^{-1}, in benzanthracene to 9500 cm^{-1}. Angular fusion of two or more benzene rings to the end rings of polyacenes increases the tendencies noted for the monobenzopolyacenes. In 3,4-benzophenanthrene the difference drops to 6700 cm^{-1}, in triphenylene to 5500 cm^{-1}. The maximum degree of angular cyclisation occurs in coronene, and this coincides, characteristically, with a minimum value of the difference $\nu_{S_1^*-T}$ (4100 cm^{-1}). The decrease in the difference $\nu_{S_1^*-T}$ is clearly illustrated by the series



It must be emphasised that 1,12-benzoperylene is not included in this series because it is regarded as the result of the linear condensation of two phenanthrene molecules.

Essentially, this series spans the whole range of $\nu_{S_1^*-T}$ values met in aromatic hydrocarbons (from 12 000 to 4000 cm^{-1}). The rule relating the relative positions of the S_1^* and T levels to the structure of the π-electron system of the molecule enables us to predict the region in which the phosphorescence spectrum of aromatic hydrocarbon molecules can be expected to occur from a knowledge of the absorption or fluorescence spectrum. A knowledge of the position of the S and T levels and of the

absorption and luminescence spectra of aromatic hydrocarbons as a function of molecular structure is valuable from many points of view. Several of these compounds show photochemical activity, being particularly susceptible to photo-oxidation. The majority of the reactions proceed through a metastable triplet state. Zander[134] pointed out that a hydrocarbon becomes more and more unstable as the energy of the triplet level drops. Pentacene and hexacene react almost like free radicals. Hexacene is readily oxidised, and reacts instantaneously with maleic anhydride, which decolourises it. Octacene and nonacene appear to be true biradicals. The higher relative position of the T level in angularly condensed hydrocarbons accounts for their high stability as compared with the acenes containing the same number of benzene rings. Many hydrocarbons form photo-oxides under illumination in the presence of oxygen. Using the well-known photo-oxidation of anthracene solutions as an example, it was shown[135] that formation of the photo-oxide involves the participation of a T state. In view of published statements that the T states of organic molecules are promising routes to the realisation of efficient lasers[136,137], it may be useful to assess the possibilities offered by aromatic hydrocarbons. On the whole, these compounds are not very promising. The phosphorescence of all the hydrocarbons examined is characterised by glow-decay times between 0.1 and a few seconds. Most of them have triplet–triplet absorption bands overlapping the absorption spectrum of the S_1^*–S_0 transitions. The phosphorescence yield is no more than one-half of the luminescence yield. Lastly, the Stokes losses during excitation are large.

Many aromatic hydrocarbons show carcinogenic properties, which were originally ascribed to the luminescence of these materials but are now regarded as being associated with the position of the levels. Muel and Hubert-Habart[119] found no unique correlation between the position of the T level and the carcinogenic activity of aromatic hydrocarbons. Attempts have also been made to correlate carcinogenic action with the electron donor or acceptor properties of the molecules[138], again without real success. This property of the molecules does not appear to be determined by a single molecular parameter, but rather by a combination of parameters.

3. Charge transfer 496
4. Ion–molecule processes 497
5. Recombination of ions 498

I. INTRODUCTION

In the present review we shall discuss the "ionic aspects" of radiolysis, that is, we shall attempt to follow the fate of the charged particles which are formed by the action of radiation and to clarify their chemical role in radiolysis. Particular attention will be paid to the condensed phase, because ionic processes in the gas phase have already been widely investigated and their role in chemical reactions induced by radiation is fully recognised. Studies of the ion–molecule reactions, discovered in 1952 by Tal'roze and coworkers, have made an important contribution to the solution of this problem: they deal with the fundamental chemical process following the formation of the ions. Several review articles[1-4] have appeared on this topic, and we shall not discuss it here in detail. Ionic processes in a condensed phase cannot, as a rule, be investigated under model conditions, as for example in the ionisation chamber of a mass spectrometer, commonly used to study ion–molecule processes in the gas phase. We shall often be compelled, therefore, when discussing various processes involving ions, to use analogies with the gas phase and to carry over to the condensed phase the relationships obtained for gaseous systems. This approach is justified when dealing with the radiolysis of organic compounds, whose molecules experience only weak mutual interactions in a condensed phase and behave in a number of respects as if they were in a rigid gas.

The action of penetrating radiation (gamma quanta, X-rays, or electrons) on matter is mainly the result of interactions between the fast primary quanta or electrons and the electrons located in the electronic shells of atoms or molecules. Interactions between primary particles and atomic nuclei can be ignored in radiation-chemical investigations.

With gamma energies of the order of 1 MeV, the fundamental primary process is Compton scattering, which gives rise to fast electrons in the irradiated material. In contrast to external irradiation with electrons, the Compton effect leads to a uniform irradiation of the material, since

it is equivalent to a number of electron sources distributed throughout the bulk.

Irrespective of the nature of the primary radiation, the active particles are essentially fast electrons. At the very beginning of their residence time in the material these electrons have an energy distribution not very different from the initial energy of the penetrating radiation. However, the number of electrons in the material quickly rises as a result of ionisation, and a wider distribution is rapidly set up. At equilibrium, the energy distribution of the electrons covers a spectrum from well below the ionisation energy of the molecules to a value equal to the original energy of the electrons [5].

The cross-sections for the ionisation and excitation processes occurring under the influence of electron impact are a function of the energy of the electrons. A common feature of all these processes in the high-energy region is a decrease in cross-section with increase of energy. However, the radiation yield of ions, or the ratio of the energies expended in ionisation and in excitation, which determines the yield, remains constant [6]. The ratio depends mainly on the distribution of excited states and on the position of the ionisation level in relation to this distribution. Some typical values of mean energies needed to generate electron–ion pairs in gases [7] are listed in Table 1.

Since the lowest electron energies I which will cause ionisation lie in the range 12–15 eV, we conclude from Table 1 that approximately 40–50% of the total irradiation energies listed goes into ionisation processes†. There is no reason to believe that this proportion decreases in a condensed phase. Indeed, electrons in molecules have practically identical energy spectra in the gas phase and in a condensed phase, and the ionisation energy is actually lowered in a condensed phase by the polarisation of the medium caused by the distributed charges [8]. The subsequent fate of the electrons and ions which are formed is the main problem. If they mutually recombine in a time so short that alternative processes involving the ion and the electron cannot compete, there will be no chemical manifestation of the ionisation process. The excited molecule formed by the recombination can be treated as the true forbear of all chemical transformations in the material. This suggestion was first put forward by Samuel and Magee [9], and has since caused the role of ions and their reactions in a condensed phase to be occasionally underrated. If the recombination of the ion and the electron is slower than some other reaction between these charged particles and a third body, ionic reactions can be expected to play an important part in the radiation-chemical processes in condensed media.

TABLE 1.

Molecule	H_2	N_2	O_2	Air	CO_2	CH_4	C_2H_6	C_2H_4	C_3H_8
Mean energy per ion pair, W, eV	36.3	34.9	30.8	33.9	32.8	27.3	24.5	26.1	25.7
Ratio W/I	2.35	2.24	2.55	—	2.38	2.10	2.10	2.48	2.25

† We should note also that the ions can be formed in an excited state, and that this will increase still further the percentage of the energy used by ionisation processes in the primary act.

The generation, motion, and recombination of ions and electrons in a condensed phase is revealed most directly by studies of the electrical conductivity induced in solids or liquids by irradiation. However, conductivity studies alone are insufficient to characterise the chemical role of the ions.

A number of recent papers have dealt with the direct observation of the ionic processes leading to chemical changes in the material, and have stressed the importance of ionic reactions during radiolysis. The most fundamental among these will be discussed below.

We shall deal first of all with studies of the physical properties of the ions formed during radiolysis. The chemical transformations of the ions will be considered next.

II. ELECTRICAL CONDUCTIVITY UNDER THE INFLUENCE OF IONISING RADIATION

1. Free and Bound Charges

The appearance of electrical conductance in a condensed phase under the influence of ionising radiation is evidence that ions and electrons are formed. The pair of charges produced by the ionisation of a molecule can contribute to the current flowing through a specimen in an electric field only if the positive ion and the electron of which it is composed do not recombine with one another. We shall refer to such electrons and ions as "free". The electron ejected by ionisation suffers collisions as it moves away from the ion, and loses its energy. If the kinetic energy of the electron is converted into thermal energy before the electron has moved to such a distance from the ion as to make the coulombic interaction energy between their charges small, the cold electron can turn back and neutralise "its own" ion. There will then be no contribution to the electrical conductivity. Some of the electrons, having a high initial energy, will be able to move to greater distances from their parent ion, and become free. For free electrons the recombination can involve any positive ion with equal probability. Obviously, the yield of "free" electrons will depend on the rate at which energy is lost by the slow electrons in the medium. An approximate calculation of the maximal energy losses consistent with the escape of an electron of initial energy E from the sphere of coulomb attraction can be made as follows.

Let δ be the fraction of its energy which an electron loses at each collision. The number of collisions needed to cool an electron from energy E to kT is then given by

$$j = \frac{1}{\delta} \ln \frac{E}{kT}$$

and the corresponding time is

$$\tau = \frac{j}{N\sigma v} = \frac{1}{\delta N \sigma v} \ln \frac{E}{kT},$$

where N is the concentration of scattering centres, σ the scattering cross-section, and v the mean velocity of the electron. "Freeing" of the electron requires that the diffusion length after time τ should be greater than or equal to the radius of the sphere of action of the coulombic field $r_c = e^2/\epsilon kT$, that is:

$$\frac{\sqrt{j}}{N\sigma} \geqslant r_c \quad \text{or} \quad \delta \leqslant \frac{(\epsilon kT)^2 \ln \frac{E}{kT}}{e^4 (N\sigma)^2}.$$

Taking the mean free path of the electron to be $\lambda = 1/N\sigma = 5$ Å, with $\epsilon = 2$ and $E = 10$ eV, we find $\delta \leq 1.8 \times 10^{-3}$.

Although this estimate takes no account of the drift of the electron in the coulombic field and is therefore only a rough approximation, it does nevertheless show that the δ values required to free the electrons lie very close to the relative energy losses occurring in the elastic scattering of electrons. We can therefore expect a strong correlation between the yield of free electrons and such parameters of the material as the dielectric constant, crystallinity, and vibrational spectrum.

When solids are irradiated at low temperatures the yield of free electrons should increase with dose of radiation, because stabilised charges accumulate in the material as the dose is increased and the spheres of action of their coulombic fields begin to overlap [10]: under these conditions the electrons need only travel a smaller distance from "their own" ion in order to "free themselves".

Studies of electrical conductance are concerned only with "free" electrons and ions, but they reflect also the behaviour of other charges produced during ionisation.

2. Liquids

Measurements of the yield of charges under the influence of ionising radiation have been made mostly in the liquid phase. The currents in liquid ionisation chambers, and their variation with applied electric field, have been measured. It was expected that at high applied fields all the free carriers would reach the electrodes, and the saturation current under these conditions would be a measure of the rate of formation of charges. It was found, however, that although the current through a liquid ionisation chamber increases more and more slowly as the potential is increased, it never reaches saturation. This happens when the current through the chamber varies linearly with the intensity of irradiation, showing that the charges are destroyed only at the electrodes [11]. Hence, one method of determining the yield was to extrapolate this current to an infinitely large field, because the absence of saturation suggested that some other mechanism was operative and competed with the separation of the ions. This method was used to estimate the ion yield of CS_2, [12,13] and also in some liquid saturated hydrocarbons [14] between C_6 and C_{10}. Yields equal to those in the gas phase [13], or close to them [14] (~ 1), were obtained. Obviously, a method involving such a long extrapolation cannot give precise values for the yield, but estimates by this method are capable in principle of giving the total yield of charges formed during irradiation. It is suggested in these papers that the lack of saturation is due to fast recombination of the charges in the tracks, where the ion density is high. An alternative mechanism, which would have a similar effect, is the recombination of the electrons with "their own" ions.

A second group of papers deals with conductance studies at low field intensities [11,15,16]. Under these conditions only a small fraction of the current carriers reach the electrodes, and the free ions and electrons are lost in the bulk. To calculate the radiation yield $G(e)$ one measures the electrical conductivity $\sigma = n\mu e$, where n is the steady-state concentration of current carriers and μ is a mobility defined as the sum of the mobilities of ions and electrons. The steady-state concentration of current carriers n is determined by the rates of recombination and of generation of free charges:

$$n = \left(\frac{GI}{100} \cdot \frac{1}{k}\right)^{1/2}.$$

Here I is the energy of the radiation in eV absorbed by 1 cm³ of the liquid per second and k the recombination coefficient. The latter can be calculated either from the mobility, $k = (4\pi e/\epsilon)\mu$, or determined experimentally from the kinetics of the decay of σ following removal of the irradiation. The mobility of the ions in the liquid under study must be known in order to calculate G. The most direct method of determining the mobility is to measure the time T required for the ions or electrons to travel the known distance l between the points of generation and of detection. The relationship is $\mu = l/TE$, where E is the strength of the field causing the motion of the current carriers. This method has been used to measure the mobility of ions in n-hexane [15,17]. Some values of μ are set out in Table 2.

The temperature variation of the mobility of electrons, measured [17] by emission from a photocathode into n-hexane under the influence of light, has been found to be exponential with an activation energy of 0.14 ± 0.02 eV. This result suggests that an electron in a liquid may spend part of its time in states which are similar to shallow traps in crystals.

The radiation yields of "free" current carriers measured at low field intensities are smaller than in gases; the following values have been reported: 0.2, [11] 0.09, [15] 0.07. [16] These low values are evidence that only a small fraction of the electrons produced manage to escape from "their own" ions. A recent calculation [21] has shown that the low yield can be satisfactorily explained by assuming that ionisation is brought about only by δ-electrons with an energy of 100–200 eV.

TABLE 2.

Current carriers	μ, cm² V⁻¹ s⁻¹ at 300°C

3. Solids

The appearance of free charges in a solid organic material under the influence of irradiation is accompanied by an increase in electrical conductivity. Since the majority of radiation-chemical investigations have been carried out on amorphous or microcrystalline organic materials, a rigid application of the band theory is not possible. However, as a matter of convenience in the present discussion, the band diagram can be replaced by an energy diagram showing the distribution of levels corresponding to the ionised states. The minimal energy needed to produce a free electron in an organic material is sometimes called the ionisation potential in the condensed phase. This quantity [8] is lower than the ionisation potential in the gas phase by the polarisation energy $2P$ gained

by bringing the two charges from a vacuum into the condensed phase‡. If the molecules of the material have a positive electron affinity Q, the lowest energy consistent with the formation of a pair of charges not interacting with each other is given by

$$E = I_{gas} - 2P - Q = I_{solid} - Q.$$

The energy diagram of the ionised states in the gas phase and in a condensed phase is shown in Fig. 1. In the "forbidden gap", that is, in the band of levels located between the level of the positive ion of the parent substance and that of the negative ion, we can find ionised states whenever impurity molecules with a lower ionisation potential or a higher electron affinity than the molecules of the major constituent are present in the system. Such levels can be produced also by structural defects. Levels in the "forbidden gap", by which electrons or positive charges can be captured, are usually called traps. In principle, the following can take part in electrical conduction: (1) electrons which are not localised on any molecule, (2) electrons captured by the molecules of the material and undergoing resonance charge transfer of negative ions (for molecules with a positive electron affinity), and (3) positive charges in the molecules of the material undergoing resonance charge transfer of ions. In addition, electrical conduction can, on occasions, result from the transport of

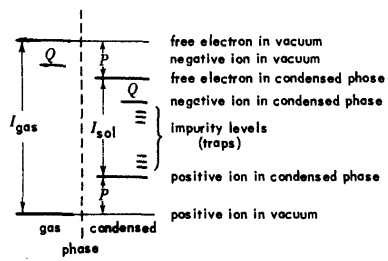

Fig. 1. Energy diagram for ionised states in the gas phase and in a condensed phase.

the ions themselves (either traps which have captured an electron or a hole or charged molecules of the major constituent).

The study of the electrical conductivity of organic substances under the influence of ionising radiation bears some similarity to the study of the photoconductivity of semiconductors and dielectrics. However, in contrast to the effect of light, radiation produces not only current carriers but also new molecules in the host material which can act as traps for the current carriers.

Studies of the electrical conductivity of solid organic materials, and particularly of polymers, have been described in numerous publications [25-33]. The main characteristic of the electrical conductivity observed under irradiation is a dependence of σ upon the dose rate (or intensity) I. In general, it is found that

$$\sigma = n\mu e = \alpha I^{\Delta} \S \qquad (1)$$

where Δ can have any value from 0.5 to 1. The value of Δ is determined by the mechanism of recombination of current carriers. Many solid organic substances give $\Delta \simeq 1$ on irradiation, and $\sigma = 10^{-18} I$ to within two orders of magnitude [34], where σ is expressed in Ω^{-1} cm^{-1} and I (the dose rate) in rad min^{-1}. Ionic conductivity does not appear to play a major role when solid organic substances are irradiated, as evidenced by measurements of the electrical conductivity induced by irradiation in solid heptane [10,35] and polyethylene [33] at liquid nitrogen temperature, when ionic motion is excluded. The electronic conduction processes described by Eqn. (1) are in satisfactory agreement with the theory of photoconduction in the presence of traps [36]. Fowler [37] was the first to apply this theory (to irradiated polyethylene): his scheme describing the participation of traps in the recombination process (scheme *I*) is reproduced in Fig. 2. The figure also shows alternative schemes by which traps can be involved in electrical conduction processes (*II* and *III*). In the first scheme we can assume, to simplify matters, that only the electrons are mobile. In all schemes the electrons, which take part in electrical conduction as long as they remain in the free (non-localised) state, are removed from the sphere of action for appreciable periods when they fall into traps. The time during which they remain untrapped, in the free state, determines their mean effective mobility μ_{eff}, which characterises the electron throughout its lifetime from generation to recombination with a positive ion¶. The extent of filling of the traps is determined by the probability of electrons falling into the traps and by the time of residence of an electron in the trap. As the traps are gradually filled, the electron mobility μ_{eff} increases. If the electron traps are distributed in depth, it is evident that at equilibrium under irradiation the deeper traps will be filled to a greater extent than the shallower traps. The total number of filled traps will depend on the intensity of irradiation, and increase with

‡ In a condensed phase, as in the case of gases, we must distinguish between the "vertical" and the "adiabatic" ionisation potential. The former is determined by an electronic transition in the molecule, and by the electronic polarisation in the medium, without any change in the position of the nuclei of the ionised molecule or of the molecules of the surrounding medium. The adiabatic ionisation potential in a condensed phase is lower than the vertical potential not only because of the different internuclear distance in the resulting ion, but also because of low-frequency polarisation of the medium when polar groups are present. A vertical transition occupies a time of the order of 10^{-15}–10^{-16} s, and is produced by electron impact ionisation or ionisation by light quanta. The low-frequency polarisation is set up, according to the properties of the medium and the temperature, in a time of 10^{-11}–10^{-13} s after the appearance of charges in the medium, and has the effect of placing the electrons and the positive charges in polarisation wells of a peculiar kind. The term polarons has been proposed in the theory of dielectrics for electrons of this type [22]. In polar media such as water and alcohols, polarons (solvated electrons) have been detected experimentally [23,24].

§ In general, electrical conduction involves both electrons and "holes". The latter term refers to positive charges which are mobile by virtue of resonance charge transfer processes. Hence, $\sigma = \mu_h n_h e + \mu_e n_e e$. In order to simplify the problem, it is often assumed that the contribution of carriers of one type can be ignored in comparison to that of carriers of the opposite sign, so that $\sigma = \mu n e$, where n is the concentration of carriers whose contribution to electrical conduction is the more significant and μ their mobility.

¶ When using the mobility μ_{eff}, the expression for the electrical conductivity becomes $\sigma = \mu_{eff} n_n e$, where n_n is the concentration of all negative charges in the material.

increasing intensity. This, in turn, will raise the electron mobility μ_{eff}. Thus, an increase in radiation intensity will, on the one hand, decrease the lifetime of the current carriers by increasing the probability of electron–ion recombination, and on the other hand it will increase the effective mobility of the current carriers. These factors are very sensitive to the distribution of the traps in depth. Thus, in scheme *I* of Fig. 2 we can assume an exponential distribution in depth[37]: this gives the number of traps lying in the range from E to $E + \Delta E$ below the free-electron level as

$$M_E dE \sim e^{-E/kT_i}\ dE,$$

where T_i is a constant characteristic of a particular substance. It turns out that $\Delta = T_i/(T + T_i)$. By suitable choice of T_i we can have any value of Δ from 0.5 to 1, but this value remains constant over a wide range of radiation intensities. The lack of dependence of Δ upon I is the strongest argument in favour of the choice of an exponential energy distribution for the traps.

A relation of the type $\sigma = \alpha I^{\Delta}$ can be obtained if all the traps in the system lie at the same depth. However, the value of Δ will then vary with intensity of irradiation. Thus, at very low intensities, when the lifetime of a current carrier is much greater than its trapped time, $\Delta = \frac{1}{2}$. At high intensities Δ tends towards unity, but it drops back to $\frac{1}{2}$ when most of the traps are filled. The large range of intensity values which has to be covered in order to observe the slow variation of Δ with I does not allow us to identify the type of distribution of the traps with confidence from the measured values of Δ alone: experimental measurements of this quantity usually fall somewhere between 0.5 and 1 and appear to be constant at this intermediate level[38]. For polyethylene it is reported[37] that $\Delta = 0.7$.

If the positive charges formed by irradiation are mobile, electrons captured in traps can recombine with the positive charges directly, without being emitted into the conduction band. This scheme is shown in Fig. 2, *II*. Lastly, we can have a third type of electrical conduction process, shown in Fig. 2, *III*, in which a current carrier is emitted from a deep trap to the conduction band as a result of energy transfer from the radiation field.

We cannot make an unambiguous choice between the various schemes of carrier recombination and trap filling on the basis of measurements of the quantity Δ. Measurements of the kinetics of the growth or decay of electrical conductivity following exposure to or removal from irradiation are also of little help, because any of the models can be made to agree with experiment by suitable choice of distribution of the traps.

The most important conclusion to be drawn from studies of electrical conductivity is that the role of traps in the recombination of free electrons is established. By assuming an exponential energy distribution of traps it has been possible to estimate the concentration of traps present in polyethylene[37] and in octacosane[39] before irradiation. Since this concentration was found to be independent of the degree of purification of the material, it was concluded that traps in saturated hydrocarbons are not impurities but structural defects (possibly perturbations in the short-range order in the molecular distribution[39,40]). The concentrations of traps were found to be very large ($\sim 10^{20}$ cm^{-3}).

4. Accumulation of Stabilised Charges Under Low-Temperature Radiolysis

The discovery of thermally stimulated currents in saturated hydrocarbons irradiated at low temperatures[41–43] is a direct proof of the accumulation of current carriers in traps. The thermally stimulated current peak shown in Fig. 3 appears when irradiated specimens are allowed to warm up and is associated with the emission of current carriers from the traps and their recombination. The appearance of conductance on heating irradiated specimens suggests that both negative and positive charges are stabilised at low temperatures.

The role of traps in recombination processes has been investigated by attempting to introduce new traps into the specimen and monitoring changes in electrical conductivity under irradiation. Thus, Wintle[44] examined the changes in the nature of the σ–I relationship for polyethylene brought about by previous exposure of the specimen to a large dose of radiation. The relationship was found to become linear, with $\Delta = 1$, in keeping with the formation of deep traps as a result of irradiation. The nature of these traps was not characterised. Yakovlev and Frankevich[10] studied the electrical conductivity of n-heptane at liquid nitrogen temperature as a function of irradiation with a constant flux of fast electrons, and found that σ under irradiation falls as the total dose of radiation is increased. They were able to relate this drop in σ to the known concentration of free radicals which had accumulated in the specimen under the

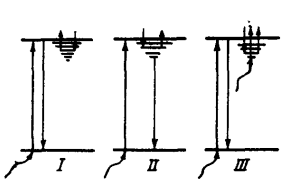

Fig. 2. Distribution of trapping levels and recombination mechanism:
I) recombination of a free electron with an ion; thermal emission of electrons from the traps; II) recombination of an electron captured in a trap with a mobile positive charge; III) recombination of free electrons with ions; excitation of trapped electrons by the transfer of radiation energy.

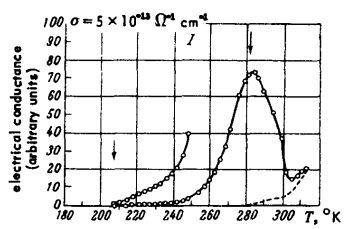

Fig. 3. Thermally stimulated conductance curve in an irradiated paraffin[41,42], dose 50 Mrad. The broken line shows the electrical conductance of the paraffin in the absence of irradiation. The initial section of the curve is replotted on an enlarged scale.

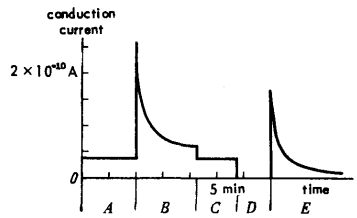

Fig. 4. Variation of the conduction current through a specimen of n-heptane under irradiation (sections *A* and *C*), combined irradiation and illumination (section *B*), and illumination of an irradiated sample (section *E*). Dose rate 0.12 Mrad min^{-1}.[47]

influence of radiation and behaved as traps for current carriers, and to calculate the concentration of traps present in the specimen before irradiation. The concentration was found[45] to be 10^{19}–10^{20} cm^{-3}. The suggestion that free radicals in saturated hydrocarbons can act as traps for charges at low temperatures was first put forward by Tal'roze[46].

The reported photoconductivity[10,35,47] of saturated hydrocarbons during and after irradiation is further confirmation of the capture and accumulation of electrons in hydrocarbons during irradiation. Photoconductivity has been observed also in irradiated aromatic hydrocarbons[48]. Fig. 4 shows typical plots of the current through a specimen of frozen n-heptane, recorded during irradiation with fast electrons and/or visible light[47]. The conductivity peak observed upon exposure to light is due to the emission of current carriers from traps, and the decay is due to the destruction of traps. The amplitude of the photoconductivity peak is proportional to the concentration of trapped current carriers, and can be used as a measure of this concentration. By measuring the amplitude of the photoconductivity as a function of dose Yakovlev and Frankevich[10] were able to monitor the filling of the traps during irradiation and to estimate the limiting concentration of filled traps. This was found to be 10^{17}–10^{18} cm^{-3}, that is, a small fraction of the total concentration of traps.

The low degree of filling implies a mechanism of annihilation of the traps other than thermal excitation, whose probability at a temperature of -196°C is extremely small. Such a mechanism is operative in schemes *II* and *III* of Fig. 2: it involves recombination with mobile "holes"[51] and excitation of trapped current carriers by the resulting energy transfer. It is probable that the positive charges (or "holes") are able to contribute to conduction for a short period following their generation, whilst they remain excited, and become stabilised only after their excitation energy has been dissipated.

The following observations are relevant to a discussion of the factors which cause freezing of the holes. Obviously, the motion of positive charges implies resonance charge transfer between neighbouring molecules. The positive charges in saturated hydrocarbons are localised at individual $-CH_2-$ groups. The ionisation potential of a $-CH_2-$ group depends on the position of the group within the molecule, being lower for central groups and increasing towards the ends of the molecule. This is because the positive charge polarises the molecule, and the gain in polarisation energy is greatest when the charge is located centrally. The existence of a difference in ionisation potential, which can be as large as 0.3 eV for 2–3 $-CH_2-$ units, makes the movement of holes very slow at low temperature. Charge transfer occurs by an electronic mechanism, and does not involve, in keeping with the Franck–Condon principle, any change in the relative positions of atoms. However, the mean interatomic distances in an ion and in a neutral molecule are different, and vibrational excitation of the ions and molecules is needed for charge transfer: this can significantly retard the charge transfer at low temperatures.

Furthermore, positive charges can fall into traps which they "dig" for themselves by undergoing ion–molecule reactions. Thus, the positive charge formed by the exothermic reaction

$$\begin{array}{l} -CH_2-CH_2^+-CH_2- \\ -CH_2-CH_3-CH_2- \end{array} \longrightarrow \begin{array}{l} -CH_2-CH_3^+-CH_2- \\ -CH_2-\dot{C}H-CH_2- \end{array}$$

on a $-CH_3^+-$ group cannot even move to one of the neighbouring $-CH_2-$ groups, because this would involve overcoming a potential energy barrier†.

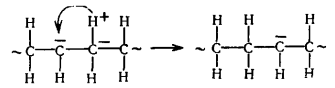
One possible cause of the low degree of filling of the traps by electrons could be the excitation of the electrons by the energy of the radiation, a term which includes here all forms of energy present in the irradiated material: non-equilibrium vibrational excitation energy, electronic excitation energy, light, and slow electrons (sometimes called "subelectrons"[49,50]). The fractional filling of the traps by electrons, n_-/N_t, is a very sensitive function of the probability of excitation of a trapped electron. For scheme *III* of Fig. 2 it can be shown that

$$\frac{n_-}{N_t} = \sqrt{\alpha}\Big/\sqrt{\frac{\sigma_c}{\sigma_r}\cdot\sqrt{\gamma}},$$

where α is the relative probability of excitation of a valence electron and of an electron captured in a trap, γ the number of traps expressed as a fraction of the total number of molecules, σ_r the cross-section for the recombination of an electron with a positive ion, and σ_c the cross-section for the capture of an electron by a neutral trap.

Calculation shows that even for $\alpha = 10^{-2}$ the fraction of filled traps is $n_-/N_t = 10^{-2}$, in qualitative agreement with the experimental value.

The concentration of all charges which accumulate in various saturated hydrocarbons has been measured[52] by studying the relaxation polarisation which appears after irradiation of the materials at low temperature (-196°C) with a 10–50 Mrad dose: the value obtained was 10^{19} cm^{-3}. Since the relaxation time of the charges was found to increase monotonically with molecular chain length in the hydrocarbon series (C_6–C_{12}, C_{25}, polyethylene) examined, a model was put forward according to which a charge localised on a deep trap (a free radical) can move as a result of proton transfer:



This process has a relatively low activation energy for intramolecular transitions (estimated[52] to be 0.06 eV), and accounts for the comparatively high mobility of positive charges within the limited potential wells associated with

† It should be noted that movement of the charge within the molecule may still be possible owing to resonance proton transfer.

the molecules. Limited motion of this type manifests itself as relaxation polarisation, observed when irradiated hydrocarbons are allowed to warm up. Molecular transitions giving rise to electrical conduction in the sample after irradiation and heating appear to need a higher activation energy (0.6 eV, as estimated from the initial portion of the thermally stimulated current curves).

5. Determination of the Electron Yield in the Solid Phase

Gemant[53] made a direct estimate of the yield of electrons in solid hydrocarbons, by measuring the time constant T for the establishment of electrical conduction in a paraffin film enclosed between two electrodes and irradiated with β particles. The intensity of irradiation was low, and the lifetime of the charges was determined only by the transit time of the current carriers between the electrodes. Under these conditions the radiation yield of charges taking part in electrical conduction is 0.036 for 100 eV, and their mobility is 5×10^{-8} cm^2 V^{-1} s^{-1}. This value is fairly close to the yield of free charges measured in liquid n-hexane[11]. The low mobility is evidence that either the current carriers move "from trap to trap" or the mobile species are ions.

Frankevich and Balabanov[54] attempted to measure the yield of all charges formed during bombardment of a paraffin with electrons. A thin film of paraffin, enclosed between two electrodes, was irradiated by a short pulse of electrons of energy 3–5 keV, and the current pulse in the specimen circuit due to the motion of the resulting charges in an electric field was measured. Immediately after their generation all charges act as current carriers and contribute to the conduction current. If a high concentration of traps is present in the specimen some of these charges are captured by traps, and charge recombination (which "confiscates" the contribution of the charges to the conductivity) takes place with a time constant equal to the lifetime in the traps. Measurements showed[54] that a large proportion of the electrons actually return to "their own" ions, and that their trapped time for the C_{25} paraffin at room temperature amounts to tens of seconds. Measurements of the conductivity pulse give $G\mu\tau = 2.6 \times 10^{-12}$ cm^2 V^{-1}. Hence, and from the maximum diffusion length of an electron in the electric field — which for an electron which does not become free cannot exceed $r = \sqrt{e/\epsilon E}$, where E is the external field strength and ϵ the dielectric constant — the yield of electrons captured by traps upon irradiation could be calculated, and the value obtained was $G > 1$. These results also showed that each electron, on the average, migrates more than 30 Å from "its own" ion if the total radiation yield of electrons is taken to be $G = 3$.

III. METHODS OF DETERMINING IONS IN CONDENSED HYDROCARBONS WHICH DO NOT DEPEND ON THE ELECTRICAL PROPERTIES OF THE IONS

In addition to their electric charge, which is their most fundamental property, ions have a number of other properties, less specific but nonetheless characteristic, which can be used to identify the ionised states formed in an organic compound by the action of radiation. The following properties have been used to detect ions: the magnetic moment (for paramagnetic ions), the absorption spectrum, and the light emitted by the recombination of ions with electrons.

Many workers have observed a light-sensitive line, which disappears on exposure to visible light, in the ESR spectrum of alcohols[55,56], polyethylene, paraffin, and rubbers[57] irradiated at low temperatures. Sensitivity to light in the visible region suggests weak bonding of the electron, and justifies the conclusion that this ESR line is due to electrons held in traps of some kind. The presence of trapped electrons is confirmed by the development of colour on irradiation and by the thermoluminescence of hydrocarbons irradiated at low temperature and allowed to warm up[55,58-60]. Heating the specimens causes luminescence and at the same time bleaches them. It has been shown[61,62] that the luminescence appears at temperatures corresponding to phase transitions in the irradiated material, and is associated with faster diffusion of the charged particles. The luminescence centres are usually provided by some impurity present in the material which is excited by acquiring the energy evolved by the recombination of charges. The recombination does not involve emission of the electrons from the traps: this follows from the observation that the depth of the traps as deduced from the photoluminescence excitation spectrum in irradiated hydrocarbons (n-hexane, nonane, 2,4-dimethylundecane, tetradecane, cyclohexane, dicyclohexyl-4-decane, polyethylene)[63] is fairly large (2–3 eV) and does not agree with the depth measured by the appearance temperature of the thermoluminescence peak. The photoluminescence excitation spectra of irradiated hydrocarbons have been found[63] to depend on the total dose of radiation. At high doses (> 10 Mrad) the spectrum is displaced towards the short-wave region, pointing to the appearance of new, deep traps on irradiation. These traps are, very probably, free radicals[45].

Many workers have studied the appearance of ions in two-component systems (solid solutions), because these systems offer the possibility of identifying certain ions either by their absorption spectra or by their ESR spectra. Therefore, additives able to give rise to such ions offer a means of monitoring their formation and accumulation under irradiation.

It should be noted that the formation of ions of the second component in two-component systems can occur by direct ionisation, but also as a result of charge transfer, excitation transfer, or ionisation by subelectrons, that is, electrons whose energy is less than the ionisation potential of the molecules of the major component. At low additive concentrations we can ignore direct ionisation, but it is not always possible to choose unequivocally among the other possible processes.

Bagdasar'yan and his coworkers[64-66] have studied the formation of positive ions of aromatic amines in matrices of methylcyclohexane, isopentane, and poly(methyl methacrylate). Samples were exposed to γ-radiation at -196°C. The ions of aromatic amines were identified by their known absorption spectra. The yield of positive ions of the amines in a hydrocarbon glass was 0.16 (at an impurity concentration of 0.005 M) on the basis of the energy absorbed by the whole of the sample; in poly(methyl methacrylate) G(ions) = 3 at an impurity concentration of 0.1 M. The limiting concentration of ions was 10^{-5} and 10^{-3} M in the two experiments respectively, and did not increase when the additive concentration was increased. The authors suggest that the amine ions are formed by the capture of positive charges (initially generated in the matrix) by solute molecules. However, they do not exclude the possibility of ionisation of the amines by excitation energy gained from the matrix[67].

The formation of positive ions of *NN*-dimethyl-*p*-phenylenediamine (DMPD) was studied spectroscopically by introducing the amine into various matrices[68] and than irradiating with γ-rays at -196°C. A high yield ($G \simeq 2$) of DMPD ions was obtained in non-polar media, but in polar media (alcohols) the yield was much lower under otherwise identical conditions. Addition of an electron-acceptor impurity to the matrix as well as the amine raised the yield of DMPD cations to 4 in non-polar media and by a small amount in polar media. These results were interpreted in terms of the capture by amine molecules of positive charges formed by ionisation of the matrix. The small yield of cations in polar media is tentatively ascribed to an ion–molecule reaction observed in the gas phase[69], of the type

$$C_2H_5OH^+ + C_2H_5OH \longrightarrow C_2H_5OH_2^+ + C_2H_5O.$$

leading to positive charge "capture". The presence of acceptor molecules lowers the mobility of electrons and precludes to some extent their recombination with positive charges.

The formation of negative ions has been observed spectroscopically and by ESR in poly(vinyl chloride) and poly(methylmethacrylate) containing electron-acceptor impurities (quinones, polycyclic aromatic compounds, etc.)[70]. These were irradiated with γ-quanta at -196°C. The concentration of additives was between 0.03 and 0.6 mole %. Under these conditions the yield of anions, calculated on the basis of the energy absorbed by the acceptor molecules in the system, amounted to 100–1000. This is evidence for energy transfer from the matrix to the impurity. The authors suggest that the impurity directly captures an electron which would otherwise by captured by a polymer molecule. They point out that the retrapping of an electron by an impurity completely suppresses the formation of conjugated bonds and the appearance of colour in poly(vinyl chloride) upon irradiation.

Guarino and coworkers[71,72] have reported a systematic investigation of the formation of negative ions in hydrocarbon matrices. Naphthalene or biphenyl impurities were introduced into a matrix of tetrahydro-2-methylfuran (THMF). The absorption spectra and the extinction coefficients of the negative ions produced from these molecules are known, since the ions can be prepared chemically by reduction with alkali metals (with formation, for naphthalene, of $Na^+C_{10}H_8^-$). The samples were irradiated with γ-rays at -196°C. In a glassy matrix of THMF containing naphthalene the limiting yield of $C_{10}H_8^-$ anions was found to be 2.6; with biphenyl as the impurity the yield (of $C_{12}H_{10}^-$ ions) was 3.2. In hydrocarbon glasses containing the same impurities the anion yield was 1.1 and 1.7 respectively, whilst in an ethanol matrix the yield of anions was 2.94. When the impurity concentration was of the order of 0.05 mole %, the yield was close to unity in all media. Evidently, as in any other two-component medium, the retrapping of an electron ejected from a molecule of the solvent is not the only possible mechanism of formation of ions of the minority component. Ionisation by excitation transfer or by subelectrons is also possible. Further experiments were needed to substantiate the authors' contention that the measured electron yields applied to free and thermally generated electrons formed by the ionisation of the substrate. Thus, it was found that an absorption band which can be bleached by light is formed in THMF even in the absence of added impurities. When the absorption band of the matrix was bleached using a specimen which had been irradiated in the presence of impurities it was found that the concentration of impurity ions rose. This points to the transfer of electrons, initially stabilised in the matrix, to the impurity molecules. The observed competition between two different impurities added to THMF[72–74] is further evidence that the impurity molecules act only as acceptors of electrons generated in the matrix. Thus, if THMF contains only naphthalene (at a concentration of 0.11 mole %) the yield of $C_{10}H_8^-$ ions is 1.63, but the value is lowered when competing substances are added. The decrease caused by various "secondary" impurities is a relative measure of their electron-capturing efficiency. The formation of anions by electron retrapping must involve the scheme

$$M \rightarrow M^+ + e$$
$$X + e \rightarrow X^-$$
$$Y + e \rightarrow Y^-,$$

where M is a molecule of the major constituent, and X and Y are impurity molecules.

If X^- is identified with the $C_{10}H_8^-$ anions, whose concentration can be measured, the measured yield G_{X^-} is related to the impurity concentrations C_X and C_Y as follows:

$$\frac{1}{G_{X^-}} = \frac{1}{G_e^0} + \frac{\sigma_Y}{\sigma_X}\frac{C_Y}{C_X}\cdot\frac{1}{G_e^0}.$$

This formula is correct if the $C_{10}H_8$ molecules capture all the electrons in the absence of a "second" impurity: G_{X^-} is equal to G_e^0 when $C_Y = 0$. Table 3 lists some relative capture efficiencies (σ_Y/σ_X) for electrons, measured experimentally[72] with different Y molecules as the "second" impurity.

The series of relative electron-trapping efficiencies obtained is consistent with the known trapping properties of many of these molecules towards thermal electrons. It was found that the lower the threshold energy in the plot of electron capture cross-section against energy, the more effectively molecules behave in competing for electron capture during radiolysis. The threshold energies for electron capture by HI and HCl molecules are 0 and 0.66 eV respectively; the threshold energies for CCl_4 and $CHCl_3$ are 0.03 and 10 eV. In keeping with these figures, we see from Table 3 that HI molecules are mo efficient electron acceptors than HCl; CCl_4 molecules are much more effective than CH_3Cl. Moreover, it was found that the relative electron trapping efficiency of these molecules increases in the same order as their polarographic half-wave potential.

TABLE 3.

* $\sigma_{I_2} = 3.2 \times 10^{-15}$ cm^2.

Similar results were obtained[74] by adding biphenyl and various benzene derivatives to a THMF matrix. The measured relative electron trapping efficiencies (σ_Y/σ_X) are set out in Table 4 (where X = biphenyl).

The results of these investigations[71-74] provide convincing proof that the yield of electrons which can be trapped by various impurities is high in hydrocarbons, and corresponds approximately to the yield of electrons in the gas phase.

By using flash irradiation, which can generate a high concentration of ions, it has been possible to estimate the ions in the liquid phase. Thus, an absorption spectrum has been observed[75] in the region of 2970 Å after flash radiolysis of liquid 2-methylpropene. Trimethylcarbonium ions are known to absorb in this region. The lifetime of the ions was 0.05 s at -15°C. These experiments are similar to those which revealed the presence of solvated electrons in water during irradiation[24].

The overall conclusion from all the data presented in Sections II and III is that the work published so far provides sufficient grounds for the confident assertion that electrons and ions are formed and have an appreciable existence in a condensed phase.

The lifetime of electrons and ions before they mutually recombine is such, even for recombination in pairs, that processes involving the capture of electrons by traps, by specially added acceptor molecules, and therefore also by electron-acceptor radiolysis products, can compete with the electron–ion recombination process. We may conclude from the results discussed above that the following are the most important processes involving charged particles in an organic material:

ionisation	$M + e \rightarrow M^+ + 2e$
recombination of an electron with "its own" ion	$M^+ + e \rightarrow M^*$
electron capture by impurities competing with recombination	$T + e \rightarrow T^-$
recombination of T^- ions (or e^-) with M^+	$T^- + M^+ \rightarrow$ products

If the time during which M^+ ions, and also X^- and T^- ions, can exist is long enough for these ions to take part in ion–molecule reactions, the products of these reactions will take part in the recombination process.

In the liquid phase the time of separate existence of electrons and ions is determined by the time which they take to diffuse towards each other from distances not exceeding r_c but greater than 30 Å (see p. 493). If we assume a mobility for electrons in n-hexane[17] of 10^{-3} cm^2 V^{-1} s^{-1}, a typical lifetime of charges in an organic liquid works out to[76]:

$$\tau = \frac{\varepsilon}{3\mu e^2} r_c^3 \simeq 10^{-7}\ \text{s}.$$

For free electrons the lifetime is very much greater, and depends on the total concentration of ions. However, the yield of free electrons is no more than 3–5% of the total, as was pointed out above.

The existence of two groups of electrons upon irradiation, with widely different lifetimes for recombination, was stressed by Williams[76] in his study of liquid cyclohexane. He showed that addition of a low concentration of ND_3 to cyclohexane leads to the formation of HD molecules, the yield being independent of the impurity concentration over the range 10^{-4}–10^{-2} M and increasing with $\sqrt{[ND_3]}$ at higher concentrations. Since the formation of HD was shown to occur by the process

$$ND_3 + C_6H_{12}^+ \longrightarrow ND_3H^+ + C_6H_{11},$$
$$ND_3H^+ + e \longrightarrow NH_3 + D \text{ (and also } NH_2D + H)$$
$$D + C_6H_{12} \longrightarrow HD + C_6H_{11},$$

it follows that the measured yield of HD is a measure of the number of charges which can be captured by ND_3 (to give ND_3H^+). The lack of dependence of the yield of HD upon the concentration of additive is evidence that the lifetime of at least some of the charges is very long: this fraction of the charges is estimated to be formed with a yield of 0.08, in good agreement with the yield of free carriers[11,15]. The lifetime of the charges formed in very much greater yield was estimated to be 10^{-7} s.

In a solid phase, and particularly at low temperatures, the lifetime can be quite high, and it is always higher than in the liquid phase.

TABLE 4.

IV. REACTIONS OF CHARGED PARTICLES IN A CONDENSED PHASE

1. Main Types of Reaction

The ions and electrons formed in a condensed phase are active particles, free to take part in many chemical reactions. The high activity of charged particles has been demonstrated in many investigations of ion–molecule processes in the gas phase, showing that exothermic or athermic ion–molecule reactions involve a negligibly small activation energy. Since the lifetime of ions in a condensed phase is greatly in excess of the time between collisions (10^{-13} s), it is obviously possible for the ions to take part in various reactions. In consequence, ionised products of these reactions can often take part in the recombination process instead of the molecules initially ionised.

Processes involving charged particles during their lifetime can have a profound effect on the chemical action of radiation. Among these processes, the following are the most important.

Processes with the participation of positive charges: unimolecular decomposition; positive charge transfer to molecules of lower ionisation potential than the molecules of the substrate; ion–molecule reactions.

Processes with the participation of electrons: electron transfer to molecules of higher electron affinity than the molecules of the substrate or to traps of structural origin;

unimolecular decomposition of a molecule containing a trapped electron; ion–molecule reactions.

The chain of transformations involving positive and negative charges ends when the charges recombine.

In most instances, workers can critically assess various processes in a condensed phase by referring to the considerable fund of experimental data on the formation of stable radiolysis products. In a condensed phase it is not possible as a rule to examine in detail any particular elementary reaction, including reactions between ions and molecules, by observing the initial particles and their transformation products, as can be done in the gas phase. Therefore, experimental results can often be "satisfactorily" explained by different mechanisms. In these circumstances, the most valuable investigations are those offering some direct evidence that the primary particles leading to the observed product by a clearly defined reaction were ions.

The main criterion of whether any given reaction proceeds with the participation of charged particles is the energy of the reaction. One usually refers to the published heats of the corresponding reactions in the gas phase. This can be justified for processes not accompanied by the disappearance of charges, because a condensed phase lowers the ionisation potential of molecules by the polarising effect of the medium and ion solvation but has no effect on the "neutral" properties of molecules. The lowering of the ionisation potential on changing from the gas phase to a condensed phase drastically decreases the exothermicity of ion recombination processes. Processes involving ions and electrons will be examined in detail in the following subsections.

2. Dissociation of Ions

A positive ion, usually in an excited state when first formed, very quickly (in 10^{-8}–10^{-13} s) loses its excitation energy by collisions with the surrounding molecules.

Dissociation of an excited ion can occur only if the resulting fragment is able to escape from its partner by diffusion: otherwise, the cage effect[77] causes recombination of the ion. It follows that, in practice, the only possible products of dissociative ionisation in a condensed phase are an H atom or a proton. An ion can dissociate from its ground state without any restriction as to the residues only if energy is evolved[78]. A thermochemical calculation shows[79] that dissociation is energetically favourable when, for example, an alkene ion is formed from a saturated hydrocarbon:

$$C_6H_{14}^+ \longrightarrow \begin{cases} \longrightarrow \textit{trans}\text{-}2\text{-}C_6H_{12}^+ + H_2\ (+4\ \text{kcal mole}^{-1}) \\ \longrightarrow \textit{trans}\text{-}3\text{-}C_6H_{12}^+ + H_2\ (+5\ \text{kcal mole}^{-1}). \end{cases}$$

The attachment of an electron to a molecule can also lead to dissociation in apparent contradiction to the cage effect: dissociation of this type occurs if the electron affinity of the resulting fragment is greater than the bond dissociation energy. Dissociation processes of the type $RX + e \rightarrow R + X^-$, well known in mass-spectrometric investigations, are found to be exothermic and to have a threshold at thermal electron energies. A similar process has been observed[80] in solid hydrocarbons containing small amounts of $C_6H_5CH_2Cl$. When an electron, freed from a trap by the action of light in irradiated methyltetrahydrofuran, becomes attached to a $C_6H_5CH_2Cl$ molecule, the formation of $C_6H_5\dot{C}H_2$ radicals can be observed in the solid phase. Similar results have been obtained in studies of other additives of the type RX (where $R = C_6H_5\dot{C}H_2$; $X = CH_3COO$, CH_3O). The efficiency of various additives towards electron capture depends critically on the appearance potential of the X^- ions in the dissociation process, and varies in the same sense as this potential.

3. Charge Transfer

The interaction between positive charges and their surrounding molecules can lead to two types of effect. The first, charge transfer, cannot lead to chemical changes in a homogeneous medium; its only effect is to facilitate the diffusional transfer of charges. In two-component or multicomponent media charge transfer enables the positive charge to become localised on the molecules of lowest ionisation potential. The energy of the ionisation process, given out when a positive and a negative charge recombine, is evolved mainly at these particular molecules[81,82]. This may be the cause of deviations from the so-called law of radiation-chemical additivity (sometimes also termed the "law of mixtures"). The deviation consists in the following: the fraction of the total yield of products contributed by the decomposition of these "acceptors" of energy is higher than expected by considering only what fraction of the energy has been directly imparted by the radiation to the molecules of low ionisation potential. If the charge transfer process is sufficiently effective, the molecules of low ionisation potential will behave as protective additives which concentrate on themselves the main effect of the radiation and thus protect the surrounding medium. According to their chemical stability, these impurities can decompose or they can scatter the energy, the protection being of the "sacrificial" or the "sponge" type in the two cases respectively[83]. It should be noted that charge transfer effects can play an essential role also in the radiolysis of one-component systems, because new molecules are formed in the course of radiolysis and these can concentrate on themselves an increasing fraction of the radiation energy if their ionisation potential is lower than that of the molecules of the major constituent of the medium.

The deviations from the law of mixtures reported so far are very numerous[84,85]. They can be explained, in principle, by the most diverse mechanisms of energy transfer, charge transfer being but one of many possibilities. Hardwick[86] has pointed out that the departures from the law of mixtures in two-component solutions of aliphatic hydrocarbons are always in the sense of energy transfer to the molecules of lower ionisation potential. This conclusion was reached from a study of the yield of hydrogen, which was a product of the decomposition of each of the components of the mixture (n-hexane–neohexane, n-hexane–2,3-methylbutane, and many others). The law of mixtures predicted a hydrogen yield varying linearly with the composition of the mixture, but in practice, owing to energy transfer, this relationship was not observed.

Molecules which behave as charge acceptors, that is, those of lower ionisation potential, can also act as acceptors of excitation energy, because their electronic excitation levels are usually lower. This phenomenon often militates against a definite clarification of the mechanism of energy transfer.

Many workers have examined, spectroscopically or by ESR methods, the state of impurities added to an irradiated substance which have a protective action on the specimen. It was found that the molecules of the additive become ionised. Thus, when poly(methyl methacrylate) is protected from degradation by adding aromatic amines, positive amine ions are detected spectroscopically[64]. The radiation yield of these ions is equal to the fall in the yield of the chain-breaking process in the polymer. Addition of electron-acceptor impurities (quinones, polycyclic aromatic compounds) to poly(vinyl chloride) (PVC) suppresses[79] the formation of conjugated bonds in the PVC and greatly lowers the yield of HCl. This, evidently, results from the transfer of a charge (an electron) to the acceptor. The spectrum of the negative ions of the impurity has been examined by ESR. Studies illustrating the transfer of positive[65-68] and negative[56,71-74] charges to molecules of impurities specially added to hydrocarbon substrates at low temperatures have already been considered in the previous subsections.

4. Ion–Molecule Processes

Ion–molecule reactions are the second type of process in which ions can take part. Two basic types of reaction have been identified in hydrocarbons in the gas phase: reactions involving the transfer of heavy particles such as an H atom, a proton, or a hydride ion, and reactions leading to the synthesis of a C–C bond[2,4,46]:

$$R'H + R''H^+ \longrightarrow R'H_2^+ + R'' \quad \text{(proton transfer)},$$

$$R'H + R''H^+ \longrightarrow R' + R''H_2^+ \quad \text{(H atom transfer)},$$

$$R'^+ + R''H \longrightarrow R'H + R''^+ \quad (H^- \text{ ion transfer}),$$

$$R'H^+ + R''H \longrightarrow R'R''^+ + H_2 \quad \text{(synthesis of a C–C bond)}.$$

In a condensed phase these reactions can act as a source of free radicals and determine the formation of cross-links. The small temperature dependence of the radiation yield of cross-linking in saturated hydrocarbons and the possibility of inhibiting cross-linking by adding suitable impurities[87,88] have been interpreted as an indication that ion–molecule reactions are responsible for the formation of cross-linked structures. Various reactions have been suggested:

$$(1)\ RH + RH^+ \longrightarrow RR + H_2^+ \ [89]$$

$$(2)\ RH + RH^+ \longrightarrow RR^+ + H_2 \ [90]$$

$$(3)\ RH^+ + R \longrightarrow RR + H^+ \ [91]$$

$$(4)\ \begin{cases} RH + RH^+ \longrightarrow RH_2^+ + \dot{R} \\ RH_2^+ + e^- \longrightarrow H_2 + \dot{R} \end{cases} \longrightarrow RR \ [92]$$

Thermochemical calculations give the heats of these reactions as -4.72, 0, -2.50, and 9 eV respectively, so that at least two of them, (2) and (4), could control the formation of cross-linking. Available data do not allow an easy choice between these two alternatives, because their occurrence in a condensed phase has not been directly reported. The distribution of isomers of the C_{12} dimer formed during the low-temperature radiolysis of n-hexane, investigated by Kevan and Libby[92], can be satisfactorily explained on the basis of reactions (2) and (4).

The positive charge, having taken part in an exothermic ion–molecule reaction, is found in a deep trap, where it loses its activity and takes no further part in chemical processes until it finally recombines. However, if the reaction involving the positive ion enables the ion to retain its original activity, the same ion can, of course, take part in a whole series of ion–molecule processes. The most important of these is ionic radiation polymerisation, proposed in order to explain the large yield of polymer in irradiated 2-methylpropene[93,94]. The characteristic features of ionic polymerisation are: a weak temperature dependence of the rate of polymerisation (even a negative temperature coefficient being reported[96]), and a constant molecular weight of the resulting polymer over a wide range of radiation intensities, due to the fact that the lifetime of the chain carriers is independent of the intensity of irradiation. These facts cannot be explained by applying the ideas of the free-radical mechanism of polymerisation, but they fit quite satisfactorily into the conceptual framework of ionic processes[93-95].

The ion R^+, leading to polymerisation, can be formed either directly in the primary ionisation event or as a result of an ion–molecule reaction:

$$M \rightsquigarrow R^+;$$

the chain propagation reactions being

$$R^+ + M \longrightarrow RM^+$$

$$RM_n^+ + M \longrightarrow RM_{n+1}^+.$$

The chain-breaking reactions can take the form of charge transfer

$$RM_n^+ + M \longrightarrow RM_n + M^+$$

or recombination

$$RM_n^+ + e \rightarrow RM_n.$$

The important role of ions in the polymerisation of 2-methylpropene has been demonstrated by many direct experiments. Thus, it has been shown[94,97,98] that the appearance of free radicals in liquid 2-methylpropene at -78°C does not lead to polymer formation. However, the introduction of positive ions formed in the gas phase into liquid 2-methylpropene causes it to polymerise[99]. The application of an electric field strength of 10^4 V cm^{-1} to 2-methylpropene during irradiation raises the yield of polymer[100] by a factor of 3. This has been ascribed[100] to the greater yield, in an electric field, of free charges which do not recombine with "their own" ions. The reaction is probably initiated by a proton, formed by the primary ionisation act:

$$(CH_3)_2C{=}CH_2 + H^+ \longrightarrow (CH_3)_2CHCH_2^+.$$

The $C_4H_9^+$ ion propagates the polymerisation chain. We know also that the $C_4H_9^+$ ion is formed in gas-phase ion–molecule reactions when 2-methylpropene is ionised.

The only real proof of the role of ion–molecule reactions in the polymerisation of liquid alkenes was obtained[103,104] in a study of the polymerisation of a mixture of C_2H_4 and C_2D_4. By plotting the mass spectrum of the products of radiation polymerisation (up to C_{18}) it was shown that the number of D atoms in the polymer molecules is invariably a multiple of four. This is evidence that the molecular ions $C_2D_4^+$ are taking part in the polymerisation reaction. The reaction itself is apparently of the form

$$C_nH_{2n}^+ + C_2H_4 \rightarrow C_{n+2}H_{2n+4}^+$$

where n = 2, 4, 6, ... The polymerisation chain is broken by the recombination of the ion with an electron. Ionic polymerisation has been recently demonstrated mass-spectrometrically in ethylene in the gas phase, under high pressures[105].

Still further proof of the role of ions in the polymerisation of unsaturated hydrocarbons is the influence of charge-acceptor impurities on the yield of polymers. Thus, addition of ammonia to liquid cyclopentadiene strongly inhibits polymer formation under irradiation [106]. Ammonia undergoes an ion-molecule reaction in pentadiene with proton transfer, giving rise to an NDH_4^+ ion which breaks the polymerisation chain. By measuring the degree of polymerisation as a function of dose in the presence of various concentrations of added ND_3 it was possible to estimate the mean growth time of the chain, equal to the lifetime of the ion, which turned out to be 10^{-3} s for the formation of chains 10^3–10^5 monomer units long. The long lifetime of the ions suggests that only free ions which have escaped recombination can be involved [107]. Of course, shorter-lived ions which have failed to escape from the coulombic interaction with "their own" electron can participate in the formation of shorter chains during polymerisation.

5. Recombination of Ions

The last reaction in which the chemical activity of ions can be utilised is ion recombination. The importance of this process in radiation chemistry was realised from the very earliest radiation-chemical investigations [108,109]. The special features of recombination processes, particularly in the gas phase, have been discussed on many occasions [81,82,110,111]. The recombination of charges results in considerable excitation of one or two molecules, whose ions take part in the process. This excitation can lead to various chemical reactions, such as dissociation or molecular rearrangement, formation of double bonds or cross-links, and so on. The energy evolved in the recombination process depends on the nature of the recombining particles. It is greatest, and equal to the ionisation potential I_M of the molecules, for recombination in the gas phase ($M^+ + e^- \rightarrow M^*$), but it becomes very much less in a condensed phase, particularly when the electron recombining with the positive ion is bound in an electronegative molecule. It should be noted that the energy evolved in recombination in a condensed phase depends essentially on the mode of dissipation of the kinetic energy of the charged particles approaching one another. Thus, if an electron or negative ion, having been captured by the sphere of action of the coulombic field of an ion of the opposite sign, begins to drift towards that ion and move in what is effectively a "viscous" medium, then the energy evolved during the recombination will obviously be

$$E = I_M - \left[\frac{e^2}{\epsilon r} + Q\right],$$

where Q is the electron affinity of the molecule on which the electron is localised before recombination; r is the distance between the charges corresponding to electron transfer rather than drift of the charges in a "viscous" medium. The sum $(e^2/\epsilon r) + Q$ can have quite large values: thus, for $r = 3$ Å and $\epsilon = 2$, $e^2/\epsilon r = 2.5$ eV. The variation of the energy evolved in the recombination with the nature of the negative ion can account for the protective action of various electron-acceptor impurities during radiolysis [83]. If the quantity E is decreased below the level required for dissociation of the molecule, protection becomes possible. This interpretation has been used, for example, in studies of the inhibition by N_2O impurities of the yield of hydrogen in the liquid-phase hydrolysis of saturated hydrocarbons [112]. Since it is known that after capturing an electron N_2O dissociates to form N_2 and O^-, the lower hydrogen yield in the presence of N_2O may be ascribed to the occurrence of the reaction $M^+ + O^-$, which does not produce hydrogen, instead of the reaction $M^+ + e^- \rightarrow H_2$, characteristic of the pure alkane.

Very few papers have dealt with direct experimental studies of the chemical effects of recombination, even in the gas phase [113,114].

The first attempt to identify the products of the recombination process in a condensed phase was made in this laboratory [115,116], relying on the fact that ions and electrons can be made to accumulate when radiolysis is carried out at low temperatures. Recombination can be induced by freeing the charges with light after irradiation, and this is a method for carrying out the ionic reaction under controlled conditions. The effect of visible light on n-heptane irradiated at -196°C is to produce a measurable evolution of hydrogen [115,116], which cannot be explained by assuming that the hydrogen has accumulated in the specimen during irradiation and is freed by the heating effect of the beam of light. We were led to conclude that the hydrogen is formed as molecules in processes such as $M^+ + e^- \rightarrow H_2$ + + double bond, or $M^+ + e^- M \rightarrow H_2$ + cross-linkage.

---o0o---

The papers discussed in the present review justify the conclusion that the part played by ionised states in radiolysis should not be underestimated. The long lifetimes of ions and electrons in condensed phases allow them to take part in many processes leading to chemical changes in the material.

We are only just beginning to explain the role of ions in various chemical systems under conditions of radiolysis in a condensed phase. Further developments in this field will no doubt advance the state of the art from a rational application of ideas concerning ionic reactions in condensed phases during radiolysis to a general application of these ideas to the interpretation of radiation-chemical processes.

3. Diagonal sections of ternary reciprocal systems 508

I. INTRODUCTION

Molten salts and their mixtures in recent years have been finding ever-increasing application in industry as high-temperature liquids, lubricants, heat-carriers, fluxes, etc. The importance which is being attached to the study of both the bulk and the surface properties of molten salts is thus obvious. Moreover, the study of the physicochemical characteristics of salt melts is a necessary prerequisite for the investigation of the nature of the liquid state and the development of a general theory of liquids.

In view of the vast amount of accumulated information on the physicochemical properties of molten salts in recently published monographs and reviews[1-4] it was impossible to give sufficient attention to each property, including the surface tension of the salts. The increasing interest in experimental data on the surface tension of salts and the non-existence of sufficiently detailed reviews in this field suggest that a review of this type will be opportune and useful.

Before discussing published data on the surface tension of melts, we would point out that we have tried to cover, as completely as possible, papers describing the experimental study of the surface tension of salts and their mixtures; as far as the surface tension of oxide systems is concerned, we have restricted ourselves in the present review to a few papers containing data on the surface tension of the simplest compounds formed in these systems.

II. REVIEW OF EXPERIMENTAL WORK ON THE SURFACE TENSION OF MOLTEN SALTS AND THEIR MIXTURES

The surface tension (σ) of molten salts appears to have been measured for the first time in 1869 by Quinke[5], who used the stationary-drop and drop-weight methods[6-8] to find the capillary constants of melts formed by a number of salts of the alkali and alkaline earth metals. Experimentally, these measurements were unreliable. For example, the temperature of the melts was indefinite, a considerable temperature gradient was unavoidable, and during the measurements there was a danger of decomposition of the melts and contamination from the flame of the heater.

These unsatisfactory features of the determination of σ are also characteristic of the work of Traube[9] and Motylewski[10], who used the drop-weight method find the capillary constants of a large number of inorganic salts.

Bottomley[11] determined σ for $NaNO_3$ and KNO_3 melts using the capillary-ascent method, for which there is much greater theoretical justification[7].

Lorenz and coworkers[12-14] measured σ for $NaNO_3$, KNO_3, $PbCl_2$, $CdCl_2$, KCl, AgCl, and various KCl + $PbCl_2$ and $CdCl_2$ + $PbCl_2$ mixtures by the capillary-ascent method. Unsatisfactory methodological features of the studies are the possibility of contamination of the melt by corrosion products from the walls of the capillaries and the temperature gradient along the capillary.

Of considerable interest in the study of σ for fused salts is the work of Jaeger[15], which has now become classical. Jaeger was the first to measure σ for salts using the maximum gas-bubble pressure method[7,8,16-18], which is apparently the most reliable and convenient and which has subsequently been widely used. Jaeger developed thoroughly a method for measuring σ by this method in the temperature range from -80° to +1650°, and in the high--temperature range he introduced a number of improvements in technique aimed at preventing contamination of the salts, maintaining constant temperature, increasing the accuracy of the measurement of the temperature and pressure, etc. An unsatisfactory feature of his procedure is that the moment when the end of the capillary comes in contact with the surface of the melt is recorded visually, and this is extremely difficult at high temperatures. Jaeger determined the values of σ for almost 200 organic and 50 inorganic liquids. The latter included the alkali metal halides (with the exception of lithium bromide and iodide), nitrates, and sulphates; sodium and potassium metaborates, metaphosphates, molybdates, and tungstates; lithium metasilicate; potassium dichromate; thallium nitrate; sulphur monochloride; the trichlorides of phorphorus, arsenic, antimony, and bismuth; tribromides of phosphorus, arsenic, and bismuth; and phosphorus triiodide. All the substances studied have negative temperature coefficients $d\sigma/dt$. In some instances the value of $d\sigma/dt$ changes with temperature and the σ polytherms are slightly convex away from the temperature axis.

In a study of the properties of salt melts used as electrolytes in magnesium baths, Zhivov[19,20] used the maximum gas-bubble pressure method to measure σ for pure NaCl, KCl, and $MgCl_2$, the binary NaCl–KCl, NaCl–$MgCl_2$, and KCl–$MgCl_2$ systems, and sections of the ternary NaCl–KCl–$MgCl_2$ system at molar ratios KCl : NaCl = = 1 : 1 and 1 : 3. The 700° isotherms for the binary systems containing $MgCl_2$ showed points of inflection corresponding to equimolar mixtures of the components, and the 800° isotherm for the NaCl–$MgCl_2$ system also showed a maximum corresponding to 86 mole % $MgCl_2$. Zhivov (see Mashovets[21]) also measured σ for molten NaF + AlF_3 mixtures at AlF_3 concentrations up to 50 mole %, and molten NaF + AlF_3 (15 mole % and 33.4% AlF_3) + Al_2O_3 (up to 10 wt. %) and Na_3AlF_6 + Al_2O_3 (up to 17.5 wt. % Al_2O_3) mixtures. Within limits of accuracy of the measurements, the addition of Al_2O_3 does not influence the value of σ for the mixtures.

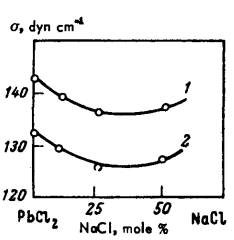

Fig. 1. Surface tension isotherms for the $PbCl_2$–NaCl system[25]: 1) 500°; 2) 600°.

Elchardus[22] used the maximum bubble-pressure method to measure σ for pure Na_3AlF_6 and its mixtures with NaF and AlF_3 (up to 20 wt. % additive). The temperature dependence of σ for Na_3AlF_6 is non-linear, and this is taken as an indication that cryolite dissociates in the molten state.

Jarrat and Prideaux[23] measured σ for melts using Sugden's version[7,24] of the maximum gas-bubble pressure method, using two capillaries; an advantage of this method is that it eliminates the measurement of the depth to which the end of the capillary is immersed in the melt. This method was used to find σ for molten $HgCl_2$ and $HgBr_2$ close to the melting points.

Barzakovskii[25,26] measured σ for the binary NaCl–KCl, $CaCl_2$–NaCl, and NaCl–$BaCl_2$ salt systems throughout the entire concentration range and for the NaCl–$PbCl_2$ system in the range 0–50 mole % NaCl. The isotherms for these systems are linear or slightly convex towards the composition axis; only the 500° and 600° isotherms for the NaCl–$PbCl_2$ system show minima corresponding to 30 mole % NaCl (Fig. 1).

Semenchenko and Shikhobalova[27-30] used the maximum gas-bubble pressure method to study σ for a number of salt melts up to 1100°. As an improvement in technique they introduced a convenient method in which the moment when the end of the capillary came in contact with the melt was recorded by direct electrical contact. The values of σ were measured for Li_2SO_4, LiCl, $NaNO_3$, Na_2SO_4, NaCl, K_2SO_4, KCl, KBr, KI, RbCl, CsCl, $BaCl_2$ and the organic salts CH_3CO_2K and $C_2H_5CO_2K$, and also for mixtures of the binary systems $NaNO_3$–(NaF, NaCl, NaBr, NaI, CH_3CO_2K, and $C_2H_5CO_2K$), Na_2SO_4–(NaCl, NaI, KCl, KBr, and KI), and K_2SO_4–KCl at concentrations of the second component not exceeding 50 mole %, and for mixtures of the systems Li_2SO_4–(NaCl, KCl, RbCl, CsCl, and $BaCl_2$), LiCl–RbCl, and $NaNO_3$–(CH_3CO_2K and $C_2H_5CO_2K$) in the concentration range from 0 to 100%. The isotherms for all the systems are convex towards the composition axis. The isotherms for the Li_2SO_4–$BaCl_2$ system show a deep minimum which was attributed to the formation of the sparingly dissociated barium sulphate (Fig. 2). On the isotherms for the Li_2SO_4–(NaCl, KCl, RbCl, and CsCl) systems, small (1–2 mole %) horizontal sections were distinguished at low concentrations of the second component. The scatter in the experimental points in these ranges is scarcely greater than the error in the determination of σ (1.5–2% according to the authors), so that these isotherms can be regarded as smooth curves. On the basis of the data obtained, it was concluded that small quantities of the additives influence the value of σ and the crystallisation of the salt mixtures. The changes in σ and the limiting surface activity when various salts were added were compared with the values of the generalised moments of the ions according to the theory of Semenchenko[8,31]:

$$\mu = z/r, \qquad (1)$$

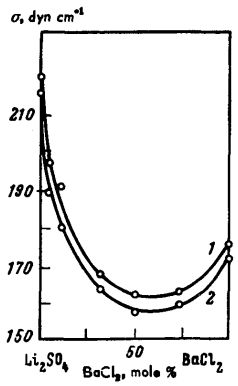

Fig. 2. Surface tension isotherms for the Li_2SO_4–$BaCl_2$ system[29,30]: 1) 1000°; 2) 1050°.

where z is the charge and r the radius of the ion. The adsorption of the surface-active components was calculated for a number of dilute mixtures.

King[32] measured σ for silicate systems up to 1600° using the hollow-cylinder detachment method which is a modification of the ring detachment method[7]. The values of σ were measured for 26 melts from the CaO–SiO_2, MgO–SiO_2, MnO–SiO_2, and FeO–SiO_2 systems, including some metasilicate compositions. Positive temperature coefficients of σ were observed for $CaSiO_3$, $MnSiO_3$, and a number of mixtures of the systems studied. This phenomenon was explained on the basis of theories regarding the breakdown of the structure of the melt. With increase in temperature the process of structure breakdown is displaced in such a way that the proportion of surface-active ions (SiO_3^{2-}) in the melt decreases; the resulting increase in σ is greater than the decrease in σ due to the decrease in the strength of the interaction between the particles with increase in temperature.

Mention may be made to the work of Shartsis and coworkers, who used the hollow-cylinder detachment method to measure σ for MO–SiO_2 (M = Li, Na, K, and Pb)[33,34] and MO–B_2O_3 (M = Li, Na, K, Ca, Sr, Ba, Zn, and Pb)[35-38] systems. The compositions of a number of systems were not brought to the metasilicate and metaborate compositions because of the limited miscibility of the components in the liquid phase.

Vajna[39] used the ring detachment method to measure σ for melts of pure cryolite and cryolite containing NaF, AlF_3, Al_2O_3, and CaF_2 additions (up to 15 wt.%).

Gromakov[40], who measured σ using Jaeger's method[15], proposed that the maximal pressures in the gas bubble be determined at two different depths of immersion of the end of the capillary in the melt, in order to eliminate the value of the density of the melt from the formula used in the calculation; this makes sense when the densities are unknown, although the error in the estimation of the density by this method is extremely large. Gromakov[41] also proposed a method for measuring the σ of small quantities of liquid by means of a capillary with thickened walls in the lower section; it was estimated that the error in the determination of σ is 10%. This method was used by Gromakov and Kostromin[42] to measure σ for a number of compositions of the $NaNO_3$–KNO_3–$RbNO_3$ ternary system.

The surface tension of systems formed by molten nitrates was also studied by Bokhovkin[43] ($AgNO_3$–KNO_3) and Manakin[44] ($NaNO_3$–KNO_3, $LiNO_3$–$NaNO_3$, and $LiNO_3$–KNO_3) by the maximum gas-bubble pressure method. In all the σ isotherms for the nitrate systems are either linear or only slightly convex towards the composition axis.

Peake and Bothwell[45] used the maximum gas-bubble pressure method to measure σ for the $BaCl_2$–KCl system, for which the 800° isotherm has a point of inflection corresponding to 35 mole % $BaCl_2$ (Fig. 3).

Peake and Neithamer[46] determined σ for the KCl–K_2SO_4 system; the isotherm is convex towards the composition axis.

Desyatnikov[47] used the maximum pressure and ring detachment methods to measure σ for NaCl, KCl, and $MgCl_2$ melts; the NaCl–KCl, NaCl–$MgCl_2$ and KCl–$MgCl_2$ binary systems; and sections of the NaCl–KCl–$MgCl_2$ ternary system at molar ratios NaCl : KCl = 1 : 3, 1 : 1, and 3 : 1. The σ isotherms for the NaCl–$MgCl_2$ and KCl–$MgCl_2$ systems show breaks (Fig. 4). The values of σ obtained for $MgCl_2$ are more reliable than those given by Zhivov[19].

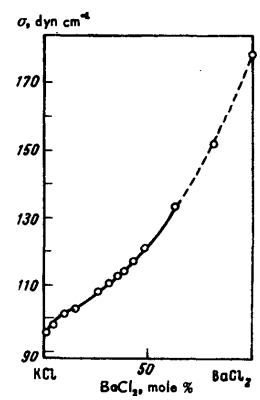

Fig. 3. 800° surface tension isotherm for the KCl–$BaCl_2$ system[45].

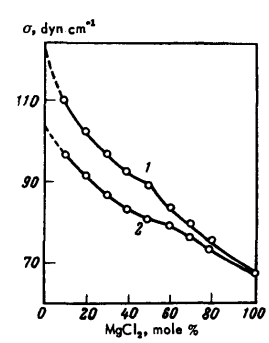

Fig. 4. 700° surface tension isotherm for the NaCl–$MgCl_2$ (1) and KCl–$MgCl_2$ (2) systems[47].

Strelets, with Desyatnikov[48,49] and Bondarenko[50,51] measured σ for the salt mixtures used in the electrolytic production of magnesium. The values of σ were measured from melts of an isoconcentrate section (10 wt.% $MgCl_2$) of the $MgCl_2$–$CaCl_2$–KCl–NaCl system at NaCl : KCl ratios of 1 : 6, 1 : 3, 1 : 1, and 6 : 1, and of isoconcentrate sections (10 wt.% and 20 wt.% $MgCl_2$) of the $MgCl_2$–$BaCl_2$–KCl–NaCl system at NaCl : KCl ratios of 2 : 1, 1 : 1, and 1 : 2, and also of the $BaCl_2$–$MgCl_2$, $BaCl_2$–NaCl, and $MgCl_2$–$BaCl_2$–NaCl (8 sections at 10 wt.% $BaCl_2$ intervals) systems. The isotherm for the $BaCl_2$–$MgCl_2$ system shows an inflection at 10–15 mole % $BaCl_2$ (Fig. 5); this is attributed to compound formation.

Bordman and coworkers[52] used the maximum gas-bubble pressure method in a glass apparatus to measure σ for 13 binary systems formed by salts with common cations or anions: AgCl–AgBr, AgBr–AgI, NaBr–KBr, KCl–KBr, $NaNO_3$–KNO_3, $CdCl_2$–$CdBr_2$, $PbCl_2$–NaCl, $PbCl_2$–$CdCl_2$, $CdCl_2$–KCl, $PbCl_2$–KCl, $PbCl_2$–AgCl, AgCl–KCl, and AgBr–KBr. The isotherms for most of the systems are linear or slightly convex towards the composition axis. The 600° isotherm for the $PbCl_2$–KCl system has a minimum at 40 mole % $PbCl_2$; this minimum is now shown by the 500° isotherm (Fig. 6). The 700° isotherm for the $CdCl_2$–KCl system passes through a maximum at 80 mole % $CdCl_2$ and through a point of inflection at the equimolar component ratio (Fig. 7). These points on the σ isotherms were attributed to the presence of ionic complexes of the type MCl_3^- in the melts. As a criterion for ideal behaviour in the binary system the authors used Zhukhovitskii's equation[53], rewritten by Guggenheim[54] for an equimolar mixture in the form

$$\sigma = {}^1/_2(\sigma_1 + \sigma_2) - (\sigma_2 - \sigma_1)^2 a/8kT, \qquad (2)$$

where σ, σ_1, and σ_2 are the surface tensions of the mixture and the pure components, k is the Boltzmann constant, and a the mean area occupied by a molecule in the surface layer, assumed to be equal to the sum

$$a = {}^1/_2\left(\frac{M_1}{d_1 N}\right)^{2/3} + {}^1/_2\left(\frac{M_2}{d_2 N}\right)^{2/3}, \qquad (3)$$

where M_1, M_2, d_1, and d_2 are the molecular weights and densities of the components, and N is Avogardro's number. For all the systems studied, with the exception of the $PbCl_2$–$CdCl_2$ system, the experimental value of σ shows a negative (up to 4%) deviation from the value calculated from Eqn. (2)†.

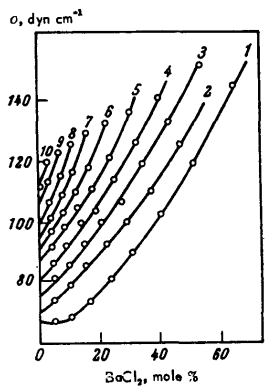

Fig. 5. 750° surface tension isotherms for $MgCl_2$–NaCl–$BaCl_2$ systems[50,51]. NaCl concentration (wt.%): 1) 0; 2) 10; 3) 20; 4) 30; 5) 40; 6) 50; 7) 60; 8) 70; 9) 80; 10) 90.

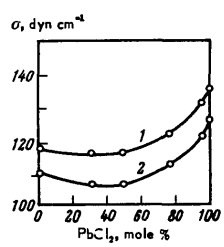

Fig. 6. Surface tension isotherms for the KCl–$PbCl_2$ system[52]: 1) 500°; 2) 600°.

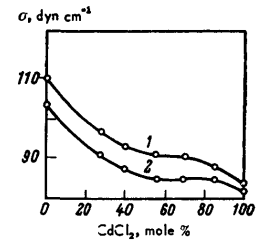

Fig. 7. Surface tension isotherms for the KCl–$CdCl_2$ system[52]: 1) 600°; 2) 700°.

Callis and coworkers[55] used the ring detachment method to determine σ up to 1000° for sodium phosphate melts at Na_2O/P_2O_5 oxide ratios from 1 to 2.2, that is, including sodium meta- and pyro-phosphates. The values of σ and $d\sigma/dt$ differ considerably from those given by Jaeger[15]. It was found that the value of σ is higher, the higher the concentration of basic oxide in the melt. The value obtained for σ and the densities of the melts were used to estimate the apparent molecular weights of the phosphates in the melt.

Dahl and Duke[56] used the maximum gas-bubble pressure method to determine σ for melts formed by $AgNO_3$–$NaNO_3$, $AgNO_3$–KNO_3, and $PbCl_2$–(LiCl, NaCl, KCl, RbCl, and CsCl) mixtures. In the $PbCl_2$–MCl systems the nature of the σ isotherms at 575° changes with increase in the dimensions of the alkali metal ion. Thus in the $PbCl_2$–LiCl system the isotherm is linear and in the $PbCl_2$–NaCl system the isotherm is convex towards the composition axis and does not show the minimum reported by Barzakovskii[25]; the σ isotherms for the $PbCl_2$–(KCl, RbCl, and CsCl) systems have minima which become deeper on going from potassium to caesium (Fig. 8). The values of σ for silver nitrate are anomalously high. The

† Conclusions regarding the extent of the deviation from ideal behaviour shown by a system on the basis of calculations from Eqn. (2) for the equimolar composition alone can of course be only approximate.

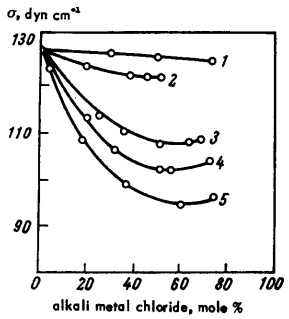

Fig. 8. 575° surface tension isotherms for the $PbCl_2$–(LiCl, NaCl, KCl, RbCl, and CsCl) systems [56]:

values of σ for $ZnCl_2$ melts are lower than those for melts formed by LiCl, NaCl, KCl, $PbCl_2$, $NaNO_3$, KNO_3, and $AgNO_3$ [57].

Ellis et al.[58] measured σ for the alkaline earth metal halides $BaBr_2$, $SrCl_2$, $SrBr_2$, $CaBr_2$, and CaI_2. For these salts, σ increases with increase in the dimensions of the cation. Ellis and coworkers[59] also studied σ for a diagonal section of the $CdCl_2$–KBr ternary reciprocal system. The σ isotherms showed a minimum at 40 mole % KBr and a point of inflection at 60 mole % KBr (Fig. 9), indicating, in the opinion of the authors, the existence of ionic complexes $CdCl_4^{2-}$ and $CdBr_4^{2-}$ in the melts; this was confirmed by the Raman spectra. The increase in the depth of the minimum on the isotherms with increase in temperature is related to the increase in the disorder and variety of the species in the melt.

Greenwood and Wade[60] determined σ for $GaCl_3$ melts and Greenwood and Worrall[61] determined σ for $GaBr_3$ and Ga_2Cl_4 melts.

Bradbury and coworkers[62,63] used the hollow-cylinder detachment method to measure σ for melts of the Na_2O–P_2O_5, K_2O–P_2O_5, and CaO–P_2O_5 binary systems from the metaphosphate composition to the pyrophosphate composition (with the exception of the CaO–P_2O_5 system) and also for $NaPO_3$ + NaF mixtures (up to 15 mole % NaF). The surface tension of the melts in all the systems increases with increase in the concentration of basic oxide or NaF in the mixture; by analogy with the silicates[32], this was attributed to breakdown of the structure of the melt‡.

Frame and coworkers[68] give values of σ for the low-melting salts KCNS, $NaNO_2$, $K_2Cr_2O_7$, and $KClO_3$, obtained by Sugden's version of the maximum gas-bubble pressure method[24]. For these salts (with the exception of $NaNO_2$) σ and σ/dt are not constant and depend on the temperature and the time for which the salt is kept above its melting point. This is related to possible decomposition of the salt or to bond redistribution. Comparison of the values of σ for alkali metal halides and nitrates shows that the influence of the dimensions of the cation is greater, the smaller the anion.

Bloom and coworkers[69] used the maximum gas-bubble pressure method to measure the surface tension of melts formed by NaCl, NaBr, NaI, KCl, KBr, KI, $NaNO_3$, $NaNO_2$, KNO_3, $AgNO_3$, $PbCl_2$, the binary $NaNO_3$–$NaNO_2$, KNO_3–KNO_2, $NaNO_3$–$AgNO_3$, KNO_3–$AgNO_3$, and $PbCl_2$–NaCl systems, and a diagonal section of the ternary reciprocal KCl–NaI system. It was suggested that the deviation of the values of σ for the salt mixtures from the values corresponding to ideal solutions be explained on the basis of theories of the surface enthalpy of mixing H^S:

$$H^s/a = \sigma - Td\sigma/dT, \qquad (4)$$

where a is the surface area and $d\sigma/cT = -\Delta S^S/a$. The formation of an ionic complex in the melt leads to a decrease in enthalpy in the bulk phase and also to a decrease in the surface enthalpy of mixing:

$$\Delta\sigma = \Delta H^s/a - T\Delta S^s/a, \qquad (5)$$

that is, when an ionic complex is formed $\Delta\sigma < 0$, if $\Delta H^S/a < 0$ and $\Delta S^S/a > 0$. For the $NaNO_3$–$AgNO_3$ and $PbCl_2$–NaCl systems, small negative deviations from the values for ideal mixtures (~ 7%) were observed. For the KCl–NaI, $PbCl_2$–RbCl[56], and $CdCl_2$–KCl[52] systems, the curves obtained by plotting $\Delta H^S/a$ against the mole fraction of the second component show maxima corresponding to 50 mole % NaI and RbCl and 75 mole % KCl. Generally speaking, the method for estimating $\Delta H^S/a$ assumed that $d\sigma/dT$ is constant over a wide temperature range, and the use of the values of $d\sigma/dT$ to calculate $\Delta H^S/a$ requires that σ be measured with a fairly high accuracy, and this is not always true.

Popel' and Esin[70] measured σ for the CaO–SiO_2–Al_2O_3 and CaO–SiO_2–MgO ternary oxide systems by stationary-drop and maximum gas-bubble pressure methods; values of σ were obtained for calcium metasilicate in the range 1460–1520°. The same methods were used by Manakov and coworkers[71] to determine σ for potassium metaniobate at 1400°.

Lantratov[72] used the gas-bubble pressure method to measure σ for melts formed by the salt systems used as electrolytes in the preparation of metallic sodium. The

‡ In systems of the type MPO_3–MX (where X = halide, SO_4^{2-}, etc.), chemical reaction takes place, accompanied by the separation of reaction products[64–67]. Bradbury and coworkers[62,63] apparently made no allowance for this feature and measured σ for non-equilibrium mixtures of indefinite composition.

$CaCl_2$–NaCl binary system and sections of the $BaCl_2$–$CaCl_2$–NaCl ternary system at $CaCl_2$: $BaCl_2$ ratios of 3 : 1 and 3 : 2 were studied. NaF and CaF_2 additives (up to 10 wt. %) were found to be surface-inactive with respect to these systems.

Janz and Lorenz[73,74] measured σ for aggressive carbonate melts up to 1000° in an atmosphere of CO_2 by the solid detachment method[7]. The solid detached from the surface consisted of the elongated tip of a gold–palladium sphere, which was also used to determine the density. Values of σ were obtained for melts formed by Li_2CO_3, Na_2CO_3, K_2CO_3, and the Na_2CO_3–K_2CO_3 binary system.

Addison and Coldrey[75] used the gas-bubble pressure method to measure σ for molten $Ca(NO_3)_2$, $Sr(NO_3)_2$, $Ba(NO_3)_2$, $LiNO_3$, $NaNO_3$, KNO_3, $RbNO_3$, $CsNO_3$, $TlNO_3$, NH_4NO_3, $AgNO_3$, $NaNO_2$, and KNO_3. The values of σ found for $TlNO_3$ were 25% lower than those given by Jaeger[15]. The values of σ for the molten nitrates and chlorides of the alkali and alkaline earth metals and magnesium close to the melting points were compared with the radii of the cations: the values of σ for the alkali metal salts decrease from Li to Cs; the values of σ for the alkaline earth metal salts increase from Mg to Ba (Fig. 10). This nature of the change in σ was attributed to the increase in the covalent forces in the subgroup formed by the alkaline earth metals and magnesium.

Morris and coworkers[76] used an assembly similar to that described by Janz and Lorenz[73] to measure σ for the $PbMoO_4$–$Bi_2(MoO_4)_3$ system. The temperature coefficients $d\sigma/dt$ for all compositions change with change in temperature.

Lehman[77] measured σ for melts of the KCl–$CaCl_2$ and CsCl–$CaCl_2$ systems§.

Sokolova and Voskresenskaya[78–80] used the maximum gas-bubble pressure method to study σ for the NaCl–$BaCl_2$ system and for the NaBr–K_2SO_4 diagonal section of the Na, K ‖ Br, SO_4 ternary reciprocal system. Reshetnikov's equation[81] in the form

$$\sigma = \sigma_1 + \frac{(\sigma_2 - \sigma_1)x}{x + k(1-x)}, \qquad (6)$$

where σ, σ_1, and σ_2 are the surface tensions of the mixture and the pure components, x the mole fraction of the second component, and k a constant, is applicable to the isotherms.

Sokolova and coworkers obtained values of σ for the metaphosphates of lithium, sodium, potassium, caesium, calcium, strontium, and barium[82] and the $LiPO_3$–$NaPO_3$, $NaPO_3$–$Ca(PO_3)_2$, and KPO_3–$Ba(PO_3)_2$ binary systems[83]. These and published data were used to construct curves giving the dependence of σ on the generalised moments μ — see Eqn. (1) — of the cations and anions forming the salt[82,84] (Figs. 11 and 12). The nature of the change in the dependence of σ on μ for the cation of the alkaline earth metal salts was compared[82] with the possible difference in the degree of dissociation of these salts[85] and the existence of MX^- ions in the melts. The values for some radium salts were estimated by interpolation from the plots of σ against μ. On the basis of the experimental facts it was suggested[84] that the values of σ for the alkali metal metaphosphates are independent of the length of the $(PO_3^-)_n$ polyanion chain and that a decisive part is played by the terminal PO_4^{2-} groups. Values of σ were determined for zinc metaphosphate and the binary $NaPO_3$–$Zn(PO_3)_2$ and KPO_3–$Zn(PO_3)_2$ systems (Figs. 13 and 14), for which the equilibrium diagrams were also studied[86]. The same authors[87] also studied σ for a number of nitrate and nitrite–nitrate salt mixtures.

Wu and coworkers[88] used the maximum gas-bubble pressure method to study σ for the FeO–Fe_2O_3–P_2O_5 system (up to 20 mole % P_2O_5), a number of (FeO–Fe_2O_3)–CaO–P_2O_5 mixtures, and the CaO–P_2O_5 system up to the metaphosphate composition.

Yakobashvili and Frumin[89,90] used the drop-weight method to obtain the values of σ for pure CaF_2 and for CaF_2 containing added CaO, MgO, SiO_2, ZrO_2, TiO_2, and Al_2O_3.

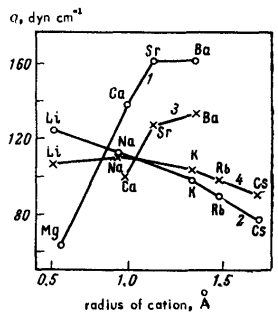

Fig. 10. Dependence of the surface tension of the chlorides and nitrates of the alkali and alkaline earth metals and magnesium on the radius of the cation[75]:
1) Group II chlorides at 1000°; 2) Group I chlorides at 800°; 3) Group II nitrates close to the melting point; 4) Group I nitrates at 425°.

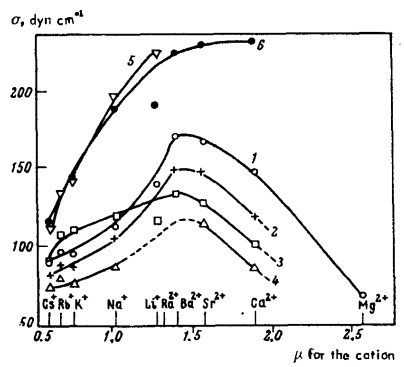

Fig. 11. Dependence of the surface tension of salts of the alkali and alkaline earth metals and magnesium at the melting points on the generalised moments of the cations[82]:
1) chlorides; 2) bromides; 3) iodides; 4) nitrates; 5) sulphates; 6) metaphosphates.

§ We have no information on the method of measurement or the shape of the σ isotherms, since only an abstract was available.

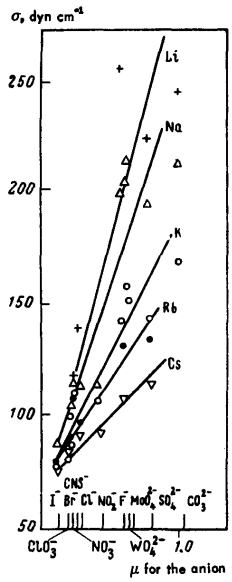

Fig. 12. Dependence of the surface tension of alkali metal salts at the melting point on the generalised moments of the anions [84].

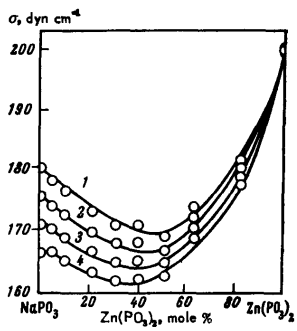

Fig. 13. Surface tension isotherms for the $NaPO_3$–$Zn(PO_3)_2$ system [86]:
1) 800°; 2) 900°; 3) 1000°: 4) 1100°.

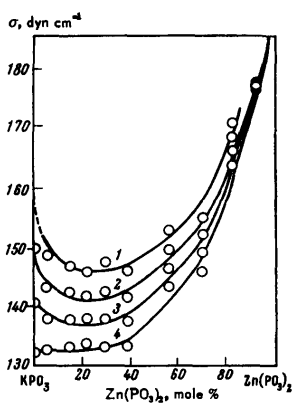

Fig. 14. Surface tension isotherms for the KPO_3–$Zn(PO_3)_2$ system [86]:
1) 800°; 2) 900°; 3) 1000°; 4) 1100°.

Nikitin and coworkers [91] used the stationary-drop method to determine the values of σ for pure CaF_2 and for CaF_2 containing added CaO, SiO_2, Al_2O_3, and MgO in the range 1470–1550°.

Moiseev and Stepanov [92] used the maximum gas-bubble pressure method in an atmosphere of CO_2 to measure σ for melts formed by Li_2CO_3, Na_2CO_3, K_2CO_3, and the binary systems and the ternary system based on these carbonates.

Owens and Mayer [93] determined the values of σ for $NaPO_3$–Li_2SO_4, $NaPO_3$–Na_2SO_4, $NaPO_3$–Rb_2SO_4, and $NaPO_3$–UO_2SO_4 mixtures; as in the work of Bradbury and coworkers [62,63], no allowance was made for possible chemical interaction between the components [65], leading to the liberation of SO_3.

Campbell and Williams [94] used the maximum gas-bubble pressure method in the range 130–170° to determine σ for $LiClO_3$ and its mixtures with H_2O (up to a mole fraction of 0.236) and with $LiNO_3$ (up to a mole fraction of 0.213).

Bertozzi and Sternheim [95] used the solid detachment method [7] to determine σ for 13 binary systems formed by the nitrates of the alkali metals and silver.

Mellors and Senderoff [96] studied σ for melts formed by the NaF–LiF–ZrF_4 ternary system (from 2.9 mole % to 60 mole % ZrF_4 in mixtures with the eutectic NaF : LiF = = 2 : 3) in the range 750–850°. On the basis of a comparison of σ and the surface enthalpy H^s/a (4) with the logarithm of the ZrF_4 concentration, it was concluded that the melts contain the $[ZrF_7]^{3-}$ ion. The $[ZrF_6]^{2-}$ ion, which is stable in the solid state, was not detected in the melts.

III. SURFACE TENSION OF ONE-COMPONENT SALT SYSTEMS

1. Surface Tension of Molten Salts at the Melting Point

Examination of the literature on the surface tension of molten salts shows that up to the present, values of σ have been determined more or less reliably for almost a hundred individual salts.

In Table 1 we have collected the published values of σ for pure salts at the melting point or at temperatures close to the melting point. The melting points were taken from various sources [15,68,97] and the surface tension values are those of Jaeger [15] and later workers, since the reliability of the results of earlier studies [5,6,9–14] is doubtful. Some of the values of σ given in Table 1 were obtained by analytical or graphical extrapolation from published data. The values of σ given in Table 1 were obtained with different degrees of experimental accuracy, which in a number of specific instances could not be estimated. In most instances the error in the determination of σ apparently amounts to not less than ±1% of the measured quantity, particularly in the high-temperature range.

2. Temperature Dependence of the Surface Tension of Molten Salts

The investigation of the temperature dependence of the surface tension of molten salts is one of the important problems associated with the surface properties of melts.

The values of the temperature coefficients for molten salts are often not indicated at all, or are given with no estimate of the accuracy of the determination; this applies to an even greater extent to the temperature coefficients for salt mixtures. In the present review, therefore, we shall restrict ourselves to general points. The surface tension of most of the salts studied decreases with increase in temperature; the course of the σ polytherms is given by the equation $\sigma = a - bt$, where a and b are empirical constants. Almost invariably the absolute value of $b = -d\sigma/dt$ does not exceed 0.1 dyn cm^{-1} deg^{-1}. For some salts, however, the values of $d\sigma/dt$ are close to zero (for example, $MgCl_2$ [20,47] and metaphosphates [82]) or even positive (silicates [32]). This phenomenon is apparently due to a change in the structure of the melts with increase in temperature (decrease in the size of the particles, dissociation), leading to the accumulation of surface-inactive particles in the melt [32,82]. The values of $d\sigma/dt$ are generally constant within the temperature ranges studied, but in a number of instances it has been found that the values of $d\sigma/dt$ are not constant, for example, for certain fluorides, nitrates, sulphates [15], molybdates [73], the low-melting $KClO_3$, KCNS, and $K_2Cr_2O_7$ [68], and Na_3AlF_6 [22]. It is possible that in some instances this is due to decomposition of the salts, leading to a change in composition.

IV. SURFACE TENSION OF BINARY SALT SYSTEMS

In the study of the surface tension of binary system, the problems of the nature of the shapes of the σ isotherms and their classification, interpretation, and analytical expression are of greatest interest. Despite the general character of these problems for binary systems of different type (organic, metallic, oxide, salt, etc.), they cannot yet be regarded as completely solved. In particular, the extent to which the value of σ for binary systems is sensitive to change in the structure of the bulk phase and the correspondence between the shape of the σ isotherms and the interaction between the components of the melt, reflected by the equilibrium diagram, are not yet clear. It is not possible in the present paper to examine in detail the literature dealing with all these problems. Of the most interesting topics we may mention the studies of Trifonov [100] (the general classification of σ isotherms for binary organic systems) and Teitel'baum [101] (factors influencing the shape of σ isotherms), the Zhukhovitskii [53]–Guggenheim [54] equation mentioned above, and the work of Esin [102] (oxide systems) and Eremenko and coworkers [103] (metallic systems).

Since information on σ isotherms has been published for more than 50 binary salt systems, it was of interest to use this material to investigate the correspondence between the shape of the σ isotherms and the equilibrium diagrams. For this purpose we compared the σ isotherms and equilibrium diagrams for three groups of binary salt systems (Tables 2–4); the fusibility data were taken from a handbook [104] and the concentrations of the components are given in mole fractions or mole %.

1. Binary Salt Systems with the Formation of Solid Solutions or Eutectics

Of the 26 binary salt systems in the first group, 25 of the systems give isotherms which are linear or convex towards the composition axis (Table 2). In accordance

Li_2SO_4—KCl	ditto	ditto	29
Li_2SO_4—RbCl	from ΔH – stable diagonal of singular system	»	29
Li_2SO_4—CsCl	reversibly-reciprocal system	»	29
Li_2SO_4—$BaCl_2$	from ΔH – stable diagonal	minimum at 30 mole % $BaCl_2$	29
		minimum at 15 mole % KCl	69
NaI—KCl	unstable diagonal		
NaBr—K_2SO_4	from ΔH – unstable diagonal	convex towards composition axis	79
KBr—$CdCl_2$	from ΔH – unstable diagonal	inflection at 60 mole % KBr, minimum at 40 mole % KBr	59

with conclusions from the Zhukhovitskii equation[53], linear isotherms are observed when the values of σ for the pure components are close to one another. In this group a minimum is observed only on the σ isotherms for the NaCl–$PbCl_2$ system. Electrical conductivity and e.m.f. data for this system[105] suggest that the melts contain unstable ionic complexes.

2. Binary Salt Systems with Compound Formation

The second group consists of binary systems for which the equilibrium diagrams indicate the formation of compounds (Table 3). This group also contains the KCl–$CaCl_2$ and CsCl–$CaCl_2$ systems, for which the nature of the isotherms is unknown[77]. This group also contains the KPO_3–$Ba(PO_3)_2$ system, for which the equilibrium diagram has not been studied but in which the possibility of compound formation is confirmed by the tendency of potassium salts to form ionic complexes with the salts of bivalent cations[2]. A characteristic feature is that the σ isotherms for 11 systems of this group show singular points (extremal points, points of inflection, and breaks), the isotherms being linear or convex towards the composition axis in only five instances. It is possible that in these last systems the compounds which crystallise from the liquid phase dissociate. The absence of interaction between the components in the liquid phases of the KNO_3–$AgNO_3$ and NaCl–$CdCl_2$ systems, whose isotherms show no singular points, is confirmed by data on a large number of their properties[2].

Thus the interaction between the components of binary salt systems, reflected by the equilibrium diagram, is in a number of instances also revealed on the σ isotherms; here the composition corresponding to a singular point on the σ isotherms does not always correspond to the composition of the compound crystallising, as is in general possible[3].

3. Diagonal Sections of Ternary Reciprocal Systems

The experimental material on σ for ternary reciprocal systems is insufficient to enable any conclusion to be reached regarding the relationships between the equilibrium diagrams and the shapes of the σ isotherms for the diagonal sections. In the third group, 8 such sections have been studied, and the diagrams are known for only 4 of these (Table 4). The classification of the remaining pairs of salts in a given system type and the form of the diagonals[106] was estimated approximately on the basis of Kablukov's rule[107] from the magnitude and sign of the heats of the exchange reactions ΔH_{298}, calculated from the heats of formation of the reacting compounds[108].

---o0o---

Thus the surface tension isotherms for binary salt systems with solid solution or eutectic formation generally show no singular points; the surface tension isotherms for binary systems with interaction between the components usually show singular points — extrema, points of inflection or breaks. The surface tension of salt melts is a property which to a certain extent is sensitive to change in the structure of the melts.

IV. Mechanism of cyclisation of alkynes 517

I. INTRODUCTION

In recent years the polymerisation of alkynes has been attracting increasing attention with the discovery of new aspects of this diverse process. Up to recently, the polymerisation of acetylene yielded only oligomers of linear structure (vinylacetylene, divinylacetylene, etc.), or high-molecular products of the cuprene type. Instances of the cyclisation of acetylene with the formation of aromatic compounds, particularly benzene, were known, but the methods of synthesis were imperfect and the mechanism of synthesis was not clear. A review of the state of the problem may be found in the monograph of Newland and Vogt[1].

The cyclisation of acetylene and its derivatives was presented in a new light after Reppe's discovery of active catalysts that permit the selective preparation of the corresponding cyclic oligomers under mild conditions[2]. Later, numerous papers appeared in which catalysts suitable for the most diverse examples were recommended. Control of the course of the reactions and high yields made cyclisation a process of practical interest. It was

shown that a virtually unlimited variety of benzene derivatives could be synthesised, the preparation of which was extremely complicated by other methods. This applies, for example, to trivinylbenzene, substituted styrene, substituted divinylbenzene and similar products.

The theoretical significance of these reactions should also be considered; this is important because it makes possible the investigation of fine details of the mechanism of action of the complex catalysts that are used for the cyclisation of alkynes. It is well known that similar catalysts are widely used for the polymerisation of alkenes and alkadienes (ethylene, propene, buta-1,3-diene, isoprene) in the preparation of synthetic rubbers and plastics. However, a study of the mechanism of action of catalysts is difficult because of the complexity of the processes of formation of macromolecules of enormous molecular weight and with a fairly wide molecular-weight distribution. This complication is completely eliminated in the cyclisation of alkynes, in which individual low-molecular products are formed.

The monograph and review literature contains very little information on the cyclisation of alkynes, notwithstanding the obvious interest in the subject. In fact, that is only one review on the subject, that of Nagihara in the Japanese language, which is not accessible to a wide circle of chemists[3]. The present review is intended to fill this gap.

Berthelot was the first to describe the cyclisation of acetylene; he obtained benzene, naphthalene and other aromatic compounds by heating acetylene above 600°[4]. Later, Mayer and coworkers[5] obtained 60% conversion by passing acetylene with hydrogen through an electric furnace at 800°; benzene, naphthalene, anthracene, biphenyl, pyrene, and a number of other compounds were separated from the resinous product obtained. Zelinskii[6] obtained aromatic hydrocarbons in high yield by passing acetylene over activated carbon at 600–650°.

Newland and Vogt give a review of papers on the high-temperature cyclisation of acetylene[1]. In recent years, interest in this process has decreased, because of the discovery of catalytic methods of cyclisation at moderate temperatures. However, occasionally papers appear on the non-catalytic cyclisation of acetylene itself and its derivatives. Thus, Rupprecht[7] reports the preparation of hexadeuteriobenzene in 20% yield from deuterioacetylene at 700°. Harris and coworkers[8] obtained hexakistrifluoromethylbenzene from perfluorobut-2-yne at 260° and 1000 atm. Shantorovich and coworkers studied the thermal polymerisation of phenyl- and cyclohexyl-acetylenes and obtained the corresponding benzene derivatives[9].

Recently, a report appeared on the spontaneous cyclic oligomerisation of t-butylfluoroacetylene, which proceeds even at low temperatures[10]; the main product of this reaction is 1,2,3-tri-t-butyltrifluorobenzene.

As a rule, the high-temperature cyclisation of acetylene and its derivatives cannot be used for the purposeful synthesis of definite compounds; many different products, including high-molecular products, are obtained at the same time. These disadvantages are largely avoided when the reaction is carried out in the presence of catalysts. Cyclisation may lead to cyclic trimers, which are derivatives of benzene, or to non-benzenoid cyclic polymers (cyclobutadiene, cyclo-octatetraene, etc.). These two synthetic routes will be considered separately.

II. CATALYTIC CYCLOTRIMERISATION OF ALKYNES

1. Cyclotrimerisation in the Presence of Catalysts Based on Nickel Carbonyls

$[Ni(CO)_2[PPh_3)_2]$, formed by the reaction of $Ni(CO)_4$ with an alcoholic solution of $P(C_6H_5)_3$, which was proposed by Reppe, was one of the first catalysts for the preparation of benzene derivatives from acetylene[11]; when suspended in benzene, acetonitrile, or tetrahydrofuran, it cyclises acetylene to benzene (88%) and styrene (12%). The trimers of prop-2-yn-1-ol, 1,3,5- and 1,2,4-tri(hydroxymethyl)benzene, were obtained in quantitative yield with the same catalyst in boiling benzene. It is interesting that the ratio of the isomers in the reaction products was 1 : 1 instead of 3 : 1, as would be expected with mutual orientation of the alcohol molecules according to the laws of statistics.

Reppe did not succeed in preparing the cyclic trimer of butynediol, which he explained by the absence of unsubstituted acetylene hydrogen from this compound. However, somewhat later Kleinschmidt obtained hexa(hydroxymethyl)benzene on the same catalyst[12].

It was shown in subsequent papers that other alkynes and their derivatives can be cyclotrimerised in the presence of nickel-carbonylphosphine catalyst. Thus, Rose and Statham[13] carried out the cyclic trimerisation of phenylacetylene and phenylethynylmethanol to give 1,2,4-triphenylbenzene and 1,3,5-tri-(α-hydroxybenzyl)benzene respectively. They also attempted to obtain benzene derivatives from 3-methylbuty-1-yn-3-ol, *NN*-diethyl-1--methylprop-2-ynylamine, benzoylacetylene and phenylpropiolic acid, but they did not succeed in obtaining trimers.

The preparation of tri-(1-hydroxyethyl-1-methyl)benzene, triisopropylbenzene[15], and 1,2,4-trivinylbenzene on the same catalyst is described in a number of patents (cited by Meriwether and coworkers[14]). Simultaneous cyclotrimerisation of acetylene and divinylacetylene gave *o*-divinylbenzene[16], and *o*-xylene was obtained in the same way from acetylene and but-2-yne[17]. It is interesting that in a number of instances the use of the catalyst $[Ni(CO)_2.$ $.(PPh_3)_2]$ may lead to the formation of linear polymers.

Using 35 different mono- and di-substituted acetylenes, Meriwether and coworkers[14] studied reactions in the presence of $[Ni(CO)_2(PPh_3)_2]$. The catalyst (0.4 mole % of the monomer) and the alkyne compound were dissolved in a suitable solvent (benzene, cyclohexane, ethanol) and boiled under reflux for 24 hours. As a rule, the reaction yielded a mixture of isomers of benzene derivatives, and linear polymers of the general formulae

$$R{-}C{\equiv}C{-}[CR{=}CH]_n{-}CH{=}CHR,$$

and

$$R{-}C{\equiv}C{-}[CR{=}CH]_n{-}CR{=}CH_2,$$

where $n = 0$–10. The preferential formation of cyclic or linear products is mainly determined by the nature of the substituent at the triple bond. Thus, for monosubstituted alkynes, the yield of aromatic products fell from 65% for propyne to 5% and lower for hept-1-yne, although the total conversion remained almost unchanged. The ratio of 1,2,4-isomers to 1,3,5-isomers varied in the homologous series without showing definite tendencies. It was found that steric factors have a great effect on the reactions. Cyclohexylacetylene formed only a linear dimer, and t-butylacetylene did not react at all.

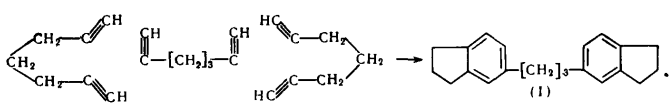
Meriwether did not succeed in polymerising more disubstituted acetylenes, conjugated diacetylenes, and also

monosubstituted acetylenes, containing t-butyl, carboxyl, amide, or nitrile groups, or halogen.

When the structures of two alkynes did not differ greatly, it was found possible to carry out simultaneous cyclotrimerisation, in particular with a mixture of hept-1-yne and pent-1-yne, or with pent-1-yne and phenylacetylene. A mixture of benzene (43%), *o*-xylene (50%), styrene, and 1,2,3,4-tetramethylbenzene was obtained by the simultaneous cyclopolymerisation of acetylene and but-2-yne.

The following qualitative order of reactivity was established for the cyclotrimerisation on $[Ni(CO)_2(PPh_3)_2]$ of alkyne ethers, esters and ketones: vinylacetylenes > > arylacetylenes > acetylene alcohols > higher alkynes > > lower alkynes, acetylene ≫ acetylenic acids.

More active monomers generally form aromatic products, and the less active more linear polymers. The cyclotrimerisation of unconjugated diacetylenes on the same catalyst is very interesting, mixed aliphatic-aromatic structures being formed[18]. Thus hepta-1,6-diyne forms, in addition to a highly unsubstituted linear polymer, an aromatic trimer, 1,3-di-(5-indanyl)-propane (I):



(I)

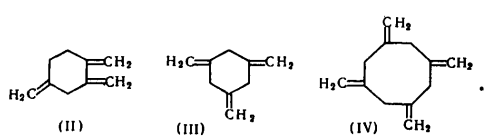
In the polymerisation of alkynes with modified catalysts, it was shown that monocarbonyltriphosphine and tetraphosphine complexes of nickel do not catalyse the cyclic polymerisation of alkynes[19]. When the phenyl group linked to phosphorus is replaced by other groups, the catalyst activity is significantly changed in the following order:

$$C_2H_4CN > C_6H_5 > H > OC_2H_5 > \text{n-alkyl} \gg OC_6H_5 \text{ and Cl.}$$

Experiments in which $Ni(CO)_4$ was used did not lead to the formation of trimers. All these results indicate the important part played by the phosphine ligands in the catalyst complex. Replacement of groups linked with phosphorus affects not only the catalyst activity but also the direction of the reaction. Thus, $[Ni(CO)_2\{P(OC_6H_5)_3\}_2]$ favours aromatisation of phenylacetylene, but $[Ni(CO)_2 \cdot \{P(C_2H_4CN)_3\}_2]$ favours linear polymerisation.

Attempts made by Meriwether and coworkers to obtain kinetic information on the cyclotrimerisation of alkynes on carbonylphosphinenickel catalysts were not successful[19]. This reaction is very rapid and has a high heat effect.

It is interesting to note that the cyclisation of allenes may be carried out on the same carbonylphosphinenickel catalysts. Benson and Lindsey[20] obtained the allene trimers (II) and (III) and the tetramer (IV) by heating allene at 105–110° in tetrahydrofuran in the presence of $[Ni(CO)_2\{P(OC_6H_5)_3\}_2]$ for 5–6 hours:



(II) (III) (IV)

The simultaneous cyclisation of allene and alkynes, which they also carried out, gave a mixture of isomeric dimethylenecyclohexenes.

Schrauzer showed that when acetylene reacts with acrylonitriles in the presence of $Ni(CO)_3(PPh_3)$, there is a considerable induction period[21]. This indicates that the true reaction catalyst is not $Ni(CO)_3(PPh_3)$. Actually, it has been shown that the reaction is more complicated:

$$Ni(CO)_3PPh_3 + 2CH_2{=}CH{-}CN \longrightarrow Ni(CH_2{=}CH{-}CN)_2 \cdot PPh_3 + 3CO.$$

In the presence of acetylene, complexes of nickel with acrylonitrile and acetylene are formed:

$$Ni(CH_2{=}CH{-}CN)_2(C_2H_2)_2 \quad \text{or} \quad Ni(CH_2{=}CH{-}CN)(C_2H_2)_2 \cdot PPh_3.$$

Similar nickel complexes were obtained with acrolein and fumaronitrile, etc.[22]

Under certain conditions the complex of $Ni(CH_2{=}CHCN)_2$ with alkyne derivatives forms aromatic nitriles (tetraphenylbenzonitrile with tolan) on decomposition, but with an excess of symmetrical alkyne hexasubstituted derivatives of benzene are formed. With acetylene itself in tetrahydrofuran under pressure, this complex gives cyclo-octatetraene and benzene. However, the yields are low, which indicates the non-catalytic nature of this synthesis. The introduction of triphenylphosphine into the complex sharply increases the yields of benzene (cyclo-octatetraene is not formed at all), and the process acquires a catalytic character[22].

2. Cyclotrimerisation in the Presence of Carbonyls of Other Metals

The carbonyls of a number of transition metals and their complexes with alkynes form another large group of active catalysts for the cyclic trimerisation of alkynes. In recent years, great successes have been achieved in the chemistry of (metal carbonyl)–alkyne complexes. This subject, which is of interest in itself, has been considered in detail in a recent review by Bennett[23]. Here it should be mentioned that in many of these complexes the component alkynes form cyclic aromatic structures.

Reppe established that when acetylene reacts under pressure with the hydrogen derivative of iron carbonyl, $Fe(CO)_4H_2$, a complex if formed, decomposition of which yields hydroquinone[24]. Later, Sternberg and coworkers reported the synthesis of an $Fe(CO)_3$–duroquinone complex from pentacarbonyliron and dimethylacetylene[25]. Hübel and coworkers prepared a large number of complexes of acetylene and its derivatives with the carbonyls of iron, manganese, tungsten, and cobalt[26]. These compounds are stable, and they may be regarded as π-complexes, constructed from an organic system and one or more metal-carbonyl groups. When the complex contains more than one alkyne molecule, a ring system with conjugated double bonds (frequently with one or two carbonyl groups in the ring) is formed within the complex. In no instance could the unchanged alkyne be recovered from the complex. Decomposition of such complexes as $[Fe(CO)_4 \cdot (Ph.C \vdots C.Ph)_2]$ or $[Fe_2(CO)_7 \cdot (Ph.C \vdots C.Ph)_2]$ and $[Fe(CO)_4 \cdot (HC \vdots CPh)_3]$ or $[Fe_2(CO)_6 \cdot (HC \vdots CPh)_3]$ gives the corresponding tetraphenylcyclopentadienone and 1,3,5-trimethylbenzene.

In subsequent papers by Hübel, it is shown that mono- and di-substituted acetylenes are converted in high yield into benzene derivatives in the presence of small quantities of some metal-carbonyl compounds[27]. The yield of trimer largely depends on the nature of the metal carbonyl. Table 1 gives information on the cyclic trimerisation of tolan with various metal-carbonyl catalysts(without solvent).

TABLE 1. Cyclic trimerisation of tolan without a solvent with various catalysts[27].

Carbonyl compound	Temperature, °C	Yield of trimer
$Fe_3(CO)_{12}$	260—280	75
$Fe_2(CO)_9$	250	25
$Fe(CO)_5$	270	20
$Fe_2(CO)_6\cdot(PhC{\equiv}CPh)_3$	270	60
$[Co(CO)_4]_2Hg$	270	70
$Co_2(CO)_8$	280	60
$Co_2(CO)_6\cdot(PhC{\equiv}CPh)_2$	150	70
$Ni(CO)_4$	260	5
$Mn_2(CO)_{10}$	270	55
$Mo(CO)_6$	270	50
$W(CO)_6$	270	15

It is more convenient to carry out the reaction in a solvent; the best cyclotrimerisation catalyst are then $Co_2(CO)_8$, $[Co(CO)_4]_2Hg$, $Co_2(CO)_6RC_2R'$ or $Co_4(CO)_{10}\cdot RC_2R'$, and dioxan is the best solvent. Table 2 gives information on the cyclotrimerisation of various alkynes with these catalysts.

Unsymmetrical alkynes are cyclised exclusively to 1,2,4-trisubstituted benzenes. Prop-2-yn-1-ol is readily cyclotrimerised by Reppe's catalyst, but all attempts to carry out the reaction in the presence of cobalt-carbonyl catalysts have been unsuccessful, as have been attempts to cyclotrimerise propargyl benzoate, propargyl acetate, and benzylacetylene. Hübel also carried out the simultaneous cyclotrimerisation of various alkynes — tolan with *pp'*-dichlorodiphenylacetylene or with phenylacetylene, and phenylacetylene with acetylene. The relative reactivity of alkynes in a given reaction can be determined by carrying out the simultaneous trimerisation of equimolecular quantities of the alkynes. When the reactivities are identical, all four possible products are obtained in the statistical ratio 1 : 3 : 3 : 1 (for example, in the simultaneous trimerisation of tolan with *pp'*-dichlorodiphenylacetylene).

Cyclotrimerisation of alkynes in the presence of cobalt carbonyls was found to be a convenient method for the preparation of benzene derivatives containing bulky substituents. A derivative of benzene with an *ortho*-tertiary group — 1,2,4-tri-t-butylbenzene — was first obtained in this way[28]. The presence of adjacent t-butyl groups distorts the benzene ring; this is indicated by spectroscopic and thermochemical data[29]. Distortion of the benzene ring has also been noted in 1,2,4,5-tetra-t-butylbenzene, which was obtained later by a similar method[30]. It is interesting that the trimethylsilyl group does not produce this effect[29]. Cyclisation of di-isopropylacetylene in the presence of catalytic quantities of $Co_2(CO)_8$ gave hexaisopropylbenzene[31], in the molecule of which rotation of the isopropyl groups is hindered almost completely for steric reasons.

TABLE 2. Cyclic trimerisation of various alkynes with cobalt-carbonyl compounds.

Alkyne compound	Catalyst	Trimer	Temperature, °C	Yield, %

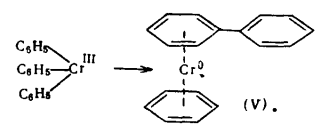
3. Cyclotrimerisation under the Influence of Organometallic Catalysts

It was established comparatively recently that organochromium compounds obtained over 30 years ago by Hein[32] are active catalysts for the cyclisation of alkynes. Zeiss and coworkers showed that in tetrahydrofuran solution triphenylchromium forms an octahedral coordination complex with three molecules of tetrahydrofuran[33]. This complex is stable in the absence of oxygen and moisture. Removal of the tetrahydrofuran leads to the rapid conversion of the triphenylchromium into a bisarylchromium(0) complex(V):



(V).

The tetrahydrofuran ligands may be easily displaced by alkyne molecules, which undergo cyclisation with the formation of benzene and polynuclear aromatic derivatives[34]. Intermediate alkyne complexes of triphenylchromium have not been isolated. Organochromium compounds are very sensitive to the action of acid acetylene hydrogen, and monosubstituted acetylenes destroy the catalyst; for this reason, it can only be used for the cyclisation of disubstituted acetylenes.

The direction of the reaction depends on the stoichiometric ratio of alkyne to the catalyst and on the nature of the organic groups linked with chromium. Thus, in the cyclisation of but-2-yne in the presence of triphenylchromium, hexamethylbenzene or 1,2,3,4-tetramethylnaphthalene may be obtained as the main products, depending on the $(C_6H_5)_3Cr$: but-2-yne ratio; some bis(hexamethylbenzene)chromium(0) is also formed.

Table 3 shows that with all catalyst : monomer ratios the reaction products contain a naphthalene derivative. Bis(hexamethylbenzene)chromium(0) is only formed when there is a large excess of but-2-yne; it is similar in structure to ferrocene, is fairly stable, and does not catalyse the cyclic trimerisation of alkynes. If triethylchromium, or a triarylchromium with *ortho*-substituted

TABLE 3. Effect of the ratio of but-2-yne to catalyst on the yields of trimers[34].

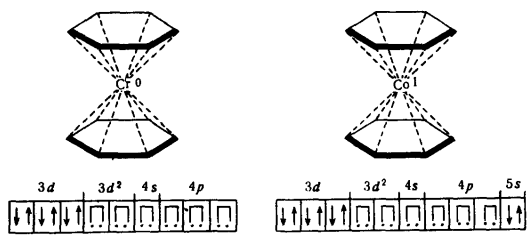
aryl groups (for example, trimesitylchromium), is used as catalyst instead of triphenylchromium, a benzene derivative is the sole reaction product.

The general character of this reaction was demonstrated by the formation of hexaphenylbenzene and 1,2,3,4-tetraphenylnaphthalene from tolan in the presence of triphenylchromium[34], and also by the formation of hexaphenylbenzene and 1,2,3,4-tetramethylphenanthrene from but-2-yne and tri-α-naphthylchromium.

Unlike chromium compounds, diphenylnickel does not react with alkynes to form naphthalene derivatives, but with tolan diethylnickel forms hexaphenylbenzene and 1,2,3,4-tetraphenylcyclohexa-1,3-diene, the latter being formed by the inclusion of the ethyl group of the catalyst in the ring[35,36].

The action of alkyl and aryl compounds of other transition metals, such as dimesityliron[37] or diphenylmanganese[38], also cyclises disubstituted acetylenes. In some respects diphenylcobalt(II) occupies a special position. Bis(hexamethylbenzene)cobalt(I), which is obtained by the reaction with but-2-yne, differs from the bisarene chromium derivatives by the presence of two electrons in excess of the complete krypton shell of the cobalt atom in this compound.



The capacity of cobalt to catalyse the reaction well outside stoichiometric proportions may be due to this special feature[38] (Table 4); in contrast, with the organochromium compounds, cyclisation occurs when the metal and the alkyne are present in stoichiometric proportions.

4. Cyclotrimerisation under the Influence of Complex Organometallic Catalysts

Ziegler's complex organometallic catalysts, which have been widely used in the polymerisation of alkenes and alkadienes, also polymerise alkynes. The polymerisation of acetylene and its homologues with the formation of linear high-molecular products was first carried out by Natta and coworkers[39]. Later, the results of more detailed study of the polymerisation of acetylene[40,41] and hexa-1-yne[42] were published. Because of the interesting properties of high-molecular alkyne polymers, a number of workers carried out the polymerisation of various alkynes in the presence of Ziegler-type[43-46] and other catalysts. Natta obtained the best results with catalysts of the type $AlR_3 + Ti(OR)_4$. Later, Hagihara and coworkers showed that with the catalytic system $Cr(t\text{-}OC_4H_9)_3 + Zn(C_2H_5)_2$ (ratio of components 1 : 3) monosubstituted acetylenes give linear dimers (vinylacetylene derivatives) in almost quantitative yield[47]. Replacement of diethylzinc by triethylaluminium led to the formation of alkylbenzenes. This shows how sensitive the alkyne polymerisation is to modifications in the catalytic system.

In 1959, Franzus and coworkers[48] first showed that cyclic trimers of disubstituted acetylenes (hexasubstituted benzenes) could be obtained with the aid of the catalytic system $Al(iso\text{-}C_4H_9)_3 + TiCl_4$; with an Al/Ti ratio within the range 1 : 1 to 3 : 1, dimethyl-, diethyl, and diphenyl-acetylene were quantitatively cyclotrimerised.

These workers note that none of the catalyst components alone catalyses cyclotrimerisation†. It was also shown that when $TiCl_4$ is replaced by $TiCl_3$ the catalytic system becomes inactive in this reaction.

Cyclic trimers of disubstituted acetylenes were also obtained by Wilke in presence of the $CrO_2Cl_2 + Al(C_2H_5)_3$ system[50]. Recently, Drefahl and coworkers made a very detailed study of the cyclotrimerisation of diphenylacetylene with Ziegler catalyst[51].

Although it was thought that monosubstituted acetylenes containing "acid" acetylene hydrogen would destroy the Ziegler catalyst, it was found that they also undergo the cyclotrimerisation reaction, forming 1,2,4- and 1,3,5-trisubstituted benzenes. A patent by Smith describes the use of a catalyst based on an organometallic compound of a non-transition metal and a transition metal halide[52]. A mixture of mesitylene (40%) and pseudocumene (60%) was obtained by the polymerisation of methylacetylene passed through a catalyst solution consisting of $Al(C_2H_5)_3$ and $TiCl_4$ in methylcyclohexane. The total yield of trimers exceeded 60%.

Lutz cyclotrimerised a number of mono- and di-substituted acetylenes in the presence of the $Al(C_2H_5)_3 + TiCl_4$ system (Table 5)[53]. He considers the use of large volumes of solvent to be the main condition for a successful synthesis. Reikhsfel'd and coworkers established that extensive dilution is not necessary, if the $Al(iso\text{-}C_4H_9)_3 + TiCl_4$ system is used as a catalyst[54]. 1,3,5-tri-n-butylbenzene was obtained from hex-1-yne, and 1,3,5-triphenylbenzene from phenylacetylene, in yields exceeding 90%. When this catalytic system is

† Under drastic conditions (pressure, temperature above 140°), Wilke obtained hexasubstituted benzenes from tolan and diethylacetylene by the action of di-isobutylaluminium hydride.

used, a change in the monomer : solvent ratio from 1 : 1 to 1 : 10 (1 : 20 according to Lutz) has no effect on the yield of trimer[55]. Replacement of $TiCl_4$ by $TiCl_3$ leads to the formation of extremely unsaturated polymers (rubber-like in the case of hex-1-yne), apparently of linear structure. Later, these workers carried out the simultaneous polymerisation of hex-1-yne and phenylacetylene[56]. With a 1 : 1 molar ratio of monomers all four possible trimers were obtained in amounts close to the statistical ratio (1 : 3 : 3 : 1). This distribution of products indicates that both alkynes have the same reactivity in the cyclotrimerisation.

A study of the effect of catalyst composition on the course of cyclotrimerisation showed that replacement of the transition metal halide in the $Al(iso\text{-}C_4H_9)_3 + TiCl_4$ system by an alkoxy-compound leads to a reduction in catalytic activity[57]; the use of tetraethoxytitanium completely deactivates the catalyst. Replacement of the alkyl group attached to aluminium by a chlorine atom has virtually no efect on the yield of cyclotrimerisation product.

Acetylenes with various substituents have been cyclotrimerised in the presence of a catalyst based on $Al(iso\text{-}C_4H_9)_3 + TiCl_4$; a number of alkynes have also been simultaneously cyclotrimerised with this catalyst[58] (Table 6).

Table 6 shows that propargyl bromide or 5-ethynyl-2-methylpyridine could not be cyclotrimerised; propargyl bromide attacks the catalyst. The direct cyclisation of t-butylacetylene was first carried out with the same catalyst, symmetrical as well as unsymmetrical isomers of tri-t-butylbenzene being obtained[59].

Hoover and coworkers used the $Al(iso\text{-}C_4H_9) + TiCl_4$ system for the cyclotrimerisation of vinylacetylene[60,61], and for the cotrimerisation of divinylacetylene and acetylene[61,62]. At -10°C vinylacetylene gave 1,2,4-trivinylbenzene in about 50% yield; when the temperature was raised to 30–50°, the yield decreased to 10%. Simultaneous cyclotrimerisation of divinylacetylene and acetylene gave *o*-divinylbenzene in 30% yield; when acetylene was replaced by methylacetylene, a mixture of trimethylbenzene isomers and dimethyl-*o*-divinylbenzene was formed. Trivinylbenzene is of interest as a cross-linking agent and as a monomer for the preparation of thermostable plastics used in rocket technology[63].

Donda and coworkers, who studied the cyclic trimerisation of phenylacetylene in the presence of $Al(C_2H_5)_3 + TiCl_4$, obtained 1,3,5- and 1,2,4-triphenylbenzene and a linear polymer[64]. The relative yields of cyclic and linear product depend mainly on the Al/Ti ratio. If this ratio was less than 4, linear polyphenylacetylene was not formed; the highest yield (75%) of aromatic compounds was obtained with an Al/Ti ratio of 2 to 4; the ratio of isomers is virtually independent of the Al/Ti ratio (60% 1,2,4-isomer and 40% 1,3,5-isomer). With higher Al/Ti ratios (4–7), the yield of benzenes fell sharply, and linear polymer was obtained as the main product. These workers point out that the solvent has an appreciable effect on the course of the reaction. The results given above refer to reactions in benzene; in heptane, with an Al/Ti ratio of unity, only oily linear polymers were obtained.

* Catalyst $Al(iso\text{-}C_4H_9)_2Cl + TiCl_4$.

These workers also studied the cotrimerisation in the presence of $Al(C_2H_5)_3 + TiCl_4$ of acetylene and methylacetylene[65], and of acetylene with phenylacetylene and tolan[66]. As with pure phenylacetylene, the preferential formation of linear or cyclic polymers is determined by the Al/Ti ratio; the highest yields of aromatic trimers were obtained with an Al/Ti ratio of 3–4.

Dale used trimethylaluminium with $TiCl_4$ as a catalyst in the synthesis of 1,3,5-tris(trimethylsilyl)benzene from trimethylsilylacetylene[29]. The reaction was carried out at 60°, and a certain amount of the 1,2,4-isomer was obtained in addition to the 1,3,5-isomer.

Kambara and coworkers[67] studied the polymerisation of acetylene in the presence of various modifications of Ziegler catalyst; they noted that when one of the components of the catalytic system is a halogen derivative of a transition metal, a considerable quantity of benzene is formed with an increased degree of conversion of acetylene. Thus, with 43% acetylene conversion in the presence of $Al(C_2H_5)_3 + TiCl_4$ at 0°, 76% of the acetylene that reacts is converted into benzene. In all instances a linear polyacetylene is formed in addition to benzene; if a tetra-alkoxytitanium or a tetra-alkoxychromium is a component of the catalyst, the sole reaction product is a linear polyacetylene. Replacement of the titanium halide by VCl_4, $VOCl_3$, or VCl_3 leads to the exclusive formation of benzene, Starik and coworkers obtaining benzene from acetylene in up to 72% yield[68].

Recently, the results of a detailed study of the cyclisation of isopropenylacetylene in the presence of various catalytic systems was published[69]. The highest yield of cyclic products (1,3,5- and 1,2,4-tri-isopropenylbenzenes) was obtained with the catalyst $Al(C_2H_5)_3 + TiCl_4$. A change in the nature of the transition metal in the catalyst was reflected both in the tendency to form cyclic trimers and in the ratios of the isomeric cyclisation products. The ratio of 1,3,5- to 1,2,4-isomers decreased with the transition from titanium to cobalt and increased slightly with the use of nickel compounds.

5. Cyclotrimerisation in the Presence of Other Catalysts

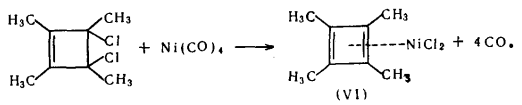
Other catalysts have also been proposed for the cyclic trimerisation of alkynes. Blomquist and Maitlis[70] found that in solvents containing no hydroxyl groups (benzene, acetone, chloroform) the complex bis(benzonitrile)palladium chloride catalyses the cyclotrimerisation of tolan in hexaphenylbenzene with a yield of 85%. The use of catalysts based on CrO_3 on aluminosilicate[71], and gel-like oxides (for example, $SiO_2 + Al_2O_3$) surface-treated with diborane[72], for the cyclisation of alkynes is described in the patent literature. Hexaphenylbenzene was obtained in

about 10% yield by the reaction of tolan with bromophenylmagnesium in a mixture of tetrahydrofuran and xylene[73]. Aromatic hydrocarbons were also obtained from acetylene derivatives by reaction of the latter with lead tetra-acetate in the dark[74].

Luttinger proposed an interesting catalytic system suitable for both the cyclisation and polymerisation of acetylenes[75]: this consists of a compound of a Group VIII metal and a hydride reducing agent; iron and metals not belonging to Group VIII are inactive. Alkali hydrides and silanes were used as reducing agents. The alkali tetrahydroborates and alkali tetrahydroaluminates were found to be the best agents. Hept-1-yne gives mainly linear polymers (dimers, trimers, and somewhat higher polymers), but other alkynes (phenylacetylene) also form aromatic products, such as 1,3,5- and 1,2,4-substituted benzenes[76]. The highest yield of benzene derivatives is obtained by the use of cobalt salts; the valence state of the metal (Co^{2+} or Co^{3+}) has no effect on the process. The usual catalyst for linear polymerisation is $NiCl_2 + NaBH_4$.

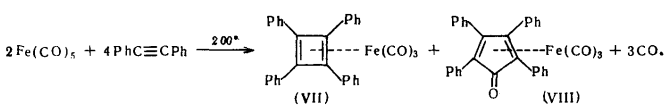
III. SYNTHESES OF NON-BENZENOID CYCLIC STRUCTURES

Under certain conditions, derivatives of cyclobutadiene, which is of great theoretical interest, may be obtained from alkynes. A compound containing the cyclobutadiene ring (VI) was first obtained by Schröder and Criegee according to the reaction[77]:



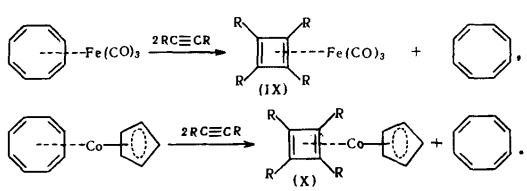
(VI)

Complex formation with compounds of a transition metal stabilises the cyclobutadiene ring. In recent years, complexes of cyclobutadiene derivatives with compounds of Fe, Co, Ag, and Pd have been obtained. Hübel and Braye[78] have reported on the reaction between $Fe(CO)_5$ and tolan, in which the tetraphenylcyclobutadiene complex (VII) is obtained in addition to other products[78]:



(VII) (VIII)

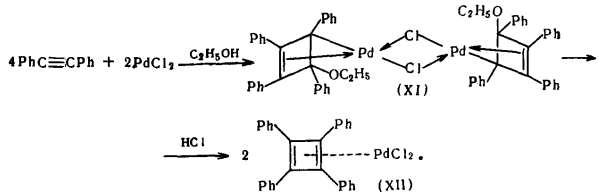
Dodge and Schomaker proved the structure of this complex from X-ray analysis[79]. Nakamura and Hagihara synthesised the same complex by the reaction of tricarbonylcyclo-octatetraeneiron with tolan[80]. Using an analogous reaction, they also synthesised the cobalt complex containing the cyclobutadiene ring (X):



(IX) (X)

Both these complexes are stable in air and they are very thermostable, being unchanged under nitrogen up to 360°; in this way they are to a certain degree reminiscent of ferrocene. Strong acids and alkalis have no action on them.

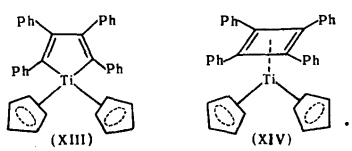
Malatesta and coworkers obtained a similar compound by the reaction of tolan with a solution of palladium(II) chloride in ethanol, with subsequent decomposition by hydrochloric acid[81]:



(XI) (XII)

Blomquist[70] confirmed Malatesta's results; by treating tolan with palladium(II) chloride in a mixture of ethanol and chloroform, he obtained the complex (XI) in 83% yield, and by passing gaseous hydrogen chloride through a solution of this in chloroform, he obtained the complex (XII) in 76% yield. The infrared and NMR spectra of the latter are very similar to the spectra of the complex of $NiBr_2$ with tetraphenylcyclobutadiene.

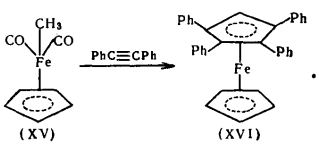
By the reaction of tolan with titanocene, Vol'pin and coworkers[82] obtained the compound π-$(C_5H_5)_2Ti(PhC{\equiv}CPh)_2$, to which structure (XIII) was assigned. Since the properties of the compound obtained are very reminiscent (stability of the pure compound and its benzene solutions, etc.) of the complexes of iron and cobalt with tetraphenylcyclobutadiene previously described, and since the electron configuration of the valence shell of the titanium atom in cyclobutadienebis(cyclopentadienyl)titanium (XIV) is similar to the inert gas configuration (like X), the compound obtained by Vol'pin and coworkers appears to have the structure (XIV):



(XIII) (XIV)

Five-membered rings may also be formed in the cyclisation of alkynes. In the cyclisation of disubstituted acetylenes in the presence of metal carbonyl catalysts, tetrasubstituted cyclopentadienones are often obtained in addition to benzene derivatives[26,31,78,83,84]. These are formed by the union of two molecules of acetylene with one of the carbonyl groups of the catalyst. As a rule, the cyclopentadiene ring formed remains in the metal carbonyl complex as an organic ligand.

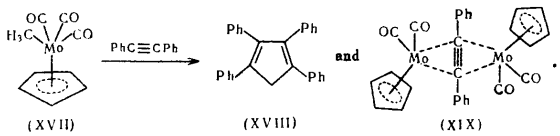
Nakamura observed an interesting reaction between carbonylcyclopentadienylalkyls of iron and molybdenum with alkynes[85]. Thus, toluene reacted with π-$C_5H_5FeCH_3$. $(CO)_2$ (XV) to give tetraphenylferrocene (XVI):



(XV) (XVI)

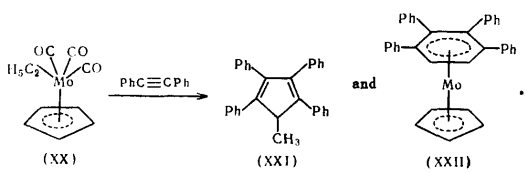
In this reaction the methyl group, which is initially linked to the iron atom, forms a cyclopentadienyl ring with two molecules of tolan. As would be expected, when tolan was replaced by acetylene, ferrocene was obtained. Ethyl and benzyl derivatives of iron carbonyl form benzene, and not ferrocene.

Cyclopentadienyl(methyl)tricarbonylmolybdenum (XVII) reacts with tolan to form tetraphenylpentadiene (XVIII) and the tolan complex (XIX), but the corresponding ethyl derivative (XX) reacts with tolan in a still more unusual manner:



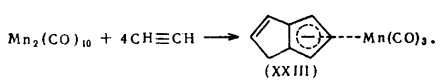
(XVII) (XVIII) (XIX)

In addition to other products, methyltetraphenylcyclopentadiene (XXI) and the "sandwich" compound cyclopentadienyl-(1,2,3,4-tetraphenylbenzene)molybdenum (XXII) are obtained, that is, in one reaction the ethyl group participates differently in the formation of a ring:



(XX) (XXI) (XXII)

Coffild and coworkers observed an unusual reaction[86]: when acetylene reacted with $Mn_2(CO)_{10}$ in tetrahydrofuran at 150° and 43 atm for 5 hours, a compound identified as tricarbonyl-π-dehydropentalenylmanganese (XXIII) was obtained:



(XXIII)

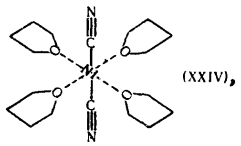
Rings containing eight and more carbon atoms may be obtained from acetylene and its derivatives. The work of Reppe[2] made an accessible one-stage synthesis of cyclo-octatetraene from acetylene possible, other cyclic higher polyalkenes being obtained at the same time in lesser quantities[2]. It is unnecessary to present well known information on the preparation of cyclo-octatetraene here; we shall merely point out that Reppe used compounds of bivalent nickel as catalysts. Later, Schrauzer showed that cyclo-octatetraene can be obtained in stoichiometric quantities by the reaction of acetylene with organic complexes of zerovalent nickel, and benzene is always obtained at the same time[22].

IV. MECHANISM OF CYCLISATION OF ALKYNES

It is generally considered that the formation of a benzene ring by the thermal cyclisation of acetylene proceeds by two successive bimolecular reactions through an intermediate stage in which vinylacetylene or its derivatives is formed[1].

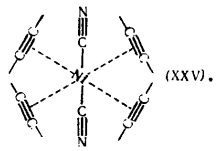
Reppe was the first to propose an explanation of the mechanism of formation of cyclo-octatetraene in the presence of catalysts[2]. According to his interpretation, the effective catalysts are unstable nickel–acetylene compounds obtained by the action of acetylene on the initial nickel compounds (for example, halides); the unstable nickel acetylide, or the metal itself, adds new molecules in such a way that 4 molecules of acetylene are arranged in coordination around the Ni^{2+} ion. This complex decomposes by way of a hypothetical intermediate biradical of four acetylene molecules to form cyclo-octatetraene and nickel compounds.

McKinley has discussed this problem in greater detail[87]. He suggests that the catalyst, for example, nickel cyanide, forms a coordination complex of type (XXIV) with tetrahydrofuran:



(XXIV),

in which four molecules of tetrahydrofuran lie in the same plane as the nickel atom, and the CN group is arranged perpendicular to this plane. Acetylene readily displaces tetrahydrofuran to give a new complex (XXV):

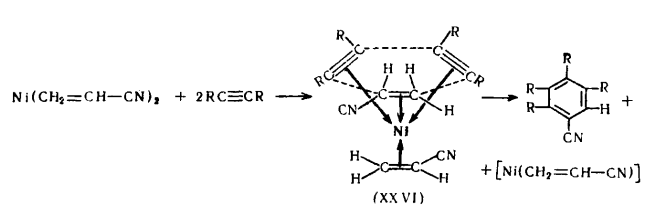


(XXV).

Since the carbon atoms of adjacent molecules are situated close to one another, it may be supposed that the electrons of the triple bond which make the bond with nickel are redistributed with the formation of simple covalent C–C bonds. The formation of octamethylcyclo-octatetraene from dimethylacetylene[87] proves that the acetylene hydrogen does not play a part in the reaction and that the metal is directly linked to the triple bond of the acetylenes. McKinley explains the exclusive capacity of nickel compounds to catalyse the synthesis of cyclo-octatetraene by favourable steric conditions for the formation of the acetylene complex, which is confirmed by the construction of Stuart–Briegleb models[87].

These ideas have been developed by Schrauzer from a more modern point of view[22,88,90]. He assumes that cyclisation reactions proceed inside metal–alkyne complexes by many-centred reactions. The first step must be considered the formation of π-complexes of the metal with the alkynes, in which a new compound is then formed on the basis of spatial proximity and geometrical arrangement. The structure of the reaction product would then be expected to depend on the structure of the π-complex transition state; this has been confirmed by experiments with bis(acrylonitrile)nickel(0)[22]. Such a complex could unite with two alkyne molecules. Since nickel here has zero valency, the complex retains the tetrahedral configuration. In the π-complex (XXVI), two molecules of alkyne are approximately coplanar with one nitrile molecule.

As would be expected, the final reaction product is benzonitrile. Under certain conditions one of the two nitrile molecules may also be displaced by an alkyne molecule with the formation of a benzene derivative.



(XXVI)

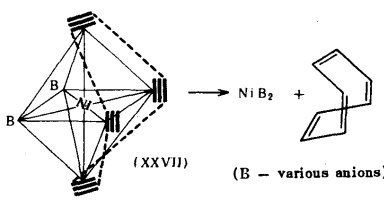
The addition of such an active electron donor as triphenylphosphine to bis(acrylonitrile)nickel(0) increases the

catalytic activity of the nickel compound in the acetylene cyclisation reaction by a factor of 100. Benzene is then the main product of the reaction.

Schrauzer and Eichler made a detailed study of the synthesis of cyclo-octatetraene on a typical catalyst, consisting of bivalent nickel with weak anion bonds, or — in the terms of modern coordination theory — with a weak ligand field[88]. They established a relationship between the structure of the complex and its magnetic properties on the one hand, and its activity in the cyclisation reaction on the other hand (Table 7).

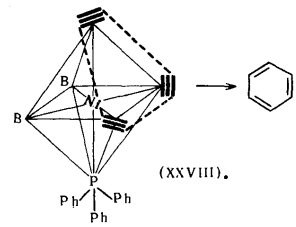
The relationship between the lability of the ligands and the catalyst activity was demonstrated in the synthesis of cyclo-octatetraene in the presence of bis(salicylaldiminato)nickel(II) and its *N*-alkyl derivatives; the methyl derivative, which is the most labile, was also found to be the most active.

Complexes with an octahedral configuration are active. The Ni^{II} ion "solvated" by acetylene molecules remains paramagnetic, because the ligand field strength (of acetylene) is insufficient for the pairing of spins of both split nickel electrons. The acetylene molecules will attempt to occupy a suitable octahedral configuration around the central field. Hence, Schrauzer and Eichler assume that the transition state in the formation of cyclo-octatetraene is a complex with four acetylene molecules with a steric arrangement suitable for the synthesis of cyclo-octatetraene (XXVII). Intermediate stages are not necessary for these molecules to form a ring:



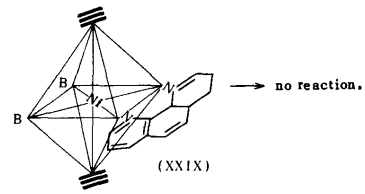
(XXVII) (B — various anions).

Experiments on the inhibition of cyclisation favour the hypothesis that cyclo-octatetraene is formed in labile acetylene complexes with an octahedral, or closely related, structure on the Ni^{II} ion[88]. Donor molecules with a strong ligand field were used as inhibitors. The addition of triphenylphosphine inhibits the formation of cyclo-octatetraene; the reaction proceeds with a tendency to form benzene, which is obviously related to blocking of one of the coordination positions in the complex (XXVIII) by a PPh_3 molecule:



(XXVIII).

The addition of compounds capable of blocking two coordination positions in the complex (*o*-phenanthroline) at once completely deactivates the catalyst:



(XXIX)

Schrauzer put forward the idea that a π-complex many-centre reaction occurs in this and similar instances. The rehybridisation of the acetylene carbon atoms from the sp- and sp^2-states, necessary for the formation of new C–C bonds, is obviously greatly facilitated by the formation of a π-complex with a transition-metal atom. The subsequent reaction of the rehybridised atom is, as a rule, not specific. Thus, with alkynes $Fe_2(CO)_{12}$ gives a large number of different organometallic complexes and organic compounds at the same time[26,27]. According to Schrauzer, nickel compounds, in contrast to compounds of other elements, can catalyse the formation of cyclo-octatetraene from acetylene, because of the difference in the energies of states in the interaction of the metal used and acetylene. In the active complexes the $3d$-terms for Ni^{II} lie in a region which favours the formation of labile compounds with acetylene molecules of just the required size. The Ni-ligand bond in these complexes shows a relatively high degree of covalency; the Ni^{II} ion carries only a weak positive charge, and therefore the energy of the $3d$-state approaches so closely to the energy of the π_g-orbitals of the acetylenes that weak dative bonds may even be formed. (In the more polar and catalytically inactive nickel halides, the energy difference between the corresponding orbitals is too great for any kind of interaction to occur between them). Analogous complexes of Co, Fe and other metals obviously do not satisfy this requirement.

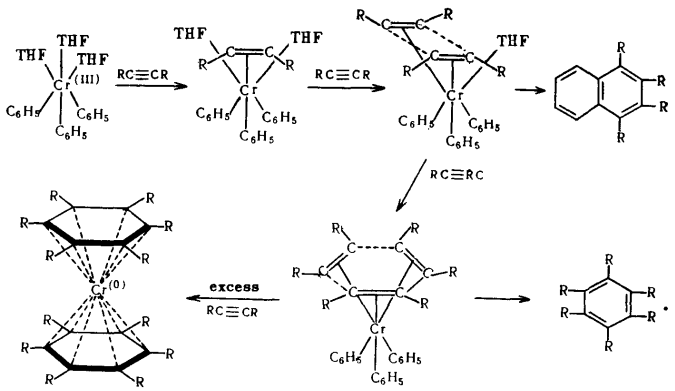
According to Schrauzer, the hypothesis previously proposed that cyclo-octatetraene results from dimerisation of cyclobutadiene, formed as an intermediate, is unsound[89]. It would be difficult to understand why catalytic quantities of cyclobutadiene produced in the presence of a large excess of acetylene would be selectively converted into cyclo-octatetraene and only give benzene in the presence of triphenylphosphine. Moreover, in its electronic structure cyclobutadiene belongs to the class of strong π-bonded ligands. The nickel complex of cyclobutadiene would therefore be more stable kinetically than the initial complex. The rate of conversion of such a complex into cyclo-octatetraene would then be the determining factor, which is not in agreement with the experimental results[90].

However, the idea of the formation of cyclobutadiene as an intermediate permits the interpretation of results on

TABLE 7. Classification of catalysts for the synthesis of cyclo-octatetraene.

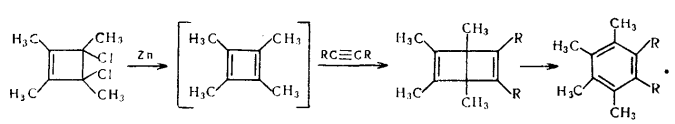
	Weak ligand field	Intermediate range	Strong ligand field
Configuration	octahedral	octahedral and planar	planar
Magnetic behaviour	paramagnetic	anomalously magnetic	diamagnetic
Exchange of ligands	rapid	moderately rapid	very slow
Catalytic activity	active	active	inactive
Examples	bis(salicylaldehydato)nickel bis(acetylacetonato)-nickel	nickel cyanide bis-(*N*-alkylsalicylaldiminato)nickel	nickel phthalocyanine bis(dimethylglyoximato)nickel

the cyclisation of alkynes in the presence of the alkyl- and aryl-metal catalysts of Zeiss[34]. The proposed mechanism is represented by the following scheme:



It is assumed that the alkyne molecules progressively displace the tetrahydrofuran ligands, the octahedral configuration of the complex being retained. The phenyl groups linked to chromium may take part in the reaction with an entering alkyne molecule. Although intermediate complexes with one, two, or three alkyne molecules have not been separated, under certain conditions products of the reaction of an acetylene molecule with one or two phenyl groups of triphenylchromium have been obtained; these are derivatives of styrene or stilbene[91]. But generally the displacement of tetrahydrofuran molecules goes further. As has already been mentioned, the products of the reaction of alkynes with triphenylchromium always contain naphthalene derivatives. According to Zeiss, this indicates the formation of an extremely reactive intermediate, tetra-alkylcyclobutadiene, in the chromium coordination sphere. The chromium atom in the complex can catalyse the elimination of hydrogen in the *ortho*-position of a phenyl group linked to it; dehydrobenzene is then obtained, which reacts with the tetra-alkylcyclobutadiene by an unusual intramolecular Diels–Alder reaction with the formation of tetra-alkylnaphthalene. When the reaction mixture contains sufficient alkyne, the tetra-alkylcyclobutadiene complex of triphenylchromium either loses the last molecule of tetrahydrofuran, which is replaced by alkyne, or it gives a hexa-alkylbenzene by an intermolecular Diels–Alder reaction. With a large excess of alkyne, small quantities of a bis(arene) complex are obtained as the product of further replacement of groups initially linked with chromium. When the *ortho*-position of the phenyl groups is occupied, for example, in trimesitylchromium, naphthalene derivatives are not formed.

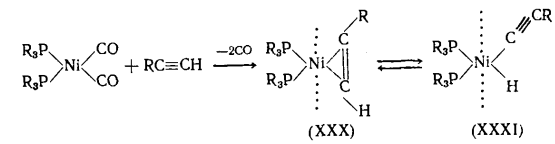
Results obtained by other workers also indicate that the cyclobutadiene ring may be formed in the cyclisation of alkynes. Berkoff and coworkers reduced 1,2,3,4-tetramethylcyclobutene in but-2-yne or dimethyl butynedioate and obtained hexamethylbenzene and dimethyl tetramethylphthalate respectively[92]. They suggest the following scheme for the reaction:



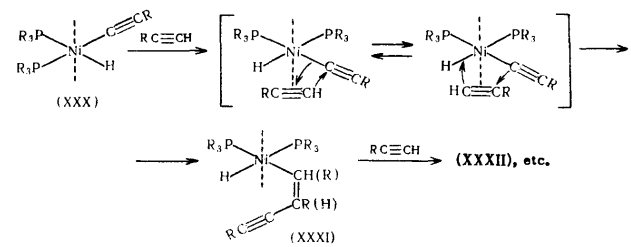
In the cyclisation of di-isopropylacetylene, Arnett and coworkers obtained, in addition to benzene and cyclopentadiene derivatives, products the formation of which is difficult to explain without the hypothesis that cyclobutadiene is produced as an intermediate[31].

Meriwether has put forward quite different interpretations on the mechanism of alkyne polymerisation and cyclisation with nickelphosphinecarbonyl catalysts[19]. Assuming the initial formation of a π-complex, he considers that the subsequent polymerisation or cyclisation steps occur with the participation of an organonickel compound having a metal–carbon σ-bond.

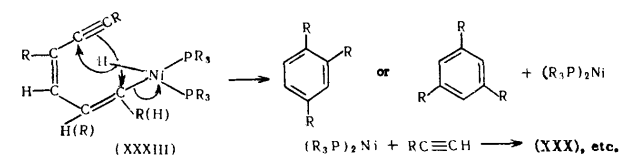
According to Meriwether, the Ni–phosphineacetylene complex obtained by replacement of carbonyl groups by acetylene molecules (XXX) is an "active" catalyst. The complex (XXX) is similar in structure to the biphosphine–Pt–acetylene complexes prepared by Chatt and coworkers[93]:



The complex (XXXI) is an active catalyst for both linear polymerisation and cyclisation. Both complexes are planar and the nickel in them has a formal valency of +2, that is, the nickel atom has a vacant p_z-orbital capable of forming π-bonds with a second acetylene molecule:

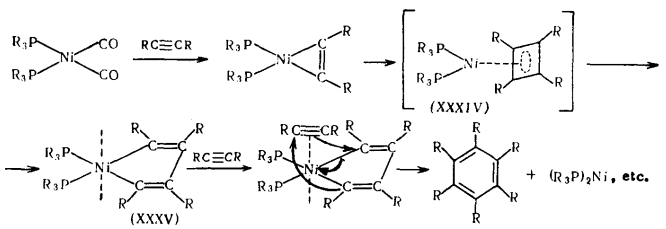


When the complex (XXXIII) has a favourable conformation, in which the first and sixth atoms of the carbon chain can approach within bonding distance, simultaneous hydrogen transfer and ring closure leads to the formation of the corresponding aromatic products:



This mechanism is not applicable to disubstituted acetylenes, since transfer of an acetylene hydrogen is its characteristic feature. Meriwether was therefore compelled to give another explanation of the polymerisation of disubstituted acetylenes. The initial type (XXX) complex formed reacts with a second acetylene molecule and, after the intermediate formation of diphosphinecyclobutadiene-nickel (XXXIV), gives a planar complex (XXXV); in this

planar complex, Ni^{2*} has a vacant *pz*-orbital and is capable of coordinating with a third acetylene molecule:

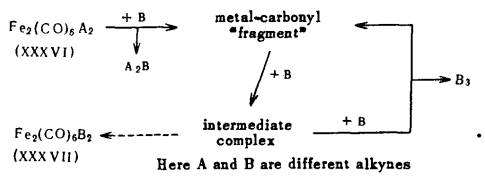


Meriwether points out that acetylene and monosubstituted acetylenes may be partly or completely polymerised by this mechanism. Meriwether's mechanism for the cyclisation of acetylenes is very artificial. This accepted scheme requires two different mechanisms for mono- and di-substituted acetylenes, which makes it doubtful.

The evidence presented in recent years that compounds of nickel with cyclobutadiene can add donor molecules (for example, the addition of triphenylphosphine or *o*-phenanthroline to tetramethylcyclobutadienenickel dichloride[94]) makes Meriwether's objection to the activation of a third acetylene molecule by the complex (XXXIV) unconvincing.

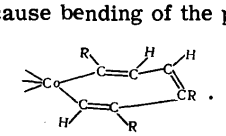
Nakamura has proposed a mechanism for the cyclisation of acetylenes which is somewhat similar to that given above; it also requires the formation of a heterocyclic compound with the metal in the ring[85].

Hübel considers that the catalytic action of metal carbonyls and their derivatives is explained by the formation of active "fragments"[27]. It is significant that the polynuclear compounds of iron and cobalt are the most active compounds. If the reaction with alkynes is carried out under conditions that exclude the formation of metal-carbonyl "fragments" (for example, with carbon monoxide under pressure), trimerisation does not occur. The following scheme is suggested:



Here A and B are different alkynes

The complex (XXXVI) reacts to only a slight degree with B, metal-carbonyl "fragments" being formed in addition to the trimer A_2B. These "fragments" react with B by way of an intermediate complex to form the trimer B_3 and new "fragments". The stable complex (XXXVII) is formed in a side-reaction. The proposed structure for the intermediate complex, for example, in the cyclotrimerisation of t-butylacetylene to 1,2,4-tri-t-butylbenzene[28], includes a non-planar seven-membered ring(bulky groups in *ortho*-positions cause bending of the plane of the ring):

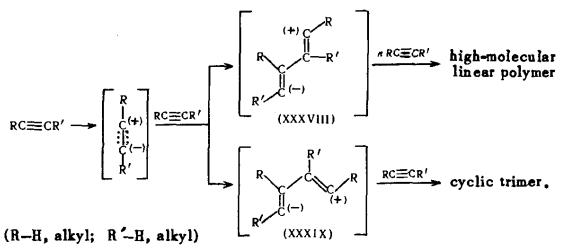


Because the ring is not planar, steric hindrance is eliminated. A benzene compound is not formed in the complex itself; this is proved by the formation of aliphatic oils when the complex is hydrogenated. The aromatic ring is closed only when the complex is decomposed (in this case, for example, by the action of bromine).

The existence of heterocyclic structures containing a metal in complexes of this kind has not been confirmed by results obtained later[95], according to which alkyne molecules in the complex can be replaced relatively easily by molecules of another alkyne present in solution. This exchange is much more probable for metal-alkyne π-complexes than for ring structures not containing triple bonds.

Ziegler's catalysts are amongst the most active in the cyclisation of alkynes. In one of the first papers in this field[53], Lutz attempted to explain the mechanism of the catalytic action of the $Al(C_2H_5)_3$–$TiCl_4$ system. Since a certain amount of linear polymers is usually obtained, according to Lutz the direction of the reaction depends on the suitability of the particular conformation of the intermediate complex. With disubstituted acetylenes, the confirmation that determines subsequent cyclisation is sterically favourable; with monosubstituted acetylenes, the probability of this route increases with the mass of the substituent.

According to Lutz, the polymerisation of alkynes is a surface-catalytic process, chain growth being effected through Al–C bonds formed by chemisorption of the alkynes on the catalyst.

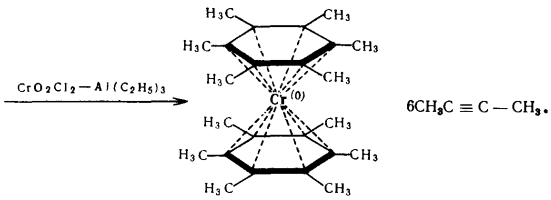


A polarised intermediate compound is formed on the catalyst, and this can react with adjacent polarised molecules by one mechanism or the other. The high selectivity shown in the cyclisation of disubstituted acetylenes indicates the importance of steric factors; steric hindrance interferes with the formation of the intermediate (XXXVIII). Even if it were formed, attack of the active end of the growing chain would be completely blocked by alkyl groups. Lutz has not solved the problem of the cyclisation of monosubstituted acetylenes. Lutz's scheme does not accomodate the catalytic system AlR_3–$TiCl_3$, which is known to have a solid surface; * this, however, promotes linear polymerisation[54], that is, according to Lutz's scheme, a less probable reaction.

It is interesting to consider Wilke's point of view on the mechanism of butadiene cyclotrimerisation[96]. As is well known, when this reaction was carried out in the presence of Ziegler-type catalysts, cyclododeca-1,5,9--triene was obtained. According to Wilke, the process comprises three steps: (1) the formation of a π-complex of butadiene with a transition metal, (2) the formation of new C–C bonds of preoriented molecules with the production of a ring, and (3) separation of the cyclic trimer, or its displacement by new butadiene molecules.

This scheme has been confirmed by experiments on the cyclisation of but-2-yne with the catalytic system CrO_2Cl_2–$Al(C_2H_5)_3$, which, like $TiCl_4$–$Al(C_2H_5)Cl$, promotes the cyclotrimerisation of butadiene[96]. The "sandwich" compound bis(hexamethylbenzene)chromium(0), which is generally obtained in the presence of Zeiss arylchromium

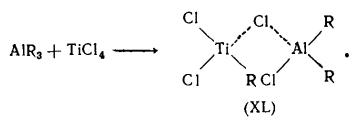
catalysts, was shown to be present in the reaction products.



This is further evidence that similar mechanisms must operate in the cyclisation of alkynes by different catalysts. Specificity in the activity of a given catalyst is determined by the nature of the metal and of the groups linked to it, and also by the reaction conditions. A general feature of all catalysts is the formation of a coordination-complex bond between the π-orbitals of the alkyne and the d-orbitals of the transition metal, together with redistribution of electrons and the formation of new C–C bonds. As Schrauzer has emphasised[88], the formation of new bonds is a non-specific reaction and nearly always occurs when an alkyne carbon atom can be brought within the sphere of action of a given transition-metal atom.

Ziegler's catalysts are no exception. On the basis of their own experiments and published results, the authors of the present review have put forward an interpretation of the mechanism of cyclotrimerisation on these catalysts[57]. Experimental results (identical course of the reaction in various solvents, identical reactivity in this reaction of acetylenes with substituents having an opposite effect on the electron density of the triple bond, etc.) suggest that the anionic mechanism usually postulated for polymerisation with Ziegler's catalysts is inapplicable. A coordination mechanism is more probable for the cyclotrimerisation of alkynes.

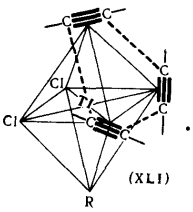
When the components of the catalytic system (for example, alkylaluminium and titanium halide) react, an active complex (XL) is formed:



(XL)

In this complex titanium is partly alkylated. The role of the alkylaluminium consists in the alkylation of titanium and the conferring of a formal charge on it. This is of great importance for the catalytic activity of the complex in cyclotrimerisation, since there is then a partial trans-hybridisation of the titanium valence electrons from the d^3s- to the sp^3-state[38]. According to the calculations of Pilcher and Skinner[97], trans-hybridisation promotes the formation of a simpler bond. It may be supposed that the main factor is the setting free in the $d^3s \rightarrow sp^3$ transition of the titanium d-orbitals, which may be used for interaction with the π-electrons of the triple bond.

The complex (XL) is highly polarised; in some papers even the possibility of the ionisation of such compounds has been considered[98–100]. It is very probable that under the reaction conditions the formation of the cyclic trimer is due to a "fragment" (an ion in the limiting case) $[TiRCl_2]$ which retains the tetrahedral configuration characteristic of both d^3s- and sp^3-hybridisation, but with one unoccupied apex. Since in the higher oxidation stages titanium has the coordination number six, the titanium atom can bind three molecules of acetylene in its coordination sphere:



(XLI)

The complex (XLI) assumes an octahedral, or close to octahedral, configuration, three molecules of acetylene being arranged approximately in the same plane. Such an arrangement facilitates the subsequent combination of the three acetylene molecules to form a ring. As Schrauzer points out[88], the transhybridisation of the alkyne carbon atoms from the sp- to the sp^2-state required for this is facilitated by the presence of a π-complex bond with the central metal atom. The benzene molecule formed in this way is very loosely bound to the remaining part of the complex and is easily displaced by new alkyne molecules. Cyclotrimerisation proceeds as a many-centred π-complex reaction (according to Schrauzer's classification). This is the most probable mechanism for the cyclisation of alkynes; however, the intermediate formation of a cyclobutadiene ring from two acetylene molecules in the coordination sphere of titanium is also possible. Because of experimental difficulties, information has not yet been obtained on the kinetics of cyclotrimerisation, which would provide a more definite answer to this question.

---o0o---

After the manuscript of this review has been submitted for publication, further reports on the cyclisation of alkynes appeared, the most interesting of which will be briefly presented here.

New catalysts for cyclotrimerisation proposed in a number of patents include: $TiCl_4$–$LiAl(C_7H_{15})_4$ and $VOCl_3$–$Al(C_3H_7)_3$[101], compounds of the bis(trialkylphosphite)nickel(0) type[102], $NbCl_5$ and $TaCl_5$[103]. Reports have been made on a detailed investigation of the cyclisation of isopropenylacetylene in the presence of Ziegler's catalyst[104], on the preparation of hexaisopropenylbenzene (a nonreactive trimer of diisopropenylacetylene)[105], the radiochemical cyclisation of methyl- and phenyl-acetylenes[106], the cyclotrimerisation of 2-methylbut-3-yn-2-ol[107], and on the synthesis in the presence of Ziegler's catalyst of [^{14}C]benzene and [$^2H_6$]benzene[108] and of trimethylbenzenes from methylacetylene for the purpose of radiocarbon analysis[109]. A number of trialkynylbenzenes were obtained by the cyclisation in the presence of cobalt carbonyls of conjugated alkadiynes in which hydrogen at the triple bond is replaced[110]. The reactions of alkadiynes and cycloalkadiynes in the presence of Ziegler's catalysts and cobalt carbonyls have been studied[111]. In nearly all instances cyclic trimers and dimers were obtained in addition to polymers. $CoCl_2$ and $(C_2H_5)_2Al$(butynyl) were observed to react in an unusual manner[112]; the reaction products included benzene, the presence of which can be explained by the elimination of but-1-yne followed by its cyclotrimerisation and dealkylation of the trimer.

Some reports deal with the preparation from alkynes of cyclobutadiene complexes of Pd[113,114], Mo, W, Co[115], and

of complexes of transition metals containing the cyclopentadienone[116] and the tropone[117] ring. When perfluorobut-2-yne reacted with π-$C_5H_5Rh(CO)_2$, π-cyclopentadienylhexakis(trifluoromethyl)benzenerhodium was obtained[118]; a study of the structure of this compound showed that only four atoms of the benzene ring are coordinated with rhodium, that is, the structure is not planar.

The addition of alkynes to cyclobutadiene derivatives[119] has been proposed as a method for the preparation of "Dewar" benzene[120]. It should be noted that great progress in the chemistry of valence isomers of benzene with non-classical Ladenburg and Dewar structures became possible when cyclic trimers of such compounds as t-butylacetylene and its derivatives had been prepared.

The observations of Schrauzer, which lead us to re-examine the mechanism of cyclisation, are of considerable interest[121]. In the reactions of alkynes in the presence of various compounds of Ni, Fe, Co, Mn and Pd, signals with a g-factor of ~ 2.0028 were obtained when the viscosity of the reaction medium was sufficiently high. The available information is not sufficient to enable a judgement to be made on the nature and role of this effect.

COMPOUNDS OF THE β-TETRALONE SERIES

V.F.Shner and N.M.Przhiyaglovskaya

CONTENTS

I. Introduction 523

II. Methods for obtaining compounds of the β-tetralone series 524

III. Chemical properties of compounds of the β-tetralone series 526

IV. Synthesis of natural products and their analogues on the basis of compounds of the β-tetralone series 527

I. INTRODUCTION

β-Tetralone — tetralone-2 [name used throughout in Russian text (Ed. of Translation)], or 3,4-dihydro-1*H*--naphthalen-2-one, or 1,2,3,4-tetrahydro-2-oxonaphthalene — and its derivatives are characterised by high reactivity and can be used for the synthesis of various compounds. Interest in them heightened after Robinson showed that they could serve as raw materials for the synthesis of steroids and terpenes. Subsequently β-tetralone was successfully used for the synthesis of compounds similar to morphine and chrysene derivatives.

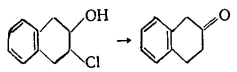
In several instances the interest lies not so much in β-tetralone itself as in various of its derivatives.

The problems of the synthesis of β-tetralone and its substituted derivatives and also the use of β-tetralone in syntheses have not been systematically covered in the

literature. The present review aims at a complete picture of work in the field of the chemistry of the compounds of the β-tetralone series.

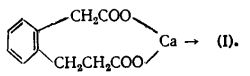
II. METHODS FOR OBTAINING COMPOUNDS OF THE β-TETRALONE SERIES

β-Tetralone (I) was first obtained in 1893 by Bamberger and Lodter [1] by the action of alkali at high temperature on 3-chloro-1,2,3,4-tetrahydro-2-naphthol. The yield of the product was somewhat increased on using quinoline or magnesium carbonate [2,3]:



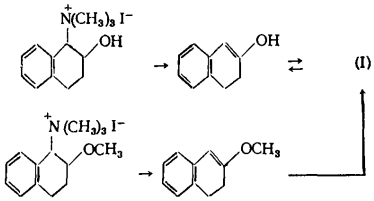
(I)

Somewhat later Einhorn and Lumsden [4] showed that β-tetralone is formed in the dry distillation of calcium 2-(carboxylatomethyl)phenylpropionate:

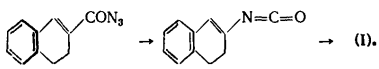


Soviet investigators [5-7] obtained β-tetralone by pyrolysis of 2-carboxymethylphenylpropionic anhydride and by Dieckmann condensation of the diethyl ester of the acid. However, their attempts to synthesise β-tetralone derivatives substituted in the aromatic nucleus by this method were unsuccessful.

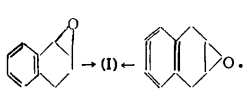
Braun and coworkers [8] obtained β-tetralone, together with α-tetralone, by the oxidation of tetralin with chromyl chloride (Étard reaction); it was shown later [9] that in this reaction both ketones are formed in approximately equal amounts. β-Tetralone is formed in the pyrolysis of trimethyl-(1,2,3,4-tetrahydro-2-hydroxynaphth-1-yl)ammonium iodide [8] and of trimethyl-(1,2,3,4-tetrahydro-2-methoxynaphth-1-yl)ammonium iodide [10] with subsequent hydrolysis of the 3,4-dihydronaphth-2-yl methyl ether:



Crowley and Robinson [11] describe the synthesis of β-tetralone and 6-methoxy-β-tetralone by the Curtius decomposition of the azides of the corresponding 3,4-dihydro-2-naphthoic acids and hydrolysis of the resulting isocyanates:

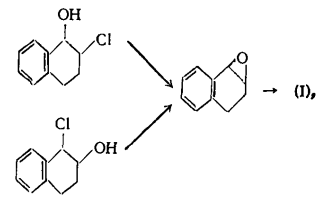


Straus and Rohrbacher [12] obtained β-tetralone in the decomposition of epoxy-3,4- and epoxy-1,4-dihydronaphthalenes and also by dehydrobromination of 1-bromo-1,2,3,4-tetrahydro-2-naphthol:



Tchoubar [13] obtained similar results. Probably the intermediate formation and decomposition of an oxide formed the basis of the production of β-tetralone in the autoxidation of 3,4-dihydronaphthalene by air [14].

The reaction for the preparation of β-tetralone from chlorotetrahydronaphthols also passes through a stage in which epoxynaphthalenes are formed [15]:



and therefore the same ketone is obtained from both isomers.

The method of decomposing epoxydihydronaphthalenes subsequently proved to be extremely useful for synthesising substituted β-tetralone derivatives.

Tchoubar [16] describes the formation of β-tetralone from the cyanohydrin of indan-2-one by hydrogenation and then deamination of the aminoalcohol obtained by the action of nitrous acid.

Compounds of the 2-naphthol series were found to be valuable starting materials for preparing β-tetralone and its derivatives. Thus Robinson and coworkers [17] obtained β-tetralone by the reduction of methyl 2-naphthyl ether with sodium and alcohol followed by hydrolysis of the 3,4-dihydronaphth-2-yl methyl ether formed. Ethyl 2-naphthyl ether behaves similarly [18].

The structure of the intermediate 3,4-dihydronaphth-2-yl methyl ether is confirmed by ozonolysis [19]. β-Tetralone, 7-methoxy-β-tetralone, and 7,8-dimethoxy-β-tetralone [20] are obtained in high yield in the electroreduction of the methyl ethers of the corresponding naphthols.

Birch [21] reduced 2-naphthol to β-tetralone by the action of sodium and alcohol in liquid ammonia. Subsequently the reaction was studied more thoroughly [22] and the side-products were investigated.

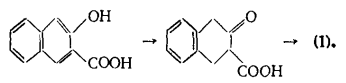
The Robinson–Cornforth and Birch methods are widely used for the synthesis of various substituted β-tetralone derivatives.

2-Naphthol is hydrogenated under severe conditions to β-tetralone [23,24] over palladium deposited on carbon, in the presence of organic bases, and over copper chromite — to 1,2,3,4-tetrahydro-2-naphthol [25], which is dehydrated by ethylene over a catalyst to β-tetralone.

Weil [26,27] obtained β-tetralone by reducing 2-hydroxy-3-naphthoic acid with sodium amalgam, but erroneously ascribed to the product the structure 1,2,3,4-tetrahydronaphthalene-3-carbaldehyde; the same product was obtained by him in reducing various 1-substituted (acetyl, amino-, chloro-, bromo-) 2-hydroxy-3-naphthoic acids.

Weil's erroneous opinion about the structure of his product was corrected by Przhiyalgovskaya and coworkers [28], who showed that when 2-hydroxy-3-naphthoic acid is reduced by sodium amalgam it gives the 3-carboxylic acid of

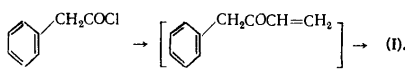
β-tetralone, which is readily decarboxylated into β-tetralone:



(I).

2-Hydroxy-1-naphthoic acid is reduced similarly, but in somewhat less yield[29].

Phenylacetyl chloride gives β-tetralone on reacting with ethylene in the presence of aluminium chloride[30]:



(I).

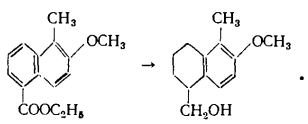
7-Methoxy-β-tetralone is obtained similarly. Much earlier this reaction was used for the synthesis of 4,4-dimethyl- and 3,4,4-trimethyl-β-tetralones[31,32] and 1-isopropyl-4,7--dimethyl-β-tetralone[33].

Of the methods for making β-tetralone which have been described, the following are sufficiently universal, that is, suitable for the synthesis of substituted derivatives: reduction of compounds of the 2-naphthol series after Robinson–Cornforth and Birch, amalgam reduction of hydroxynaphthoic acids, and decomposition of epoxydihydronaphthalenes.

Thus, reduction of the corresponding naphthyl ethers has yielded: 5-methoxy-β-tetralone[27,34-36], 6-methoxy-β--tetralone[17], 7-methoxy-β-tetralone[37-40], 5-methoxymethyl-β-tetralone[41], 5-methoxy-1-methyl-β-tetralone[17,42], 5-hydroxy-1-methyl-β-tetralone[34], 5,8-dimethoxy-β--tetralone[43-47], 7,8-dimethoxy-β-tetralone[38,48], 5-acetamido-β-tetralone[42], 1-methyl-β-tetralone[17], 6-methyl-β--tetralone, and 6-vinyl-β-tetralone[49,50], 6-n-hexyl-β--tetralone[51], 6-(1-hydroxyethyl)-β-tetralone[52], 6-vinyl--β-tetralone[52], 5-(1-ethyl-1,3-dihydroxy-2,2-dimethylpropyl)-β-tetralone[52], 2-(2-hydroxy-2-methylpropyl)--1-methyl-3-(5,6,7,8-tetrahydro-6-oxo-2-naphthyl)cyclopentanol[52], 5-acetamido-4-carboxy-β-tetralone[53].

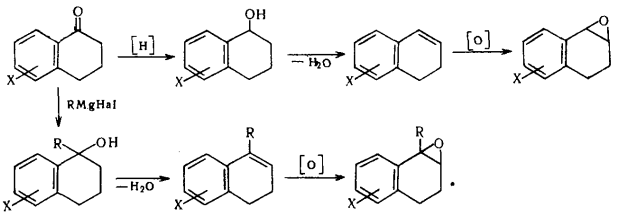
The reaction is usually carried out in an excess of alcohol — sometimes in an inert solvent (toluene)[51] — or in liquid ammonia[19,34,41,42,54].

The reduction of naphthyl ethers does not always proceed smoothly. Robinson and coworkers[17] note that the 1-methyl-β-tetralones are obtained in poor yield, but in a subsequent communication[42] they report a higher yield. The yield was low also for 5-acetamido-β-tetralone[42] owing to the loss of the acetyl residue during the reaction and the tarring of the aminoketone produced. In the reduction of 6-bromo-2-naphthyl methyl ether[52] debromination occurs; sometimes dehydration takes place when there is an alcohol group in a side-chain[52]; with ethyl 6-methoxy--5-methyl-2-naphthoate[52] the nucleus which contains the ethoxycarbonyl group is reduced; simultaneously hydrogenation and esterification of the group occurs and 1,2,3,4-tetrahydro-2-hydroxymethyl-6-methoxy-5-methyl naphthalene is obtained:



6-n-Hexyl-β-tetralone[51] and 6-isopropyl-β-tetralone[54,55] were obtained by reduction by the Birch method. Among the merits of the method are the mild conditions (low temperature, no large excess of sodium); sometimes, however, the yield is worse[51] than by the Robinson–Conforth method.

Decomposition of epoxydihydronaphthalenes provides a rather simple method of obtaining compounds of the β-tetralone series, as epoxy-3,4-dihydronaphthalenes can be synthesised from α-tetralones:



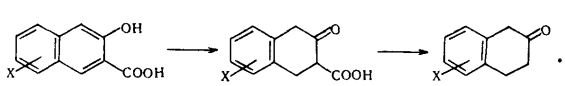
Hence a simple conversion from the readily available α-tetralones to the more difficultly accessible β-tetralones is provided. The following have been synthesised by this method: 6-methoxy-β-tetralone[56-61], 1-methyl-β-tetralone[62-65], 1-ethyl-β-tetralone[65], 1-phenyl-β-tetralone[66,68-71], 1-(2-biphenylyl)-β-tetralone[63,73], 5-methoxy-1-methyl-β--tetralone[63,74,75], 7-methoxy-1,6-dimethyl-β-tetralone[76,77], 7-isopropyl-6-methoxy-1-methyl-β-tetralone[78], 6,7-dimethoxy-1-methyl-β-tetralone[63], 5,8-dihydroxy-1-methyl--β-tetralone and its ethers at the hydroxyl group[79-81], 5,6-dimethoxy-1-methyl-β-tetralone[82], 5-isopropyl-6--methoxy-1-methyl-β-tetralone[83]. This is the best of all the known methods for synthesising 1-alkyl-β-tetralones.

The following oxidants have been proposed for the conversion of 3,4-dihydronaphthalenes into β-tetralone: peracids: perbenzoic[56-59,62,63,68,69,71,72,75-79,83], perphthalic[56,58,72,79], peracetic[60,61,66]; or a solution of hydrogen peroxide in acetic acid in the presence of ammonium molybdate[65,70]; and also inorganic oxidants: osmium tetroxide[79-81], Pb_3O_4 in acetic acid and lead tetra-acetate[63,64,67,73,74,79,82], or potassium permanganate in alkali[62]. Howell and Taylor[63] consider that the best results are given by perbenzoic acid.

After oxidation, ketones are often obtained directly[56-58,62,63,72,75,79], but sometimes an intermediate epoxide is obtained, which on decomposition (for example, by sulphuric acid) gives a diol, which is immediately dehydrated to a ketone[59,63,68,72]. The diols were isolated as diacetates when Pb_3O_4 in acetic acid was used for the oxiation; the diacetates were readily hydrolysed into ketones.

It is noted[65,66,70] that in the oxidation of dehydronaphthalenes by peracetic acid products of the oxidation of the hydrogenated naphthalene nucleus are formed as well as the ketone and diol.

Comparatively recently there was an interesting proposal of a new method for obtaining β-tetralone by reducing 2-hydroxy-3-naphthoic acid by sodium amalgam. It is found that substituted 2-hydroxy-3-naphthoic acids are converted, like the unsubstituted acid, into the corresponding β-tetralones:



6-Bromo-β-tetralone[84], 6-acetamido-β-tetralone[85], and 7-methoxy-β-tetralone[86] were obtained in this way.

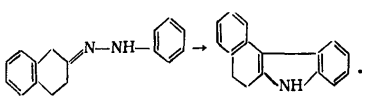
The method of indirect electroreduction differs favourably from the methods described above for preparing β-tetralones, by its mild reaction conditions. The substance to be reduced is treated in neutral or weakly acid medium (pH 6–7) at room or reduced temperature with very dilute sodium amalgam. Thanks to this even in the most complex instances, such as the preparation of halogenotetralones and acylaminotetralones, the reaction proceeds unambiguously and the substituted β-tetralones are obtained in good yields.

Other preparations of certain substituted β-tetralones have been described but have a partial nature and will not be described here. This relates to 1,1-dimethyl-β-tetralone[87,88], 1,3,3-trimethyl- and 1,3,3,7-tetramethyl-β-tetralones[89], 1-chloromethyl-1-methyl-β-tetralone[87], 1-dichloromethyl-1-methyl-β-tetralone[90], 5-bromo-7,8-dimethoxy--1-methoxycarbonyl-β-tetralone[91], 5,8-dimethoxy-β-tetralone[20,47], and 1,1,4,4-tetramethyl-β-tetralone[92].

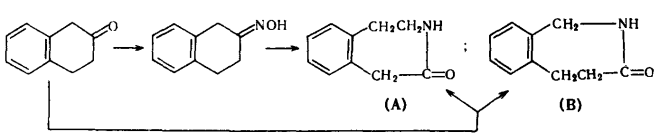
III. CHEMICAL PROPERTIES OF COMPOUNDS OF THE β-TETRALONE SERIES

β-Tetralone forms derivatives at the keto-group; the semicarbazone[8,12], phenylhydrazone[8,12], oxime[12,96], and 2,4-dinitrophenylhydrazone[28] have been described.

Some of these derivatives have been used in organic syntheses. Thus β-tetralonephenylhydrazone[93,94] and 5-, 6-, and 8-quinolylhydrazones[95] are cyclised by the method of Fischer into the corresponding dihydrobenzocarbazoles:



Knunyants and Fabrichnyi[96] carried out a Beckmann rearrangement of the β-tetralone oxime, and obtained the lactam (A):



In addition to this, lactams (A) and (B) were obtained[96] by the action of hydrazoic acid on β-tetralone.

The Beckmann rearrangement of the 1,1-dimethyl-β--tetralone and 1,1,4,4-tetramethyl-β-tetralone have also been studied[97].

β-Tetralone gives a crystalline bisulphite compound[1-3], but one is not formed (probably because of steric hindrance) when there is a basic substituent in position 1 of β-tetralone[17].

β-Tetralone forms an enol acetate when heated with acetic anhydride and sodium acetate[98].

The formation of a cyclic ketal with ethylene glycol has been described for 5-bromo-7,8-dimethoxy-1-methoxycarbonyl-β-tetralone[91].

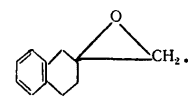
The keto-group in the compounds of the β-tetralone series is reduced after Kishner into a CH_2 group[43,99,100] and also into a hydroxyl group, by aluminium isopropoxide[101,102], lithium tetrahydroaluminate[41,92], and hydrogen over Raney nickel[33].

2,2-Dichloro-1,2,3,4-tetrahydronaphthalene is formed in the reaction of β-tetralone with phosphorus pentachloride.

The ketones of the β-tetralone series react with organomagnesium compounds[8,40,50,51,104,105] and organolithium compounds[106], and undergo a Reformatsky reaction[89,107,108] to form tertiary alcohols.

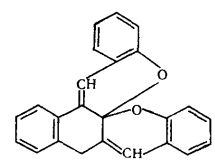
However, the yields in these reactions are usually low because the enols which are readily formed by β-tetralones decompose the organometallic compounds.

Mosettig and Burger[109] carried out the reaction of β-tetralone with diazomethane; ring expansion did not occur but an epoxide of the following structure was formed:

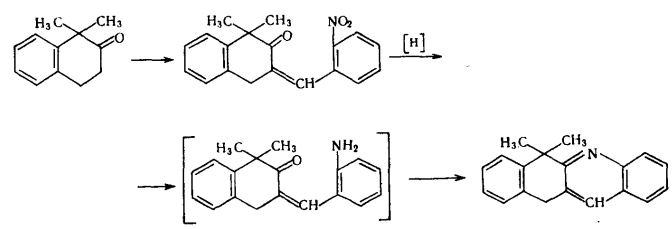


The authors did not isolate the reaction product, but its structure is confirmed by various transformations.

Braun and coworkers[8] condensed β-tetralone with aldehydes in alkali but could not isolate any definite product. Condensation proceeded normally in acid[110]; 1,3-dibenzylidene-β-tetralone and 1,3-disalicylal-β-tetralone (the latter in the form of a ketal) were obtained:



Cromwell and David[111] condensed 1,1-dimethyl-β-tetralone with *o*-nitrobenzaldehyde to synthesise substituted dihydrobenzacridines:

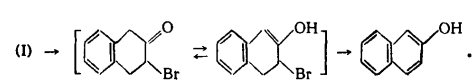


Condensation with aldehydes can be used to characterise substituted β-tetralones[106].

Braun and coworkers[8] studied the bromination of β-tetralone but did not establish the structure of the product. Soffer and coworkers[112] showed that on bromination in ether β-tetralone is dehydrated and forms 2-naphthol with a yield close to quantitative.

In chlorination, β-tetralone gives the stable 3-chloro--β-tetralone[102]; the same compound is obtained[103] by the decomposition of 3-chloro-1,4-dihydronaphthalene.

The formation of 2-naphthol in the bromination of β-tetralone becomes understandable when it is assumed that the first stage of the reaction is the formation of 3-bromo--β-tetralone, which is dehydrobrominated to form 2-naphthol:



The method of converting β-tetralones into 2-naphthols can be applied to a variety of β-tetralones substituted either in the aromatic or in the aliphatic nuclei of the molecule, dehydrogenation by bromine giving the best results [84-86,113].

The methods of studying the structure of compounds of the β-tetralone series have not been developed in the literature. The 2-naphthol derivatives formed in dehydrogenation by bromine have been rather fully described in the literature; therefore the method described above can be recommended for finding the structure of various compounds in the β-tetralone series.

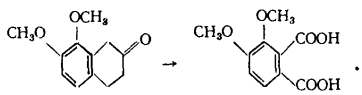
1,1-Dialkyl-substituted β-tetralones — 1,1-dimethyl-β--tetralone [114,115] and 1-(2-dimethylaminoethyl)-1-methyl--β-tetralone [100,116,117] — are brominated in position 3.

Einhorn and Lumsden [4] in oxidising β-tetralone with dilute nitric acid, obtained a dibasic acid to which was ascribed the structure of *o*-phenylenediacetic acid. However, Hückel and Friedrich [118] found that this compound is 2-(2-carboxyphenyl)propionic acid, that is, the bond between the first and second carbon atoms in the hydrogenated ring is broken.

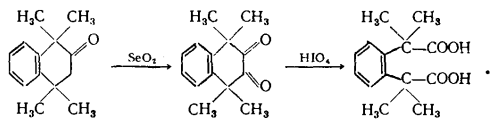
There are analogous results in the oxidation of β-tetralone by peracetic acid [119].

The formation of 2-(2-carboxyphenyl)propionic acid has also been observed in the vacuum distillation of β-tetralone in a stream of air [29].

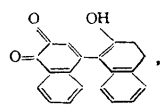
Oxidation under more drastic conditions completely destroys the hydrogenated ring; thus, on oxidation by permanganate in alkali 7,8-dimethoxy-β-tetralone gives the corresponding dimethoxyphthalic acid [38]:



The oxidation of 1,1,4,4-tetramethyl-β-tetralone has been described [120,121]; *o*-di-t-butyl benzene is obtained through *o*-phenylenedi-isobutyric acid:



On treating β-tetralone with alkali in the air it becomes intensely blue [12]. An analogous coloration is also produced in the presence of aliphatic amines [119]. The reaction is characteristic for all the β-tetralones unsubstituted in the first position [11]. The reaction is very sensitive and can be used to detect traces of β-tetralones. In studying this reaction, German investigators [110] showed that β-tetralone is rapidly oxidised in alkali by atmospheric oxygen, with the formation of 4-(3,4-dihydro-2-hydroxynaphth-1-yl)--1,2-naphthaquinone:



to which the blueness of the solution is due.

The Cornforths and Robinson [17] observed that β-tetralone is methylated in position 1 on heating with methyl iodide and sodium isopropoxide in isopropyl alcohol; by this method they obtained 1-methyl-β-tetralone.

The great ease of alkylation of β-tetralone compared with the aliphatic ketones explains its tendency to enolisation in alkali by conjugation of the double bond formed with the aromatic nucleus.

Subsequently similar reactions were studied both for β-tetralone and various substituted β-tetralones. Some think [91] that the process takes place in a single stage and that a mixture of products of 1-mono- and 1,1-di--alkylation is formed, this being difficult to separate. Some compounds, for example, 5-methoxy-β-tetralone [17,34] and 5,8-dimethoxy-β-tetralone [43] are methylated so readily that the monoalkylation product is not obtained at all, or is obtained in only insignificant quantities. The use of potassium t-butoxide [87,99,122] in this reaction improves the yield of monoalkylation products.

It is much more convenient to carry out the reaction not in alcohol, but in an inert solvent using as the base metallic sodium, potassium, sodium hydride, or sodium amide. By varying the molar ratio of the reagents it proved possible to introduce sharply one or two alkyl substituents, including also those instances when alkylation in alcohol was unsuccessful.

It is also possible to introduce two different radicals into position 1 of the β-tetralones, by performing the alkylation successively with different alkyl halides [106,116,123].

The following is the order of activity of the condensing media:

$$NaH \simeq NaNH_2 > K > Na \simeq t\text{-}C_4H_9OK > (CH_3)_2CHONa > CH_3ONa.$$

Carrying out the reaction in an atmosphere of inert gas is recommended, as β-tetralone in alkali is oxidised by air.

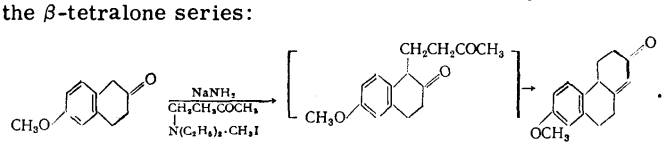
Examples of the alkylation of compounds of the β-tetralone series which have been described are given in the Table.

In recent years the Stork reaction has been used with success for the alkylation of β-tetralones — alkylation of the enamines of the β-tetralones [37,54,55,67,117,132-134]. 1-Alkyl-β-tetralones are obtained by this method in good yields and free from 1,1-dialkyl-β-tetralones as impurities.

Biquard [135-137] described the ultraviolet and Raman spectra of β-tetralone. The infrared spectra of some substituted β-tetralones have also been described. The relation between the structure and the infrared spectra of β-tetralones substituted in the aromatic and aliphatic nuclei of the molecule have also been studied [138].

IV. SYNTHESIS OF NATURAL PRODUCTS AND THEIR ANALOGUES ON THE BASIS OF COMPOUNDS OF THE β-TETRALONE SERIES

Crowley and Robinson [11] suggested a method of constructing phenanthrene systems by starting from compounds of the β-tetralone series:



Methyl vinyl ketone [73,79,139] and ethyl vinyl ketone [73,139] can also be used in this reaction.

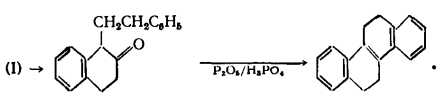
The synthesis opens great possibilities, as the most diverse substituted β-tetralones can be used in it. The

TABLE. Preparation of 1-substituted β-tetralone derivatives.

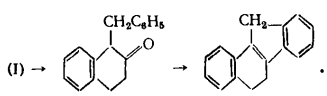
Initial ketone	Substituent introduced	Degree of substitution	Reference
β-Tetralone	methyl	mono-	17,67,123
	methyl	di-	48,87,115
	allyl	mono-	101,124
	benzyl	mono-	125
	m-methoxybenzyl	mono-	125
	phenethyl	mono-	59,125
	2-dimethylaminoethyl	mono-	126
	2-diethylaminoethyl	mono-	125,127
	2-piperidinoethyl	mono-	127
	3-piperidinopropyl	mono-	127
	2-methoxyethyl	mono-	126
	2-benzyloxy	mono-	104
	1-methoxycarbonylethyl	mono-	128
	2-ethoxycarbonylethyl	mono-	129
	3-methoxycarbonylpropyl	mono-	129
	3-cyanopropyl	mono-	129
	methoxycarbonylmethyl	di-	48,99
	cyanomethyl	di-	48
	2-methoxycarbonylethyl	di-	48
	2-ethoxycarbonylethyl	di-	99,129
	2-cyanoethyl	di-	99
	3-methoxycarbonylpropyl	di-	129
	3-cyanopropyl	di-	129
1-Methyl-β-tetralone	2-dimethylaminoethyl		100
	2-diethylaminoethyl		116
	2-ethoxycarbonylethyl		123
3-Methyl-β-tetralone	methyl	mono-	113
5-Methoxy-β-tetralone	methyl	mono-	34,35
	methyl	di-	17
	phenethyl	mono-	122,130
	3-methoxyphenethyl	mono-	122,130
6-Methoxy-β-tetralone	3-methoxybenzyl	mono-	125
	3-methoxyphenethyl	mono-	59,125
	2-ethoxycarbonylethyl	mono-	129
	3-methoxycarbonylpropyl	mono-	
	3-cyanopropyl	mono-	
7-Methoxy-β-tetralone	methyl	mono-	37
	ethyl	mono-	117
5,8-Dimethoxy-β-tetralone	methyl	mono-	43,131
	methyl	di-	43,131
7,8-Dimethoxy-β-tetralone	methyl	mono-	106
	ethyl	mono-	
	2-ethyl-1-methyl	di-	
7,8-Dimethoxy-1-methyl-β-tetralone	ethyl		106
7-Methoxy-1,6-dimethyl-β-tetralone	4-oxo-hexyl		76,77

phenanthrene group is present in extremely important natural products — steroids, the alkaloids of the morphine series, terpenes, resin acids. It is understandable, therefore, that the synthesis proposed by Robinson immediately aroused lively interest and work in this direction is continuing even now [34-37,43,54,55,63,67,74-78,80-82,123,126,134,139-142]. As a result of these investigations several complex natural compounds and their synthetic analogues have been obtained.

Salzer [59,143] used β-tetralone and 6-methoxy-β-tetralone for the synthesis of the tetracyclic chrysene system:

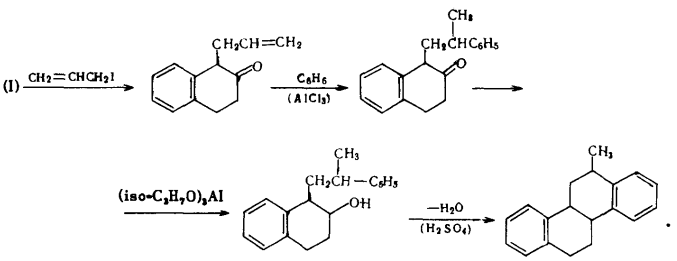


Pentacyclic systems can be obtained similarly by using naphthylethyl bromide for the alkylation [144]. Benzofluorenes have also been synthesised like this [143,145]:

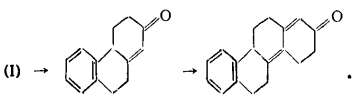


5-Methoxy-β-tetralone was alkylated with 2-phenylethyl bromide and 2-(*o*-methoxyphenyl)ethyl bromide and the compounds obtained were cyclised to chrysenes [122,130].

Indian investigators [101,124] propose an original method for synthesising chrysenes [101,124]:

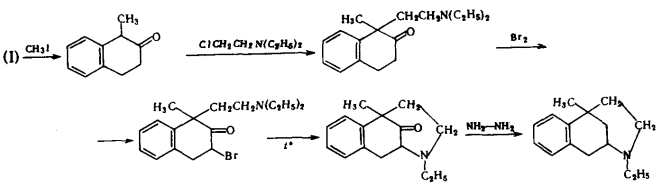


A method for obtaining tetracyclic compounds by successive repetition of the Robinson phenanthrene synthesis has been described [139,146,147]:



Among the compounds of the chrysene series which have been synthesised there are steroid analogues with a six-membered *D* ring and also carcinogenic substances.

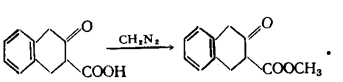
The compounds of the β-tetralone series have been used for building heterocyclic structures similar to morphine. A bicyclic analogue of morphine (benzomorphan) was thus obtained [116]:



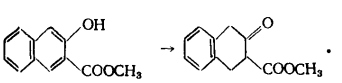
and then the tricyclic analogue [126]. May and coworkers have studied the chemistry of the benzomorphanes [100,105,117,148].

As is evident from what has been said above, various syntheses are based on the high reactivity of the hydrogen atoms in position 1 of the β-tetralone molecule. The first stage of a synthesis is usually the introduction of a substituent into this position of the molecule and then further substitutions are carried out.

The methyl ester of β-tetralone-3-carboxylic acid has recently become available, having been obtained for the first time by the authors of the present review [149]:



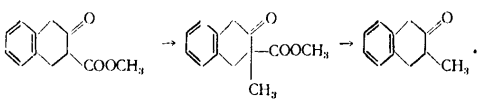
A convenient preparative method for obtaining this ester is the reduction of methyl 3-hydroxy-2-naphthoate with sodium and alcohol in liquid ammonia [150]:



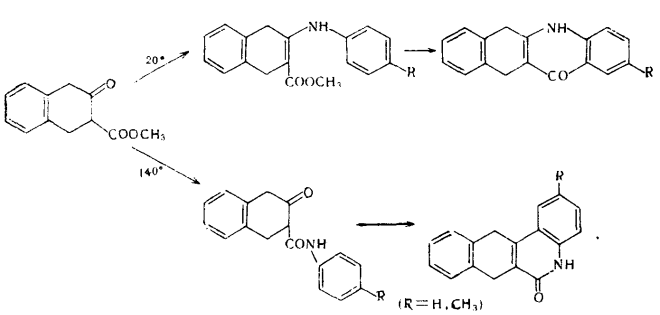
The methyl esters of the 6-bromo-, 6-acetamido-, and 7-methoxy-β-tetralone-3-carboxylic acids have been obtained from the substituted β-tetralone-3-carboxylic acids [84-86].

Pelletier and Parthasarathy [151] obtained 5-methoxy--β-tetralone-3-carboxylic acid and its methyl ester by treating 5-methoxy-β-tetralone with methylmagnesium carbonate. All these compounds contain a labile hydrogen atom in position 3 and therefore are of independent synthetic interest.

By the example of the simplest of these, methyl β-tetralone-3-carboxylate, Przhivalgovskaya and coworkers carried out a series of transformations. This ester was unambiguously methylated in position 3, which makes possible the simple preparation, after ketonic cleavage, of previously inaccessible 3-substituted β-tetralones [113]:



The condensation of methyl β-tetralone-3-carboxylate with aromatic amines [152] takes place at the carbonyl or the ester group according to the conditions. Further conversion of the condensation products allows them to be changed into complex heterocyclic compounds of the benzacridine and benzophenanthridine series containing a dihydronaphthalene nucleus.



The use of the esters of β-tetralone-3-carboxylic acid and the substituted acids for other synthetic purposes is very promising.

I. INTRODUCTION

The problems of the synthesis of polynucleotides are now attracting attention from scientists. Enzymes have been used to obtain deoxyribopolynucleotides [1] and ribopolynucleotides [2-5] of high molecular weight (from 30 000 to 2 000 000) and a random distribution of purine and pyrimidine bases along the polynucleotide chain, which have played an exceptionally important role in investigations which have been undertaken as the start of the study of the amino-acid code [6,7]. For several investigations there is a need for polynucleotides of definite composition and comparatively low molecular weight [8,9]. In studying the influence of the chain length of polyuridylic acid on the inclusion of phenylalanine in a cell-free yeast system it was found that the polyuridylic acid is active from the nonanucleotide onwards [10]. A sharp increase in the inclusion of phenylalanine was noted on going from U_8† to U_9 from U_{11} to U_{12} and from U_{14} to U_{16} (up to U_{22} studied), but for definite conclusions it was necessary to check the results on pure specimens of the polynucleotides.

† The nomenclature, abbreviations, and representation in diagrams corresponds to that generally accepted [11,12].

Preliminary experiments with hexauridylic acid having a terminal 3′-phosphate group showed that in a mixture with a high-polymer polyuridylic acid the hexanucleotide inhibits its activity by ~30% in relation to the synthesis of polyphenylalanine [13]. When hexauridylic acid is treated with dicyclohexylcarbodiimide (DCC) under conditions leading to the cyclisation of the 3′-monophosphate into the 2′,3′-cyclic phosphate, inhibition is not observed. An analogous effect, but with oligouridylic acids having a terminal 5′-phosphomonoester group was observed by Jones and coworkers [14]. The dependence of the synthesis of peptides of lysine on the length of the polyadenylic acid chain has also been noted [15].

Homopolynucleotides with different terminal groups are frequently used in work to determine the specificity of nucleases [16-18] and as formerly is of interest for determining the sequence of the purine and pyrimidine bases in the nucleic acids and in the investigations of enzymes which synthesise the nucleic acids [19].

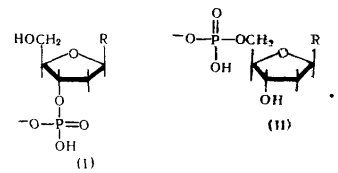
The availability of polynucleotide with a chain of known dimensions, known composition, and with known terminal groups should facilitate the study of systems which synthesise polypeptides, and apparently show the direction of further work on the synthesis of specific ribopolynucleotides of interest in the study of the amino-acid code [20]. The problems connected with obtaining such polynucleotides should also be solved by chemical methods of polynucleotide synthesis.

Chemical methods of synthesising polynucleotides are developing in two directions: (1) the stepwise synthesis of oligonucleotides, and (2) polycondensation. The stepwise synthesis of oligonucleotides recently formed the subject of a special review [21]. The present review will consider methods of synthesising polynucleotides by condensation‡ of mononucleotides or other "monomeric" units.

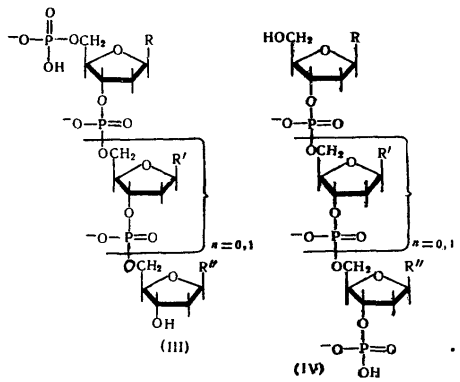
II. METHODS OF POLYMERISATION

1. Types of "Monomers"

It must be specially emphasised that in developing methods of synthesis of polynucleotides it must be taken into account that the polymeric chain should be formed by molecules of sugar (deoxy-D-ribose or D-ribose) joined by residues of phosphoric acid through the OH-group at the $C_{(3')}$ atom of one carbohydrate molecule and the OH group at the $C_{(5)}$ atom of another. In accordance with this requirement, the "monomers" for obtaining the polynucleotides can be derivatives of nucleotides of the following types: (a) for the deoxyribopolynucleotides series:

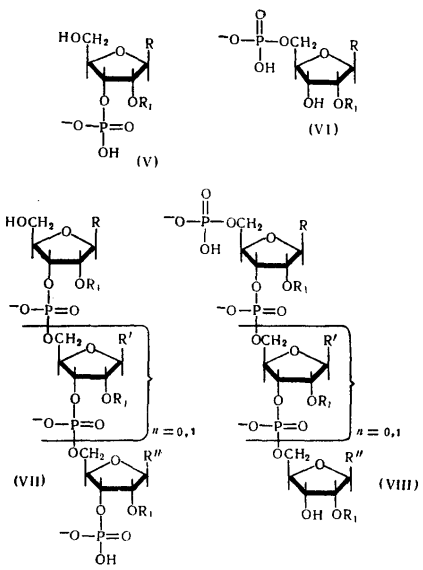


‡ Usually in the literature devoted to the problems of obtaining polynucleotides this method is inaccurately termed polymerisation; we will keep to this name subsequently as it is the most widely employed.



(III) (IV)

(b) for the ribopolynucleotides series:



(V) (VI) (VII) (VIII)

where R, R′, and R″ are purine or pyrimidine bases with protected amino-groups for adenine, guanine, and cytosine, and R_1 is acyl or alkyl. Of the types of monomer listed, the following have been used for the synthesis of polynucleotides:

(I) R = thymine [22-24].
(II) (a) R = thymine [25,26]; (b) R = *N*-benzoyladenine [27]; (c) R = *N*-anisylcytosine [28]; (d) R = *N*-acetylguanine [29].
(III) n = 0; (a) R = *N*-anisylcytosine, R″ = *N*-acetylguanine [12]; (b) R = thymine, R″ = *N*-benzoyladenine [30]; (c) R = *N*-anisylcytosine, R″ = thymine [31].
(V) (a) R = *N*-benzoyladenine, R_1 = acetyl [32]; (b) R = = uracil, R_1 = acetyl [13,33].

Khorana and coworkers [30] proposed to obtain a monomer of type (IV), but there has not yet been any work in this direction. Monomers of types (VI) and (VIII) cannot be obtained at present (there are still no methods which allow the hydroxyl group at the $C_{(2')}$ atom to be selectively protected when there is a free hydroxyl group at $C_{(3')}$). Monomers of type (VII) can be obtained but have not yet been described. There is only a brief reference [34] to the use of the following trinucleotides as a monomer: (1) (VII) with n = 1, R = adenine, R′ = guanine, R″ = cytosine, R_1 = = H; (2) (VII) with n = 1, R = adenine, R′ = guanine, R″ = = uracil, R_1 = H.

In addition to those listed, the starting materials for polymerisation have included nucleoside-2′,3′ cyclicphosphates [35], but monomers of this type form both $C_{(3')}$–$C_{(5')}$ and $C_{(2')}$–$C_{(5')}$ internucleotide bonds in polymerisation, therefore they are not of great interest (see below for details).

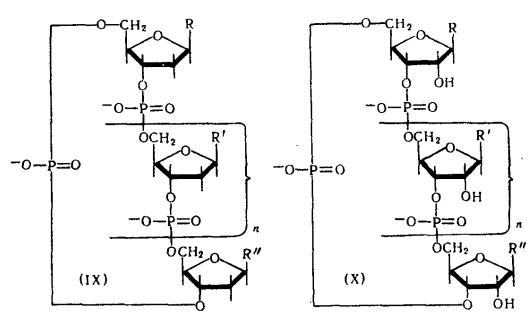
2. Conditions for the Polymerisation, Isolation, and Identification of Polynucleotides

The polymerisation of appropriate monomers is usually brought about by use of such activating agents as DCC [dicyclohexylcarbodi-imide (Ed. of Translation)][25], *p*-toluenesulphonyl chloride [25], diphenyl phosphorochloridate [36], tetraethyl pyrophosphate [34], enol phosphates [37], polyphosphates [38], etc. The analysis of mixtures obtained in polymerisation in the presence of the above substances shows that the most suitable activating agent is DCC, since with all the others the mixture is more complex. An attempt to obtain a more homogeneous reaction mixture by the carbodi-imide method, using di-isopropylcarbodi--imide, was not successful, since in the presence of the latter polynucleotides with a rather less degree of polymerisation are obtained [11].

Usually the polymerisation is carried out in anhydrous pyridine solution at room temperature for 4–7 days. The concentration of the monomer in the reaction mixture is 1 M, that of DCC up to 2.5 M. The mixture of polymers is usually subjected to dialysis and separated by chromatography on DEAE or ECTEOLA-cellulose and paper chromatography. The chain length is determined by enzymic splitting of the corresponding polynucleotide to the nucleoside-3′ phosphate and nucleoside with subsequent determination of their concentrations by the methods of paper chromatography and spectrophotometry, and also by direct comparison with specimens obtained by partial enzymic splitting of the corresponding polynucleotide of high-molecular weight [13].

It has been found that the reaction mixture is quite complex: it contains linear polynucleotides, cyclic polynucleotides, non-symmetrical pyrophosphates, nucleoside-2′,3′ or nucleoside-3′,5′ cyclic phosphates, 5′-*C*-pyridinium nucleoside-3′ phosphates, and also several unidentified side-products.

The linear polynucleotides — (III), n = 0–10; (VII), n = = 0–8 — contain a different number of nucleotide residues, depending on the initial monomer, but not more than 12 (linear polynucleotides of higher molecular weight are present in the reaction mixture but they were not identified):



(IX) (X)

where R, R′, and R″ are purine or pyrimidine bases.

The cyclic polynucleotides (IX) and (X) are formed in large amounts (up to 16–18%) (with increase in the chain length their proportion decreases) and for pyrimidine monomers cyclic dinucleotides — (IX), (X), $n = 0$ — are formed predominantly[25], whereas for purine monomers, the formation of cyclic trinucleotides — (IX), (X), $n = 1$ — is characteristic[27,29]. Mixed monomers — for example, (III)(b) — form cyclodinucleotides[12].

To suppress the formation of cyclic forms, attempts were made to find new conditions for polymerisation[26]. The derivative of another nucleotide which would be the start of polymeric chains incapable of cyclisation was added to the mixture being polymerised, more concentrated solutions were used, monomers were taken admixed with a derivative of the same nucleotide but having only one phosphate group free — for example; (1) pT + pT-OAc§ (3 : 1)[26]; (2) (d)-pC^{An} + (d)-C^{An}-OAc (3 : 1)[28]; etc. The use of such a mixture for polymerisation is especially desirable in the ribonucleotide series, since the nucleoside-3′ phosphates — monomers of type (V) — have a greater tendency to form intramolecular 3′,5′-cyclicphosphates[39], than the nucleoside-5′ phosphates which can be used as monomers in the polymerisation of deoxyribonucleotides. Thus the addition of 2′,5′-*O*-diacetyluridine-3′ phosphate to 2′-*O*-acetyluridine-3′ phosphate should suppress side-reactions owing to the acceleration of the formation of oligonucleotide chains having 5′-*O*-acetyl terminal groups[13]. However, these measures have not yet led to a significant change in the results (Table 1).

For the cleavage of pyrophosphates, which are also formed during the polymerisation, the reaction mixture is first treated with aqueous pyridine[13] and then with an excess of acetic anhydride in dry pyridine[40].

In extending the number of monomers it was shown that the standard conditions under which polymerisation is carried out are not always acceptable: in some instances the starting materials are insoluble in pyridine, in others the pyridinium salts formed during dissolution are precipitated. To avoid these difficulties, the medium used was a mixture of pyridine and formamide with Dowex-50 in the pyridinium form[29], a mixture of dimethylformamide and pyridine with Dowex-50 in the pyridinium form[12], or the monomer was changed into another, soluble form (for example, TppT was used instead of Tp)[22].

§ See the first note on p. 531.

Linear polynucleotides with a small degree of polymerisation (for example, up to hexa-) are isolated, as already noted, by use of ion-exchange chromatography on DEAE-cellulose in the carbonate or hydrogen carbonate form at pH 8–9, by eluting the corresponding fractions with triethylammonium hydrogen carbonate. Polynucleotides of higher molecular wieghts are purified by repeatedly chromatographing appropriate fractions on DEAE-cellulose in the chloride form and using linear gradient elution with solutions of lithium chloride or lithium acetate. The homogeneity of the polynucleotides obtained is confirmed by enzymic treatment and also by chromatography and electrophoresis on paper.

III. HOMOPOLYNUCLEOTIDES

1. Deoxyribopolynucleotides.

Polymers have now been obtained of all four fundamental deoxyribonucleotides. The greatest number of work relates to the production of thymidine polynucleotides. (I), (II)(a) and also TppT have been used as monomers[22]. The reagents which activate the monomers are DCC, trichloroacetonitrile[24], and diethyl 1-ethoxy-2-ethoxy-carbonylvinyl phosphate[23]. The best results were given by polymerisation of (II)(a) mixed with pT-OAc (3 : 1) in anhydrous pyridine in the presence of DCC (in Table 1).

The polymerisation of (II)(b) mixed with (d)-$pA^{Bz}OBz$ (3 : 1) and (II)(c) mixed with (d)-$pC^{Ac}OAc$ (3 : 1) under standard conditions (anhydrous pyridine, DCC, room temperature), with subsequent removal of the protective groups led to a mixture of polymers, of which the constituent with the highest molecular weight had a degree of polymerisation of 8 (higher members were not identified) (see Table 1). The use of this method for obtaining deoxyguanosine polynucleotides met with several difficulties[29]. The monomer (II)(d) was almost insoluble in dry pyridine. Some other protected derivatives of guanosine-5′ phosphate containing more lipophilic groups were therefore obtained: *N*-benzoyl-, *N*-naphthyl, and *N*-di-*p*-methoxytrityl-deoxyguanosine-5′ phosphate. Of these, the last compound is sufficiently soluble in anhydrous pyridine. However, its polymerisation under standard conditions did not gave satisfactory results: 55% of the original monomer, 8% of a dinucleotide, and only 12% of higher oligonucleotides were obtained. Other studies also showed that the size of the protective groups affects the formation of the internucleotide bond[31,41], therefore the derivatives obtained could not be used as monomers. An attempt was made to use for polymerisation salts of *N*-acetylguanosine-5′ phosphate and stronger bases (tri-n-decylamine), which are more soluble in pyridine than the pyridinium derivatives. As the use of DCC as a polymerising agent does not permit such strong bases as trialkylamines to be used[11,42], the salt mentioned was polymerised in the presence of *p*-toluenesulphonyl chloride.

However, the polymerisation mixture was very complex and many of its components could not be identified. The most successful was an attempt to polymerise (II)(d) mixed with dimethylformamide and pyridine by adding the pyridinium form of Dowex-50 to create the proton concentration needed for carrying out the reaction in the presence of DCC[11]. Nevertheless, deoxyguanosine polynucleotides could not be obtained pure and identified by the usual means, since on treating the polymerisation products with concentrated ammonia to remove the *N*-acetyl groups, polymers were obtained which form, according to the results of enzymic studies, high-molecular-weight aggregates with an ordered secondary structure[29,43]. Therefore subsequently the polymerisation mixture (without removal of the protective groups) was separated on a column of DEAE-cellulose in the hydrogen carbonate form under conditions which excluded the detachment of *N*-acetyl groups. Table 2 gives the results.

2. Ribopolynucleotides

The preparation of ribopolynucleotides is a more complex task because the corresponding monomers are less accessible and the reaction mixture contains more components.

Michelson[44] proposed to obtain ribonucleotides by using ribonucleoside-2′,3′ cyclic phosphates as the monomers. Preliminary work with glycerol-2(or 1) phosphate showed that on treatment of the monomer with diphenyl phosphorochloridate or tetraphenyl pyrophosphate[45], a polyglycerophosphoric acid is readily obtained through the intermediate stage of P^1-glycerol-2(1)-P^2-diphenyl pyrophosphate, which is rapidly converted into glycerol-1,2 cyclic phosphate. Similar treatment of adenosine-2′(3′) phosphate with diphenyl phosphorochloridate gives initially adenosine-2′,3′ cyclic phosphate[46], subsequent polymerisation of which leads to a polyadenylic acid with a chain length varying from that of a dinucleotide to polynucleotides containing up to 15 monomeric units.

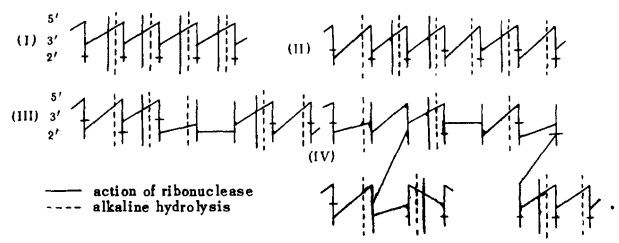
The method is easily extended to the synthesis of polymers of guanosine-2′(3′) phosphate, uridine-2′(3′) phosphate[47], pseudouridine-2′(3′) phosphate[36]. A similar polymerisation of cytidine-2′(3′) phosphate led to a polymer stable against treatment with alkalis and diesterases, and probably containing phosphoramide bonds between the 2′(3′)-phosphate groups and the 6-amino-group of the cytosine. Selective acetylation of the amino-group in cytidine-2′,3′ cyclic phosphate and treatment of the product with diphenyl phosphorochloridate followed by removal of the acetyl groups allowed polycytidylic acids with chains of various lengths to be obtained[36].

In addition polymers have been obtained from analogues of nucleotides, including *N*-methyluridylic, 5-bromouridylic, and 5-iodouridylic acids[48]. The mean chain lengths of the polymers thus obtained amounted to 10–12 nucleotide residues. Study of the properties of these polymers showed that they contain ~50% $C_{(2')}$–$C_{(5')}$ internucleotide bonds.

TABLE 2.

Polynecleotide	Yield, %
N-Acetylguanosine-dinucleotide	15.4
N-Acetylguanosine-trinucleotide	9.4
N-Acetylguanosine-tetranucleotide	5.2
N-Acetylguanosine-pentanucleotide	4.9
Higher	9.78
Cyclotrinucleotide	26.8

Schramm and coworkers[38] reported the preparation of polyadenylic, polycytidylic, polyguanylic, polyuridylic, and polythymidylic acids of high molecular weight (15 000–50 000). To avoid intramolecular cyclisation these authors recommend the use of reaction mixtures as concentrated as possible, by mixing the nucleotides to be polymerised directly with a viscous ester of a polyphosphoric acid. However, the work does not contain a direct proof that the polynucleotides formed contain only $C_{(3')}$–$C_{(5')}$ bonds. At the same time, Kochetkov and coworkers[49] showed that the condensation of a nucleoside-2′(3′) phosphate under the conditions specified can lead theoretically to the formation of compounds of the following types:



Polymers of type (I) should give only mononucleotides on treatment with ribonuclease, polymers of type (II), di- and oligo-nucleotides. Alkaline hydrolysis leads predominantly to mononucleotides with (II) and predominantly to mononucleotides with (III), only with (IV) do both enzymic and alkaline hydrolyses lead to a complex mixture consisting chiefly of oligonucleotides. The results of treating polynucleotides obtained by Schramm's method with ribonuclease and 2*N* KOH suggest that bonds of the non-native type predominate in these polynucleotides.

Khorana and coworkers obtained adenine[32] and uridine[13,33] polynucleotides by taking (V)(a) and (V)(b) as monomers. They treated a mixture of (V)(a) and *N*, 2′, 5′-triacetyladenosine-3′ phosphate (3 : 1) with DCC in dry pyridine by the standard method for 6 days and after the usual treatment (cleavage of the pyrophosphate bonds and removal of the protective groups), the product was separated on DEAE-cellulose (see Table 1). A mixture of (V)(b) and 2′,5′, *O*-diacetyluridine-3′ phosphate was polymerised in a similar way, and after repeated chromatography on DEAE-cellulose polynucleotides up to decauridylic acid inclusive were obtained in an individual state (see Table 1). However, many side-products remained to be identified. They probably contain chiefly two series of compounds: homologous oligonucleotides with 2′3′-cyclic phosphate terminal groups and with 3′-phosphate or 2′,3′-cyclic phosphate groups on one end of the chain and *C*-5′-pyridine group on the other. The presence of a large number of side-products in the polymeric mixture emphasises the additional difficulty of work with ribonucleotides.

IV. HOMOPOLYNUCLEOTIDES WITH DIFFERENT TERMINAL NUCLEOTIDES

Khorana and coworkers[26] have proposed a general method for obtaining homopolynucleotides having another nucleotide

TABLE 3.

at the 3′ end of the chain. The method consists of the addition to a monomer (nucleoside-5′ phosphate) of a completely substituted derivative of another nucleotide. In particular, a mixture of thymidine-5′ phosphate and *NO*-3′-diacetyldeoxycytidine-5′ phosphate was subjected to polymerisation under standard conditions. Table 3 gives the results.

In the same laboratory[12] it was proposed to obtain homopolynucleotides with a distinctive terminal nucleotide by treating the mixture after polymerisation of the nucleoside-5′ phosphate with the appropriate protected nucleoside having a free 3′-OH group, in the presence of a condensing agent. Thus a mixture of *N*-anisyldeoxycytidine polynucleotides immediately after polymerisation was treated with an excess of 5′-*O*-dimethoxytritylthymidine and DCC in anhydrous dimethylformamide. After removing the protective groups and chromatographing the mixture on DEAE-cellulose the results in Table 4 were obtained. Attempts to treat in a similar manner not a mixture of polymers but a purified oligonucleotide showed that best results are obtained in working with a mixture.

V. POLYNUCLEOTIDES WITH A RANDOM DISTRIBUTION OF PURINE AND PYRIMIDINE BASES ALONG THE CHAIN

Polynucleotides consisting of different nucleotide units with a random distribution of purine and pyrimidine bases were obtained by Michelson[47] from various mixtures of nucleoside-2′,3′ cyclic phosphates. However, the copolymers obtained are not of great interest, as they contain, in addition to the $C_{(3')}$–$C_{(5')}$ internucleotide bonds, ~50% $C_{(2')}$–$C_{(5')}$ bonds, and therefore we will not consider them in detail. The longest polynucleotide chain obtained in this way did not exceed 10–12 nucleotide units.

Mixed polynucleotides were also obtained by condensing a mixture of nucleoside-2′(3′) phosphates in the presence of a polyphosphate ester[49]. Table 5 gives information on the reagent proportions, reaction conditions, yields, and compositions of the polymers. As noted above, non-native bonds predominate in these polynucleotides.

VI. POLYNUCLEOTIDES WITH REGULARLY ALTERNATING PURINE AND PYRIMIDINE BASES

At present we know of only three works on the preparation of polynucleotides with regularly alternating bases. In the first, on the polymerisation of dinucleotides[30] the monomer was (III)(b). Interest in studying polynucleotides with such a sequence was stimulated by the knowledge that in some types of crabs there is found a DNA containing predominantly two of these nucleotides in alternating sequence[50-52]. The polymerisation of (III)(b) was carried out in the presence of DCC under standard conditions and after the usual treatment the results shown in Table 6 were obtained.

The study of the ultraviolet absorption (260 nm) as a function of temperature was made in the presence of 1 M NaCl (pH 7) and showed that the polynucleotides obtained have a secondary structure. It was preliminarily found that the dodecanucleotides and the fraction containing higher nucleotides act as seeds for the catalysable DNA-polymerase [DNA nucleotidyltransferase (Ed. of Translation)] synthesis of large T-(d)-A copolymers.

The polymerisation of (III)(a) was effected in a mixture of dimethylformamide, pyridine, and the pyridinium form of Dowex-50 in the presence of DCC. The resulting mixture, after the standard treatment, was separated on DEAE-cellulose in the presence of 7 M urea[53]. It should be noted that in both instances a large amount of a cyclodinucleotide is formed and the degree of polymerisation is not high (Table 7).

Finally, Schramm and coworkers recently published a brief communication[34] on the polymerisation of ApGpCp and AdGpUp in ethyl tetrametaphosphate and trisdimethylaminophosphate. The polymers were separated on Sephadex G-75. Information was not given about the composition of the mixture, degree of polymerisation, etc.

In conclusion, it must once again be emphasised that the methods of chemical synthesis of polynucleotides are now at present quite imperfect and require improvement and further development. In particular, one of the principal

TABLE 5.

Reagents				Reaction conditions		Yield of polymer, %	Composition of bases (A/C or A/U)

(d)-(pCpG, O, pCpGpCpG)	3.43
(d)-pCpGpCpGpCpG + higher + + pyrophosphates	8.75

deficiences in the method is that despite many attempts, it has so far proved impossible to obtain and isolate polynucleotides containing more than 12 nucleotide residues and the yield of the longest of the identified polynucleotides does not exceed 1–2%. In this connection the main tasks of the chemical synthesis of polynucleotides consists in increasing the degree of polymerisation and yield of polymers and also in the development of methods of separating the high-molecular-weight oligonucleotides. It is quite probable that a more careful study of the kinetics and thermodynamics of the polycondensation reactions, a choice of new condensing agents, and the introduction into the "monomer" of more active groups which participate in the reaction are needed. A new approach to the chemical synthesis of polynucleotides should make available polynucleotides with a known succession of purine and pyrimidine bases in the polynucleotide chain, which is known to be impossible in the enzymic synthesis of polynucleotides. This allows the solution on the molecular level of the problems connected with the structure and functions of the nucleic acids, the mechanism of protein synthesis, etc.

† Lecture delivered before a Liège meeting of the Belgian Chemical Society and a Cracow meeting of the Polish Chemical Society.

1. INTRODUCTION

In the present lecture I shall endeavour to discuss the electronic theory of catalysis from the point of view of the experimentalist who wishes to apply its results rather than from the point of view of the theoretician who is contributing to its development. I shall be talking of the experimental material on which the theory is based: that which has given rise to the theory and that which, in turn, stems from the theory.

Some simple relationships exist in general (and in the field of catalysis, in particular) between physical theory and experiment which can be expressed by the trite statement that theory divorced from experiment is effectively meaningless whilst experiments lacking a theory are blind. Experiment is the fertile soil in which theory can grow; theory, like a theatrical spotlight, throws light on experiment.

The electronic theory of catalysis has a twofold aim: on the one hand, to reveal the elementary mechanism of the catalytic act and at the same time to discover the relationship between the chemisorption and the catalytic properties of a surface, and on the other hand to relate those characteristics to the electronic properties of the crystal as a whole. The electronic theory of catalysis does not, in general, conflict with other contemporary theories of catalysis: it differs from them only in its approach to the problem. It is concerned with the elementary (electronic) mechanism of the phenomenon, and it tackles problems in catalysis from just this point of view.

The electronic theory of catalysis proved to be the gate through which contemporary solid state theory and the theory of the chemical bond, together with their associated quantum mechanics and quantum statistics, were able to enter the field of catalysis. The history of science has no comparable examples to offer of an invasion by physics of the territory of chemistry. Consider, for instance, the theory of the chemical bond, which even 50 years ago consisted of nothing more than dashes denoting valencies. Quantum mechanics has given those dashes a physical content, thus uncovering the physical nature of chemical forces.

We can distinguish two aspects of the interplay between the electronic theory of catalysis and experiments, which the present article aims to discuss.

Firstly, the theory provides an explanation of known experimental facts. These can be *old* facts, fitting more or less well into old theories, on which the electronic theory throws new light. Or they can be *new* facts, transcending the scope of the older theories, and deriving some theoretical interpretation, for the first time, from the electronic theory.

Secondly, the electronic theory leads to a number of experimental predictions. Like any other theory, it contains explicit or implicit rules and relationships which can be (and should be) identified and tested experimentally.

It is useful and interesting to gather together and analyse the basic experimental material which is satisfactorily interpreted by means of the electronic theory and which can therefore be entered on the credit side.

At the same time, it is particularly interesting to collect and analyse all the corollaries of the electronic theory still awaiting experimental confirmation. Such is the aim of the present paper.

This paper is divided into three sections of unequal length and importance: (1) first of all we shall deal (rather briefly) with some well known experimental facts on which the electronic theory has thrown new light; (2) we shall then list (again, rather briefly) some predictions of the electronic theory which have already been confirmed; (3) lastly, and this will form the major part of the paper, we shall attempt to summarise those theoretical predictions still awaiting experimental confirmation.

2. SOME OLD FACTS IN A NEW LIGHT

a. "Induced" Non-Uniformity

When discussing well-established experimental facts to which the electronic theory has given new meaning one should mention first of all the reluctance of real surfaces to show Langmuir adsorption behaviour.

Classical theory copes with this fact by introducing the concepts of surface non-uniformity or interaction between adsorbate particles. The electronic theory introduces yet a third alternative: a special kind of "interaction, transmitted through the electron gas, which enables each chemisorbed particle to experience the presence of all the others despite the absence of direct force interactions[1,2]. This effect arises because the properties and the nature of the bond between each individual particle and the surface are determined by the state of the whole system of adsorbent + adsorbate. We are also dealing with a special kind of "non-uniformity", because at any given time particles of a single kind form different types of bond with the surface. This is the effect to which Boudart recently applied, rather unsuccessfully, the term "induced non-uniformity".[3]

Allowing for this special kind of "interaction" or of "non-uniformity" — the two concepts are equivalent in this context — brings the Fermi level[4] into the expression for the differential heat of adsorption q. Thus, it follows from the electronic theory that[1]

$$q = q^0 - kT \ln (1 - \eta), \tag{1}$$

where q^0 is the binding energy between a chemisorbed particle in its electrically neutral state and the lattice of the adsorbent, and η is the proportion of the charged form of chemisorption on the surface. The quantity η is of the form

$$\eta = \frac{1}{1 + \exp [\pm (\epsilon_s - v)/kT]}, \tag{2}$$

so that, substituting (2) into (1), we arrive at the following expression for q:

$$q = q^0 + kT \ln \{1 + \exp [\mp (\epsilon_s - v)/kT]\}. \tag{3}$$

The significance of the symbols adopted here is clear from Fig. 1, showing the energy diagram for a semiconductor, on which FF denotes the Fermi level and A is the localised surface level associated with an adsorbed particle. In formulae (2) and (3) we must choose the upper or the lower sign according to whether the adsorbed particle is an acceptor or a donor. If $\eta = 0$, that is, if all the particles are in the same (electrically neutral) state, Eqn. (1) gives $q = q^0$ (the classical result).

The Fermi level ϵ_s, as well as the heat of adsorption q, enters into the isotherm equation

$$\theta = \frac{1}{1 + (b/p) \exp (-q/kT)}, \tag{4}$$

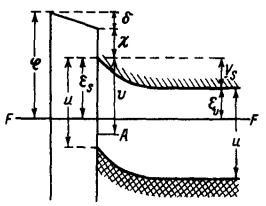

Fig. 1.

where q has the form of (3). Of course, the position of the Fermi level at the crystal surface, ϵ_s, is itself a function of the degree of coverage of the surface, θ:

$$\epsilon_s = \epsilon_s(\theta). \tag{5}$$

Thus, Eqn. (4) is still not an isotherm equation, because it does not explicitly contain the variation of θ with p. By solving Eqn. (4) for θ we obtain various non-Langmuir isotherms (corresponding to different approximations) which agree with experimental observations. This was done by Kogan and Sandomirskii[5] as long ago as in 1959.

In this way, the electronic theory leads to non-Langmuir isotherms for surfaces which are uniform (in the classical sense) and in the absence of interactions between adsorbed particles (again, in the classical sense).

b. Physical Nature of the "Distribution Function" in the Theory of Non-Uniform Surfaces

"Induced non-uniformity", a concept typical of the electronic theory, does not, of course, prelude surface non-uniformity of the usual type. The phenomenological theory of adsorption at a non-uniform surface developed by Roginskii's school[6] can be fitted, in its entirety, into the electronic theory. Furthermore, some of the concepts acquire a new significance thereby. We can take as an example the concept of a "distribution function", fundamental in Roginskii's theory yet lacking physical significance in that theory, which serves to characterise the non-uniformity of a surface.

Consider a surface which is "non-uniform with respect to the heat of adsorption q". This means that the surface consists of different areas characterised by different values of q. The "distribution function with respect to the heat of adsorption q" which we shall denote by $F(q)$, where q varies over some interval between q_{min} and q_{max}, gives the fraction of the surface characterised by a given value of q. By definition

$$F(q) = ds/dq, \tag{6}$$

where ds is the fraction of the surface for which q lies between q and $q + dq$.

If ϵ_s varies over the surface, the latter will have, according to Eqn. (3), a non-uniform behaviour with respect to the heat of adsorption q even if the binding energy q^0 is constant for all points on the surface. We must remember that the value of ϵ_s, that is, the depth of the Fermi level below the conduction band in the plane of the surface, is determined by the concentration of impurities at the surface and in the bulk of the crystal. Therefore ϵ_s will vary from point to point of the surface if the impurities in the crystal are not homogeneously distributed, that is, whenever a concentration gradient of impurity exists along

the surface — the impurity can be of one and only one given kind, and does not itself take part in the act of adsorption: the only requirement is that it must be distributed non-uniformly.

For each arrangement of the impurity there will be a corresponding "distribution function" $F(q)$. In this way, the "distribution function" acquires some physical meaning. The problem was recently discussed by Peshev and the present author[7]. We shall list, as an example, some of their results.

The first example concerns the distribution function

$$F(q) = ds/dq = \text{const}, \quad (7)$$

that is, a uniform distribution of the elements of surface with respect to heat of adsorption, which can be realised by a gaussian arrangement of the impurity along the surface (around any point taken as the origin):

$$N(r) = C\exp(-r^2/r_0^2), \quad (8)$$

where $r = \sqrt{x^2+y^2}$, the coordinate axes x and y lying in the plane of the surface, and N being the concentration of impurity at the surface.

Second example. An exponential distribution function

$$F(q) = ds/dq = \alpha\exp(-\beta q) \quad (9)$$

is obtained when the impurity arrangement is parabolic:

$$N(x) = C(x - x_0), \quad (10)$$

where β and γ are uniquely related.

Thus, the various non-uniform arrangements of the impurity give rise to various "distribution functions". This is a possible interpretation of the "distribution function", but not the only possible one.

c. Active Centres

Another concept very widely used in the study of catalysis, and physically even less understood than the "distribution function" in the theory of adsorption at non-uniform surfaces, is the concept of "active centres". The term refers to specific points on the surface which support the catalytic reaction, in contrast to the remainder of the surface, which is catalytically inert.

The notion of "active centres", without specifying their physical meaning, is all that is required to construct a phenomenological theory of catalysis. This leaves obscure, however, the physical nature of such active centres. In Kobozev's theory of ensembles the active centres are identified with various combinations of catalyst atoms (pairs, groups of three, etc.), the catalyst being deposited as an amorphous phase on a catalytically inert substrate. A. A. Balandin's multiplet theory dispenses with this concept altogether. However, as a rule the concept of "active centres", devoid of any concrete physical significance, is widely adopted by students of catalysis.

According to the electronic theory[1], the catalytic activity of a surface is determined by the fraction of the total number of chemisorbed molecules which is found to be in a reactive state. The reactive molecules are those in the form of radicals or radical-ions, unlike the valency-saturated molecules, which are considered to be unreactive to a first approximation. As in other theories of catalysis, "active centres" are invoked: a molecule is in a reactive state when it is adsorbed at an "active centre". It is the binding to the "active centre" which makes the molecule reactive.

In the electronic theory, free (unsaturated) surface bonds play the role of "active" centres. These include valencies freely wandering along the surface, pointing from the surface into the bulk of the crystal, and pointing from the bulk towards the surface. Alternatively, the free valencies can be fixed (localised) at various structural defects of the surface. It can be shown that free electrons and holes in the crystal lattice play the role of unsaturated valencies. Thus, these entities fulfil the function of "active centres" in the electronic theory.

Having adopted this model for the "active centres", we should be able to predict some of their properties. Generally speaking, the centres are not immobile: they wander along the surface until they encounter chemisorbed molecules to which they become bound. This causes localisation of the centres. At the same time, the binding of the molecule to the surface becomes stronger, and the molecule is converted into a radical-ion and becomes reactive. Alternatively, the "active centre", having spent some time bound to the molecule, can break free and resume its wandering along the surface. When this happens the molecule left on the surface loses its reactivity and reverts from the radical-ion to the valency-saturated (and therefore electrically neutral) state. The concentration of "active centres" of this type on the surface is not fixed: they can be supplied from the bulk of the semiconductor (or, conversely, they can be adsorbed into the bulk) both during catalyst preparation and in the course of the reaction.

Thus, the idea of "active centres" acquires a concrete physical meaning in the electronic theory, and this clarifies their properties and their mode of operation.

d. Reversible and Irreversible Form of Chemisorption

As a further example of the way in which old facts acquire a new meaning in the light of the theory we shall consider the problem of the reversible and the irreversible form of chemisorption: the coexistence of both these forms appears to be characteristic of semiconductors.

From the point of view of the electronic theory, particles chemisorbed at a semiconductor surface can be either in an electrically charged or in an electrically neutral state. Under conditions of electronic equilibrium the relative amount of each kind is strictly fixed. However, electronic equilibrium can be disturbed in a number of instances. It is never achieved in the early stages of adsorption, and it can be destroyed during desorption. This type has been examined in detail in a recent paper by Peshev and the writer[8].

In this system, only the neutral form of chemisorbate, effectively, leaves the surface. Only later, as they become discharged, do the particles in the charged state vacate the surface. In this way, slow electronic transitions can inhibit the desorption process. If desorption of the charged form is sufficiently slow, it can be treated as irreversible. A significant increase of temperature is needed to remove the adsorbate completely from the surface.

Thus, the neutral and the charged form of chemisorption can, under certain conditions, behave as the reversible and the irreversible form respectively. This also

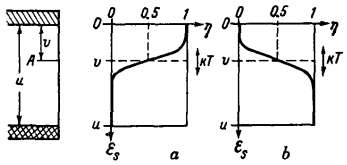

Fig. 2.

explains the occurrence of the two forms of chemisorption: it is one possible (but not the only possible) mechanism for the appearance of the two forms of chemisorption so familiar to the experimenters.

To conclude this section, we shall note that the coexistence of neutral and charged chemisorption forms on the surface is one of the crucial conclusions of the electronic theory. We must always remember, however, and this remark applies particularly to experimentalists attempting to "confirm" or "refute" the electronic theory, that under a given set of conditions practically the whole of the particles chemisorbed on the surface will be found in the neutral state (or alternatively in the charged state). Instances in which both forms are present in comparable amounts are quite rare.

This should be clear from Fig. 2, which shows, on the basis of Fermi statistics, the variation of the fractional amount of the charged form, η, with the position of the Fermi level, ϵ_s, under conditions of electronic equilibrium for acceptor particles (Fig. 2*a*) and for donor particles (Fig. 2*b*). A is the localised level due to the chemisorbed particles. We can see that the quantity η differs appreciably from zero or from unity only when the Fermi level lies fairly close to the level A (within a distance smaller than or of the same order as kT).

Thus, it is possible to convert the neutral (reversible) form of chemisorption into the charged (irreversible) form or vice versa by shifting the Fermi level, that is, by varying the conditions or the previous history of the sample.

3. SOME PREDICTIONS WHICH HAVE BEEN CONFIRMED

a. Relationship between Catalytic Activity and Electrical Conductivity

Turning now to the predictions of the electronic theory which have already been put to experimental test, we must, of course, point out first of all the relationship between the catalytic activity and the electrical conductivity of a semiconductor. The correlation between these two characteristics was predicted theoretically[9] as early as in 1950, when no experimental work of any kind existed in this field.

At the present time we can refer to a whole series of researches in which this correlation has been experimentally observed: many workers have measured the electrical conductivity and the catalytic activity of differently treated samples, and have observed a direct or an inverse relation between these two characteristics of the semiconductor on going from sample to sample.

We shall not enumerate all these investigations: they are quite well known. We shall only refer to a few of them to illustrate the point. Keier and coworkers[10] studied the oxidation of carbon monoxide on specimens of nickel oxide containing different amounts of lithium added as an impurity. They established an unmistakable inverse relationship between activity and electrical conductivity: the higher the initial conductivity, the lower was the activity of the material. Rienäcker[11] studied the decomposition of dinitrogen monoxide on the same semiconductor, nickel oxide, doped with different amounts of aluminium. He found that the electrical conductivity and the activity varied in the same sense. The same result was obtained by Heckelsberg and coworkers[12] in their study of the hydrogen–deuterium exchange reaction on zinc oxide containing various impurities.

b. Relationship between Catalytic Activity and Work Function

The thermionic work function is another parameter which physically characterises a semiconductor and which, according to the electronic theory, should be related to the catalytic activity even more directly than the electrical conductivity.

The electrical conductivity is determined by the value of ϵ_v (the depth of the Fermi level below the conduction band in the bulk of the crystal, see Fig. 1), whereas the adsorption properties and the catalytic activity are determined by the quantity ϵ_s (the depth of the Fermi level at the surface). There is a definite relationship between ϵ_v and ϵ_s, but this can often be distorted or obscured, thus upsetting the correlation between electrical conductivity and activity. On the other hand, the work function φ (see Fig. 1), ignoring the dipole contribution δ and to the accuracy of the constant term χ, is equal to ϵ_s by definition ($\varphi = \epsilon_s + \chi + \delta$). It is therefore unequivocally related to the adsorption properties and to the catalytic activity.

A correlation between catalytic activity and work function, that is, a variation in the same or in the opposite sense between these two quantities, was predicted in theoretical papers[2] published in 1948–1950. Many papers published since that date have described experimental confirmations of this theoretical prediction: we shall not attempt to list them comprehensively here. Two examples will suffice. Margolis and coworkers[13], in their study of the oxidation of propene on copper(II) oxide doped with various impurities, observed an inverse relationship between activity and work function: the materials with the lowest work function were the most active in causing complete oxidation. A similar correlation was found by Zhabrova and coworkers[14], who investigated the dehydrogenation of isopropyl alcohol on variously doped specimens of zinc oxide.

c. Changes in Work Function and Electrical Conductivity upon Adsorption

When discussing the relationship between the work function and the electrical conductivity of a semiconductor on the one hand, and between the work function and the adsorption properties and catalytic activity on the other hand, we often have in mind the changes in work function and electrical conductivity induced by adsorption itself, or occurring in the course of a catalytic reaction, rather than just a correlation between these two quantities among a number of differently prepared samples. The effect is caused by

the charging of the surface upon adsorption, leading to a shift of the Fermi level and a change in the concentrations of free electrons and holes in the layer of semiconductor immediately below the surface.

The charging of adsorbed particles resulting from the localisation of free electrons or holes from the crystal lattice onto those particles, was demonstrated theoretically as long ago as in 1948–1951 [2,9,15]. The effect has now been studied experimentally in fair detail on a variety of systems. Experimentalists often use it to establish the nature (acceptor, or donor) of the adsorbate when the nature of the adsorbent is known (n- or p-type semiconductor). It can also be used to establish the nature of the adsorbent if the nature of the adsorbate is known.

We shall not attempt to review all these experimental investigations. They are very numerous, and quite well known. Indeed, we must beg the indulgence of the readers for dwelling on familiar material in this section of the paper.

d. The Photoadsorption Effect

The photoadsorption effect must be mentioned among those instances in which theory did not follow experiment, but rather led the way. The effect can be positive or negative: an increase or a decrease in the adsorption properties of the material under the influence of light. It was discovered, and originally investigated, by Terenin and coworkers, and by Hedwall, in the 1930's. However, the factors which determine the sign of the effect remained obscure for many years.

The first attempts [4] to set up a theory of the photoadsorption effect, in 1958, showed that the sign of the effect depends, under otherwise constant conditions, on the previous history of the specimen, and can be changed by suitable pretreatment. Shortly afterwards, Fujita and Kwan [16], working in Japan, were able to demonstrate sign inversion for oxygen on zinc oxide by controlling the departure from stoichiometry of the sample.

Further theoretical work by the writer and Karpenko [17] showed that the sign of the effect is determined by the position of the Fermi level within the crystal, ϵ_v, and by the bending of the bands, V_s (see Fig. 1). Fig. 3, reproduced from that paper [17], shows the region of possible values of ϵ_v and V_s compatible with a Boltzmann distribution of free carriers throughout the crytal for acceptor particles on an n-type semiconductor (for example O_2 on ZnO). The straight line AA divides this region into areas of positive and negative effects, denoted by different cross-hatching on the Figure. The segment v (compare Fig. 1) indicates the position in the energy spectrum of the crystal of the localised surface level corresponding to the adsorbate particles of the kind being considered; the segment V_s characterises the initial bending of the bands, existing in the absence of any adsorbed particles on the surface and therefore caused by surface states arising otherwise than by adsorption; u denotes the width of the forbidden gap between the bands. It is evident that we can pass from the region of positive to the region of negative photoadsorption effect, and vice versa, by shifting the Fermi level ϵ_v, or by changing the band bending V_s, or by changing both parameters at the same time.

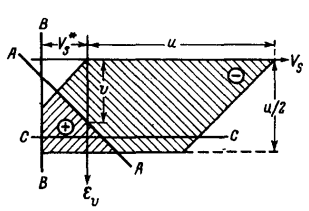

Fig. 3.

In the light of this theoretical prediction, it is relevant to mention some recent results obtained by Kwan [18], who studied the effect by investigating the adsorption of oxygen on zinc oxide containing lithium or aluminium. In the former a positive effect was observed, in the latter a negative, as was indeed to be expected on the basis of Fig. 3, since the replacement of an acceptor impurity (lithium) by a donor (aluminium) must always move the Fermi level upwards. Referring to Fig. 3, we see that this may cause a transition from the region of positive photoadsorption to the region of negative photoadsorption.

Also in agreement with Fig. 3 are some recent results of Haber and Kowalska [19], who investigated the same system (oxygen on zinc oxide). Oxidation of the surface was found to change the effect from positive to negative, as required by Fig. 3. This is because oxidation of the surface is accompanied by an increase in V_s, which causes a shift from left to right in Fig. 3 (for example, from the positive effect towards the negative effect region).

e. The Electroadsorption Effect

We shall consider one other phenomenon predicted theoretically in 1958 and experimentally observed only very recently. This is the phenomenon for which we have suggested the term "electroadsorption effect".

The theory leads us to expect a change in the adsorption properties of a semiconductor upon application of an external electric field normal to the adsorbent surface. This effect, resulting from the displacement of the Fermi level under the influence of the field, was computed by Sandomirskii and the writer [20] for a semiconductor located between two condenser plates and therefore retaining electrical neutrality when the field is applied. For the field effect technique, when the semiconductor under study acts as one of the electrodes and acquires an induced charge upon application of the field, the calculation was carried out by the writer in cooperation with Baru [21].

The field effect method, though widely used in semiconductor studies and ideally suited to the investigation of the role of electronic factors in chemisorption and catalysis, is only just beginning to make its first tentative steps in catalysis laboratories, owing to a number of specific practical difficulties. Thus, the use of single crystals (which is the rule in field effect experiments) makes it difficult if not altogether impossible to carry out direct adsorption measurements. The extent of adsorption has to be inferred indirectly from the change in surface conductivity. The electrical charge in the gas phase, which appears at not too low pressures and high enough fields, is another complication. Great care is needed to ensure that the new effect being sought is not confused with trivial electrochemical effects.

Among the experimental studied we can single out that of Lyashenko and coworkers[22], and also that of Mikheeva and Keier[23], who actually observed the expected change in the adsorption properties of the surface under the influence of an external electrical field (adsorption of acceptor and of donor gases on germanium). The former used a direct adsorption method (by monitoring pressure changes in the adsorption volume), the latter relied on changes in electrical conductivity.

4. SOME PREDICTIONS STILL AWAITING CONFIRMATION

We have now reached the final, yet the most important, section of the paper. We shall examine a numer of predictions implicit in the electronic theory which have not yet been fully formulated, or subjected to experimental test.

a. Role of an External Electric Field

We must deal first of all with the phenomena stemming from the influence of an external electric field on the properties of the surface.

The field effect method, already considered above, can be used as a new and very sensitive procedure for determining the surface coverage of the charged form of chemisorption, and can also be used to measure adsorption on single crystals. The electric circuit for the field effect method is shown in Fig. 4*a*: the current i is measured as a function of the field strength E. The specimen is shown cross-hatched in Fig. 4*a*.

Fig. 4*b* shows some typical field effect curves (variation of the surface conductance σ with E). The heavy line corresponds to a specimen in a vacuum: the thin line corresponds to the same specimen in a gaseous medium (the diagram refers to conditions when the adsorbent is an n-type semiconductor and the adsorbate behaves as an acceptor). Assume that we are at point A on the heavy curve; admission of gas takes us to point B, showing a fall in conductance from the initial value σ_0 to σ_1. We now change the field by an amount ΔE (from E_0 to $E_1 = E_0 + \Delta E$), in such a way as to travel along the thin curve from point B to point C. This restores the conductance to its initial value σ_0.

From the value of ΔE we can arrive at the amount of charge gained by the surface as a result of adsorption. We have

$$\Delta E = -(4\pi e/\varkappa) N^-, \qquad (11)$$

where N^- is the surface concentration of chemisorbed particles which are in the uncharged state, e is the absolute value of the electronic charge, κ is the dielectric constant of the gaseous medium.

Thus, from the "compensating" field ΔE and from the dependence of ΔE on E_0 we can determine both the surface coverage by the charged form, N^-, and the "electroadsorption effect", that is, the change in the above coverage brought about by the external field (N^- as a function of E_0):

$$N^- = N^-(E_0).$$

This simple "compensation method" is the most direct way of measuring the effect of an external field on the adsorption properties of the surface.

As regards the effect of the field on the catalytic activity (acceleration or inhibition of the catalytic reaction by the applied field), an effect for which we propose the name "electrocatalytic effect", it also follows from the theory and for the same reasons, but it still remains a theoretical prediction awaiting experimental confirmation. Experimental studies of the effect of an external field on the chemisorption and catalytic properties of a semiconductor surface are only just beginning. We may hope that they will expand in the coming years.

b. Role of a Magnetic Field

A magnetic field should have an effect similar to that of an electric field. Consider a plane-parallel slab of a semiconductor to which are simultaneously applied an electric and a magnetic field, parallel to the adsorbing surface but mutually perpendicular (see Fig. 5). Due to the Hall effect one of the surfaces will be depleted of current carriers whilst the other is enriched by the same factor. As a result, the adsorption capacity of the specimen as a whole becomes greater, as we shall proceed to show.

Let N_0 be the concentration of chemisorbed particles on each of the surfaces in the absence of a magnetic field, and ΔN_1 and ΔN_2 be the increments caused by the magnetic field on the two adsorbing surfaces respectively. As can readily be shown[21] we have

$$\left.\begin{aligned} \frac{\Delta N_1}{N_0} &= \eta_0\left[\exp\left(-\frac{\Delta V_s}{kT}\right) - 1\right], \\ \frac{\Delta N_2}{N_0} &= \eta_0\left[\exp\left(+\frac{\Delta V_s}{kT}\right) - 1\right], \end{aligned}\right\} \qquad (12)$$

where $-\Delta V_s$ and $+\Delta V_s$ are the changes in surface potential V_s (see Fig. 1) induced by the magnetic field on the corresponding surfaces, and η_0 is the relative amount of the charged form of chemisorption on the surface in the absence of the magnetic field.

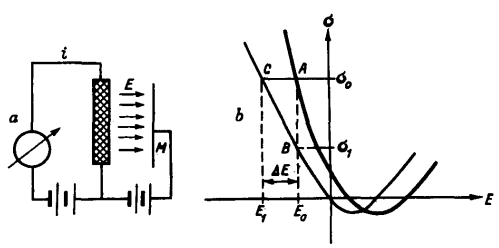

Fig. 4.

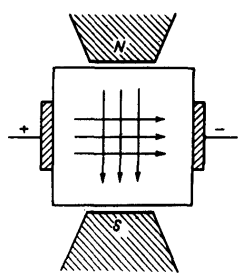

Fig. 5.

Clearly,

$$\left.\begin{array}{ll} \text{if} & \frac{\Delta N_1}{N_0}<0, \text{ then } \frac{\Delta N_2}{N_0}>0, \\ \text{if} & \frac{\Delta N_1}{N_0}>0, \text{ then } \frac{\Delta N_2}{N_0}<0. \end{array}\right\} \quad (13)$$

The relative change in the adsorption capacity of the specimen as a whole becomes, from Eqn. (12):

$$\frac{\Delta N}{N_0}=\frac{\Delta N_1}{N_0}+\frac{\Delta N_2}{N_0}=4\eta_0 \sinh^2\frac{\Delta V_s}{kT}\geqslant 0. \quad (14)$$

The increased adsorption capacity can be detected not by direct adsorption measurements, which would be very difficult under the conditions of this experiment, but from the changes in electrical conductivity occurring during adsorption. The change should be more pronounced in the presence than in the absence of a magnetic field (provided, of course, that all the other conditions remain the same).

It can be shown that the magnetic field will increase, at the same time as the adsorption capacity, also the catalytic activity towards any catalytic reaction which proceeds by an electronic mechanism.

c. Role of Illumination

Let us return to the photoadsorption effect, already discussed above. We shall define the magnitude of the effect by the quantity

$$\Phi=\frac{\Delta N}{N_0}, \quad (15)$$

where N_0 is the concentration of adsorbed particles in the dark, ΔN is the increment brought about by the illumination. The quantity Φ is the relative change in the adsorption capacity of the surface under the influence of light. Obviously, Φ can be positive (photoadsorption) or negative (photodesorption).

Fig. 6 shows the theoretical curve for the variation of the photoadsorption effect Φ with position of the Fermi level in the bulk of the crystal ϵ_v (see Fig. 1). The Figure, reproduced from a paper by the writer and Karpenko[24], refers to acceptor-like adsorbed particles. The quantity u in Fig. 6 denotes the width of the forbidden gap between the bands, V_s is the bending of the bands, v is the depth of the localised energy level A due to the chemisorbed particle below the conduction band. The meaning of the symbols used is made clear by comparing Figs. 6 and 1.

It is obvious from Fig. 6 that we must expect a correlation between the magnitude of the photoadsorption effect and the initial dark conductivity of the semiconductor, determined by ϵ_v: the greater ϵ_v, the smaller will be the electronic conduction and the greater the hole conduction in the semiconductor. We see that if all other conditions are equal the algebraic value of the photoadsorption effect should be higher, the smaller the dark conductivity of the specimen. This is true, as can also be seen from Fig. 6, of n- and p-type semiconductors alike: the former corresponds to the upper half of Fig. 6 ($\epsilon_v < u/2$), the latter to the lower half ($\epsilon_v > u/2$). It would be interesting to test this prediction experimentally. Equally interesting would be a study of the photoadsorption effect in conjunction with the field effect, that is, a study of the combined effects of light and of an external electric field on a semiconductor. This is because an external field allows the band bending V_s to be varied over very wide limits without affecting the value of ϵ_v. In other words, a change in the intensity of the external field results in a horizontal movement in Fig. 3 (for example, along the line CC), and it is evident from Fig. 3 that this may lead to a change in the sign of the photoadsorption effect. We must expect, therefore, that sometimes either photoadsorption or photodesorption will occur on a particular specimen under a constant set of conditions, according to the magnitude and direction of the external electric field applied to the specimen.

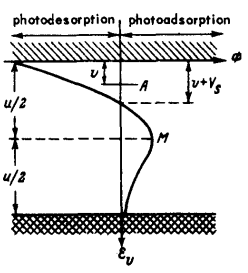

Fig. 6.

d. Role of Impurities

An electric field, a magnetic field, and illumination are factors which affect the chemisorption and catalytic properties of a semiconductor, all things considered, by the same mechanism. They bring about a change in the concentration of the electron or hole gas at the crystal surface. This is enough to explain the mechanism of their influence on the chemisorption properties and on the catalytic activity of a surface.

Impurities added to the bulk of the crystal are yet another factor involving the same mechanism. This statement applies to impurities contained in the crystal in a state of atomic subdivision; impurities forming a separate phase are, of course, excluded. Impurity effects on the activity of a catalyst (catalyst promotion or poisoning) have been known for a long time; they are now well characterised from the point of view of experiment as well as theory (including the electronic theory).

The effect of impurities on the adsorption properties of a surface has received much less attention. We refer to impurities added to the bulk of the crystal and not wholly residing on the surface. Impurities deposited on the surface can act as adsorption centres, or, conversely, they can block existing adsorption centres. We are not concerned here with this simple mechanism of impurity action, but with the influence of impurities on the properties of the surface through their effect on the electronic state of the system as a whole, not involving direct contact between the impurity and the adsorbate.

The electronic theory predicts a decrease in the adsorption capacity of the surface for acceptor gases, and an increase in the adsorption capacity for donor gases, when an acceptor impurity is added to the crystal. A donor impurity should have the opposite effect. It must be noted, however, that a given impurity will behave as an acceptor or as a donor not only according to its own nature, but also according to the nature of the crystal to which it is

added and to the way in which it is added to the host crystal. By the same token, adsorbed molecules behave as acceptors or donors according to the nature of the centres on which they are adsorbed as well as to their own nature. The unambiguous criterion of the acceptor or donor role of an impurity is the way in which it affects the electrical conductivity (whether it increases or decreases the electron and the hole contributions to the conductivity). The unambiguous criterion of the acceptor or donor role of an adsorbed molecule is its effect on the work function (whether it increases or lowers it, respectively).

If we compare the adsorption of a particular gas under otherwise constant conditions on differently doped specimens of a given semiconductor we expect to find a family of adsorption isotherms such as those shown in Fig. 7, which are numbered in order of increasing (or decreasing) concentration of impurity in the crystal.

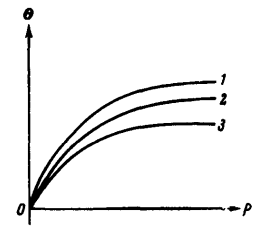

Fig. 7.

At the same time, we should expect a correlation between the adsorption capacity and the electrical conductivity, similar to the correlation which exists between catalytic activity and electrical conductivity (see Section 3, a). For an *n*-type semiconductor the adsorption capacity towards an acceptor gas should change in the same sense as the electrical conductivity and the adsorption capacity towards a donor gas should change in the opposite sense. For a *p*-type semiconductor the reverse is true.

Of course, such a correlation can be expected only if the impurity added to the bulk of the semiconductor has no effect at all on the system of surface states. The correlation between electrical conductivity and work function can be used as a criterion that such is the case.

Impurities which affect the relative amounts of the neutral and the charged form of chemisorption in the surface affect *ipso facto* the relative proportions of reversible and irreversible chemisorption. We can expect, therefore, that different amounts of irreversibly adsorbed gas will be retained, on pumping, by specimens with different impurity concentration, even if the nature of the gas and all other conditions are constant.

An experimental study of the influence of impurities dissolved in the semiconductor upon the adsorption properties of the semiconductor surface would be very interesting. Such a study, however, would meet with a number of practical difficulties. One would have to ensure that the impurity was entirely within the semiconductor, and that none had been retained on the surface, in order to observe this effect in a "pure" form.

e. Semiconducting Films on Metals. Role of Disperseness

We shall discuss the results of yet another theoretical piece of work susceptible to (but still awaiting) experimental test. The writer has investigated, with Sandomirskii and Kuznetsov[25], the adsorption and catalytic properties of a thin semiconductor film covering a metal surface. It is well known that many metals are covered, under most conditions, with a film of a binary compound, that is, they are clad with a semiconductor coating. Statements as to the catalytic action of a metal often relate, in fact, to the catalytic action of this semiconductor film. This has been stressed on many occasions by Roginskii[46] and others. If, however, the thickness of the film is small compared with the dielectric screening length of the semiconductor, then the adsorption and catalytic properties can be shown to depend on the thickness of the film and on the properties of the metal substrate: the film behaves as if it were "translucent" to the characteristics of the metal.

In most practical instances, the semiconductor film arises as a result of oxidation of the metal, and its thickness can often be controlled to some extent. The film of copper(I) oxide which grows on a copper matrix is a typical example. By varying the thickness of the coating, it is possible to apply a measure of control on the adsorption capacity, the catalytic activity, and the selectivity of the specimen. This effect is due to the fact that the position of the Fermi level in a film of this type depends on the thickness of the film. It would be interesting to study the adsorption and catalytic properties of a semiconducting film on a metal, and their changes, during growth of the film.

There is another effect which can be said to have the same origin: the variation of the specific (that is, calculated per unit surface area) adsorption capacity and catalytic activity of very finely divided materials with degree of dispersion (or grain size). This effect was studied theoretically by Kogan[27] four years ago. It offers yet another topic for experimental work, yet another incursion of theory into experiment.

f. Relationship between Differential Heat of Adsorption and Work Function

We shall return now to formula (3), which expresses the variation of the differential heat of adsorption q with the position of the Fermi level ϵ_s at the surface of the crystal, and also to Fig. 1. It can be seen from the diagram that the electron work function, labelled φ in Fig. 1, is related to the Fermi level ϵ_s, by definition, as follows:

$$\varphi = \varepsilon_s + \chi + \delta, \qquad (16)$$

where δ is the so-called "dipole contribution" to the work function (that is, the additional potential step at the crystal surface arising from the polarisation of the adsorbed molecules), whilst χ is a constant which characterises the lattice of the adsorbent (the affinity of the ideal lattice for a free electron), so that the differential heat of adsorption q is unambiguously related to the work function φ if we ignore the dipole contribution δ as is commonly done.

Thus, a correlation between the differential heat of adsorption and the work function can be expected under certain conditions. As the surface coverage is progressively increased the differential heat and the work function should vary together and in the same sense if the adsorbate behaves as a donor, or in the opposite sense if it behaves

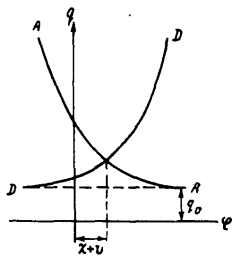

Fig. 8.

as an acceptor. The two cases correspond to the upper and lower sign in formula (3) respectively. Fig. 8 is an idealised plot of the relationship between q and φ for the adsorption of donor (curve DD) and of acceptor species (curve AA) on the assumption that $\delta = 0$.

This is yet another theoretical prediction amenable to experimental test.

We must now bring to a close this list of predictions stemming from the theory and ready to be handed over to the experimental scientists in the hope of enlisting their active interest. This is not because the list is now complete but rather because it would be unrealistic to attempt to make it complete in the space of one article.

---o0o---

In conclusion, I would like to deal with a number of criticisms which could be levelled at the present article, and argue with an imaginary opponent. We can forsee three kinds of criticism (this is the last of the "theoretical predictions").

Firstly, it could be argued that the suggested experiments are difficult, and perhaps even unrealistic, for a number of reasons. To this I would reply that the present paper does not propose any definite procedures: we have only put forward the ideas of a few experiments with no other aim than to bring them to the attention of the experimental scientists. The present list of theoretical predictions, though idealised and curtailed, is a list of the points of arrest in the development of the theory where the theoretician would like to meet the experimenter.

Secondly, a list of facts which the theory has so far failed to explain could be contrasted with the facts which have been interpreted more or less successfully by the theory. There may well be unexplained facts, and more may come to light in increasing numbers. But these facts are the fertile soil in which the theory can continue to grow, improve, and perhaps even remodel itself in parts.

Thirdly, and lastly, facts allegedly in conflict with the theory could be put forward. Of course, theory must be judged by experiment. We always begin with experiment and always come back to it. However, as experiment itself shows, the experimental investigations which "refute" the electronic theory (and also, indeed, some of those which "confirm" it) should be treated with greater caution. Often these investigations, despite the claims of their authors, "refute" nothing and "prove" nothing, being the outcome of an insufficiently critical reading of the theory.

What, then, can the theoretician and the experimenter ask of each other when they meet on the domain of catalysis? The experimenter cannot, of course, expect from the electronic theory predictions of the numerical values of various physical quantities: he can expect the theory to discover the physical mechanism of the observed rules, and to predict new rules and relationships. We must therefore remember that in the field of catalysis (as indeed, in every other field) reality is immeasurably more complex than any theory and never ceases to challenge our understanding. As for the theoretician, he has the right to expect from the experimenter not casual observations but experiments which put a clear question to Nature and elicit an answer.

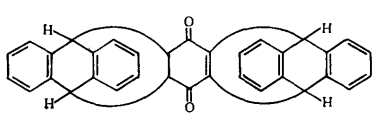
Optically active compounds and compounds whose molecules have a rigid three-dimensional configuration may prove extremely useful in the study of the mechanism of catalysis and the structure of the active surface of catalysts. The advantages of catalytic studies of this kind arise because the initial molecules has a definite well known configuration and it is possible to construct stereochemical models for the intermediate complexes, to follow the stereochemical reaction pathways, and to obtain information about the structure of the active surface of the catalyst.

Such studies are being made both to investigate the geometry of the catalyst surface, using reactions of molecules with a complex three-dimensional structure, and to elucidate the configurational and energy interactions between the groups of the optically active compounds adsorbed on the surface.

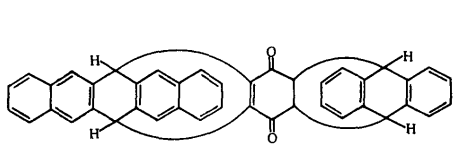
The first approach to the study of the active surface of catalysts has been achieved by hydrogenating triptycene derivatives[1] such as 2,3(9,10-anthrylene)-5,6-(9,10-anthrylene)-2-cyclohexene-1,4-dione (I), for example:



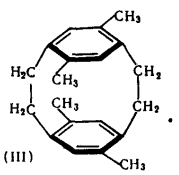
(I)

The hydrogenation of the C=C bond in the central ring of this compound occurs at an appreciable rate on a nickel catalyst even at 45°.[1] The preservation of the rigid structure of the molecule during the catalytic process, which excludes any appreciable deformation or reversal of the configuration by an S_N2 mechanism, makes it possible to construct stereochemical models of the active centre. Since chemical valence forces are of short range, the molecules are in contact with the catalyst via the reacting C=C atoms, which determines the orientation of the molecule during catalysis. The edgewise orientation on the surface is excluded in this case by the structure of the molecule and therefore it is necessary to postulate a planar disposition of the central ring on the (111) plane of the nickel crystal. Since the molecule has a complex three-dimensional structure, it cannot lie flat on this plane and it must be assumed that the correct orientation of such a molecule on the centre requires a projecting centre bounded by the (111) plane and adjacent to a number of "hollows" where the non-reacting parts of the molecules are located. On the basis of the actual dimensions of the molecular model, the height of the projecting centre in an optimum catalyst of this kind must be not less than 4.30 Å.

On catalysts with both "rougher" and more "even" surfaces the reaction of such a compound is hindered because of the reduced probability of occurrence on the surface of centres corresponding to the structure of the reacting molecule. Equally, the reaction rate may be reduced also because of an increase in "catalytic difficulties" as a result of an increase in the complexity of the three-dimensional structure of the molecule, for example when instead of compound (I) compound (II) is hydrogenated:

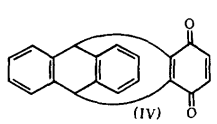


(II)

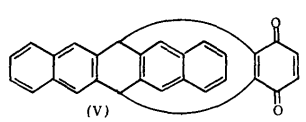


(III)

It is interesting that tetramethyl[2,2]paracyclophane (III)[2] is not hydrogenated at the usual temperature and pressure on 10% Pd/C catalysts or PtO_2. In the general case breakdown of the coplanarity of the molecule hinders hydrogenation. However, when the non-coplanar part of the molecule is not in immediate contact with the catalyst, as, for example, in the hydrogenation of triptycenequinone (IV) and dibenzotriptycenequinone (V), the rates of hydrogenation (1 atm, 45°) are almost indistinguishable[3].

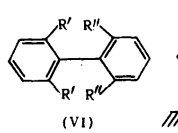


(IV)

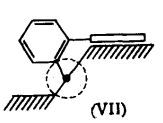


(V)

The structure of the molecule is the decisive factor in the catalytic reaction and when the structure is sufficiently complex and rigid, preventing the contact of the molecule with the active catalyst surface, the reaction cannot be achieved. For example, the biphenyl derivatives (VI)[4] are not hydrogenated as a result of the hindrance of the catalysis by the substituents R′ and R″ [structure (VII)], while hydrogenation of triptycene derivatives, although small, is in fact possible[3]:



(VI)



(VII)

The study of the catalytic reactions of homologous compounds with a complex three-dimensional configuration allows the statistical distribution of the active catalyst centres with respect to size to be found in principle[5].

Another approach which makes it possible to estimate not only the geometry of the active catalyst surface but also to take into account the energy interaction between the catalyst and various functional groups in the substrate molecule is the study of the mechanism of the hydrogenolysis of optically active compounds[6]. In this reaction the bond $\overset{*}{C}-X$ at the asymmetric carbon atom of the molecule (VIII) is ruptured with formation of the compound (IX); since the reaction involves the asymmetric centre, this

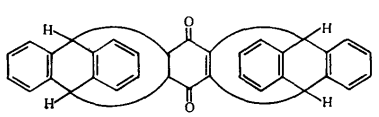
STEREOCHEMISTRY OF HYDROGENATION AND HYDROGENOLYSIS

E.I. Klabunovskii

Optically active compounds and compounds whose molecules have a rigid three-dimensional configuration may prove extremely useful in the study of the mechanism of catalysis and the structure of the active surface of catalysts. The advantages of catalytic studies of this kind arise because the initial molecules has a definite well known configuration and it is possible to construct stereochemical models for the intermediate complexes, to follow the stereochemical reaction pathways, and to obtain information about the structure of the active surface of the catalyst.

Such studies are being made both to investigate the geometry of the catalyst surface, using reactions of molecules with a complex three-dimensional structure, and to elucidate the configurational and energy interactions between the groups of the optically active compounds adsorbed on the surface.

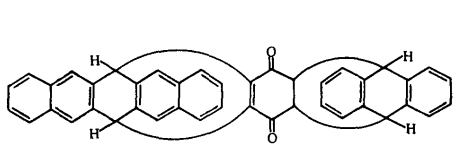
The first approach to the study of the active surface of catalysts has been achieved by hydrogenating triptycene derivatives[1] such as 2,3(9,10-anthrylene)-5,6-(9,10-anthrylene)-2-cyclohexene-1,4-dione (I), for example:



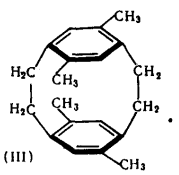
(I)

The hydrogenation of the C=C bond in the central ring of this compound occurs at an appreciable rate on a nickel catalyst even at 45°.[1] The preservation of the rigid structure of the molecule during the catalytic process, which excludes any appreciable deformation or reversal of the configuration by an S_N2 mechanism, makes it possible to construct stereochemical models of the active centre. Since chemical valence forces are of short range, the molecules are in contact with the catalyst via the reacting C=C atoms, which determines the orientation of the molecule during catalysis. The edgewise orientation on the surface is excluded in this case by the structure of the molecule and therefore it is necessary to postulate a planar disposition of the central ring on the (111) plane of the nickel crystal. Since the molecule has a complex three-dimensional structure, it cannot lie flat on this plane and it must be assumed that the correct orientation of such a molecule on the centre requires a projecting centre bounded by the (111) plane and adjacent to a number of "hollows" where the non-reacting parts of the molecules are located. On the basis of the actual dimensions of the molecular model, the height of the projecting centre in an optimum catalyst of this kind must be not less than 4.30 Å.

On catalysts with both "rougher" and more "even" surfaces the reaction of such a compound is hindered because of the reduced probability of occurrence on the surface of centres corresponding to the structure of the reacting molecule. Equally, the reaction rate may be reduced also because of an increase in "catalytic difficulties" as a result of an increase in the complexity of the three-dimensional structure of the molecule, for example when instead of compound (I) compound (II) is hydrogenated:

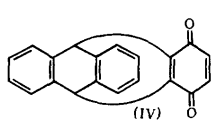


(II)

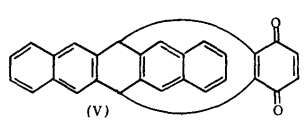


(III)

It is interesting that tetramethyl[2,2]paracyclophane (III)[2] is not hydrogenated at the usual temperature and pressure on 10% Pd/C catalysts or PtO_2. In the general case breakdown of the coplanarity of the molecule hinders hydrogenation. However, when the non-coplanar part of the molecule is not in immediate contact with the catalyst, as, for example, in the hydrogenation of triptycenequinone (IV) and dibenzotriptycenequinone (V), the rates of hydrogenation (1 atm, 45°) are almost indistinguishable[3].

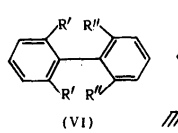


(IV)

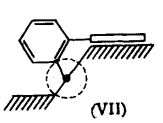


(V)

The structure of the molecule is the decisive factor in the catalytic reaction and when the structure is sufficiently complex and rigid, preventing the contact of the molecule with the active catalyst surface, the reaction cannot be achieved. For example, the biphenyl derivatives (VI)[4] are not hydrogenated as a result of the hindrance of the catalysis by the substituents R′ and R″ [structure (VII)], while hydrogenation of triptycene derivatives, although small, is in fact possible[3]:



(VI)

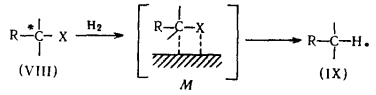


(VII)

The study of the catalytic reactions of homologous compounds with a complex three-dimensional configuration allows the statistical distribution of the active catalyst centres with respect to size to be found in principle[5].

Another approach which makes it possible to estimate not only the geometry of the active catalyst surface but also to take into account the energy interaction between the catalyst and various functional groups in the substrate molecule is the study of the mechanism of the hydrogenolysis of optically active compounds[6]. In this reaction the bond $\overset{*}{C}-X$ at the asymmetric carbon atom of the molecule (VIII) is ruptured with formation of the compound (IX); since the reaction involves the asymmetric centre, this

compound can remain either optically active (with retention of inversion of the initial configuration) or lose activity as a result of racemisation:



(VIII) M (IX)

A heterogeneous catalyst, on the surface of which an intermediate state *M* is established, makes its own contribution to the stereochemistry of the complex. On general grounds, it may be expected that the introduction of an interface lowers the symmetry of the system and therefore one would expect retention of the configuration of the reacting molecule. However, experiment shows that reactions often take place with inversion of configuration. The use of optically active compounds in catalysis provides valuable information about the nature of the intermediate state: whether it is symmetrical or asymmetric, and to what extent the non-reacting parts of the molecule are involved in the intermediate complex (for example, by comparing the reactions of a number of homologues). Racemisation at a centre not participating directly in the reaction would indicate that adsorption of the substituents plays a role; in conjunction with isotope exchange, it can provide additional information about the details of the mechanism of the reaction on the catalyst surface.

The number of systematic investigations of the mechanism of catalysis using optically active and sterically complex compounds is so far inadequate and only recently has this field been developed vigorously, particularly by Japanese investigators who have published a series of experimental papers and brief reviews[7], which are of considerable interest from the viewpoint of the stereochemical relations between the configuration of the reacting molecule and the geometry of the catalyst surface. Unfortunately, so far these data are only qualitative but their complete review is nevertheless desirable (up to 1965 inclusive).

The studies in this field, which were begun by Bonner and coworkers as early as 1952 and then continued by Mitsui, Imaizumi, and others[7], developed on the basis of the hypothesis of the electronic nature of catalytic reactions, the latter being divided into several types depending on whether their mechanisms on the catalyst surface are S_N1, S_N2, or S_Ni. A detailed study has been made of the effect of the structure of the reacting optically active molecule on the type of mechanism and the effect of the nature of the catalyst (mainly Raney nickel and palladium deposited on carriers have been studied).

Extensive experimental data have been accumulated, which in most cases make it possible to establish without ambiguity the mechanism of hydrogenolysis and to draw certain general conclusions concerning the stereospecifity of the action of active catalyst centres.

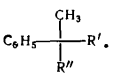
Hydrogenolysis and hydrogenation of oxygen-containing and other compounds have been widely studied by Mitsui, Imaizumi, and a number of other workers[8,9], who showed that the steric requirements of the reacting molecule have a considerable influence on the rate and mode of reaction.

Bonner[10] was the first to use extensively optically active compounds for the investigation of the mechanism of desulphuration. Optically active sulphides, sulphoxides, and sulphones were initially studied as compounds which are firmly chemisorbed on the catalyst surface. The study of the hydrogenolysis of such compounds were also of considerable practical interest for the understanding of the mechanism of the desulphuration of petroleum and many other compounds.

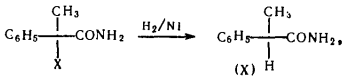
Earlier such studies of the hydrogenolysis of the C–S bond concerned carbohydrates, biotin, and amino-acids, but they were confined to the investigation of hydrogenolysis by a mechanism in which a symmetrical optically inactive product is formed,

which meant that steric factors were not investigated. However, the reaction proved to be very sensitive to the three-dimensional structure of the substrate. For example, steric hindrance in hydrogenolysis is shown by the greater difficulty of the hydrogenolysis on nickel of phenylthiodiphenylacetic acid compared with the methylthio-compound, etc.[8] Bonner's studies, which were initially undertaken to elucidate the special case of the desulphuration mechanism (hydrogenolysis of the C–S bond), served as a basis for the development of a hypothesis concerning the mechanism of the hydrogenolysis of C–O, C–Cl, and C–N bonds; although formal, this hypothesis fairly correctly reflects the essential features of the processes.

The technique used to study hydrogenolysis is simple. The hydrogenolysis is usually carried out at atmospheric or elevated pressure in boiling ethanol over a period of 1–5 h in the presence of a 2–10-fold excess of catalyst. After the reaction the catalyst is filtered off and the optical activity of the reaction products is studied. Since it is easy to prepare in an optically pure form and has a benzyl group, atrolactic acid, and its derivatives are used as model compounds in most investigations; they have the general formula:



In his initial studies Bonner[10,11] investigated the hydrogeneolysis of the optically active amides of phenylpropionic acid derivatives containing sulphide, sulphinyl, or sulphonyl groups:



(X)

where X = SC_6H_5, SOC_6H_5, or $SO_2C_6H_5$. These compounds showed the following unusual types of behaviour (see Table 1).

1. The phenylthio-derivative (X = SC_6H_5) gives rise to a completely racemic amide, the loss of optical activity being due to the stereochemical course of the reaction and not secondary racemisation of the amide formed, since under the experimental conditions the optically active compound (X) is racemised only to the extent of 20%.

2. The hydrogenolysis of the optically active sulphoxides (X = SOC_6H_5)[11] also leads to the racemic propionamide (X), which indicates the similarity of the mechanisms of the

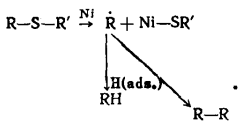
desulphuration of these compounds to the thoroughly investigated mechanism of the hydrogenolysis of sulphides[12-14], which is of the dissociative free-radical type:

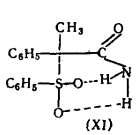


The study of the sulphoxide (X = SOC_6H_5) is complicated by the fact that this compound has two asymmetric atoms (carbon and sulphur) and forms diastereoisomers:

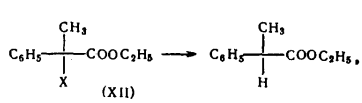
I(+)$_C$(+)$_S$]; I(+)$_C$(−)$_S$]; I(−)$_C$(+)$_S$]; I(−)$_C$(−)$_S$].

However it has been shown[11] that all the stereoisomers give the racemic amide (X) on hydrogenolysis.

3. The hydrogenolysis of the optically active sulphone (X = $SO_2C_6H_5$) proceeds with the retention of up to 90% of the optical activity but with inversion of the configuration. The hypothesis that this behaviour may be accounted for by the structure of the substrate molecule, cyclic structures involving hydrogen bonds with the amide group being formed as in (XI),



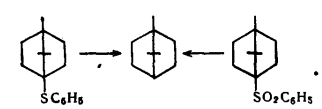
(XI)



(XII)

where X = SC_6H_5, SOC_6H_5, or $SO_2C_6H_5$, is probably incorrect, since the same results (racemisation of the sulphide and reversal of the configuration of the sulphone) are also obtained when the amide group is replaced by an ester group as in compound (XII). In the latter case[16] the degree of racemisation was somewhat greater (25% for *p*-tolylsulphonylpropionate) but the configurational relations remained the same as before. This indicates mainly the specificity of the stereochemical mechanism of the hydrogenolysis and not a peculiarity in the structure of the substrate molecule although in some cases the effect of structure may be significant.

The fact that the hydrogenolysis of ethylthio- and phenylthio-phenylpropionate results in the formation of slightly optically active α-phenylpropionic acid (0.24 and 0.35% of the optical activity[16]) shows that an associative mechanism operates at the same time as the main, dissociative mechanism. A rigid structure, excluding the possibility of the reversal of configuration, favours a process involving the retention of configuration. Thus the desulphuration on nickel of both 4-bornyl phenyl sulphone and phenylthiobornane results in the formation of bornane[17]:

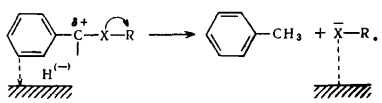


The desulphuration of compounds (XIII) on nickel gives 3α,9α-epoxy-11-oxocholanoic acid (XIV) ($[\alpha]_D$ = 88.1°), also with retention of the configuration by virtue of the rigid structure[18]:

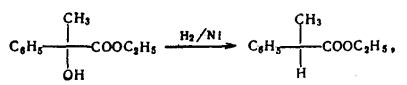
3-Ethylthio-3α,9α-epoxy--11-oxocholanoic acid (XIII) → 3α,9α-epoxy-11-oxocholanoic acid (XIV)

If one bears in mind that the behaviour in the last cases described is determined by the presence of a rigid molecular skeleton and they can scarcely be considered together with the hydrogenolysis of sulphur-containing propionates, the most rational explanation of the very great difference in the behaviour of sulphides and sulphones must be that provided by Bonner's mechanism, according

to which the adsorption of a sulphone molecule on the surface occurs via an oxygen atom, this being followed by the reaction of the hydrogen already adsorbed on the surface with the substrate molecule. The details of this process are as follows. It may be expected that in the hydrogenolysis of benzyl compounds of the type $C_6H_5CH_2-X-R$ adsorption on nickel will result in the transfer of the ring π electrons to the catalyst, as a result of which the α-carbon atom will acquire a certain positive charge which will facilitate attack by a hydride ion formed on the catalyst surface by dissociation of the H_2 molecule into H^+ and H^-. The reaction proceeds with reversal of configuration by an associative mechanism:



Thus if the molecule contains strongly chemisorbed groups which enhance the electron-donor properties of the catalyst, then, as for sulphones, the rupture of the C–S bond does in fact result in inversion of configuration. The validity of this mechanism and the effect of chemisorption have been confirmed by the study of hydrogenolysis of atrolactic acid and its *O*-derivatives. Indeed under the conditions of the hydrogenolysis of sulphides methyl and ethyl L-(+)-atrolacetates gave methyl and ethyl L-(-)-2-phenylpropionate:



with a low degree of racemisation[10,11] (Table 2).

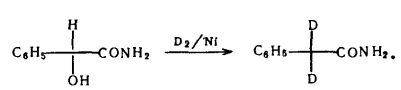
* The ring is hydrogenated.

** Foraminate palladium was used.

A product with rotation of the opposite sign was obtained when L-(-)-atrolactate was used as the starting material. Consequently hydrogenolysis occurs with retention of the configuration. Thus the hydrogenolysis of C–SR and C–SOR bonds involves racemisation, the hydrogenolysis of $C–SO_2R$ occurs with retention of the optical activity and reversal of the configuration, while the hydrogenolysis of C–OH bonds occurs with retention of both the optical activity and configuration, which confirms Bonner's mechanism [19]. This mechanism is also confirmed by studies of isotope exchange in the hydrogenolysis of optically active compounds [20].

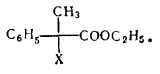
When a deuteriated Raney nickel catalyst in deuteriomethanol acts on L-(+)-mandelamide, dideuteriophenylacetamide is formed [21]:



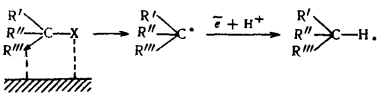
In this process up to 1.7 atoms of deuterium per molecule enter into the benzene ring, which is regarded as proof that the ring is adsorbed on the catalyst surface. Under the same conditions the exchange in (+)-2-phenylpropionamide occurs at the α-C atom and in CH_3 and C_6H_5 groups.

The rate of exchange exceeds initially the rate of racemisation but after 8.5 h the two rates differ only slightly[22]. Identical rates of isotope exchange and racemisation are characteristic of an associative mechanism[23]. These data confirm that, when the substrate contains molecules strongly adsorbed on the catalyst surface and behaving as a catalyst poison (thioethers, sulphoxides), the hydrogenolysis products are fully racemic, but when the molecules contain substituents which do not give rise to appreciable hindrance of the catalytic process and can be adsorbed reversibility, Walden inversion of configuration takes place with almost complete retention of the optical activity, and in some cases the initial configuration is also retained (in atrolactate). These observations led Bonner and then Mitsui, Imaizumi, and others to formulate a hydrogenolysis mechanism based on the hypothesis of nucelophilic substitution at the catalyst surface[24].

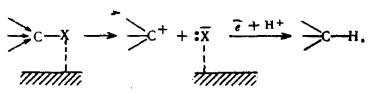
Several reviews exist, mainly in Japanese, but these are very incomplete[7,25] and it is therefore desirable to summarise studies in this field, considering them from the point of view of the study of the nature of the active surface. The following possible reaction mechanisms are examined below, using the hydrogenolysis on nickel of a 2-phenylpropionate or similar compounds as example:



1. Radical splitting is observed for sulphur-containing compounds (X = SC_6H_5, SOC_6H_5); these are powerful poisons of the nickel catalyst on which the SR group is strongly adsorbed; one of the substituents behaves as an electron acceptor, while the adsorption of C_6H_5 and $COOC_2H_5$ groups is much weaker. The C–S bond splits, a proton and an electron adding to the resulting radical and forming a racemic product:



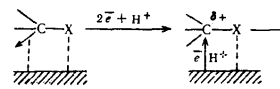
2. An S_N1 mechanism is possible when one or several substituents are weakly chemisorbed and behave as electron donors; The C–X bond (X = SC_6H_5, SOC_6H_5) splits with the formation of a carbonium ion, the addition of hydrogen to which is non-stereospecific and results in the formation of a racemic product:



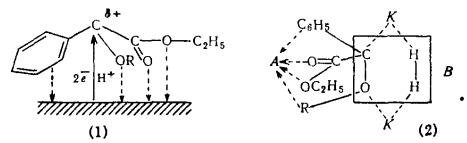
When the carbonium ion is unstable, the addition of $H^+ + 2e$ occurs before the removal of X and the product may contain an admixture of an active compound with inverted initial configuration. Steric hindrance favours the occurrence of the S_N1 mechanism.

3. An S_Ni mechanism is possible when adsorption of X (X = OH, OAlk) is weak and insufficient for the rupture of the C–X bond, and in the absence of appreciable steric hindrance involving the C_6H_5, $COOC_2H_5$, and OR groups. It is assumed that a kind of a cyclic compound is formed from the reacting molecule and the catalyst surface.

The presence of the donor benzyl group results in the attraction of electrons to the catalyst surface which causes the α-carbon atom to acquire a certain positive charge; electrons and protons pass from the catalyst to this atom with the formation of a product with initial configuration:



Mitsui[24], who considered the details of the geometry of the transition state, suggests that the adsorption of all the groups (C_6H_5, $COOC_2H_5$, and OR) occurs on the same area of the catalyst surface [scheme (1)]. In terms of the multiplet theory, this scheme may be represented by formula (2):



(1) (2)

In this scheme the centres A and B cannot be identified with the K' centres which are postulated in the multiplet theory to satisfy the principle of micro-reversibility[6].

4. The reaction has an S_N2 mechanism when there is steric hindrance to adsorption of the groups at the asymmetric carbon atom (the hindrance may occur on the catalyst side — when inhomogeneous and geometrically or energetically distinct centres are present on the catalyst surface). For example, in phenoxypropionates (X = OC_6H_5) this group [the CH_3 group? (Ed. of Translation)] cannot be adsorbed alongside the C_6H_5 and $COOC_2H_5$ groups on the same surface, as in the S_Ni mechanism, and they are in fact adsorbed on different areas of the surface, which lowers the steric hindrance to adsorption. Mitsui[24] assumes that, for adsorption of this type to occur, the molecule must be adsorbed on sterically opposite regions of the surface, for example on different sides of the surface of narrow pores.

The multiplet mechanism makes it possible to represent this type of disposition of "extra-indicial"† substituents at the asymmetric carbon atom by assuming the adsorption of the phenyl group in C_6H_5O at the centre A and of the methyl and ethoxycarbonyl groups at a second centre (B). The hydrogenolysis of the C–O bond for this type of disposition of the "extra-indicial" groups results in inversion of configuration (see the mechanism on p. 552).

The suggested mechanism of catalytic hydrogenolysis is based on the study of the hydrogenolysis of a large number of compounds of different structures, mainly derivatives of atrolactic acid and compounds containing the benzyl group with the substituents R′ and R″:

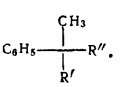


Table 2 lists all the known (up to 1965 inclusive) examples of the hydrogenolysis of such optically active compounds, whose number is steadily increasing. The

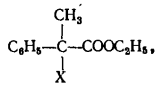
† A group of atoms on the catalyst surface which fits the configuration of the reacting group of the adsorbed molecule is known as the "index" in multiplet theory (Ed. of Translation).

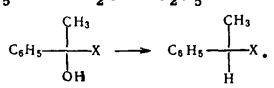
hydrogenolysis of C–O, C–N, C–Cl, and C–C bonds on Raney nickel and palladium catalysts has now been investigated.

Hydrogenolysis of the C–O Bond

The hydrogenolysis of compounds with the general formula



has been studied. The hydrogenolysis of methyl and ethyl atrolactates on nickel occurs stereospecifically by an S_Ni mechanism with retention of the initial configuration[19,26]. The effect on the hydrogenolysis of increasing distance between the $COOC_2H_5$ group and the asymmetric carbon atom has been examined in compounds with X = $= CH_2CH_2COOC_2H_5$ and $CH_2COOC_2H_5$:

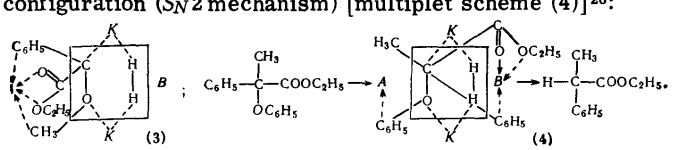


In these compounds, as in the atrolactates[19], the initial configuration is retained, a higher percentage of optical activity being preserved (up to 100% for X = CH_2CH_2. $.COOC_2H_5$[27,28]). However, on palladium/charcoal catalysts these compounds behave differently: the configuration of esters is inverted, while that of the acid (X = $= CH_2CH_2COOH$) is retained, as with the nickel catalyst[28].

If the carboxy group is close to the asymmetric carbon atom, as for example in ethyl 2-hydroxy-2-phenylbutyrate and its benzoyl derivative[29], the hydrogenolysis of the ester on nickel in the presence of added alkali takes place with retention of the configuration and the optical activity (up to 94%), the lowering of reaction temperature favouring greater stereospecificity (S_Ni mechanism). In the benzoyl derivative the optical activity is retained only to the extent of 10%, which is evidence of S_N2 and S_N1 mechanisms, predominantly the latter. This also indicates that the approach of the asymmetric carbon atom to the catalyst surface favours a change to an ionic reaction mechanism involving extensive racemisation of the product.

Alkoxypropionates. The hydrogenolysis of this group of compounds has been studied using nickel and palladium catalysts. On nickel methoxy- and ethoxy-propionates (X = OCH_3 and OC_2H_5) yield 2-phenylpropionate of high optical purity (72–90%) with retention of the initial configuration [multiplet scheme (3)][30,31].

Greater structural complexity of a substituent has differing effects on the reaction. Thus introduction of the benzyloxy-group (X = $OCH_2C_6H_5$) does not influence the stereospecificity of adsorption and the retention of the optical activity (up to 87%), while introduction of propyloxy- or butyloxy-groups (X = OC_3H_7 and OC_4H_9) prevents hydrogenolysis altogether, as a result of high steric hindrance and weak adsorption. An increase in the extent of adsorption of the substituent, for example when a phenoxy--group (X = OC_6H_5) is introduced, favours hydrogenolysis with retention of optical activity (93–95%) and inversion of configuration (S_N2 mechanism) [multiplet scheme (4)][26]:



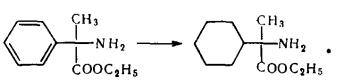
Inversion of configuration with retention of much of the optical activity (88–95%) is also observed for *o*- and *p*-cresyloxy- (X = $OC_6H_4CH_3$), *o*- and *p*-anisyloxy- (X = $= OC_6H_4OCH_3$), and β-naphthyloxy-propionates (X = $= OC_{10}H_7$).[32]

The hydrogeneolysis on 5% palladium/charcoal takes place in a different manner. Phenoxy- and *o*- and *p*-cresyloxy-propionates react by an S_Ni mechanism with retention of configuration (albeit with low specificity – 47, 48, and 52% respectively) which indicates that an S_N2 mechanism makes a certain contribution. However, *o*- and *p*-anisyloxypropionates undergo hydrogenolysis on palladium/charcoal by an S_N2 mechanism with reversal of configuration, the relatively low optical activity (49 and 64%) of the product indicating a greater contribution of the S_N1 mechanism[24,32].

Acyloxypropionates (X = OCOR). Whereas the hydrogenolysis of methoxy- and ethoxy-propionates on nickel occurs with retention of configuration, the hydrogenolysis of aceotoxy- and propionyloxy-propionates on nickel proceeds by an S_N2 mechanism with inversion of configuration and fairly high stereospecificity (67 and 82% of optical activity retained). On the other hand, the benzoyloxy-derivatives also undergo the inversion of configuration (S_N2 mechanism) but in addition there is a marked decrease in the optical activity of the product (optical purity 34%), which suggests the simultaneous occurrence of the S_N1 mechanism as a result of strong adsorption of the benzoyloxy-group[33].

Attempts at Hydrogenolysis of the C–N Bond.

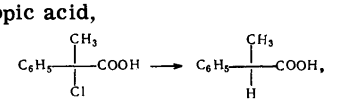
The replacement of the oxygen atom in the atrolactate molecule by nitrogen may result in a change of the mode of reaction. Thus methyl (+)-formamido-2-phenylpropionate is not hydrogenated on Raney nickel, while in ethyl (+)-2--amino-2-phenylpropionate the benzene ring is hydrogenated with the formation of ethyl (+)-2-amino-2-cyclohexyl-propionate[30]:



Probably the free amino-group facilitates the hydrogenation of the ring[34]. It is striking that this reaction takes place only under hydrogenolysis conditions: on platinum at 4 atm (25°) the ring is not hydrogenated. However, recently[33] it has been shown that at 150° and 60 atm the hydrogenolysis of the C–N bond in 2-amino-2-phenyl-propionic acid occurs on palladium/charcoal with retention of configuration and 70% of the optical activity.

Hydrogenolysis of the C–Cl Bond (X = Cl)

The hydrogenolysis of the C–Cl bond in L-(+)- and D-(-)-2-chloro-2-phenylpropionic acid on 7.7% palladium/charcoal catalyst with formation of L-(-)- and D-(+)-hydratropic acid,

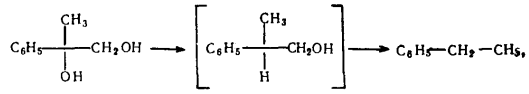


was the first example of hydrogenolysis of an optically active benzyl derivative[35]. The reaction takes place by an S_Ni mechanism with retention of configuration (the

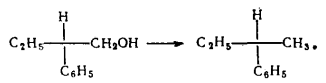
statement in Ref. 35 that the configuration changes is erroneous, see Bonner and coworkers[19]). When the hydrogenolysis is carried out on nickel at a higher temperature, the product is partially or completely racemised, i.e. the reaction takes place to a considerable extent by an S_N1 mechanism[26].

Hydrogenolysis of the C–O and C–C Bonds in Alcohols and Glycols

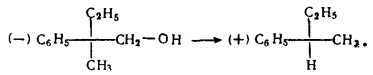
The reduction of the ester group in atrolactates yields a number of corresponding optically active glycols whose hydrogenolysis takes place both at C–O and C–C bonds, for example with formation of ethylbenzene from 2-phenylpropanediol by the following mechanism:



probably via the intermediate formation of phenylpropanol. This pathway is indicated by the hydrogenolysis of 2-phenylbutan-1-ol, for example, which takes place with retention of the configuration of 2-phenylbutane[36]:

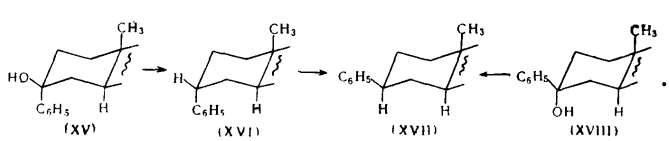


In the hydrogenolysis of phenylpropanediol carbon monoxide is formed from the C_1 atom as a result of the rupture of the C–C bond, which has been demonstrated by the hydrogenolysis of labelled [1-^{14}C]2-phenylpropane-1,2-diol.[37] Reaction by this mechanism should take place largely with retention of configuration, and this has been confirmed by the hydrogenolysis of (-)-2-methyl-2-phenylbutanol on nickel to (+)-2-phenylbutane[21], with retention of 70% of optical activity:



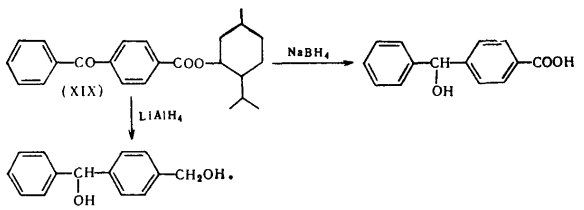
(Bonner[38] erroneously put forward an S_N2 mechanism; actually there is no inversion of configuration and the reaction has an S_Ni mechanism[39].) The hydrogenolysis of (-)-2-phenylbutan-2-ol also occurs with retention of configuration and leads to (-)-2-phenylbutane, 42% of optical activity being preserved[40,41].

These data show that the presence of two strongly adsorbed groups, phenyl and hydroxyl, favours the retention of the initial configuration in hydrogenolysis on nickel. The structure of that part of the molecule which is not adsorbed has little effect on the reaction mechanism. Thus the hydrogenolysis on nickel of the OH group in 3α-phenylcholestan-3β-ol (XV) proceeds with high stereospecificity and retention of configuration, 3α-phenylcholestane (XVI)[42] being formed, which is then slowly converted into 3β-phenylcholestane (XVII). The latter is readily obtained by the hydrogenolysis of 3β-phenylcholestan-3α-one (XVIII):

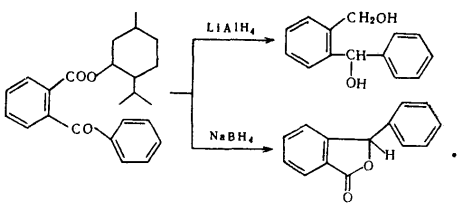


In the hydrogenolysis of 2-phenylethanol the introduction of substituents at the C_2 atom has a significant effect on the proportions of C_1–C_2 and C–O bonds hydrogenolysed, whereas the introduction into the *para*-position of electron-donor or electron-acceptor groups does not affect these proportions[39,43]. The absence of the latter effect indicates only a weak electron interaction and only a weak steric effect of these groups on the stereospecific adsorption of the asymmetric atom participating in the hydrogenolysis.

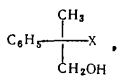
Indeed the steric effect of the asymmetric group is not "transmitted" via the benzene ring when attempts are made to achieve asymmetric synthesis. Thus in the reduction of *p*-benzoylbenzoate by $LiAlH_4$ or $NaBH_4$ inactive products are formed[44]. The action of CH_3MgI on the keto-group in compound (XIX) (asymmetric McKenzie synthesis) also leads to an optically inactive product:



The same result was obtained[45] in the reduction of the corresponding *ortho*-substituted menthyl ester:

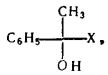


The study of the hydrogenolysis of the hydroxy-ethers of the general formula



where X = OC_6H_5, $OC_6H_4CH_3$, $OC_6H_4OCH_3$-*o*, and $OC_6H_4OCH_3$-*p*, showed that these substances undergo reversal of configuration both on nickel and on 5% palladium/charcoal but retain a high percentage (up to 84–92%) of their optical activity. This finding differs from the results obtained with phenylpropionates of the corresponding structure (replacement of CH_2OH by $COOC_2H_5$) whose initial configuration was retained on hydrogenation on palladium[46].

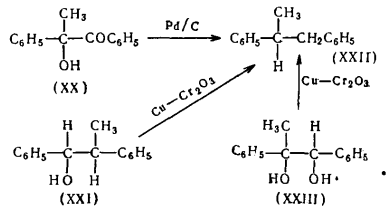
When the distance of the CH_2OH group from the asymmetric centre in the molecule is increased, the configuration is inverted on palladium/charcoal and preserved on nickel. The compound tested had the formula



where X= CH_2CH_2OH and $CH_2CH_2CH_2OH$.

Hydrogenolysis on other catalysts has been little studied. Barnes and Juliano[47] showed that in the hydrogenation of compounds (XX) on palladium/charcoal at a low temperature and of compound (XXI) on a Cu–Cr_2O_3 catalyst at 200°

and 100 atm the optically active 1,2-diphenylpropane (XXII) is formed, with retention of configuration:



However, the formation of L-(+)-(XXII) in the hydrogenolysis of L-(-)-(XXIII) involves extensive racemisation (81.9%).

Comparison of the Stereospecificity of Nickel and Palladium Catalysts in Hydrogenolysis

The study of the hydrogenolysis of optically active compounds permits a more profound understanding of the interaction between the reacting molecule and the catalyst surface. The differences in the mechanisms of hydrogenolysis may be due, on the one hand, to the structure of the reacting molecule, and, on the other hand, to the nature of the catalyst surface. The occurrence of S_Ni and S_N2 mechanisms on various catalysts is interpreted[24] as a result of the adsorption of various groups of the reacting molecules on "different sites" on the catalyst surface or on the opposite sides of the narrow pores in the surface where the adsorption of different sterically hindered groups of the molecule is facilitated, which in fact results in the inversion of configuration. Accordingly, it is to be expected that finely porous catalysts with a larger surface area will tend to give rise to reactions by an S_N2 mechanism, while catalysts with a more homogenous surface, without projecting centres, will give rise to reactions by an S_Ni mechanism.

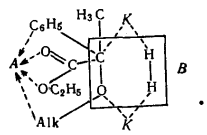
This difference may serve as experimental proof of the presence of projecting centres on the catalyst surface, which are active in relation to the adsorption of particular groups in the molecule; this can serve as an additional technique in the attempts to study the surface of a catalyst by catalytic reactions involving complex molecules which do not undergo inversion of configuration during the reaction[1].

A number of striking features in the behaviour of nickel and palladium has already been noted in the examination of the hydrogenolysis of compounds of different structures. Let us consider these findings in greater detail. Table 2 summarises all the experimental data on hydrogenolysis on nickel and palladium catalysts.

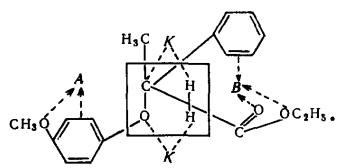
The hydrogenolysis of ethyl 2-phenoxy-2-phenylpropionate (X = OC_6H_5) and also the *o*- and *p*-cresyloxy- and *p*-anisyloxy-derivatives (X = *o*- and *p*-$OC_6H_4CH_3$ and *p*-$OC_6H_4OCH_3$) takes place on nickel by an S_N2 mechanism with inversion of configuration (Table 2). This presupposes the adsorption of aryloxy- and other groups on sterically different surfaces as a result of steric hindrance to adsorption on a single area of the surface. The hydrogenolysis of alkoxy-compounds, for which steric hindrance is less, can also occur on a single area of the surface, which involves no inversion of configuration, the reaction having an S_Ni mechanism. According to Mitsui and Imaizumi[24], "the Raney nickel catalyst has a surface structure such that aryloxypropionates are readily adsorbed on different areas of the surface". ‡ It is suggested that nickel has this type of structure, suitable for the adsorption of molecules whose reaction is sterically hindered because it contains many pores formed as a result of the leaching of the alloy[24]. However, the finding that foraminate palladium in no way differs from metallic palladium is evidence against this[46].

Palladium catalysts on carriers behave differently. Here the effect of the degree of coverage of the carrier surface by the metal on the mechanism of hydrogenolysis is observed. There are no data on the hydrogenolysis of alkoxypropionates and the reaction of phenoxypropionates on 5% palladium/charcoal proceeds, in contrast to the reaction on nickel, with retention of configuration (but it is less stereospecific, 47–52% of the optical activity being retained). When the substrate : catalyst ratio is changed from 1.4 : 0.1 to 1.4 : 15, the percentage of the optical activity retained is almost unaffected (it changes from 30 to 47%). However, the hydrogenolysis of *o*- and *p*-anisyloxypropionates on 5% palladium/charcoal takes place with inversion of configuration[24,26,32] (Table 2).

These data show that the product obtained on nickel retains its initial configuration when fairly strong adsorption of the alkoxy-group in the *A* centre takes place:



Starting with X = OC_6H_5, steric hindrance prevents the location of all three groups at the *A* centre and therefore the phenyl and carboxy-groups are adsorbed at the *B* centre, since OC_6H_5 is held in addition by the "index" centre *K*.



In view of the strong adsorption of oxygen on nickel, such displacement of the phenyl and carboxy-groups from the *A* centre occurs even in the presence of the phenoxy--group whereas on palladium/charcoal this happens only after the introduction of a second oxygen atom — in the anisyloxy-derivative (X = $OC_6H_4OCH_3$).

An increase in the palladium content above 10% alters the type of the mechanism (S_Ni) of the hydrogenolysis of phenoxypropionate[24] and leads to a product with inverted configuration, the reaction having an S_N2 mechanism. Furthermore, Table 3 shows that an increase in the palladium content from 1 to 10% sharply reduces the optical activity of the product (from 65 to 6%), but, starting with

‡ This quotation cannot be found in Ref. 24. Mitsui and Imaizumi[24] use an argument based on the simultaneous adsorption of a sterically hindered molecule on two opposing sides of a catalyst surface; this could occur in suitable pores in the catalyst (Ed. of Translation).

10% Pd, there is a gradual increase in the percentage of optical activity retained in the inverted product, up to 77% for 90% palladium/charcoal (Fig. 1, constructed on the basis of the data in Table 3, shows that the change in the mechanism of hydrogenolysis occurs when the palladium/charcoal catalyst contains 8% Pd). On pure palladium the percentage of the optical activity retained by the product is much lower.

Other Carriers

The deposition of palladium on barium sulphate instead of charcoal (5% Pd/$BaSO_4$) does not change either the reaction mechanism or the stereospecificity, compared with pure palladium (Table 3). However, comparison with the 5% palladium/charcoal catalyst shows that the mechanisms of the reactions on these catalyst are different: S_Ni for palladium/charcoal and S_N2 for palladium/barium sulphate.

According to Mitsui[24], the reason for this behaviour is that at a low palladium concentration the catalytic surface on which phenoxypropionate can be adsorbed is relatively small, since palladium is spread in a thin layer. As the thickness of the layer increases, which is achieved by increasing the concentration of palladium or reducing the surface area of the carrier (the use of barium sulphate),

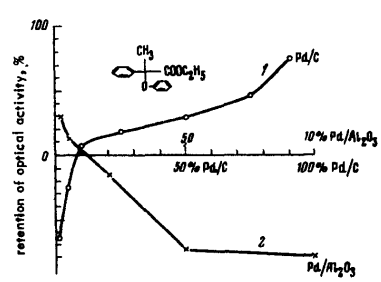

Fig. 1.

the microroughness of the surface becomes more pronounced and a substrate molecule can be adsorbed at two points on the surface, which leads to an inverted product. The stereospecificity of the reaction increases with the number of such centres, reaching a maximum (77% for Pd/C = = 9 : 1) and then falling sharply (44% for pure palladium).

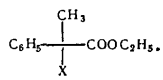
The explanation of this behaviour of pure palladium is[24] its lower dispersion and the absence of pores of suitable

dimensions. The behaviour of palladium/barium sulphate, whose specific surface and porosity are low, is also similar.

The replacement of charcoal by alumina leads to similar results, but here a change in the mechanism of hydrogenolysis is observed for 1.2 Pd/Al_2O_3 (Fig. 1, curve *2*). For this reason, the formation of structures favouring three-point adsorption on sterically different centres, which leads to inversion of configuration, begins on Pd/Al_2O_3 catalysts with a much lower palladium content. This type of behaviour of the Pd/Al_2O_3 catalysts may be due to the smaller specific surface of alumina compared with charcoal[24]. The change in mechanism on the palladium/charcoal and palladium/alumina catalysts is observed at the same degree of coverage of the carrier surface: about 3% of the monolayer. Hence it follows that for palladium dispersed into atoms on the surface the Pd–Pd distances between the centres are 13–15 Å, which corresponds to the dimensions of the phenyl(phenoxy)propionate molecule (Fig. 2). When the distances between the centres are reduced, conditions favouring an S_N2 mechanism are created. Regardless of the method of preparation, the nickel catalysts (Raney nickel, nickel on Kieselguhr, Urushibara nickel) probably have a surface structure such that the distances between the active centres do not exceed about 10 Å. On such centres the hydrogenolysis of phenoxypropionate takes place with inversion of configuration (Table 3).

The study of the effect of additives (NaOH, HCl, KBr) to the catalysts (nickel and palladium/charcoal) showed that, in the presence of alkali or potassium bromide (and to a lesser extent sodium chloride), the degree of inversion increases on both catalysts — on nickel catalysts there is an increase in the degree of inversion and on palladium catalysts a decrease in the percentage retention of the initial configuration: the contribution of the S_N2 mechanism increases. Addition of HCl to palladium/charcoal also increases the contribution of the S_N2 mechanism, but to a lesser degree than the addition of alkali and potassium bromide (Table 3)[48].

For other groups of the molecule, with different adsorption capacity and steric relations, a different type of variation with the catalyst concentration on the carrier and with the additive may be observed. Thus the hydrogenolysis of the sterically more complex molecule, ethyl 2-(*p*-anisyloxy)-2-phenylpropionate (X = $OC_6H_4OCH_3$),



on both nickel and palladium/charcoal and palladium/alumina catalysts involves the reversal of configuration over a wide range of palladium concentrations. The high degree of retention of the optical activity by the product also shows that here the structure of the substrate molecule determines the sterospecificity of the process. When the palladium content is increased from 0.2 to 50% on charcoal and alumina, there is little change in stereospecificity (53–81%)[24].

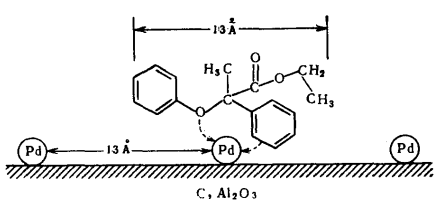


Fig. 2.

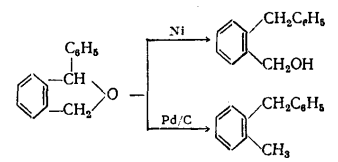
Hence it is evident that the difference between the nickel and palladium catalysts is also due to their different capacity to adsorb polar groups. In the case of phenoxypropionate steric factors predominate and the degree of coverage of the carrier surface by palladium greatly influences the reaction mechanism. In the hydrogenolysis of compounds with strongly adsorbed groups, for example the anisyloxy-group, the affinity of palladium for polar groups is the decisive factor; they become strongly adsorbed and the reaction proceeds with inversion of configuration, regardless of the palladium concentration on the carrier.

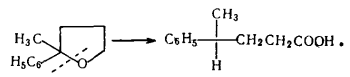
The much lower degree of adsorption on 7.7% palladium/charcoal compared with the nickel catalyst may be the reason for the partial retention (up to 18%) of the initial configuration (S_N2 + S_Ni mechanisms) in the hydrogenolysis of ethyl 2-chloro-2-phenylpropionate (Table 2)[26,35]. For example, the lower affinity of palladium, compared with nickel, for oxygen-containing groups explains also the different pathways of the hydrogenolysis of phenylphthalenes[48]; hydrogenolysis on nickel leads to *o*-benzoylbenzyl alcohol while on palladium/charcoal *o*-benzyltoluene is formed:



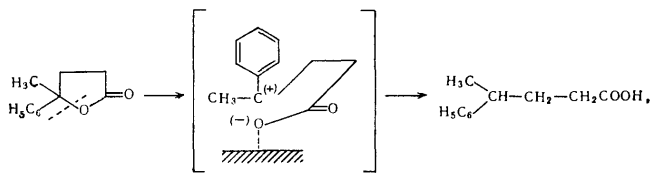
The presence in the reacting molecules of groups which can be strongly adsorbed has a significant effect on the reaction mechanism and it is interesting to compare the hydrogenolysis on nickel and palladium of a number of glycols and hydroxy-acids and their oxygen-containing derivatives. Thus the hydrogenolysis of atrolactic acid derivatives on nickel takes place mainly with the inversion of configuration, and the replacement of $COOC_2H_5$ by CH_2OH in these molecules does not alter the hydrogenolysis mechanism. However, the removal of the methoxycarbonyl group to a position more distant from the asymmetric centre by one or two CH_2 groups alters the mechanism to S_Ni on nickel, cobalt, and copper, probably because, as a result of an increase in the mobility of the alkyl chain, the molecule can be adsorbed without inversion of configuration on "one side" of the catalyst surface by way of "W-shaped" adsorption. In hydrogenolysis on palladium/charcoal catalysts the replacement of $COOC_2H_5$ by CH_2OH changes the S_Ni mechanism to the S_N2 mechanism, probably as a result of only weak chemisorption of the molecule on the surface. Here the removal of the $COOCH_3$ group further away from the asymmetric centre favours hydrogenolysis by an S_N2 mechanism[27]. However, if chemisorption is enhanced, for example by the replacement of methyl γ-hydroxy-γ-phenylvalerate (Table 2) by the free acid, then the reaction on both palladium and nickel proceeds by an S_Ni mechanism[28] and a change in the concentration of palladium does not alter the reaction mechanism and has little effect on the retention of optical activity (Table 3)[49]. The addition of HCl to the 5% palladium/charcoal catalyst is also without effect.

As pointed out above (see Table 2), benzoylated hydroxy-acids impede adsorption on nickel and change the mechanism from S_N2 to S_N1 [33]. There are no such data for hydrogenation on palladium. However, it is known that the hydrogenolysis of methyl γ-hydroxy-γ-phenylvalerate and butyrate involves the inversion of configuration [27] (Table 2), while the hydrogenolysis of the free acids proceeds by an S_Ni mechanism. In the hydrogenolysis of a benzoylated acid on palladium/charcoal catalyst in the presence of alkali a decrease in the degree of retention of the optical activity with increase in palladium content in the catalyst is observed, which indicates a gradual increase of the contribution of the S_N2 mechanism [49] (Table 3).

Different mechanisms are also observed in the hydrogenolysis of 2-methyl-2-phenyltetrahydrofuran (S_Ni on nickel and S_N2 on palladium/charcoal [27]).



However, when a second oxygen atom is present in the ring, for example in the hydrogenolysis of γ-phenylvalerolactone on palladium/charcoal,



the reaction proceeds by an S_N1 mechanism with extensive racemisation (10% of optical activity is retained) [28] (Table 2). The difference in the action of the catalysts can probably be accounted for by the lower affinity of palladium for electronegative elements [27].

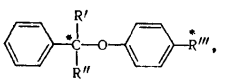
The stereospecificities of the nickel and palladium catalysts may be compared and the effect of the palladium concentration may be assessed by studying the hydrogenolysis of compounds capable of being adsorbed without much steric hindrance for any orientation on the catalyst surface. 2-Phenylbutan-2-ol was chosen as a model compound of this kind [50]. Tables 2 and 3 show that the hydrogenolysis of this alcohol and its methyl ether on foraminate (Raney) nickel, cobalt and copper catalysts and also nickel promoted with palladium and platinum proceeds with formation of 2-phenylbutane, retention of configuration, and high (up to 97%) stereospecificity [50]. It should be noted that in other studies [40,41] such high percentage retention of optical activity was not observed.

Palladium catalysts of different origins and with different palladium concentrations on charcoal as well as catalysts containing added acid (Pd/C–A) or base (Pd/C–B) also showed high stereospecificity, but the hydrogenolysis of 2-phenylbutan-2-ol and its methyl ether occurs with inversion of configuration (S_N2). Furthermore, whereas the hydrogenolysis of 2-phenylbutan-2-ol on the palladium/charcoal catalyst in alcohol occurs with inversion of configuration, in benzene the initial configuration is retained [50]. This demonstrates the different stereospecificities of the nickel and palladium/charcoal catalysts, which form intermediate complexes of different geometry because of the differences in the bond energies of the hydroxyl and the catalyst surface. The latter is significantly influenced by the solvent. In contrast to palladium/charcoal, the rate of hydrogenolysis on nickel is higher in polar oxygen-containing solvents.

However when significant steric hindrance prevents adsorption, as for example in the hydrogenolysis of 1-methyl-1-phenylpropyl hydrogen phthalate, then on Raney nickel promoted with platinum and palladium and also on palladium/charcoal, platinum/charcoal, and metallic palladium hydrogenolysis proceeds only by an S_N2 mechanism with inversion of configuration (Table 3) [50]. Thus the nature of the catalyst and the concentration of palladium on the carrier do not play any role in this case. Hydrogen adds, as it were, from "behind" the substituents adsorbed on the surface and hydrogenolysis proceeds with inversion of configuration.

Thus the study of the mechanism of the hydrogenolysis [51] of optically active compounds opens up new possibilities for the investigation of the active surface of catalysts and it is extremely interesting to investigate, apart from palladium/charcoal and palladium/alumina catalysts, also catalysts on other carriers with specific surfaces of the order of 10–100 $m^2\ g^{-1}$ in order to establish the lower limit of the concentration of palladium at which the mechanism of hydrogenolysis changes.

An increase in stereospecificity can probably also be obtained on dilute catalysts using specific carriers which adsorb selectively the optically active groups of the substrate molecule. This can be shown, for example, in the hydrogenolysis of diastereoisomers of the type:



(where $\overset{*}{R}'''$ contains the asymmetric centre) on a catalyst deposited on a carrier (natural or synthetic polymer, silica gel formed by a specific procedure [52–54], etc.) capable of asymmetric adsorption [55]. According to Kubitscheck and Bonner [44], in such a compound the asymmetric centres $\overset{*}{C}$ and $\overset{*}{R}'''$ do not interact sterically and consequently the reaction of the asymmetric carbon atom $\overset{*}{C}$ can serve as a kind of indicator of the stereospecificity of the process and $\overset{*}{R}'''$ determines the asymmetric adsorption.

Thus a change in the reaction mechanism can serve as an indicator of the stereospecificity of chemisorption during catalysis, which is sensitive both to steric and energy factors in the interaction between the groups of the substrate molecule and the catalyst surface. Thus for palladium/charcoal there is a limiting surface coverage equal to 3% of a monolayer, which results in a change of the mechanism (from S_Ni to S_N2) in the hydrogenolysis of phenyl phenoxypropionate.

Both pronounced sorption and strong steric interactions are observed on nickel. The adsorption is strong in the hydrogenolysis of chloropropionate (X = Cl, S_N1 mechanism). The adsorption is weaker in the hydrogenolysis of propionates with X = OH, OCH_3, C_2H_5, and $OCH_2C_6H_5$, alcohols, and glycols, and compounds with a long chain between the two adsorption points (S_Ni mechanism). Adsorption and steric hindrance occur in the hydrogenolysis of propionates when $X = OC_6H_4{-}OCOC_2H_5$, and of ethylene glycol monoethers (S_N2). Pronounced steric hindrance ($X = OCOC_6H_5$) leads to a mixed mechanism ($S_N2 + S_N1$).

Since strong adsorption and marked steric hindrance lead to a non-specific S_N1 mechanism, it is evident that the nickel surface exhibits considerable inhomogeneity, of both the geometrical and the energy type, i.e. a considerable degree of "microroughness", since an S_N1 mechanism

presupposes that the asymmetric carbon atom is distant from the catalyst surface.

Weak steric and adsorption interaction has been observed on the palladium/charcoal catalyst: (1) the weak adsorption of propionates with X = Cl, OC_6H_5, and $OC_6H_4CH_3$ leads to an S_Ni mechanism; (2) weak adsorption also gives rise to steric hindrance for the propionates with R = OC_6H_5 and OCH_3, alcohols, glycols, and compounds with long chains between the two points of weak adsorption (methyl esters of hydroxy-acids): an S_N2 mechanism obtains. However, enhanced adsorption (hydroxyvaleric acid) changes the mechanism to S_Ni (as on nickel).

Hence it may be concluded that the surface of the palladium/charcoal catalyst is geometrically and energetically more homogeneous than that of nickel and that polar groups are not strongly adsorbed on it. The reaction is always stereospecific: the asymmetric carbon atom is close to the surface and the reaction mechanism is largely S_Ni or S_N2. The steric hindrance associated with the "extraindicial" substituents in the multiplet reaction "index" can play a considerable role. Thus phenylpropionates with X = OC_3H_7 and OC_4H_9 do not react at all, while those with X = OC_2H_5 and $OCH_2C_6H_5$ undergo hydrogenolysis with retention of the original configuration. The bond energies Q_{OK} in the hydrogenolysis "index" must be corrected for the steric interaction between the OR radicals, in conformity with the principle of the energy correspondence of the multiplet theory of catalysis[56].

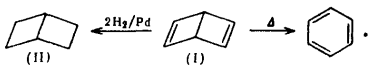
REVERSIBLE VALENCE ISOMERISATION

T. V. Domareva-Mandel'shtam
and I. A. D'yakonov

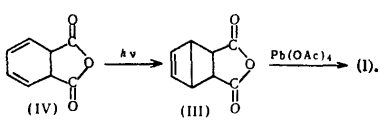
In recent years many examples of isomeric conversions have become known that differ phenomenologically from most ordinary isomerisations. A characteristic of the new type of isomerisation is that it occurs without displacement of atoms or atomic groups within the molecule. The isomerisations are accompanied by corresponding changes in the relative arrangement of σ- and π-bonds and only by small changes in interatomic distances and valence angles. In the literature, this kind of isomeric conversion has been given the name valence isomerisation [1]†.

A striking example of a valence-isomeric conversion is the recently described thermal isomerisation of "Dewar benzene", or bicyclo[2,2,0]hexa-2,5-diene (I) to ordinary benzene [5]:



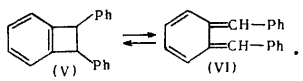
At room temperature "Dewar benzene" is fairly stable, having a half-life of 2 days, but at 90° it is converted into benzene in 30 min.

The structure of "Dewar benzene" was confirmed by examination of its nuclear magnetic resonance (NMR) spectrum and by its conversion on careful hydrogenation into bicyclo[2,2,0]hexane (II). The structure was also determined by synthesis: "Dewar benzene" was obtained by oxidising the anhydride of bicyclo[2,2,0]hex-2-ene-5,6-dicarboxylic acid (III) with lead tetra-acetate. It is of interest to note that the anhydride is formed by the photo-initiated valence-isomerisation of 1,2-dihydrophthalic anhydride (IV):



Valence isomerisations, like non-valence isomerisations, may be classified as reversible or irreversible. The isomerisation of the hydrocarbon (I) to benzene is an example of irreversible valence isomerisation. Isomerisations of this kind are very numerous (see reviews [2-4,6] and some original papers of recent years [7-37]).

Irreversible valence isomerisation occurs when two valence isomers differ greatly in their thermodynamic stability. When this difference is not great, dynamic equilibrium may be established between the valence isomers. This type of valence isomerism is termed reversible. An example that may be quoted is the recently described reversible valence isomerisation of *trans*-1,2-diphenylbenzocyclobutene (V) to *trans-trans*-5,6-dibenzylidenecyclohexadiene ($\alpha\alpha'$-diphenyl-*o*-quinodimethane) (VI) [38] (see also Freedman and coworkers [39]):



We shall give a number of other examples of this type of isomerisation below.

In recent years the term "valence tautomerism" has been increasingly used in publications outside the Soviet Union to describe the phenomenon of equilibrium valence isomerism. According to Rhodes [4], for the correct use of this term the following condition should be observed: "the corresponding isomers must be converted into each other under normal working conditions and the energy barrier to be overcome must be relatively small. If the latter condition is not fulfilled, it is better to call the compounds valence isomers".

The author does not say what is to be understood by normal working conditions. A study of the literature shows that other authors do not adhere to this kind of limitation in the definition of valence tautomerism. It is clear from papers we shall refer to later that valence-tautomeric conversions may include conversions that occur at widely different temperatures and pressures, and under widely different conditions of illumination, etc. The position of equilibrium between the valence tautomers can also have any value. As is pointed out below, at present systems are known in which equilibrium is largely displaced in the direction of one of the tautomers‡. Hence it follows that the energy barrier to be overcome when one tautomer is converted into another may vary appreciably from case to case.

Notwithstanding what has just been said, it must be recognised that the term "valence tautomerism" is not a good one. Firstly, although this term was proposed a long time ago, the concept of valence tautomerism itself was invested with a somewhat different meaning (see, for example, Ingold [40]).

The idea that valence tautomerism can occur was first put forward by Kekulé, who proposed a dynamic formula for the structure of benzene in 1872. [41] The term "valence tautomerism" itself was first used by Wieland in 1920–1922, who, like many other chemists of that time, regarded valence tautomerism as the rapid intramolecular oscillation of valence bonds [42,43]. Later, a meaning not differing substantially from the modern concept of resonance began to be applied to the concept of "valence tautomerism". As is known, the concept of resonance is based on the idea that the real state of a given molecule may be described by the superposition of several limiting structures, none of which occurs alone in the unexcited state. It is characteristic of the limiting structures that they have the same distances between corresponding atomic nuclei and the same angles between the atoms; they differ only in the arrangement of the π-electrons. Resonance structures do not have the significance of structural formula of real compounds and

† At present only three review articles on the subject of valence-isomeric conversions can be cited, and these have appeared in foreign journals [2-4]. These articles are, to a certain extent, already out-of-date, because many new experimental papers have been published since they appeared. No reviews of this kind have yet appeared in Soviet literature.

‡ In this connection it should be noted that a sharp line cannot be drawn between reversible and irreversible isomerisation. Processes that are now regarded as irreversible may in the future turn out to be reversible when new sources of energy are used or more sensitive methods of analysis are applied.

are only arbitrary constructs which may be used for molecular calculations by the method of valence diagrams. In contrast, valence tautomers, which are being considered here, are structures that really exist. Moreover, they differ from one another not only in the order of alternation of single and double bonds, as, for example, the oscillating benzene structures proposed by Kekulé and by Dewar, but also in the distances between atoms, in the valence angles, and in free energy content.

Secondly, the use of this term may give rise to the idea that the concept of valence tautomerism is related to, or even identical with, the concept of electronic tautomerism[44,45]. In fact both concepts differ in their content.

Notwithstanding what has been said above, the term "valence tautomerism" is now widely used in the literature. For this reason, and also because there is no other suitable name for this phenomenon, we are forced to retain this term in our review.

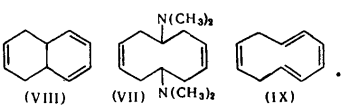
Since valence tautomerism is associated with reversible-valence-isomerisation phenomena, it should be possible to make a suitable change of terms and use the term "reversible valence isomerisation" instead of "valence tautomerism". To this, however, it must be objected that the new term is longer than the old one and therefore less convenient in use. The idea of tautomerism does not always fully correspond with the idea of reversible isomerisation. The difference lies in that in tautomerism a state of dynamic equilibrium is established, but this is not a necessary condition for reversible isomerisation. As confirmation of this we may cite as an example those reversible valence isomerisations (they are considered below) in which the direct reaction occurs under some conditions, for example, with ultraviolet irradiation, and the reverse reaction occurs under other conditions, for example, with heating. There is no state of equilibrium between valence isomers in such instances (and therefore these isomers cannot be regarded as valence tautomers), although this state could be achieved under certain conditions of irradiation and heating (and then a system of this kind should be regarded as tautomeric). Thus, the idea of reversible valence isomerisation embraces the idea of valence tautomerism, but the converse is not true. The question whether one term should be replaced by the other must therefore be answered in the negative.

The present review is devoted to a description of the phenomena of reversible valence isomerisation, which here also covers the field of valence tautomerism. Another no less interesting field, that of valence (intramolecular) rearrangements, is not considered. We might well have limited our remarks on valence rearrangements to this observation, if the error[4] was not frequently encountered that isomerisations can be called rearrangements and conversely. In this connection, it would be useful to consider what is meant by intramolecular rearrangement and how it differs from isomerisation.

In a number of available theoretical handbooks on organic chemistry a definition of the concept of rearrangement is either not given (see, for example, Ingold[46]) or the proposed definitions are not sufficiently rigorous and reliable[47,48]. Some authors[49-51], however, are agreed that the term molecular rearrangement should only be applied to a special group of reactions, be they substitutions, eliminations, or additions, in which the principle of minimal structural change is violated. Although this formulation of the concept of a new type of reaction must be considered somewhat vague (because of the vagueness of the principle itself), nevertheless at the present time it best meets the requirements of reality. On the other hand, it is quite clear that this definition is not applicable to the concept of isomerisation. Thus, it would be absurd to consider the question whether the principle of minimum structural change is preserved in isomerisation reactions. In these reactions only the structure changes, and not the composition, since only one molecule of final product is formed from one reacting molecule. In reactions of the intramolecular-rearrangement type a change always occurs not only in structure but also in composition, although in isolated instances the number of molecules reacting may be the same as the number of molecules formed.

The question of the mechanism of rearrangements requires special consideration. It is difficult to draw any conclusion on this point from the actual definition of these reactions (see above). However, there is now convincing published evidence (see p. 511 of the book by Temnikova[51]) that rearrangements may proceed in two ways, either by way of an active reaction complex (brought about by a so-called reaction with reaction-centre transfer), or by the rapid isomerisation in the course of the reaction of the initial compound or one of its intermediates. The fact that the reaction can proceed in the first way is a further argument against identifying rearrangements with isomerisations.

Everything that has been said here on reaction mechanism is also valid for valence rearrangements. It should be noted, however, that the experimental investigation of the mechanism of valence rearrangements presents great difficulties, because of the absence of appreciable displacement of the atomic nuclei in the conversion process. Only one example of valence rearrangement will be given here. The dioxide of the diamine (or the diquaternary ammonium salt) obtained from 1,6-bis(dimethylamino)-cyclodeca-3,8-diene (VII) undergoes thermal decomposition (120–150°) with the formation of *trans*-1,4,9,10-tetrahydronaphthalene (VIII). According to Grob and Schies[52], the latter is formed by valence isomerisation of the unstable tetraene (IX), a product of the normal cleavage of the diamine dioxide (VII) or quaternary salt. Since the intermediate tetraene (IX) has not been isolated, the proposed mechanism cannot be considered proved. It is possible that the tetrahydronaphthalene (VIII) is formed directly from the diamine dioxide (or the diquaternary ammonium salt), without an intermediate stage (see, however, Grob and coworkers[53]).

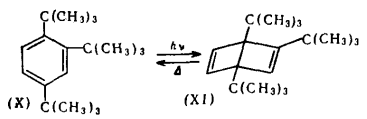


(VIII) (VII) (IX)

After the foregoing discussion on valence isomerisation (reversible and irreversible), valence tautomerism, and finally, molecular rearrangements including valence rearrangements, we may proceed to a more detailed examination of the phenomena of reversible valence isomerisation, which in fact is the main theme of the present paper.

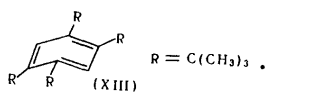
In recent years the valence-isomeric conversions of benzene and its homologues have attracted particular attention. It is curious to note that the structures of the valence isomers of benzene have a formal similarity to the benzene structures proposed in their time by Dewar and by Ladenburg (hence the names "Dewar benzene" and "Ladenburg benzene"). An example of the irreversible valence

isomerisation of "Dewar benzene" into ordinary benzene was given on p. 559 (see also Criegee and Zanker[54]). An example of reversible valence isomerisation of this kind is the conversion of 1,2,4-tri-t-butylbenzene (X) into 1,2,4-tri-t-butylbicyclo[2,2,0]hexa-2,5-diene (XI), which proceeds under the action of light[55]. The isomer (XI) can be separated from the remaining products of photoconversion by thin-layer chromatography and purified by distillation under high vacuum at room temperature. It has been proved that the hydrocarbon (XI) is monomeric; its structure has been confirmed by ultraviolet and NMR spectra. When heated to 200° for 15 min, it is converted into the initial tri-t-butylbenzene (X):



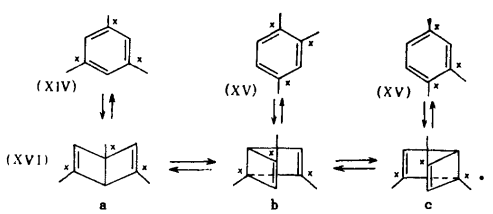
There is no dynamic equilibrium between the isomers, but it may be supposed that this equilibrium would be achieved under suitable conditions (illumination + heating).

In this instance the formation of the bicyclic isomer (XI) from tri-t-butylbenzene is promoted by the steric effect of the substituents. There are grounds for supposing that the carbon atoms in the 1,2,4-tri-t-butylbenzene ring are not coplanar, because of the proximity of bulky substituents. A similar phenomenon occurs, for example, with 2,4,6-tri-t-butyltoluene (XII),[56] or 1,2,4,5-tetra-t-butylbenzene (XIII),[57] which have the form of a tub:

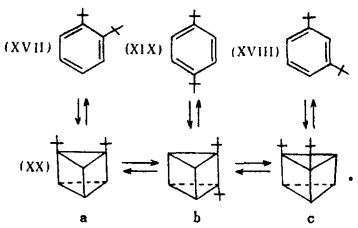


The non-planar structure of the molecule (X) must lower the stability of this hydrocarbon in comparison with other aromatic compounds that do not contain sterically hindered alkyl groups and thereby facilitate its conversion into the strained bicyclic form (XI).[6]

A number of papers deal with the displacement of alkyl groups in benzene homologues under the action of ultraviolet light[58-60]. Using an isotope marker, Kaplan and coworkers[60] established that isomerisation of 1,3,5-trimethylbenzene (XIV) to 1,2,4-trimethylbenzene (XV) (30°, λ = 2537 Å) proceeds not as a result of 1,2-shift of the methyl group, as it might well do, but by a change in the positions of the carbon atoms in the ring — in (XV), as well as in (XIV), the methyl groups are attached to labelled carbon atoms in the ring. This change is said to be effected by the equilibrium compound (XIV) and the three "Dewar isomers" (XVI, a, b, and c) which is rapidly established under ultraviolet irradiation; the "Dewar isomers" are, in turn, in equilibrium with the initial and final compounds.

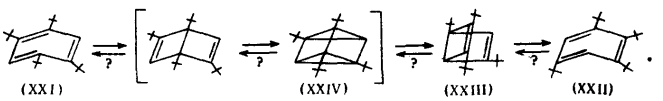


Because of the great strain set up in the molecule by the proximity of the t-butyl radicals, when *o*-di-t-butylbenzene (XVII) is irradiated with ultraviolet light, it is converted into an equilibrium mixture of the *meta*- and *para*-isomers (XVIII) and (XIX) (in the ratio 1 : 4):



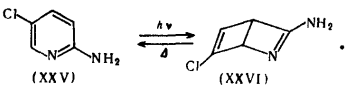
Burgstahler and coworkers[59,61], who described this phenomenon, suggest that the conversion of (XVII) into (XVIII) and (XIX) is accomplished by valence isomerisation of the initial molecule, at first into homologues of "Ladenburg benzene" (XX, a, b, and c) and then into the observed reaction product.

Later, Arnett and Bollinger[62] observed that when 1,2,4,5-tetra-t-butylbenzene (XXI) is irradiated with ultraviolet light, 1,2,3,5-tetra-t-butylbenzene (XXII) is formed, together with the "Dewar isomer" 1,2,3,5-tetra-t-butylbicyclo[2,2,0]hexa-2,5-diene (XXIII).[62] In the opinion of these workers, the fact that irradiation of the highly strained compound (XXI) gives the still more highly strained compound (XXII) excludes any other isomerisation mechanism except intramolecular reorganisation of bonds with the intermediate formation of the homologue of "Ladenburg benzene", "tetra-t-butylprismane" (XXIV) according to the following scheme:

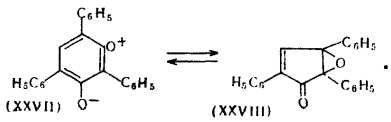


The reversibility of the valence isomerisation (XXI) $\rightleftharpoons$ $\rightleftharpoons$ (XXII) in this example has not yet been demonstrated.

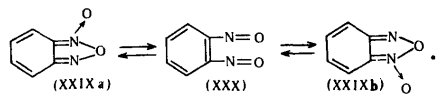
Reversible valence isomerisation similar to the isomerisation of benzene homologues to bicyclohexadiene homologues is observed in a number of heterocyclic compounds. Thus, illumination with sunlight converts 2-amino-5-chloropyridine (XXV) into the bicyclic isomer (XXVI), which was characterised by its ultraviolet and NMR spectra[63,64]. When set aside at room temperature, the isomer (XXVI) is reconverted into the initial compound; this is indicated by the reappearance of the characteristic absorption spectrum of the aminochloropyridine in the ultraviolet region:



Another type of valence isomerisation occurs with triphenylpyrilium oxide (XXVII),[65] which is converted on irradiation with light of wavelength greater than 4500 Å into 1,2,4-triphenylcyclopentadienone oxide (XXVIII) (see also other work[66-68]). On irradiation with light of wavelength 3200–3930 Å, the latter is converted into the starting compound (XXVII).



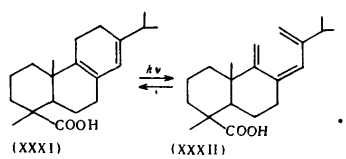
Instances of ring-chain valence tautomerism of heterocycles are known[69-72]. Thus, it was established[70,71] from the temperature dependence of the NMR spectrum of ^{17}O in benzofurazan oxide (XXIX) between -60° and +100° that this compound is in a state of rapid valence-tautomeric conversion, which includes an *o*-dinitrosobenzene (XXX) stage:



(XXIXa) (XXX) (XXIXb)

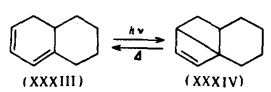
The life period of each tautomer is so short that none of them can be isolated in the pure state.

Under the action of light, compounds that have the 1,3-cyclohexadiene-ring system as a component undergo reversible valence isomerisation, which may proceed in two directions[73]. In the first, the six-membered ring containing two conjugated double bonds opens to form a hexa-1,3,5-triene grouping. In the other, a second smaller ring is formed inside the cyclohexadiene ring. An example of a conversion of the first type is the equilibrium between palustric acid (XXXI) and the triene (XXXII), which is set up by the action of light[74] (see also other work[26,75-81]):



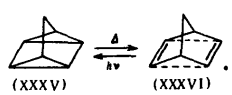
(XXXI) (XXXII)

A conversion of the second kind occurs when 1,2,3,4,9,10-hexahydronaphthalene (XXXIII) is irradiated with ultraviolet light; this compound then isomerises to the tricyclic hydrocarbon (XXXIV). When (XXXIV) is heated to 150°, (XXXIII) is regenerated[77] [see above, conversion (IV) ⇌ (III), also Dauben and Fonken[82], and Prinzbach and coworkers[83]]:



(XXXIII) (XXXIV)

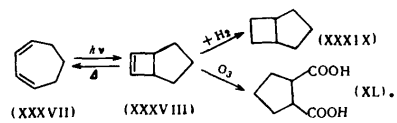
There is great interest[84-87] in the reversible isomerisation of quadricyclo[2,2,1,$0^{2,6}$,$0^{3,5}$]heptane (XXXV) to norbornadiene (XXXVI):



(XXXV) (XXXVI)

The existence of interaction between the 2 and 6, and between the 3 and 5 carbon atoms of the excited norbornadiene molecule facilitates this reaction[88].

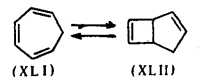
On ultraviolet irradiation, cyclopenta-1,3-diene (XXXVII) is converted into bicyclo[3,2,0]hept-6-ene (XXXVIII), the structure of which has been proved in an exhaustive manner (see scheme). When the photoisomer (XXXVIII) is heated to 400°, the reversible conversion (XXXVIII) → (XXXVII) occurs[89]:



(XXXVII) (XXXVIII) (XXXIX) (XL).

Some derivatives of cycloheptadiene undergo an analogous reversible photoisomerisation[90-93].

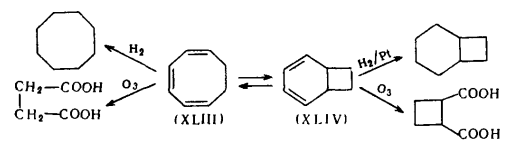
Under the action of light, cycloheptatriene, or tropilidene (XLI), isomerises to bicyclo[3,2,0-[hepta-2,6--diene (XLII);[89] tropilidine derivatives behave in the same way[30,94-96]. At high temperature, the bicyclic isomer (XLII) is converted into tropilidene:



(XLI) (XLII)

A great many cyclic polyenes undergo the so-called intracyclic diene synthesis, in which one double bond plays the part of a dienophile, and the other that of a conjugated diene system[97]. In turn, the bicyclic "adducts" obtained by this reaction can undergo retrodiene decomposition to give the starting compound; it not infrequently happens that both these reactions of cyclic polyenes occur under the same conditions, and as a result two valence-isomeric compounds are found to be in a state of tautomeric equilibrium.

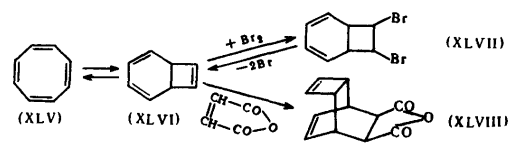
The most striking example of valence tautomerism is intracyclic diene synthesis and decomposition is the equilibrium between bicyclo[4,2,0]octa-2,4-diene (XLIV) and cyclo-octa-1,3,5-triene (XLIII), which is established at 100°.[97-101] The equilibrium position corresponds to a concentration of 15% of the bicyclic and 85% of the monocyclic tautomer. Both tautomers can be obtained in the pure state, and their structures have been proved conclusively (see scheme); when heated to 100° each of the tautomers gives the same mixture, (XLIII) + (XLIV):



(XLIII) (XLIV)

The activation energy for this conversion is 27.1 kcal × × mole^{-1}.[102]

The cyclo-octatetraene (XLV)–bicyclo[4,2,0]octatriene (XLVI) system is an example of widely displaced equilibrium:



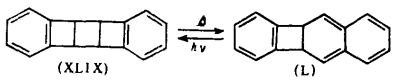
(XLV) (XLVI) (XLVII) (XLVIII).

It has long been known that cyclo-octatetraene reacts in two ways[103-109]. Thus, hydrogenation of (XLV) gives cyclo-octane, but halogenation and diene synthesis give the derivatives (XLVII) and (XLVIII) respectively, the formation of which would be expected on the basis of the tautomeric bicyclo-octatriene (XLVI). However, up to recently no reliable proofs that this tautomer really existed could be adduced. In 1964, the kinetics of the diene synthesis of cyclo-octatetraene with a number of dienophiles of different activity was studied[110]. The results showed that valence tautomerism does in fact exist between cyclo-octatetraene and bicyclo-octatriene, but the concentration of the bicyclic form is only about 0.01%. Nevertheless it is this form that determines the course of the diene-synthesis reaction.

Later, Vogel and coworkers succeeded in obtaining bicyclo-[4,2,0]octatriene (XLVI) in the pure state[111] by elimination of bromine from the dibromide (XLVII) at -78° with the aid

of the disodium derivative of phenanthrene. The structure of the hydrocarbon (XLVI) obtained in this way was confirmed by a number of chemical and spectroscopic data. At room temperature this hydrocarbon spontaneously isomerises to (XLV); the activation energy of the isomerisation is 18.7 kcal mole^{-1}.

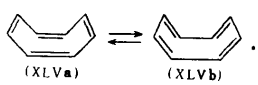
Derivatives of bicyclo[4,2,0]octatriene that are stable at room temperature are known [112,113]. On irradiation, some of them undergo valence isomerisation to the corresponding tricyclo[4,2,0,$0^{2,5}$]octadiene (XLIX) derivatives, for example [103]:



(XLIX) (L)

See also Wittig and Weinlich [112], Criegee and coworkers [113], and Keller and coworkers [114]. When (XLIX) is heated to 200°, (L) is regenerated.

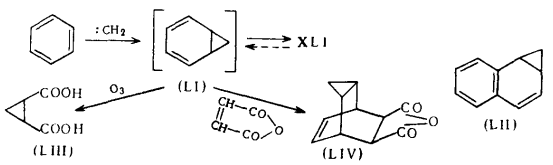
The results of a recent study of the temperature dependence of the NMR spectrum of cyclo-octatetraene led Anet and coworkers to the conclusion that there is a rapid displacement of single and double bonds within the cyclo-octatetraene ring [115]:



(XLVa) (XLVb)

The conversion (XLVa) $\rightleftharpoons$ (XLVb) does not lead to the formation of a new compound; it is an example of what is termed degenerate valence tautomerism. It is doubtful if degenerate valence tautomerism could be recognised by a chemical method, but it nevertheless has a real existence. Other examples of this kind of tautomerism will be given below. The activation energy of the conversion is 12 kcal × × mole^{-1}.

The problem of the existence of valence tautomerism in the tropilidene (XLI)–norcaradiene (LI) system has still not been solved [116,117]. Unsubstituted norcaradiene should be formed by the action of methylene on benzene, in the same way as benzonorcaradiene (LII) is obtained in the analogous reaction with naphthalene [118]:

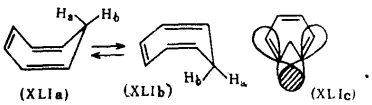


However, when diazomethane was decomposed in benzene, tropilidene was obtained instead of norcaradiene [119]. This may be explained by the isomerisation of norcaradiene to tropilidene immediately it is formed.

It was further noted that tropilidene has some anomalous properties: in oxidations it gives the compound (LIII), and in the diene-synthesis it gives the compound (LIV), both of which contain the three-membered ring [120–123]. Two possible explanations of the results of these reactions have been put forward [120]: either the reagent causes isomerisation of tropilidene to norcaradiene, which then reacts in the normal way, or even in the absence of the reagent the initial tropilidene contains norcaradiene as impurity, with which it is in a state of valence tautomerism. Up to now the presence of norcaradiene has not been detected in the reactions enumerated above, nor could it be shown that it is formed as an intermediate.

Spectroscopic data [123–128] indicate that if the equilibrium of the two forms actually exists, it must be almost wholly displaced in the direction of tropilidene; in any case, the concentration of the bicyclic tautomer does not exceed 0.01%. The preponderance of tropilidene can easily be accounted for: approximate calculations show that this hydrocarbon must be more stable than norcaradiene by 12 kcal mole^{-1}. [129]

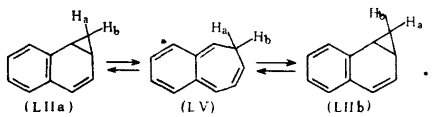
A study of the NMR spectrum of tropilidene at different temperatures [125,126,130], and X-ray studies of (XLI) and some of its crystalline derivatives [131,132] have shown that this hydrocarbon has a non-planar molecule in the form of a tub, with alternate single and double bonds. Even at room temperature tropilidene undergoes ring inversion (XLIa) $\rightleftharpoons$ $\rightleftharpoons$ (XLIb).



(XLIa) (XLIb) (XLIc)

The shape of the ring in this compound is such that the π-electrons of the carbon atoms at positions 1 and 6 partly overlap under the "tub", giving rise to an unusual π-bond (XLIc). [132] The existence of such a bond might explain the dual reactivity of tropilidene (reactions with transfer of reaction centre); however, the existence of valence tautomerism between the quasiaromatic compound (XLI) and norcaradiene is considered to be possible in principle [133]. It is clear that the detection of the bicyclic tautomer when it is present in insignificant concentration is no easy task.

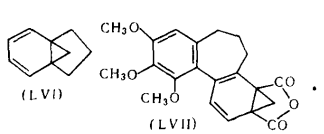
Under ordinary conditions, the benzonorcaradiene (LII) mentioned above is stable. This appears to be due to the high energy content of the valence-isomeric benzocycloheptatriene (LV), resulting from the formation of an *ortho*--quinoid structure [134]:



(LIIa) (LV) (LIIb)

Nevertheless, at temperatures of the order 150–180° a change of position is noted in the signals of the methylene--group protons in the NMR spectrum of benzonorcaradiene. According to Vogel and coworkers [135,136], this indicates that at high temperature a state of equilibrium is set up between the *exo*- and *endo*-forms of benzonorcaradiene, (LIIa) and (LIIb), the compound (LV) being formed as an intermediate [135,136]. The activation energy for the conversion of (LII) into (LV) was calculated from the temperature dependence of the chemical shifts of H_a and H_b; the value found was 19.4 kcal mole^{-1}.

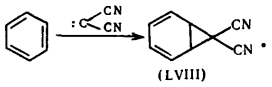
Norcaradiene derivatives fully resistant to isomerisation into the corresponding tropilidene derivatives may be obtained by linking the 1- and 6-carbon atoms of norcaradiene by a three-atom bridge, as in (LVI) [15] or (LVII) [137] (compare Knox and coworkers [138]):



(LVI) (LVII)

Recently it was found that the introduction of two nitrile groups at the seventh carbon atom of norcaradiene also makes

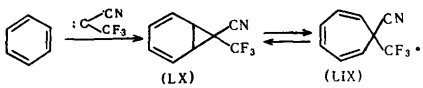
this system stable [139]. The synthesis of 7,7-dicyanonorcaradiene (LVIII) is shown by the following scheme:



(LVIII)

The structure of (LVIII) has been proved by ultraviolet and NMR spectra and by chemical methods.

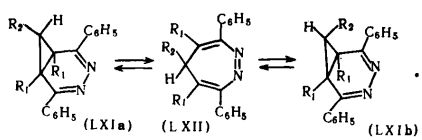
In contrast to (LVIII), 7-cyano-7-trifluoromethylcycloheptatriene (LIX), which is obtained by reaction of the corresponding carbene with benzene, is in equilibrium at room temperature with 7,7-disubstituted norcaradiene (LX): [140]



(LX) (LIX)

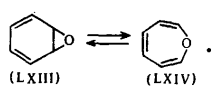
The preparation of stable derivatives of norcaradiene, and the existence of valence tautomerism between (LII) and (LV), and between (LIX) and (LX), definitely confirm the hypothesis of valence tautomerism in the norcaradiene-tropilidene system.

In 1963, Maier prepared nitrogen-containing analogues of norcaradiene (LXI) [141] and was subsequently [142,143] able to show the existence of a tautomeric equilibrium between (LXI) (R_1 = H, R_2 = CH_3) and the monocyclic form (LXII). The concentration of the latter, however, is so low that the compound (LXII) cannot be detected by chemical or by spectroscopic methods. The existence of equilibrium in the system (LXI) $\rightleftharpoons$ (LXII) can only be deduced on the basis of *exo/endo*-transfer of the 7-methyl group in the system (LXIa) $\rightleftharpoons$ (LXIb), which has been demonstrated by means of NMR spectroscopy:



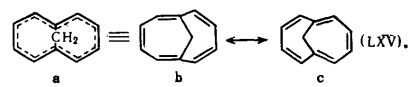
(LXIa) (LXII) (LXIb)

Valence tautomerism, analogous to the conversion (LXI) $\rightleftharpoons$ (LXII) has also been described in a number of three-membered heterocycles [144,145]. The position of the NMR signals and the ultraviolet absorption spectrum of benzene oxide (LXIII) [1a,5a-dihydrobenzoxiran] suggest that this compound is in a state of mobile equilibrium with oxepin (LXIV) (compare Vogel and coworkers [146]):



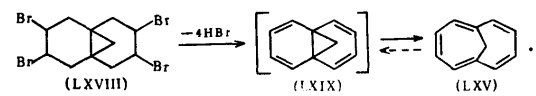
(LXIII) (LXIV)

Vogel and Roth [147] (see also Vogel and coworkers [146]) utilised the ability of norcaradiene to undergo spontaneous valence isomerisation with opening of the three-membered ring in the synthesis of 1,6-methanocyclodecapentaene§ (LXV). This hydrocarbon is of interest because it contains 10 π-electrons and according to Hückel's rule should be aromatic in character¶. In this case its structure would be represented by formula (LXVa) with delocalised double bonds, or, in terms of resonance theory, by the superposition of the two structures (LXVb) and (LXVc):



a b c (LXV).

The synthesis of (LXV) is effected according to the following scheme:



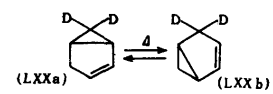
(LXVIII) (LXIX) (LXV)

When alkali acts on the tetrabromo-compound (LXVIII), 9,10-dihydro-9,10-methanonaphthalene (LXIX) should be obtained. However, this hydrocarbon contains the unstable norcaradiene grouping and might be expected to isomerise to (LXV) immediately it is formed. Moreover, the possibility of the formation of an equilibrium mixture of both compounds must be considered.

The ultraviolet and NMR spectra of the reaction product provide evidence against the structure (LXIX). The presence of a ring current in the molecule [147] and the chemical properties of the reaction product, for example, its tendency to undergo substitution reactions [151], are some indications of its aromatic character. However, the possibility of valence tautomerism between (LXIX) and (LXV) cannot be entirely ruled out.

The tendency of norcaradiene and related structures to isomerise to tropilidene and its derivatives is due to strain on the three-membered ring [2,3]: the energy for the breaking of the C–C bond of cyclopropane is less by 19 kcal mole^{-1} than the energy required to break the single bond in ethanol (81 kcal mole^{-1}). A further reduction in the C_1–C_6 bond energy in norcaradiene in comparison with saturated hydrocarbons occurs, because after this bond has been broken, two allyl radicals, capable of conjugation and therefore relatively stable, are formed. This reduces the C_1–C_6 bond energy by a further 2.22 kcal mole^{-1} (where 22 kcal mole^{-1} is the stabilisation energy of one allyl radical). As a result, the activation energy for the isomerisation of norcaradiene to tropilidene is only ~20 kcal mole^{-1}. [3,135]

Because of the favourable occurrence of a three-membered ring in conjunction with a double bond, valence isomerisation of compounds containing the vinylcyclopropane grouping is found to be very common [31,76,83,152–155]. An interesting example of this kind is the conversion of 6,6-dideuterobicyclo[4,1,0]hex-2-ene (LXXa) into 2,2-dideuterobicyclo-[4,1,0]hex-3-ene (LXXb) by heating to 225°. [3] It may be noted that this conversion only occurs because one of the carbon atoms of the initial molecule is labelled with deuterium; the isomerisation is degenerate. The NMR spectrum may be used to distinguish the initial molecule (LXXa) from the mixture of valence isomers (LXXa) and (LXXb) obtained after heating:

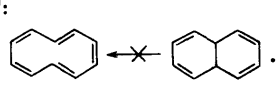


(LXXa) (LXXb)

Compounds containing two double bonds and a three-membered ring undergo valence isomerisation still more easily [118,156–165], as shown, for example, by the isomerisation of 1,2-divinylcyclopropane (LXXI) to cyclohepta-1,4-diene (LXXII); [3,33] the *cis*-isomer of this hydrocarbon is

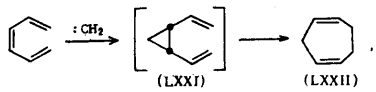
§ Bicyclo[4,4,1]undeca-1,3,5,7,9-pentene (Ed. of Translation).

¶ Attempts to prepare unsubstituted cyclodecapentaene (LXVI) by valence isomerisation of 9,10-dehydronaphthalene (LXVII) were not successful [148–150]:



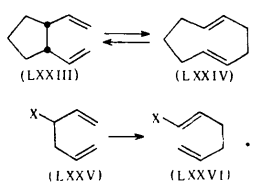
(LXVI) (LXVII)

converted into (LXXII) immediately it is formed from hexatriene and methylene at -40°:



In most instances the conversion turns out to be irreversible, because of the great difference in free energy between the initial and final compounds. This difference is less for divinylcyclobutane than for divinylcyclopropane [33], but the free energy of divinylcyclopentane (LXXIII) is found to be even somewhat less than that of the valence-isomeric cyclononadiene (LXXIV). Vogel and coworkers found that at 200° (LXXIII) and (LXXIV) are in a state of dynamic equilibrium [191]. The equilibrium position corresponds to a concentration of 95% of divinylcyclopentadiene and 5% of cyclononadiene.

The valence isomerisation of divinylcycloalkanes is a special case of the well-studied thermal isomerisation of 1,5-dienes called the Cope rearrangement [166,167] (LXXV)–(LXXVI):

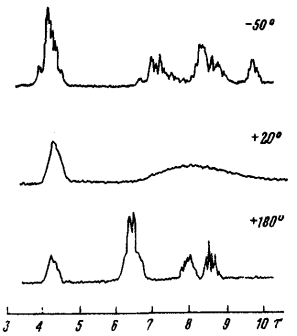


It is known that neither ionic nor radical intermediates are formed in the course of this reaction [2,3]: the reaction is effected via a cyclic transition state in which old bonds are broken and new bonds are simultaneously formed. Atoms or atomic groups do not migrate during the reaction; the Cope rearrangement is a typical example of valence conversion. However, in accordance with the definitions of rearrangement and isomerisation (see p. 560), these reactions should not be called rearrangements but isomerisations. The Cope isomerisation has been the subject of several reviews [2-4,33,168]; for this reason, we shall confine ourselves to a reference to some new examples of valence conversions of this type [52,53,169-179].

The valence tautomerism of homotropilidene, or bicyclo[5,1,0]octa-2,5-diene (LXXVII), and of other compounds containing the homotropilidene grouping occupies a special position among valence isomerisations. A special feature of these conversions is that they are degenerate (the initial and final stages of the conversion are indistinguishable) and that they occur very rapidly. It is concluded that tautomerism actually occurs, because the NMR spectra of homotropilidene and its derivatives undergo reversible changes with change of temperature, while the infrared spectra remain unchanged.

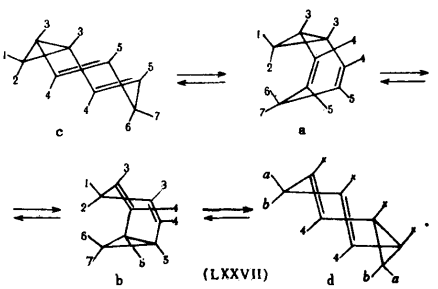
At -50° the NMR spectrum of homotropilidene [3,168,180] shows signals corresponding in position and intensity to the seven types of protons in homotropilidene (see Figure); at this temperature the rate of valence tautomerism of homotropilidene is relatively low.

When the temperature is increased, the conversion (LXXVIIa) ⇌ (LXXVIIb) is accelerated. Tautomerism leads to an exchange of the positions of protons, H_1 with H_7, H_2 with H_6, and H_3 with H_5. With very rapid mutual transfers (+180°), the half-life of each tautomer does not exceed 0.004 s; the H_1 and H_7 protons become indistinguishable in the NMR spectrum and give only one signal of type $2H_a$. Similarly,



NMR spectrum of homotropilidene.

H_2 and H_6 form one signal $2H_b$. Rapid mutual conversions of $2H_3$ and $2H_5$ lead to one new $4H_x$ signal. Only the $2H_4$ signal retains its position corresponding to two vinyl protons. Thus, from the point of view of NMR spectroscopy, the fairly rapid valence tautomerism of homotropilidene leads from a compound with seven types of protons to a compound with four types.



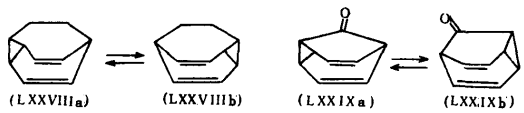
Because of the existence of rapid degenerate valence tautomerism, a single formula does not represent the structure of homotropilidene over a long time interval. Homotropilidene belongs to a group of compounds with what is termed a fluctuating structure [180].

Quite a number of compounds with fluctuating structures are now known; these include: tricyclo[3,3,2,$0^{4,6}$]deca-2,7-diene (LXXVIII), [181] tricyclo[3,3,1,$0^{2,8}$]nona-3,6-dien-9-one or barbaralone (LXXIX), [182] tricyclo[3,3,2,$0^{1,8}$]deca-2,5,9-triene or bullvalene (LXXX), [181,183-185] and also some derivatives of these [186-191].

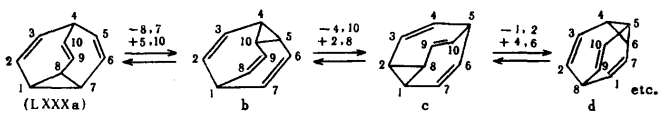
Homotropilidene exists in two forms, the cisoid (LXXXVIIa) and the transoid (LXXVIIc), and only the cisoid form undergoes isomerisation [180], but with barbaralone and bullvalene the unsuitable transoid conformation of the molecule is excluded, and valence isomerisation may be expected to occur still more readily. The question than arises whether a limit has been reached at which two separate classical structural formulae cease to correspond to two separate potential energy minima (each with its own set of vibrational levels) and are converted into two limiting structures representing the same compound. Here the concept of tautomerism would have to be equated with the concept of mesomerism.

A study of the NMR spectrum of barbaralone has shown that at -60° this ketone exists in the form of two tautomers. At higher temperatures, the spectrum shows some intermediate proton positions, which are occupied during the

rapid transformation from one tautomer to the other. The activation energy of the valence-tautomeric conversion of barbaralone is only 8.1 kcal mole^{-1}.



As would be expected, bullvalene (LXXX), which was predicted in 1962 by Doering [168] and synthesised in 1963 by Schröder [183,184], has only one signal in its NMR spectrum at 100°. This means that, at this temperature, because of very rapid valence-tautomeric conversions, all the protons, and therefore all the carbon atoms, of the molecule become, as it were, equivalent. It can be shown by means of successive Cope isomerisations, associated with the rupture of any of the three C–C bonds of the three-membered ring (the molecule has a threefold axis of symmetry), that each carbon atom can occupy the position of any other atom, for example:



It has been calculated that there are more than a million different mutual arrangements of the carbon atoms in bullvalene, and all these combinations (permutations [186]) occur in the molecule over a short time interval, comparable with the relaxation period of the nuclear spins of the protons linked with these carbon atoms. Thus, the carbon atoms of bullvalene are not in "fixed" positions but move at relatively high speed over the "surface" of the molecule [168]. These displacements of atoms do not, however, lead to a change in the structure of the compound.

It should be noted that the high rate of bullvalene valence--tautomeric conversions must, however, not be regarded as evidence that all the 1 209 600 tautomers that undergo mutual conversion can be obtained one from the other at the same rate, since the conversion of one into another occurs in many stages – for example, (LXXXa) into (LXXXd). [186]

The question whether bullvalene is an equilibrium mixture of a tremendous number of valence isomers undergoing rapid conversion or an individual compound which is a resonance hybrid of a number of electronic structures has been decided with the aid of the theory of groups: ten points cannot be arranged on the surface of a sphere in such a way that a geometrical figure completely symmetrical in three dimensions is obtained. It is quite clear that only with such a construction would bullvalene have ten really equivalent carbon atoms. Since this construction is impossible, it follows that even at high temperature bullvalene is a mixture of 1.2 million irregular polyhedra, rapidly being converted into one another. The minimum energy of this system is represented not by one average state but by 1.2 million states identical in energy (degenerate), but separated from one another by an energy barrier (11.8 kcal mole^{-1} [185]). In other words, in bullvalene we also have an instance of valence tautomerism, and not of mesomerism.

The number of examples of reversible valence isomerism has increased to such an extent in recent years that it would be difficult to give all the examples in a single review. However, even the foregoing presentation will be quite sufficient to attract the attention of chemists to this new interesting type of isomerisation†.

I. INTRODUCTION

The boron hydrides occupy a special place among the various classes of boron compounds, being typical representatives of electron deficient compounds. The study of their structure and reactivity has been the largest contribution to the theory of the chemical bond. The boron hydrides also find practical application as fuel additives, lubricants, neutron absorbers, intermediates in the production of polymers with special properties, selective reductants, etc. The first series of boron hydrides were obtained by Stock at the beginning of the XXth century after his development of special apparatus suitable for work with thermally unstable compounds sensitive to moisture and air. The chemistry of the boron hydrides has begun to develop extremely rapidly in the last decade, and now about 50 years after their discovery, the structure and chemical properties of a series of stable and unstable boron hydrides and their derivatives have been rather well studied.

The present article is a brief review of most of the investigations on the structure and chemical reactions of the boron hydrides containing from three to nine boron atoms in the molecule, the main attention being directed to the chemical properties of these compounds. The literature cited is mainly up to 1st July 1964. The problem of the structure of the boron hydrides received detailed discussion in Lipscomb's book [1], in which the chemical reactions of individual boron hydrides received comparatively little attention. The structure and chemical properties of diborane were reviewed by Mikhailov [2] and the chemistry of decaborane by Stanko and coworkers [3]. Some problems of boron hydride chemistry have been briefly discussed in the book by Samsonov and coworkers [4].

II. GENERAL CONSIDERATIONS ABOUT THE NATURE OF THE BONDS IN BORON HYDRIDES

Lipscomb proposed and developed the modern theory of the structure of boron hydrides, explaining their special properties on the basis of the concept of three-centre bonds. As is well known, with the usual covalent (two-centre) bond the two atoms have two orbitals (one bonding and one antibonding) in common and one electron from each atom; the pair of electrons fill the bonding orbital and form a two-centre bond. In the formation of a three-centre bond three atoms

have three orbitals in common use, in the interaction of which one bonding and two antibonding orbitals are formed. A pair of electrons fills only the bonding orbital. These types of bond are instances of the general type of multi-centre bonds. In considering the structure of the boron hydrides studied by him and other investigators, Lipscomb arrives at the following fundamental conclusions.

1. The hybrid orbitals of the boron atoms belong to the usual types of hybridisation: tetrahedral sp^3 or trigonal planar sp^2. The nature of the hybridisation is determined by energetic factors favourable to the formation of the most stable bonds. The hydrogen atoms use only the 1s-orbitals.

2. Each terminal B–H bond is a "normal" two-centre bond; on account of the very small difference in electronegativity of the boron and hydrogen atoms these bonds are considered non-polar. Each boron atom has not more than two terminal B–H bonds.

3. For the formation of the skeleton of the boron hydride molecule, bonds of four types are used in addition to the terminal B–H bonds; (a) B–H–B bridging three-centre bonds of "open" type; the electron density in this type of bond is concentrated along the lines joining the atoms; (b) two-centre covalent B–B bonds; (c) "open" three-centre B⟨B⟩B bonds, in which the π-orbital of the central boron atom and two σ-orbitals of the outer boron atoms are used; (d) the "central" three-centre bond B⟨B⟩B, using the σ-orbitals of all three boron atoms; the electron density is concentrated near the centre of the triangle connecting the boron atoms.

4. The orbitals and electrons of the boron atoms are so distributed as to first satisfy the requirements of the terminal B–H bonds and bridging B–H–B bonds. The remaining orbitals and electrons are used for bonds with the other boron atoms, which form the molecular skeleton. The molecules of the boron hydrides are constructed from a few "structural units" and for a given empirical formula the number of possible structural units and bonds is strictly limited and can be determined by use of the topological theory developed by Lipscomb.

5. The following are the most apparent principles in the geometry of most boron hydride molecules: the arrangement of the boron atoms as fragments of octahedra or icosahedra; the presence of hydrogen bridge atoms in the open parts of the molecule; coordination numbers of 5 or 6 for the boron atoms; and a marked tendency to the formation of triangles of boron atoms. Triangles formed by a bridge hydrogen and the two boron atoms adjacent to it, and triangles of boron atoms, can replace one another on going from one member of the series to another.

III. TRIBORANE

1. Structure

Triborane itself, B_3H_9, has not been obtained, owing to its instability. In several studies [5-8] the formation of B_3H_9 or B_3H_7 as intermediates in the conversion of diborane into higher boron hydrides is assumed, and also in the action of HCl on NaB_3H_8. [9] The B_3H_9 molecule contains 18 electrons and 21 orbitals. Lipscomb [10,11] has proposed the most satisfactory structure for B_3H_9, in which each boron atom forms two terminal B–H bonds; three BH_2 groups are connected by bridging hydrogen atoms, forming a ring, similar to cyclopropane (Fig. 1; one of the terminal hydrogen atoms of the BH_2 groups is not shown).

Triborane derivatives in the form of complexes of neutral, $B_3H_7.L$ (where L is a Lewis base), or ionic, $X^+B_3H_8^-$, type have been isolated and studied in detail. Their structure was established by X-ray diffraction and by NMR spectra.

Nordman and Reimann [12,13] showed that the complex $NH_3.B_3H_7$ has two crystalline modifications: low-temperature (monoclinic crystals with group symmetry $P2_{1/n}$, unit-cell parameters a = 10.40, b = 4.824, c = 9.997 Å, β = 115.2°), which is converted at 297.0°K into the high-temperature form with partly disordered crystals (tetragonal with unit-cell parameters a = 6.11, c = 6.57 Å). The low-temperature modification of $NH_3.B_3H_7$ has been studied in sufficient detail and the positions of the B, N, and H (bound to B) atoms have been accurately determined; those of the H atoms bound to N have not, probably because of their rapid random motion in relation to the B–N bond. These authors, and also Kodama and Parry [14], ascribed to the complex $NH_3.B_3H_7$ the structure shown in Fig. 2.

The following interatomic distances have been determined (in Å): $B_{(1)}-B_{(2)}$ = 1.744 ± 0.005, $B_{(1)}-B_{(3)}$ = 1.820 ± ± 0.006, $B_{(2)}-B_{(3)}$ = 1.803 ± 0.006, $N-B_{(3)}$ = 1.581 ± 0.003, $B-H_{terminal}$ = 1.13 ± 0.07, $B_{(1)}-H_{(3)}$ = 1.23 ± 0.03, $B_{(2)}-H_{(3)}$ = = 1.39 ± 0.05, $B_{(3)}-H_{(6)}$ = 1.12 ± 0.03, $B_{(2)}-H_{(6)}$ = 1.75 ± 0.03; the angles between bonds are: $\angle NB_{(3)}B_{(1)}$ = 111.0° ± 0.5°, $\angle NB_{(3)}B_{(2)}$ = 115.3° ± 0.5°, $\angle NB_{(3)}B_{plane}$ = 117.2° ± 0.5°.

The B_3H_7 group is considered to be a fragment of a tetraborane molecule, formed from it in the symmetrical splitting of a bridge bond. A triangle of boron atoms forms two bridge bonds $B_{(1)}H_{(3)}B_{(2)}$ and $B_{(2)}H_{(6)}B_{(3)}$ and one covalent bond $B_{(1)}B_{(3)}$, and the NH_3 group is connected with the $B_{(3)}$ atom and located at an angle of 65° to the plane formed by the boron atoms.

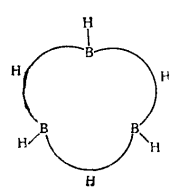

Fig. 1.

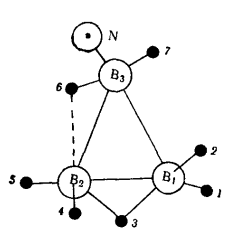

Fig. 2.

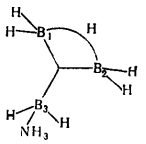

Fig. 3.

Muetterties and coworkers [15], on the basis of the ^{11}B-NMR spectrum of $B_3H_7.O(C_2H_5)_2$ and NaB_3H_8, which showed the identity of all three boron atoms, ascribed to $B_3H_8^-$ and B_3H_7 another type of structure, in which three identical boron atoms are connected by six bridging hydrogen atoms. Furthermore, the molecule contains two hydrogen atoms of another type, each of which is joined to all three boron atoms. Such a structure does not agree with the results of the X-ray analysis of $NH_3.B_3H_7$ [12] and $N(CH_3)_3.B_3H_7$, [10] which show that these molecules do not possess a third-order axis of symmetry. The results on the geometry of $NH_3.B_3H_7$ also agree rather well with the structure shown in Fig. 3. Here the $B_{(3)}-H_{(6)}$ bond is a terminal B–H bond and the $B_{(2)}$ atom is not connected to the $H_{(6)}$ atom. All three boron atoms are connected to one another by a central three-centre bond and each boron atom has two terminal hydrogen atoms. The atoms $B_{(1)}$ and $B_{(2)}$ are linked by hydrogen bridge bonds and a vacant orbital of the atom $B_{(3)}$ is used for a coordinate bond with the nitrogen atom. This structure is supported by the following facts: (1) the length of the $B_{(1)}-B_{(3)}$ bond is appreciably greater than the length of the B–B covalent bond in B_4H_{10} (1.712 Å); (2) the distance between the atoms $B_{(1)}$ and $B_{(2)}$ (1.744 Å) is less than that between the boron atoms joined by hydrogen bridging atoms (1.84 Å); (3) the B_3H_6 distance equals the mean of the terminal B–H bonds whereas B_2H_6 is 0.4 Å greater than the length of the usual bridging bond.

The structure of the ion $B_3H_8^-$ was found by X-ray diffraction and NMR spectra. The X-ray structural analysis [16] of the "diammoniate of tetraborane" $[(NH_3)_2BH_2]^+.[B_3H_8]^-$ at 25° and -100°C shows that the boron atoms in the anion form a triangle of icosahedra with a base of 1.80 Å and sides of 1.77 Å. On the basis of these results the structure shown in Fig. 4 is proposed. $B_{(1)}-B_{(3)} = 1.80$ Å, $B_{(1)}-B_{(2)} = B_{(2)}-B_{(3)} = 1.77$ Å, $B-H_{terminal} = 1.05-1.20$ Å, $B_{(2)}-H_{bridge} = 1.5$ Å, $B_{(1)}-H_{bridge} = B_{(3)}-H_{bridge} = 1.2$ Å.

In the ion $B_3H_8^-$ there is a tautomerism of the hydrogen atoms [10,17] which is facilitated by the increase in the interatomic distances and the presence of a negative charge. This exchange explains the ^{11}B- and ^1H-NMR spectra of NaB_3H_8 [15] and $(CH_3)_4NB_3H_8$ [18] leading to the conclusion that all the boron atoms are equivalent and connected to the same hydrogen atoms, as in $Al(BH_4)_3$, where all the hydrogen atoms are identical.

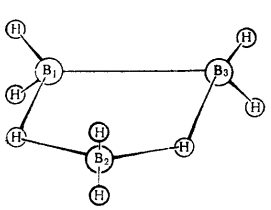

Fig. 4.

2. The Compounds $B_3H_7.L$

The triborane derivative which has been studied in most detail is triborane ammine, $NH_3.B_3H_7$, first obtained by Kodama and coworkers [14] by the action of NH_4Cl on an ethereal solution of NaB_3H_8: [19]

$$NaB_3H_8 + NH_4Cl \xrightarrow[25°]{(C_2H_5)_2O} NH_3.B_3H_7 + H_2 + NaCl\downarrow.$$

However, the compound is obtained in small yield (20–30%) and insufficiently pure; therefore Kodama and coworkers [14,20] also developed a method by which $NH_3.B_3H_7$ is obtained from B_4H_{10} by a series of reactions analogous to those for preparing $NH_3.BH_3$ from B_2H_6. In the action of NH_3 on an ethereal solution of B_4H_{10} at -78°C, the tetraborane undergoes unsymmetrical splitting with the formation of tetraborane diammine, $[(NH_3)_2BH_2]^+[B_3H_8]^-$. On treating this compound with dry HCl in an ethereal solution at low temperature, the reaction:

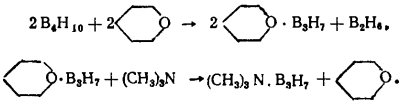
$$[(NH_3)_2BH_2]^+[B_3H_8]^- + HCl + (C_2H_5)_2O \xrightarrow[-78°]{} [(NH_3)_2BH_2]^+Cl^-\downarrow + B_3H_7\cdot(C_2H_5)_2O + H_2,$$

occurs. When the triborane–ether product is treated with ammonia $NH_3.B_3H_7$ is obtained:

$$NH_3 + B_3H_7\cdot(C_2H_5)_2O \xrightarrow[-78°]{(C_2H_5)_2O} NH_3.B_3H_7 + (C_2H_5)_2O.$$

When tetrahydropyran is used instead of ether, pure $NH_3.B_3H_7$ is obtained in 70–94% yield [14]. Triborane–ammonia is a white, crystalline substance, which melts at 73–75°C with weak liberation of hydrogen, and sublimes slowly in a high vacuum. It does not decompose in air and is stable to hydrolysis: the substance is completely hydrolysed only after heating with 6 *N* HCl for several days; the compound dissolves readily in ether, liquid ammonia (at -75°C), and benzene, and is also soluble in acetone and alcohol. The vapour pressure–temperature relation [21], heat capacity, and other thermodynamic constants [22] of $NH_3.B_3H_7$ have been measured, and some of its chemical properties have been studied [14]. It has been found that it does not react with trimethylamine at -78°C, but at 25°C they form $N(CH_3)_3.BH_3$ and an unidentified solid substance, which probably has the composition $HB[N(CH_3)_3]$. [23] NH_3 could not be replaced by $(CH_3)_3N$. When sodium in liquid ammonia acts on $NH_3.B_3H_7$, the B_3H_7 is again destroyed, an equimolecular quantity of hydrogen being released and $NaBH_4$ formed.

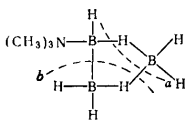
Trimethylamine–triborane $(CH_3)_3N.B_3H_7$ was obtained [24] by a method analogous to that for $NH_3.B_3H_7$:



The yield of $(CH_3)_3N.B_3H_7$ was 65–70%. The compound resembles $NH_3.B_3H_7$ in its properties: when pure it is stable to hydrolysis (for complete hydrolysis heating with 10% HCl for 100 h at 150°C is necessary), it does not decompose on heating to 300°C, does not dissolve in water, is sparingly soluble in ether, and can be recrystallised from alcohol and toluene without decomposition. Crystals of $(CH_3)_3N.B_3H_7$ have two modifications with a transformation point at 209.6°K. The thermodynamic functions of this compound have been determined [24].

Some chemical properties of $(CH_3)_3N.B_3H_7$ have been studied and the instability of the B_3H_7 fragment has been demonstrated. An excess of $(CH_3)_3N$ leads to the splitting of the compound with the formation of $(CH_3)_3N.BH_3$ and $H[B(CH_3)_3]_x$. [25]

A mechanism has been proposed for this reaction[23,26], according to which in the presence of an excess of $(CH_3)_3N$ there is "symmetrical" splitting of the B_3H_7 skeleton, during which the B–H–B bridge bond is broken first (a) with liberation of a BH_3 group and then splitting of the B–B bond occurs with the formation of another BH_3 group (b):



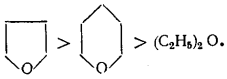
$$\xrightarrow{(CH_3)_3N} 2(CH_3)_3N\cdot BH_3 + HB[N(CH_3)_2]_x.$$

$(CH_3)_3N.B_3H_7$ is also split by triphenylphosphine[27], but there is then incomplete splitting of the triborane skeleton:

$$3(C_6H_5)_3P + (CH_3)_3N.B_3H_7 \xrightarrow[80°]{C_6H_6} [(C_6H_5)_3PBH_2]_2 + (C_6H_5)_3P\cdot BH_3 + N(CH_3)_3.$$

The triborane addition compounds with phosphine Lewis bases were made by a method developed for making $NH_3.B_3H_7$. When $(C_6H_5)_3P$ acts on the addition compound of B_3H_7 with tetrahydrofuran (THF), the THF is displaced and the complex $(C_6H_5)_3P.B_3H_7$ is formed in 54% yield[27]; when $(C_6H_5)_3P$ reacts with $(CH_3)_2S.B_3H_7$ a little $(C_6H_5)_3P.B_3H_7$ is formed and much more $(C_6H_5)_3P.BH_3$. It has been shown that the direction of the reaction depends on the strength of the bond between the ligand and the boron atom in the original complex $B_3H_7.L$: the stronger this bond the greater the destruction of triborane and the quantity of $(C_6H_5)_3P.BH_3$ formed – the strength diminishes in the sequence $(CH_3)_3N > (CH_3)_2S > C_4H_8O$. The displacement of the comparatively weak base tetrahydropyran (THP) from the complex $B_3H_7.THP$ also takes place under the action of a bicyclic phosphite – 4-methyl-2,6,7-trioxa-1-phosphabicyclo[2,2,2]octane, $CH_3C(CH_2O)_3P$, in which the complex $CH_3C(CH_2O)_3P.B_3H_7$ is formed with almost quantitative yield[28].

The strength of the B–P dative bond in the coordination compounds of B_3H_7 is less than that of the B–N bond in $(CH_3)_3N.B_3H_7$. Study of the B_3H_7 complexes with various Lewis bases (ethers, NH_3, amines, substituted phosphines, sulphides, etc.) showed that the stability of the $B_3H_7.L$ complexes depends on the coordination capacity of the base. The weaker Lewis bases, such as $(C_2H_5)_2O$, $(CH_3)_2S$, and thiophen, form unstable complexes with B_3H_7, stable only at low temperatures. Strong Lewis bases – pyridine, $(CH_3)_3N$, $(n\text{-}C_3H_7)_3N$ – form stable complexes, but an excess of the amine destroys them, with the formation of BH_3 and polymeric compounds[26]. It has been shown[14] that the stability of the $R_2O.B_3H_7$ complexes decreases in the order:



$$> (C_2H_5)_2O.$$

B_3H_7 is a stronger Lewis acid than BH_3 [26] and displaces the latter from its complexes; therefore under the action of tetraborane the BH_3.amine complexes are converted into B_3H_7.amine complexes with subsequent slow decomposition of the latter into B_2H_6, B_5H_9, and H_2.

3. Properties of Compounds of the Type $X^+.B_3H_8^-$

Triborane compounds with an ionic structure which have been obtained are NaB_3H_8, $(CH_3)_4NB_3H_8$, and $[BH_2(NH_3)_2]^+[B_3H_8]^-$.

Sodium octahydrotriborate(-1) NaB_3H_8 was first obtained by Hough and coworkers[19,29] in yields up to 80% by reaction of sodium amalgam with diborane(6) in ether at room temperature:

$$2Na + 2B_2H_6 \rightarrow NaBH_4 + NaB_3H_8.$$

NaB_3H_8 was the first representative of triborane(9) derivatives of ionic type. It is thermally stable up to a temperature as high as 200°C, readily soluble in ether, methanol, water, and liquid ammonia; it is more stable to hydrolysis than $NaBH_4$; it is solvated in ether, poly- and mono-ether addition compounds having been identified. Dissolution in water and aqueous HCl is accompanied by partial hydrolysis, but complete hydrolysis requires heating with water at 100°C for some days.

NaB_3H_8 is readily formed also by the action of sodium on a solution of "diammoniate of tetraborane" in liquid ammonia[20]:

$$[H_2B(NH_3)_2]^+[B_3H_8]^- + Na \xrightarrow[-78°]{NH_3} NaB_3H_8 + H_2BNH_2 + NH_3 + {}^1/_2H_2.$$

The yield reaches 60–70%. This reaction is analogous to the reaction for producing $NaBH_4$ from "diborane diammine". NaB_3H_8 is obtained in yields of up to 90% by the reaction of $NaBH_4$ with diborane in dimethoxyethane[30].

A neutral triborane complex, $B_3H_7.NH_3$, is formed by the action of ammonium chloride in ether on NaB_3H_8 at 25°C.[14] The behaviour of NaB_3H_8 in this reaction is also analogous to $NaBH_4$, from which $NH_3.BH_3$ is formed under the same conditions.

Gaines and coworkers[31] proposed a rapid and convenient method for preparing $X^+.B_3H_8^-$ compounds by the hydroboration with diborane of the products of the addition of alkali metals to triphenylboron or naphthalene, or by the reaction of metal hydroborates with B_2H_6 in ethereal solution at 100°C. The salt $(CH_3)_4NB_3H_8$ was obtained in high yield. The mechanism of the reaction is unexplained. An interesting path for the preparation of compounds with the $B_3H_8^-$ anion has been proposed, consisting in the stepwise decomposition of decaborane by methanol under strictly controlled conditions[18]:

$$B_{10}H_{14} + 2(C_2H_5)_2S \xrightarrow[80°]{C_6H_6} B_{10}H_{12}\cdot[(C_2H_5)_2S]_2 + H_2; \quad (1)$$

$$B_{10}H_{12}\cdot[(C_2H_5)_2S]_2 + 3CH_3OH \xrightarrow{65°} B_9H_{13}\cdot(C_2H_5)_2S + H_2 + (C_2H_5)_2S + B(OCH_3)_3; \quad (2)$$

$$B_9H_{13}\cdot(C_2H_5)_2S + (CH_3)_4NOH \xrightarrow{C_2H_5OH} B_9H_{12}\cdot(CH_3)_4N + (C_2H_5)_2S + H_2O; \quad (3)$$

$$B_9H_{12}\cdot(CH_3)_4N + 18CH_3OH \xrightarrow{25°} [B_3H_8]^-[(CH_3)_4N]^+ + 6B(OCH_3)_3 + 11H_2. \quad (4)$$

The reaction takes place readily and this method of making $(CH_3)_4N.B_3H_8^-$ (35% yield) is convenient preparatively. $[(CH_3)_4N]^+[B_3H_8]^-$ is a stable, white, crystalline substance, which does not melt below 275°C and is insoluble in cold methanol. It reacts with $(CH_3)_3N.HCl$ in tetrahydrofuran at its boiling point, and forms $(CH_3)_3N.B_3H_7$ in good yield[18]:

$$[(CH_3)_4N]^+[B_3H_8]^- + (CH_3)_3N\cdot HCl \rightarrow (CH_3)_3N\cdot B_3H_7 + H_2 + (CH_3)_4NCl.$$

Hence here, as for NaB_3H_8, the anion $B_3H_8^-$ is converted into the neutral fragment of triborane B_3H_7.

IV. TETRABORANE(10) B_4H_{10}

1. Structure of Tetraborane

Tetraborane was the first of the boron hydrides to be definitely characterised as a chemical compound by Stock and Massenez[32] in 1912. The position of the boron and

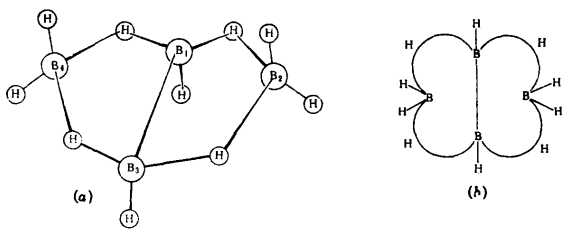


Fig. 5.

hydrogen atoms in B_4H_{10} was unequivocally established by X-ray diffraction [33-35] and electron diffraction [36], also with the aid of ^1H- and ^{11}B-NMR spectra [37]. On the basis of these results for tetraborane the structure shown in Fig. 5 was proposed [10,11]. A quantum-chemical calculation for the molecule was made [38].

The interatomic distances for B_4H_{10} determined by the electron and X-ray diffraction methods differ somewhat from one another. Lipscomb quotes [10] the X-ray results as the more accurate for the distances between the boron atoms and the molecular angles, and the electron diffraction results for the B–H distances. The main data about the geometry of the B_4H_{10} molecule are (in Å): $B_{(1)}-B_{(2)}$ = = 1.842, $B_{(1)}-B_{(3)}$ = 1.712, $B_{(2)}-B_{(4)}$ = 2.800, $B-H_{terminal}$ = = 1.19, $B_{(1)}-H_{bridge}$ = 1.16, $B_{(2)}-H_{bridge}$ = 1.37; the angles (in degrees) are: $\angle B_{(1)}-B_{(2)}-B_{(3)}$ = 56.6, $\angle B_{(1)}-B_{(3)}-B_{(2)}$ = = 61.7, $\angle B_{(2)}-B_{(1)}-B_{(4)}$ = 98, $\angle B_{(1)}-B_{(3)}-H_{(1)}$ = 118; angle between the $B_{(1)}-B_{(3)}-B_{(2)}$ and $B_{(1)}-B_{(3)}-B_{(4)}$ planes = 118.1.

The B_4H_{10} molecule contains two types of boron atom. Each atom of type I forms one two-centre B–H bond and two bridging three-centre B–H–B bonds; furthermore, these two boron atoms are connected to one another by a covalent bond making use of the remaining orbitals and electrons of each atom. The atoms of type II form two two-centre B–H bonds and two three-centre B–H–B bridge bonds, these using all four sp^3-orbitals and all three electrons of the boron atom. The planes of the two triangles formed by the boron atoms are disposed at an angle of 118.1°. The framework formed by the boron atoms of B_4H_{10} can be considered as a fragment of an octahedron or icosahedron as the $B_{(2)}-B_{(1)}-B_{(4)}$ valence angle (98°) is the mean between the angles for an octahedron (90°) and an icosahedron (108°).

Williams and coworkers [37] made a detailed study of and interpreted the ^1H- and ^{11}B-NMR spectra of B_4H_{10}, which confirmed the structure of the molecule shown in Fig. 5. The ^{11}B-NMR spectrum contains a triplet in the weak field region corresponding to the BH_2 groups, and a doublet in the strong field region, corresponding to BH groups; the interpretation of such a doublet structure as a consequence of the $^{10}B-^{11}B$ interaction [37] seemed incorrect, as such interaction is not observed in ^{11}B-NMR spectra of deuterated tetraborane [39]. The ^1H-NMR spectrum of tetraborane shows the presence in it of two types of terminal hydrogen atoms and bridging hydrogens.

The determination of the dipole moment of B_4H_{10}, [38,40] 0.56 ± 0.1 D (in benzene) shows that all the boron atoms are electrically neutral; the slight polarisation of the molecule is due to second-order effects.

2. Preparation of Tetraborane

Tetraborane(10) was first obtained by the action of HCl on magnesium boride [32]:

$$Mg_3B_2 + HCl \rightarrow B_4H_{10} + MgCl_2.$$

This method gives a negligible yield (~ 1%) of a contaminated product. Subsequently several other methods for preparing it were developed. Stock and his coworkers studied the decomposition of several metal borides with various mineral acids [41] and found [42] that the yield is somewhat better in the decomposition of beryllium boride by hydrochloric acid (~ 1.5–2%) and pure B_4H_{10} is obtained (it does not contain silicon hydrides as impurity). Wiberg and Schuster [43] found that when magnesium boride (or a mixture of magnesium and boron trioxide) is decomposed by 8 N H_3PO_4 tetraborane is obtained in ~ 11% yield:

$$B_2O_3 + Mg \rightarrow Mg_3B_2;\ Mg_3B_2 + H_3PO_4 \rightarrow B_4H_{10} + Mg_3(PO_4)_2.$$

In later work [44] it was shown that in this way B_4H_{10} can be obtained in yields of up to 14.5%. Tetraborane was prepared [45] from B_2H_5I and sodium amalgam in 30% yield:

$$2\,B_2H_5I + 2\,Na \xrightarrow[-35°]{} B_4H_{10} + 2\,NaI.$$

However, the method is not very suitable for obtaining comparatively large amounts of tetraborane on account of the instability of B_2H_5I.

After the development of a method of making diborane from boron halides and hydrogen in an electric discharge [46], tetraborane began to be made by the pyrolysis of B_2H_6, initially through the intermediate stage of converting it into B_5H_{11} (100°C, 10 min) and the pyrolysis of the latter [47], and later by direct pyrolysis of B_2H_6 at 180°C and reduced pressure (450 mmHg). [48] Pyrolysis of diborane at elevated pressure (50 atm, 50–75°C) leads to the production of B_4H_{10} in yields of 20–35%. [49] All these methods had various drawbacks. In 1958 a convenient laboratory method for obtaining B_4H_{10} or B_5H_{11} (depending on the reaction conditions) by the pyrolysis of B_2H_6 was proposed [50], and made these compounds accessible. The novelty in this method was the construction of the reactor, which consisted of two tubes, nesting one within the other. The outer tube is cooled and the inner is heated to the required temperature. The reaction zone is the space between the tubes. This reactor ensures that the removal of the unstable boron hydrides from the reaction zone is as fast as possible. Low-temperature, high-vacuum fractionation [41], or gas chromatography [51] is used to isolate pure B_4H_{10} from the mixture of boron hydrides; the yield of B_4H_{10} reaches 83%. Tetraborane is also formed in the reduction of diboron tetrachloride by metal tetrahydroborates at low temperature [52]:

$$B_2Cl_4 + 4\,LiBH_4 \xrightarrow[-45°]{} B_4H_{10} + B_2H_6 + 4\,LiCl.$$

The reaction is complex, and a mixture of boron hydrides is formed.

Kreyl and Marcus [53] studied the photochemical conversion of B_2H_6 into B_4H_{10} and showed that the mechanism of this reaction is different from the thermal process. The authors think that the reaction proceeds by a free radical path with the intermediate formation of B_2H_5:

$$B_2H_6 + h\nu \rightarrow B_2H_5^{\cdot} + H^{\cdot};\ 2\,B_2H_5^{\cdot} \rightarrow B_4H_{10};\ 2\,H^{\cdot} \rightarrow H_2.$$

An analogous mechanism was proposed for the mercury-sensitised conversion of B_2H_6 into higher boron hydrides [54]. Several patents were taken out on the production of B_4H_{10}:

from B_2H_6 in a silent electric discharge[55] (yield of B_4H_{10} 43–97% in the conversion of 7–36% of the B_2H_6); from B_5H_{11} by its partial hydrolysis at 0°C, 15–50 mmHg pressure, and a time of contact of B_5H_{11} with ice of 1 min.[56,57] The yield of B_4H_{10} reaches 95%.

3. Physical and Chemical Properties of Tetraborane

Tetraborane is a mobile liquid, b.p. 18°C, f.p. -120°C, vapour pressure at 0°C 388 mmHg, density 0.56 at -35°C.[41] It exhibited a high toxicity[58]. As Stock showed[41], B_4H_{10} is unstable at room temperature and slowly breaks down into B_2H_6, B_5H_9, H_2, and involatile boron hydrides. A prolonged experiment, which lasted 340 h,[41] in which B_4H_{10} was put in the cell of an infrared spectrograph at 20° and its infrared spectrum periodically recorded showed that equilibrium is reached between B_4H_{10} and its decomposition products. Study of the kinetics of the conversion of B_4H_{10} into B_5H_{11} [59,60] showed that the reaction proceeds in two stages, the first of which determines the rate of the process:

$$1)\ B_4H_{10} \rightleftarrows B_4H_8 + H_2; \quad 2)\ B_4H_8 + B_2H_6 \rightarrow B_5H_{11} + BH_3.$$

The conversion of B_4H_{10} into B_5H_{11} depends only on the B_4H_{10} concentration; the activation energy of the reaction is 23.4 kcal mole^{-1}. Proof of this course of the reaction is provided by the formation of B_4H_8CO from a mixture of B_4H_{10} and CO in the temperature range 80–110°C.[60] Mass-spectrometric study of the pyrolysis of B_4H_{10} showed[61] that the radicals BH_2 and BH_3 are formed.

In studying the kinetics of deuterium exchange between B_2D_6 and B_4H_{10} at 25–45°C it was found[62] that the exchange can proceed by two different paths. In the first reaction, which has the greater rate at this temperature, two hydrogen atoms are exchanged, with formation of $B_4H_8D_2$; the activation energy is 25.5 kcal mole^{-1}. The exchange is explained by a series of bimolecular reactions in which two hydrogens in the B_4H_{10} molecule which have greater reactivity under ordinary conditions are excited. It is suggested[63] that these are the terminal atoms connected with boron atoms 1 and 3. Under the conditions of the experiment apparently B_4H_8 is not formed, as is confirmed by the lower rate of deuterium exchange between B_4H_{10} and D_2 in comparison with the reaction of B_4H_{10} with B_2D_6:

$$B_4H_{10} + B_4H_{10} \rightleftarrows B_4H_{10}^* + B_4H_{10},$$

$$B_4H_{10} + B_2D_6 \rightleftarrows B_4H_{10}^* + B_2D_6,$$

$$B_4H_{10}^* + B_2D_6 \rightleftarrows B_4H_8D_2 + B_2D_4H_2.$$

At higher temperatures[60,64] loss of the two most mobile hydrogen atoms and the formation of B_4H_8 probably takes place.

In the second path[62] of the deuterium exchange between B_4H_{10} and B_2D_6, eight (or all ten) hydrogen atoms are exchanged. The reaction has an activation energy of 14.1 kcal mole^{-1}, and the rate of this reaction is less temperature-dependent than the first type. The rate-determining stage is the reaction of BD_3 with B_4H_{10}:

$$^{10}B_2D_6 \rightleftarrows 2\,^{10}BD_3,$$

$$^{10}BD_3 + B_4H_{10} \rightarrow {}^{10}BD_3B_3H_7 + BH_3,$$

$$BH_3 + {}^{10}BD_3 \rightarrow BH_3{}^{10}BD_3.$$

The exchange of the atoms ^{10}B–^{11}B between $^{10}B_2H_6$ and B_4H_{10} takes place at one-third of the rate of deuterium exchange[62,64]. The presence of this exchange shows the instability of the B_4H_{10} skeleton. The rate-determining stage is the dissociation of B_4H_{10} into BH_3 and B_3H_7.

In the mass-spectrographic study of the fragments obtained in the bombardment of B_4H_{10} and B_4H_8 by fast electrons (energy 70 eV), Fehlner and Koski[63,65] found that the greatest intensity in the mass spectra was possessed by ions arising as a result of the loss of two atoms of hydrogen or deuterium from the tetraborane molecule: a considerable number of metastable ions obtained by loss of three hydrogens or three deuteriums from the tetraborane molecule was also observed. The authors state that two hydrogen atoms bound to the same boron atom (that is, a terminal and a bridge hydrogen) are lost, leading to the formation of a two-centre B–B bond instead of a B–H–B bridging bond and the liberation of a molecule of H_2. The same authors[8] pyrolysed B_2H_6 and B_4H_{10} in the presence of H_2 in a reactor with a pulsating heater, making possible the isolation of unstable intermediates. It was shown that B_4H_{10} is a precursor of B_5H_{11} in the pyrolysis of B_2H_6, and B_4H_8 is an intermediate. The following equations represent the mechanism:

$$B_4H_{10} \rightleftarrows B_4H_8 + H_2, \qquad B_6H_{12} \rightleftarrows B_6H_{10} + H_2,$$

$$B_4H_{10} \rightleftarrows B_3H_7 + BH_3, \qquad n\,B_4H_8 \rightarrow m\,(\text{solid}) + H_2,$$

$$B_4H_8 + B_2H_6 \rightleftarrows B_5H_{11} + BH_3, \qquad B_3H_7 + H_2 \rightleftarrows B_3H_9,$$

$$B_4H_8 + B_2H_6 \rightarrow B_6H_{12} + H_2, \qquad B_3H_9 + B_2H_6 \rightarrow B_5H_9 + 3\,H_2,$$

$$B_5H_{11} \rightleftarrows B_4H_8 + BH_3.$$

B_2H_6, B_5H_9, B_5H_{11}, B_6H_{10}, and higher boron hydrides have been observed in the pyrolysis products. An increase in the hydrogen concentration has been shown to retard the formation of B_4H_8 as the amount of B_5H_{11} then decreases and the amount of B_5H_9 increases. Schaeffer and Tebbe[9] made boron-labile tetraborane containing three ^{10}B atoms and one ^{11}B atom from $^{10}B_3H_8Na$ and $^{11}B_2H_6$, and also $^{10}B_4H_{10}$, and they showed with the aid of ^{11}B-NMR spectra that ^{11}B is present in four (or two) positions of the tetraborane molecule (the triplet in the weak field region in the $^{10}B_3H_7{}^{11}BH_3$ spectrum corresponding to the BH_2 group has a greater intensity than in the $^{10}B_4H_{10}$ spectrum). The reaction is represented by the following equations:

$$Na^{10}B_3H_8 + HCl \rightarrow NaCl + {}^{10}B_3H_9,$$

$$3/2\,{}^{10}B_2H_6 \leftarrow {}^{10}B_3H_9 \rightarrow {}^{10}B_3H_7 + H_2,$$

$${}^{10}B_3H_7 + {}^{11}B_2H_6 \rightarrow {}^{10}B_3{}^{11}BH_{10} + {}^{11}BH_3.$$

This synthesis is the first example of the preparation of a boron hydride with an isotopic boron atom in a definite position and demonstrates the different mobilities of the boron atoms in the B_4H_{10} molecule.

Tetraborane is slowly hydrolysed by water according to the equation[41,66]:

$$B_4H_{10} + 12\,H_2O \rightarrow 4\,H_3BO_3 + 11\,H_2.$$

The hydrolysis is accelerated on heating or stirring the mixture; the slowness of the hydrolysis is explained by the poor solubility of B_4H_{10} in water. Hydrolysis by dilute acids follows an analogous path. B_4H_9Cl is formed by the action of dry HCl on B_4H_{10}:[66]

$$B_4H_{10} + HCl \rightarrow B_4H_9Cl + H_2.$$

The reaction at room temperature is very slow even in the presence of $AlCl_3$. The reaction product is unstable and breaks down into B_4H_{10} and BCl_3. B_4H_{10} is decomposed

by HCl at 50°C. Reaction of alkali metal amalgams with an excess of B_4H_{10} at 170°C leads to the formation of salts of B_4H_{10} of the composition $K_2B_4H_6$ (or $Na_2B_4H_6$) and the release of hydrogen[67]; on further heating, the mixture gives off hydrogen and $M_2B_4H_6$ and $M_2B_4H_4$ are formed. Under the action of HCl, H is replaced by Cl in the salt[67]. The reaction of NaCN with B_4H_{10} [68] leads to splitting of the latter and the formation of salts with mixed anions:

$$B_4H_{10} + \xrightarrow{NaCN} NaB_3H_7CN + NaB_2H_6CN.$$

In reaction with C_2H_5OH at -78°C, tetraborane is partly (13%) converted into a colourless polymer containing ethoxy--groups but forms mainly $HB(OC_2H_5)_2$ and $B(OC_2H_5)_3$, and also traces of B_2H_6; during the course of the reaction an equimolecular amount of hydrogen is liberated[25]. Shapiro and Weiss[69] studied the alcoholysis of B_4H_{10} by deuterated ethanol at 20°C and showed that the reaction is somewhat different from that for B_2H_6 on account of the presence of B–B bonds. The intermediates in the reaction are $DB(OC_2H_5)_2$ and $HB(OC_2H_5)_2$, that is, the B–B bonds are destroyed simultaneously with the breaking of the B–H bonds. The final product of the reaction is $B(OC_2H_5)_3$.

When iodine in methanol acts on B_4H_{10} there is a rapid exothermic decomposition of the latter with release of hydrogen. This reaction has been proposed for the analytical determination of B_4H_{10}:[70]

$$B_4H_{10} + 9\,I_2 + 12\,CH_3OH \rightarrow 4\,B(OCH_3)_3 + 18\,HI + 2\,H_2.$$

In addition to the above reactions of B_4H_{10}, leading to breakdown of its molecule, it has characteristic reactions in which there is "symmetrical" double bridge splitting, leading to formation of BH_3 and B_3H_7, and "unsymmetrical" double bridge splitting in which BH_2^+ and $B_3H_8^-$ ions are formed. Both these reactions occur when bases act on B_4H_{10}. Fig. 6 shows the decomposition schemes and also the "symmetrical" decomposition of the B_2H_6 molecule for comparison.

Most Lewis bases bring about the symmetrical breakdown of B_4H_{10};[23,25,26,71] this shows a similarity between tetraborane and diborane chemistries.

On treating B_4H_{10} with ethers, amines, or organic sulphides, $B_3H_7.L$ complexes are formed:

$$B_4H_{10} + THF \rightarrow B_3H_7 \cdot C_4H_8O + {}^1/_2\,B_2H_6,$$

$$B_4H_{10} + 2(CH_3)_3N \rightarrow B_3H_7 \cdot (CH_3)_3N + BH_3 \cdot (CH_3)_3N.$$

A second product of the reaction is B_2H_6 or the complex BH_3L, depending on the coordination capacity of the base; the stability of the complex B_3H_7L which is formed also depends on this[26]. As symmetrical decomposition of B_3H_7L also takes place in the presence of an excess of the amine, the reaction of B_4H_{10} under these conditions is by the equation[25]:

$$B_4H_{10} + (3+x)(CH_3)_3N \rightarrow 3(CH_3)_3N \cdot BH_3 + BH[(CH_3)_3N]_x.$$

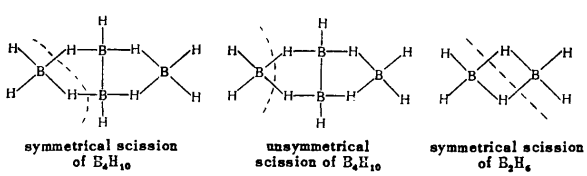

Fig. 6.

An excess of B_4H_{10} decomposes the complex B_3H_7L into B_2H_6, B_5H_9, and H_2.

The reaction of tetraborane with NH_3 follows the path of "unsymmetrical" splitting of the molecule. Stock[66,72] has shown the formation of two unstable compounds of tetraborane with ammonia, $4NH_3.B_4H_{10}$ and $2.5NH_3.B_4H_{10}$. On repeating and studying in greater detail the reaction of B_4H_{10} with NH_3 under various conditions, Kodama and Parry[20,73] established that the substances obtained by Stock are not individual compounds, but a mixture of several. They isolated in the pure state a new compound, "diammoniate of tetraborane" as a stable, white, finely crystalline powder and studied its physical and some of its chemical properties:

$$B_4H_{10} + 2\,NH_3 \xrightarrow[-78°]{(C_2H_5)_2O} B_4H_{10} \cdot 2\,NH_3.$$

A necessary condition for obtaining "diammoniate of tetraborane" is a low temperature and the constant presence of an excess of B_4H_{10}. On the basis of the chemical reactions, an ionic structure was advanced for the compound, $[H_2B(NH_3)_2]^+ . [B_3H_8]^-$, confirmed by the results of X-ray diffraction[16]. It reacts with sodium by the equation:

$$[H_2B(NH_3)_2]^+[B_3H_8]^- + Na \xrightarrow[-78°]{NH_3} NaB_3H_8 + H_2BNH_2 + NH_3 + {}^1/_2\,H_2$$

In this, NaB_3H_8 is obtained in 60–70% yield. This reaction reveals the structure of the anion. Proof of the structure of the cation is provided by reaction with HCl, as a result of which diammineboronium chloride and triborane(7)–ether were produced:

$$[H_2B(NH_3)_2]^+[B_3H_8]^- + HCl \xrightarrow[-78°]{(C_2H_5)_2O} [H_2B(NH_3)_2]Cl + B_3H_7 \cdot O(C_2H_5)_2 + H_2.$$

It was also established that the compounds $6NH_3.B_4H_{10}$ and $7NH_3.B_4H_{10}$ are formed in the prolonged reaction of tetraborane with an excess of NH_3 at -78°C without a solvent[20]. It was shown that in the reaction of NH_3 with B_4H_{10} the solvent plays an important part. When a solvent with considerable coordination capacity (THF, THP) is used there is symmetrical splitting of B_4H_{10} and $B_3H_7.NH_3$ is formed, whereas when a weak Lewis base is used as solvent – $(C_2H_5)_2O$, which does not react with B_4H_{10} at a low temperature (-78°C) – unsymmetrical decomposition of the molecule under the action of ammonia takes place. In these reactions there is an analogy between the chemistries of B_4H_{10} and B_2H_6.

An interesting reaction, leading to greater complexity in the skeleton of the B_4H_{10} molecule, was discovered by Boone and Burg[57]. In the action on B_4H_{10} of bis(dimethylamino)borane at -78°C an addition product of empirical formula $[(CH_3)_2N]_2BH.B_4H_{10}$ is formed, which on heating to -15°C decomposes with formation of B_5H_9, B_4H_{10}, B_2H_6, $[(CH_3)_2N]_2BH$, and $(CH_3)_2NBH_2$. The reaction of B_4H_{10} with 1,2-dimethyldiborane(6) gives a derivative of B_5H_{11}:[74]

$$B_4H_{10} + {}^1/_2(BH_2CH_3)_2 \rightleftarrows B_5H_{10}CH_3 + H_2.$$

The next type of B_4H_{10} reactions are those in which hydrogen atoms are replaced without decomposition of the skeleton of the molecule. $B_4H_9CH_3$ is obtained by the action of $CH_3B_2H_5$ on B_4H_{10}:[74]

$$B_4H_{10} + B_2H_5CH_3 \overset{45°}{\rightleftarrows} B_4H_9CH_3 + B_2H_6,$$

which was identified and characterised by the aid of infrared, NMR, and mass spectra. The infrared spectrum of $B_4H_9CH_3$ shows the asymmetry of the molecule: the principal changes are found in that part of the spectrum which characterises the vibrations of the BH_2B group; therefore the authors think that a hydrogen atom connected with a type II boron atom is replaced.

Harrison and coworkers[75] first studied the reaction of boron hydrides with unsaturated hydrocarbons in the reaction of ethylene with B_4H_{10} in the presence of aluminium chloride. They showed that here also there is replacement of the terminal B–H bonds in the BH_2 group by B–C bonds, with the formation of dimethyltetraborane (70%). The compound is more stable than B_4H_{10}:

$$B_4H_{10} + C_2H_4 \rightarrow B_4H_8C_2H_4 + H_2.$$

The infrared spectrum shows the absence of a BH_2 group and the presence of two types of B–H bonds. The authors consider that the compound has a cyclic bridging structure of unique type, unknown earlier (Fig. 7). The NMR spectra show[76] that the replacement of hydrogen atoms takes place at boron atoms 2 and 4.

The chemical properties of the compound (hydrolysis and alcoholysis) are consistent with the proposed structure[75].

Tetraborane(8)–carbonyl is a very interesting derivative of tetraborane; it was first prepared by Burg and Spielman[77] by the reaction of B_5H_{11} with carbon monoxide in a sealed ampoule at room temperature; later it was obtained[60] by heating B_4H_{10} in the presence of an excess of carbon monoxide at 80–100°C. It is an unstable liquid, which decomposes at room temperature, with liberation of carbon monoxide and higher boron hydrides, and which ignites spontaneously in air (m.p. -114°C, vapour pressure 71.2 mmHg at 0°C, b.p. 59.6°C [77]). A detailed description of the preparation of B_4H_8CO from B_4H_{10} or B_5H_{11} and CO and of its physical and chemical properties has been published[78,79]. Spectroscopic methods were used to establish its structure. The infrared spectrum shows that the molecule contains BH_2 groups, and that the B–CO bond is similar to the bond in BH_3–CO; the infrared spectrum and Raman spectrum of B_4H_8CO differ considerably from those of B_4H_{10}.[79,80] The ^{11}B-NMR spectrum of B_4H_8CO [77,79] contains a doublet in the strong field region typical of the B–H group, and a non-symmetrical triplet in the weak region, which can be ascribed to the BH_2 group. The asymmetry of the triplet is ascribed[78] to the tautomerism of the hydrogen atoms of the B–H–B bridge and terminal B–H bonds (there is a similar tautomerism in the B_5H_{11} molecule)[81]. The structure and the mechanism of formation of B_4H_8CO were not established unambiguously but it was suggested that the most probable place for the addition of CO to the B_4H_8 residue is the boron atom corresponding to the apex in B_5H_{11}, or type I in B_4H_{10}.[73] The most probable structure has the boron atoms at the corners of a trigonal pyramid; the apical boron atom is probably connected by two-centre bonds with two boron atoms of the base, to one of which the CO group is attached; the apical atom is connected with the third boron atom of the base through bridges, similar to the unique bridge in B_5H_{11}. One of the structures proposed for B_4H_8CO is shown in Fig. 8.

The chemical reactions of B_4H_8CO are characterised by rapid but incomplete loss of carbon monoxide and by strong

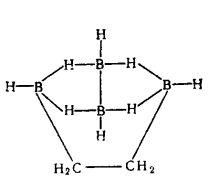

Fig. 7.

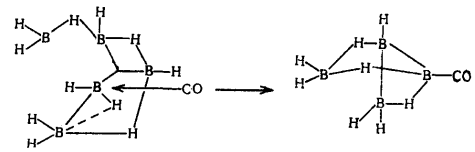

Fig. 8

electron-acceptor properties of the B_4H_8 group[78]. B_4H_8CO has two decomposition paths:

$$B_4H_8CO \rightarrow B_4H_8 + CO, \quad (1)$$

$$B_4H_8CO \rightarrow BH_3 + B_3H_5CO. \quad (2)$$

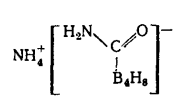
The first path is shown by the formation of B_4H_{10} in the presence of hydrogen or B_5H_{11} in the presence of B_2H_6, the second by the fact that when heated in a vacuum B_4H_8CO does not liberate carbon monoxide, but forms a high-molecular-weight substance containing boron and carbon monoxide[78].

The reactions of B_4H_8CO with electron-donor compounds – $(CH_3)_3N$, C_2H_4, and $(C_2H_5)_2O$ – have been studied[78] and it has been shown that B_4H_8CO exhibits a tendency towards hydrogen replacement reactions; the B–CO bond is rather stable. The reaction with ethylene is most unambiguous:

$$B_4H_8CO + 4\,C_2H_4 \rightarrow (C_2H_5)_4B_4H_4CO.$$

Water hydrolyses B_4H_8CO, but not quantitatively; the residue, which contains B–B bonds, has not been identified.

Parry and coworkers[82] have shown that B_4H_8CO reacts with an excess of ammonia at a low temperature (from -95° to -50°C) to form a compound of composition $B_4H_8CO.2NH_3$, to which, on the basis of its chemical reactions, infrared spectra (the presence of N–H and B–H bonds and of an amide CO bond), and also by analogy with the structure of $BH_3CO.2NH_3$ (studied by the same authors), was ascribed an ionic structure with an anion analogous to carbamate (if it is assumed that the B_4H_8 group is isoelectronic with oxygen):



The following reactions are proof of such a structure:

$$NH_4^+[B_4H_8CONH_2]^- + Na \xrightarrow[-78°]{\text{liq. } NH_3} Na^+[B_4H_8CONH_2]^- + {}^1/_2H_2, \quad (1)$$

$$NH_4^+[B_4H_8CONH_2]^- + LiBH_4 \xrightarrow[14\text{ h}]{\text{THF}} H_3NBH_3 + Li^+[B_4H_8CONH_2]^- + {}^1/_2H_2, \quad (2)$$

and the structure of the cation:

$$NH_4^+[B_4H_8CONH_2]^- + NaB(C_6H_5)_4 \xrightarrow[0°,\ 15\text{ m}]{H_2O} NH_4B(C_6H_5)_4\downarrow + Na^+[B_4H_8CONH_2]^-. \quad (3)$$

The precise structure of the anion $[B_4H_8CONH_2]$ has not been explained; two more probable variants have been proposed. The CO group in B_4H_8CO is readily replaced by PF_3 reversibly[78]:

$$B_4H_8CO + PF_3 \rightleftarrows B_4H_8 \cdot PF_3 + CO.$$

It was shown that when $F_2PN(CH_3)_2$ reacts with B_4H_8CO at -20°C, replacement of CO again takes place readily:

$$B_4H_8CO + F_2PN(CH_3)_2 \rightarrow (CH_3)_2NPF_2 \cdot B_4H_8 + CO.$$

In this compound B_4H_8 is coordinated with a phosphorus atom (P–B bond in the ^{34}P–NMR spectrum). The infrared spectrum is similar to the infrared spectrum of B_4H_8CO.[83]

When B_4H_8CO reacts with an excess of a strong Lewis base — $(CH_3)_3N$ or PF_3 — initially CO is replaced by H, and then B_4H_8 is destroyed and $(CH_3)_3N.BH_3$ or $PF_3.BH_3$ is formed [83,84].

V. PENTABORANE(9)

1. Structure of Pentaborane(9)

Pentaborane(9) is one of the most studied boron hydrides and the geometry of its molecule has been accurately determined by several physical methods, which give concordant results: X-ray diffraction [85,86], electron diffraction [87], and microwave spectroscopy [88]. All these results suggest that the B_5H_9 molecule has the structure shown in Fig. 9.

The most accurate data on the interatomic distances in B_5H_9, obtained from the microwave spectra [88], are: $B_{(1)}-B_{(3)} = 1.687 \pm 0.005$ Å; $B_{(3)}-B_{(4)} = 1.800 \pm 0.003$ Å; $B-H_{terminal} = 1.22 \pm 0.04$ Å; $B_{(2)}-H_{bridge} = B_{(3)}-H_{bridge} = 1.35 \pm 0.02$ Å; $\angle B_{(1)}B_{(2)}H_{(2)} = 136° 10' \pm 30'$; angle between planes $B_{(1)}B_{(2)}B_{(3)}$ and $B_{(2)}B_{(3)}H_{bridge} = 196° \pm 2°$. X-Ray diffraction [85,86] showed that B_5H_9 crystals have C_{4v} symmetry and contain two molecules in the unit cell with parameters $a = 7.16$, $c = 5.38$ Å.

On the basis of the geometry of the molecules Lipscomb and coworkers [11] proposed a structure for B_5H_9 in which the five boron atoms form a tetragonal pyramid, which is a fragment of an octahedron. Each boron atom in the base of the pyramid (type *II* in Fig. 9) forms one terminal B–H bond and two B–H–B bridging bonds. Three sp^3-orbitals and two electrons of the base boron atoms are used in these bonds; the remaining sp^3-orbital and electron of each B_{II} atom is used for a bond with an apical boron atom (type *I* in Fig. 9), which forms one terminal B–H bond directed along the axis of symmetry of the molecule. The remaining three orbitals and two electrons of the apical boron atom are used for bonds with the basal boron atoms. It is assumed that one of these orbitals has sp-hybridisation and is directed along the axis of symmetry towards the centre of the molecule; two other orbitals are "pure" p-orbitals directed perpendicularly to the symmetry axis, one of them being situated in the $B_{(2)}-B_{(1)}-B_{(4)}$ plane and directed towards $B_{(4)}$, and the other being in the $B_{(3)}-B_{(1)}-B_{(5)}$ plane and directed towards $B_{(3)}$. Rather later Lipscomb [10,89] and also Moore [90], in calculating the molecular orbitals of B_5H_9 and their overlap integrals, concluded that the apical atom $B_{(1)}$ forms two two-centre bonds with two of the boron atoms of the base and one open three-centre bond with the other two boron atoms of the base, using in this all the remaining six electrons and seven orbitals of the boron atoms. As in this the molecule does not have C_{4v} symmetry; the authors assume that here it is possible to write two equivalent structural formulae (as in the C_6H_6 molecule) in which the open three-centre $B_{II}-B_I-B_{II}$ bond and two two-centre B_I-B_{II} bonds exchange places. Moore [90] also calculated the formal charges of the boron atoms ($B_I = -0.870$ e, $B_{II} = +0.217$ e) and from these results obtained a calculated value of the dipole moment of $B_5H_9 = 1.7-2.0$ D (with allowance for the hydride character of the bridge hydrogen atoms, -0.2 e, and apical hydrogen atom, -0.1 e). This agrees with the experimental value, 2.13 ± 0.04 D. [88]

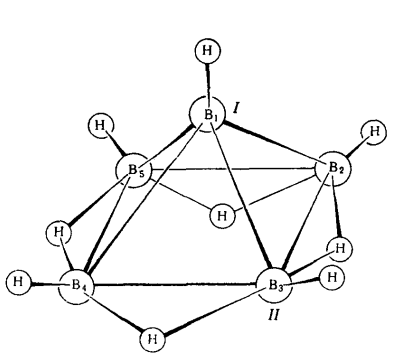


Fig. 9.

The ^{11}B-NMR spectrum of B_5H_9 [91] shows that the molecule has four identical boron atoms (each of which is connected with one terminal hydrogen atom) and one boron atom having resonance in the region of higher field, that is, more negative, also connected with one hydrogen atom (two doublets with ratio of peak intensities 4 : 4 : 1 : 1). These results agree with the structure proposed for B_5H_9. The ^1H-NMR spectrum of B_5H_9, [91,92] obtained by use of the technique of "spin saturation" of ^{11}B nuclei, suggests that the terminal hydrogen atom of the apical boron atom is somewhat more negative than the terminal hydrogens on the basal boron atoms, but less negative than the bridge hydrogen atoms.

On the basis of the experimental results on the geometry of the molecule [85,87] Glockler [93] calculated the energies of the bonds in B_5H_9. The heat of formation obtained from the calculated data ($\Delta Ha_\circ = 1146.7$ kcal mole^{-1}) is considerably different from that determined experimentally (1092.73 kcal mole^{-1}).

2. Preparation of Pentaborane(9)

B_5H_9 is present in small amounts in the gas mixture obtained on decomposing metal borides with acids. Stock and Kuss first isolated pentaborane(9) from this mixture [94] but the yield of B_5H_9 in this is extremely small (< 1%), and the compound is contaminated with other boron hydrides, particularly B_5H_{11}, from which B_5H_9 is difficult to separate owing to their similar boiling points (the difference in b.p. at 100 mmHg is 4 deg). Therefore B_5H_9 was an almost inaccessible compound until Schlesinger and Burg [46] obtained it in 1931 in 20% yield by heating B_2H_6 at 120–130° with a little dry HCl or BCl_3. Somewhat later the same authors [47] increased the yield of B_5H_9 to 33%. Then Stock found [48] that a mixture of B_5H_9 (54–56%) and B_5H_{11} (10–26%) is formed in the pyrolysis of diborane over mercury at 250–300° or tetraborane at 100–200°.

A detailed study was made [95] of the kinetics of pyrolysis of B_2H_6 in the temperature range 80–120°, by three methods: (1) from the rate of increase of the total pressure in the system; (2) from the rate of formation of H_2, and (3) mass spectrometrically. The following conclusions were drawn: (1) the reaction products are H_2, B_4H_{10}, B_5H_{11}, B_5H_9, and higher boron hydrides; (2) the process has a complex path; (3) B_5H_{11} is an intermediate in the formation of most other boron hydrides from B_2H_6; (4) the formation of B_5H_9 from B_5H_{11} is a first-order reaction. It was suggested [96] that the rate-determining stage of the pyrolysis of B_2H_6 is the reaction:

$$B_5H_{11}+H_2 \rightleftarrows B_4H_{10}+\tfrac{1}{2}B_2H_6.$$

The B_4H_{10} formed reacts with B_5H_{11}:

$$B_4H_{10} + B_5H_{11} \rightarrow B_5H_9 + 2B_2H_6.$$

These two stages were proposed to explain the conversion of B_5H_{11} into B_5H_9. Fehlner and Koski[8] showed, by pulsation heating of B_2H_6, that the reaction products are H_2, B_4H_{10}, B_5H_9, B_5H_{11}, B_6H_{10}, B_6H_{12}, B_7H_{11}, B_7H_{13}, and higher boron hydrides. Using isotopic labelling, and on the basis of the composition of the intermediate and final products of the reaction, the authors established the mechanism of the pyrolysis of diborane, which includes a series of competing reactions and equilibria. It was shown that the formation of B_5H_9 proceeds along a path different from the formation of B_4H_{10} and B_6H_{10}, namely through the formation of triborane by the reactions:

$$B_2H_6 \rightleftarrows 2BH_3,$$

$$BH_3 + B_2H_6 \rightarrow B_3H_9,$$

$$B_3H_9 + B_2H_6 \rightarrow B_5H_9 + 3H_2.$$

Confirmation is given by the fact that in the pyrolysis of B_4H_{10} in the presence of hydrogen raising the concentration of the latter increases the degree of conversion of B_4H_{10} into B_5H_9, which also proceeds through the formation of B_3H_9:

$$B_4H_{10} \rightleftarrows B_3H_7 + BH_3,$$

$$B_3H_7 + H_2 \rightleftarrows B_3H_9,$$

$$B_3H_9 + B_2H_6 \rightarrow B_5H_9 + 3H_2.$$

With the aim of finding the most favourable conditions for the conversion of B_2H_6 into B_5H_9, McCarty and Di Giorgio[97] studied the effect of temperature (in the range 175–250°), additions of hydrogen and nitrogen, and time on the reaction; they showed that the pyrolysis of diborane is exothermic and that varying the conditions makes possible the direction of the process towards the boron hydride required. Conditions were found under which B_5H_9 is obtained without B_5H_{11} as impurity, which removed one of the main disadvantages of this method of making B_5H_9 — previously the B_5H_9 was freed from B_5H_{11} by either further heating of the mixture until the B_5H_{11} had decomposed, or contacting the mixture at 0°C with Lewis bases and then distilling off the pure B_5H_9; during this the loss of pentaborane(9) was considerable. On the basis of this work[97] and that of Bragg and coworkers[95] a method for the industrial production of B_5H_9 was developed[98]. The overall pyrolysis of diborane is represented by the following schemes:

$$5B_2H_6 \rightarrow 2B_5H_9 + 6H_2, \quad (1)$$

$$5B_2H_6 \rightarrow B_{10}H_{14} + 8H_2, \quad (2)$$

$$B_2H_6 \rightarrow (BH)_x(\text{solid}) + H_2. \quad (3)$$

Of the B_2H_6 taken 70–85% decomposes by reactions (1) and (2); the residue consists of high-molecular-weight boron hydride of unknown composition. The conditions for obtaining B_5H_9 are: temperature of the reaction zone 240–290°C, pressure ~3.5 atm, time of B_2H_6 at this temperature 3 s (then the reaction gases are cooled to 35°C), and an equimolecular quantity of hydrogen is used as the reaction medium. Not less than 80% of the B_2H_6 enters into the reaction and the yield of pure B_5H_9 is 38% (purity 99.9%).

Jeffers[99] has proposed a convenient path for the preparation of pentaborane(9): pyrolysis of diborane by the method of hot (200°C) and cold (-90°C) tubes; the yield of B_5H_9 is 60% at a 90% conversion of B_2H_6.

A patent has been taken out[100] for preparing B_5H_9 by a similar method: hot zone temperature 205°C, cold -40°C, contact time 2 s, yield 80%.

3. Physical Properties of Pentaborane(9)

B_5H_9 is a colourless mobile liquid with an unpleasant odour, b.p. 58°C [41] or 60.0°C,[101] m.p. -46.6°C [41] or 226.41° ± 0.02°K.[102] Several values are given for the density of B_5H_9 at 0°C: 0.61 g ml^{-1},[41] 0.642 g cm^{-3},[103] 0.637 ± ± 0.002 g ml^{-1};[104] the last two results are evidently the most accurate; the temperature dependence of the density of B_5H_9 is $d = 0.8674 - 0.00082T$.[103] The vapour pressure of B_5H_9 at 0°C is 66 mmHg;[41] according to more recent data[102] $P_{B_5H_9} = 64.77$ mmHg at 272.99°K; the variation of the vapour pressure of B_5H_9 with temperature in the range 226–298°K is described by the equation.

$$\log p_{\text{mmHg}} = 9.96491 - \frac{1951 \times 14}{T} - 0.0036884T.$$

The viscosity of B_5H_9 at 274.1°K has been measured (η = 3.94 mP), as has the surface tension at 269.5°K (γ = 24.5 dyn cm^{-1}) and 286.2°K (γ = 22.0 dyn cm^{-1}).[103] The electrical properties of B_5H_9 have been measured[102] and it has been shown that liquid B_5H_9 has a high dielectric constant, which varies between the limits 21.1 (298°K) and 53.1 (at the melting point, 226.41°K). The apparent dipole moment of B_5H_9 varies from 3.37 D at 298°K to 4.54 D at the melting point, and in the gas phase the dipole moment is 2.13 D, that is, pentaborane(9) is a highly polar substance[102]. The value of 2.13 D for B_5H_9 has been given elsewhere[88]. Crystals of B_5H_9 have two modifications[102]: the body-centred tetragonal crystals are converted into simple tetragonal crystals in the range 130–140°K. The heat of formation of gaseous B_5H_9 from the elements[105] is 12.99 ± 0.39 kcal mole^{-1} and its entropy[106] is 65.75 cal × × deg^{-1} mole^{-1}.

Pentaborane(9) is a highly poisonous compound[107], more toxic than diborane or decaborane. Systematic inhalation of B_5H_9 at a concentration of 0.2 parts per million by various animals leads to loss of appetite and weight, apathy, and a drop in physical and mental activity.

4. Chemical Properties of Pentaborane(9)

(a) Stability of pentaborane(9). The mass-spectrometric investigation of pentaborane(9) and deuteriopentaborane(9) [101] shows a clear tendency for these molecules to lose two or four hydrogen (or deuterium) atoms, and a much smaller tendency to lose one or three hydrogen atoms. Starting from the values of the energies of the terminal B–H and bridge B–H–B bonds (4.04 and 4.66 eV respectively) Kaufman and coworkers[108] gave reasons why, in the attack of fast electrons of 70 eV energy, the terminal B–H bonds in the B_5H_9 molecule are broken more readily, and then the molecule is reconstituted: probably a three-centre B–H–B bond is changed into B–H and B–B two-centre bonds. However, the precise path for the reconstitution of the molecule during the formation of fragment ions has not been established[65]. The authors determined the potentials for the appearance of $^{11}B_5H_9^+$ and $^{11}B_5D_9^+$, 10.39 and 9.78 eV respectively. Previously[109] the ionisation potential of B_5H_9 had been given as I = 10.8 ± 0.5 eV.

When an electric discharge acts on B_5H_9 [110] a terminal B–H bond at the apical boron atom is broken and a B_5H_8 radical is formed, which combines with a second such radical to form a $B_{10}H_{16}$ molecule. As Hall and Koski have shown[111], an analogous reaction occurs when B_5H_9 is irradiated with deuterons of 2 MeV energy. These authors

established[112] that the products of the reaction are H_2, B_2H_6, $B_{10}H_{16}$, and polymeric boron hydrides; B_5H_9 undergoes 5% decomposition. The radiochemical yields of the products were found to be: $G_{H_2} = 13.1$, $G_{B_2H_6} = 1.7$, $G_{B_{10}H_{16}} = 0.8$ mole per 100 eV. A radical mechanism for the reaction was proposed, based on experiments using D_2 as indicator, inert gases (He, Ne, Ar) as sensitisers, and I_2 as an inhibitor of the process.

NMR spectra showed[113] that in the reaction of B_5H_9 with B_2D_6 only terminal hydrogen atoms are replaced by deuterons, the bridge hydrogens not taking part in the exchange reaction. The rate of exchange of the apical hydrogen atom in this was the same as that of the terminal basal hydrogen atoms (within the limits of experimental error, ±10%). Similar results were obtained in studying deuterium exchange between B_5H_9 and B_2D_6 at 80° without a catalyst, using infrared and mass spectra[114,115].

All the hydrogen atoms are replaced by deuterium in the reaction of B_5H_9 with an excess of deuterium in the presence of a chromium–aluminium dehydrogenation catalyst ($Cr_2O_3.Al_2O_3$) at 20–25°C.[106]

Onak and Williams[116] made a directed deuterium exchange between B_5H_9 and DCl in the presence of $AlCl_3$ at 20°C: only the apical hydrogen atom is exchanged; the compound B_5H_8D which is obtained is rather stable; it is unchanged after heating for 17 h at 105°C. The H–D exchange in the presence of an electrophilic catalyst confirms the greater susceptibility to electrophilic attack of the apical hydrogen atom. The authors showed[117] that intramolecular H–D exchange takes place in the B_5H_8D molecule in the presence of 2,6-dimethylpyridine at 20°C, but without a Lewis base at elevated temperatures (145–200°C) there is intermolecular exchange. In all the reactions mentioned above there is a clear difference in the behaviour of the terminal and bridging hydrogen atoms in the B_5H_9 molecule, and also in that of the apical hydrogen and the basal hydrogen atoms.

The stability of the B_5H_9 molecule was shown by studying the exchange of ^{11}B and ^{10}B atoms: under conditions at which exchange of ^{11}B for ^{10}B takes place in diborane or tetraborane molecules there is no exchange in the pentaborane(9) molecule[118]; reaction between B_5H_9 and $^{10}B_5H_9$ does not take place up to 100°C in the liquid phase or up to 250°C in the gas phase. H–D exchange is observed between B_5H_9 and B_5D_9 at 200°C in the absence of a catalyst. Shapiro and coworkers[119] showed that in the presence of a catalyst (γ-Al_2O_3) at 90°C there is exchange of boron atoms between $^{10}B_2H_6$ and B_5H_9 through the intermediate formation of the complex $Al_2O_3.^{10}B_2H_6$, which then slowly exchanges ^{10}B atoms with the pentaborane. This reaction occurs much more slowly than for B_2H_6.

According to the results of Stock and coworkers[67], pentaborane(9) reacts with alkali metal amalgams like B_4H_{10} and B_2H_6, forming salts of composition $M_2B_5H_9$; they could not be obtained pure. However, Ford and coworkers[120] showed that B_5H_9 does not react with sodium amalgam and sodium hydride in ether at 20–25°C.

(b) Oxidation of pentaborane(9). B_5H_9 ignites spontaneously on mixing with air. The kinetics and mechanism of the oxidation of pentaborane have been studied several times to determine the conditions for the most convenient use of this reaction. A kinetic study of the B_5H_9–O_2 system[121] showed that the lower explosive limit at room temperature is at very low pressures of B_5H_9 and O_2; a B_5H_9 pressure between 1 and 5 mmHg is critical. The reaction proceeds by a type of branched-chain mechanism. Later work[122] confirmed the conclusion about the reaction type. Intermediate products were not isolated, but it was observed that $Fe(CO)_5$ has a strong inhibiting action, showing that oxygen atoms participate in the chain development. The lower explosive limits were determined for B_5H_9–O_2 mixtures at B_5H_9 pressures from 1 to 90 mmHg and temperatures of 15° and 21.5°C, and it was also shown that the final reaction product is H_3BO_3. It was shown[123] that during the slow oxidation of B_5H_9 initially H_2, B_2H_6, and a more solid substance of unknown composition are formed; the formula $B_4H_{12}O$ was proposed for the latter on the basis of its infrared and mass spectra[124]. It was concluded in a more detailed study of the partial oxidation of B_5H_9 by spectrometric methods[125] that the intermediate compound has the formula $B_2H_2O_3$ and a trigonal bipyramidal structure formed by boron and oxygen atoms with a terminal hydrogen atom at each boron. It was shown[126] that during the explosive oxidation of B_5H_9 yet another intermediate product is formed, $B_3O_3H_3$, identical with boroxole[127].

(c) Reaction of pentaborane(9) with oxygen compounds. Pentaborane(9)[41] is slowly hydrolysed by water at room temperature; for complete hydrolysis prolonged heating of it with water at 90°C is necessary. However, in aqueous dioxan solution the reaction is rather rapid and the hydrolysis rate can be measured by the increase in pressure[128]:

$$B_5H_9 + 15\,H_2O \rightarrow 5\,B(OH)_3 + 12\,H_2.$$

The first stage of the hydrolysis was studied by mass spectroscopy[129]; B_5H_9 was hydrolysed by water contained in silica gel in a combined form as OH^- ions. The mass spectrum of the product of the reaction was similar to that of B_4H_{10}. It is assumed that the first stage of the hydrolysis is the displacement by water of a boron atom from the B_5H_9 molecule (probably one of the four basal atoms) with subsequent regeneration of hydrogen. The balance in boron and hydrogen of the reaction products found on the silica gel and in the volatile products confirms this conclusion.

The interaction of B_5H_9 with alcohols[130] leads to the formation of borate esters and hydrogen:

$$B_5H_9 + 15\,ROH \rightarrow 5\,B(OR)_3 + 12\,H_2.$$

When the alcohol is added to B_5H_9 in stoichiometric proportion the borate ester is formed in quantitative yield under mild conditions; the reaction is exothermic. The intermediate product, diethoxyborane $HB(OC_2H_5)_2$, was isolated pure. Alcoholysis of the B–B bond in pentaborane was studied by using deuterated ethanol[69] and compared with the alcoholysis of diborane. It was shown that the course of the alcoholysis with B_5H_9 is different from that for B_2H_6, and similar to the alcoholysis of B_4H_{10}; during the action of alcohol on B_5H_9 there is simultaneous formation of $HB(OC_2H_5)_3$ and $B(OC_2H_5)_3$, that is, the B–B bonds are split simultaneously with the B–H bonds and not subsequently. The relative concentrations of the intermediate products $HB(OC_2H_5)_2$ and $DB(OC_2H_5)_2$ depend on the structures of the boron hydrides (B_4H_{10} and B_5H_9), and thus on the nature and number of the B–B bonds and B–H–B bridge bonds. In the splitting of the B–H–B bond by deuterioethanol only $HB(OC_2H_5)_2$ is formed; in the splitting of the B–B bonds, $DB(OC_2H_5)_2$. Pentaborane(9) reacts exothermically with acetone both at room

temperature and at -80°C.[130] The reaction is complex and the reaction mechanism is still unexplained. Isopropyl borate (25–30% yield) has been separated from the reaction mixture. When dry acetone acts on B_5H_9 hydrogen is not liberated, that is, reaction probably does not occur.

(d) Halogen derivatives of pentaborane(9). Under carefully controlled conditions B_5H_9 reacts with halogens, hydrogen halides, or BCl_3 with replacement of one hydrogen atom by halogen. Schlesinger and Burg[71] obtained B_5H_8Cl by direct chlorination of B_5H_9 at -80°C. B_5H_8Cl, B_5H_8Br, and B_5H_8I were obtained by halogenation of pentaborane(9) in the presence of $AlCl_3$ in a medium of CS_2;[131] during this B_5H_8Br (m.p. 32–34°C) and B_5H_8I (m.p. 53°C) were obtained pure with good yields; B_5H_8Cl could be obtained only in trace amounts (owing to its explosive properties) and contaminated by CCl_4. A patent had been issued earlier[132] on a method of obtaining B_5H_8Br by brominating B_5H_9 under specified conditions (yield 70%, m.p. 34–36°C, b.p. 80–82°/34 mmHg). The precise position of the halogen in the monohalogenopentaborane molecules was established by infrared and NMR spectra. The infrared spectra of B_5H_8Br [133] is similar to the spectrum of B_5H_9; the symmetry of the molecule is retained, which is possible only if the bromine replaces the hydrogen atom of the apical boron atom. The NMR spectrum of B_5H_8X [134] also shows with certainty that the substitution occurs at the apical boron atom; the ^1H–NMR spectra of B_5H_8Br and B_5H_8I contain a doublet of peaks of equal intensity, which show equal numbers of terminal and bridge hydrogen atoms; the ^{11}B-NMR spectra of B_5H_8Br and B_5H_8I do not show the doublet corresponding to the interaction of the apical boron atom with the terminal hydrogen, it being converted into a singlet of double intensity; the doublet corresponding to the basal BH groups is unchanged. The inductive influence of halogens on the ^{11}B-chemical shift in the ^{11}B-NMR spectrum of B_5H_8X (X = Br or I) is observed. The effect of a change in the shift to low field with increase in the electronegativity of the atoms bound to boron has also been shown for other boron compounds[135]. An exchange reaction between the halogen in 1-BrB_5H_8 and chlorine has also been carried out[136], in which the halogen atom is transferred from the apical boron atom to a basal boron atom. The reaction proceeds in the presence of $AlCl_3$ and is the first instance of an exchange of a halogen atom in a higher boron hydride taking place with change in bonding position. The mechanism of the reaction is not clear. Attempts to obtain 2-BrB_5H_8 by the reaction of 1-BrB_5H_8 with $AlBr_3$ or 2-ClB_5H_8 by the reaction of 1-BrB_5H_8 with BCl_3 were unsuccessful.

In a mass spectrometric study of halogenopentaboranes (1-ClB_5H_8, 1-BrB_5H_8, and 1-IB_5H_8) it was found[131] that: (1) the B–I bond is relatively easily broken; (2) the detachment of the Br (or Cl) atom from a B_5H_8X molecule occurs only when the skeleton is destroyed, that is, by loss of a BBr (BCl) group; (3) the general distribution of fragment ions in the mass spectrum of B_5H_8I (and to some extent B_5H_8Br) is similar to that in B_5H_9. From these results a sequence was derived for the relative ease of bond-breaking in the halogenopentaboranes: BI > BH > BB > BBr or BCl.

(e) Reactions of pentaborane(9) with nitrogen and phosphorus compounds. The reaction of B_5H_9 with secondary and tertiary amines has been studied in detail by Zhigach and coworkers[137]. At a low temperature (up to 0°C, usually from -3° to -5°C) B_5H_9 adds secondary amines with formation of complexes of composition $n NHR_2.B_5H_9$ (n = 2, 3, 4, or 5; R = CH_3 or C_2H_5); under the action of tertiary amines the compounds $2NR_3.B_5H_9$ are formed (R = CH_3 or C_2H_5) stable up to 0°C. At elevated temperature (100–120°C) the complexes are completely decomposed with liberation of hydrogen, splitting of the B_5H_9 molecule, and formation of alkylamino-derivatives of diborane and borane and of polymers. An increase in the proportion of amine in the original complex leads to an increase in the amount of borane derivatives and a decrease in the amount of diborane derivatives in its decomposition products.

Burg[138] showed simultaneously that $(CH_3)_3N$ at -78°C adds to B_5H_9 with formation of a complex $2(CH_3)_3N.B_5H_9$, which on heating in a vacuum is partly decomposed to the initial substances and partly converted into $(CH_3)_3N.BH_3$ and a polymer of composition $(BH)_x$. On heating the complex above 100°C with an excess of trimethylamine 2 moles $(CH_3)_3N.BH_3$ are formed per 1 mole B_5H_9 and a polymer which exhibits thermoplastic properties[139].

In the reaction of B_5H_9 with $(CH_3)_2NH$ and also with $(CH_3)_2NBH_2$ or $[(CH_3)_2N]_2BH$ in stoichiometric amount, Burg[138] obtained a compound of low stability in air, which as X-ray analysis showed[140], is a trimer of dimethylaminoborane. Campbell and Johnson[141] came to the same conclusion, in studying the reaction of B_5H_9 with $[(CH_3)_2NBH_2]_2$ and identifying the reaction products by ^1H- and ^{11}B-NMR spectra, analysis, and molecular weight.

Hough and coworkers[142] also studied the reaction of B_5H_9 with $(CH_3)_3N$ and considered that at 20–25°C the reaction proceeds according to the equation:

$$B_5H_9 + (CH_3)_3N \xrightarrow{\text{rapid}} [(CH_3)_3N]_2 \cdot B_5H_9 \xrightarrow{\text{slow}} (CH_3)_3N \cdot BH_3 + (CH_3)_3N \cdot B_4H_8.$$

Under the action of an excess of the amine two moles $(CH_3)_3N.BH_3$ and 1 mole of the polymer $[(CH_3)_3N]_x.(B_3H_3)_x$ are formed per mole B_5H_9.[143] From what has been said above it is evident that the reaction of B_5H_9 with amines is complex with splitting of the B_5H_9 molecule. There has been little investigation of the reaction of pentaborane with ammonia. Schlesinger and Burg[71] state that "tetra-ammoniate of pentaborane" is formed in the reaction of B_5H_9 with NH_3; one of the nitrogens in it is in the form of an ammonium ion: further slow reaction of B_5H_9 with NH_3 leads to the formation of "tetra-ammoniate of pentaborane"; however, it was not found whether this substance was pure.

In Schaeffer's work[144] on the reaction of decaborane with CH_3CN it is stated that B_5H_9 reacts with CH_3CN with liberation of hydrogen and formation of a substitution product. The mixed salt NaB_5H_9CN is formed by the reaction of B_5H_9 with NaCN.[68]

Muetterties and coworkers[145] showed that in the reaction of B_5H_9 with *NNN'N'*-tetramethylethylenediammine (TMED) at 25°C the addition product TMED.B_5H_9 is formed, which under the action of CH_3OH at 0°C is converted into TMED.B_4H_8. The authors consider these two addition products to be derivatives of the hypothetical anions $B_5H_{11}^{-2}$ and $B_4H_{10}^{-2}$.

Burg[139] studied the reaction of B_5H_9 with phosphorus-containing Lewis bases and showed that during this the B_5H_9 molecule is split although with much greater difficulty than for B_4H_{10}. The reaction products are a cyclic trimer of composition $[R_2P-BH_2]_3$ and the tetramer $[R_2P-BH_2]_4$ in small amount and also the extremely stable boron hydride thermoplastic polymers. The polymer is unchanged on heating to 250–300°C and does not liberate H_2, $(CH_3)_3P$, or

$(CH_3)_3P.BH_3$; on heating to 400°C, there is partial liberation of hydrogen and an increase in the B : P ratio. Pentaborane(9) reacts with aminophosphines and diphosphines in a similar manner, during which it also forms the corresponding cyclic trimers and polymers. Jeffers[99] studied the reaction of B_5H_9 with $(CH_3)_3P$ and the pyrolysis of the addition compounds thus formed, as a result of which a polymer with empirical formula $BH(PR_3)_{0.2}$ is obtained. It is assumed that the polymer forms a boron hydride chain of rubber type in which are introduced molecules of the base coordinated to the boron atoms.

(f) Alkylation of pentaborane(9). The alkylation of B_5H_9 has been studied in some detail. The alkylation has been carried out under conditions of electrophilic and nucleophilic reactions using various alkylating agents. The products have been isolated and their structure determined with the aid of chromatography and infrared and NMR spectra.

In electrophilic (Friedel–Crafts) alkylation of B_5H_9 the apical hydrogen, where the charge density is greatest, is replaced. In the nucleophilic attack of alkenes on B_5H_9, the basal hydrogen atoms are replaced.

Williams and coworkers[146] carried out the reaction of ethylene with diborane at 100°C and obtained a complex mixture of products which was separated chromatographically into two homologous series: ethylpentaborane(9)s (mono-, di-, and poly-ethylpentaboranes) and ethyldecaborane(14)s (mono-, di-, and poly-ethyldecaboranes). Evidently under these conditions reaction occurred between the B_5H_9 and $B_{10}H_{14}$ formed from the diborane and the alkylating agents: C_2H_4, ethyldiboranes, and $(C_2H_5)_3B$. It was shown that the basal hydrogen atoms are replaced. Ryschkewitsch and coworkers[147] obtained a series of alkyl derivatives of B_5H_9 by the reaction of alkenes (but-1-ene, 2-methylprop--1-ene, but-2-ene, ethylene) with pentaborane(9) at 150°C. Replacement also took place at the basal boron atoms; alkenes apparently directly attack the B_5H_9 molecule at the points of least electron density. The absence of isomeric alkyl radicals attached to the boron hydride is explained by the alkene molecule's adding to the B_5H_9 at the carbon atom having the highest electron density. The reactivity of the alkenes increases in the sequence:

$$C_2H_4 < CH_2{=}CH{-}CH_2CH_3 < CH_3CH{=}CHCH_3 \leqslant CH_2{=}\overset{\displaystyle CH_3}{\overset{|}{C}}{-}CH_3.$$

The ^{11}B-NMR spectra of RB_5H_8 contain two doublets, which shows the presence of a hydrogen atom at the apical boron. The alkylpentaboranes obtained[147] are colourless mobile liquids with a characteristic odour; in a homogeneous mixture with water they are rapidly hydrolysed; in contact with pure water they are hydrolysed slowly owing to the low solubility; they are rapidly oxidised in air and are capable of spontaneous ignition; they slowly decompose when heated in a vacuum to 150°C; they react with aliphatic amines like B_5H_9.

When pentaborane reacts with ethylene under conditions of electrophilic substitution in the presence of $AlCl_3$, ethylpentaborane is obtained[133,148]; it was shown chromatographically and with the aid of infrared and NMR spectra that under these conditions only the apical hydrogen atom is replaced. Similar results were obtained in the alkylation of B_5H_9 at 100°C by methyl chloride or ethylene in the presence of $AlCl_3$;[149] $1\text{-}CH_3B_5H_8$ is obtained in 80% yield and $1\text{-}C_2H_5B_5H_8$ in 50% yield. It was proposed[150] to use the reaction of alkenes or alkyl halides with pentaborane in the presence of $AlCl_3$, $FeCl_3$, or $SnCl_4$ as a general method for making alkylpentaboranes with an apical alkyl radical. In this way the following compounds were prepared and characterised: 1-methylpentaborane, 1-ethylpentaborane, 1-isopropylpentaborane, 1-s-butylpentaborane, and also a disubstituted product: 2-s-butyl-1-methylpentaborane. The production of a disubstituted pentaborane shows that the alkylation does not deactivate the B_5H_9 molecule in relation to further catalytic alkylation. Apical-substituted B_5H_8R derivatives are thermodynamically less stable than those substituted at a basal boron atom by 3 kcal $mole^{-1}$; therefore the direction of the substitution is determined by the mechanism of the reaction and not by the thermodynamic stability of the compounds. 1-Alkylpentaboranes are very sensitive to oxidation and hydrolysis and do not react with anhydrous HCl, but are decomposed by HCl in the presence of $AlCl_3$.

A series of patents have been taken out on methods for making alkylpentaboranes, and can be classified as follows:

1. Reaction of B_5H_9 with an alkene in the presence of catalysts — Lewis acids ($AlCl_3$, $FeCl_3$, $AlBr_3$),[151,152] the yield of 1-alkylpentaboranes being 65–68%.
2. The reaction of B_5H_9 with an alkene in the presence of basic catalysts (pyridine and alkylpyridines[153], yield of $t\text{-}C_4H_9B_5H_8$ 40.4%; tetrahydrofuran[154]; lower alkylamines[155], yield of $t\text{-}C_4H_9B_5H_8$ 43%).
3. Reaction of B_5H_9 with alkyl monohalides using Friedel–Crafts catalysts, the yield of 1-alkylpentaboranes being 80–90%.[156,157]
4. Alkyl borates, alkyl silicates, diethylborane, alkyl ester–BF_3 adducts are used as alkylating agents in the reaction with B_5H_9.[158-160]

To free alkylpentaboranes from impurities they are heated with metal oxides, the best being Fe_2O_3 or Al_2O_3.[161]

In 1961 Onak[162] observed that 1-alkylpentaborane(9) (R = CH_3 or C_2H_5) is quantitatively converted into 2-alkylpentaborane(9) in the presence of 2,6-dimethylpyridine at room temperature. The structure of the initial and final products was shown by infrared and ^{11}B-NMR spectra. The analogous conversion of 1-ethylpentaborane, obtained from B_5H_9 and C_2H_4 in the presence of $AlCl_3$, into its isomer takes place on heating to 200°C [149] but ethylpentaboranes of a higher degree of alkylation are not obtained. This rearrangement is explained by the greater thermodynamic stability of basal-substituted alkylpentaborane[150]. Hough and coworkers[163] studied such a rearrangement of $1\text{-}C_2H_5B_5H_8$ into $2\text{-}C_2H_5B_5H_8$ in the presence of $(CH_3)_3N$ at 27–28°C. Rearrangement takes place in the presence of Lewis bases (2,6-dimethylpyridine or trimethylamine), probably by intramolecular exchange of alkyl groups facilitated by the formation of an addition product of alkylpentaborane with the base. Such an addition product, $[(CH_3)_3NHB_5H_7C_2H_5]$, formed from $1\text{-}C_2H_5B_5H_8$ and $(CH_3)_3N$, was isolated at a low temperature[163]; it dissociates at 27–28°C, that is, at the temperature of formation of $2\text{-}C_2H_5B_5H_8$. To explain the mechanism of the rearrangement allowance must also be made for the recurrence of the intramolecular hydrogen exchange in B_5H_9 (as in the other boron hydrides), shown by Williams[17,81]. Onak and coworkers[117] showed that in the presence of 2,6-dimethylpyridine an intramolecular exchange takes place in 1-deuteriopentaborane(9) and intermolecular exchange does not occur; at elevated temperatures (above 145°C) exchange of H for D takes place by an

intermolecular mechanism in which di- and poly-deuteriopentaboranes are formed. With alkylpentaboranes the absence of di- and poly-alkylpentaboranes in thermal rearrangement makes more probable the hypothesis that the migration of alkyl groups proceeds by an intramolecular path. The reaction mechanism in which there is a slow "symmetrical" splitting of 1-alkylpentaborane and a rapid recombination with formation of a 2-alkylpentaborane, first proposed by Onak[149] on the basis of a theory of Parry[23], seems improbable in the light of later investigations.

A study of the thermal stability of gaseous ethylpentaborane[164] shows that it is less stable than B_5H_9. The decomposition products are H_2, CH_4, involatile boron hydrides, and traces of $B_{10}H_{14}$.

A compound derived from two B_5H_9 molecules containing a methylene bridge, bis-(1-pentaboranyl)methane $(B_5H_8)_2CH_2$, is obtained[165,166] by the reaction of B_5H_9 with alkyl halides (CH_2Cl_2, CH_2Br_2, CH_2BrCl) in the presence of $AlCl_3$. The greatest yield (~ 5%) is obtained when CH_2Cl_2 is used. Its infrared spectrum showed apical boron substitution. $(B_5H_8)_2CH_2$ is a very unstable compound, which reacts rapidly and explosively with air; in a vacuum it slowly decomposes at room temperature. Furthermore, the authors succeeded in obtaining (in insufficiently pure state) the extremely unstable dichloroborylpentabor(9)an--1-ylmethane $B_5H_8CH_2BCl_2$, in which apical substitution also takes place (as indicated by the infrared spectrum). A patent has been obtained[167] for the preparation of bispentaboranylalkanes with two B_5H_8 residues connected by an alkylene bridge by the reaction of a conjugated alkadiene with an excess of B_5H_9 at 135–145°C and elevated pressure.

VI. PENTABORANE(11)

1. Structure of Pentaborane(11)

Pentaborane(11) has been studied less than pentaborane(9). The structure of the B_5H_{11} molecule was determined by X-ray analysis and with the aid of NMR spectra. An X-ray analysis of B_5H_{11} was made by Lavine and Lipscomb[168,169], and then the calculation of the interatomic distances was refined by Lipscomb and coworkers[33]. B_5H_{11} forms monoclinic crystals with group symmetry $P2_1/n$, lattice parameters a = 6.76, b = 8.51, c = 10.14 Å; β = 94°3′; the unit cell contains four B_5H_{11} molecules. The B_5H_{11} molecule has a planar symmetry, the boron atoms forming a skeleton which is a fragment of an icosahedron; it can also be obtained from the B_5H_9 tetragonal pyramid by opening one B–H–B bond of the base (Fig. 10). The interatomic distances in the B_5H_{11} molecule have been determined: $B_{(1)}$–$B_{(3)}$ = 1.71 ± 0.02 Å; $B_{(1)}$–$B_{(2)}$ = 1.87 Å; $B_{(2)}$–$B_{(3)}$ = 1.76 ± 0.01 Å; $B_{(3)}$–$B_{(4)}$ = 1.77 Å; B–$H_{terminal}$ = = 1.10 ± 0.09 Å; $B_{(2)}$–H_{bridge} = 1.17 Å; $B_{(3)}$–H_{bridge} = 1.08 Å; $B_{(3)}$–H_{bridge} = 1.01 Å; $B_{(4)}$–H_{bridge} = 1.24 Å; $B_{(4)}$–H_{bridge} = = 1.37 Å; $B_{(5)}$–H_{bridge} = 1.44 Å; $B_{(1)}$–$H_{(11)}$ = 1.09 Å; $B_{(2)}$–$H_{(11)}$ = 1.77 Å; $B_{(5)}$–$H_{(11)}$ = 1.68 Å. Some contraction (by 0.1 Å) of the B–H bonds is probably explained by a systematic error in the method of calculation. The molecular angles in B_5H_{11} have also been measured[169]. The ^{1}H- and ^{11}B-NMR spectra of pentaborane(11)[92,170] confirm this structure for B_5H_{11}. The ^{1}H-NMR spectrum of B_5H_{11}[170] shows the presence of four types of hydrogen bonds: (1) the

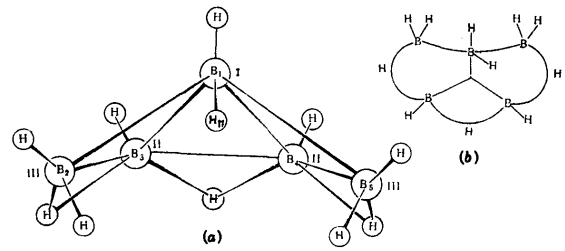

Fig. 10.

six terminal hydrogen atoms form quartets; (2) the apical terminal H_4; (3) three bridge hydrogens (multiplet); (4) the "unique" $H_{(11)}$ forms a sharp peak. The ^{11}B-NMR spectrum of B_5H_{11} shows three types of boron atom. The spectra given by Schaeffer and coworkers[92] differ somewhat from those given by Williams and coworkers[170], but they all contain peaks corresponding to three types of boron atom. The interpretation of the NMR spectra agrees with the structure of B_5H_{11}, but the distribution of charges calculated by Lipscomb[89] disagrees with some conclusions from the spectra. The ^{1}H-NMR spectrum of B_5H_{11}, specially purified by chromatography, recorded by Lutz and Ritter[74], differed slightly from the B_5H_{11} spectra mentioned above and the distribution of the charges of the boron atoms calculated from this spectrum agrees with Lipscomb's calculated data[38].

Eberhardt and coworkers showed[11] that in the B_5H_{11} molecule the apical atom $B_{(1)}$ is connected with two terminal hydrogen atoms, one of which (the "unique" $H_{(11)}$) has in addition a very weak bond with two basal boron atoms. These boron atoms (type B_{III}) are each bound by two-centre bonds with two terminal hydrogen atoms and one bridge hydrogen atom; the remaining basal boron atoms (type B_{II}) have one terminal hydrogen atom and each is bound to two bridge hydrogens. After forming these bonds, at the apical boron atom B_I there remain two orbitals and one electron; one orbital and one electron at the B_{II} atoms; one orbital and a half electron at the B_{III} atoms, that is, six orbitals and four electrons in all, which are used to form the bonds of the apical B_I atom with the basal B_{II} atoms. It is assumed that for the bonds of B_I with B_{II} atoms the sp^2-orbital of B_I and the two sp^3-orbitals of B_{II} are used, which form a central three-centre bond concentrated in the B_{II}–B_I–B_{II} triangle. For the bond of B_I with the B_{III} atoms, the p-orbital of the B_I atom and the sp^3-orbitals of the B_{III} atoms are used and by this means an open three-centre bond is formed. The formal distribution of the charges between the boron atoms was calculated[35]: $B_I = -\frac{2}{3}$, $B_{II} = +\frac{1}{3}$, $B_{III} = 0$. This charge distribution demands asymmetry of the B_{II}–H–B_{III} bridges; however, definite conclusions could not be drawn from their experimental results, measurements of greater accuracy being needed for this.

2. Preparation of Pentaborane(11)

There are several papers on the preparation of B_5H_{11} under laboratory conditions. In 1933 Burg and Schlesinger proposed a method of preparing B_5H_{11} by pyrolysis of diborane at 100–115°C,[47] a method which they subsequently improved[25].

The most convenient method of obtaining B_5H_{11} by pyrolysis of B_2H_6 was proposed by Klein and coworkers [50], using the technique of cold–hot tubes. Conditions were selected under which B_5H_{11} is obtained in 70% yield from B_2H_6: the temperature of the cold tube is -30°C, that of the hot tube +120°C, duration of the experiment 2.5 h, the B_5H_{11} and H_2 formed being removed from the reaction zone every 15 min:

$$2B_2H_6 \rightarrow B_4H_{10} + H_2;$$
$$5B_4H_{10} \rightleftarrows 4B_5H_{11} + 3H_2.$$

The conversion of B_4H_{10} into B_5H_{11} is a reversible reaction:

$$2B_5H_{11} + 2H_2 \rightleftarrows 2B_4H_{10} + B_2H_6.$$

Study of the kinetics of the pyrolysis of diborane at 80–120°C [95] suggests that B_5H_{11} is an intermediate in the formation of most other boron hydrides from B_2H_6. The scheme of the reaction is:

$$B_2H_6 \rightleftarrows 2BH_3, \quad (1)$$
$$B_2H_6 + BH_3 \rightarrow \text{intermediate products}, \quad (2)$$
$$\text{intermediate products} + B_2H_6 \rightarrow B_5H_{11} + 2H_2, \quad (3)$$
$$B_5H_{11} \rightarrow B_5H_9 + H_2, \quad (4)$$
$$B_5H_{11} \rightarrow B_2H_6 - \text{higher boron hydrides}. \quad (5)$$

The pyrolysis of diborane in a pulsation heater [8] showed that B_5H_{11} is formed through a tetraborane(10) fragment (B_4H_8):

$$B_4H_8 + B_2H_6 \rightarrow B_5H_{11} + BH_3; \; B_5H_{11} \rightleftarrows B_4H_8 + BH_3.$$

Experiment confirmed the hypothesis [95,96] that tetraborane is an intermediate in the formation of B_5H_{11} from B_2H_6.

When B_2H_6 is irradiated by light of wavelength 1849 Å a mixture of H_2, B_4H_{10}, B_5H_{11}, and, at low pressure, also the polymer $(BH)_x$ is formed [53]. On the basis of kinetic data it is assumed that B_5H_{11} and B_4H_{10} are obtained independently of one another. The condition for the formation of B_5H_{11} is the dissociation of B_2H_6 into BH_3 radicals and the reaction of the latter in an excited state. Raising the pressure lowers the rate of formation of B_5H_{11} owing to deactivation of B_2H_6 and recombination of BH_3. The mechanism of formation of B_5H_{11} is:

$$B_2H_6 + h\nu \rightarrow B_2H_6 \rightarrow 2BH_3$$
$$\downarrow M$$
$$B_2H_6 + M, \quad (M = \text{third body})$$
$$BH_3 + B_2H_6 \rightarrow B_3H_7 + H_2,$$
$$B_3H_7 + B_2H_6 \rightarrow B_5H_{11} + H_2.$$

There is a difference between the kinetics and the mechanism of thermal and photochemical conversion of B_2H_6 into B_5H_{11}.

A patent has been obtained [171] on a method for the catalytic conversion of B_2H_6 into B_5H_{11} at 175°C. The catalyst is zirconium boride and the yield of B_5H_{11} is 74.5% at a diborane conversion of 7.9%.

The preparation of completely pure B_5H_{11} was described by Spielman and Burg [78]. To purify B_5H_{11} the authors used an efficient low-temperature fractionation column, with a high reflux ratio. The B_5H_9 impurity slowly distilled into a trap (-196°C). The ^{11}B-NMR spectrum shows the complete absence of B_5H_9 impurity and other boron hydrides. B_5H_{11} has the following characteristics [78]: m.p. -122.0 ± ± 0.1°C (value given earlier -123.3°C [41]); vapour pressure 52.8 mmHg at 0°C, 103.1 mmHg at 13.5°C, 116.1 mmHg at 16.1°C. Previously a b.p. of 63°C was found for B_5H_{11} from the equation for the temperature dependence of vapour pressure:

$$\log P_{mmHg} = 7{,}901 - (1690.3/T).$$

Pentaborane(11) is unstable at room temperature and gradually decomposes on storage. At -78°C and prolonged storage mass spectroscopy shows that B_5H_{11} partly decomposes with formation of B_5H_9 and higher boron hydrides (B_6H_{10}, B_9H_{13}, $B_{10}H_{14}$). [172]

3. Isotopic Exchange and Pyrolysis of Pentaborane(11)

The reactions of B_5H_{11} show the instability of the molecule of this boron hydride. Koski has established [64] that when B_5H_{11} reacts with B_2D_6 or $^{10}B_2H_6$ exchange of hydrogen or boron atoms occurs, and study of the kinetics of the reaction in both instances shows that the reaction is half-order in B_5H_{11} and is first-order with respect to B_2D_6 or $^{10}B_2H_6$. Pentaborane(11) is split during this and all the ^{11}B, ^{10}B, H, and D atoms of both molecules participate in the exchange (mass spectra data) and the reaction proceeds by an intermolecular mechanism. Mass spectrometric study under mild conditions of the exchange reaction of B_5H_{11} with B_2D_6 showed that all the D atoms in B_2D_6 are exchanged at the same rate; all the B atoms also have a single rate of exchange, the exchange rate for the D and H atoms being twice that for the ^{10}B–^{11}B exchange. Similar results were obtained in studying the exchange of boron and deuterium between pentaborane(11) and diborane with infrared spectra.

The author proposes the following mechanism for the reaction:

$$B_5H_{11} \rightleftarrows BH_3 + B_4H_8$$
$$BH_3 + B_2D_6 \rightarrow B_2H_3D_3 + BD_3 \quad \left.\right\} \text{rate-determining stages of the process}$$
$$B_4H_8 + B_2D_6 \rightarrow B_5H_5D_6 + BH_3 \quad \left.\right\}$$
$$BH_3 + BD_3 \rightarrow B_2H_3D_3$$

The D (and ^{10}B) atoms thus introduced into the pentaborane molecule can be rapidly redistributed into the various positions of the molecule as a result of intramolecular exchange. The mass spectrum of B_5H_{11} also shows the instability of its molecule [65]. On heating (100°C), pentaborane(11) decomposes with formation of H_2, B_2H_6, B_4H_{10}, B_5H_9, and mixtures of involatile higher boron hydrides, including decaborane [46]. In the presence of hydrogen the main products of the pyrolysis of B_5H_{11} are B_4H_{10} and B_2H_6 (100°C, 10 min).

The equilibrium constants of this reversible reaction were measured in the range 100–140°C and the entropy and enthalpy of the process were determined [173]. On heating B_5H_{11} in the presence of hydrogen [8], in addition to B_2H_6, B_4H_{10}, and higher boron hydrides, B_5H_9 and B_6H_{10} are also formed in small amounts; when a mixture of B_5H_{11} and B_2H_6 (8 and 92% respectively) is heated the main products of the reaction are B_4H_{10}, B_5H_9, B_6H_{10}, and higher boron hydrides.

4. Reaction of B_5H_{11} with Lewis Bases

Stock and Poland [174] studied the reaction of B_5H_{11} with NH_3 at temperatures between -130° and +20°C and found that pentaborane(11) forms an addition compound with ammonia. The structure of the compounds obtained and the course of the reaction were not found. On heating, the addition product was changed into borazole.

Burg and Boone showed, in a series of papers, the ability of B_5H_{11} to be changed into other boron hydrides under the influence of Lewis bases and controlled conditions. This is an interesting property of B_5H_{11}, which once again shows its instability. Under the action of water at low temperature (the reagents were heated from -78° to 0°C until the ice started to melt) and a short time of contact (1 min) pentaborane(11) is partly hydrolysed, with formation of tetraborane(10) in 96% yield[56,57]:

$$B_5H_{11} + 3H_2O \rightarrow B_4H_{10} + B(OH)_3 + 2H_2.$$

The conversions of B_5H_{11} into B_6H_{10} [175,176] (on passing B_5H_{11} over a large surface of diglyme [bis-(2-methoxyethyl) ether] at temperatures from -78° to -20°C the yield of B_6H_{10} is up to 65%) and into B_9H_{15} [176] (with hexamethylenetetramine at 0°C, yield of B_9H_{15} up to 13%) have been proposed as convenient laboratory methods for these boron hydrides which previously were practically inaccessible. These are the main new methods for the conversion of some boron hydrides into others with chemical reagents, and not by thermal decomposition of the molecule.

Detachment of a BH_3 group from the B_5H_{11} molecule and subsequent disproportionation of the fragments occurs under the influence of Lewis bases — $(CH_3)_3N$, $[(CH_3)_2N]_2BH$, $(CH_2)_6(NH_2)_4$, $(CH_3)_2O$, $CH_3OCH_2CH_2OCH_2CH_2OCH_3$ — and in this both boron hydrides with less boron (B_2H_6, B_4H_{10} [56,175]) and also higher boron hydrides [175,176] are formed (B_6H_{10}, B_9H_{15}, $B_{10}H_{14}$); part of the pentaborane(11) is always converted into stable pentaborane(9). $(CH_3)_2O$ and B_5H_{11} at -78°C form an addition product with the empirical formula $B_5H_{11}.1.5(CH_3)_2O$.[176] It is assumed that the ether is coordinated to two type B_{II} boron atoms. The bonding of the ether to these boron atoms weakens the bond with the bridge hydrogens and facilitates the conversion of the B_5H_{11} molecule into other boron hydrides. A similar explanation is given for the conversion of B_5H_{11} into B_4H_{10} under the influence of water: the detachment of a B–H fragment, obtained from a B_{II} atom coordinated with oxygen and the formation of a B_4H_{10} molecule with minimal and localised rearrangement of the structure. The reaction of pentaborane(11) with amines also probably starts with electron-donor attack of the atom at these B_{II} atoms (specially bound) and with the formation of corresponding addition compounds.

In the reaction of $(CH_3)_3N$ with B_5H_{11},[175] as well as boron hydrides, trimethylamine-borane $(CH_3)_3N.BH_3$ is formed, the yield of which rises as the ratio $(CH_3)_3N : B_5H_{11}$ is raised to 2:1. Much less boron hydrides are then formed. It was also found[176] that $(CH_3)_3N.BH_3$ is a catalyst for the conversion of B_5H_{11} into other boron hydrides, which shows the greater acceptor ability of B_5H_{11} in comparison with BH_3. It has been shown that the strength of the Lewis base affects the composition of reaction products in the disproportionation of B_5H_{11}: addition products of B_5H_{11} with weak Lewis bases are readily decomposed with liberation of BH_3. Then high yields of B_2H_6 and B_4H_{10} are obtained; too strong Lewis bases form stable complexes with BH_3 group scission from the B_5H_{11}, continually removing it from the reaction zone, leading to a decrease in the yield of higher boron hydrides, particularly B_6H_{10}. The best yield of B_6H_{10} is obtained when Lewis bases of medium strength are employed, for example, diglyme.

When carbon monoxide acts on B_5H_{11} under mild conditions (20–25°C, CO pressure 7–20 atm) scission of the molecule (typical for B_5H_{11}) into BH_3 and B_4H_8 and formation of B_4H_8CO occur[77]. A detailed description of the preparation of B_4H_8CO and of its physical and chemical properties has appeared[78].

The course of the reaction of B_5H_{11} with CO is expressed by the equations:

$$B_5H_{11} \rightarrow B_4H_8 + BH_3,$$
$$B_4H_8 + CO \rightarrow B_4H_8CO,$$
$$BH_3 + CO \rightarrow BH_3CO.$$

The method of obtaining B_4H_8CO from B_5H_{11} is simpler and faster than that from B_4H_{10}, but completely pure pentaborane(11) is necessary for it, and this is not readily available. Therefore at present the preparation of B_4H_8CO from B_4H_{10} is more rational.

PF_3 reacts with B_5H_{11} like CO [78] with the formation of $B_4H_8.PF_3$ and $BH_3.PF_3$ under mild conditions (at ~ 30°C for 2 h). $B_4H_8.PF_3$ is quantitatively and reversibly converted into B_4H_8CO with CO (1 h at 18°C):

$$B_4H_8 \cdot PF_3 + CO \rightleftarrows B_4H_8 \cdot CO + PF_3.$$

5. Alkyl Derivatives of Pentaborane(11)

Various alkylating agents have been used to alkylate B_5H_{11}, these reactions also showing the lability of the pentaborane(11) molecule and its tendency to split into B_4H_8 and BH_3 groups. The alkyl derivatives of B_5H_{11} are unstable compounds.

Lutz and Ritter[74] obtained methyl derivatives of pentaborane(11) by its reactions with $CH_3B_2H_5$ under mild conditions (at 35°C for 30 min) or by reaction of B_4H_{10} with 1,2-dimethyldiborane at 100° for 15 min:

$$B_5H_{11} + B_2H_5CH_3 \rightleftarrows B_5H_{10}CH_3 + B_2H_6,$$
$$B_4H_{10} + {}^1/_2(BH_2CH_3)_2 \rightleftarrows B_5H_{10}CH_3 + H_2.$$

Methylpentaborane(11) $B_5H_{10}CH_3$ rather rapidly disproportionates at room temperature (16% after 30 min) with formation of B_5H_{11} and $B_5H_9(CH_3)_2$; on heating (90°C), the substance partly decomposes with liberation of B_5H_{11}, B_2H_6, $B_2H_5CH_3$, $B_5H_8CH_3$, traces of B_5H_9, solid boron hydrides, and $B_5H_9(CH_3)_2$. During the reaction of methylpentaborane(11) with diborane there is an exchange reaction with formation of $B_2H_5CH_3$ and B_5H_{11}: 72% of the $B_5H_{10}CH_3$ reacts after 30 min at 25°C. At a low temperature (from -78° to 0°C) diethyl ether decomposes $B_5H_{10}CH_3$ with release of B_5H_9, B_5H_{11}, and a little $B_5H_9(CH_3)_2$. $B_5H_{10}CH_3$ and $B_5H_9(CH_3)_2$ were identified and characterised with the help of infrared, NMR, and mass spectra. In the mass spectrum of $B_5H_{10}CH_3$ the most intense peaks correspond to the ions $B_5H_6CH_3^+$, $B_5H_8CH_3^+$, and $B_5H_4CH_3^+$; in the mass spectrum of $B_5H_9(CH_3)_2$ the most intense peaks are those of the ions $B_5H_5(CH_3)_2^+$, $B_5H_7(CH_3)_2^+$, and $B_5H_3(CH_3)_2^+$; that is, in methylpentaborane(11) and in dimethylpentaborane(11) the B–H bonds are split more easily than the B–C bond; furthermore, the tendency to the loss of hydrogen atoms in pairs is kept.

$B_5H_9(CH_3)_2$ is partly disproportionated at room temperature; the mass spectrum of a specimen of $B_5H_9(CH_3)_2$ which has been kept standing at 20–25°C contains peaks corresponding to $B_5H_8(CH_3)_3$.

The ^1H-NMR spectra of $B_5H_{10}CH_3$ and B_5H_{11} show that: (1) the CH_3 group is localised at B_{III} atoms; (2) geometrical isomerism exists in the $B_5H_{10}CH_3$ molecule; (3) an inductive effect may appear in a delocalised polyhedral

system. The infrared spectra of $B_5H_{10}CH_3$ and $B_5H_9(CH_3)_2$ confirm these conclusions.

Maguire and coworkers [177] studied the reaction of ethylene with pentaborane(11). After 30 min at 25°C and a pressure of 500 mmHg $C_2H_5B_5H_{10}$ is formed in 96% yield at 18% conversion of the B_5H_{11}; furthermore, small quantities of B_4H_{10}, H_2, $C_2H_5B_2H_5$, $C_2H_4B_4H_8$, and traces of $(C_2H_5)_2B_5H_9$ are formed. The formation of dimethylenetetraborane identical with the reaction product of B_4H_{10} and C_2H_4 was unexpected. The authors showed that $B_4H_8C_2H_4$ is not a decomposition product of $B_5H_{10}C_2H_5$ but is formed independently, together with $C_2H_5B_5H_{10}$:

$$B_5H_{11} \rightleftarrows B_4H_8 + BH_3,$$
$$C_2H_4 + B_4H_8 \rightarrow C_2H_4B_4H_8,$$
$$C_2H_4 + BH_3 \rightarrow C_2H_5BH_2,$$
$$C_2H_5BH_2 + B_4H_8 \rightarrow C_2H_5B_5H_{10}.$$

The decomposition of $C_2H_5B_5H_{10}$ in the liquid and gas phase in the presence of other boron hydrides has been studied to try to establish the mechanism of the reaction. A very complex mixture of products is obtained here, and the authors could not draw any definite conclusions.

The same authors studied the exchange reaction of $C_2H_5B_2H_5$ with B_5H_{11} [178] under mild conditions (30 min, 0°C) and found that there are then competing reactions of exchange of H at the C_2H_5 group and symmetrisation of $C_2H_5B_2H_5$:

$$C_2H_5B_2H_5 \xrightarrow{} {}^1/_2\,B_2H_6 + {}^1/_2(C_2H_5)_2B_2H_4$$
$$C_2H_5B_2H_5 \xrightarrow{B_5H_{11}} B_2H_6 + C_2H_5B_5H_{10}$$

Pentaborane(11) also undergoes an exchange reaction with symmetrical $(C_2H_5)_2B_2H_4$ to give $(C_2H_5)_2B_5H_9$ with C_2H_5 groups at different boron atoms. Other boron hydrides (B_4H_{10}, B_5H_9, $B_{10}H_{14}$) which have been studied under these conditions do not react with $C_2H_5B_2H_5$ and $(C_2H_5)_2B_2H_4$. These reactions are yet another proof of the lability of the H and B atoms in the B_5H_{11} molecule, and probably proceed with scission of the reacting molecules:

$$B_5H_{11} \rightleftarrows BH_3 + B_4H_8; \quad RB_2H_5 \rightleftarrows RBH_2 + BH_3.$$

The exchange reaction between $C_2H_5B_2H_5$ and B_5H_{11} reaches an equilibrium.

There are several patents on methods of alkylating B_5H_{11}. The reaction of an alkyl halide (C_2H_5Br, n-C_3H_7Cl, n-C_4H_9Cl) with a mixture of pentaboranes (70–90% B_5H_{11} and 10–30% B_5H_9) in the presence of $AlCl_3$ under mild conditions (20°C, 560 mmHg) for 1 h gives a mixture of alkylated pentaboranes [179] which was separated by fractionation. Liquid products were obtained in the reaction of B_5H_{11} with conjugated dienes [180] at 20–40°C but their composition is not given.

VII. HEXABORANE(10)

1. Structure of Hexaborane(10)

The molecular structure of hexaborane(10), B_6H_{10}, was established by X-ray analysis and NMR-spectroscopy. Lipscomb and coworkers [181,182] showed that the boron atoms in B_6H_{10} form a pentagonal pyramid (Fig. 11), which is a fragment of an icosahedron, and they determined the interatomic distances by an X-ray diffraction method.

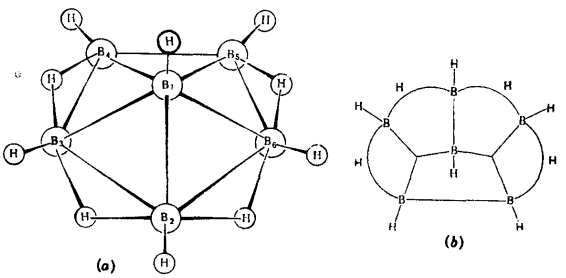

Fig. 11.

They give [182] the following data: $B_{(1)}-B_{(4)} = B_{(1)}-B_{(5)} = 1.795 \pm 0.01$ Å; $B_{(1)}-B_{(3)} = B_{(1)}-B_{(6)} = 1.753 \pm 0.009$ Å; $B_{(1)}-B_{(2)} = 1.740 \pm 0.014$ Å; $B_{(4)}-B_{(5)} = 1.596 \pm 0.012$ Å; $B_{(4)}-B_{(3)} = B_{(5)}-B_{(6)} = 1.737 \pm 0.001$ Å; $B_{(3)}-B_{(2)} = B_{(6)}-B_{(2)} = 1.79 \pm 0.009$ Å; $B-H_{terminal} = 1.21 \pm 0.07$ Å; $B_{(4)}-H_{bridge} = 1.35$ Å; $B_{(8)}-H_{bridge} = 1.31$ Å; $B_{(3)}-H_{bridge} = 1.48$ Å; $B_{(4)}-H_{bridge} = 1.32$ Å.

For the six boron atoms which form a pentagonal pyramid, two types of distributions of the bonds have been proposed [183]. After detailed study and calculations for the B_6H_{10} molecule Lipscomb and coworkers [10,182] proposed a structure which does not contain BH_2 groups, has four B–H–B bridge bonds, and a planar symmetry. Each of the five boron atoms which form the base of the pyramid are connected to a terminal hydrogen atom; in the base there are four B–H–B three-centre bonds and one B–B two-centre bond, connecting the atoms $B_{(4)}$ and $B_{(5)}$. The last atoms use one orbital and half an electron for a bond with the apical boron atom; the atoms $B_{(3)}$, $B_{(2)}$, and $B_{(6)}$ use for this purpose one sp^3-orbital and one electron. The apical boron atom is connected with one terminal hydrogen, the remaining three orbitals and two electrons being used for bonds with the basal boron atoms: one two-centre bond $B_{(1)}-B_{(2)}$ and two central three-centre bonds between the atoms $B_{(4)}-B_{(1)}-B_{(3)}$ and $B_{(5)}-B_{(1)}-B_{(6)}$ are formed on both sides of the plane of symmetry. The authors explain the unusually short distance between atoms $B_{(4)}$ and $B_{(5)}$ (1.596 Å) by all the bonds formed by these atoms (the $B_{(4)}-B_{(1)}-B_{(3)}$ and $B_{(4)}-H-B_{(3)}$ three-centre bonds and the B–H and $B_{(4)}-B_{(5)}$ two-centre bonds) exhibiting quite marked departures of the valence angle from the tetrahedral configuration and a corresponding bond shortening. This situation is comparable with that in the cyclopropane ring, where the strong strain in the ring leads to unusually short interatomic distances. Starting from the assumed structure for B_6H_{10}, the charges of the boron atoms were calculated [182]: $-\frac{1}{3}$, $-\frac{1}{6}$, $+\frac{1}{3}$, and 0 for the atoms $B_{(1)}$, $B_{(4)}$, $B_{(3)}$, and $B_{(2)}$†. The NMR spectral data [184] agree with this structure of hexaborane in the main. The ^{11}B-NMR spectrum contains two doublets with relatively intense peaks 5 : 5 : 1 : 1, corresponding to the B–H groups of the base and the B–H group at the apex of the pyramid. The basal boron atoms in the B_6H_{10} molecule are more electropositive [184] than the corresponding boron atoms in B_5H_9. However, the conclusion can be drawn from the ^{11}B-NMR spectrum of B_6H_{10} that all the boron atoms lying in the base of the pentagonal pyramid are identical; that is, the third type of boron atom, indicated by

† The original reference lists these charges in the order $B_{(1)}$, $B_{(2)}$, $B_{(3)}$, $B_{(4)}$ (Ed. of Translation).

Lipscomb's results, is not observed. The identity of these boron atoms is explained [185] by a tautomeric conversion of the two isomers of B_6H_{10}, which differ from one another in the type of bonds. The second isomer of B_6H_{10}, which is less stable, also has a structure of a pentagonal pyramid, but in it the basal boron atoms form three B–H–B three-centre bonds and the $B_{(4)}$ atom is bound to two terminal hydrogens, that is, there is a BH_2 group in the base.

The energies of the bonds in B_6H_{10} have been calculated from the lengths of the B–B and B–H bonds. The calculations show that some of the data on interatomic distances need to be determined more accurately.

2. Preparation and Properties of Hexaborane(10)

Hexaborane(10) was first obtained by Stock [41,94] in very small quantities by the hydrolysis of metal borides with acids; it was mixed with other boron hydrides and was practically inaccessible. Later Lipscomb and coworkers [181], and then Kotlensky and Schaeffer [186] obtained B_6H_{10} by the action of a silent electric discharge (15 kV) on diborane, followed by low-temperature fractionation of the mixture. The yield of B_6H_{10} was small (~ 1%), the main reaction products being B_4H_{10}, B_5H_9, and B_5H_{11} (yields of 40, 20, and 30% respectively); in addition, small amounts of B_9H_{15} and $B_{10}H_{14}$ are formed.

Hexaborane(10) became available after Boone and Burg [57,175,176,187] developed a method of making it from B_5H_{11} by the action of basic reagents. On passing B_5H_{11} vapour over a large surface of diglyme at a low pressure pure B_6H_{10} was obtained in 65% yield [176]. This method of obtaining hexaborane(10) is most convenient. A proposal has been made [188] to obtain B_6H_{10} by the hydrolysis of Mg_3B_2 under somewhat modified conditions compared with those of Stock. The total yield of boron hydrides does not exceed 12%, B_6H_{10} being obtained in a yield from 2 to 6%.

The physical properties of B_6H_{10} have been determined: m.p. -62.3°C [176] or -63.2° ± 0.1°C; [189] b.p. 108°C [176] or 82.2°C (calculated) [189]; the temperature dependence of vapour pressure is described by the equation $\log P_{mmHg} = 5.2124 - (1566.3/T) + 0.005841T$. [189] The heat of vaporisation of B_6H_{10} and its Trouton constant (= 25.7) have also been found [189], the latter showing that the B_6H_{10} molecule is not associated in the liquid state. The mass spectrum of pure B_6H_{10} [189] (differing somewhat from the mass spectrum recorded earlier for insufficiently pure B_6H_{10} [186]) shows that the most stable ion is $B_6H_8^+$; the general tendency for all boron hydrides to lose hydrogen atoms in pairs is observed. The infrared spectrum of B_6H_{10} contains bands corresponding to $B{-}H_{terminal}$ and $B{-}H_{bridge}$ bonds; bands of the BH_2 groups are absent [189]. B_6H_{10} slowly decomposes above 0°C, [189] although it is more stable than B_5H_{11} (a method has been proposed for purifying B_6H_{10} from B_5H_{11}, based on the lower stability of B_5H_{11} at -80°C and at +100°C in the presence of hydrogen). B_6H_{10} is thermally a little more stable than B_4H_{10}. [94]

A preliminary study of the deuterium exchange of B_6H_{10} with B_2D_6 showed [189] that the terminal hydrogen atoms of B_6H_{10} react more rapidly than the bridge hydrogens.

The chemical reactions of B_6H_{10} have been little studied. B_6H_{10} reacts slowly with water in the cold [94], and on heating the reaction:

$$B_6H_{10} + 18H_2O \rightarrow 6H_3BO_3 + 14H_2,$$

occurs. The hydrolysis is faster in acid than in alkali.

VIII. HEXABORANE(12)

1. Structure of Hexaborane(12)

The structure of hexaborane(12) has not been determined experimentally, but Lipscomb has proposed [185] for it the structure of a pentagonal pyramid by analogy with the structure of B_6H_{10} and on the basis of the principles of boron hydride topology. The proposed structure contains two BH_2 groups, four B–H–B bridge bonds, two B–B–B central three-centre bonds, and one B–B two-centre bond; the B_6H_{12} molecule has eight terminal hydrogen atoms and four bridging hydrogen atoms. The other possible structure for B_6H_{12} is apparently less stable, has three BH_2 groups, three B–H–B bridge bonds, and an apical boron atom, connected by three B–B–B three-centre bonds with boron atoms lying in the base of the pyramid. Gaines and Schaeffer [190] on the basis of the topology of the molecule (4212), the ^{11}B-NMR spectra, and the method of preparation from B_3H_7, proposed for B_6H_{12} a structure of an open type unusual for boron hydrides, and which is not a fragment of an icosahedron. Lutz and coworkers [191] consider that the structure of B_6H_{12} is similar to the structure of B_5H_{11} and gives a structure obtained from the B_5H_{11} molecule by replacing one B–H–B bond by a BH_2 group. This structure also agrees with the topology of the molecule, and in the main, with the ^{11}B-NMR spectrum. The absence of X-ray diffraction data does not at present permit a choice to be made between these structures.

2. Preparation and Properties of Hexaborane(12)

Gibbins and Shapiro [192] first isolated B_6H_{12} from the mixture of boron hydrides obtained by the action of an electric discharge on B_2H_6 [186] and identified it by mass spectroscopy. The authors showed that B_6H_{12} is much less stable than B_6H_{10}; it decomposes at room temperature. Gaines and Schaeffer [190,193] obtained B_6H_{12} in ~ 4% yield by the reaction of $(CH_3)_4NB_3H_8$ with polyphosphoric acid and isolated it by high-vacuum distillation. B_6H_{12} slowly decomposes at ~ 20°C with liberation of hydrogen and boron hydrides; the decomposition is accelerated in the presence of water or $(CH_3)_2O$. NMR spectra of B_6H_{12} and its vapour pressure (17 mmHg at 0°C) have been given. Lutz and coworkers [191] isolated and identified B_6H_{12}, which they obtained in low yields (~ 1%) in the decomposition of B_4H_{10} and B_5H_{11} under different conditions. Hexaborane(12) has been purified by gas–liquid chromatography. Its physical properties are: m.p. -82.3°C, vapour pressure 17.1 mmHg at 0°C, 3.8 mmHg at 23.6°C. [191] Study of the decomposition of hexaborane(12) at 25°C (pure and in the presence of B_2H_6) showed that the chemical stability of B_6H_{12} increases with increase in the purity of the compound [191]; the infrared and mass spectra of B_6H_{12} have been recorded. The chemical properties of B_6H_{12} have hardly been studied at all. With water or $(CH_3)_2O$, hexaborane(12) decomposes rapidly according to the equations [191]:

$$B_6H_{12} + 6H_2O \rightarrow B_4H_{10} + 2B(OH)_3 + 4H_2,$$

$$2B_6H_{12} \xrightarrow{(CH_3)_2O} 2B_5H_9 + B_2H_6.$$

IX. HEPTABORANES

Heptaboranes have not been obtained pure, although in several papers [8,186,192,194] it has been shown that they are present in mixtures of boron hydrides. Lipscomb [185] considers possible the existence of three B_7 boron hydrides:

B_7H_{11}, B_7H_{13}, and B_7H_{15}, and proposes for each of them a structure with a less compact arrangement of the boron atoms than for the other boron hydrides, which explains the extremely low stability of these compounds. Schaeffer and coworkers [195] in a mass spectrometric examination of tetraborane obtained from B_2H_6 observed in individual specimens peaks of a previously unknown boron hydride, to which the authors ascribed the formula B_7H_{13}. In the same work there is a statement on the existence of B_7H_{15}. Fehlner and Koski [8] showed that, in the distillation and mass spectrometric analysis of the products of the pyrolysis of B_2H_6, two heptaboranes B_7H_{11} and B_7H_{13} are probably formed (although they did not exclude the possibility of the formation of another pair of heptaboranes: B_7H_{13} and B_7H_{15}). Heptaboranes have not been isolated from mixtures of boron hydrides.

Ditter and coworkers [196] have doubted the existence of heptaboranes on the basis of the mass spectra of specimens of the "heptaborane" fraction after its purification on a chromatograph. The authors consider that ethylpentaboranes, triethoxyboranes, and other impurities, formed from traces of ethane and diethyl ether usually present in boron hydrides, have been erroneously taken for heptaboranes.

X. OCTABORANE(12) B_8H_{12}

The first indication of the formation of octaborane(12) in the pyrolysis of B_5H_{11}, based on measurements of the vapour pressure of the compound obtained, was in a study by Burg and Schlesinger [47], but it was found later [176] that B_9H_{15} is formed in this. Shapiro and coworkers [197,198] recorded the mass spectrum of octaborane(12) present in a mixture with other boron hydrides, and on the basis of this the compound was given the formula B_8H_{12}. Lipscomb and coworkers [199] succeeded in obtaining, isolating in the pure form, and finding the structure of octaborane(12). B_8H_{12} was obtained by the action of an electric discharge on a mixture of B_2H_6 and B_5H_9 (molar ratio 2 : 1), and rapid separation of the reaction products by vacuum low-temperature fractionation with simultaneous mass spectrometric analysis of the fraction. X-Ray analysis of the compound showed that the B_8H_{12} molecule has a plane of symmetry and is a fragment of an icosahedron. Fig. 12 shows the structure of B_8H_{12}.

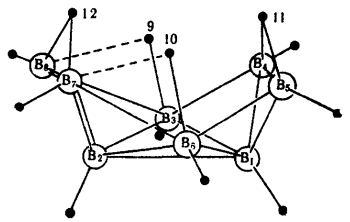

Fig. 12.

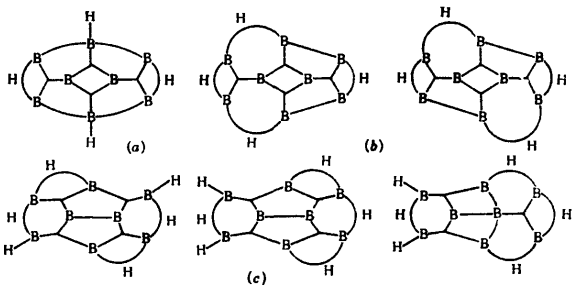

Fig. 13.

The following interatomic distances have been determined: $B_{(1)}-B_{(3)} = B_{(2)}-B_{(3)} = B_{(3)}-B_{(4)} = B_{(5)}-B_{(6)} = B_{(6)}-B_{(7)} = B_{(2)}-B_{(6)} = 1.790 \pm 0.007$ Å; $B_{(1)}-B_{(4)} = B_{(1)}-B_{(5)} = 1.690 \pm 0.006$ Å; $B_{(2)}-B_{(7)} = B_{(2)}-B_{(8)} = 1.720 \pm 0.002$ Å; $B_{(1)}-B_{(2)} = 1.803$ Å; $B_{(3)}-B_{(8)} = 1.800$ Å; $B_{(4)}-B_{(5)} = 1.672$ Å; $B_{(7)}-B_{(8)} = 1.706$ Å; $B-H_{terminal} = 1.10 \pm 0.03$ Å; $B_{(3)}-H_{(9)} = B_{(6)}-H_{(10)} = 1.28 \pm 0.02$ Å; $B_{(8)}-H_{(9)} = B_{(7)}-H_{(10)} = 1.47 \pm 0.01$ Å. Each boron atom in the B_8H_{12} molecule has one terminal hydrogen atom; furthermore, there are two symmetrical hydrogen bridges $B_{(4)}-H_{(11)}-B_{(5)}$ and $B_{(7)}-H_{(12)}-B_{(8)}$ and two unsymmetrical bridges $B_{(3)}-H_{(9)}-B_{(8)}$ and $B_{(6)}-H_{(10)}-B_{(7)}$, in which the hydrogen atom is situated close to the $B_{(3)}$ and $B_{(6)}$ atoms. The character of the bonds between the boron atoms was not analysed in this work; however, previously Lipscomb [1], on the basis of the topology of B_8H_{12} (4420) had proposed a structure (Fig. 13) in which the molecule contains four central B–B–B three-centre bonds and two B–B two-centre bonds, in addition to bonds with hydrogen atoms. B_8H_{12} is an extremely unstable compound; therefore the study of its structure is done at a low temperature (below -20°C).

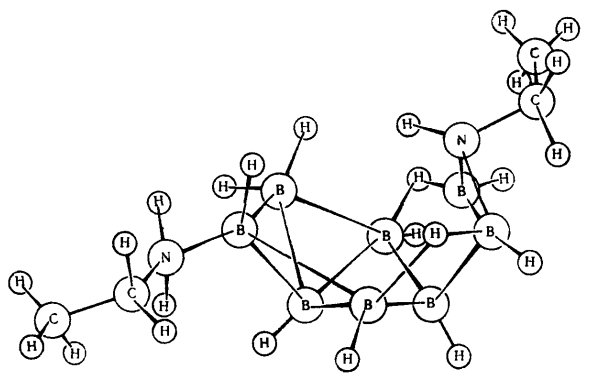

Fig. 14.

In addition to B_8H_{12}, a derivative of octaborane of the composition $C_2H_5NH_2B_8H_{11}NHC_2H_5$ has been obtained [200] by the action of $C_2H_5NH_2$ on a nonaborane complex, $B_9H_{13}S.(C_2H_5)_2$; it was isolated in the pure state and studied by X-ray diffraction [200,201]. It was shown that there is a B–N–B bridge bond in this compound, like the bond in aminodiborane, formally replacing one B–H–B bond. This type of bond was first observed in the higher boron hydrides in this example. It is assumed that this compound is a derivative of the hypothetical ion $B_8H_{13}^-$; its structure is shown in Fig. 14.

The geometry of the molecule shows that the lattice of boron atoms is a fragment of an icosahedron. All the interatomic distances were determined and the precise positions

of all the boron, nitrogen, and carbon atoms were found, and of all the hydrogen except one hydrogen atom in the NH_2 group and three hydrogens in one CH_3 group. The compound is rather stable thermally and chemically, probably owing to stabilisation by the ethylamine molecules. If the bridge nitrogen atom is formally replaced by hydrogen, then (by analogy with $B_2H_5NR_2$ and B_2H_6) B_8H_{12}.L (where L denotes ligand) is obtained, from which it is possible to obtain the hypothetical $B_8H_{13}^-$ ion, which is a derivative of B_8H_{14}. The authors suggested the instability of this octaborane is due to steric hindrance.

Hence the octaboranes are also extremely unstable representatives of the boron hydrides and at present have been very little studied.

XI. NONABORANE(15)

Nonaborane(15), B_9H_{15}, is yet another boron hydride which has been obtained comparatively recently. Mention of some nonaborane among the decomposition products of pentaborane(11) when the latter is kept for a long period is made by Norton [172]. B_9H_{15} was first obtained by Kotlensky and Schaeffer [186] as a by-product produced in extremely small amounts in a mixture with B_6H_{10} and $B_{10}H_{14}$ (total amount of the three boron hydrides ~ 1%) by the action of a silent electric discharge on diborane. Its formula and structure were established by X-ray analysis and mass spectrometrically [202,203], in which extremely small quantities of material were used and were of insufficient purity. In 1962, Burg and Kratzer [176] developed a method for obtaining B_9H_{15} by the catalytic decomposition of B_5H_{11} in the presence of hexamethylenetetramine at 0°C, yield of B_9H_{15} ~ 13%. The constants obtained for pure nonaborane (m.p. +2.8°C, vapour pressure 0.8 mmHg at 28°C) differ considerably from those of the specimen used earlier by Lipscomb [202,204] for establishing the structure of B_9H_{15} (m.p. -18° to -20°C); however, Burg and Kratzer showed with the aid of ^{11}B-NMR, infrared, and mass spectra that the specimens were identical in chemical structure, and the difference in constants is explained by the presence of other boron hydrides as impurities. Ditter and coworkers [196] obtained nonaborane(15) from B_5H_{11} and B_2H_6 (excess of diborane, pressure 27 atm) and recorded the mass spectrum of pure B_9H_{15}.

Nonaborane(15) has the structure shown in Fig. 15.

The interatomic distances [202] are (in Å): $B_{(1)}-B_{(3)} = B_{(1)}-B_{(8)} = 1.76$; $B_{(3)}-B_{(8)} = 1.80$; $B_{(3)}-B_{(9)} = B_{(8)}-B_{(9)} = 1.86$; $B_{(3)}-B_{(4)} = B_{(7)}-B_{(8)} = 1.95$; $B_{(1)}-B_{(4)} = B_{(1)}-B_{(7)} = 1.75$; $B_{(1)}-B_{(2)} = 1.77$; $B_{(2)}-B_{(4)} = B_{(2)}-B_{(7)} = 1.82$; $B_{(2)}-B_{(5)} = B_{(2)}-B_{(6)} = 1.76$; $B_{(5)}-B_{(6)} = 1.78$; $B_{(4)}-B_{(5)} = B_{(6)}-B_{(7)} = 1.84$; $B-H_{terminal} = 1.15 \pm 0.32$; $B-H_{bridge} = 1.36 \pm 0.32$; accuracy of B–B distances 0.07 Å.

The boron atoms in the B_9H_{15} molecule are disposed in the form of a fragment of an icosahedron, but there is some deformation of the boron framework owing to an increase in the distances $B_{(3)}-B_{(4)}$ and $B_{(7)}-B_{(8)}$. Each boron atom is connected to a terminal hydrogen atom, the direction of these bonds approximately coinciding with the lines leading from the centre of the icosahedron to the boron atom concerned. The atom $B_{(9)}$ has two terminal hydrogen atoms so that these atoms are directed perpendicular to the plane formed by the atoms $B_{(8)}B_{(9)}B_{(3)}$, and are situated on opposite sides of this plane. In the B_9H_{15} molecule there are five B–H–B bridge bonds and six types

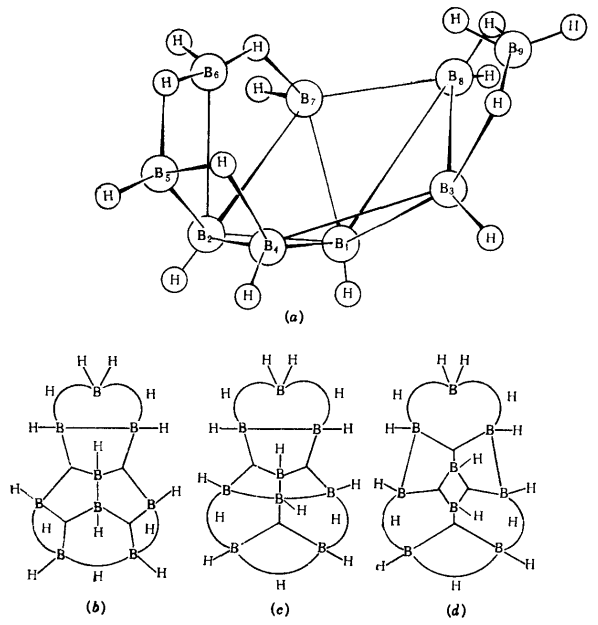

Fig. 15.

of boron atoms. The structure of the valence bonds in the molecule around the atoms $B_{(2)}-B_{(4)}-B_{(5)}-B_{(6)}-B_{(7)}$ is reminiscent of the structure of the B_5H_{11} molecule; just as in this compound, three B–H–B bridge bonds are directed inwards towards the centre of the icosahedron. On the other hand (near the BH_2 group) the bonding of the molecule is reminiscent of B_4H_{10}. In the molecule of B_9H_{15} the boron atoms are bound to one another (apart from the five B–H–B bridge bonds) by another two two-centre and four three-centre bonds. A topological calculation has shown [183] that such a structure is the best for B_9H_{15}. There are three possible ways of arranging the three-centre bonds between the boron atoms in a B_9H_{15} molecule which is a fragment of an icosahedron, when a plane of symmetry is present (Figs. 15*b*–15*d*). All these structures can be converted into one another by a small change in atomic orbitals. The LCAO–MO method was used to calculate the charge distribution between the boron atoms, the bond energies, and the ionisation potentials [38] for the ideal B_9H_{15} molecule. The ^{11}B-NMR spectrum of B_9H_{15} [176] contains two triplets in the low and high potential regions; the interpretation of this spectrum is complex but it evidently agrees with the structure of B_9H_{15} obtained by the X-ray analysis of the compound. The infrared spectrum is also very complex; it contains lines corresponding to three types of B–H–B bond, five types of terminal B–H bond, and also several types of B–B bond.

2. Properties of B_9H_{15}

Some information has been obtained on the stability of B_9H_{15}: [176] the compound is unchanged after 1 h at 0°C; on holding for 40 s at 74.9°C and 3.89 mmHg (to determine the molecular weight), the melting point of the compound is lowered to 0.6–0°C and a little hydrogen is released (0.016 moles hydrogen per mole B_9H_{15}), that is, there is slight decomposition of the B_9H_{15}. However, the stability of B_9H_{15} surpasses that of B_8H_{12} and the B_7 hydrides and is

comparable with that of B_5H_{11}. The kinetics of the decomposition of nonaborane(15) into B_8H_{12} and B_6H_{10} have been studied with the mass spectrograph[196].

Nonaborane derivatives of the type $B_9H_{13}.L$ (where L is a ligand) are derivatives of the hypothetical anion $B_9H_{14}^-$ and were first obtained and characterised by Graybill and coworkers[205,206] by the action of diethylamine on decaborane(14) followed by treatment with aqueous HCl, when the following reactions take place:

$$B_{10}H_{14} + (C_2H_5)_2NH \xrightleftharpoons{\text{rapid}} (C_2H_5)_2\overset{+}{N}H_2B_{10}H_{13}^- \xrightarrow[\text{slow}]{(C_2H_5)_2NH}$$

$$\rightarrow (C_2H_5)\overset{+}{N}H_2B_{10}H_{13}^- \cdot [(C_2H_5)_2NH],$$

$$B_{10}H_{13}^- \cdot [(C_2H_5)_2NH] + H_3\overset{+}{O} + 2H_2O \rightarrow 2H_2 + B(OH)_3 + B_9H_{13} \cdot [(C_2H_5)_2NH].$$

The same compounds are obtained by alcoholysis of $B_{10}H_{12}L_2$ (L = CH_3CN or Et_2S):

$$B_{10}H_{12}L_2 + ROH \rightarrow B_{10}H_{13}L \cdot (ROH) + L,$$

$$B_{10}H_{12}L \cdot (ROH) + 2ROH \rightarrow B_9H_{13}L + B(OR)_3 + H_2.$$

The authors showed that in the compound $B_9H_{13}S(C_2H_5)_2$ the ligand undergoes substitutions with CH_3CN, $P(C_5H_5)_3$, pyridine and its derivatives, $(C_2H_5)_2NH$, or $(C_2H_5)_3N$. When this compound is treated with an excess of diethylamine there is partial degradation of the anion and formation of a derivative of octaborane, $C_2H_5NH_2B_8H_{11}NHC_2H_5$.[200] When $B_9H_{13}S(C_2H_5)_2$ is treated with strong bases L is replaced and a derivative of a new anion, $B_9H_{12}^-$, is formed[205]:

$$B_9H_{13}S(C_2H_5)_2 + (CH_3)_4NOH \rightarrow (CH_3)_4N^+ + B_9H_{12}^- + H_2O + S(C_2H_5)_2.$$

The compounds $B_9H_{13}.L$ can give derivatives of $B_9H_{12}^-$ also on reaction with pyridine. The anion $B_9H_{12}^-$ is much less stable than $B_9H_{14}^-$; its structure has not been established. Methanolysis of $B_9H_{12}N(CH_3)_4$ leads to decomposition of the anion $B_9H_{12}^-$ and the relatively stable anion $B_3H_8^-$, which is a method of obtaining the latter[18].

The structure of $B_9H_{13}CNCH_3$ was found by X-ray diffraction[207,208], and is shown in Fig. 16.

The boron atoms form a fragment of an icosahedron and are arranged like nine of the boron atoms in the $B_{10}H_{12}(CNCH_3)_2$ molecule, from which $B_9H_{13}CNCH_3$ is obtained; two of the boron atoms have two terminal hydrogens, the rest each have one hydrogen atom; in addition, there are two B–H–B bridge bonds in the molecule. The character of the bonds between the boron atoms in the $B_9H_{13}CNCH_3$ molecule is somewhat different from that of the B_9H_{15} molecule; the authors attribute this difference to tautomerism of the hydrogen atoms in the boron hydride

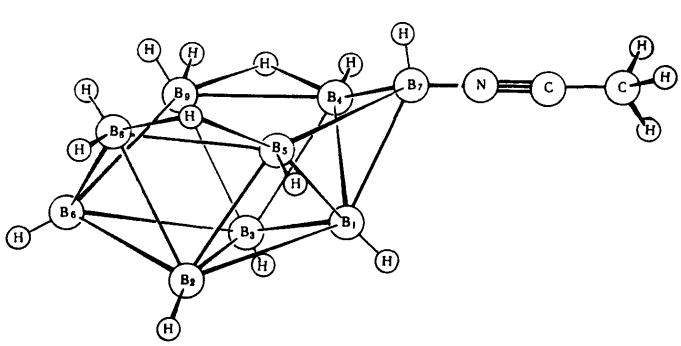

Fig. 16.

as a result of which yet another BH_2 group and a negative ion (or its derivative) are formed. Graybill and coworkers[205] suggest that the boron atom connected to the ligand molecule has sp^2-hybridisation (analogous to the atoms $B_{(6)}$ and $B_{(9)}$ in $B_{10}H_{12}.L_2$). The authors found that in the excited state in $B_9H_{13}.L$ (where L is pyridine itself or a pyridine substituted in the ring) there is an interaction between the π-electron orbital of the pyridine ring and the open three-centre bond B–B–B (p-orbitals) of the B_9H_{13} molecule: the excitation energy depends linearly on the Hammett constant (σ) in the pyridine series. A compound of the $B_9H_{13}.L$ type (where L is a neutral molecule, a donor of electrons) form a unique class of complex compound united by the properties of compounds with infra- and inter-molecular exchange of charges.

Muetterties and Aftandilian[209] obtained a compound of yet another type of nonaborane derivative, $B_9H_{14}P(C_6H_5)_2$ (however, the problem of the composition of the fragment has not been settled conclusively) by the alkaline hydrolysis of $B_{10}H_{13}P(C_6H_5)_2$ in alcoholic medium:

$$B_{10}H_{13}P(C_6H_5)_2 + 3H_2O \rightarrow B_9H_{14}P(C_6H_5)_2 + B(OH)_3 + H_2O.$$

A few salts of the anion $B_9H_{14}^-$ – with the cations Cs^+, $(CH_3)_4N^+$, and $(CH_3)_3\overset{+}{N}H$ – have been obtained[210] in the hydrolysis of $B_{10}H_{14}$ by aqueous bases; the salts were isolated and the anion characterised. Several reciprocal conversions of the compounds $B_9H_{13}.L$ and $X^+B_9H_{14}^-$ have been made, which confirm the structural similarity of these types of molecule.

---o0o---

The boron hydrides are extremely reactive compounds, capable of various types of chemical reaction depending on the types of bond in them. Boron hydride chemistry is now developing very intensively both as regards the study of compounds already known and also in the preparation and study of new representatives of this class. The theory of the chemical structure of the boron hydrides still requires greater precision as the geometry of some boron hydrides and their NMR spectra have not been completely explained.

---o0o---

NOTE ADDED IN PROOF

After submission of this paper for publication several review articles and collections of papers were published: Adams[211] dealt with the chemistry of the boron hydrides, Schaeffer[212] with the NMR spectra, Campbell[213] with structure, and Levinskass[214] with the toxicity of boron hydrides; new boron hydrides were also obtained: the anion $B_6H_6^{2-}$, octaborane(18) B_8H_{18},[216] and iso-nonaborane iso-B_9H_{15}.[217] Furthermore, articles have appeared on individual questions of boron hydride chemistry: on triborane[218], tetraborane[218-224], pentaboranes[225-229], hexaboranes[215,230-232], octaboranes[196,230,231,233], and nonaboranes[196,227,234].

COVALENT ORGANODIELEMENTARY COMPOUNDS

N. S. Vyazankin and O. A. Kruglaya

CONTENTS

I. Introduction 593
II. Methods of preparation 593
III. Properties of compounds of the type $(R_3M)_nM'$ (M = = Si and its analogues; M' = Hg, Cd, Sb, etc.) 596
IV. Properties of compounds of type $R_3M-M'R_3$ (where M and M' are elements of Group IV*b*) 599

I. INTRODUCTION

Among organodielementary compounds we include compounds containing, apart from the usual elements (C, H, O, N, Cl, etc.), two inorganic elements. When the latter are metals, the compounds will be termed organodimetallic compounds.

In organodielementary compounds the inorganic elements may be separated by hydrocarbon groups or may be adjacent to one another. In the latter case the bond between them may be either ionic or covalent. Razuvaev and his coworkers are playing an active part in developing methods for the synthesis of organodielementary compounds having a covalent bond between the inorganic elements and also in examining their reactivity. The present paper reviews work in this field and is based on the literature up to May 1965. Investigations on organodielementary compounds having an ionic bond between the inorganic elements have been discussed several times in reviews and monographs [1-5].

II. METHODS OF PREPARATION

Organodielementary compounds containing an M–M' bond (here and below M and M' denote the inorganic elements) are usually prepared by reaction of R_3SiLi and analogous compounds with inorganic or organoelementary halides (method A), e.g.

$$(C_6H_5)_3SiK + (C_6H_5)_3SnCl \longrightarrow KCl + (C_6H_5)_3SiSn(C_6H_5)_3, \quad (1)$$

$$3(C_6H_5)_3GeNa + SiHCl_3 \longrightarrow [(C_6H_5)_3Ge]_3SiH + 3NaCl. \quad (2)$$

The yield of triphenyltriphenylsilyltin from reaction (1) is 76%;[6] tristriphenylgermylsilane is formed in quantitative yield in conformity with Eqn. (2).[7]

Method A has been used to synthesise several compounds containing Si–Ge,[6,8-12] Si–Sn,[7,13-16] Ge–Sn[17,18], Ge–Pb[18], and Sn–Pb[18] groups. Covalent organotrielementary compounds have been obtained in a similar manner[1]:

$$[(C_6H_5)_3Ge]_3SiLi + ClSn(C_6H_5)_3 \longrightarrow [(C_6H_5)_3Ge]_3SiSn(C_6H_5)_3 + LiCl.$$

In 1964 this method was used to synthesise a series of organodimetallic compounds having a neopentane configuration of metal atoms [18-21]:

$$4(C_6H_5)_3MLi + M'Cl_4 \longrightarrow [(C_6H_5)_3M]_4M' + 4LiCl,$$

$$4(C_6H_5)_3MLi + 2PbCl_2 \longrightarrow [(C_6H_5)_3M]_4Pb + Pb + 4LiCl,$$

where M = Pb, Sn and M' = Sn, Ge.

The attempt to obtain tetrakistriphenylgermyltin from triphenylgermyl-lithium and tin tetrachloride was unsuccessful[18], since in this case metal–halogen exchange predominates, with the formation of hexaphenyldigermane:

$$(C_6H_5)_3GeLi + SnCl_4 \longrightarrow (C_6H_5)_3GeCl + [LiSnCl_3],$$

$$(C_6H_5)_3GeCl + (C_6H_5)_3GeLi \longrightarrow LiCl + (C_6H_5)_6Ge_2.$$

This work showed that, in the synthesis of compounds of the type $[(C_6H_5)_3M]_4M'$ the tendency for metal–halogen exchange to occur diminishes in the sequence

$$(C_6H_5)_3GeLi > (C_6H_5)_3SnLi > (C_6H_5)_3PbLi.$$

The occurrence of this secondary process, which often leads to the formation of difficultly separable mixtures of products[8,17], is a substantial disadvantage of method A. Thus the interaction of $(C_6H_5)_3GeK$ with $(C_6H_5)_3SiCl$, for example, yields a difficultly separable mixture containing $(C_6H_5)_6Ge_2$, $(C_6H_5)_6Si_2$, and $(C_6H_5)_3GeSi(C_6H_5)_3$.[8,17] The attempt to prepare $(C_6H_5)_3SnSi(CH_3)_3$ from $(CH_3)_3SiCl$ and $(C_6H_5)_3SnLi$ failed, since in this system metal–halogen exchange and its accompanying processes occur preferentially[14]:

$$(C_6H_5)_3SnLi + (CH_3)_3SiCl \longrightarrow (C_6H_5)_3SnCl + (CH_3)_3SiLi,$$

$$(C_6H_5)_2SnCl + (C_6H_5)_3SnLi \longrightarrow LiCl + (C_6H_5)_6Sn_2 \text{ (yield 69\%)},$$

$$(CH_3)_3SiLi + (CH_3)_3SiCl \longrightarrow LiCl + (CH_3)_6Si_2.$$

Blake et al. have made the interesting observation that the interaction of $(CH_3)_3SiCl$ with $(C_4H_9)_3SnLi$ is preceded by dissociation of the latter compound[22]:

$$(C_4H_9)_3SnLi \rightleftarrows (C_4H_9)_2Sn + C_4H_9Li,$$

$$C_4H_9Li + (CH_3)_3SiCl \longrightarrow LiCl + (CH_3)_3SiC_4H_9,$$

the yield of butyltrimethylsilane being 54%. Such a process is not characteristic of the reaction of triphenylstannyl-lithium with triphenylchlorosilane[14].

Method A has been employed also for the synthesis of organodielementary compounds containing Si–Hg bonds. Attempts to use the reaction of triphenylsilyl-lithium with mercury halides, phenylmercuric chloride, or diphenylmercury were unsuccessful[23]. It was therefore supposed

that the Si–Hg bond in organosilicon compounds of mercury was unstable. This conclusion was subsequently disproved by the work of Wiberg [15], Razuvaev [24,25], and their coworkers. Wiberg, in particular, synthesised by method A triphenylsilyl derivatives of mercury, zinc, and aluminium:

$$n\,(C_6H_5)_3SiK + MCl_n \longrightarrow [(C_6H_5)_3Si]_nM + n\,KCl,$$

where M = Hg, Zn, Al and n = 2, 3. He showed also that interaction of R_3SnLi with chlorotrimethylsilane or a dialkyldichlorosilane in ether at -20° gives yields of up to 60–70% of compounds of types $R_3SnSi(CH_3)_3$ and $(R_3Sn)_2SiR'_2$, where R = C_2H_5, C_4H_9, C_6H_5 and R' = CH_3, C_6H_5.

The method was further developed by Schumann and Schmidt [26], who achieved the reaction

$$3\,(C_6H_5)_3SnLi + MCl_3 \longrightarrow [(C_6H_5)_3Sn]_3M + 3LiCl,$$

where M = As, Sb, Bi. The yield of the required products is ~80%. The chloride MCl_3 can be replaced by mixed organometallic compounds R_2MCl. In this way these workers obtained compounds containing one Sn–As covalent bond. The first representative of this class of compounds, diphenyltrimethylstannylarsine, had been obtained previously by a different method [27]. For the synthesis of compounds of the $R_3SnM(C_6H_5)_2$ series, where R = CH_3, C_2H_5, C_3H_7, C_4H_9 and M = As, Sb, see also Ref. 28. The infrared spectra of compounds containing covalent Sn–As and Sn–Sb bonds are discussed in Ref. 29.

Repeated attempts have been made to use method A [23,30] for the synthesis of compounds containing an Si–Bi, Si–Hg, Si–Cd, or Si–Zn bond. The reactions of triphenylsilyl--lithium with metal halides have been studied for this purpose. In the $(C_6H_5)_3SiLi$–$BiCl_3$ system the predominant reaction is metal–halogen exchange, leading to the formation of hexaphenyldisilane [30]. In some cases, nevertheless, the intermediate formation of organodielementary compounds is assumed [23] (e.g. in the reactions with mercury, lead, and tin halides). For the occurrence of unstable compounds containing an Si–P, Si–As, or Si–Sb bond in the reactions of triphenylsilyl-lithium with halides of Group V elements see Ref. 31.

Method A has been employed also for the synthesis of organodielementary compounds containing an Sn–P [32–34], Sn–Ti [35], Sn–B [36], or Pb–Ti [35] bond. There is no doubt that its synthetic possibilities have not yet been completely exhausted.

In 1963 Razuvaev and his coworkers began to apply the reaction of alkylated hydrides of Group IV elements with organometallic compounds to the synthesis of compounds containing covalent M–M'–M bonds (method B) [24,25,37–44]. The yield of organodielementary compounds is usually high:

$$n\,(C_2H_5)_3MH + (C_2H_5)_nM' \longrightarrow n\,C_2H_6 + [(C_2H_5)_3M]_nM',$$

where

M=Ge, Si;	M'=Hg, Cd, Zn;	n=2
M=Ge, Sn;	M'=Se;	n=2
M=Ge, Si;	M'=Tl;	n=3
M=Ge, Si, Sn;	M'=Bi, Sb;	n=3

Bistriethylgermylmercury was obtained at the same time, independently, and by the same reaction by Neumann and Kühlein [45]. These workers established [46,47], however, that method B can be used to synthesise complicated organodielementary compounds containing chains of inorganic elements, e.g.

$$4\,(C_6H_5)_2GeH_2 + 4\,(C_2H_5)_2Hg \longrightarrow 8C_2H_6 + 4/n\,[-(C_6H_5)_2GeHg-]_n \xrightarrow{h\nu} [(C_6H_5)_2Ge]_4 + [(C_6H_5)_2Ge]_n + 4Hg. \quad (3)$$

In 1964 method B was employed for the synthesis of bistriphenylstannyl sulphide [48]:

$$2\,(C_6H_5)_3SnH + (C_6H_5CH_2)_2S \longrightarrow 2C_6H_5CH_3 + [(C_6H_5)_3Sn]_2S.$$

Vyazankin et al. found that triethylsilane [24] and pentaethyldisilane [25] react with diethylmercury to form mainly products containing Si–Hg–C groupings:

$$R\,(C_2H_5)_2SiH + (C_2H_5)_2Hg \longrightarrow C_2H_6 + R\,(C_2H_5)_2SiHgC_2H_5, \quad (4)$$

where R = C_2H_5, $(C_2H_5)_3Si$. The yield of the symmetrical products — bistriethylsilylmercury and bis(pentaethyldisilanyl)mercury — was only 3.3% and 8.1% respectively. This has permitted the synthesis of triethylgermyl(triethylsilyl)mercury (26.2%) and of pentaethyldisilanyl(triethylgermyl)mercury (50.4%), which are the first organotrielementary compounds containing an Si–Hg grouping:

$$(C_2H_5)_3GeH + C_2H_5HgR \longrightarrow C_2H_6 + (C_2H_5)_3GeHgR, \quad (5)$$

where R = $(C_2H_5)_3Si$, $(C_2H_5)_3SiSi(C_2H_5)_2$.

It follows from Eqns. (4) and (5) that triethylgermane is more reactive than triethylsilane. This is confirmed by reactions (6)–(8), which constitute a further development of method B and from which it can be concluded that the reactivity of the hydrides in the above processes decreases in the sequence

$$(C_2H_5)_3SnH > (C_2H_5)_3GeH > (C_6H_5)_3SiH > (C_3H_7)_3SiH \simeq (C_2H_5)_3SiH\ [44]:$$

$$(C_2H_5)_3SnH + [(C_2H_5)_3Ge]_3M' \longrightarrow (C_2H_5)_3GeH + [(C_2H_5)_3Sn]_3M', \quad (6)$$

$$(C_2H_5)_3GeH + [(C_2H_5)_3Si]_3M' \longrightarrow (C_2H_5)_3SiH + [(C_2H_5)_3Ge]_3M', \quad (7)$$

$$(C_6H_5)_3SiH + [(C_2H_5)_3Si]_3M' \rightarrow (C_2H_5)_3SiH + [(C_6H_5)_3Si]_3M', \quad (8)$$

where M' = Bi, Sb.

Reaction (8) does not go to completion even under very severe conditions (230° for 20 h). The yield of hydrides and of the corresponding organodimetallic compounds in conformity with Eqns. (6) and (7) is quantitative.

In a study of the reaction of triethylgermane with triethylbismuth, Kruglaya et al. [42] established that, depending on the relative proportions of the starting materials, method B can be used to obtain not only $[(C_2H_5)_3Ge]_3Bi$ but also products of the partial replacement of ethyl by triethylgermyl groups:

$$n\,(C_2H_5)_3GeH + (C_2H_5)_3Bi \longrightarrow n\,C_2H_6 + [(C_2H_5)_3Ge]_nBi\,(C_2H_5)_{3-n},$$

where n = 1–3.

Method B has not yet been further developed on these lines. Nevertheless, this method has certain limitations. Thus compounds containing Sn–Cd, Sn–Tl, Sn–Zn [41], and Sn–Hg [24,25] bonds cannot be obtained in this way. It may merely be supposed that compounds of this type are intermediates in the reaction of $(C_2H_5)_3SnH$ with ethyl derivatives of cadmium, thallium, zinc, and mercury, since ethane and hexaethyldistannane are formed in high yield in all these cases, e.g. [24,25]

$$2\,(C_2H_5)_3SnH + (C_2H_5)_2Hg \longrightarrow 2C_2H_6 + [(C_2H_5)_3Sn]_2Hg \xrightarrow{} (C_2H_5)_6Sn_2 + Hg$$

Method B has not yet been widely used with success for the synthesis of substances containing M–M′ groupings, where M and M′ are elements of the silicon subgroup. However, there are grounds for assuming[49] that this limitation can be overcome:

$$(C_6H_5)_3GeH + (C_4H_9)_3SnN(C_2H_5)_2 \longrightarrow (C_2H_5)_2NH + (C_4H_9)_3SnGe(C_6H_5)_3.$$

In spite of the above disadvantages, this is undoubtedly a general method. In particular, method B can be used to obtain organodielementary compounds containing an ionic bond between the inorganic elements as well as those in which the bond is covalent. The metallation of organogermanium hydrides by organolithium compounds in tetrahydrofuran medium is well known[2,12,50]. In some cases, e.g. in the reaction of triphenylgermane with butyl-lithium, the yield is quantitative:

$$(C_6H_5)_3GeH + C_4H_9Li \longrightarrow C_4H_{10} + (C_6H_5)_3GeLi. \quad (9)$$

Discussing this reaction, Gilman[50] indicates, not without justification, that it is analogous to corresponding reactions of diphenylphosphine and of triphenylmethane[51,52]:

$$(C_6H_5)_2PH + C_4H_9Li \longrightarrow C_4H_{10} + (C_6H_5)_2PLi^{[51,52]},$$

$$(C_6H_5)_3CH + C_4H_9Li \longrightarrow C_4H_{10} + (C_6H_5)_3CLi^{[53,54]}.$$

Compounds containing Sn–Li[55], As–Li[56], P–Mg[57], and Sb–Li[58] ionic bonds have been prepared in a similar manner.

Recently, after a series of unsuccessful attempts[50], $(C_6H_5)_3GeMgCl$ has been prepared by the reaction of triphenylgermane with allylmagnesium chloride in tetrahydrofuran[59]. Finally, reports have recently appeared of the use of method B for the synthesis of compounds containing Ge–P [54], Sn–P [60], and Sn–As[60] bonds:

$$(C_6H_5)_2PH + (C_2H_5)_3GeN(CH_3)_2 \longrightarrow (CH_3)_2NH + (C_2H_5)_3GeP(C_6H_5)_2,$$

$$(C_6H_5)_2MH + R_3SnN(CH_3)_2 \longrightarrow (CH_3)_2NH + R_3SnM(C_6H_5)_2,$$

where M = P, As and R = CH_3, C_2H_5.

Besides the general methods A and B, several less developed routes are known for the synthesis of organodielementary compounds of the type under discussion. Thus triethyltriethylsilylgermane was obtained in 1963, for example, by the action of sodium on a mixture of bromotriethylsilane and bromotriethylgermane in the absence of solvents[61]; symmetrical products, containing Si–Si and Ge–Ge bonds, are formed at the same time.

Wiberg et al. [15], in an endeavour to use the Wurtz reaction to obtain compounds containing an Si–Si bond, studied the action of liquid sodium amalgam on halogenotrimethylsilanes. This led them to the synthesis of bistrimethylsilylmercury:

$$2(CH_3)_3SiX + 2Na + Hg \rightarrow [(CH_3)_3Si]_2Hg + 2NaX,$$

where X = Cl, Br. The compounds $Hg[Si(CH_3)_{3-n}H_n]_2$, where n = 1, 2, could not be obtained by the action of sodium amalgam on methylbromosilanes, but there is no doubt that they are formed as intermediates in this process.

Several original methods were developed during 1963–1964 for the preparation of compounds containing Pb–S [62], Sn–Se [63,64], Sn–Te [63,64], Sn–S–Pb[65], Sn–S [63,66], Ge–S [67], and Si–Sb[68] bonds.

Organodimetallic and organopolymetallic compounds having covalent bonds between transition metals and metals of Group IV*b* have been investigated intensively during recent years. The possibility of preparing compounds of this type was first reported by Hein and his coworkers[69]: by the action of organolead hydroxides on $Ca[HFe(CO)_4]_2$ they obtained two types of compounds containing a covalent Pb–Fe bond – $[Alk_2PbFe(CO)_4]_2$ and $(R_3Pb)_2Fe(CO)_4$, where R represents phenyl or cyclohexyl.

A method based on the reactions of salts of hydrocarbonyls with organometallic halides of Group IV*b*, e.g. [70]

$$R_{4-n}SnCl_n + n\,Na[Co(CO)_4] \longrightarrow n\,NaCl + R_{4-n}Sn[Co(CO)_4]_n,$$

where n = 1,2 and R = CH_3, C_4H_9, proved to be more generally applicable. The compounds $(C_4H_9)_2SnFe(CO)_4$,[70] $[(C_6H_5)_2PbFe(CO)_4]_2$,[71] $C_5H_5Fe(CO)_2Si(CH_3)_3$,[72,73] $(C_6H_5)_3GeMn(CO)_5$,[74] and $(C_6H_5)_3GeFe(CO)_2C_5H_5$ [74] have been obtained in this way. Gorsich[75] used the same method to synthesise compounds containing covalent Sn–Mn, Pb–Mn, and Sn–Fe bonds.

In recent years two further methods have been worked out for the preparation of compounds containing an Sn–Fe bond. Compounds of the type $[R_2SnFe(CO)_4]_2$, where R = CH_3, C_4H_9, have been obtained in low yields by the interaction of pentacarbonyliron and $R_2Sn(C_6H_5)_2$ in boiling ethylcyclohexane[76]. The second method is based on the reaction[77]

$$[C_5H_5Fe(CO)_2]_2 + SnCl_2 \longrightarrow [C_5H_5Fe(CO)_2]_2SnCl_2 \xrightarrow{+2C_2H_5MgBr} [C_5H_5Fe(CO)_2]_2Sn(C_2H_5)_2. \quad (A)$$

The compound A has also been synthesised by the reaction

$$2C_5H_5Fe(CO)_2Na + Cl_2Sn(C_2H_5)_2 \longrightarrow 2NaCl + A.$$

In 1964 Nesmeyanov and his coworkers prepared organodimetallic compounds containing Re–M, Mo–M, and W–M bonds, where M = Sn, Pb, by the reaction of organometallic chlorides with $NaRe(CO)_5$,[78] $NaMo(CO)_3C_5H_5$, $NaW(CO)_3C_5H_5$, and $NaCr(CO)_3C_5H_5$.[79]

Quite recently these workers[80] have obtained new polymetallic compounds of tin with carbonyls of metals in Groups VI–VIII by the reactions

$$(CO)_5MnSn(C_6H_5)_2Cl + NaM(CO)_n \longrightarrow (CO)_5MnSn(C_6H_5)_2M(CO)_n, \quad (M = Co, Re)$$

$$(CO)_5MnSn(C_6H_5)_2Cl + NaM'(CO)_3C_5H_5 \longrightarrow (CO)_5MnSn(C_6H_5)_2M'(CO)_3C_5H_5. \quad (M' = Mo, W)$$

The elaboration of methods for the synthesis of the above compounds has been accompanied by an investigation of their structure and reactivity. As early as 1957 it was suggested[70] that the tin and cobalt atoms in the compound $(C_4H_9)_2Sn[Co(CO)_3P(C_6H_5)_3]_2$ were linked indirectly through carbonyl groups. The view was also expressed[72,75] that the metal atoms were joined by a covalent bond in these compounds. In 1964 Bryan[81] studied the crystal structure of $(C_6H_5)_3SnMn(CO)_4P(C_6H_5)_3$, and found that the Sn, Mn, and P atoms are collinear and are linked covalently. X-Ray examination[79] of $C_5H_5(CO)_3Mo–Sn(C_6H_5)_3$ also confirms the presence of a σ-bond between molybdenum and tin atoms.

The reactivity of these compounds is determined by the nature of the atoms forming the metal–metal bond. Some of the compounds (e.g. those containing Sn–Co[70], Fe–Si[72], Fe–Sn[76], Pb–Mn[75], and Sn–Mn[75] bonds) tend to undergo oxidation, and are prepared in an atmosphere of nitrogen. In contrast, compounds containing Cr–M, Mo–M, and

W–M bonds, where M = Sn, Pb[79], and also Sn–Re, Pb–Re[78], are quite stable.

Chlorine, bromine, and hydrogen chloride do not cleave Sn–Mn[75] and Sn–Re[78] bonds. They do cleave an Sn–C bond[75,78,79]:

$$(C_6H_5)_3SnMn(CO)_5 + 3Cl_2 \longrightarrow Cl_3SnMn(CO)_5 + 3C_6H_5Cl,$$
$$(C_6H_5)_3SnRe(CO)_5 + 2Br_2 \longrightarrow (C_6H_5)Br_2SnRe(CO)_5 + 2C_6H_5Br,$$
$$(C_6H_5)_3SnMo(CO)_3C_5H_5 + 2HCl \longrightarrow (C_6H_5)Cl_2SnMo(CO)_3C_5H_5 + 2C_6H_6.$$

Hydrogen chloride has a similar effect on $(C_6H_5)_3SnW(CO)_3(C_5H_5)$, $(C_6H_5)_2Sn[Mo(CO)_3C_5H_5]_2$, $(C_6H_5)_2Sn[W(CO)_3C_5H_5]_2$, and $(C_6H_5)_3SnFe(CO)_2C_5H_5$.[77,79]

According to Gorsich[75] pentacarbonyltriphenylstannylmanganese, like simple metal carbonyls[3], reacts with triphenylphosphine and triphenylarsine, a molecule of carbon monoxide being displaced. The resulting product (B) has been prepared also by an alternative synthesis:

$$(C_6H_5)_3SnMn(CO)_5 + P(C_6H_5)_3 \xrightarrow{-CO} (C_6H_5)_3SnMn(CO)_4P(C_6H_5)_3 \quad (B)$$
$$(C_6H_5)_3SnCl + NaMn(CO)_4P(C_6H_5)_3 \xrightarrow{-NaCl} (C_6H_5)_3SnMn(CO)_4P(C_6H_5)_3 \quad (B)$$

On treatment with chlorine in dichloromethane, compound (B) is converted into $Cl_3SnMn(CO)_4P(C_6H_5)_3$ in 64% yield.

III. PROPERTIES OF COMPOUNDS OF THE TYPE $(R_3M)_nM'$ (M = Si AND ITS ANALOGUES; M' = Hg, Cd, Sb, etc.)

Organodielementary compounds of the type $(R_3M)_nM'$ are very reactive and have very varied chemical properties. Unfortunately their structural analogues $(R_3C)_nM'$ have in general been little studied, and therefore it is impossible to make a precise comparison of the properties and reactivities of these two classes of compounds. Most of the chemical reactions which these compounds undergo involve cleavage of covalent M–M' bonds with preservation of the R_3M fragments.

1. Thermal and Photochemical Decomposition

In most compounds of the type $(R_3M)_nM'$ extraordinary reactivity is combined with great thermal stability. In the absence of atmospheric oxygen, tristriethylsilylantimony and all its isologues other than tristriethylstannylbismuth can be distilled in a vacuum without appreciable decomposition[44]. This property is possessed also by bistrimethylsilylmercury[15], bistriethylsilylmercury[24], and bistriethylgermylmercury[39]. The examples of $(C_2H_5)_3SiHgC_2H_5$, $(C_2H_5)_3SiSi(C_2H_5)_2HgC_2H_5$, $(C_2H_5)_3SiHgGe(C_2H_5)_3$, and $(C_2H_5)_3SiSi(C_2H_5)_2HgGe(C_2H_5)_3$ show that compounds containing Si–Hg–C, Si–Si–Hg–C, Si–Hg–Ge, and Si–Si–Hg–Ge groupings are more stable than the usual unsymmetrical organomercury compounds[24,25]. In spite of the complexity of their structure, they distil in a vacuum without decomposition or symmetrisation.

The thermal stability of compounds of the type $[(C_2H_5)_3M]_3M'$ is determined by the stability of the M–M' bonds, and diminishes in the sequence Si–Sb ≃ Ge–Sb > Si–Bi ≃ Ge–Bi > Sn–Sb > Sn–Bi > Ge–Tl [44]. The least stable compounds of this series break down according to the equation

$$2[(C_2H_5)_3M]_3M' \rightarrow 3(C_2H_5)_6M_2 + 2M', \quad (10)$$

where M = Ge, M' = Tl and M = Sn, M' = Bi; and of the $[(C_2H_5)_3M]_2M'$ series according to the equation

$$[(C_2H_5)_3M]_2M' \rightarrow (C_2H_5)_6M_2 + M', \quad (11)$$

where M = Si, Ge and M' = Cd. Bistrimethylsilylmercury decomposes in the same way[15].

Tristriethylsilylantimony decomposes at ~300° with the quantitative liberation of antimony and the formation of $(C_2H_5)_3Si^{\bullet}$ radicals. The latter abstract hydrogen from surrounding molecules, giving triethylsilane and a complicated mixture of high-boiling organosilicon compounds.

According to Eaborn and his coworkers[82] the decomposition of bistrimethylsilylmercury in solvents also goes by a free-radical mechanism. The trimethylsilyl radicals can dimerise, abstract hydrogen from toluene and other solvents, replace the methyl group in anisole, and undergo other elementary reactions.

The thermal breakdown of compounds of general formula $[(C_2H_5)_3M]_nM'$ usually involves, independently of its mechanism, quantitative separation of the metal M' in the free state[40,44]. The element M, on the other hand, remains combined even when $(C_2H_5)_3M$ fragments are subject to free-radical attack. Tristriethylstannylantimony is an exception, decomposing with partial separation of tin[44]. In the presence of 2–3 wt.% of $AlBr_3$ the decomposition of tristriethylstannylantimony and its bismuth analogue follows a quite different path, the reaction conforming exactly to the equation

$$4[(C_2H_5)_3Sn]_3M' \rightarrow 9(C_2H_5)_4Sn + 3Sn + 4M', \quad (12)$$

where M' = Sb, Bi. Compounds of the type of $AlCl_3$ have a similar effect on the mechanism of the thermal decomposition of hexaethyldistannane[83].

According to Wiberg the thermal breakdown of polymeric dimethylsilylenemercury, obtained by the action of sodium amalgam on dimethyldibromosilane[15], is accompanied by the separation of the free metal and the formation of Si–Si bonds:

$$[(CH_3)_2SiHg]_n \rightarrow nHg + [(CH_3)_2Si]_n.$$

Organosilicon and organogermanium compounds of mercury have proved very sensitive to the action of light, which has enabled Neumann[46,47] to use ultraviolet radiation to decompose a polymer containing a $[Ge–Hg]_n$ chain — see Eqn. (3).

Razuvaev and his coworkers have shown[39] that bistriethylgermylmercury, while possessing quite high thermal stability, readily undergoes photolysis

$$[(C_2H_5)_2Ge]_2 \cdot Hg \xrightarrow{h\nu} (C_2H_5)_6Ge_2 + Hg,$$

even if the ultraviolet radiation is filtered through molybdenum glass.

This process probably does not involve the formation of kinetically independent $(C_2H_5)_3Ge$ radicals, since, when it is conducted in cumene, tetraethyltin, or t-butyl peroxide, these compounds act as inert solvents. This hypothesis is consistent also with the fact that the photolysis of triethylgermyltriethylsilylmercury does not result in the formation of compounds containing Si–Si and Ge–Ge bonds, as

might have been expected if $(C_2H_5)_3Ge^{\bullet}$ and $(C_2H_5)_3Si^{\bullet}$ radicals had escaped "from the cage" into the bulk of the solution [25]:

$$(C_2H_5)_3GeHgSi(C_2H_5)_3 \xrightarrow{h\nu} Hg + (C_2H_5)_3GeSi(C_2H_5)_3.$$

All the above information on the decomposition of organodielementary compounds has been obtained in work with pure substances in the absence of atmospheric oxygen. The literature also contains data on the breakdown of several unstable organodielementary compounds in the course of their synthesis. In considering these results it must be borne in mind that the mechanism of the decomposition may be very different in the presence of foreign substances — cf. Eqns. (10) and (12).

Wiberg et al. [15], investigating the possibility of synthesising compounds of type $[Si(CH_3)_nH_{3-n}]_2Hg$ (n = 1, 2) by the action of sodium amalgam on methylbromosilanes, found that they break down in two ways in the process of preparation — (*a*) with the formation of disilanes $[Si(CH_3)_nH_{3-n}]_2$ by a reaction analogous to (11) and (*b*) with the formation of compounds $(CH_3)_nSiH_{4-n}$ and $(CH_3)_nSiH_{2-n}$ by the disproportionation of silicon-containing groups split off from the mercury.

When n = 3 reaction takes place solely by the first route, and when n = 1 solely by the second. When n = 2 both types of decomposition occur at the same time, but disproportionation processes predominate. These workers also studied the interaction of mercury dichloride with triphenylsilylpotassium in liquid ammonia, and showed that the bistriphenylsilylmercury formed decomposes to a considerable extent during the synthesis:

$$[(C_6H_5)_3Si]_2Hg \xrightarrow{a} (C_6H_5)_6Si_2 + Hg$$
$$[(C_6H_5)_3Si]_2Hg \xrightarrow{b} Hg + (C_6H_5)_4Si + (C_6H_5)_2Si$$

Route (*b*), which represents a side-reaction in the decomposition of bistriphenylsilylmercury, is the main reaction in the thermolysis of bistriphenylsilylzinc and bistriphenylsilylbarium [15]. The diphenylsilene $(C_6H_5)_2Si$ which is thus formed is converted into phenylated polysilanes $(C_6H_5)_3Si[Si(C_6H_5)_2]_nSi(C_6H_5)_3$.

2. Reactions with Atmospheric Oxygen and with Peroxides

Compounds of the type $(R_3M)_nM'$ are readily oxidised, and react vigorously with organic peroxides. The reactions occur at room temperature with the evolution of heat. The oxidation of bistriethylgermylmercury [39,45] is accurately represented by the equation

$$2[(C_2H_5)_3Ge]_2Hg + O_2 \longrightarrow 2[(C_2H_5)_3Ge]_2O + 2Hg.$$

The reaction can be employed for the determination of mercury in a substance. Bistriphenylgermylmercury [45], bistriethylgermylcadmium [40], and bistriethylsilylmercury [24] are oxidised in a similar manner.

According to results obtained by Vyazankin et al. [24] the oxidation of ethyltriethylsilylmercury is preceded by its symmetrisation. As a result, the oxidation products are found to contain diethylmercury, metallic mercury, and hexaethyldisiloxane:

$$2(C_2H_5)_3SiHgC_2H_5 \longrightarrow (C_2H_5)_2Hg + [(C_2H_5)_3Si]_2Hg$$
$$[(C_2H_5)_3Si]_2Hg \xrightarrow{+\frac{1}{2}O_2} Hg + [(C_2H_5)_3Si]_2O$$

The reactions with acyl peroxides are represented by equally simple stoichiometric equations [24,39,44]:

$$[(C_2H_5)_3M]_2Hg + (C_6H_5COO)_2 \longrightarrow Hg + 2(C_2H_5)_3MOCOC_6H_5, \quad (13)$$

where M = Ge, Si; and

$$2[(C_2H_5)_3M]_3M' + 3(C_6H_5COO)_2 \longrightarrow 2M' + 6(C_2H_5)_3MOCOC_6H_5, \quad (14)$$

where M = Si, Ge, Sn and M′ = Sb, Bi.

Bistriethylgermylmercury reacts with dicyclohexyl peroxodicarbonate in a similar fashion, with a quantitative yield of mercury [25]:

$$[(C_2H_5)_3Ge]_2Hg + (C_6H_{11}OCOO)_2 \rightarrow Hg + 2(C_2H_5)_3GeOCOOC_6H_{11}.$$

The second product is unstable, and is readily decarboxylated with the formation of cyclohexyloxytriethylgermane.

When bistriethylgermylcadmium [40], its silicon analogue [43], and compounds containing Ge–Zn bonds [41] are treated with benzoyl peroxide, cadmium (zinc) benzoate is formed as well as $C_6H_5COOM(C_2H_5)_3$ (M = Ge, Si). Reduction of the central atom to the elementary state — cf. Eqns. (13) and (14) — does not take place. The reaction of tristriethylgermylthallium with benzoyl peroxide is represented by the equation

$$[(C_2H_5)_3Ge]_3Tl + 2(C_6H_5COO)_2 \rightarrow 3(C_2H_5)_3GeOCOC_6H_5 + TlOCOC_6H_5.$$

In the authors' opinion the reactions with acyl peroxides take place by a latent-radical mechanism with the intermediate formation of cyclic active complexes. This is consistent with the following facts:

1. The reactions of acyl peroxides with organodielementary compounds are exothermic. At 5–10° they are complete within a few minutes. Under these conditions the starting materials are severally stable, and do not initiate free-radical processes.

2. Free-radical reactions are usually complicated. They involve the formation of multicomponent mixtures, which does not occur in the present cases.

3. Dibromoethane (see below) reacts similarly to acyl peroxides with organodielementary compounds. Reactions with monobromo-derivatives, in which the formation of cyclic active complexes is improbable, take place only under the influence of heat or light.

The ability of organodielementary compounds to react with acyl peroxides under mild conditions is not a specific property of substances containing M–M′–M groupings: benzoyl peroxide reacts equally vigorously with ethyltriethylsilylmercury, which contains a single Si–Hg bond [24]. Finally, the earlier papers of Razuvaev, Vyazankin, and their collaborators showed that acyl peroxides react at ~20° with hexaethyldistannane [83–85], diethyltin [37] (the polymeric nature of which has recently been rigorously proved [86]), and also with substances containing branched chains of tin atoms [85,87], by smoothly cleaving the Sn–Sn bonds. Polymeric diphenyltin reacts with benzoyl peroxide with the partial rupture of Sn–Sn bonds [88].

The Si–Si bond in hexaethyldisilane, on the other hand, is not cleaved by acyl peroxides even under conditions such that the latter break down, when the reaction aquires a free-radical character [83] and shows great complexity.

In contrast to acyl peroxides, t-butyl peroxide does not react with organodielementary compounds at room temperature. Moreover, as has been stated above, under mild conditions it is possible to accomplish the photodecomposition of bistriethylgermylmercury without affecting the t-butyl peroxide [24]. This is probably the first case

of a homolytic process in which a peroxy-compound acts as an inert solvent.

3. Reactions with Halogenated Derivatives

The photochemical reactions of halogeno-derivatives with ordinary organometallic compounds containing a single metal atom have been investigated in detail and discussed by Razuvaev and his coworkers [89-91]. The reactions usually occur by a free-radical mechanism:

$$R_nM \xrightarrow{h\nu} R_{n-1}M^{\cdot} + R^{\cdot},$$
$$R_{n-1}M^{\cdot} + R'X \longrightarrow R_{n-1}MX + R',$$

where R and R′ are aliphatic or aromatic groups, M is an n-valent metal, and X = Cl, Br, more rarely I. The fate of the radicals R and R′ which are formed is determined by their structure, also by the nature of the halogeno-derivative R′X, and by the properties of the initial organometallic compound R_nM.

The photochemical reactions of alkyl halides with organodielementary compounds follow a quite different scheme, e.g. [24,39]

$$[(C_2H_5)_3Ge]_2Hg + 2RBr \xrightarrow{h\nu} 2(C_2H_5)_3GeBr + R_2Hg,$$

where R = C_2H_5, C_6H_5, $C_6H_5CH_2$, 1-$C_{10}H_7$. The authors assume these reactions to occur "in a cage" with homolytic cleavage of C–Br and Ge–Hg bonds. Alkyl bromides react in a similar way with compounds of type $[(C_2H_5)_3M]_3Sb$ on heating [44]:

$$[(C_2H_5)_3M]_3Sb + 3RBr \longrightarrow 3(C_2H_5)_3MBr + R_3Sb,$$

where M = Sn, Ge; R = $C_6H_5CH_2$, cyclo-C_5H_9. The yields of the compounds R_3Sb vary from 57% to 75%. Finally, the reaction of bistriethylsilylcadmium with ethyl bromide (~80° for 2 h) yields bromotriethylsilane (36%) and diethylcadmium (76%). [43] Under comparable conditions bistriethylgermylcadmium [40] reacts with alkyl bromides by a different, more usual route:

$$[(C_2H_5)_3Ge]_2Cd + 2RBr \rightarrow CdBr_2 + 2(C_2H_5)_3GeR,$$

where R = C_2H_5, $C_6H_5CH_2$.

Bisdibutylstibylmagnesium reacts similarly with allyl bromide, the products being allyldibutylantimony (31%) and magnesium bromide [68]. The reaction of ethyl bromide with compounds containing Ge–Zn bonds also proceeds "normally", with the formation of $ZnBr_2$ and $R_3GeC_2H_5$. [41]

A very characteristic reaction of organodielementary compounds containing M–M′–M groupings is that with 1,2-dibromoethane, which is exothermic and is complete at room temperature within a few minutes, e.g. [42]

$$[(C_2H_5)_3Ge]_2Hg + CH_2BrCH_2Br \rightarrow 2(C_2H_5)_3GeBr + Hg + C_2H_4.$$

The yields of mercury, ethylene, and bromotriethylgermane are respectively 97%, 75%, and 58%. Tristriethylsilylantimony reacts similarly with excess of dibromoethane [44]. With equimolecular proportions of the reactants, ethylene and bromotriethylsilane are formed together with a viscous, coloured, readily oxidisable substance, which is regarded as polymeric triethylsilylantimony:

$$n[(C_2H_5)_3Si]_3Sb + nCH_2BrCH_2Br \rightarrow nC_2H_4 + 2n(C_2H_5)_3SiBr + [(C_2H_5)_3SiSb]_n.$$

This hypothesis is consistent with the reactions of (cyclo-$C_6H_{11})_2SbLi$ [58] and $C_6H_5AsLi_2$ [92] with dibromoethane, in the course of which Sb–Sb and As–As bonds are formed. The products are tetracyclohexyldistibine and arsenobenzene, together with ethylene and lithium bromide.

The reaction of dibromoethane with bistriethylgermylcadmium [40] differs somewhat from those considered above. In this case the central atom (cadmium) is not reduced to the free metal. The reaction products are cadmium bromide (74%), ethylene (73%), and bromotriethylgermane (86%). In the reaction between dibromoethane and tristriethylgermylthallium the thallium passes from the tervalent to the univalent state:

$$[(C_2H_5)_3Ge]_3Tl + 2CH_2BrCH_2Br \rightarrow 2C_2H_4 + 3(C_2H_5)_3GeBr + TlBr.$$

4. Reactions with Metals and Their Salts

The reactions with metals of ordinary organometallic compounds (containing a single metal atom), accompanied by the transfer of radicals from one metal to the other, have been investigated in detail and are widely employed for synthetic purposes. The first attempt to transfer a trimethylsilyl radical from metal to metal (from mercury to zinc and aluminium) was undertaken by Wiberg et al. [15] They showed that, when bistrimethylsilylmercury reacts with zinc, which occurs only at high temperatures, the mercury is not replaced by zinc but dimethylmercury is formed. The mechanism of the process was not discussed. Reaction of bistrimethylsilylmercury with activated aluminium takes place at a more moderate temperature (80°) with the quantitative separation of mercury and a mixture of products containing no Si–Al bonds.

In the authors' opinion this is explained by the instability of the $>Al-Si(CH_3)_3$ groups in the tristrimethylsilylaluminium formed as intermediate:

$$[(CH_3)_3Si]_3Al \rightarrow Al(CH_3)_3 + 3(CH_3)_3Si.$$

This is followed by "saturation" of the dimethylsilene by the $(CH_3)_3Si$ groups of the bistrimethylsilylmercury, with the production of polysilanes of the $(CH_3)_3Si[Si(CH_3)_2]_nSi.(CH_3)_3$ series. In an investigation of the same problem Vyazankin et al. [93] showed that at 50° metallic mercury displaces cadmium from diethylcadmium, bistriethylsilylcadmium, and its germanium analogue:

$$Hg + R_2Cd \rightarrow Cd + R_2Hg,$$

where R = C_2H_5, $(C_2H_5)_3Si$, $(C_2H_5)_3Ge$.

Mercury reacts more vigorously (within 1½ h at 20°) with tristriethylgermylthallium, the yield of bistriethylgermylmercury reaching 78%. The resulting mercury compound can in turn act as starting material for the synthesis of triethylgermyl-lithium and its sodium analogue in high yields:

$$[(C_2H_5)_3Ge]_2Hg + 2M \rightarrow Hg + (C_2H_5)_3GeM,$$

where M = Li, Na. The reaction goes readily in tetrahydrofuran medium.

Organodielementary compounds acts as reducing agents towards metal salts. Wiberg et al. found [15] that bistriphenylsilylbarium and bistriphenylsilylzinc reduce silver nitrate to metallic silver. Similar behaviour is shown by the compound containing Al–Si bonds obtained by the action of triphenylsilylpotassium on aluminium chloride in tetrahydrofuran.

According to Razuvaev and his coworkers [93] bistriethylgermylcadmium reacts with mercuric chloride to form mercury (71%), cadmium chloride (82%), and chlorotriethylgermane (31%), the reaction being exothermic. Metallic mercury is formed also by the interaction of mercuric chloride with compounds containing Ge–Zn–Ge groups [41].

5. Other Reactions

The interaction of organodielementary compounds with acids involves cleavage of the M–M′–M grouping, the central atom separating as the free metal, e.g. [42]

$$2\,[(C_2H_5)_3Ge]_3Bi + 3\,CH_3COOH \rightarrow 3\,(C_2H_5)_3GeOCOCH_3 + 3\,(C_2H_5)_3GeH + 2\,Bi,$$

Acetic acid reacts similarly with bistriethylgermylmercury [42] and with bistriethylgermylcadmium [93]. Bistrimethylsilylmercury reacts with hydrochloric acid [15] in the same way; the reaction is quantitative, and may serve as a method of analysis for mercury.

Under normal conditions bistriethylgermylmercury and its silicon analogue are stable to hydrolysis or alcoholysis even after many months of contact with water or alcohols. Bistriethylgermylcadmium [40,93], on the other hand, interacts with these reagents under mild conditions:

$$[(C_2H_5)_3Ge]_2Cd + RH \longrightarrow (C_2H_5)_3GeH + (C_2H_5)_3GeR + Cd,$$

where R = OH, n-C_3H_7O.

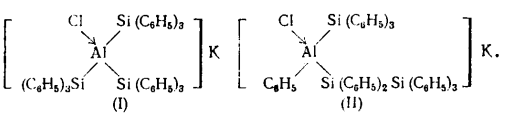
The hydrolysis of bistriphenylbarium with moist methanol proceeds differently [15]:

$$[(C_6H_5)_3Si]_2Ba + 4H_2O \longrightarrow Ba(OH)_2 + 2H_2 + 2\,(C_6H_5)_3SiOH.$$

In the authors' opinion the complex $KCl.Al[Si(C_6H_5)_3]_3$, which is the first organodielementary compound containing covalent Si–Al bonds, is hydrolysed by alcoholic potassium hydroxide in a similar manner. The fact that this involves the evolution of only two moles of hydrogen, not the three that might have been expected from the equation

$$KCl\cdot Al[Si(C_6H_5)_3]_3 + 6H_2O \longrightarrow KCl + Al(OH)_3 + 3\,(C_6H_5)_3SiOH + 3H_2,$$

led the authors to assign to the complex the structure (II) instead of (I)



(I) (II)

For the reaction of this substance with hydrochloric acid see Ref. 15.

Zinc hydroxide and triphenylsilane have been isolated from the hydrolysis of bistriphenylsilylzinc with dilute hydrochloric acid [15]. Compounds of the type $(C_2H_5)_3GeZn.[Ge(C_2H_5)_2]_nGe(C_2H_5)_3$, which are formed by the interaction of triethylgermane and diethylzinc, are hydrolysed in a similar manner [41].

IV. PROPERTIES OF COMPOUNDS OF TYPE $R_3M–M'R_3$ (WHERE M AND M′ ARE ELEMENTS OF GROUP IV*b*)

In comparison with the compounds described in the preceding Section, those of the $R_3M–M'R_3$ series, where M and M′ represent elements of the silicon subgroup, possess immeasurably smaller reactivity. The completely arylated compounds $(C_6H_5)_3SiGe(C_2H_5)_3$, [8] $(C_6H_5)_3SiSn(C_6H_5)_3$, [94] and $(C_6H_5)_3GeSn(C_6H_5)_3$ [17] are closely similar in chemical properties to hexaphenyldisilane and its analogues, and differ sharply from hexaphenylethane in the absence of any tendency to dissociate into radicals. These compounds are stable to atmospheric oxygen, and are not cleaved by water, alcohols, or acids. In the fully phenylated compounds the Si–Ge bond is not ruptured by iodine in boiling chloroform or by organolithium compounds, whereas the Ge–Sn bond is unstable towards these reagents. According to Gilman and his coworkers, replacement of phenyl by alkyl groups in compounds of this type leads to a strengthening of the M–M′ bonds.

Metals of the lithium subgroup and their alloys are extremely effective agents for the cleavage of M–M′ bonds. Correct choice of solvent is extremely important for the successful conduct of the reactions. Triphenyltriphenylsilylgermane is cleaved by a sodium–potassium alloy in ether [8]. In the case of triphenyltriphenylstannylgermane this alloy is effective only in tetrahydrofuran [17]. Trimethyltriphenylsilyltin is split by sodium in liquid ammonia [95]. Triphenyltriethylsilylgermane is cleaved at the Si–Ge bond by lithium in triethylamine [10]. Aliphatic derivatives containing Si–Ge [61] and Si–Sn [15] bonds have recently been synthesised, but very little work has been done on their chemical properties. It has been established that stannylsilanes of the types $R_3SnSiR'_3$ and $(R_3Sn)_2SiR'_2$ (where R = C_2H_5, C_4H_9, C_6H_5, and R′ = CH_3, C_6H_5) are stable in air. They undergo an exothermic reaction with $TiCl_4$, reducing it to $TiCl_3$. The latter can be isolated from the mixture in a polymerisation-active state [15].

---o0o---

This review makes it plain that three types of organodielementary compounds containing covalent M–M′ bonds exist. Compounds in which M and M′ are elements of the silicon subgroup belong to the least varied type. Representatives of this group are the least reactive. Substances containing M–M′–M groups (M = Si and its analogues and M′ = Hg, Cd, Al, Bi, etc.), on the other hand, are highly reactive, and their properties are extremely unusual.

The third type of compounds, which has been studied intensively, contains metal–transition metal bonds. The striking features of compounds of this type are their variety and the unexpected stability of the M–M′ groupings.

All the compounds which have been described are of great interest for study of the nature of the chemical bond in general and of the metal–metal bond in particular. As research develops, they will undoubtedly also find practical application.

STEREOCHEMISTRY OF ORGANIC COMPOUNDS OF PHOSPHORUS AND ARSENIC

G. Kamai and G. M. Usacheva

CONTENTS

I. Introduction 601
II. Stereochemistry of organic compounds of tervalent phosphorus and arsenic 601
III. Stereochemistry of quaternary phosphonium and arsonium compounds 604
IV. Stereochemistry of oxides and sulphides of phosphorus and arsenic 606
V. Stereochemistry of organic acids of phosphorus and arsenic and of their derivatives 607

I. INTRODUCTION

Acquaintance with the world's chemical literature must lead to the conclusion that interest has grown appreciably during recent years in problems of the stereochemistry not only of carbon compounds but also of those of other elements — nitrogen, phosphorus, sulphur, arsenic, antimony, etc. — in the Periodic System. The reason for the increasing number of stereochemical investigations is undoubtedly that this field, which until not long ago was regarded as one of the most abstract, is beginning to acquire ever increasing practical importance. Stereochemical features of structure have a great influence on the biochemical properties of organic compounds. Knowledge of the configurational relationships among various types of optically active compounds is of practical and theoretical importance. It is required in many fields of biochemistry for the study of metabolism and the action of drugs, in working out theoretical problems of biogenesis, etc. The use of optically active reactants often considerably facilitates study of the mechanism of chemical reactions. A systematic study of the stereochemistry of reactions will inevitably lead in the future to a more profound understanding of the chemical changes occurring in living Nature.

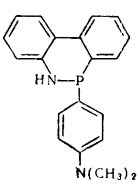
Interest has grown considerably during recent years in the stereochemistry of organic compounds of phosphorus and arsenic, especially the former. The first attempts to obtain optically active compounds containing asymmetric phosphorus and arsenic atoms were made at the beginning of the present century. In 1911 Meisenheimer[1,2] showed for the first time, with ethylmethylphenylphosphine oxide as example, that phosphorus can act as an asymmetric centre in a molecule. The first optically active organic compound of arsenic — the dextrorotatory benzylmethyl--1-naphthylphenylarsonium iodide — was obtained in 1921 by Burrows and Turner[3].

A. Michaelis, J. Meisenheimer, A. E. Arbuzov, B. A. Arbuzov, G. Kh. Kamai, D. M. Coyne, H. S. Aaron, L. Horner, J. Michalski, and many others have devoted their researches to the difficult but interesting field of the stereochemistry of organophosphorus and organoarsenic compounds, and definite progress has now been achieved.

II. STEREOCHEMISTRY OF ORGANIC COMPOUNDS OF TERVALENT PHOSPHORUS AND ARSENIC

The phosphorus atom has the electronic configuration $(1s^2)(2s^2)(2p^6)(3s^2)(3p^3)$, so that it can have covalencies of 3–6 in its compounds. Organic derivatives of tervalent phosphorus can be regarded as derivatives of phosphine PH_3 in which one, two, or three hydrogen atoms have been replaced by organic radicals. Phosphines have the configuration of a trigonal pyramid. This is evident from the fact that in the tervalent state phosphorus utilises only $3p$-electrons, as is confirmed by the valency angle of 94° in phosphine and 101 ± 3° in trimethylphosphine. Thus a tertiary phosphine $PR^1R^2R^3$ should exist in the form of two optical isomers, related to one another as an object to its mirror image. Until recently derivatives of tervalent phosphorus remained almost uninvestigated from the point of view of optical isomerism. The calculated frequency of oscillation of the phosphorus atom[4] is 5×10^6 s^{-1}. Calculations by Weston[5] showed on the basis of the oscillation frequency that the half-life (or rate of racemisation) for trimethylphosphine is 2 h at 7°. It appeared that optical isomers of asymmetric tertiary phosphines would be stable only at low temperatures. Until recently investigators adhered to this view, and in fact no-one attempted to resolve tertiary phosphines of the type $PR^1R^2R^3$ into optical isomers.

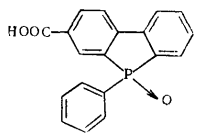
It was suggested that the stability of optical isomers of tervalent phosphorus compounds should be increased if the phosphorus atom formed part of a ring system, since oscillation of the phosphorus atom would then be impeded. Campbell and Way[6] have resolved the cyclic phosphine 10-*p*-dimethylaminophenyl-9,10-dihydro-9-aza-10-phosphaphenanthrene



into optical isomers by reducing the optically active isomeric oxides of this phosphine with lithium tetrahydroaluminate. The isolated isomers of the phosphine proved to have far greater optical stability than could have been expected from Weston's calculations[5]. The dextrorotatory isomer, which has an initial rotation of $[\alpha]_D^{21} = 141°$, acquires a rotation of 114° after 5 h; the corresponding specific rotation of the laevorotatory isomer changed from -128° to -97° in 4 h. It was discovered that the decrease in the angle of rotation was due not to racemisation

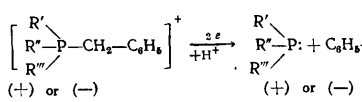
but to oxidation of the phosphine to the phosphine oxide. Molecular asymmetry is entirely probable in the phosphine owing to the presence of a ring containing nitrogen and phosphorus. In the opinion of Campbell and Way, the above azaphosphaphenanthrene proved an unfortunate example for elucidating the possibility of obtaining asymmetric compounds of tervalent phosphorus in an optically active form because of (1) the presence of a ring containing nitrogen and phosphorus, which may itself be a source of molecular asymmetry, and (2) the comparatively ready oxidisability of the phosphine to the phosphine oxide.

In order to avoid these drawbacks, Campbell and Way[7] synthesised a series of substituted phosphafluorenes and their oxides. They were able to resolve 9-phenyl-9-phosphafluorene-2-carboxylic acid



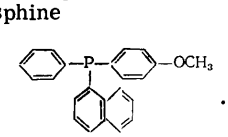
into optical isomers. However, reduction was accompanied by complete racemisation with both optically active oxides: the resulting phosphines were optically inactive. Racemisation of the phosphafluorene was not unexpected, in view of Weston's calculations[5], but it was inconsistent with the result obtained by Campbell and Way for reduction of the azaphosphaphenanthrene oxide[6]. These workers postulate that the participation of the nitrogen atom in the reduction confers on it a stereospecific character in the case of the azaphosphaphenanthrene. Thus Campbell and Way's investigations gave no positive answer to the possible existence of tervalent phosphorus compounds in an optically active form, since molecular asymmetry is possible, besides the asymmetric phosphorus atom, in azaphosphaphenanthrene derivatives, while phosphafluorene derivatives were not obtained in an optically active form.

It was only in 1961 that Horner and his coworkers[8] showed for the first time that asymmetric tertiary phosphines can be resolved into optical antipodes. They reduced the corresponding optically active benzylphosphonium salts at a mercury cathode:



and obtained[8] dextrorotatory methylphenyl-n-propylphosphine $(CH_3)(C_6H_5)(n\text{-}C_3H_7)$ having $[\alpha]_D = +16.8°$ (concentration 5.170 g/100 cm³ toluene), laevorotatory allylmethylphenylphosphine $(CH_2:CH.CH_2)(CH_3)(C_6H_5)P$ having -10.0° (4.5 in toluene), and dextrorotatory ethylmethylphenylphosphine $(C_2H_5)(CH_3)(C_6H_5)P$ having +15 ± 0.5° (6 ± 2 in toluene).

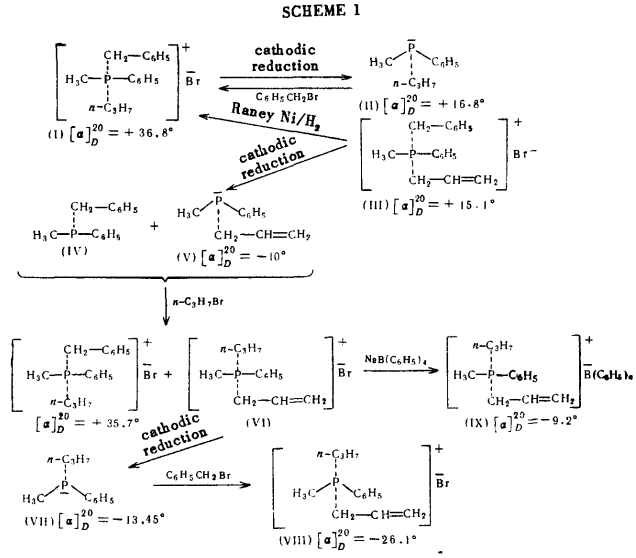
Using the same method, Horner et al.[9] were the first to obtain in an optically active form the asymmetric non-heterocyclic triarylphosphine — *p*-methoxyphenyl-1-naphthylphenylphosphine



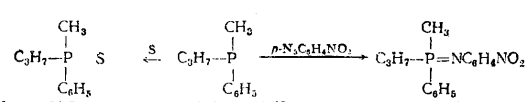
McEwen et al.[10] isolated dextrorotatory and laevorotatory isomers of benzyl-n-butylmethylphosphine having specific rotations $[\alpha]_D^{27}$ of +24 ± 2° and -28.2° (2.9 in benzene), by reducing with sodium methoxide[11] the optically active D(-)- and L(+)-benzyl-n-butyl-2-cyanoethylmethylphosphonium hydrogen dibenzoyltartrates.

Optically active tertiary phosphines proved to be optically far more stable than would have been expected from Weston's calculations[5]. Dextrorotatory methylphenyl-n-propylphosphine was very slowly racemised in boiling toluene[8]. Horner and Winkler[12] found that this compound was racemised according to a first-order equation in high-boiling solvents such as methylnaphthalene, decahydronaphthalene, and n-decane, whereas in diethylaniline and cyclohexanone the kinetics of racemisation was more complicated[12].

SCHEME 1



The separation of racemic asymmetric tertiary phosphines into optical isomers was a remarkable development in the chemistry of phosphorus. The application of optically active tertiary phosphines made possible a very delicate study of the mechanism of the reactions. Horner and his coworkers[8,13], who investigated the interconversion of optically active tertiary phosphines and optically active phosphonium salts (Scheme 1), ascertained that the configuration of the asymmetric phosphorus atom is preserved during these changes. The use of optically active tertiary phosphines facilitated the elucidation of the structure of phosphine dihalides[14-16]. Dextrorotatory and laevoroatory benzyl-n-butylmethylphosphines were converted into the optically active benzyl-n-butylmethylphosphine sulphides by the action of cyclohexene sulphide, monatomic sulphur, and octa-atomic sulphur. The configuration of the asymmetric phosphorus atom was preserved in all these reactions[17]. The reactions of dextrorotatory methylphenyl-n-propylphosphine with sulphur and with *p*-nitrophenyl azide also take place with preservation of the configuration of the asymmetric phosphorus atom[18]:

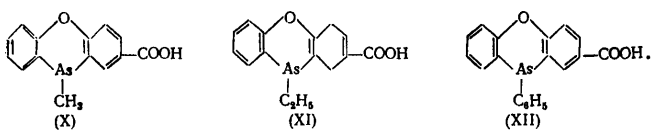


Study of the oxidation of optically active methylphenyl-n-propylphosphine with t-alkyl hydroperoxides[19] confirmed the view expressed previously that the reactions of tertiary

phosphines and phosphites with these hydroperoxides involve nucelophilic attack by hydroxyl oxygen.

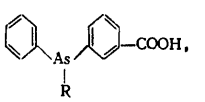
The arsenic atom has the electronic configuration $(1s^2)(2s^2)(2p^6)(3s^2)(3p^6)(3d^{10})(4s^2)(4p^3)$, and, like the phosphorus atom, it may have covalencies of 3–6. Organic derivatives of tervalent arsenic are regarded as derivatives of arsine in which one, two, or three hydrogen atoms have been replaced by organic radicals. Arsines have the configuration of a trigonal pyramid, as is indicated by measurements of dipole moments and by the valency angles determined by different physicochemical methods[20-22]. The oscillation frequency of the arsenic atom in arsine is $16 \times \times 10^4$ s^{-1} [23] (in phosphine it is 5×10^6 s^{-1},[4] and in an amine 2.3×10^{10} s^{-1} [24]). Weston calculated[5] the energy barrier to racemisation of an arsine, the results being expressed as the temperature at which the half-life (or rate of racemisation) would be 2 h. For trimethylarsine this temperature is 107° according to his calculations[5]. Until 1962 no single case had been described of the resolution of an asymmetric tertiary arsine: As(R′R″R‴) into optical isomers.

Tervalent compounds in which arsenic forms part of a cyclic system have been successfully resolved into optical isomers.



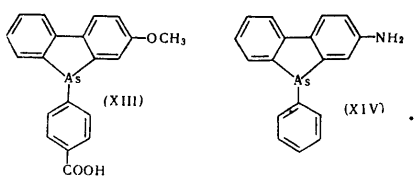
(X) (XI) (XII)

Lesslie and Turner[25] resolved 10-methylphenoxarsine-2-carboxylic acid (X), as well as the 10-ethyl (XI) and 10-phenyl (XII) homologues of this acid. These acids proved to be optically stable, racemising quite slowly even on being heated. Their optical activity is probably due mainly to molecular asymmetry, since the similar acids of tervalent arsenic synthesised by Kamai[26-30], differing from those of Lesslie and Turner in the absence of the oxygen atom linking the two phenyl radicals, and of general formula



could not be resolved into optical antipodes.

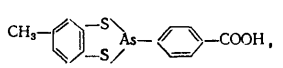
Campbell and Poller[31] resolved the two cyclic compounds of tervalent arsenic — 2-methoxy-9-phenyl-9-arsafluorene-*p*-carboxylic acid (XIII) and 2-amino-9-phenyl-9-arsafluorene (XIV)



(XIII) (XIV)

The isomers thus obtained were optically stable at room temperature.

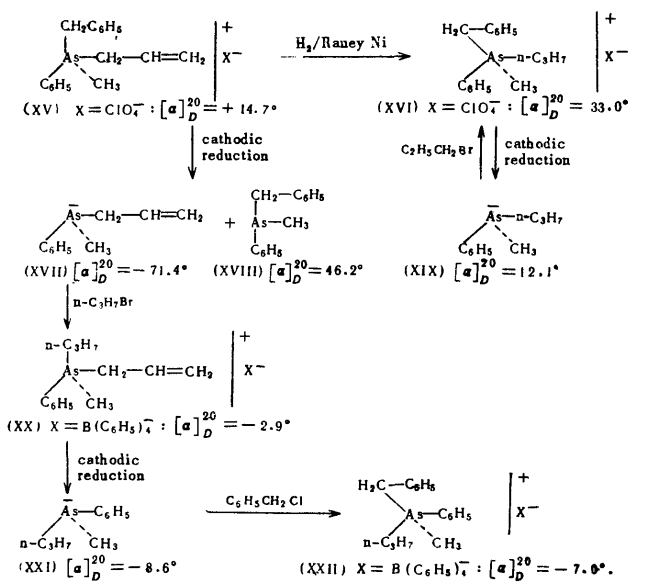
The compound 2-*p*-carboxyphenyl-5-methyl-1,3-dithia-2-arsindane



which was resolved by Campbell[32], was optically stable in chloroform and ethanol, but racemised in aqueous alkali, probably owing to cleavage of an arsenic–sulphur bond. The existence of arsindane enantiomers provides further evidence that arsenic is able to maintain a stable pyramidal configuration when present as a tervalent atom in a heterocyclic compound.

Horner and Fuchs[33] isolated optical isomers of ethylmethylphenylarsine and butylmethylphenylarsine by cathodic reduction of the optically active benzylethylmethylphenylarsonium and benzylbutylmethylphenylarsonium perchlorates by the technique used to reduce quaternary ammonium[34] and phosphonium[35] salts. Dextrorotatory ethylmethylphenylarsine $(C_2H_5)(CH_3)(C_6H_5)As$ boiled at 64–65° (3.3 mm) and had a specific rotation $[\alpha]_D^{20}$ of 1.9°, while the laevorotatory isomer of this arsine boiled at 69–71° (4 mm) and had a specific rotation of -1.15°. The corresponding optically active arsine sulphides were isolated by the addition of sulphur to the optically active arsines.

SCHEME 2



Horner and Fuchs[36] studied the interconversion of optically active tertiary arsines and quaternary arsonium salts (Scheme 2). The interconversions (XVI) → (XVII) and (XVII) → (XVI) indicate that the configuration of the arsenic atom is maintained during these changes. Compounds (XVIII) and (XIX) were separated by distillation. The difference in rotation between (XXI) and (XVII) (with the opposite sign of rotation) is explained by partial racemisation of (XX), since optically active quaternary arsonium halides (in contrast to the sulphates and perchlorates) are more or less rapidly racemised in organic solvents. The arsonium salts (XV) and (XVI) have the same configuration, since the asymmetric centre is unaffected by catalytic hydrogenation.

The preparation of stable optically active non-heterocyclic tertiary phosphines and arsines has been an important event in the stereochemistry of organophosphorus and organoarsenic compounds: it has opened up a path for the stereochemical study of reaction mechanisms involving asymmetric phosphorus and arsenic atoms, and it has

shown once again that certain concepts which have been regarded as "absolute" at some stage in the development of science prove to be "extremely relative" and yield place to new concepts, which are sometimes the direct opposite. This has occurred in connection with the oscillation of tervalent phosphorus and arsenic atoms in phosphines and arsines. Until recently the vast majority of investigators regarded the presence of this oscillation as indisputable. The researches of Horner and his collaborators [8-10,12,13,17,18,33,36] have now convincingly demonstrated that tervalent phosphorus and arsenic atoms do not undergo such oscillation.

III. STEREOCHEMISTRY OF QUATERNARY PHOSPHONIUM AND ARSONIUM COMPOUNDS

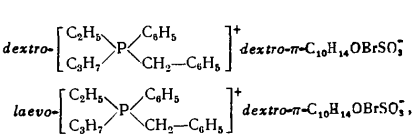
The first attempts to resolve unsymmetrical phosphonium and arsonium compounds into optical antipodes were made at the beginning of the present century. Michaelis [37,38] synthesised and tried to resolve ethylmethylphenyl-*p*-tolylphosphonium iodide (I), ethylmethylphenyl-2,4,5-trimethylphenylphosphonium iodide (II)

(I) (II)

and ethylmethylphenyl-*p*-tolylarsonium iodide (III)

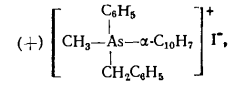
(III)

but no positive results were obtained. Wedekind [39] tried unsuccessfully to resolve ethylmethylphenyl-*p*-tolylphosphonium and benzylmethylphenyl-*p*-tolylphosphonium iodides. Winmill [40] was likewise unsuccessful in resolving a series of unsymmetrical arsonium salts into optical isomers. Nor did the endeavours of Radcliffe and Brindley [41], Meisenheimer [2], or Kamai [42] lead to a positive result. Meisenheimer considered that all the failures in resolving asymmetric phosphonium salts of the type [abcdP]Hal into optical antipodes were due merely to experimental difficulties, since the salts [Pabc(OH)]X (oxides with *dextro*-π-bromocamphorsulphonic acid) were obtained in an optically active form [1,2]. Kamai and Khismatullina [43] were able to isolate the crystalline *dextro*-π-bromocamphorsulphonate salt from allylbenzylbutylphenylphosphonium bromide. Two diastereoisomeric *dextro*-π-bromocamphorsulphonates

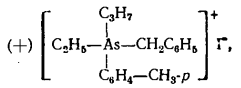


were obtained from allylbenzylethylphenylphosphonium bromide, but the individual isomers could not be isolated when these diastereoisomers were decomposed, this being explained by the great experimental difficulties. Kumli et al. [44] successfully resolved a non-heterocyclic phosphonium salt — benzylethylmethylphenylphosphonium iodide — into optical antipodes, as will be discussed in greater detail later.

Experiments on the resolution of asymmetric arsonium salts have proved more successful. Burrows and Turner [3] isolated the dextrorotatory isomer of benzylmethyl-1-naphthylphenylarsonium iodide



having a maximum rotation of $[\alpha]_D = 0.1°$ and $[M]_D = 12°$ in alcoholic acetone; the rotation of the solution fell rapidly even at room temperature. Kamai [45] isolated the dextrorotatory isomer of benzylethylpropyl-*p*-tolylarsonium iodide



with a rotation of $[\alpha]_D = 9.86°$ and $[M]_D = 45°$. The salt lost its optical activity very rapidly. Kamai and Gatilov [46] resolved benzylethylpentylphenylarsonium bromide, but the optical isomers rapidly racemised when isolated. These workers [47] separated dextrorotatory and laevorotatory isomers of benzylethylpentylphenylarsonium iodide by adsorption on dextrorotatory and laevorotatory quartz, but the isomers rapidly lost their optical activity. Thus the optical isomers of arsonium halides are optically unstable and racemise rapidly, whereas, as recent investigations by Horner [36] have shown, arsonium perchlorates are optically stable.

Quaternary ammonium halides often racemise comparatively rapidly in such solvents as chloroform, whereas the sulphates and nitrates possess greater stability. Pope and Harvey [48] suggested that this racemisation is due to equilibrium dissociation of quaternary ammonium halides into a tertiary amine and an alkyl or aryl halide:

$$[abcdN]\,Hal \rightleftarrows abcN + dHal,$$

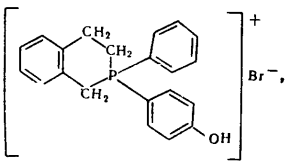
which in their view explained the optical stability of the nitrates and sulphates, these being incapable of undergoing such ready dissociation as the quaternary ammonium halides. Burrows and Turner [3] assumed that the instability of optically active non-heterocyclic arsonium salts was due to the occurrence of similar equilibrium dissociation in solution, and obtained some evidence for this assumption. They showed [3] that, if dimethylphenylarsine is treated with ethyl iodide, ethyldimethylphenylarsonium iodide is formed mixed with a considerable quantity of phenyltrimethylarsonium iodide:

$$(CH_3)_2(C_6H_5)As + C_2H_5I \rightleftarrows [(CH_3)_2(C_2H_5)(C_6H_5)As]I \rightleftarrows CH_3I + (CH_3)(C_2H_5)(C_6H_5)As,$$
$$(CH_3)_2(C_6H_5)As + CH_3I \rightleftarrows [(CH_3)_3(C_6H_5)As]I.$$

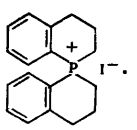
These results are readily explained by the equilibrium dissociation theory.

Mann [49] tried to explain by the presence of equilibrium dissociation the numerous unsuccessful attempts to resolve asymmetric phosphonium salts of the type [abcdP]Hal into optical antipodes, although Wedekind [39] had shown long before that ethylmethylphenyl-*p*-tolylphosphonium iodide does not dissociate into an alkyl or aryl halide and a tertiary phosphine in chloroform solution at room temperature or at the boiling point of chloroform. Holliman and Mann [49] attempted to resolve into optical antipodes two phosphonium salts — 1,2,3,4-tetrahydro-2-*p*-hydroxyphenyl-2-phenyl-phosphinolinium and -isophosphinolinium

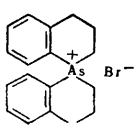
bromides — which were structurally incapable of dissociating into a tertiary phosphine and an alkyl halide. All attempts at the resolution of the former compound were unsuccessful, but a dextrorotatory form of the isophosphinolinium bromide



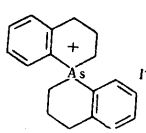
was isolated having a molecular rotation of $[M]_D = 32.9°$, although attempts to repeat its separation were unsuccessful. Hart and Mann[50] synthesised and successfully resolved into optical isomers a spirocyclic phosphonium salt possessing molecular asymmetry — *P*-spirobi-1,2,3,4-tetrahydrophosphinolinium iodide



The resolution of this salt was proof of the tetrahedral configuration of the phosphonium cation. Holliman and Mann's work[51,52] on the resolution of two spirocyclic arsonium salts — *As*-spirobi-1,2,3,4-tetrahydroarsinolinium bromide

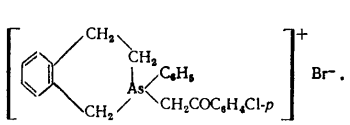


and the isomeric iodide



— confirmed the tetrahedral configuration of the tetrasubstituted arsonium cation. The isomers of the spirocyclic arsonium salts were optically stable.

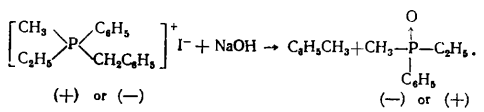
Holliman and Mann[53] resolved 1,2,3,4-tetrahydro-2-*p*-chlorophenacyl-2-phenylisoarsinolinium bromide



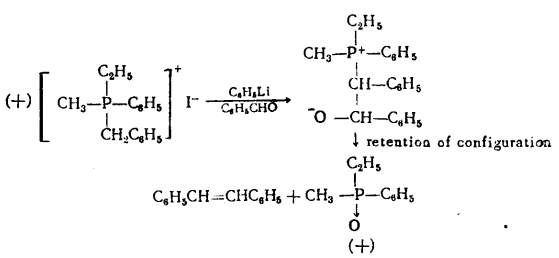
The isomers possessed relatively high optical stability, the rotation changing, in chloroform solution at room temperature, over the course of 5 days. The optical stability is assumed to be a consequence of the great chemical stability of this compound.

As already noted above, the first successful resolution of a non-heterocyclic asymmetric phosphonium salt — benzylethylmethylphenylphosphonium iodide — was accomplished by Kumli et al.[44] by means of the silver hydrogen salts of dextrorotatory and laevorotatory dibenzoyltartaric acid. The benzylethylmethylphenylphosphonium iodide isomers thus obtained were optically stable. The dextrorotatory benzylethylmethyl-*p*-tolyphosphonium chloride, bromide, and iodide prepared by Kamai and Usacheva[54] also exhibited high optical stability, which supports Wedekind's conclusion that equilibrium dissociation into a tertiary phosphine and an alkyl or aryl halide is absent in non-heterocyclic quaternary phosphonium salts containing at least one alkyl group attached to the phosphorus atom.

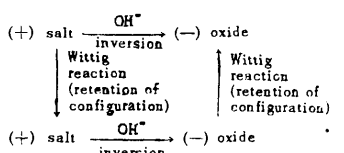
Kumli and his coworkers studied the conversion of dextrorotatory and laevorotatory benzylethylmethylphenylphosphonium iodide into the corresponding optically active ethylmethylphenylphosphine oxides:



This is a third-order reaction — of first order with respect to the concentration of phosphonium salt and of second order with respect to the concentration of sodium hydroxide[55] — involving inversion of the configuration of the asymmetric phosphorus atom[56]. The dextrorotatory benzylethylmethylphenylphosphonium iodide gave with inversion 100% of the laevorotatory ethylmethylphenylphosphine oxide, and the laevorotatory isomer of the phosphonium salt yielded dextrorotatory ethylmethylphenylphosphine oxide. In the Witting reaction with the optical isomers of benzylethylmethylphenylphosphonium iodide, the configuration of the phosphorus atom was maintained[56,57]:



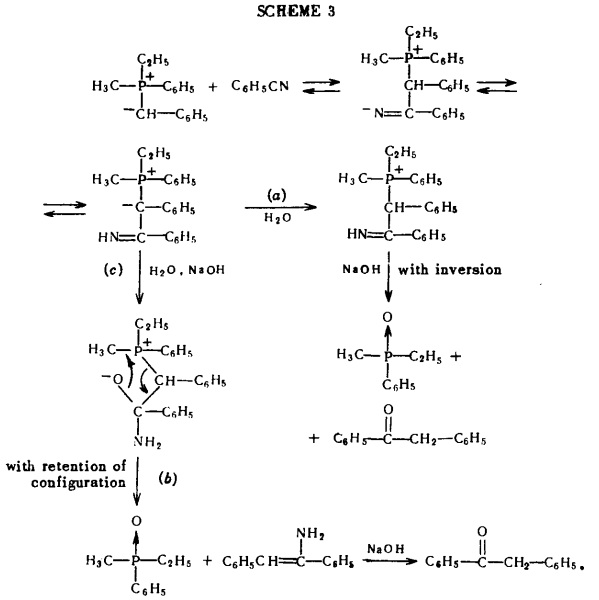
The two conversions of the optically active phosphonium isomers can be represented in the form of a cycle of processes:



Bladé-Font et al. studied the stereochemical course of the reaction of optically active ethylmethylphenylbenzylidenephosphorane[58], prepared by the interaction of laevorotatory

benzylethylmethylphenylphosphonium iodide with phenyl-lithium[44,56], with benzonitrile (see Scheme 3).

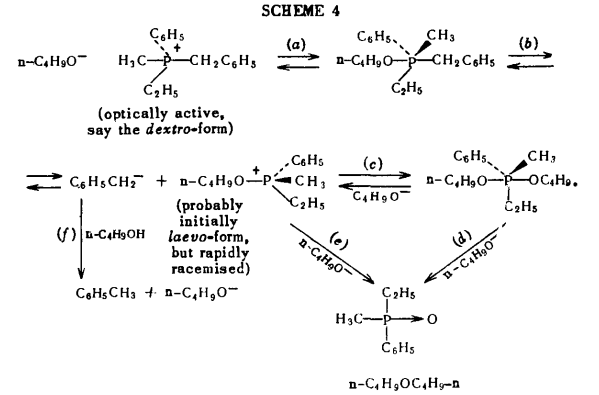
SCHEME 3



It was calculated that the reaction was accompanied by 68% inversion of configuration at the asymmetric phosphorus atom. They supposed that two competing reactions were taking place, one of which (*a*) gave ethylmethylphenylphosphine oxide with inversion of configuration, while the other reaction (*b*) gave the same oxide with maintenance of the configuration. Quite recently the reaction of optically active ethylmethylphenylbenzylidenephosphorane with styrene oxide has been studied[59], and shown to give ethylmethylphenylphosphine oxide with 50% inversion of configuration at the asymmetric phosphorus atom.

Grayson and Keough[60] showed that phosphonium alkoxides of the type $[R_3PCH_2C_6H_5]^+OR^-$ yield on decomposition toluene, a phosphine oxide, and an ether. Parisek et al.[61] investigated the stereochemistry of this reaction with optical isomers of benzylethylmethylphenylphosphonium n-butoxide, obtained from sodium n-butoxide and the optical isomers of the phosphonium iodide. Decomposition of the optically active phosphonium n-butoxide yielded ethylmethylphenylphosphine oxide with almost complete racemisation. This result can be explained by a reaction mechanism in which stage (*d*) or (*e*) is the slowest, whereas stage (*f*) is comparatively rapid (Scheme 4).

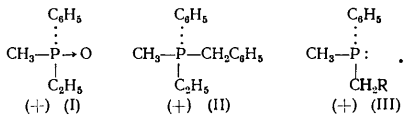
SCHEME 4



IV. STEREOCHEMISTRY OF OXIDES AND SULPHIDES OF PHOSPHORUS AND ARSENIC

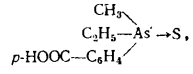
Meisenheimer and Lichtenstadt[1] were the first to show that phosphorus can give optically active compounds. Successful experimental resolutions of the oxides of tertiary amines into optical enantiomers[62,63] led Meisenheimer to study asymmetric phosphine oxides. By means of *dextro*-π-bromocamphorsulphonic acid he was able to isolate a dextrorotatory isomer of ethylmethylphenylphosphine oxide having a molecular rotation of $[M]_D = 50°$ and high optical stability. It is interesting that the value calculated by Sokolov and Reutov[64] for the molecular rotation of this phosphine oxide, using Brewster's rule of conformational asymmetry[65], is close to the value found experimentally[2] and by Meisenheimer[1,2]: a calculated value[64] of 40° compares with experimental values[2] of 47° in benzene and 40° in water or hydrochloric acid.

The laevorotatory isomer of ethylmethylphenylphosphine oxide was obtained by Meisenheimer only 14 years later[2]. The isolation of optically active isomers of this oxide, and later of benzylmethylphenylphosphine oxide[2], permitted Meisenheimer to conclude that phosphorus, like nitrogen, is able to give optically active compounds, for which it is sufficient to replace the five valencies of phosphorus by four different radicals. At the present time new paths for the synthesis of optically active oxides of tertiary phosphines have been opened as a result of the excellent work done by Horner et al.[8] and by Kumli and his coworkers[44,55,56] — (1) by the oxidation of optically active tertiary phosphines[8] and (2) by the action of sodium hydroxide on optically active phosphonium salts or by the Wittig reaction on the latter[55,56].



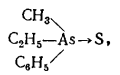
Sokolov and Reutov[64] assign the absolute configuration (I) to the dextrorotatory ethylmethylphenylphosphine oxide, on the basis of theoretical calculations of the molecular rotation of this isomer from Brewster's molecular asymmetry rule[65] and the indication by Limburg[66] that this rule correctly predicts the sign of rotation of compounds containing an asymmetric silicon atom. Since the configurational relationship among (I)–(III) has been established[67], (II) represents the absolute configuration of the optically active tetrasubstituted phosphonium cation, while (III) is the absolute configuration of the optically active tertiary phosphine.

Oxides of tertiary arsines have not yet been prepared in optically active form. The reason for this is still not understood. Sulphides of arsenic, on the other hand, have been successfully resolved into optical isomers. Mills and Raper[68] prepared optical isomers of *p*-carboxyphenylethylmethylarsine sulphide



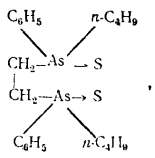
having rotations $[M]_{5780}$ of 51° and -52°. Both isomers possessed considerable optical stability: an aqueous solution of the sodium salt remained optically unchanged on

prolonged boiling. Horner and Fuchs[33] obtained dextrorotatory ethylmethylphenylarsine sulphide



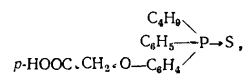
with a rotation of $[\alpha]_D^{20} = 24.5°$, by the addition of sulphur to the dextrorotatory arsine.

Chatt and Mann[69] isolated two forms of ethylene-1,2--bis-(n-butylphenylarsine sulphide)



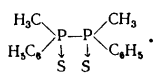
but were unable to determine which was racemic and which was the *meso*-form.

Davies and Mann[70] were the first to resolve butyl-*p*--carboxymethoxyphenylphenylphosphine sulphide

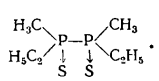


the resulting isomers having rotations $[M]_D$ of 9.6° and -9.7° with relatively high optical stability. The work of Horner[8] has opened up a new path for the synthesis of optically active phosphine sulphides, by the addition of sulphur to optically active tertiary phosphines.

Wheatley[71] isolated two forms (*meso* and racemic) of 1,2-dimethyl-1,2-diphenyldiphosphine disulphide

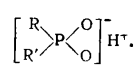


He established by means of X-rays that the modification having the higher melting point was centrosymmetric and represented the *meso*-form, while the other modification was the racemic form. Maier[72] tried to resolve the racemate by chromatographic adsorption on D(-)-mannitol, D(-)-lactose, and calcium D(-)-tartrate, but was unsuccessful. He isolated[72] two forms (racemic and *meso*) of 1,2-diethyl-1,2-dimethyldiphosphine disulphide



V. STEREOCHEMISTRY OF ORGANIC ACIDS OF PHOSPHORUS AND ARSENIC AND OF THEIR DERIVATIVES

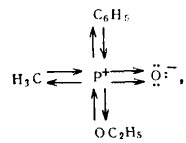
Interest in the organic acids of four-coordinate phosphorus from the point of view of stereochemical research arose as long ago as the beginning of the twentieth century. Kipping and Luff[73,74] were the first to try to resolve the phenyl *p*-tolyl and phenyl 2-naphthyl esters of phosphoric acid, but without success. Nor was a positive result obtained from Pope and Gibson's experiments[75] on the separation of methylphenylphosphinic acid into optical isomers or from those of Turner[76] on the resolution of benzylphenylarsinic acid. The former workers[75] tried to explain their failure by the ease of transformation of the phosphinic acid into the ortho-form $(CH_3)(C_6H_5)P(OH)_3$, which entails loss of asymmetry at the phosphorus atom. The optical inactivity of compounds containing hydroxyl and double-bonded oxygen attached to the phosphorus atom can be explained on the basis of Werner's theory, as Meisenheimer[77] did mainly for ammonium, phosphonium, and similar compounds. The structure of phosphorus compounds of the type RR'P(O)OH can be represented



In this case the inner complex is not asymmetric. The replaceable hydrogen in the outer sphere does not affect the asymmetry of the molecule. It was deduced on the basis of these arguments that compounds of the type

cannot be obtained in an optically active form.

Gibson and Johnson[78], starting from the electronic theory, reached the opposite conclusion. In their opinion the structure of ethyl methylphenylphosphinate can be written

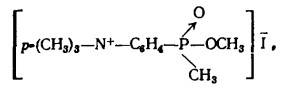


in which it can be seen that the outer octet of the phosphorus atom is complete without the oxygen atom. The octet of the oxygen atom can be complete only if the lone pair of electrons of the phosphorus atom are distributed between the two atoms, as is represented by the two arrows pointing in the same direction. The phosphorus atom thus becomes positive, while the oxygen becomes negative. The phosphorus–oxygen bond most probably becomes semipolar, as is confirmed by the change in parachor[79].

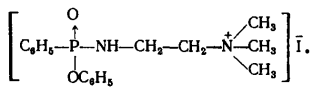
It would appear that compounds of the type

should exist in an optically active form. However, experiments by A. E. and B. A. Arbuzov[80] on the resolution of asymmetric phosphonecarboxylic acids, as well as those of A. E. Arbuzov and I. A. Arbuzova[81] on the resolution of isobutylphenylphosphinic and phenyltriphenylmethylphosphinic acids, did not yield a positive result. It was only in 1956 that Coyne[82], Marsi[83], and their collaborators obtained optically active forms of asymmetric derivatives

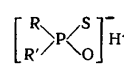
of phosphinic acids, as the quaternary ammonium salts — *p*-methoxy(methyl)phosphinylphenyltrimethylammonium iodide



and trimethyl-2-phenoxy(phenyl)phosphinylaminoethylammonium iodide

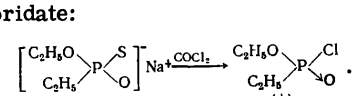


The first attempts to resolve asymmetric phosphinothioic acids, whose structure remains asymmetric



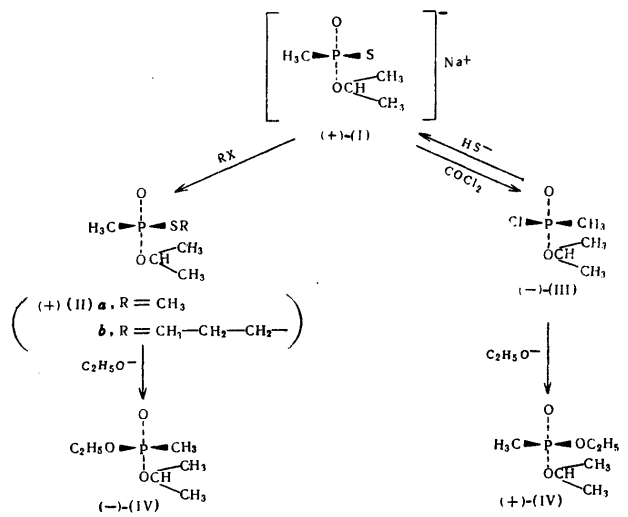
on Werner's coordination theory, were unsuccessful. Arbuzov and Kamai[84] prepared a series of these acids RR'PSOH, and hoped to separate them into optical isomers, since Mills and Raper[68] had successfully resolved the arsine sulphides RR'R"As → S, which were closely similar in type. Their experiments yielded no positive result. Aaron and Miller[85] were the first to resolve a derivative of phosphonothioic acid — ethyl hydrogen ethylphosphonothioate $C_2H_5PS(OC_2H_5)OH$ — by means of quinone. The isomers were isolated in the form of the dicyclohexylammonium salts, and were optically stable[86]. Subsequently[87] five more *O*-alkyl hydrogen alkylphosphonothioates — the ethyl, isopropyl, and methyl *P*-methyl esters, the ethyl *P*-isopropyl ester, and the methyl *P*-ethyl ester — were resolved via the brucine and quinine salts. The synthesis of racemic *O*-alkyl hydrogen alkylphosphonothioates has been described by Kabachnik et al.[88] and by Hoffmann et al.[89] Green and Hudson[90] resolved ethyl(phenyl)phosphinothiolic acid $C_2H_5(C_6H_5)POSH$, and Michalski et al.[91] have resolved *OO'*-dialkyl hydrogen phosphorothioates — the butyl ethyl and the ethyl isopropyl esters — through the cinchonine and cinchonidine salts. The successful separation of asymmetric derivatives of phosphinothioic acids has opened a new chapter in the investigation of optically active organophosphorus compounds, by permitting the study of (1) the stereochemistry of substitution reactions at an asymmetric phosphorus atom and (2) the biological activity of optical isomers of organophosphorus compounds.

By treating racemic *O*-ethyl hydrogen ethylphosphonothioate and its laevorotatory isomer with carbonyl chloride, Aaron[92] was able to isolate racemic ethyl ethylphosphonochloridate. By the action of carbonyl chloride on the sodium salt of laevorotatory *O*-ethyl hydrogen ethylphosphonothioate be obtained dextrorotatory *O*-ethyl ethylphosphonochloridate:



The racemisation half-life of the isolated optically active acid chloride was 6 h in dry acetone and 4 days in dry benzene at room temperature. The action of carbonyl chloride on dextrorotatory sodium *O*-isopropyl methylphosphonothioate gave laevorotatory *O*-isopropyl methylphosphonochloridate[92], irrespectively of whether the reaction took place in hexane, acetone, or dioxan.

SCHEME 5

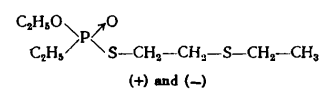


The optically active acid chloride thus obtained was subjected to various reactions as indicated in Scheme 5, the relative configurations of the compounds in which were deduced by the following reasoning. Dextrorotatory *O*-isopropyl *S*-methyl methylphosphonothiolate (+)-(II*a*) and laevorotatory *O*-isopropyl methylphosphonochloridate (-)-(III) were converted by the action of the ethoxide ion into the optical antipodes of ethyl isopropyl methylphosphonate:

(+)-(II*a*) → (−)-(IV) and (−)-(III) → (+)-(IV).

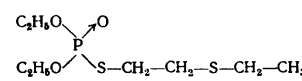
The compounds (+)-(II*a*) and (-)-(III) probably had opposite configurations. The compounds (+)-(II*a*) and (+)-(II*b*) had the same sign of rotation and the same configuration. This was confirmed by the synthesis of both laevorotatory esters from laevorotatory sodium *O*-isopropyl methylphosphonothioate (I) under conditions such that the *S*-alkylated product was formed exclusively[93].

Aaron and Michel[94] used the optical isomers of *OO'*-diethyl hydrogen phosphorothioate to synthesise dextrorotatory and laevorotatory ethyl *S*-2-ethylthioethyl ethylphosphonothiolate



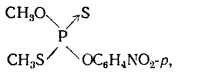
(+) and (−)

which were similar to the cholinesterase-inhibitor diethyl *S*-2-ethylthioethyl phosphorothiolate[95]

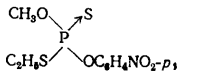


Study of the rate of suppression of cholinesterase by the two optical isomers of ethyl *S*-2-ethylthioethyl ethylphosphonothiolate showed that the laevorotatory isomer was a stronger inhibitor than the dextrorotatory isomer by a factor of 10–20.

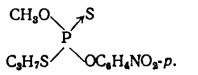
The difference in physiological activity between isomeric thionates and thiolates of phosphorus[95,96] and the biological activity of *cis* and *trans*-isomers of vinyl[97] and propenyl phosphates[98] led Hilgetag and Lehmann[99] to prepare the optically active thiophosphates — *OS*-dimethyl *O'*-*p*-nitrophenyl phosphorothiolothionate



S-ethyl *O*-methyl *O'*-*p*-nitrophenyl phosphorothiolothionate



and *O*-methyl *O'*-*p*-nitrophenyl *S*-propyl phosphorothiolothionate

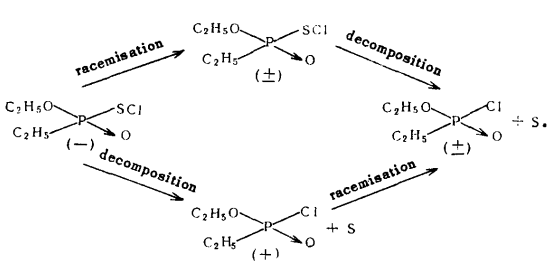


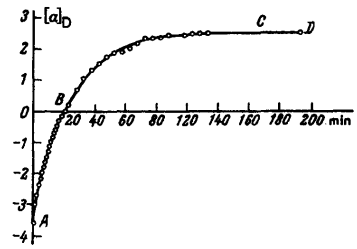
The optical isomers of *OS*-dimethyl *O'*-*p*-nitrophenyl phosphorothiolothionate were tested biologically on the fly *Drosophila funebris*. The enantiomers had the same effect on the fly, but exhibited different toxicities towards warm-blooded creatures: the values of LD_{50} were 135 and 25 mg kg^{-1} (mouse) for the dextrorotatory and laevorotatory isomers respectively.

Very interesting investigations have recently been made by Michalski and Ratajczak with the optical isomers of *O*-ethyl hydrogen ethylphosphonothioate, which had been obtained by Aaron et al.[85] These were converted by means of sulphuryl chloride into the optically active sulphenyl chlorides[100,101]

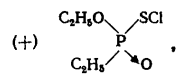
which lost their optical activity comparatively rapidly (racemisation half-life 6.8 min)[101]. A detailed study was made of the behaviour of laevorotatory ethyl chlorothio-(ethyl)phosphinate[101]. The rotation of this isomer changed from (-) to (+) only a few minutes after preparation, reached a maximum value in 3 h, and then gradually fell to zero. This variation in rotation of the laevorotatory sulphenyl chloride was explained[101] not only by racemisation but also by chemical changes, the sulphenyl chloride gradually decomposing into ethyl ethylphosphonochloridate and sulphur, with the former product also racemising comparatively rapidly.

The changes undergone by the laevorotatory ethyl chlorothio(ethyl)phosphinate were represented[101] by the cyclic scheme (see also diagram)

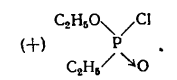




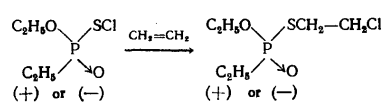
The diagram shows that the section *AB* of the curve predominates in racemisation of the dextrorotatory sulphenyl chloride itself



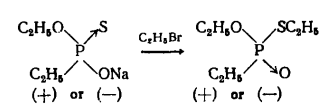
and corresponds to a first-order reaction. Section *CD* represents racemisation of dextrorotatory ethyl ethylphosphonochloridate



Addition of ethylene to the optically active ethyl chlorothio(ethyl)phosphinates gave dextrorotatory and laevorotatory *S*-alkyl esters[101,102]:



These were written A–S–R, where A = $C_2H_5OPO(C_2H_5)$– and R = $ClCH_2CH_2$–. Dextrorotatory and laevorotatory sodium *O*-ethyl ethylphosphonothioate gave with ethyl bromide the dextrorotatory and laevorotatory ethylthio-derivatives:



or A–S–C_2H_5. Michalski and Ratajczak[102] first studied the conversion of both dextrorotatory *S*-alkyl esters A–S–R

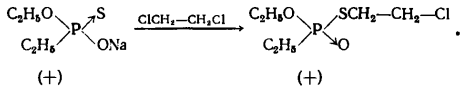
$$\begin{cases} A = (C_2H_5O)(C_2H_5)P(O)— \\ R = ClCH_2—CH_2—,\ C_2H_5 \end{cases}$$

into the optically active ethyl ethylphosphonochloridates by chlorolysis of the P–S bond:

$$A—S—R \longrightarrow A—Cl + R—S—Cl \quad \begin{cases} A = (C_2H_5O)(C_2H_5)P(O)— \\ R = ClCH_2—CH_2—,\ CH_3—CH_2— \end{cases}$$

Michalski and Ratajczak then carried out a similar reaction with the laevorotatory alkyl *S*-alkyl esters A–S–R.[103] They discovered that the direction of chlorolysis of the optically active alkyl alkylthio-derivatives A–S–R (where R = $ClCH_2CH_2$ and C_2H_5) to the acid chlorides A–Cl was

affected by the nature of the aliphatic radical attached to the sulphur: chlorolysis of the dextrorotatory *S*-alkyl ester (+)-$C_2H_5OPO(C_2H_5)SCH_2CH_2Cl$ gave the dextrorotatory ethyl ethylphosphonochloridate (+)-$C_2H_5OPO(C_2H_5)Cl$, whereas chlorolysis of the dextrorotatory *S*-alkyl ester (+)-$C_2H_5OPO(C_2H_5)SCH_2CH_3$ yielded the laevorotatory ethyl ethylphosphonochloridate (-)-$C_2H_5OPO(C_2H_5)Cl$. The two initial dextrorotatory *S*-alkyl esters A–S–R have the same configuration, since the dextrorotatory chloroethylthio-derivative was obtained also by reaction of dextrorotatory potassium or sodium *O*-ethyl ethylphosphonothioate with dichloroethane:



This reaction probably occurs without inversion of configuration at the asymmetric phosphorus atom, since the bonds around it are not involved.

Thus the dextrorotatory *S*-alkyl esters

$$(+)\,(C_2H_5O)\,(C_2H_5)\,P\,(O)\,SCH_2-CH_2-Cl \text{ and } (+)\,(C_2H_5O)\,(C_2H_5)\,P\,(O)\,S-CH_2-CH_3,$$

have the same configuration, whereas the ethyl ethylphosphonochloridates obtained from them by chlorolysis of the P–S bond have opposite configurations. Most probably chlorolysis of the two *S*-alkyl esters takes place by different mechanisms, the configuration being preserved with the chloroethylthio-derivative and inverted with the ethylthio-derivative. This mechanism for the latter derivative is supported also by the fact that laevorotatory ethyl ethylphosphonochloridate is converted into dextrorotatory diethyl ethylphosphonothiolate on treatment with sodium ethyl sulphide:

$$(-)\,(C_2H_5O)\,(C_2H_5)\,P\,(O)\,Cl \xrightarrow{C_2H_5SNa} (+)\,(C_2H_5O)\,(C_2H_5)\,P\,(O)\,S-CH_2-CH_3,$$

the reaction involving inversion of configuration at the asymmetric phosphorus atom [104].

In order to investigate the effect of chlorine in the side-chain on the stereochemical course of chlorolysis of *S*-alkyl esters A–S–R, the optically active compounds

$$(C_2H_5O)\,(C_2H_5)\,P\,(O)\,SCH_2-CH_2-CH_2-Cl,$$
$$(C_2H_5O)\,(C_2H_5)\,P\,(O)\,SCH_2-CH_2-CH_2-CH_2-Cl,$$

were examined. Chlorolysis of both these alkylthio--derivatives is accompanied by inversion of configuration at the asymmetric phosphorus atom. Table 1 lists results obtained for the chlorolysis to optically active ethyl ethylphosphonochloridates of all the optically active *S*-alkyl esters $C_2H_5OPO(C_2H_5)SR$ studied [103].

Ratajczak [105] studied the substitution of optically active ethyl ethylphosphonochloridates with various nucelophilic reagents such as RS^-, RO^-, R_2NH, and $C_2H_5OPS(C_2H_5)O^-$. Since kinetic data [104,106] indicate that the reactions of various organophosphorus acid chlorides with nucleophilic reagents have an S_N2 mechanism, while Ratajczak [107] and Green and Hudson [108,109] have shown that substitutions at the phosphorus atom under similar conditions involve inversion, Ratajczak [105] postulated that the reactions of optically active ethyl ethylphosphonochloridates with the

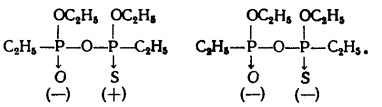
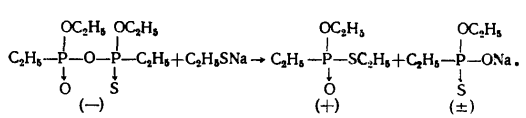
above nucleophilic reagents entail inversion of configuration at the asymmetric phosphorus atom. The results obtained are indicated in Table 2.[105]

Of the compounds listed in Table 2, special interest attaches to (VII), obtained by reaction (5)[107]. It contains two asymmetric centres PO and PS, and can exist in four optically active and two racemic forms. Since thio-acids are acylated at the oxygen atom[101], the pyrophosphonothionate (VII) should exist as a mixture of diastereoisomers

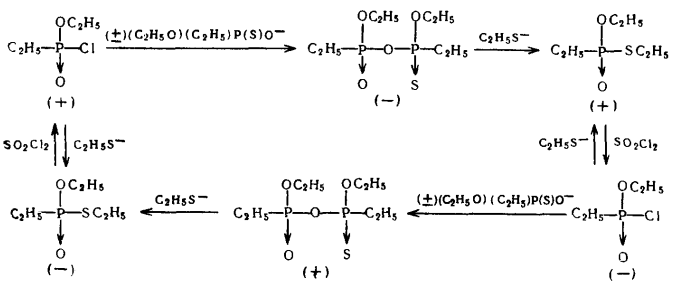


Studies had previously been made of the reactions of pyrophosphonothionates with the nucleophilic reagents sodium methoxide [110,111] and dimethylamine [112]. The latter were shown to attack the more electrophilic phosphorus (P→O) in the pyrophosphonothionate. Since organophosphorus anhydrides react with nucleophilic reagents by an S_N2 mechanism [113], it was supposed that reactions of the latter with pyrophosphonothionates should entail inversion [112]. The pyrophosphonothionate (-)-(VII) (Table 2) reacted with sodium ethyl sulphide to form racemic sodium *O*-ethyl ethylphosphonothioate and dextrorotatory diethyl ethylphosphonothiolate [107]:

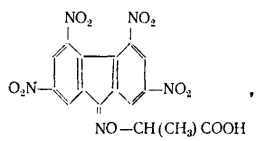


All the transformations of optically active acids of quadricovalent phosphorus derivatives studied Michalski and Ratajczak [103,105,107] can be summarised in the form of a

cycle similar to the Walden cycle in the chemistry of carbon, in which every change involves inversion[107]:

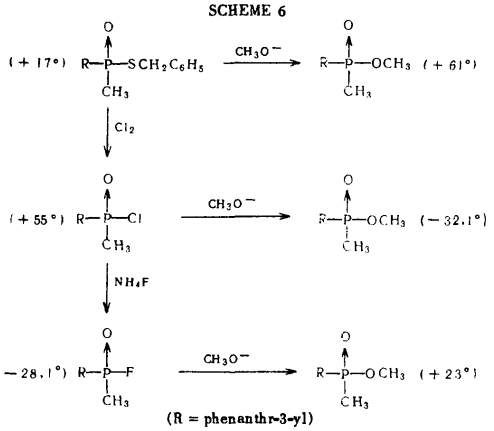


A very interesting method which has recently been discovered for resolving racemates into optical isomers is based on the spontaneous selective crystallisation of inclusion compounds formed by a complexing agent of open spiral structure with molecules of the compound to be separated which have penetrated into the cavities in its lattice[114]. Green and Hudson[115] isolated, via inclusion products with α-(2,4,5,7-tetranitrofluoren-9-ylideneamino-oxy)propionic acid



the dextrorotatory isomer of methyl 1-naphthyl methylphosphonate (+)-(1-$C_{10}H_7O$)CH_3POOCH_3 and both optical isomers of benzyl methyl(phenanthr-3-yl)phosphinothiolate. They used the dextrorotatory isomer of the ester to study[116] some of the substitutions shown in Scheme 6.

SCHEME 6



(R = phenanthr-3-yl)

---o0o---

Research on the stereochemistry of organic compounds of phosphorus and arsenic, begun as long ago as the beginning of the century, entered a new phase around 1956–1959. Whereas before 1956 workers had devoted their efforts mainly to preparing individual representatives of various classes of organophosphorus and organoarsenic compounds in an optically active form, during recent years serious investigations have been started on the mechanism of various reactions involving optically active compounds of phosphorus and arsenic, and some interesting results have already been obtained. There is no doubt that the amount of work done on the stereochemistry of organic compounds of phosphorus and arsenic will increase every year, and will lead to still more interesting results.

After the present paper had been written, a series of communications appeared reporting interesting work on the stereochemistry of organophosphorus and organoarsenic compounds. Peerdeman et al.,[117] for the first time in the history of the stereochemistry of organoelementary compounds, have determined the absolute configuration of dextrorotatory benzylmethylphenyl-n-propylphosphonium bromide by X-ray examination, which has enabled absolute configurations to be determined for the optically active benzylmethylphenyl-n-propylarsonium and benzylmethylphenyl-n-propylammonium bromides[118].

Horner and Winkler[119] have determined by asymmetric synthesis the absolute configuration of dextrorotatory methylphenyl-n-propylphosphine. Horner and Balzer[120] have studied the stereochemical course of the reduction of optically active oxides of tertiary phosphines to the phosphines by means of trichlorosilane. Denney and Gershman[121] have taken the first step in studying the stereochemical course of the reaction of optically active methylphenylpropylphosphine with chloral. Horner and Hofer[122] have studied the dependence of the rate of racemisation of optically active quaternary arsonium salts on the chemical structure of the salts and the nature of the solvent, and have also put forward a new mechanism for this racemisation. Krawicki and Michalski[123] have resolved *O*-ethyl hydrogen ethylselenophosphonothioate by means of quinine.

PROGRESS IN THE STUDY OF THE OXIDATION OF ORGANOMETALLIC COMPOUNDS

T. G. Brilkina and V. A. Shushunov

CONTENTS

1. Introduction 613
2. Oxidation of organometallic compounds with oxygen 613
3. Oxidation of organometallic compounds with peroxides 617

1. INTRODUCTION

The chemistry of organometallic compounds has a history of more than one hundred years. Various organic compounds of zinc[1,2], boron[3,4], lead[5], and tin[6,7] were prepared as early as the middle of last century. A number of methods have now been developed, for the preparation of a variety of organic derivatives of a given metal, including those containing several atoms of different metals.

Considerable attention has been and is being paid to the study of the properties and reactions of organometallic compounds, since these compounds and their reactions are of considerable theoretical and practical interest. One of the most important reactions of organometallic compounds is their oxidation by oxygen and peroxides. It is well known that certain organometallic compounds, for example those of magnesium, zinc, and boron, are oxidised extremely readily by oxygen, but systematic studies in this direction were begun only in the last ten years.

Recent studies[8-15] have shown conclusively that the reaction of organometallic compounds with oxygen is accompanied by the formation of organometallic peroxides, which subsequently undergo various types of rapid conversion, including reaction with the original organometallic compounds. It has thus become necessary to study the reactions of organometallic compounds with various peroxides.

Systematic studies of the reactions of organometallic compounds with oxygen and peroxides are being carried out successfully in the USSR and abroad. The comprehensive, systematic, and detailed studies of Razuvaev are outstanding.

2. OXIDATION OF ORGANOMETALLIC COMPOUNDS WITH OXYGEN

Organometallic compounds differ extremely widely in their behaviour towards oxygen. Organic compounds of the alkali and alkaline-earth metals, zinc, cadmium, boron, aluminium, and titanium are often spontaneously flammable even at room temperature, whereas organic derivatives of germanium, tin, and lead have a high stability towards oxygen under ordinary conditions; organosilicon compounds are oxidised extremely slowly by oxygen even at elevated temperature.

The reactivity is undoubtedly influenced greatly by the energy of the metal–carbon and metal–oxygen bonds and by the electronic structure of the metal atoms in the organometallic compounds. In the reactions of these compounds with oxygen an important part may also be played by the formation of inorganic and organic peroxides and various complexes and associates, and also by temperature and the nature of the solvent.

It is not yet possible to put forward a fully substantiated single mechanism for the oxidation of all organometallic compounds by oxygen. This is due chiefly to the fact that there are no published data characterising quantitatively the influence of the above factors on the rate of the reaction of organometallic compounds with oxygen. For example, the energy of the metal–carbon bond is known only for a very small number of compounds[16]. Despite the difficulties, however, it is worth summarising the extensive information obtained by many workers on the oxidation of organometallic compounds by oxygen and trying to distinguish the characteristic features of the mechanism of these reactions. No one has yet undertaken this task, although the mechanism of the oxidation by oxygen of the organic compounds of certain metals, chiefly alkali metals, has been examined in a number of papers[17,18].

The oxidation of organometallic compounds by oxygen is a complex process involving several elementary chemical-conversion stages, the number of which depends on the specific conditions under which the reaction is carried out. Various intermediate or final stable products of the chemical transformation of organometallic compounds may be formed, depending on these conditions.

It is appropriate to consider first of all the oxidation by oxygen of those organometallic compounds which undergo this reaction very readily at room temperature or at even lower temperatures. The most characteristic feature of this group of compounds is that the formation of organometallic peroxides is much more rapid than their subsequent transformation. This relationship between the rates

of formation and decomposition of the organometallic peroxides makes it possible to use the reaction of organometallic compounds with oxygen to prepare various organic peroxo-compounds, and this is of interest in preparative chemistry.

It is assumed [14,19-21] that the first elementary step in the reaction of organometallic compounds with oxygen is the formation of an oxygen-containing complex:

$$RM + O_2 \rightleftarrows RM \cdot O_2 \qquad (1)$$

where M is a univalent metal atom and R an alkyl or aryl group.

The assumption that organometallic compounds form an oxygen-containing complex finds considerable justification in the fact that the organic compounds of many metals form stable complexes with ethers, amines, and certain other compounds. Moreover, in many cases very stable complexes consisting of the organic compounds of two different metals are formed.

The stability of the complex formed according to reaction (1) undoubtedly depends on a number of factors, particularly the nature of the original organometallic compounds. It is possible that under appropriate conditions these complexes will be fairly stable, and their dissociation to give the original products will take place slowly, so that their existence may somehow be proved. Some years ago an attempt was made to confirm experimentally the formation of a complex of this type in the oxidation of tri-n-butylboron with oxygen [20]. The results indicated unambiguously that the reaction mixture contained the stable complex $(C_4H_9)_3B \cdot O_2$. More careful experiments by other workers [22] showed convincingly, however, that the earlier results [20] were not reproducible and were therefore erroneous. Thorough examination of the results obtained by other workers in the study of the oxidation of organoboron compounds by oxygen leads to the conclusion that only unstable oxygen-containing complexes are formed in this reaction.

The complex formed may undergo subsequent rearrangement with formation of the corresponding organometallic peroxide [17]:

$$RM \cdot O_2 \rightarrow \begin{matrix} R^{-\delta} & O^{+\delta} \\ | & \cdot \; \| \\ M^{+\delta} & O^{-\delta} \end{matrix} \rightarrow \begin{matrix} R{-}O \\ | \\ M{-}O \end{matrix}. \qquad (2)$$

Rearrangement takes place in exactly the same way in the organometallic compounds of bivalent and tervalent metals:

$$R_2M \cdot O_2 \rightarrow RMOOR, \qquad (3)$$

$$R_3M \cdot O_2 \rightarrow R_2MOOR. \qquad (4)$$

We can represent the further oxidation of RMOOR, R_2MOOR, and $RM(OOR)_2$ in analogous fashion, with the formation of $M(OOR)_2$, $RM(OOR)_2$, and $M(OOR)_3$ respectively.

The formation of organometallic peroxides has been observed in the oxidation by oxygen of many organometallic compounds. As early as 1890 it was established that the reaction of diethylzinc with oxygen was accompanied by the formation of a peroxo-compound assumed to have the composition $C_2H_5ZnOOC_2H_5$. [23] In this case, however, the product was definitely not an organometallic peroxo-compound but a peroxo-compound of the diethyl ether used as solvent.

The oxidation by oxygen of the alkyl derivatives of the alkali and alkaline-earth metals, zinc, boron, and aluminium in a number of cases can be carried out in such a way that the yield of the resulting organometallic peroxides reaches 70-90%. [10,11] This makes it possible to use the reaction of organometallic compounds with oxygen to prepare alkyl hydroperoxides, which can be isolated from the reaction mixture after hydrolysis of the organometallic peroxides. This method sometimes has considerable advantages over other methods for the preparation of alkyl hydroperoxides.

Depending on the conditions of oxidation, the organometallic peroxides formed may subsequently undergo various transformations, particularly reaction with the original organometallic compound to form the alkoxide:

$$RM + MOOR \rightarrow 2MOR. \qquad (5)$$

The reaction of organic derivatives of bivalent and tervalent metals is analogous.

Organometallic peroxides may undergo not only intermolecular but also intramolecular reactions:

$$RMOOR \rightarrow M(OR)_2, \qquad (6)$$

$$R_2MOOR \rightarrow RM(OR)_2, \qquad (7)$$

$$RM(OOR)_2 \rightarrow (RO)_2MOOR, \qquad (8)$$

$$R(RO)MOOR \rightarrow M(OR)_3. \qquad (9)$$

It is next necessary to consider the possibility of reaction between the organometallic peroxides and the intermediate or final products of their transformation. Reaction in this case is accompanied by the rupture of carbon–carbon or carbon–hydrogen bonds. Finally, there is a definite probability of reaction between the organometallic peroxides and the solvent.

Thus a high yield of organometallic peroxides in the oxidation of organometallic compounds by oxygen can be obtained only when the reaction is carried out under definite conditions (low temperature, low concentration of oxidisable organometallic compounds, and relatively high oxygen concentration in the solution). These conditions are necessary in order that the rate of formation of the organometallic peroxides may exceed appreciably the rate of their transformation in a given direction.

The elucidation of regularities in the oxidation of organometallic compounds by oxygen might be facilitated considerably by kinetic studies of this reaction. Very few such studies have been made, so that information on the mechanism of the reaction of organometallic compounds with oxygen can be obtained only from papers giving the yields of the compounds formed when the reaction is carried out under certain conditions. In a number of cases these data are undoubtedly insufficiently reliable, since some of the products of the oxidation of organometallic compounds by oxygen, for example organometallic peroxides, are unstable compounds and their yield depends on the duration of the experiment.

The formation of organometallic peroxides in the reaction of the alkyl derivatives of metals with oxygen has been demonstrated by many workers, although in the great majority of cases the peroxo-compounds were not isolated from the reaction mixture. The situation is quite different for the oxidation by oxygen of aryl derivatives of metals. In this case attempts have been made to detect hydroperoxides or peroxides containing a peroxo-group directly attached to an aromatic radical, formed in the oxidation of the corresponding organometallic compounds [10,24]. However, no definite results have been obtained. It has been found [10] that the oxidation of phenylmagnesium halides, *p*-bromophenylmagnesium bromide, and mesitylmagnesium

bromide with oxygen in diethyl ether at -75° gives peroxo--compounds in yields amounting to 1–9% of the calculated quantity, but these compounds were not isolated from the reaction mixture and identified, and their presence was established only by iodometric titration.

Other workers [24] made a more thorough study of the oxidation of aryl compounds of lithium and magnesium, and established that the reaction of phenylmagnesium halides with oxygen in diethyl ether even at -120° takes place without the formation of peroxo-compounds. The oxidation of 9-anthryl-lithium in very dilute solution at -75° was accompanied by the formation of peroxo-compounds, hydrolysis of which gave 9.6 mole % of hydrogen peroxide and 14 mole % of an unidentified organic peroxide. The oxidation of anthrylmagnesium bromide with oxygen led to the formation of peroxo-compounds whose hydrolysis gave only hydrogen peroxide (12.5 mole %). [24]

Thus the results cited are not unambiguous, as the authors themselves point out. It may be suggested that the peroxo-compounds formed are oxidation products of the solvent. This suggestion is supported by the fact that benzoic acid was formed in the reaction of phenylmagnesium halides with oxygen; the benzoic acid is apparently a product of the oxidation of 1-phenylethanol, whose presence in the reaction mixture was also established. Hydrogen peroxide probably results from the hydrolysis of lithium peroxide or magnesium peroxide. The formation of these peroxides in the oxidation of the corresponding aryl derivatives with oxygen is quite possible, although unfortunately this possibility was not investigated in the works cited.

If the formation of organometallic peroxides took place only by reactions (1)–(4) and their transformation only by reactions (5)–(9), formation of hydrocarbons should not be observed in the oxidation of organometallic compounds by oxygen or air. However, the formation of hydrocarbons R–R and R–H has been observed repeatedly in these processes. For example, in the oxidation of phenyl-lithium with oxygen in benzene, biphenyl and lithium phenoxide were isolated in approximately equal quantities as the chief reaction products [25]. The oxidation of tolyl-lithium with oxygen in diethyl ether was accompanied by the formation of a number of compounds, including toluene and products of the dimerisation of tolyl radicals [26]. The formation of biphenyl was also observed in the oxidation by oxygen of phenylmagnesium bromide [27-29], diphenylmagnesium [30], diphenylzinc [30,31], diphenylmercury [32], and triphenylaluminium [33]. The yield of biphenyl depended to a marked extent on the reaction conditions, chiefly the nature of the solvent used. In the oxidation of phenylmagnesium bromide with oxygen in diethyl ether, benzene was formed in 10.6% yield. The oxidation of diphenylzinc with oxygen at room temperature was also accompanied by the formation of benzene, in 28% and 32% yield in cyclohexane and chloroform respectively. When the reaction was carried out in carbon tetrachloride, the product was not benzene but chlorobenzene, in 58% yield [31].

The formation of hydrocarbons in the oxidation of various organometallic compounds in the liquid phase by oxygen can readily be explained if we assume that this reaction takes place partly or entirely by a free-radical mechanism. Such a mechanism may involve the following elementary stages:

$$RM \cdot O_2 \longrightarrow R^{\cdot} + MOO^{\cdot}, \quad (10)$$

$$R^{\cdot} + O_2 \longrightarrow ROO^{\cdot}, \quad (11)$$

$$RM + ROO^{\cdot} \longrightarrow MOOR + R^{\cdot}, \quad (12)$$

$$RM + MOO^{\cdot} \longrightarrow MOOM + R^{\cdot}, \quad (13)$$

$$SH + R^{\cdot} \longrightarrow RH + S^{\cdot}, \quad (14)$$

$$R^{\cdot} + R^{\cdot} \longrightarrow R_2, \quad (15)$$

$$R^{\cdot} + R^{\cdot} \longrightarrow RH + R_{-H}, \quad (16)$$

$$R^{\cdot} + S^{\cdot} \longrightarrow RS, \quad (17)$$

$$S^{\cdot} + S^{\cdot} \longrightarrow S_2. \quad (18)$$

Here SH represents the solvent or another compound present in the reaction mixture.

When R is an alkyl radical, reaction (11) takes place very readily with a low activation energy, so that in the oxidation of alkyl derivatives of metals, reactions (14)–(18) play a significant part only at very low concentrations of oxygen in the reaction mixture. Chain termination in the oxidation of alkyl derivatives of metals with oxygen takes place chiefly with the participation of peroxy-radicals.

If the rate of reaction (12) is much greater than the rate of reaction (13), the oxidation of an organometallic compound by oxygen gives chiefly the organometallic peroxide, not the metal peroxide.

The peroxo-compounds formed in reactions (12) and (13) may interact with the original organometallic compounds by reactions (5) and (19).

$$RM + MOOM \rightarrow MOM + ROM. \quad (19)$$

The situation is quite different when R is an aryl radical. Oxygen does not add on to aryl radicals with the formation of peroxy-radicals, so that reactions (14), (15), (17), and (18) play an important part in this case. The oxidation of these organometallic compounds by oxygen may involve the elementary stages (10), (13), and (20)–(27).

$$RM + MOO^{\cdot} \longrightarrow MOM + RO^{\cdot}, \quad (20)$$

$$RM + RO^{\cdot} \longrightarrow MOR + R^{\cdot}, \quad (21)$$

$$MOOM + R^{\cdot} \longrightarrow MOR + MO^{\cdot}, \quad (22)$$

$$RM + MO^{\cdot} \rightarrow MOM + R^{\cdot}, \quad (23)$$

$$MOO^{\cdot} + R^{\cdot} \longrightarrow RO^{\cdot} + MO^{\cdot}, \quad (24)$$

$$MO^{\cdot} + R^{\cdot} \longrightarrow MOR, \quad (25)$$

$$MO^{\cdot} + MO^{\cdot} \longrightarrow MOOM, \quad (26)$$

$$RO^{\cdot} + R^{\cdot} \longrightarrow ROR. \quad (27)$$

Chain termination in this case takes place by reactions (15) and (25)–(27), and may also take place by reactions (17) and (18), depending on the nature of the solvent. Confirmation of our assumption that reaction (17) is possible is provided by the formation of phenyltrichloromethane in the oxidation of diphenylzinc with oxygen in chloroform or carbon tetrachloride [31].

When a mixture of alkyl and aryl derivatives of a given metal is oxidised with oxygen, it is necessary to make allowance not only for the above stages but also for the possibility of reaction of the aryl organometallic compounds with an alkyl organometallic peroxide, and also with alkylperoxy-radicals. This is shown, for example, by the fact that the addition of alkylmagnesium halides to solutions of phenylmagnesium halides leads to a sharp increase in the yield of phenol in the oxidation of a mixture of these organometallic compounds with oxygen [34,35].

Reactions (19), (22), and (26) are characteristic only of the case where more or less stable metal peroxides are formed in the oxidation of aryl organometallic compounds by oxygen. In other cases, however, when these peroxides

are not formed, reactions (19), (22), and (26) must be excluded from the above scheme for the oxidation mechanism. This may be the case, for example, in the reaction of oxygen with aryl derivatives of boron and aluminium.

Some workers[18] conclude that the formation of hydrocarbons in the oxidation of organometallic compounds by oxygen results from the termolecular reaction

$$ROOM + 2RM \rightarrow ROM + MOM + R{-}R, \qquad (28)$$

but the following objections may be made to this conclusion. Firstly, there are no sufficiently convincing data on the formation of peroxides of the type ROOM in the oxidation of aryl organometallic compounds. Secondly the termolecular reaction (28) cannot explain the formation of hydrocarbons RH, although in a number of cases the formation of such compounds is an extremely characteristic feature. Thirdly and finally, reaction (28) makes no allowance for the participation of the solvent, despite the fact that a considerable number of studies have now established directly or indirectly that the solvent takes part in these processes. Thus the oxidation of tolyl-lithium with oxygen in diethyl ether leads to the formation of toluene and 1-tolylethanol[26]. In the case of phenylmagnesium bromide, formation of 1-phenylethanol was observed[27]. Phenol and biphenyl, formed in the oxidation of diphenylmagnesium with oxygen in deuterated benzene, contain deuterated phenyl radicals[30]. Similarly the oxidation of diphenylzinc in deuterated benzene gives deuterated biphenyl[30]. The same reaction in deuterated chloroform was accompanied by the formation of benzene containing 60% of deuterium[31].

These data indicate that in the oxidation of organometallic compounds by oxygen, hydrocarbons are formed not by reaction (28) but as a result of the formation of free radicals. An analogous conclusion was reached in a study of the products of the oxidation of trialkylborons in the liquid phase[36].

Kinetic studies of the oxidation of dimethylzinc, diethylzinc[37,38], triethylboron, and tri-n-propylboron[39] by oxygen in the gaseous phase also indicate a free-radical mechanism for this reaction.

The above chain mechanism for the oxidation of organometallic compounds by oxygen makes it possible to explain the fact that the alkyl derivatives of metals are more readily oxidised than the aryl derivatives. This difference is due chiefly to the marked tendency of alkyl radicals to react with oxygen with formation of the corresponding peroxy-radicals, and the complete absence of this tendency in aryl radicals. Therefore the oxidation of the readily oxidised alkyl organometallic compounds by oxygen takes place with the formation of a smaller number of reaction products than in the oxidation of the corresponding aryl organometallic compounds. Thus in the oxidation of dibutylzinc with oxygen in diethyl ether at 0° the yield of organometallic peroxide reached 90% of theoretical[11]. The oxidation of diphenylzinc with oxygen in cyclohexane, however, gives chiefly benzene, phenol, and biphenyl[31].

It is quite possible that the process may take place with the participation of free radicals or by molecular rearrangement of an oxygen-containing complex, depending on the specific conditions of the reaction. The ratio of the rates of these two processes may vary over a very wide range.

Papers dealing with the oxidation of organotitanium compounds by oxygen are particularly noteworthy. The chemistry of organotitanium compounds is still in the initial stage of its development (see, for example, a recently published review[40]). Systematic studies in this field are being successfully carried out by Razuvaev and his coworkers. It has been found that dicyclopentadienyltitanium[41], cyclopentadienylphenyltitanium[42], diphenyltitanium[43], and dicyclopentadienyldiphenyltitanium[41] are extremely readily oxidised by oxygen. It is significant that the rate of oxidation of dicyclopentadienyldiphenyltitanium depends to a marked extent on the nature of the solvent in which the reaction is conducted[41,44].

Other authors have also noted the extremely ready reaction of oxygen with dicyclopentadienyltitanium[45], trimethylcyclopentadienyltitanium[46,47], methyltitanium trichloride[48], ethyltitanium trichloride[48,49], and tetramethyltitanium[50].

The mechanism of the oxidation of organic compounds of mercury, silicon, tin, and lead differs significantly from that examined above. Here it should first of all be noted that the rate of oxidation of the organic compounds of these metals by oxygen depends to a very marked extent on the nature of the organic radicals present and also on the valency state of the metal atom. For example, the dialkyl and diaryl derivatives of tin[51-62] and lead[63-65], and the alkylated and arylated silanes[66-72] and stannanes[41,54,73-76], are readily oxidised by oxygen. The tetra-alkyl and more particularly the tetra-aryl derivatives of silicon, tin, and lead in most cases have a high stability towards oxygen, which decreases appreciably on going from the organic derivatives of silicon to the corresponding lead compounds. For example, tetraphenylsilicon is not oxidised appreciably when heated in air to 400°,[77] whereas tetraphenyl-lead inflames in air at a much lower temperature[78].

The influence of the nature of the organic radicals in the tetra-alkyl compounds of silicon, tin, and lead on the rate of the reaction of these compounds with oxygen is extremely marked. Replacement of primary alkyl radicals in a tetra-alkyl-lead by secondary alkyl radicals is accompanied by a significant increase in the rate of oxidation of these organolead compounds by oxygen[79,80]. Tetrabenzyl--lead is particularly readily oxidised by oxygen[81].

The oxidation of organomercury compounds by oxygen is of considerable interest. With a very early exception[82], no papers on these reactions have appeared until recently, since the opinion has long been held[83] that the organic compounds of mercury have a high stability towards oxygen. This incorrect opinion is convincingly refuted by the work of Razuvaev and his coworkers, which shows that in a number of cases organomercury compounds are very readily oxidised by oxygen. For example, dicyclohexylmercury in isopropyl alcohol is oxidised at a considerable rate even at room temperature[84]. Di-isopropylmercury[85-87], di-t-pentylmercury[86], and dibenzylmercury[86] show analogous behaviour.

A characteristic feature of the oxidation of dialkylmercury compounds by oxygen is the formation of a complex mixture of reaction products. For example, the oxidation of di-isopropylmercury by oxygen in carbon tetrachloride gave isopropylmercuric chloride, acetone, isopropyl chloride, chloroform, carbon monoxide, carbon dioxide, and metallic mercury[86]. This led to the suggestion that an organomercury peroxo-compound is formed[84,86] and that free radicals take part in the reaction of dialkylmercury with oxygen[86]. The suggestion that free radicals

are involved in the reactions of certain organomercury and organolead compounds with oxygen is confirmed by the results of a study of the nature of this process. The oxidation with oxygen of di-isopropylmercury[87] or tetraethyl-lead[88] shows a clearly defined induction period. Moreover, the addition of inhibitors decreases considerably the rate of reaction of di-isopropylmercury with oxygen[87].

A characteristic feature of the reaction of oxygen with alkyl compounds of mercury and metals in Group IVB of the Periodic System is the large temperature coefficient of reaction rate[87-90]; thus at low temperatures these reactions take place very slowly, and with increase in temperature several parallel and successive chemical processes take place simultaneously. With rise in temperature the peroxo-compounds formed undergo rapid reaction with the original organometallic compounds or with products of their transformation, so that it is very difficult to detect compounds containing peroxide oxygen in the reaction mixture.

If the organometallic compounds contain metal–metal bonds in addition to metal–carbon bonds, there is a marked increase in their reactivity. The rate of the reaction of these compounds with oxygen varies over a very wide range, depending on the nature of the metals forming the metal–metal bond. The reactions of this type of compound, including the reactions with oxygen, have been reviewed in detail[91].

3. OXIDATION OF ORGANOMETALLIC COMPOUNDS WITH PEROXIDES

The reactions of organometallic compounds with organic and inorganic peroxides are extremely numerous and varied, and in the past ten years a very large number of papers have been devoted to their study. The greatest contribution to the study of the reactions of organometallic compounds with peroxides has been made by Razuvaev and his coworkers, who have published a large number of papers reporting a systematic study of the reaction of the organic compounds of several metals with alkyl and acyl peroxides.

The character of the reaction of organometallic compounds with peroxides is influenced by the nature of the original compounds and the reaction conditions. These processes may take place by homolytic or heterolytic mechanisms. In a number of cases the mechanism is extremely complex.

The most characteristic heterolytic reaction of organometallic compounds with peroxides is nucleophilic substitution:

$$R_{n-1}MX + R'OOZ \rightarrow R_{n-1}MOOR' + XZ, \qquad (29)$$

where $n \geq 1$, M = metal, R = alkyl or aryl, R′ = metal, hydrogen, alkyl, or aryl, X = OH, NH_2, halide, alkyl, aryl, alkoxyl, aryloxy-radical, or some other substituent, and Z = metal or hydrogen. In a number of cases reaction (29) is reversible.

If M = mercury, silicon, germanium, tin, or lead and X = alkyl or aryl, reaction (29) takes place with great difficulty and extremely slowly. If the temperature is raised in order to increase the reaction rate, the organic compounds of these metals react with peroxides chiefly by a homolytic mechanism with rupture of the oxygen–oxygen bond.

Reaction (29) can be used to obtain a wide variety of organometallic peroxo-compounds, i.e. compounds containing both metal and peroxide oxygen. For example, the reaction of hydroperoxides with the oxides, hydroxides, alkoxides, hydrides, or amides of alkali and alkaline-earth metals gives the corresponding organometallic peroxides[92-102]. Peroxo-compounds are formed also by the reaction of hydroperoxides with dialkylzinc[12], dialkylcadmium[103], and trialkylaluminium[15]. Organometallic peroxides of boron[104], silicon[105-112], germanium[113,114], tin[114-116], and lead[114] are obtained by the reaction of hydroperoxides with organometallic compounds containing halogeno-, hydroxo-, or amino-groups joined to the metal.

If anhydrous hydrogen peroxide is used instead of hydroperoxides, it is possible to obtain metallo-organic peroxides. The difference between organometallic and metallo-organic peroxides is that the former contain a "carbon–peroxide oxygen" bond and the latter a "metal–peroxide oxygen–metal" bond.

All organometallic peroxo-compounds exhibit a number of common properties. In most cases they readily undergo hydrolysis and decompose rapidly in reactions with compounds containing labile hydrogen. All organometallic peroxo-compounds are powerful oxidising agents and very readily oxidise, for example, the organic compounds of a large number of metals, as noted in the first part of the present review.

A very interesting heterolytic reaction of organometallic peroxides is the intramolecular rearrangement of some of them:

$$R_3MOOCOR' \rightarrow R_2(RO)MOCOR'. \qquad (30)$$

There are sufficient grounds for assuming that the rearrangement takes place by a mechanism analogous to the familiar heterolytic rearrangement of peroxy-esters. This assumption is confirmed fairly convicingly by the results of a kinetic study of the heterolytic rearrangment of a number of acylperoxy-compounds of triphenyltin.

It was established that the product of reaction (30) in the case which we studied is readily hydrolysed by water:

$$C_6H_5O(C_6H_5)_2SnOCOR + H_2O \longrightarrow HO(C_6H_5)_2SnOCOR. \qquad (31)$$

The acyloxyhydroxydiphenyltin readily undergoes further transformation, owing to the ready disproportionation of the corresponding organotin compounds:

$$2\cdot HO(C_6H_5)_2SnOCOR \longrightarrow (C_6H_5)_2Sn(OH)_2 + (C_6H_5)_2Sn(OCOR)_2, \qquad (32)$$

$$(C_6H_5)_2Sn(OH)_2 \longrightarrow (C_6H_5)_2SnO + H_2O, \qquad (33)$$

$$2\cdot(C_6H_5)_2Sn(OCOR)_2 \longrightarrow (C_6H_5)_3SnOCOR + C_6H_5Sn(OCOR)_3, \qquad (34)$$

$$3\cdot C_6H_5Sn(OCOR)_3 \longrightarrow (C_6H_5)_2SnOCOR + 2Sn(OCOR)_4. \qquad (35)$$

The assumption that these disproportionations take place is convincingly confirmed by the results of a study of the composition of the reaction mixture formed under various hydrolysis conditions. Thus triphenyltin acetate was detected and isolated when aqueous diethyl ether was used for the hydrolysis of phenoxydiphenyltin acetate, which is in turn a product of the rearrangement of triphenyltin peracetate.

It might be suggested that the organotin compound formed by reaction (30) should react further with the peroxy-acid:

$$C_6H_5O(C_6H_5)_2SnOCOR + RCO_3H \rightarrow RCOO(C_6H_5)_2SnOCOR + C_6H_5OH. \qquad (36)$$

The organotin peroxo-compound newly formed by reaction (36) should, by analogy with reaction (30), have undergone transformation with the loss of peroxide oxygen. It was established, however, that this did not take place, and the yield of phenol never exceeded 1 mole per mole of original organotin compound.

Depending on the nature of the original organotin compound and the experimental conditions, the rate of formation of acylperoxytriphenyltin by the reaction

$$(C_6H_5)_3SnX+RCOOOH \rightarrow (C_6H_5)_3SnOOCOR+HX, \quad (37)$$

may be greater or less than the rate of reaction (30). The difference in the molecularities and hence in the orders of these reactions makes it possible to establish, from kinetic data, which of these processes is the slower.

If in the original organotin compound $(C_6H_5)_3SnX$ the substituent X is a hydroxo-, methoxy-, or nitrophenoxy--group, reaction (37) takes place very rapidly, and the rate of formation of the organotin compound $C_6H_5OSn(C_6H_5)_2OCOR$, containing no peroxo-group, is determined by the rate of reaction (30). On the other hand, if the substituent X in the original organotin compound is a chloro- or acyloxy--group, reaction (37) takes place much more slowly than the rearrangement of the organotin peroxo-compound formed from the starting materials. In this case the rate of formation of the acyloxyphenoxydiphenyltin, and hence the rate of decrease in the concentration of peroxo-compounds in the reaction mixture, is determined by the rate of reaction of the starting materials.

The rearrangement of organotin peroxo-compounds containing an acylperoxy-radical is a first-order reaction. The rate of this reaction depends to a marked extent on the nature of the organotin peroxo-compound, the nature of the solvent, and the temperature.

The rate of rearrangement of these compounds in anhydrous methanol increases with change in the radical R in $(C_6H_5)_3SnOOCOR$ in the sequence

$$CH_3 < n\text{-}C_6H_{13}C_6H_5 < C_6H_4NO_2\text{-}m\ (p) < C_6H_4NO_2\text{-}o.$$

The replacement of methanol by toluene leads to an increase in the rate of rearrangement of the acylperoxytriphenyltin. In methanol this reaction takes place at a high rate in the temperature range from -20° to 10°, whereas in toluene it takes place at approximately the same rate in the range from -30° to 0°.

In the reaction of triphenyltin acetate with peracetic acid in toluene, reaction (37) is much slower than reaction (30). This is quite understandable, since in the formation of triphenyltin peracetate a weak acid is displacing a stronger acid from its salt. The rate of decrease in the concentration of peroxo-compounds in the reaction mixture in this case is determined by the rate of the bimolecular reaction (37).

Acetic acid is liberated in the reaction of triphenyltin acetate with peracetic acid. It was found that the addition of acetic acid decreases considerably the rate of the reaction of peracetic acid with triphenyltin acetate in toluene. Study of the kinetics of this reaction shows that the free energy of activation increases regularly, while the entropy of activation decreases, with increase in the concentration of acetic acid in the reaction mixture.

It should be noted that the reaction of peracetic acid with triphenyltin acetate in toluene takes place at a measurable rate in the range 5–30°, where thermal decomposition of peroxycarboxylic acids is quite insignificant.

The rearrangement of various organic compounds of silicon[105], germanium[113], and lead[117] takes place in analogous fashion.

Interesting results were obtained in a study of the reaction of ethoxytriethyltin with benzoyl peroxide[118,119]. In an inert solvent, e.g. benzene, ethoxydiethyltin benzoate and ethyl benzoate are formed in 80–90% yield. It is suggested[118,119] that in this case the initial product is triethyltin perbenzoate, which subsequently undergoes the heterolytic rearrangement (30).

The spontaneous decomposition of organometallic peroxo-compounds by a homolytic mechanism is often accompanied by the formation of a complex mixture of chemical compounds. These compounds are products of the interaction of primary and secondary radicals with the solvent or with other substances present in the reaction mixture. The formation of free radicals during the spontaneous decomposition of organometallic peroxo-compounds is proved by the initiation of the polymerisation of various monomers as a result of the addition of, for example, organosilicon[105,106] and organotin[120-122] peroxides.

The reactions of organometallic compounds with organic peroxides in many cases also involves the participation of free radicals. The most interesting results on this type of reaction have been obtained by Razuvaev and his coworkers, who began to investigate the reactions of organometallic compounds more than thirty years ago. Even at that early date, in a study of the thermal decomposition of organic compounds of mercury, Razuvaev obtained the first evidence of the formation of free aryl radicals in solution[123-125]. Subsequent work proved the formation of free radicals in the thermal and photochemical decomposition of a number of organometallic compounds, for example in the thermal decomposition of diphenylmercury[123-127], tetraethyl-lead[128], and hexaethyldiplumbane[128], and also in the photochemical decomposition of dimethylmercury[129,130], diphenylmercury[21,131-135], and various other organic compounds of mercury[136-139].

Proof of the formation of free radicals in the thermal or photochemical decomposition of organometallic compounds was obtained using tracer atoms[21,126,127,133,134]. This method also provided proof that organic radicals of the organometallic compounds underwent exchange with the solvent.

Subsequently, Razuvaev and his coworkers found that oxygen and organic peroxides increase considerably the rate of decomposition of organometallic compounds and their exchange of organic radicals with the solvent[21,126]. This established the interrelationship of the thermal and photochemical decomposition of organometallic compounds with their oxidation by oxygen and peroxides.

Of the large number of homolytic reactions of organometallic compounds with peroxides, only those of alkyl and acyl peroxides with organic compounds of mercury[140], silicon[141-143], germanium[144], tin[142,143], and lead[141,142,145] have been studied in detail.

Benzoyl peroxide reacts with diethylmercury, di-isopropylmercury, and diphenylmercury[140] with the formation of a complex mixture of products, probably resulting from simultaneous molecular and free-radical processes.

The reaction of di-isopropylmercury with t-butyl hydroperoxide takes place fairly readily. It is suggested

that this reaction involves the intermediate formation of an organomercury peroxo-compound.

Tetra-alkyl derivatives of silicon, germanium, tin, and lead react readily at 80–95° with acyl peroxides, the direction of the reaction depending to a marked extent on the metal. Thus in the reaction of benzoyl peroxide with tetraethylsilane [141,142] and hexaethyldisilane [143] no rupture of the Si–C bond is observed, whereas the reaction with tetraethylgermanium gives products which indicate rupture of the Ge–C bond [144]. This is shown to an even greater extent in the reactions of acyl peroxides with tetraethyltin [142] and tetraethyl-lead [141,142], and also with hexaethyldistannane [142] and hexaethyldiplumbane [145]. The reaction at 130–150° of t-butyl peroxide with tetraethylgermanium [144], tetraethyltin [142], and hexaethyldistannane [143] is to some extent analogous.

The experimental results indicated that the reactions of acyl and alkyl peroxides with alkyl derivatives of mercury, silicon, germanium, tin, and lead take place either completely or partly by a free-radical mechanism.

The formation of free radicals in the oxidation of organometallic compounds by oxygen or peroxides can be used to initiate various chain reactions. Among these reactions, radical polymerisation is of particular interest. The most important results in this connection have been obtained in the study of polymerisation initiated by organoboron and organoaluminium compounds in the presence of oxygen or peroxides.

It is now firmly established that trialkylborons in the presence of oxygen are powerful initiators of the radical polymerisation of many unsaturated compounds. The first papers on the study of organoboron compounds as initiators for the polymerisation of unsaturated compounds were published in 1957 [146–149]. These were followed by others [150–158] containing more or less detailed information on the initiating power of various trialkylborons and the mechanism of the reactions taking place.

It was first found that tributylboron initiates the polymerisation of acrylonitrile [146,149], methyl methacrylate [147,149], ethylene [148], styrene [147,149], vinyl chloride, vinyl acetate, and n-butyl vinyl ether [149]. It was established that the emulsion polymerisation of acrylonitrile at 20° and 50° in the presence of tributylboron takes place only if oxygen is also present [150]; it was shown that peroxo-compounds of the type R_2BOOR, $RB(OOR)_2$, or $B(OOR)_3$ are formed. The addition of isobutyldi-isobutylperoxyboron to acrylonitrile brings about polymerisation of the latter [159], indicating homolytic dissociation of this organoboron peroxo-compound.

It has been suggested [153,155–158] that the mechanism of polymerisation initiation is more complex than oxidation of the trialkyborons by oxygen to the corresponding peroxides followed by their homolytic dissociation. It was first suggested that a complex $R_3B.O_2$ is formed and acts as polymerisation initiator [155], but, as already noted, if this complex is formed at all, it may well undergo rapid rearrangement to a more stable peroxo-compound or decompose to the original components.

Published data on the part played by organoboron peroxides in the initiation of radical polymerisation are contradictory. It has been shown [159] that the initiating power of isobutyldi-isobutylperoxyboron is the same as that of tri-isobutylboron in the presence of air, yet it has also been stated [156] that neither tri-n-butylboron nor its peroxide is by itself an effective initiator for the polymerisation of methyl methacrylate, but that when taken together these compounds are extremely active. On this basis it was suggested that the initiation involves the stages

$$R_3B+M \rightleftarrows R_3B\cdot M, \qquad (38)$$

$$R_3B\cdot M+R_2BOOR \rightarrow R_3B\cdot M\cdot RO^{\cdot}+R_2BO^{\cdot}, \qquad (39)$$

where M represents a molecule of the monomer.

Study of the influence of the $[R_3B]:[O_2]$ ratio on the degree and initial rate of polymerisation showed that the process takes place most readily when this ratio is close to unity [158]. When $[R_3B] \ll [O_2]$, all the organoboron compound is converted into the peroxide, whereas when $[R_3B] \gg [O_2]$ the peroxide formed is very rapidly used up in the reaction with R_3B, so that the polymerisation is rapidly quenched. Here, as before [156], it is suggested that the formation of radicals takes place readily only by reaction of the trialkylboron with its peroxide.

The role of oxygen in polymerisation initiated by a trialkylboron can be played by various other oxygen-containing compounds — hydrogen peroxide, manganese dioxide, copper(II) oxide, etc. [153]

Organoaluminium compounds, like organoboron compounds, initiate radical polymerisation in the presence of oxygen or peroxides. The initiation of the polymerisation of various monomers by a trialkylaluminium has been studied by a number of workers [160–167]. It has been established [161] that the polymerisation of vinyl chloride, initiated by triethylaluminium in the presence of oxygen, involves an induction period. The existence of the induction period was attributed to preliminary oxidation of the original organoaluminium compound by oxygen. This reaction gives compounds containing oxide and peroxide oxygen, introduced at the "aluminium–carbon" bond. These organoaluminium peroxo-compounds react more or less readily with organoaluminium compounds still containing unoxidised "aluminium–carbon" bonds. This stage [161] also determines the initiating power of the "trialkylaluminium–oxygen" system. Instead of trialkylaluminium compounds, it is possible to use for this purpose alkylalkoxyaluminium compounds with varying degrees of replacement of alkyl radicals by alkoxy-radicals. Study of the initiating power of these compounds for the particular case of ethyl derivatives of aluminium showed that, in the presence of oxygen, diethylaluminium ethoxide is a most active initiator for the polymerisation of vinyl chloride.

The influence of the nature of the alkyl radicals in trialkylaluminium on the initiating power in the presence of oxygen has also been studied [163]. It was concluded that the organoaluminium compounds bring about radical polymerisation only under conditions which ensure their conversion into corresponding peroxo-compounds.

The initiating activity of trialkylaluminium compounds in the presence of organic peroxides has been studied [162,163,168].

Triethylaluminium reacts vigorously even at 0° with cumenyl hydroperoxide [163] with the liberation of ethane and the formation of an organoaluminium peroxo-compound, which undergoes further transformation more or less rapidly depending on the reactant concentrations.

The "triethylaluminium–cumenyl hydroperoxide" system does not effectively initiate the polymerisation of vinyl acetate. If diethylaluminium ethoxide is used instead of triethylaluminium, the system is an effective initiator for

the polymerisation of this monomer. If ethylaluminium diethoxide is used instead of diethylaluminium ethoxide, a considerable decrease in initiating power is observed.

The systems formed by triethylaluminium and tri-isobutylaluminium with benzoyl peroxide are effective initiators for the radical polymerisation of vinyl acetate, methyl methacrylate, and acrylonitrile[162,168]. It was found that these initiators bring about polymerisation of the monomers even at -30°. Replacement of an alkyl derivative of aluminium by an alkoxy-derivative is accompanied by complete loss of initiating power in the presence of benzoyl peroxide.

A kinetic study has been made[168] of the polymerisation of vinyl acetate initiated by triethylaluminium in the presence of benzoyl peroxide.

IV. Transesterification of phosphonites 627
V. Mechanism of the transesterification of esters of acids formed by tervalent phosphorus 629

I. INTRODUCTION

Twenty years ago the chemistry of the organic compounds of phosphorus entered a period of vigorous development. About a hundred years were required, after the first organophosphorus compounds had been prepared, for sufficient experimental results to accumulate and for the theoretical and practical value of certain compounds to be assessed, which determined the further development of this branch of organic chemistry. The most important work, which provided a foundation for further investigations, was undertaken by Michaelis, Arbuzov, and their many students.

At the present time the practical application of organophosphorus compounds is being continually extended. Because of their high thermal and chemical stability they are successfully employed as plasticisers for synthetic resins, on which they confer non-flammability, resistance to frost[1-3], and sometimes stability towards radiation[4]. The use of organic compounds of phosphorus as extractants[5,6] and flotation agents[7] is no less valuable. Substances containing phosphorus have proved to be valuable additives for lubricating oils, giving to the latter durability and several other desirable properties[8]. Polymers and oligomers containing phosphorus are used for the manufacture of ion-exchange resins, surface-active agents, adhesives, glasses with unique optical properties, etc.[9]

A large number of physiologically active substances of practical interest have been found among organophosphorus compounds. The chemistry of phosphorus occupies a primary place in the number and variety of pesticides. The products Thiophos, Chlorophos, Carbophos, Octamethyl, Butaphos, Ragor, Systoxes, etc. have received wide publicity, and are used in large quantities in agriculture.

Organophosphorus poisons, discovered during recent decades, are more toxic than all hitherto known poisons, and in this respect approach the most virulent compounds of vegetable and animal origin.

Organophosphorus compounds are used also as drugs, e.g. in the treatment of glaucoma (Phosarbin, Armin, Fosfakol)[10], tumours (TEPA, Thio-TEPA, DIPIN, etc.)[11,12], and cardiovascular diseases (hydrazides and amides of thiophosphates)[13]. Natural substances containing phosphorus – nucleic acids, phosphatides, coenzymes, glycopyrophosphates, and many others – are extremely important for the vital activity of organisms[14].

The organophosphorus compounds which find practical use or which are of importance in biochemical processes are mainly esters and amide–esters of phosphoric, phosphorothioic, and pyrophosphoric acids, derivatives of alkylphosphonic acids, and phosphine oxides. It is essentially the chemistry of phosphates and pyrophosphates which is of concern to industry and biochemistry. The importance of phosphates, phosphorothioates, and pyrophosphates is determined not only by their usefulness but also by their availability.

A common feature of several methods of obtaining these compounds is the use of acid and normal phosphorous esters as intermediates in their synthesis. Thus various phosphates are obtained by oxidising phosphites by the addition of sulphur to them, chlorination, reaction with sulphur chlorides, disulphides, thiocyanates, sulphenyl chlorides, chloramines, etc. The alkylation of sodium phosphites by Michaelis' method and of normal phosphites by Arbozov's method or the addition of dialkyl phosphites to unsaturated compounds, etc. yields phosphonates.

Thus phosphites, while being of intrinsic value in their use as such, possess high reactivity, and are therefore

key materials for the preparation of various organic compounds of phosphorus. However, the synthesis of phosphites by the reaction of alcohols with phosphorus trichloride often gives poor yields of the desired products, and sometimes leads to negative results, especially in the preparation of esters containing acid-labile groups. A good method for the synthesis of esters is transesterification, which is widely known in organic chemistry. Its application to the chemistry of carboxylic esters has especially varied aspects, and it has been studied in detail in the preparation of these compounds. The reaction occurs under comparatively mild conditions, is not accompanied by the liberation of corrosive products, and gives good yields of the required materials, so that it is often employed in the preparation of vitamins[15], proteins[16-18], lipids[19,20], and other labile compounds[21,22]. Alcoholysis of esters of dibasic and polybasic acids with glycols and polyols is employed for the synthesis of polymeric compounds[23]. For example, lavsan (Terylene) is obtained by the interaction of dimethyl terephthalate with ethylene glycol.

Study of transesterification has shown that, as a rule, the alkoxy-group of the ester is replaced by an alcohol radical of higher molecular weight. In some cases this does not apply: esters formed by phenols, glycol, glycerol, and some other hydroxy-compounds having enhanced acidic properties are transesterified by simple alcohols[21,24-26]. The presence of a double bond in the $\alpha\beta$-position to the alkoxycarbonyl group of the initial ester hinders transesterification[21,27,28], while the presence of electrophilic groups (phenyl, acetyl, acetoxyl, carboxyl, nitrile, carbonyl) favours alcoholysis[21,29-34]. Transesterification is accelerated by the addition of mineral acids[33,35], sodium alkoxides[36-39], and in isolated cases pyrophoric lead[40], oxides of magnesium and lead, and acetates of cadmium, zinc, and cobalt or a mixture of the oxides and acetates of these metals[41].

Esters of boric[42], silicic[43-46], titanic[47-49], antimonous[50], arsenious[51,52], and phosphoric acids also undergo transesterification, but considerably less work has been done on these reactions.

II. TRANSESTERIFICATION OF NORMAL PHOSPHITES

Esters of acids containing tervalent phosphorus readily undergo transesterification, which involves all or only some of the ester groups depending on the conditions, the structure of the initial reactants, and especially the proportions of the latter. In the former case symmetrical esters are produced, and in the latter mixed esters:

$$(RO)_3P + 3R'OH \longrightarrow (R'O)_3P,$$
$$(RO)_3P + 2R'OH \longrightarrow (R'O)_2POR,$$
$$(RO)_3P + R'OH \longrightarrow (RO)_2POR'.$$

The most detailed study of the reaction has been made on the alcoholysis of triethyl phosphite.

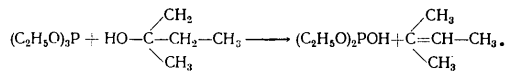
The exhaustive transesterification of triethyl phosphite was first studied by Arbuzov and Vinogradova: with a phosphite : alcohol molar ratio close to 1 : 3–4 in the presence of orthophosphoric acid, they obtained 30–50% yields of trihexyl, trioctyl, trinonyl, trihexadecyl, and tricyclohexyl phosphites[53]. The relatively low yield of products of complete transesterification is explained by the formation, with the above relative proportions of the reactants, of considerable quantities of mixed phosphites. This was subsequently confirmed by other investigators, who conducted the reaction in the presence of sodium alkoxides[54]. Even with a phosphite : alcohol ratio exceeding 1 : 5, unsymmetrical phosphites were detected among the reaction products[53-56]. With a ratio of 2 : 1 the reaction can be halted[55] at the first stage, i.e. at the formation mainly of monosubstituted products.

The mixed phosphites $(RO)_2POR'$ which are thus formed can react with another alcohol to form phosphites containing three different alkoxy-groups[54]:

$$(RO)_2POR' + HOR'' \longrightarrow (RO)(R'O)(R''O)P.$$

Derivatives of the lower alcohols are unstable and readily disproportionate on distillation. Mixed esters containing residues of higher alcohols are more stable to disproportionation: butyl dihexyl phosphite remains practically unchanged on distillation[54].

The character of the transesterification is greatly influenced by the structure of the initial alcohol. Whereas the alcoholysis of trialkyl phosphites by primary and secondary alcohols proceeds normally, diethyl hydrogen phosphite and 2-methylbut-2-ene have been isolated from the reaction between triethyl phosphite and t-pentyl alcohol[55]:

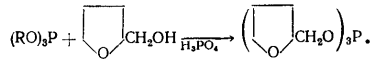


It was not established whether initial partial transesterification to diethyl isopentyl phosphite was followed by decomposition of the latter into the alkene and diethyl hydrogen phosphite, or whether the initial alcohol was dehydrated and the initial phosphite hydrolysed.

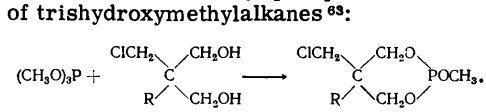
Alcoholysis by alcohols containing electronegative substituents (2,2,2-trichloroethanol, 2,2,2-trifluoroethanol) is extremely sluggish: with the latter alcohol only 4% of the monotransesterification product can be isolated[55]. This process goes considerably better with 2-alkylthioethanols, which possess less acidic hydroxyls[57-59]:

$$(RO)_3P + HOCH_2CH_2SR' \longrightarrow (RO)_2POCH_2CH_2SR'.$$

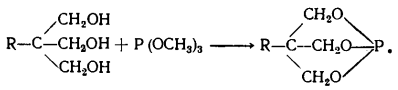
while with tetrahydrofurfuryl alcohol the product of complete transesterification is obtained in good yield[60]:



Trialkyl phosphites are transesterified not only by monohydric but also by polyhydric alcohols. However, few relevant data are available, and these are not soundly based. For example, it has been suggested that the use of glycol yields polyesters[61,62], although the conditions of the synthesis are not cited, and no evidence is given for the structure of the products. It is quite possible that in this case cyclic phosphites were obtained, as in the transesterification of trimethyl phosphite with monochlorohydrins of trishydroxymethylalkanes[63]:



Trialkyl phosphites react with trishydroxymethylalkanes themselves to form products of complete transesterification — bridged cyclic phosphites — which it is difficult to prepare by other methods[63]:



Phosphites are not transesterified by thiols, with which they interact to form hydrocarbons and phosphorothionates[64-66]:

$$RSH + P(OC_2H_5)_3 \longrightarrow RH + S{=}P(OC_2H_5)_3.$$

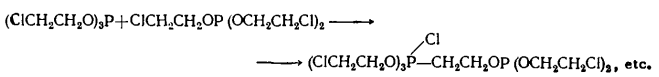
The reaction is catalysed by free radicals, and probably proceeds by a radical mechanism:

$$RS\cdot + P(OC_2H_5)_3 \longrightarrow RS{-}\dot{P}(OC_2H_5)_3,$$
$$RS{-}\dot{P}(OC_2H_5)_3 \longrightarrow R\cdot + S{=}P(OC_2H_5)_3,$$
$$R\cdot + HSR \longrightarrow RH + RS\cdot.$$

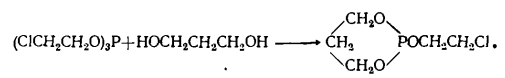
Benzenethiol reacts with triethyl phosphite to form diethyl hydrogen phosphite and ethyl phenyl sulphide[65]:

$$C_6H_5SH + P(OC_2H_5)_3 \longrightarrow C_6H_5SC_2H_5 + HOP(OC_2H_5)_2.$$

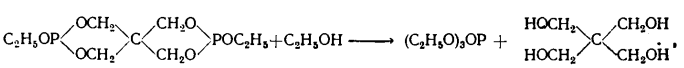
Phosphites of more complicated structure are also capable of undergoing transesterification. It has been stated that tris-2-chloroethyl phosphite can be completely transesterified more readily than triethyl phosphite with 2-ethylhexanol and benzyl alcohol even in the absence of a catalyst[62,67], but concrete data on the yields of the final products of alcoholysis are lacking. It was reported[67] that transesterification was accompanied by alkylation of the tris-2-chloroethyl phosphite with formation of a mixture of difficultly separable products:



Reaction of tris-2-chloroethyl phosphite with propane-1,3-diol leads to the formation of a cyclic phosphite[68]:



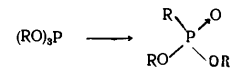
Another example of the alcoholysis of a complex phosphite is the transesterification of the dicyclic ester formed by pentaerythritol with two molecules of ethyl dihydrogen phosphite



which also occurs under milder conditions than with simple phosphites[69].

The transesterification of triaryl phosphites has been studied mainly on the reactions of triphenyl phosphite with monohydric alcohols, glycols, and polyhydric phenols. This reaction also occurs in stages, but under milder conditions than with trialkyl phosphites.

The earliest data on the possibility of transesterifying esters of acids containing phosphorus were obtained in 1917 by Milobendzki and Szulgin using triphenyl phosphite[70]. These workers first tried to transesterify triphenyl phosphite with methanol and propanol by heating in glass tubes, but obtained negative results: under the experimental conditions the trialkyl phosphites formed isomerised into alkylphosphonates:



The complete transesterification product could be obtained only by using the alkoxides instead of the alcohols[70]:

$$(C_6H_5O)_3P + 3RONa \longrightarrow (RO)_3P + 3C_6H_5ONa.$$

Considerably later, a communication appeared on the preparation of trimethyl and triethyl phosphites by complete transesterification of triaryl phosphites with alcohols[71]. It was remarked that the reaction goes smoothly in the presence of calcium or lead oxide, or sodium phenoxides or alkoxides. According to results obtained by the present Reviewers, the transesterification of triaryl phosphites with methanol and ethanol yields a difficultly separable mixture of products[72]. Satisfactory (60–99%) yields of the complete transesterification products are achieved only by using alcohols containing six or more carbon atoms and 2-naphthol.

The partial transesterification of triaryl phosphites has been studied more thoroughly[73-76]. Alkyl diaryl phosphites have been obtained by the reaction of triphenyl and tritolyl phosphites with butanol, octanol, hexadecanol, and cyclohexanol in equimolecular proportions. Mixed phosphites containing higher alkyl radicals, e.g. hexadecyl, have found application as antioxidants for lubricating oils[73,74].

Triaryl phosphites are readily transesterified by various substituted alcohols, the completeness of the transesterification being found to depend on the proportions of the reactants. When allyl and 2-methylallyl alcohols are used with a phosphite : alcohol ratio close to 1 : 6, trialkenyl phosphites are obtained[77]:

$$(C_6H_5O)_3P + HOCH_2CH{=}CH_2 \longrightarrow (CH_2{=}CH{-}CH_2O)_3P.$$

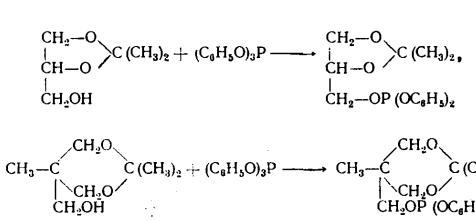
At lower concentrations of the alcohol mixed alkenyl aryl phosphites are observed in the reaction products. Alcoholysis of triaryl phosphites (one mole) with aminoalkanols (one equivalent) yields partly substituted products[78]:

$$3(C_6H_5O)_3P + (HOCH_2CH_2)_3N \longrightarrow [(C_6H_5O)_2POCH_2CH_2]_3N.$$

Triphenyl phosphite reacts with glycols to form cyclic phosphites[79]:

With glycols in which the hydroxyls were well separated ($n > 5$) polymeric products were formed, but were not characterised.

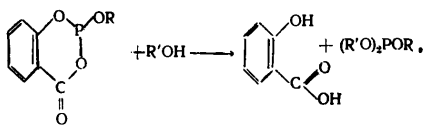
Transesterification of triphenyl phosphite with the isopropylidene derivatives of glycerol and metriol in equimolecular proportions gives high yields of the isopropylidenedioxyalkyl diphenyl phosphite, only one ester group of the phosphite being transesterified[80]:



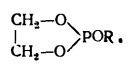
Reaction of triphenyl phosphite with cellulose at 130–135° yields a phosphorylated cellulose containing up to 5–6% of phosphorus[81].

When dihydric and trihydric phenols are used in this reaction, good yields are obtained of cross-linked or branched poly(arylene phosphites)[82]. The phenolic components used were quinol, 2,2-diphenylpropane-*pp'*-diol, and benzene-1,2,4-triol. Phenolysis occurred quite readily, and was accompanied by separation of almost the theoretical quantity of phenol. The presence of catalysts has little influence on the transesterification or the quality of the polymers. Poly(arylene phosphites) of network structure form an infusible, stable vitreous mass, which is insoluble in organic solvents.

Alkyl salicyloyl phosphites react with alcohols to form a mixed trialkyl phosphite and salicylic acid[83]:



The first stage probably involves cleavage of the anhydride link with formation of an *o*-dialkoxyphosphino-oxybenzoic acid, after which the aromatic radical of the phosphorous ester undergoes transesterification. The reaction goes vigorously with ethanol, isopentyl alcohol, and ethylene glycol, with formation in the last case of a cyclic ester



III. TRANSESTERIFICATION OF ACID PHOSPHITES

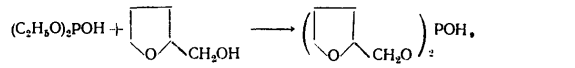
Dialkyl and diaryl phosphites, like normal phosphites, are transesterified by monohydric alcohols, glycols, and polyhydric phenols. The reaction occurs in stages (complete and partial), and can be terminated at the formation of unsymmetrical phosphites.

The complete transesterification of dialkyl phosphites was used for the first time by Arbuzov and Vinogradova for the synthesis of higher dialkyl phosphites[43]. With a phosphite : alcohol molar ratio of 1 : 2 in the presence of orthophosphoric acid they obtained symmetrical dialkyl phosphites mixed with considerable quantities of unsymmetrical phosphites, resulting from partial alcoholysis.

Interaction of dialkyl phosphites with cyclohexanol, benzyl alcohol, octan-2-ol, and ethylene glycol gave a complex mixture, from which pure substances could not be isolated. It was later found that the formation of transesterification products is accelerated in the presence of alkaline catalysts and an increased molar ratio of alcohol to phosphite[84–86]. With a phosphite : alcohol ratio of 1 : 3 in the presence of sodium ethoxide, symmetrical dialkyl phosphites were obtained in yields of 70–90%.[83]

The complete transesterification of dialkyl phosphites by aliphatic alcohols goes smoothly in xylene (with yields up to 85%) and in the absence of a catalyst[87]. Bis-2-ethylhexyl and bis-2-chloroethyl phosphites have been obtained in this way; in the presence of orthophosphoric acid without a solvent the yield of the latter is only 43%.[88]

Transesterification of diethyl phosphite with tetrahydrofurfuryl alcohol and 2-methoxyethanol in the presence of sodium gave the complete substitution products in yields of 44%[89] and 60.5%:[88]



$$(C_2H_5O)_2POH + CH_3OCH_2CH_2OH \longrightarrow (CH_3OCH_2CH_2O)_2POH.$$

When diethyl phosphite was treated with β-hydroxypropionitrile in proportions of 1 : 3 in the presence of phosphoric acid, a 30% yield of the product of complete transesterification was obtained[88]. The reaction of phosphorus trichloride with β-hydroxypropionitrile results in a complex mixture of products, which it is almost impossible to separate[90].

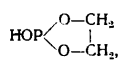
Complete replacement of alkoxy-groups has been reported in the transesterification of simple dialkyl phosphites with alcohols containing ethylenic and acetylenic bonds[91]. The reaction of bis-2-chloroethyl phosphite with 2-ethylhexan-1-ol occurs similarly[87]. Alcoholysis of dialkyl phosphites occurs more readily the more strongly electrophilic the substituents in their ester groups. Thus diethyl phosphite is transesterified by decanol at 160–170°, bis-2-chloroethyl phosphite at 140–150°, and bis-2-fluoroethyl phosphite at 120–130°.[88] With equimolecular proportions of the reactants in the presence of orthophosphoric acid or sodium ethoxide, or in the absence of a catalyst, mixed dialkyl phosphites are formed in yields of 24–45%.[43,85,92]

Unsymmetrical phosphites can be used to obtain various unsymmetrical esters of phosphoric and phosphonic acids[93], individual representatives of which possess physiological activity.

The transesterification of dialkyl phosphites with glycols is of great interest. Several papers have been published on the reactions of diethyl hydrogen phosphite with ethylene glycol, but results obtained by different investigators are mutually contradictory. It has been reported[68] that in the presence of sodium a bisphosphite containing a ten-membered ring is obtained:

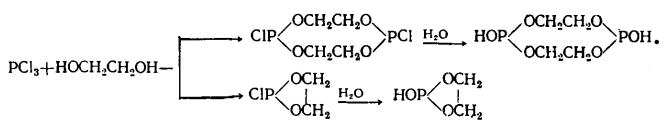
while with other glycols, in particular propane-1,2-diol, a phosphite containing a five-membered ring is formed:

Several other papers suggest that the transesterification of dialkyl phosphites with glycols, mainly ethylene glycol (under similar conditions), yields polymeric products[94–96]. In no case, however, is any evidence given for the structure of the substances which are formed. Nevertheless, we cannot exclude the formation, in the transesterification of diethyl phosphite with a glycol, of a linear bisphosphite — the partial transesterification product $C_2H_5OP(OH).OCH_2CH_2OP(OH)OC_2H_5$ — and the five-membered cyclic phosphite



which are similar in composition to the ten-membered cyclic bisphosphite. The linear bisphosphite is unknown;

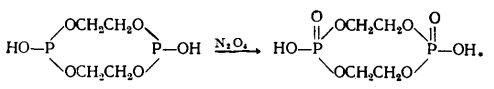
cyclic mono- and bis-phosphites have previously been obtained from the same starting materials under analogous conditions[97-103], and their structures have also not been proved:



It has subsequently been shown, as a result of a detailed study of this reaction[104], that, with equimolecular proportions of diethyl phosphite and glycol in the presence of sodium at 135–140° (200 mm) a substance is obtained which distils almost completely under vacuum. Elementary analysis and molecular weight determination† show it to correspond to a ten-membered cyclic bisphosphite.

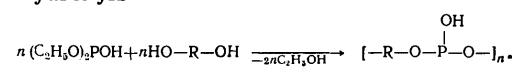
The same product is obtained by the action of ethylene glycol on bis-2-chloroethyl phosphite.

On oxidation with nitrogen dioxide the cyclic bisphosphite is converted into the corresponding bisphosphate, which can be titrated as a dibasic acid:



Polyesters containing two or three residues of the starting materials are formed when diethyl phosphite is transesterified with di-, tetra, and hexa-ethylene glycols, propylene glycol, butane-1,3-diol, butane-1,4-diol, but-2-yne-1,4-diol, and bis-2-hydroxyethylamine[96].

Polyphosphites of high molecular weight are readily formed by the reaction of diethyl phosphite and other simple dialkyl phosphites with glycols which either possess spatially isolated hydroxyls or are unstable in conformations with adjacent hydroxyls[105,106]:



Positive results were obtained with the following glycols — pentane-1,5-diol, hexane-1,6-diol, diethylene glycol, triethylene glycol, diethanols, pentafluoropentane-1,5-diol, 1,4:3,6-dianhydrosorbitol, *p*-bishydroxymethylbenzene, and 2,2-bischloromethylpropane-1,3-diol — but polyphosphites could not be obtained with 1,4-diols, dehydration of the glycol probably occurring in this case with the formation of tetrahydrofuran.

Polyphosphites were synthesised by heating an equimolecular mixture of the reactants with a catalytic quantity of metallic sodium in a stream of an inert gas at 130–150°,

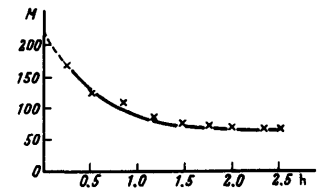


Fig.1. Dependence of molecular weight *M* of diethylene bisphosphite on time of storage of the solution .

first at atmospheric pressure and then at reduced pressure (200 mm). Reaction was complete in 5–6 h. It is considerably more difficult to transesterify phosphites with 1,4:3,6-dianhydrosorbitol and pentafluoropentane-1,5-diol. This is probably due in the first case to the use of a secondary alcohol, and in the second case to the fact that the glycol is considerably more acidic than the other diols. Better results are obtained in the transesterification of bis-2-chloroethyl phosphite.

The polyphosphites obtained are thick liquids or vitreous materials, faintly yellowish, and soluble in most polar organic solvents; polyphosphites containing a heteroatom in the alkylene radicals are soluble in water. An exception to this rule is provided by the polyphosphite obtained from *p*-bishydroxymethylbenzene, which dissolves in no known solvent. This polymer is distinguished also by high thermal stability: under conditions of prolonged heating it begins to change only at 300–500° (Fig. 2).

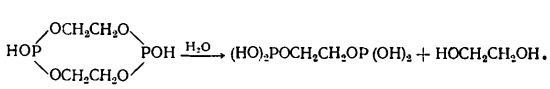
The linear polyphosphites had molecular weights of $23-150 \times 10^3$ determined by light scattering.

As the excess of glycol in the reaction mixture is increased, polymers of lower specific viscosity are formed on transesterification. The regular fall in viscosity of the products is probably due to the formation of oligomers under the given conditions.

Thus the transesterification of dialkyl phosphites with glycols is a convenient method of synthesising polyphosphites. From the point of view of practical application, however, the method has the disadvantage that many glycols are still relatively difficult to obtain. It is therefore of interest to use the readily accessible polyols — glycerol and pentaerythritol[106,107].

The molecular weights of the polyphosphites obtained do not usually exceed 1000–1500, probably owing to contamination of the polyesters with cyclic phosphites of the polyols. On prolonged storage and heating, the cyclic esters are converted into polymeric compounds, since the specific viscosities of the solutions are greatly increased.

† The molecular weight was determined cryoscopically in water. Its value depends on the time of storage of the solution, the maximum of 220 (found by extrapolation) falling to 60 and then remaining unchanged for a long time (Fig. 1). This is probably explained by hydrolysis of the cyclic bisphosphite:



Titration of the hydrolysis product showed that a dibasic acid had been formed.

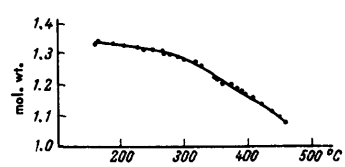


Fig.2. Thermal stability of poly-(*p*-xylylene phosphite).

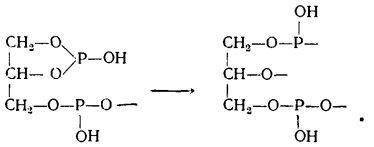
Thus the product obtained from glycerol and diethyl phosphite, for example, having a specific viscosity of 0.36, has almost double this viscosity after storage for 2 months; after heating at 175–180° for 10 h the viscosity rises to 0.50, and for 20 h to 0.74.



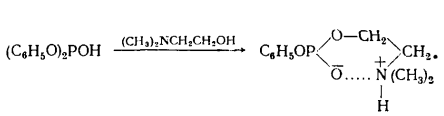
Transesterification of diethyl phosphite with cellulose in the presence of sodium at 160–165° yields a cellulose phosphite containing up to 6.4% of phosphorus[81].

Poly(arylene phosphites) have been obtained by the transesterification of dialkyl phosphites with dihydric phenols[106,108–110].

The transesterification of diaryl phosphites has been studied only with diphenyl phosphite, which is almost quantitatively transesterified by butyl, isopentyl, hexyl, octyl, nonyl, and decyl alcohols even at 100° without the phenol being distilled off from the reaction mixture during the process[111,112]. The duration of the reaction depends on the molecular weight of the alcohol used, normally varying over the range 4–10 h. The synthesis goes smoothly both in the presence and in the absence of a catalyst (sodium). Yields of the products of complete transesterification are 90–95%. It is noteworthy, however, that our own experiments under the conditions described have not given positive results.

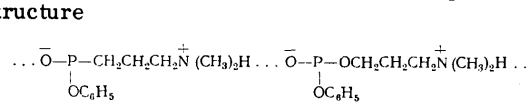
Diphenyl phosphite reacts readily with substituted alcohols[111]. The reactions with 2-chloroethanol and ethyl glycollate, for example, gave the complete transesterification products in yields of 93% and 94% respectively.

Diphenyl phosphite is also readily transesterified by aminoalcohols. When equimolecular quantities of diphenyl phosphite and dimethylaminoethanol are mixed, for example, heat is evolved, and one mole of phenol separates; the crystalline product is formed in almost quantitative yield. The substance is soluble in water and is readily oxidised. In view of this, and also the results of elementary analysis, the compound may be assumed to be an internal salt of dimethylaminoethyl phenyl hydrogen phosphite:

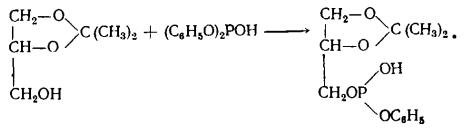


Diethylhydroxyethylmethylammonium iodide reacts with greater difficulty.

Alcoholysis of diphenyl phosphite with dimethylaminopropanol under similar conditions yields a thick oil, which does not crystallise on prolonged standing. The product is soluble in certain polar organic solvents, e.g. in *p*-cresol. Its molecular weight (determined cryoscopically in this solvent) is 4000. The structure of the polymer was not elucidated. By analogy with the product of the transesterification of diphenyl phosphite with dimethylaminoethanol, we may assume that in this case the polymer has the structure

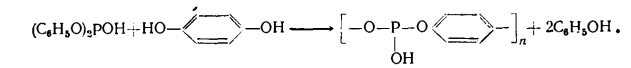


Alcoholysis of diphenyl phosphite with isopropylidene derivatives of glycerol and metriol gives good yields of the isopropylidenedioxyalkyl phenyl hydrogen phosphites[80]:



Cross-linked polyphosphites have been obtained by the transesterification of diphenyl phosphite with α-methyl-, *N*-phenyl-, and α-propyl-glucosides[113].

Reaction of diphenyl phosphite with quinol yields a poly(arylene phosphite)[62]:



The poly(arylene hydrogen phosphite) is unstable to hydrolysis whether in neutral, acid, or alkaline medium.

Diethyl phosphorothioite is transesterified by alcohols with considerably greater difficulty than are dialkyl (or diaryl) phosphites: in this case only 32–39% yields of the partial substitution products are obtained[114]:

IV. TRANSESTERIFICATION OF PHOSPHONITES

Few papers have been published on the transesterification of normal esters of alkylphosphonous acids. The complete transesterification of diethyl butylphosphonite with butanol in the presence of metallic sodium occurs more readily than in the case of phosphites[115]. Transesterification of simple phosphonites with substituted alcohols containing electrophilic groups takes place under more severe conditions[88], the yields of the complete transesterification products being considerably diminished. Thus diethyl phenylphosphonite is transesterified by ethyl glycollate, tetrahydrofurfuryl alcohol, and furfuryl alcohol in the presence of sodium to give yields of 40.7%, 61.5%, and 19.2% respectively. In the absence of catalysts the alcoholysis of phosphonites results in the formation of mixtures of complete and partial transesterification products[58,116]. Unsymmetrical phosphonites, obtained by the transesterification of phosphonous esters with 2-alkylthioethanols, have been used for the synthesis of Systoxes[58,117].

The polytransesterification of dimethyl and diethyl phenylphosphonites and diethyl ethylphosphonite with equimolecular quantities of various glycols has been investigated[118]. The rate and the degree of completion of the reaction decrease in the sequence ethylene, diethylene, and tetraethylene glycols. The reaction was found to involve the intermediate formation of cyclic phosphonous esters.

The transesterification of diethyl phenylphosphonite with glycerol and pentaerythritol has been studied[107] with various relative proportions of the reactants and under various temperature conditions. The best results were obtained at 140°. The polymers obtained were thick, viscous liquids or vitreous masses, yellow or light brown in colour, insoluble in water but soluble in benzene and dichloroethane; many of the polyesters were soluble in

ethanol and dimethylformamide. Bis-2-chloroethyl phenylphosphonite shows a great tendency to transesterification [119], undergoing the reaction even at 30–40°.

Phenyl esters of alkyl(or aryl)phosphonous acids react readily [72]:

$$RP(OC_6H_5)_2 \xrightarrow{R'OH} RP(OR')_2,$$

the yields of the complete transesterification products being 78–84%. Diphenyl methyl- and phenyl-phosphonites have been successfully employed for the phosphorylation of various nucleotides [120] and glucosides [113], mixed esters being obtained in the first case, and network polyphosphonites in the second case.

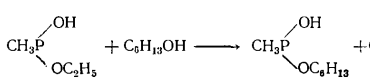
The transesterification of aromatic esters of phosphonous acids with dihydric and trihydric phenols yields poly(arylene phosphonites) [82]:

$$RP(OC_6H_5)_2 + HOR'OH \xrightarrow{-C_6H_5OH} \left[-\underset{\displaystyle R}{\overset{|}{P}}-OR'O-\right]_n,$$

where R = CH_3, C_6H_5 and R′ = C_6H_4, $C_6H_4.C_6H_4$, $C_6H_4.C(CH_3)_2.C_6H_4$. Diphenyl methyl- and phenyl-phosphonites have been used as the phosphorus-containing components, and quinol, biphenyl-*pp*′-diol, and 2,2-diphenylpropane-*pp*′-diol as the phenolic components. Phenolysis was accomplished quite readily, and was accompanied by the separation of almost the theoretical quantity of phenol. The yields of polyphosphonites were close to quantitative.

Hardly any work has been done on the transesterification of dialkylphosphinous esters. There is only the statement that the alcoholysis of propyl dipropylphosphinite with β-hydroxypropionitrile, 2-hydroxyethanol, and furfuryl alcohol in the presence of sodium gives the complete transesterification products in yields of 44.3%, 28.4%, and 36.3% respectively [88].

A detailed study has been made of the transesterification of acid esters of methylphosphonous acid. The dependence of the reaction on the temperature conditions, the relative proportions of the reactants, and the catalyst has been investigated with the interaction of ethyl hydrogen methylphosphonite and hexan-1-ol as example [121]:



The best results are obtained with equimolecular proportions of the reactants in the presence of metallic sodium as catalyst at 150–160°. The temperature can be somewhat lower if the process is conducted in a slight vacuum, but the yield of phosphonite is then diminished. A definite though smaller catalytic effect is also shown by zinc borate; zinc chloride, orthophosphoric acid, and aluminium chloride impede transesterification.

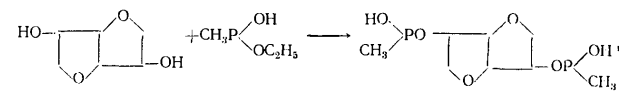
The transesterification of phosphonites takes place more readily the lower the molecular weight of the alkoxy-residue. Under optimum conditions (after 5 h) the yields obtained with hexan-1-ol were respectively 71.5% and 44.4% for methyl and isopropyl methylphosphonites. Methyl methylphosphonite (yield 64.3%) constitutes an exception to this rule, for it partly decomposes under the reaction conditions.

Transesterification occurs more readily with primary alcohols, and less readily with secondary alcohols [121]. Attempts to effect alcoholysis with tertiary alcohols (in the case of 1,1-dimethylpentan-1-ol) were unsuccessful.

Investigation of the transesterification of ethyl hydrogen methylphosphonite with alcohols containing functional groups has shown that the yield of ester depends substantially on the nature of the substituent and on its position in the alcohol molecule: the more electrophilic the substituent and the closer it is to the carbon atom attached to the hydroxyl the more difficult is it to effect transesterification [88]. Thus 2-chloroethanol reacts with greater difficulty (yield 45%) than does 3-chloropropanol (60%), furfuryl alcohol (10%) reacts less readily than does tetrahydrofurfuryl alcohol (69.7%), etc. Ethyl hydrogen methylphosphonite readily undergoes alcoholysis with 2-methoxyethanol and aminoethanol, the yields of the transesterification products being 70% and 100% respectively.

Ethyl hydrogen methylphosphonite reacts smoothly with glycols to give good yields of bismethylphosphonites [122], e.g.

A similar reaction occurs with 1,4:3,6-dianhydromannitol:



as also with 1,2:3,4-di-isopropylidenegalactose [123]. Transesterification of ethyl hydrogen methylphosphonite with 1,4:3,6-dianhydrosorbitol occurs under more severe conditions, and yields only the monophosphonite of dianhydrosorbitol. When isopropylidene derivatives of glycerol and metriol are used in this reaction, the isopropylidenedioxyalkyl phosphonites are formed in high yields [80].

It has not proved possible to transesterify an acid ester of methylphosphonous acid with ethylene glycol to involve only one of the hydroxyls: in all cases, even with a large excess of the glycol present, only the bisphosphonite is formed [122].

The bisphosphonites obtained are thick liquids or else solids, which can be distilled without decomposition only in a high vacuum. They are sparingly soluble in most of the usual solvents; the simplest of them are soluble in water and in alcohol [124].

A phosphorylated cellulose having a high phosphorus content (up to 19.1%) has been obtained by transesterifying methyl and ethyl hydrogen methylphosphonites with cellulose, while a phosphorylated polysaccharide containing up to 23% of phosphorus has been obtained with inulin [81].

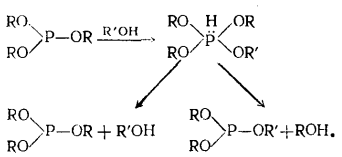
Diethyl methylphosphonodithioite reacts with both primary and secondary alcohols to form methylphosphonous esters [125]:

$$CH_3P(SC_2H_5)_2 + 2ROH \longrightarrow CH_3P(OR)_2 + 2C_2H_5SH.$$

The yield of phosphonites did not exceed 25–50%, being lower than in the transesterification of acid phosphonous esters. The probable reason is that the thiol liberated in the reaction and its oxidation product (disulphide) interact with the phosphonite to form a complicated mixture of compounds.

V. MECHAMISM OF THE TRANSESTERIFICATION OF ESTERS OF ACIDS FORMED BY TERVALENT PHOSPHORUS

No detailed study has been made of the mechanism by which esters of acids containing tervalent phosphorus are transesterified. The mechanism is assumed[55,121] to involve alternating addition of a proton to the phosphorus atom with addition of an alkoxide anion to the phosphonium cation and elimination of alcohol from the intermediate product containing quinquevalent phosphorus to form either the original or a different phosphite or phosphonite:



Indirect evidence for the formation of an intermediate addition product is provided by data on the mechanism of the Arbuzov reaction and its various modifications, and also by experimental results on the alcoholysis of esters of tervalent phosphorus acids.

The primary step in the reaction is necessary but insufficient to achieve transesterification of the phosphite (or phosphonite). As shown above, the adduct can break down in two ways. An equilibrium is established in the alcoholysis of any phosphite with any alcohol:

Transesterification will take place if the equilibrium is displaced to the right, i.e. if an alkoxyl (or phenol residue) of the original phosphite — not the alkoxyl of the alcohol taken for the transesterification — splits off from the adduct. Thus the second step in the reaction — cleavage of the addition product — plays the decisive part in the process of transesterification, and probably determines not only the direction but also the rate of the reaction.

Which alcohol will be eliminated from the intermediate product depends directly on the electrophilic character of the alkoxy(or phenoxy)-groups involved. It is obvious that the more electrophilic an alkoxyl the more preferentially will it be eliminated together with a proton in the form of the "more acidic" alcohol. Hence it is desirable, in the preparation of phosphites by transesterification, for the alkoxy-groups in the original phosphite to be more electrophilic than the alkoxyl of the alcohols used in the reaction.

The above arguments are consistent with data obtained for the transesterification of diethyl, bis-2-chloroethyl, bis-2-fluoroethyl, and diphenyl phosphites with decanol, of diethyl phosphite with β-hydroxypropionitrile, 2-chloroethanol, and 2-methoxyethanol, of ethyl hydrogen methylphosphonite with aminoethanol, 2-methoxyethanol, β-hydroxypropionitrile, 3-chloropropanol, etc.

The transesterification equilibrium can be shifted to the right by distilling off the alcohol which is liberated. This procedure is widely used to prepare various phosphites when the liberated alcohol boils at a lower temperature than the original alcohol.

Another possible mechanism consists in attack on the oxygen atom by an alkyl cation (formed by heterolytic cleavage of the alcohol) with simultaneous liberation of the alkyl cation of the original ester[55]:

However, this reaction is only of secondary importance, since transesterification with the two optically active butan-2-ols and with optically active neopentanol yields phosphites which on hydrolysis give alcohols having 75% and 100% respectively of the original optical activity. If only the second type of reaction had taken place, hydrolysis of the products of transesterification should have produced optically inactive alcohols.

I. INTRODUCTION

The chemistry of sulphide phosphors of the ZnS type is an important and very interesting area of solid state chemistry†. Because of their high luminescence efficiency under a variety of excitation conditions, and of the unusually wide range of their properties, crystal phosphors of this class have found extensive technical applications in television tubes, radar screens, oscilloscopes, electron--optical converters, X-ray screens, electroluminescent panels, electron microscopes, dosimeters and detectors of different types of radiation, etc. Cadmium sulphide crystals, which belong to the same class of materials, are among the most sensitive photoconductors.

The influence of very small traces of impurities on these two properties of crystalline sulphides — luminescence and photoconductivity — was recognised at the turn of the century. The efficiency with which the absorbed radiant energy is transformed into visible light (of spectral composition determined by the nature of an impurity, termed the activator) suggested that energy transfer takes place from the sites where energy is absorbed to the sites where the activator is located. This gave rise to the theory that the luminescence centres are special groupings where the act of light emission occurs. The ability of ZnS and CdS crystals to transmit the absorbed energy with high efficiency to the luminescence centres accounts for their high luminescence yield, their high photoconductivity, and the extreme sensitivity of phosphors of this class to a number of impurities, which can effect the optical properties of these phosphors even at a concentration of 10^{-6}–10^{-8} gramme per gramme of the sulphide.

Elucidation of the nature of the luminescence centres and of the relationship between the optical properties of phosphors and the structure of these centres, being one aspect of the more general problem of establishing the relation between the atomic-molecular structure and the properties of materials, is the key problem in luminescence and is of great importance in the general development of solid state chemistry and physics. Yet the first serious studies in this field began only towards the end of the 1940's, when research on the kinetics of luminescence and on the accompanying internal photoeffect provided, on the basis of the band model of solids, a fairly orderly picture of the physical effects involves in the luminescence of zinc sulphide luminous compositions. The work done in the last 15–20 years and still in progress has significantly changed our ideas on the nature of the luminescence centres and on the processes by which they are formed, and has made it clear that the solution of the problem lies in the domain of chemistry to a much greater extent than had originally been realised. Many difficulties still remain to be overcome, in particular those associated with the extreme sensitivity of the optical properties of zinc sulphide phosphors to various impurities present at a concentration level which defies analytical control with the required degree of precision, and also with our inadequate knowledge of the nature of structural defects and of the role played by these defects in the formation of sulphide phosphors. The situation is made worse by the abundant literature and by the close interplay of chemistry and physics: as a result, authors attempting to interpret their

† Luminescent crystals of zinc sulphide were prepared for the first time 100 years ago by Sidot, in Sainte-Clare Deville's laboratory.

results are often unaware of many relevant factors discussed in earlier publications. This causes a great deal of confusion and inconsistency in many of the papers devoted to the present problem. Hence, a review article discussing the work of all the main research schools and all the most important points of view would be very timely: such is the aim of the present paper, with the stipulation that we shall not attempt to consider all the questions which have a bearing on our problem. The reason for this is that zinc sulphide phosphors contain centres of two types. One type of centres, for example those produced by manganese or rare-earth ions, gives rise to luminescence as a result of electronic transitions within the activator ion itself ("direct activation"). The radiation from centres of the second type is not characteristic of the particular activator to the same extent. Thus, ZnS phosphors activated by impurities as diverse as Ag, Cu, Al, and Cl, can, under certain preparative conditions, produce blue radiation of very similar spectral composition. In this case we cannot ascribe the observed luminescence to electronic transitions within the ions (or atoms) of the activator. Centres of this second type are the most characteristic of zinc sulphide phosphors, the most important from a practical point of view, the most thoroughly investigated, and the least understood. The present paper is devoted to a discussion of centres of this type.

II. ACTIVATORS AND COACTIVATORS

1. Luminescence Centres Produced by Activators

Luminescence centres were originally thought to be rather coarse aggregates of many atoms, but in the early 1930's the suggestion was put forward, on the basis of several results, that the centres consist of single atoms (or ions) of the activator located at lattice or interstitial sites[1-4]. It has been commonly assumed, with Lennard[5], that only heavy metal atoms can act as activators. Since their energy levels are closely spaced[6], they emit radiation which is not absorbed by the phosphor matrix. The discovery[7] that zinc sulphide can emit bright blue luminescence in the absence of any deliberately added activators had a marked effect on the development of views on luminescence centres. This discovery was made possible by the improved methods of preparation of sulphide of a high degree of purity. An analogous phenomenon was observed with zinc oxide. Since it was assumed that only metals can serve as activators, the effect was interpreted as self-activation by the excess of zinc produced by thermal dissociation of the zinc oxide and sulphide[8], experimental confirmation being forthcoming in the case of ZnO. Arguing that ZnS should behave very much like ZnO, Seitz[2,9] suggested that free atoms of Zn give rise to luminescence centres by moving to interstitial sites, and that activation by silver and copper occurs by a similar mechanism. In favour of this point of view, Riehl and Ortmann[10] put forward some arguments based on earlier experiments by Tiede and Weiss[11], who had shown that, when a mixture of roasted ZnS and copper sulphide is heated, the diffusion of Cu, leading to the formation of luminescence centres, begins at a temperature as low as 330°. Adopting an ionic model for zinc sulphide, we can think of the material as an array of close-packed sulphur ions with half of the tetrahedral cavities occupied by zinc ions[12]. The presence of free tetrahedral cavities accounts, according to Riehl and Ortmann, for the diffusion of the activator deep into the lattice even at relatively low temperatures, the process being assisted by the fact that the activator enters the lattice in the form of atoms rather than ions. However, Riehl and Ortmann subsequently rejected[13] the last assumption. Bundel'[14] produced additional arguments in favour of the Schleede–Seitz–Riehl hypothesis. According to his observations, the quenching of luminescence produced by heating the phosphor in sulphur vapour occurs more readily the lower the dissociation pressure of the sulphide of the activator metal. This may be due to the fact that activation occurs when activator atoms formed by thermal decomposition of their sulphides are introduced into the crystal lattice[15]. Bundel' quotes as further evidence for this point of view the fact that luminescence quenching by vacuum heat-treatment occurs more readily in "self-activated" phosphors than in phosphors activated by copper or silver, in keeping with the greater volatility of Zn and Cd as compared with Ag and Cu[16]. Very similar views were put forward by Cherepnev[17-20], who considered that the activator may be present in zinc sulphide in a state involving different degrees of dispersion.

The model according to which luminescence centres are formed by free atoms of the activator was dominant until the end of the 1940's. However, several authors have doubted the correctness of the suggested "self-activation" of zinc sulphide by zinc in excess of stoichiometry when the material has been heat-treated in the presence of a flux and oxygen[21], and also the possibility that copper can exist in an atomic state in zinc sulphide[22] and that ZnS–Ag luminescence centres are created by atomic silver. (The latter assumption is inconsistent with the deleterious effect of a reducing atmosphere on ZnS–Ag[23].) A fundamental defect of the above model, stressed by a number of workers[21,24,25], is that it fails to explain a very remarkable feature of zinc sulphide phosphors — the favourable effect of halides, commonly used as fluxes, on their formation — which was noted long ago in the literature[5,26]. Whereas the flux used in the preparation of other phosphors serves only to lower the temperature to which the charge has to be heated, and often is not merely unnecessary but may even diminish the brightness of the luminescence[24], in the case of sulphides the use of halide fluxes (usually alkali or alkaline-earth metal chlorides) is essential to the achievement of efficient luminescence. Schlegel[27] pointed out that considerable quantities of $ZnCl_2$ are formed when ZnS is heated with NaCl, and, whilst ascribing this to reaction between the ZnS and NaCl, he nevertheless suggested that the role of the flux is to assist dissociation of the sulphide of the activator metal. Gugel'[28] stressed the importance of exchange reactions between ZnS and the chlorides of alkali and alkaline-earth metals, and suggested that these reactions assist diffusion of the activator into the crystal lattice of the sulphide by eroding the surface. The direct participation of chlorine in the formation of luminescence centres has also been considered[24,29]. An important function of the chloride, unrelated to its mineralising action, was convincingly demonstrated by Strange[24], who heated ZnS in evacuated quartz bulbs at 1000° for several hours, and found that the characteristic green luminescence of ZnS–Cu appeared in the presence of 0.001% CuS and an equivalent amount of NH_4Cl, but that the luminescence was weak or altogether absent in the presence of CuS alone (i.e. without NH_4Cl) or when the ZnS was heated without any intentional additive. A similar result was obtained with silver.

The role of halides in the formation of phosphors was examined in detail in a series of papers by Kröger[30-33], which marked the beginning of a new stage in the study of the nature of luminescence centres. Whereas the first stage of these researches, discussed above, was made possible by the development of effective methods for the purification of zinc sulphide from metallic activators, especially Cu, and luminescence "quenchers", such as Fe, Ni, Co, which led to the discovery of "self-activated" ZnS phosphors, the second stage began when attention was turned to the need to remove anionic impurities as well from the experimental material. In order to remove the chloride and oxygen present in commerial "phosphorescent grade" ZnS, Kröger subjected the material to a preliminary heat-treatment in a stream of H_2 or H_2S. Later workers[34-37] recommend deoxidation and dechlorination of ZnS by a two-stage treatment in hydrogen sulphide, first at a relatively low temperature (400°), and then at a more elevated temperature (900–1200°), because if the process is carried out with a high initial temperature the recrystallisation which occurs at the same time inhibits the removal of impurities from deep within the crystals. Another experimentally valuable innovation introduced by Kröger was to replace heating with a flux by heating in an atmosphere of HCl and H_2S. This permitted a more precise regulation of the preparation process and made it easier to interpret the results. The method has since found technical applications, particularly in the synthesis of electroluminescent materials[38,39].

Kröger showed, in agreement with the results of Strange[24], that ZnS–Cu, ZnS–Ag, and ZnS s/a ("self-activated") phosphors are not formed in an atmosphere of H_2S when the system is free from chlorine. The normal luminescence appears on heating in a stream of gas containing HCl. The refinements in experimental technique mentioned above allowed these phenomena to be observed with satisfactory reproducibility. Kröger interpreted his results on the basis of the principle of charge compensation, well known from crystal chemistry and mineralogy[40,41] and successfully applied to the chemistry of semiconductors[42]. Essentially, this principle states that in the formation of substitutional solid solutions the sum of the charges on the substituent ions must be equal to the sum of the charges on the ions replaced. This principle is a simple corollary of the requirement that the electrical neutrality of the crystal must be preserved. If, for example, a Zn^{2+} ion is replaced by a Cu^{+} ion, the result is to create a defect with an effective charge of -1, which we propose to denote Cu'_{Zn}. This charge can be compensated by the simultaneous insertion of a Cl^- ion in an S^{2-} site, which produces a defect with an effective charge of +1 ($Cl^{\cdot}_{S}$). In the absence of chlorine, compensation can be achieved by the formation of an anion (sulphur) vacancy of effective charge +2 ($V^{\cdot\cdot}_{S}$) and therefore able to balance the charges of two Cu′ defects; however, Kröger regards the formation of solid solutions in which the compensation is of this type as thermodynamically the less probable. In the terminology of crystal chemistry[41], the formation of normal isomorphous mixed crystals ZnS.CuCl with heterovalent replacement (mixed crystals of a new kind, in Grimm's terminology) proceeds more readily than the formation of anomalous mixed crystals $ZnS.Cu_2S$ with addition or subtraction. ZnS and CuCl have the same atomic ratios of constituent elements and therefore have chemical formulae of the same type, similar atomic dimensions, and a similar bond type[43]. Hence, the two compounds are isomorphous, and are quite likely to form mixed crystals. This is confirmed by the fact that the concentrations of Cl and of Cu in the ZnS lattice increase in the same proportion[32,44,45]. Under these conditions the concentration of Cl can reach much higher values than when ZnS is heated in the presence of a copper-free chloride flux. An analogous situation exists in the case of silver activation. Formation of AgCl has been shown, by chemical analysis[46], to take place when sulphide phosphors are heated with silver and a chloride flux under normal conditions (in the air). It may also be imagined that charge compensation occurs by the simultaneous introduction of sulphide activator and zinc chloride[47]:

$$n\mathrm{ZnS} + \mathrm{Cu_2S} + \mathrm{ZnCl_2} \rightarrow \mathrm{Zn}_{n+1}\mathrm{Cu_2S}_{n+1}\mathrm{Cl_2}. \qquad (1)$$

The zinc chloride can be replaced by the sulphide of a tervalent metal[48], such as Al_2S_3:

$$n\mathrm{ZnS} + \mathrm{Cu_2S} + \mathrm{Al_2S_3} \rightarrow \mathrm{Zn}_n\mathrm{Cu_2Al_2S}_{n+4}. \qquad (2)$$

In this case charge compensation occurs through the formation of $Al^{\cdot}_{Zn}$ defects in equivalent amounts of Cu'_{Zn}. The activator and the tervalent metal are sometimes added to the charge in the form of a double sulphide, $CuAlS_2$, $CuInS_2$, $AgGaS_2$, etc.[49,50] The favourable effect of some tervalent metals on the formation of ZnS phosphors was recognised even before the work of Kröger[51], but application of the theory of charge compensation has made it possible to give a unified explanation of the effect of chloride and of tervalent metals, and furthermore has led to the development of a much wider range of luminescent systems of this type. The action of tervalent metals can be taken as proof[52] that Cu and Ag enter lattice sites, i.e. form substitutional solid solutions, in ZnS, since the effect could not occur if interstitial solid solutions were formed. From the fact that the spectral composition of the radiation from ZnS–Cu and ZnS–Ag phosphors is independent of the type of compensating ion it was concluded[33] that the activator and the compensating ion are located far from each other in the lattice, and that the luminescence centre does not contain the latter ion. Since halogens and tervalent metals merely assist penetration of the activator into the phosphor matrix but do not affect the luminescence spectrum, these substances have been termed "coactivators". We can see from the Periodic Table that activators, which include Au[53] and also P, Sb, and As[54-56] besides Cu and Ag, occupy a position to the left of the constituent elements of the phosphor in the neighbouring group, whereas the coactivators are found to the right of the main components[57] (Fig. 1). Under certain conditions, however, activators and coactivators can exchange roles[58,59].

As a rule, halides are more effective coactivators than are tervalent metal sulphides, in particular because the latter (especially Al_2S_3) are readily hydrolysed and oxidised.

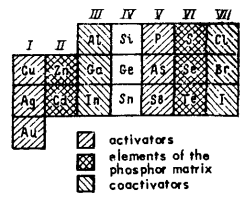

Fig. 1. Position of activators and coactivators of binary compounds of the ZnS type in the Periodic Table[57].

Indium dissolves in ZnS more easily than other Group III metals[60], and chemical analysis has shown[61] that this metal can enter the lattice. It has also been reported[60] that a higher concentration of Cu can be introduced into ZnS in the presence of In. Aluminium, on the other hand, goes into the ZnS lattice with difficulty in the absence of an activator[59]. Since aluminium salts are easily converted into Al_2O_3, which is transformed into the sulphide only to an insignificant extent[62] when heated in H_2S, the preparation of ZnS–Cu,Al and ZnS–Ag,Al requires special precautions[61] to enable a large proportion of the added Al to enter the lattice. The presence of the activator favours the dissolution of Al_2S_3, and therefore also makes possible its formation. In any case, the ability of aluminium to act as a coactivator has been demonstrated on many occasions[35,36,48,50,61,63]. Experiments in which Al is added to the charge in the formation of Al_2O_3 without an activator[64] give no grounds for refuting this statement. It is equally incorrect to ignore, as is often done, the fate of the partner of the impurity ion which replaces an ion of the main lattice, since we are dealing with the formation of a solid solution of the impurity compound, not of the free element.

When applying the principle of charge compensation, we have assumed that ZnS is an ionic crystal. In fact, however, the bond in zinc sulphide is more covalent than ionic[43,65,66]. But this does not alter the situation, since the principle of charge compensation can be replaced by the more general principle of valency compensation[67]. Consider the covalent model of a ZnS phosphor. The zinc atom has two valency electrons occupying a single s-shell ($4s^2$), and the sulphur atom has six valency electrons ($3s^2p^4$). In the crystal lattice every zinc atom is surrounded by four sulphur atoms, and every sulphur atom by four zinc atoms. The valency electrons are shared, as it were, between the zinc and the sulphur. As a result, four hybrid sp^3 orbitals appear in each atom[68], and form tetrahedral bonds where they overlap similar orbitals of neighbouring atoms. If an impurity atom is added to such a crystal, it tends to take up the electronic structure of the Zn and S atoms of which the host lattice is composed. If, for example, a sulphur atom with six valency electrons is replaced by a Cl atom, having seven valency electrons, one "excess" electron appears; this is very easily lost by the Cl atom, and enters the conduction band. The introduction of a Cu atom with one valency electron at the site of a Zn atom leads to the formation of a defect which, in contrast, tends to capture the one electron which it lacks. It is obvious that impurities of the Cl type will raise the electronic conductivity: in the study of semiconductors these impurities are called donors. Impurities similar to Cu decrease electron conduction or increase hole conduction: these are called acceptors. When both donors and acceptors are present together in the crystal, electrons tend to pass from the former to the latter. This process is accompanied by a gain in energy. As a result, the solubility of an acceptor impurity is increased by the simultaneous dissolution of a donor impurity. It is interesting to note that this phenomenon occurs also in elementary semiconductors. For example, the solubility of lithium in silicon is increased by the presence of boron[69]. Equal numbers of donors and acceptors produce what is known as a compensated semiconductor. The most effective ZnS–Ag,Cl and ZnS–Cu,Cl phosphors also appear to be compensated semiconductors[70]. If the number of acceptors is not equal to the number of donors, compensation can arise through sulphur vacancies in the case of an excess of acceptors, or through zinc vacancies in the case of an excess of donors[71,72]. However, after loss (or gain) of one electron the vacancy acquires a charge, which makes the loss (or gain) of a second electron more difficult. This is, obviously, one of the reasons why AgCl and CuCl dissolve in ZnS more readily than do Ag_2S and Cu_2S. The higher solubility is also partly due to the fact that the energy expenditure associated with the formation of vacancies is eliminated[47].

Studies of the influence of impurities on the dark conductivity and on the photoconductivity of zinc and cadmium sulphides have confirmed that activators (Ag and Cu) act as acceptors when they are introduced into the lattice, whereas coactivators (Cl, Ga, In, etc.) are donors[61,65,73–76]. This is one of the weightiest arguments[75] against the hypothesis that Ag and Cu enter the lattice as free atoms, since if that were the case they would give rise to donor defects[77]. It has been shown that ZnS, CdS, and (Zn,Cd)S phosphors are n-type semiconductors (i.e. their conductivity is due to electrons)[78,79], the conductivity increasing when cadmium and zinc chlorides are introduced into the lattice[73,76]. Activation with silver and copper does not convert the n-type conduction into p-type (positive-hole) conduction because of the high ionisation energy of the acceptor defects produced in the lattice of the sulphides[65], but there is a decrease in the n-type conduction, and this can be taken as evidence that Ag and Cu act as acceptors. Hence it is incorrect to assume, as is sometimes done[80,81], that the n-type conduction points to activation of ZnS by the free metals.

The hypothesis of activation by free metals is also inconsistent with experiments on the electrolytic activation of zinc sulphide with copper[63,82] and with the results of a study of the magnetic properties of ZnS phosphors. Measurements of the temperature variation of the magnetic susceptibility of ZnS–Cu phosphors[71] by a method sensitive to 0.0001% of a paramagnetic impurity have shown that copper enters the lattice in a diamagnetic state. This argues not only against the hypothesis of activation by free copper atoms, which have one unpaired s-electron, but also against an earlier suggestion[25] that the "green" copper centres are formed by a Cu^{2+} ion. We should also remember that CuS is unstable above 200°.

As we mentioned above, the fact that the nature of the coactivator does not affect the spectral positions of the green band of ZnS–Cu and the blue band of ZnS–Ag phosphors has been interpreted as a consequence of the spatial separation of activator and coactivator. This means that the phosphor contains, as a rule, at least two kinds of defects, which are not related to one another. On an energy diagram (or band diagram) these defects are represented by two kinds of level in the forbidden gap: levels close to the conduction band, formed by the coactivator, and levels located above the valency band, formed by the activator (Fig. 2*a*). It follows from the above arguments that in an unexcited phosphor, which is a compensated semiconductor, the electrons reside mostly on the activator levels, whose distance from the conduction band determines to a first approximation the luminescence spectrum. On excitation the electrons pass into the conduction band, and may be captured by the coactivator levels, from which they are freed by thermal vibrations. Different coactivators can be expected to give rise to levels (electron traps) at different depths below the conduction band. The application of the so-called thermal glow method, which enables trap depths to be measured, has demonstrated the correctness of this hypothesis: it was found that the depth

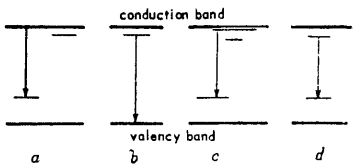

Fig.2. Energy-level models of the centres (explained in the text). The arrows denote electronic transitions.

of the electron traps is indeed determined by the nature of the coactivator and is independent of the nature of the activator[83-85]. In this way, Blokhintsev's hypothesis[86] of the spatial separation of luminescence centres and traps was verified, and furthermore the nature of the defects which may be responsible for the appearance of the trapping levels was established. The fact that the depth of the latter is independent of the activator does not in any way imply that the thermoluminescence and the afterglow are also independent of the activator, for the activator takes an active part in the luminescence process. Thus, in the case of a phosphor with two activators the thermal glow curves for the bands corresponding to these activators are not identical, since as the temperature is raised the probability of electron emission from the valency band to the activator levels increases, producing shorter-wavelength radiation. Under these conditions, holes migrate to the luminescence centres formed by the second activator, and are captured by them. Hence, the contribution of the long-wavelength band to the thermoluminescence spectrum increases with increase in temperature. The dependence of the afterglow on the nature of the activator can be explained in a similar way. It is also clear that the intensity of the thermoluminescence is related not only to the concentration of the trapping centres but also to that of the luminescence centres, since the radiation intensity I is proportional to the product of the concentration n of electrons freed from the traps and the concentration p_t of holes localised at luminescence centres: $I = \beta n p_t$, where β is the coefficient of recombination. Neglect of these principles leads to groundless conclusions[87,88] as to the relation between electron traps and luminescence centres.

Thus, we can now point to a whole series of proofs that chlorine and other coactivators actually enter the sulphide lattice at the same time as the activators. The fact that a coactivator must be present for activation by copper or silver to occur, established by the work of Strange, Kröger, and Schleede[89], was later confirmed in experiments with evaporated films[90] and single crystals[76]. It should be noted that the majority of workers (including the originators — Schleede[89,91] and Riehl and Ortmann[13] — of the hypothesis that the sulphides are activated by free atoms) now believe that the blue silver band and the green copper band are due to Ag^+ and Cu^+ ions located at lattice sites. (When referring to ions, here and subsequently, we have in mind the fact that the activators enter the lattice as compounds rather than as free atoms.) We must point out, however, that the mere fact that an impurity such as Cl must be present to cause luminescence to appear in the band of any particular activator cannot be taken as proof that this impurity is a coactivator, since cases are known in which the role of the impurity is to sensitise the luminescence[92-94], i.e. to form centres which absorb the energy of the exciting radiation and later transfer it to the activator centres.

2. Association of Activators and Coactivators

It has been suggested[30,95] that, at the normal temperature of formation of ZnS phosphors (800–1200°), the coulombic interaction of the activator and coactivator ions will favour their association, whereas the tendency of the system to maximise its entropy will act in the opposite sense. According to Prener and Williams[57,72,96], the relatively high impurity concentration (10^{-4} g-atom mole^{-1}) and the relatively low dielectric constant of ZnS should cause the tendency to association of the activator and coactivator to predominate, forming donor–acceptor pairs. These pairs of activator and coactivator atoms, associated as second or third nearest neighbours, are identified with the luminescence centres. Thus, Prener and Williams ascribe to the coactivator even more active a role than does Kröger, since they assume that it forms part of the luminescence centre by contributing an excited level close to the conduction band (Fig. 2*c*). This must increase the probability of capture of a conduction electron by the luminescence centre[57,97]. The suggestion that the luminescence centre of ZnS–Cu phosphors includes an excited level close to the conduction band is supported by the observation[98] that at low enough temperatures the photoconductivity of ZnS–Cu single crystals irradiated with light corresponding to the characteristic absorption band of the Cu centres vanishes, whereas the luminescence persists. However, the excited level is not necessarily associated with the presence of a coactivator. Prener and Williams quote[72] as an experimental proof of their theory the fact that the luminescence of ZnS is unaffected by the transmutation of ^{65}Zn atoms (obtained from ^{64}Zn by irradiating the sample with a neutron flux) to ^{65}Cu atoms, despite the fact that in this case the Cu appears at lattice sites and the lattice contains randomly distributed Cl ions. However, this could be ascribed, rather than to absence of associated Cu–Cl pairs, to the fact that luminescence centres are formed by univalent copper, whereas the nuclear reaction yields bivalent copper at the lattice sites[99]. Thus, the Prener–Williams hypothesis can hardly be said to be substantiated for systems such as ZnS–Cu,Cl and ZnS–Ag,Cl, whose radiation has a spectral composition independent of the nature of the coactivator[48,61,90]. It is true that Williams[100] explains this by postulating electronic transitions from the excited donor level — or even from the bottom of the conduction band — to the main acceptor level, and states (in contrast to his earlier hypothesis) that the activator and coactivator atoms are situated at an appreciable distance from each other — no nearer than seventh-nearest neighbours — in systems of this kind. But when modified in this way the views of Williams are hardly different from the generally accepted views. We should note that the postulated direct participation of the coactivator in the makeup of the green luminescence centres of ZnS–Cu phosphors and the blue luminescence centres of ZnS–Ag phosphors conflicts with reports in the literature that phosphors can be prepared without valency compensation by a coactivator[63,101] if the preparative conditions are such that Ag^+ and Cu^+ ions can reside at lattice sites.

Moreover, studies of ZnS phosphors containing Group III elements as coactivators have revealed luminescence bands which can in fact be ascribed to associated centres. Kröger had established that the luminescence spectrum of these phosphors sometimes exhibits long-wavelength bands in addition to the normal luminescence bands due to the activator[48]. Since these additional bands, which lie in the orange–red region of the spectrum, shift towards longer

wavelengths with increase in the depth of the electron trap formed by the coactivator, the suggestion was put forward[83] that these bands are due to the recombination of free holes with electrons trapped at coactivator centres (Fig. 2*b*). Thus, the latter act as luminescence centres as well as trapping centres. However, an experimental determination of the depth of the traps has shown that the radiation associated with this process should lie on the short-wavelength side (rather than on the long-wavelength side) of the luminescence bands due to silver and copper[84]. For this reason, Hoogenstraaten[84] proposed that an electron trapped at a coactivator centre recombines with a hole in a localised level above the valency band ("holding state") rather than in the valency band itself. The observed dependence of the spectral position of the long-wavelength band on the nature of the activator has led to the conclusion[49] that this level is bound to the activator and that the corresponding luminescence centre is therefore the result of association of the activator and the coactivator. This is confirmed by the fact that the proportion of long-wavelength radiation in the spectrum increases when the concentration of activator and coactivator (taken in equimolar amounts) is raised. Bands in the orange–red appear only when coactivators whose concentration in the ZnS phase can reach quite high values are used (e.g. Ga, In, Sc). Aluminium, which enters ZnS with difficulty, does not give this effect.

An attempt was made[49] to interpret the nature of centres responsible for the long-wavelength radiation in terms of the above-mentioned theory of Prener and Williams, developed on the basis of concepts[102] similar to those used in the theory of strong electrolytes. Assuming that in this case the radiative transition occurs from the ground level of the donor to the ground level of the acceptor (Fig. 2*d*), Apple and Williams calculated that the centre responsible for this radiation must consist of atoms of the activator and coactivator associated as fourth–sixth nearest neighbours[49,100], when overlapping of the ground state of the acceptor and the ground state of the donor sets in. With larger separations of the activator and coactivator atoms this overlapping does not occur, and the spectrum of the radiation shows only the normal activator band. However, the smaller the distance between the activator and the coactivator atom, the nearer their levels move towards the corresponding bands. Therefore, once the long-wavelength radiation appears, it can be expected to shift towards shorter wavelengths when the concentration of activator and coactivator is raised still further, and to disappear completely when the association becomes very close, owing to the fact that the ground levels of the donor and the acceptor have penetrated into their corresponding energy bands. van Gool[61] found that the long-wavelength band probably consists of several sub-bands, but that an increase in the concentration of activator and coactivator causes a shift towards longer rather than shorter wavelengths. Nevertheless, there can be no doubt as to the associated nature of the luminescence centre in this case. The location of the excited level within the forbidden gap is confirmed by the fact that the long-wavelength band has a lower thermal stability than the short-wavelength band, which would be impossible if the transition took place from the bottom of the conduction band. It should be noted that a long-wavelength emission with similar properties has been observed also in the absence of the main activator (Ag, Cu), for example when In [103,104] or Ga [105] impurities are added to ZnS. The luminescence centre responsible for this effect could also result from some kind of association — most probably that of Ga$^{\cdot}$ (or In$^{\cdot}$) with $V_{Zn}Ga'$ (or $V_{Zn}In'$). [105]

Thus, the hypothesis that a coactivator enters the lattice at the same time as the activator during the preparation of sulphide phosphors, and that this gives rise to a normal substitutional solid solution, provides an explanation of a large number of phenomena encountered in the preparation and in the study of ZnS phosphors. Nevertheless, a great deal still remains to be explained. This is because, in addition to the normal solid solutions with heterovalent substitution, which include the most effective and technically important cathodo-, röntgeno-, radio-, and photo-luminescent materials, solid solutions involving vacancies or interstices are also formed. A particularly difficult problem was that of interpreting the nature of the blue luminescence centre in self-activated (s/a) ZnS, and also the blue and the red luminescence of ZnS–Cu phosphors. Most objections to the views on the role of coactivators discussed above have been raised in connection with these particular problems. We shall consider these objections in the following sections.

III. LUMINESCENCE CENTRES OF "SELF-ACTIVATED" PHOSPHORS

In an attempt to produce a unified theory of the nature of the luminescence centres in s/a ZnS, ZnS–Ag, and ZnS–Cu phosphors, Kröger suggested[30] that the blue luminescence centre of s/a ZnS consists of a $Zn^{\cdot}$ ion whose deficiency of one positive charge is compensated by the simultaneous introduction of a Cl^{-} ion, so that in effect an s/a ZnS phosphor is a solid solution of the subchloride ZnCl in zinc sulphide. Generally speaking, subchlorides of this type are known. They are formed, for example, when the metal is dissolved in a melt of its normal chloride. Thus, Kröger's original hypothesis is equivalent to assuming that zinc in excess of stoichiometric (or, at least, partly reduced zinc) is involved in the formation of the luminescence centres. Subsequently, however, relying on the results of Bube[106–108], who had observed a blue luminescence in what he assumed to be pure ZnS which had been heated to a high enough temperature, and also noting that in the ionic model $Zn^{\cdot}$ is indistinguishable from a free electron in the conduction band, Kröger[109] changed his point of view and suggested that the blue luminescence centre in s/a ZnS is a cation vacancy (in this case, a zinc vacancy V'_{Zn}) with one electron missing from its immediate surroundings. Such a centre, however, should be paramagnetic, which conflicts with the results of magnetic susceptibility[71] and electron spin resonance (e.s.r.) measurements[110] on s/a ZnS phosphors. A model of the centre which satisfies these results was put forward by Prener and Williams[111], who suggested that the defect responsible for the formation of the centre is a zinc vacancy immediately adjacent to a donor impurity, e.g. $V_{Zn}Cl_S^{\cdot}$. This defect behaves very much like Ag'_{Zn} and Cu'_{Zn}. We should note that the association of a vacancy with an oppositely charged impurity defect is regarded as very important in the theory of the ionic conductivity of crystals[112].

Riehl and Ortmann's discovery[113] that no visible luminescence at room temperature is produced when ZnS is heated with NaCl in the complete absence of traces of oxygen revealed a new difficulty. This observation was confirmed by several other workers[36,76,114–116]. Similar statements on the role of oxygen are to be found also in earlier papers[117]. Although some authors[59,114] state that it is sufficient to introduce oxygen in combined form, e.g. as

ZnO, others[36,91,101,118] have been unable to obtain a blue luminescence when ZnO, moisture, and other oxygen compounds are present in the system. In this connection it is relevant to record a number of statements[113,115] that minute traces of free oxygen in the nitrogen or argon are sufficient to cause the characteristic blue luminescence when a ZnS(NaCl) charge is heated in a stream of these gases. Hence it is desirable to carry out these experiments under static conditions.

To explain these results it was initially suggested[114,118] that oxygen atoms are involved in the structure of the luminescence centres. However, this hypothesis conflicts with the fact that bright phosphors can be prepared from deoxygenated ZnS in HCl medium[30,115,119], and especially with the fact that a similar luminescence can be produced by introducing elements of Group III into the ZnS using an H_2S atmosphere[101]. In an attempt to make these two sets of data mutually compatible, and adopting the hypothesis that the luminescence centres are produced by V_{Zn} vacancies, Riehl and Sizmann[120] suggested that the Zn^{2+} ion tends to take up a position adjacent to the O^{2-} ion, which is smaller than the S^{2-} ion. In doing so, it can move into an interstitial site, i.e. into a normally empty tetrahedron, and this process gives rise to a V_{Zn} vacancy. However, this contradicts the above results (including those of Riehl and Ortmann[118]), according to which the presence of zinc oxide alone is insufficient to give rise to luminescence. Thus the situation concerning the nature of the luminescence centres in s/a ZnS was very confusing[121]. However, shortly afterwards, a way was found to correlate the results of Kröger[30,101] with those of Riehl and Ortmann: this was to make a combined study of the effect of preparative conditions on the luminescence and on the chemical reactions taking place in the system[46,67,91,122]. It was found that direct reaction between ZnS and NaCl with formation of $ZnCl_2$, whose possibility had been suggested previously[27,28], leads to such a large increase in the free energy of the system as to be negligible in practice[46,105]. In the presence of oxygen, on the other hand, we have the so-called "chlorinating roast"[113,123], which can be described by the overall equation

$$ZnS + 2NaCl + 2O_2 = ZnCl_2 + Na_2SO_4. \quad (3)$$

If we assume that the blue luminescence of s/a ZnS results from the dissolution of $ZnCl_2$ in ZnS, the role of oxygen is clearly to make reaction (3) possible. Hence, no oxygen is needed to bring about the blue luminescence in the cases where $ZnCl_2$ can be formed even in the absence of oxygen, e.g. when ZnS is heated in the presence of HCl or with fluxes such as $MgCl_2$.[124] The ability of $ZnCl_2$ to activate ZnS with formation of a typical s/a ZnS phosphor has been demonstrated by direct experiment[36,125]. The failure of $ZnCl_2$ to give good phosphors when used as a flux[113] has been ascribed to its volatility (b.p. 733°) and also to the fact that it is a poor mineraliser[126]. Hence it is necessary, in order to prepare efficient phosphors, to heat the material with $ZnCl_2$ either in a closed vessel[36,91] or with a flux, such as NaCl, which promotes crystal growth and also inhibits the volatilisation of $ZnCl_2$ by complex formation with the latter[46].

The effect of ZnO dissolved in ZnS is to give rise to luminescence quenching rather than to the formation of luminescence centres[36]. This, evidently, is the reason for the frequently reported[7,127,128] sharp drop in the brightness of luminescence of an s/a ZnS phosphor prepared in the air after transition from sphalerite to wurtzite, in which ZnO has a much higher solubility[39,101,113] because it, too, has the wurtzite structure. In this case it is possible to raise the intensity of the luminescence by restricting the access of oxygen[26,125] or by using chlorinating agents able to form $ZnCl_2$ without the participation of oxygen[115,124,125]. According to Riehl[120] we can envisage the formation of deep oxygen traps which act as quenching centres. However, since oxygen also causes the luminescence band to shift to longer wavelengths, it is conceivable that the oxygen becomes associated with the defect responsible for the luminescence, forming a new centre with a lower recombination coefficient[36].

For steric reasons, the Cl^- ions are unlikely to reside in interstitial sites. Hence they are most likely to replace sulphur ions in lattice sites, and in order to satisfy the principle of valency compensation the appropriate number of V_{Zn} vacancies must appear when $ZnCl_2$ is dissolved in ZnS:

$$n\,ZnS + ZnCl_2 \rightarrow Zn_{n+1}V_{Zn}S_nCl_2. \quad (4)$$

In a system of this type three main kinds of defect — $Cl_S^{\cdot}$, $V_{Zn}Cl_S^{\cdot}$, and V_{Zn}'' — can arise. As already mentioned, it has been suggested[111] that the acceptor defect $V_{Zn}Cl_S^{\cdot}$ is the one responsible for the formation of the blue luminescence centres. An analogous situation should arise when activation is by sulphides of tervalent metals, because these, too, should generate zinc vacancies when dissolved in ZnS. The association of V_{Zn}'' with a tervalent metal ion which has entered the lattice gives a centre similar to $V_{Zn}Cl_S^{\cdot}$, but in this case the ion associated with V_{Zn}'', e.g. $Al_{Zn}^{\cdot}$, will occupy a Zn site rather than an S site. Thus we can expect some difference in the spectral composition of the luminescence between s/a ZnS phosphors prepared by doping with halides and those containing tervalent metals. It has been shown experimentally[35,61] that this difference actually exists.

Thus, the "self-activated" ZnS phosphor is in fact activated by halogens or tervalent metals, i.e. by impurities which act as coactivators in ZnS–Cu and ZnS–Ag phosphors. A similar state of affairs exists in the case of CdS, which, like ZnS, does not show luminescence (and does not change its electrical conductivity) when heated with NaCl in the absence of free oxygen[36,76,91,115]. Nevertheless, CdS is activated by cadmium chloride[36,91], whose formation under ordinary conditions of heat-treatment in air has been demonstrated by chemical analysis[46].

It must be stressed that the concentration of luminescence centres in ZnS–Cl and CdS–Cl phosphors, and even more so the intensity of luminescence, do not necessarily vary in parallel with the concentration of Cl in the sulphide phase, although in some cases such parallelism has been observed[31,125]. We must remember firstly that some of the Cl may not be at lattice sites but on internal surfaces of the crystallites[64,129], secondly that only Cl associated with V_{Zn} gives rise to luminescence centres (the extent of association depending on the temperature of heat-treatment and on other preparative conditions), and lastly that the luminescence yield is determined not by the concentration of luminescence centres but by the ratio between this concentration and the concentration of quenching centres, the latter also being a function of the preparative conditions[125]. Therefore the reported[106–108,129] lack of agreement between the concentration of Cl determined by chemical analysis and the luminescence intensity cannot be used as an argument to refute the above ideas. The fact that the sulphide phase contains, in addition to Cl, cations originating from the flux (or from its interaction with ZnS and atmospheric

oxygen[67]) does not provide grounds for doubting[64] that Cl enters the lattice at lattice sites, as many workers have confirmed (see Section II).

In recent years many new data in keeping with the Prener–Williams model have been reported[110,130,131]. The development of a method for growing single crystals of ZnS from the melt has made it possible to use Feofilov's polarisation method[132] to study the nature of the luminescence centres in crystals belonging to the cubic system. Shionoya and coworkers[130,133] have shown that the observed anisotropy of the luminescence and its dependence on the properties of the exciting radiation are consistent with the hypothesis that the luminescence centre in a ZnS–Cl crystal has a characteristic C_{3v} symmetry, as should be the case with a $V_{Zn}Cl'$ centre. The e.s.r. method gave similar results[110,134-136]. When the crystal is excited at 77°K with ultraviolet radiation, ionisation of the luminescence centres and electron capture by the traps takes place. As a result, both defects become paramagnetic, and give a signal from whose characteristics we can derive information on the symmetry of the corresponding centre and on whether the signal is the result of electron capture or hole capture. A parallel study of the magnitude of the signals and of the luminescence intensity can identify which of the two signals corresponds to the luminescence centre. An analysis of the results obtained for ZnS–Cl and ZnS–Al phosphors has shown that the Prener–Williams model is consistent with the e.s.r. measurements.

The views described here have found numerous supporters. It must be stressed, however, that the chemical nature of the blue luminescence centres in s/a ZnS phosphors is one of the points of greatest disagreement. In particular, many workers restate outdated opinions that self-activation is actually present in this case, some[15,137-142] following Schleede's original views[6] in regarding the luminescence centres as formed by a stoichiometric excess of Zn or Cd, while others[143,144] adopt the opposite view, and suggest, following Bube[107,108], that the luminescence centres are formed by zinc vacancies. Schleede himself[91] gave convincing arguments against activation by excess zinc or cadmium, and abandoned his original point of view (though more gradually than did Kröger): he found that, after being heated in a sealed tube, ZnS gives a bright luminescence if $ZnCl_2$ is present as well as an excess of sulphur, whereas the characteristic luminescence of "self-activated" phosphors does not appear if the Zn or Cd is in excess. Other workers[36,127,139] also obtained negative results in their attempts to induce luminescence by an excess of Zn or Cd. The lack of luminescence of ZnS heat-treated in hydrogen[15,30,118,125] is evidence of the same kind. According to a number of reports[35,36,61], no luminescence is obtained also on heating ZnS and CdS prepared by precipitation and completely free from chlorine, whether or not an excess of sulphur is present. Work on the preparation of ZnS films by synthesis from the ultrapure elements[145] has confirmed that departures from the stoichiometric composition cannot give rise to the blue luminescence. These observations cannot be ascribed to imperfections in the crystal structure, because, as already pointed out, addition of a mineraliser such as NaCl does not induce luminescence in the complete absence of oxygen[113-115,146]. Furthermore, a hydrogen atmosphere, which inhibits the development of luminescence, favours the recrystallisation of ZnS.[22] Lastly, the most perfect single crystals of ZnS and CdS, prepared by sublimation of the precipitated sulphides, very often do not show luminescence[76]. The relative instability of s/a ZnS and s/a CdS when heated in a vacuum[14], on which Riehl and Ortmann have cast doubt[118], can be explained by the volatility of $ZnCl_2$ and $CdCl_2$. In the light of these results, there are no grounds for attempting to explain the "gap" in the luminescence intensity in the series of s/a ZnS–CdS(hex.) phosphors at 5–10% CdS by postulating the displacement of the emission band due to excess zinc by the cadmium band[14,138], especially since a similar "gap" (though less marked) is found also in the series of ZnS. .CdS(hex.) phosphors activated by Ag, Cu, and Au.[53,147].

The luminescence of sulphides not containing deliberately added activators is usually due either to the presence of activating impurities (in particular Cl) in the sulphide source material or to impurity pick-up from the walls of quartz crucibles[148,149]. Technical "phosphorescent" ZnS and CdS usually contain an appreciable amount ($\geq 0.005\%$) of chloride[36,76,113,135,150], which is readily coprecipitated with sulphides[151,152] or derived from absorption of HCl, a common constituent of the atmosphere in chemical laboratories and workshops. Both the importance[21] and the difficulty[153] of removing chlorine have long been stressed in the literature. Even when the material is synthesised from the elements it is necessary to guard against the presence of activating impurities, in particular In, Ga, and Al.[154]

Thus, there is still no convincing experimental proof of the hypothesis that the blue luminescence of ZnS or the corresponding red luminescence of CdS can be ascribed exclusively to structural defects, and the term "self-activated" is retained for phosphors of this type largely on grounds of tradition.

The green luminescence displayed by ZnS under certain conditions of heating in the absence of deliberately added metal activators[23,91,155-157] has attracted less attention. It is observed most often when the sulphide is slightly oxidised. Leverenz, noting the similarity between this luminescence and the green emission of ZnS–Cu, suggested that the true activator in all cases of luminescence of this type is oxygen, the only function of the copper being to promote the oxidation of ZnS.[23] This hypothesis, however, does not account for the observed activation by copper in the absence of oxygen[32]. Bundel'[155] also suggested that oxygen can act as an activator, but he did not identify the oxygen centres with those responsible for the green luminescence of ZnS–Cu. An important aspect of this problem is the fact that this effect is shown only by free oxygen in amounts insufficient to cause extensive oxidation of ZnS. We may therefore assume that the activating effect of oxygen shows itself in the initial stages of its reaction with ZnS. The suggestion has been put forward[36] that this initial stage consists in addition of oxygen to ZnS with formation of a defect of effective charge -2, i.e. a cation vacancy adjacent to an oxygen atom in an anion site:

$$n\mathrm{ZnS} + {}^1/_2\mathrm{O}_2 \rightarrow \mathrm{Zn}_n\mathrm{V}_{\mathrm{Zn}}\mathrm{OS}_n. \qquad (5)$$

Other workers also have assumed that oxygen reacts with zinc in the first instance[22,158]. Kröger holds the opposite opinion[101]. He explains[159] the green luminescence band of a preparation heated in zinc vapour, not in terms of zinc vacancies, V_{Zn}, but, on the contrary, by the presence of an excess of zinc in the lattice, thus resorting to the oldest explanation[2,8] of the blue band of s/a ZnS phosphors. Other authors[36,91,139], however, failed to confirm these observations. Browne[156], referring to experiments by Hamilton on the heat-treatment of CdS in sulphur vapour, considers that the green band of ZnS and

the corresponding band of CdS are due to cation vacancies. Kulp[160] expressed a similar opinion with respect to CdS. However, the preparation by this method of ZnS with green luminescence has not been confirmed[36,61,116]. It is obvious that further experimental work with careful control over copper and oxygen impurities is needed to solve the problem of the true nature of the green luminescence centres, since this luminescence has been observed also in sublimed phosphors[143,145] and in single crystals[150,161].

Many workers[15,116,145,162,163] have reported also the appearance of an orange and a red luminescence in ZnS free from deliberately added metal activators‡. The only suggestion put forward to explain this phenomenon is that an excess of sulphur can induce luminescence[116].

In addition to the bands situated on the long-wavelength side of the blue band of s/a ZnS phosphors, and of the corresponding red band of s/a CdS, short-wavelength bands have also been reported[59,164-167], in particular a band having λ_{max} = 380–390 nm with ZnS [59] and 580 nm with CdS,[98,166] observed on excitation of the phosphors at low temperatures. Kröger[164] ascribed this band in ZnS to the Na^+ cation of the flux, assumed to form a luminescence centre analogous to Cu'_{Zn} and Ag'_{Zn}. However, as shown by Rothschild[59], the same band can be obtained also in the absence of Na^+. The condition for the predominance of this band in the spectrum is that the concentration of Cl or other halogen in the ZnS phase shall be low enough. This is achieved, for instance, by heat-treatment in an atmosphere which almost suppresses the chlorinating roast[59,105]. However, this luminescence band also disappears when the "coactivators" are completely removed. According to Rothschild, the role of luminescence centres in this case is played by the "coactivator" ions, which replace sulphur ions in the lattice: these are defects which give rise to electron traps. We may suppose that a decrease in the concentration of Cl causes the ratio $[Cl_S]/[V_{Zn}Cl_S^{\cdot}]$ to increase, owing to dissociation of $V_{Zn}Cl_S^{\cdot}$. This, besides lowering the probability of electron emission from the trap when the temperatures fall, increases the probability of radiative recombination of a trapped electron with a free hole in the valency band. This is evidently a specific case of the scheme (Fig. 2*b*) proposed by Klasens to explain the long-wavelength emission of phosphors containing tervalent metals as coactivators (see above). Consequently, there is no sharp boundary between trapping centres and luminescence centres[168], and the coactivators are in fact activators in this case as with the blue self-activated luminescence, because they determine the spectral composition of the radiation. It has been suggested[169,170] that sulphur vacancies may also be a cause of the luminescence at 380–390 nm. However, direct experiments with sulphides which had been dechlorinated in hydrogen sulphide failed to confirm this suggestion[105]. The effect of heat-treatment in zinc vapour on sulphides containing chlorine, which is to increase the contribution of the short-wavelength band to the emission spectrum[170], can be explained by a shift towards the right-hand side in the equilibrium

$$V_{Zn}Cl' \rightleftarrows V''_{Zn} + Cl,$$

caused by the interaction of V''_{Zn} with $V_S^{\cdot\cdot}$ formed under these conditions of heat-treatment. This results from the fact that the product of the concentrations of V''_{Zn} and $V_S^{\cdot\cdot}$ must be constant. The role of excess zinc may also be to influence the occupancy of the Cl levels by electrons.

Perhaps the only radiation which cannot be eliminated by even the most thorough purification of the sulphides is the so-called "edge-emission"[171-173], observed mostly at low temperature and consisting of a series of narrow bands close to the edge of the absorption band of the main lattice. Most of the work on this type of luminescence has been done on cadmium sulphide. Essentially, there are at least two "edge emissions", lying in the green and the blue regions of the spectrum in the case of CdS. Kröger[171] ascribed the green radiation to interband transitions in the undisturbed lattice. However, this interpretation had to be abandoned for two reasons: firstly, the energy of the quanta corresponding to the green radiation is less than the width of the forbidden gap[172,174], and secondly the green luminescence is strongly affected (even in the absence of emission bands in the visible and infrared regions) by the preparative conditions, the most perfect single crystals with the smallest number of structural defects being free from this luminescence[36,175-177]. There are reports[76,91,141,178-180] that the green band can occasionally be observed in the photoluminescence spectrum of CdS single crystals and powders even at room temperature, particularly in the case of activation by metallic indium[105], and that an excess of cadmium enhances the effect[91,181]. On the other hand, it is stated[142] that single crystals showing green luminescence have a high resistance, whereas an excess of cadmium in the lattice should raise the electrical conductivity. Some workers[182,183] have ascribed the green luminescence to an excess of sulphur. The view that the defects responsible for the green luminescence are pairs of vacancies of the two kinds ($V_{Zn}V_S$) has become increasingly popular in recent years[97,184]. The fact that a strong green luminescence is occasionally observed at room temperature suggests that the defects responsible for this effect are located at special sites in the crystals, most probably at the surface[105] or at dislocations[185]. Several observations[186,187] may indicate that even the short-wavelength component of the edge emission is ultimately produced by structural defects, possibly localised just below the crystal surface[187]. Thus, only the edge radiation can with sufficient justification be linked with centres produced by self-activation.

IV. LUMINESCENCE CENTRES OF COPPER- AND SILVER-ACTIVATED PHOSPHORS

The theoretical concepts discussed in Section II provide a satisfactory description of the structure of one luminescence centre in the ZnS–Cu phosphor. In fact, the nature of this phosphor is far more complex. In the visible region of the spectrum alone, four emission bands — blue, green, yellow, and red — have been observed[25,188]. Three emission bands have been found in the infrared region[156].

Much of the work has been concerned with the origin of the green and blue emission bands. As a rule, an increase in the copper content initially enhances the green luminescence at the expense of the blue luminescence of "self-activated" ZnS, but subsequently the blue luminescence again predominates over the green[17,25,32], and the phosphor begins to develop a grey colour. This has led a number of authors[19,71,115,189] to suggest that the copper is simply precipitated from the ZnS lattice as a separate phase,

‡ We are not concerned here with the yellow and red fluorescence often observed in precipitated ZnS and in ZnS which has been heated below the normal temperature of formation of the crystal phosphor.

with restoration of the ability of the "self-activation" centres to emit radiation. According to several workers [190-193], however, this hypothesis conflicts with observed differences between the properties of the bands in question. The blue copper band, when it can be clearly resolved from the green band by suitable preparative or excitation conditions, occurs at significantly shorter wavelengths, and is appreciably narrower, than the blue self-activated band [45,190,192]. On decreasing the temperature the Cu band shifts to shorter wavelengths, and the self-activated band to longer wavelengths [45,61,193,194]. Phosphors with a strongly developed blue Cu band, unlike the self-activated phosphors, have a sharp characteristic absorption band [32,193,195,196] and a corresponding blue luminescence excitation band [197,198]. It must be noted that, with phosphors prepared by conventional techniques in air, the blue and the green bands are poorly resolved in the luminescence spectrum at room temperature. This evidently accounts for discrepancies [189,193,198,199] between various measurements of absorption and excitation spectra. Hence the following facts provide more convincing evidence of a difference in chemical nature between the defects responsible for the formation of "blue" luminescence centres in ZnS–Cu and in s/a ZnS phosphors: (1) when ZnS–Cu(NaCl) is heated in hydrogen a strong blue luminescence appears, whereas when a copper-free charge is heated under otherwise identical conditions no luminescence is obtained [192], because the chlorinating roast of the ZnS is suppressed; (2) introduction of Cu into s/a ZnS phosphors at relatively low temperatures (290–550°) enables the gradual displacement of the self-activated band by the blue Cu band to be monitored [193].

Another question which has been the subject of lively discussion is the mechanism of the enhancement by oxygen, established by many workers [101,200-203], of the formation of the "green" luminescence centres. Grillot and Bancie-Grillot [128,200-202] assumed that the difference between the "green" and the "blue" centres is determined essentially by their environment: if they consist of sulphur ions exclusively a blue luminescence centre is formed, whereas if an oxygen ion is present in the immediate vicinity of the Cu^+ a green luminescence centre is formed. These views are not very different from those of Konstantinova-Schlezinger [204-206], who considers the luminescence centre to be a complex (quasi-molecule) formed by an activator ion with the anions surrounding it. Grillot's explanation conflicts, however, with the fact that ZnS–Cu phosphors showing a strong green luminescence can be prepared from deoxidised ZnS even in an atmosphere which contains no oxygen, such as dry HCl. [32,116] Grillot's more recent suggestion [207] that a V_S vacancy (rather than an oxygen ion) is the neighbour of Cu^+ which can alter the nature of the centre is also unable to explain these facts, particularly since a hydrogen atmosphere, which should favour the formation of V_S, leads to enhanced blue, not green, luminescence in ZnS–Cu. [25,192] Kröger [208] points out that, when NaCl is used as a flux, only the blue luminescence is produced in the absence of oxygen, and suggest that oxygen can somehow assist the separation of Cl from Na. The mechanism of this effect of oxygen has subsequently been clarified [67,124] by thermodynamic calculations: CuCl is not formed by the direct interaction of Cu_2S and NaCl, since the process would involve a large increase in the free energy of the system, but in the presence of oxygen CuCl can be formed by a chlorinating roast similar to reaction (3). This explanation is of limited application, however, since cases are known in which oxygen assists the formation of "green" centres even in the absence of chloride fluxes [101]. Kröger points out that oxygen has a similar effect on the formation of ZnS–Ag phosphors, which he explains on the basis of the principle of volume compensation [101], assuming that the small volume of the O^{2-} ion (as compared with S^{2-}) favours the entry into lattice sites of Cu^+ ions, which are larger than Zn^{2+}. Unlike Cl^-, the oxygen ion appears as a nearest neighbour of Cu^+, but this causes only a slight shift of the green band of the Cu^+ centre to longer wavelengths, rather than converting a blue centre into a green centre, as postulated by Grillot. The same principle was later used to explain the favourable effect of $MgCl_2$ on the formation of ZnS phosphors [124]. It is possible, on the other hand, that the true mechanism of the reported effect of ZnO, which is specially evident in the case of ZnS(hex.)–Cu, consists in the formation of additional structural defects of the dislocation type, which assist diffusion into the bulk of the lattice [36]. To some extent, this could also be the role played by chlorinating agents.

When Cu_2S is dissolved in ZnS containing ZnO, valency compensation is achieved (at least partly, if chloride is present) by sulphur vacancies, which give rise to trapping centres. Furthermore, the higher electronegativity of oxygen as compared with sulphur should cause the zinc atoms situated next to oxygen atoms to become trapping centres. Hence we can expect a sharp change in the nature of the thermal glow curves if the phosphor is prepared in the presence of oxygen. Experiments have shown [84,85] that this effect actually occurs.

Many investigations have been devoted to determining the nature of the Cu blue luminescence centres. The fact that the blue luminescence appears at high copper concentrations suggests that the centres are associated. Riehl and Ortmann arrived at this conclusion from their experiments on the introduction of copper at a relatively low temperature (450°) into s/a ZnS or ZnS–Cu phosphors which had been previously heated at a high temperature [209]. Since the blue luminescence band appears only after the copper concentration exceeds a definite limit, they suggest that this limiting concentration is determined by the concentration of point defects generated in the previous high-temperature treatment ("acceptors"), and able to take up copper with formation of "green" centres. This model recalls Smekal's early views [210]. Noting, in common with other workers, that chlorides promote the appearance of green luminescence and raise the limiting concentration of copper, Riehl and Ortmann ascribe the effect to the desulphurising action of chlorides, leading to the formation of V_S vacancies, which, as originally suggested [118,203], are associated with a neutral Zn atom located at a regular lattice site. Replacement of the Zn atom by a Cu atom produces a "green" centre. If the concentration of copper exceeds the concentration of $Zn_{Zn}V_S$ defects, the excess of copper goes into interstitial sites with formation of blue luminescence centres $Cu_i Cu_{Zn} V_S$, where the subscript i denotes an atom in an interstice. Subsequently [13], taking into account the results of magnetic susceptibility measurements on ZnS–Cu phosphors, Riehl and Ortmann modified their views and admitted that the whole of the copper is present in the lattice as Cu^+, the blue luminescence centre being formed by the association of Cu_i^+ with a "green" centre, i.e. a Cu^+ ion at a lattice site. However, they retained their assumption regarding the desulphurising action of chlorides, and ascribed to the resulting sulphur vacancies the function of charge compensation. Having observed that heating even at temperatures of the order of 100–200° converted green centres into blue centres, which did not require charge compensation according to their

new model, they were faced with the problem of explaining the fate of the sulphur vacancies during this conversion. This led them to yet another hypothesis [13,211], according to which charge compensation is ensured by interstitial Zn_i^{2+} ions during formation of the "green" centres. The conversion of "green" centres into "blue" centres involves exchange of places between Cu^+ and Zn_i^{2+} ions, accompanied by the formation of $Cu_i^+Cu_{Zn}^+$ associations. This idea has found the support of other authors [191,212-214], despite the fact that it became necessary, for example, to postulate blocking of interstices [212] by Zn_i^{2+} ions to explain the failure of some ZnS–Cu phosphors to accept additional quantities of copper at low temperature with formation of "blue" centres. (It may be recalled that the number of free tetrahedral cavities is equal to the number of lattice sites occupied by zinc ions.) We could list a number of phenomena which cannot be explained satisfactorily within the limits of Riehl and Ortmann's theory. This applies primarily to the role of chlorides. Their suggested desulphurising action still lacks convincing experimental proof [215,216], and is inconsistent with the results of a thermodynamic analysis [119]. The exact role of this factor is also obscure if charge compensation is achieved by interstitial Zn_i^{2+} ions. Furthermore, as has already been pointed out, an atmosphere of H_2, known to assist desulphurisation, favours the formation of "blue" rather than "green" centres [25,192]. Also unexplained is the appearance of red luminescence in ZnS–Cu phosphors prepared in the absence of coactivators and oxygen [148,188]. In their more recent papers [13,211,217,218] Riehl and Ortmann admit the possibility of charge compensation by chlorine, and also of reactions of type (6) (see below), but they have not yet modified their model accordingly.

In an attempt to reconcile the assumption of associated blue luminescence centres with the fact that these centres are not formed when ZnS–Cu is heated in H_2S in the absence of coactivators, Kröger [219] concluded that phosphors showing blue luminescence are produced by dissolution of the subchloride Cu_2Cl in ZnS. To make the idea more concrete, he put forward a model according to which the "blue" centre arises as a result of association between a Cu^+ ion at a lattice site and a neutral Cu atom in an interstitial site. In support of his model, Kröger quotes the results of a chemical analysis which shows that the concentration of Cu in phosphors with a blue luminescence band is double the Cl concentration, and also some approximate thermodynamic calculations in agreement with experiment. It was found, however, that an atmosphere of sulphur vapour favours the appearance of blue luminescence [91,190], which makes the presence of free atoms seem unlikely, particularly in view of the diamagnetic nature of the centres [71]. A more accurate chemical analysis, allowing for the fact that part of the copper is on the surface of the crystals [45], showed that $[Cu]:[Cl] < 2$, and in many cases approaches unity. A kinetic study of the formation of ZnS–Cu phosphors on heating in a chloride flux in the presence of air showed that the appearance of a blue luminescence band is preceded, as a rule, by the green luminescence: this led to the hypothesis [67,124] that the formation of "blue" centres is a secondary process occurring in the ZnS phase after dissolution of CuCl and consisting in an atomic rearrangement leading to the association of two Cu^+ ions in adjacent cation sites of the lattice. This process can be envisaged as a preliminary to the formation of Cu_2S as a separate phase, as shown by the equation [67,192]

$$2\,(CuCl) + ZnS \rightleftarrows (ZnCl_2) + (Cu_2S), \qquad (6)$$

(where the symbols in brackets denote species dissolved in the ZnS phase), resembling the reaction between AgCl and ZnS which occurs on the surface of ZnS–Ag phosphors [46]. The fact that HCl must be present for blue luminescence to appear on heating in H_2S [32] is explained, on this model, by the solubility of CuCl in ZnS being greater than that of Cu_2S; thus, since the $ZnCl_2$ formed by reaction (6) remains in the lattice, Tomlinson's analytical results [45] are readily explained. When ZnS–Cu is heated in H_2, a treatment which gives rise to sulphur vacancies, entry of Cu_2S occurs by the scheme

$$Zn_nS_{n-1}V_S + Cu_2S \rightarrow Zn_{n-1}Cu_2S_nV_S + Zn, \qquad (7)$$

similar to the one proposed earlier by Riehl and Ortmann for the formation of "green" centres.

Later researches [192,193] showed that conversion of the "green" centres in ZnS–Cu,Cl phosphors into "blue" centres usually occurs at relatively low temperatures (below 250°). The favourable effect of quenching on the green luminescence and of slow cooling on the blue luminescence had been pointed out earlier by Rothschild [25]. Some authors [220-222] regarded the increase in the blue luminescence at the expense of the green as an irreversible process ("aging" of the phosphor), but it has been shown [13,192,223,224] that heating at 250–300° restores the green luminescence. According to Riehl and his coworkers [13,211], who heated the phosphor in a vacuum, this conversion of blue into green luminescence is irreversible unless it is carried out in a closed, evenly heated space. However, experiments with ZnS–Cu, Cl phosphors prepared with a chloride flux in air have indicated [192] complete reversibility of the interconversion of "green" and "blue" centres even when the process is carried out in an open vessel at atmospheric pressure. If we assume that the reaction can be described by Eqn. (6) or that it somehow involves the association of Cu^+ ions into pairs and the dissociation of these pairs, we are faced with the problem of suggesting how the necessary movement of ions in the lattice can occur so readily below the Tammann temperature. Riehl's hypothesis of the diffusion of Cu^+ ions through interstices is no real answer, because, as was stated above, it does not explain why diffusion occurs in some cases and not in others. The suggestion that dislocations play an important part in these processes is more reasonable [192,198]. There has been a growing realisation in recent years that many phenomena observed in crystal phosphors [144,225-229] are controlled by the presence of dislocations. The diffusion of activators in ZnS at low temperatures is probably one of these phenomena. This is confirmed by the observation [230] that single crystals with a high dislocation density can take up abnormally large amounts of Cu. Riehl and Ortmann point out [190] that in diffusion experiments of this type the "blue" centres behave as intermediate states, since prolonged heating results in conversion of the "blue" centres into "green" centres. Wendel [212] drew attention to the fact that often the appearance of blue luminescence goes hand in hand with the electroluminescent properties of the phosphors, and attempted to relate both phenomena to the presence of Cu^+ in interstices, despite the numerous reported instances of blue luminescence not accompanied by electroluminescence [193]. However, all these observations help to establish an interrelation between the various sets of phenomena: one possible explanation is based on the assumption that dislocations play an important part both in the formation of "blue" centres and in the erection of the barriers needed for electroluminescence. Kinetic studies of the conversion of "green" centres into "blue" centres [231] support the suggestion that the process consists in the "expulsion" of Cu^+ ions to remote regions of the dislocation field, where Cu'_{Zn}–Cu'_{Zn} dimer formation takes place as indicated by Eqn. (6). These

dimers can be regarded as an intermediate state between single Cu^+ ions and more or less coarse agglomerations of these ions around dislocations, known as "Cottrell atmospheres" (since ZnS and Cu_2S are not isomorphous, the latter tends to appear in regions where the lattice is disturbed[232,233]). The segregation of Cu^+ ions around dislocations under certain conditions gives rise to the barriers to which the electroluminescent properties of ZnS–Cu phosphors are attributed. Thus, both the formation of "blue" centres, arising from defects of the Cu'_{Zn}–Cu'_{Zn} type, and the electroluminescent properties result from the process which precedes the precipitation of copper from the ZnS lattice as a separate Cu_2S phase. This hypothesis is consistent with the fund of experimental data obtained in the investigation of electroluminescent materials[193,212,225,234]. The study of phenomena such as the diffusion of activators and in particular the low-temperature interconversion of luminescence centres has shown a need for a wider application of the new concepts, which are now relegated to a separate branch of science — the chemistry of the defect solid state.

In addition to the views considered above, there are others on the nature of the Cu centres giving rise to blue luminescence. According to Curie[235,236] it is the "green", not the "blue", centres which have an associated structure comprising both activator and coactivator ions. But the association of Cu^+ and Cl^- should be enhanced by increasing the concentration of Cu^+, leading to conversion from blue to green luminescence, which is at variance with the facts. Nor is this hypothesis consistent with the fact that the spectral position of the green luminescence band is independent of the nature of the coactivator[237].

It has been suggested[45,156] that the blue and the green luminescence bands belong to a single centre having two levels, the difference between phosphors with blue and with green luminescence arising, according to Browne[156], from differences in the occupancies of these levels. An attempt was made to interpret the infrared luminescence of ZnS–Cu phosphors from this point of view. Essentially, Browne identifies the "blue" and the "green" centres of "self-activated" phosphors with those of copper-activated phosphors, and ascribes a decisive role to the zinc vacancies. We have already listed the arguments against identifying in this way centres of different kinds. In general, this seems an unlikely standpoint from which to attempt to explain the great variety of facts relating to the influence of preparative conditions on the optical properties of phosphors.

Some complications arise from the fact that the blue Cu band is again displaced by the green band as the concentration of copper is increased[32]. This happens under conditions which give a fairly high solubility of Cu in ZnS.[198] Several workers[32,45,71] point out that the green bands corresponding to a low ("green-I") and to a high ("green-II") concentration of copper have the same shape and occupy the same position in the spectrum. The slight differences observed by other authors[106,236] may be due to incomplete resolution of the blue and the green band, to the formation of a Cu_2S filter on the surface of the phosphor, to the faster conversion of wurtzite into sphalerite when the phosphor is cooled in the presence of high concentrations of copper[238], and to the influence of ZnO in the ZnS lattice on the position of the maximum and on the half-width of the band. There is some evidence[198] that the excitation spectra of the green-I and the green-II bands are identical, although even this question involves divergence of opinion[199], no doubt resulting from the influence of preparative conditions. Studies of the temperature dependence of the luminescence suggest[32,45,52,71] that the appearance of a green-II band in place of the blue luminescence band is caused by a fall in the temperature of incipient quenching of both bands under the influence of an increase in the concentration of quenching centres: as a result, the blue luminescence band ceases to be observable at room temperature. The quenching centres can be more or less coarse aggregates of Cu^+ ions[124,222], whose formation within the ZnS phase becomes possible only at high enough concentrations of dissolved Cu. Thus, the green-II band does not appear when the Cu is introduced by diffusion at 450°,[239] or when ZnS–Cu is heated in H_2 or ZnS–Cu, Al is heated in H_2S.[198] Hence there are grounds for regarding the green-I and the green-II bands as identical, produced by the same luminescence centres, in spite of the fact that some anomalies[198] in the behaviour of phosphors showing a green-II band are still unexplained.

According to Froelich[188,240] and others[61,63,148,241-243], it is possible to prepare a ZnS–Cu phosphor with a red luminescence band (λ_{max} = 670–720 nm) in an atmosphere of H_2S at relatively high Cu concentrations (optimum 0.1%[188]), when the system has been rigorously freed from coactivators and oxygen. It has been suggested that the "red" centres, like the "blue" luminescence centres, are formed by the association of two Cu atoms[148,188]. Froelich believes that, in the absence of coactivators which stabilise the Cu in the Cu^+ state, the copper is more readily reduced to neutral copper atoms, which can then form red luminescence centres by becoming associated with Cu^+. However, this hypothesis is inconsistent with the lack of paramagnetic properties of the "red" centres[71]. Aven and Potter[148] have suggested that Cu^+ is oxidised to Cu^{2+} under the influence of the S_2 produced by the dissociation of H_2S. Two Cu^{2+} ions at neighbouring cation sites undergo charge transfer and form a $Cu'Cu^{\bullet}$ red luminescence centre. This hypothesis is not consistent with the fact that phosphors having a red luminescence band are not formed in an atmosphere of sulphur vapour. van Gool and Shionoya ascribe the decisive role to another product of the dissociation of H_2S — hydrogen — since they believe that hydrogen can penetrate ZnS[241] or form sulphur vacancies[242], whose association with Cu^+ gives rise to red luminescence centres. This hypothesis, however, conflicts with their own experimental finding that no red luminescence is produced by heating in H_2, and also with reports of red luminescence in phosphors heated in CS_2[188,244] in the absence of H_2. Furthermore, a $Cu_{Zn}V^{\bullet}_S$ centre should be compensated by a Cu'_{Zn} centre giving green emission, but this has not been observed. Bowers and Melamed[71], having found a blue and a red luminescence band in the same sample, made the suggestion that the Cu^+ is displaced into interstitial sites, the resulting cation vacancy acting as the blue luminescence centre, whilst the Cu^+ ion accounts for the red emission. However, other workers have shown[148,241,242] that the appearance of red luminescence is by no means invariably accompanied by the blue luminescence band.

Presland et al.[245] obtained ZnS–Cu phosphors with yellow and red luminescence by rapidly cooling (quenching) the phosphor after heat-treatment in hydrogen sulphide or argon. The effect was not inhibited by the presence of a chloride flux. A subsequent low-temperature heat-treatment at first increased the relative contribution of the red band to the spectrum, and then produced the usual blue and green luminescence. These workers[245] suggested that the excess of Cu remaining in the ZnS lattice after quenching perturbs the levels of the "blue" and "green" centres, con-

verting them into "yellow" and "red" centres respectively. The possibility of producing ZnS–Cu phosphors with a yellow (λ_{max} = 590 nm) and a red luminescence in the presence of Cl has been mentioned also by Vlasenko [90] and Kazankin [193]. It has recently been shown [231] that a ZnS(hex.)–Cu phosphor with strong yellow and red bands in its luminescence spectrum can be prepared also in the presence of oxygen by heating the phosphor at 145–150° for 10–30 min after it has been heated in the air with a chloride flux and quenched. In contrast to the findings of Presland et al., the "quenched" phosphor had a green luminescence, which became yellow and then red only after low-temperature baking. The same result was obtained [246] in a study of "quenched" phosphors prepared in a medium of HCl + H_2S. An interpretation of these observations is [231] that, in the absence of coactivators and oxygen, and if the heating conditions do not favour the formation of sulphur vacancies, one-half of the Cu^+ ions remain in interstitial sites when Cu_2S is dissolved in ZnS. The tendency of Cu_2S to be precipitated as a separate phase induces a tendency for the interstitial Cu_i^+ ions to combine with Cu_{Zn}^+ ions located at lattice sites. At high enough copper concentrations (~ 0.1%) this process occurs even in the presence of coactivators and oxygen, but the latter promote the transfer of Cu^+ ions to lattice sites during cooling. However, if the phosphor is "quenched" and then baked at a low temperature, it is possible to freeze the intermediate state corresponding to the formation of Cu_i^+–Cu_{Zn}^+ associations; these are evidently responsible for the formation of luminescence centres, the "yellow" and the "blue" centres corresponding to different extents of association.

An analysis of the published data reveals a large measure of similarity in the physicochemical behaviour of ZnS–Cu and ZnS–Ag phosphors, although some of the phenomena are less easy to observe in the case of ZnS–Ag. This is clearly because the large size of Ag^+ makes it difficult to achieve sufficiently high concentrations of activator and the formation of associations in the ZnS phase. At high Ag concentrations and low amounts of coactivator, a short-wavelength band is observed (λ_{max} = 620 nm in CdS and 380–395 nm in ZnS). [247-251] Although a band close to this one has also been observed in phosphors not containing Ag, and has given rise to the suggestion [169] that the emission is due in both cases to sulphur vacancies, the slight difference in the position of the two maxima [98], and especially the effect of baking on the spectrum of the CdS–Ag phosphor with a short-wavelength luminescence band [231,248], indicate that the centres responsible for this band may be similar to the "blue" centres in ZnS–Cu phosphors. Heat-treatment of ZnS–Ag in H_2S in the absence of coactivators and oxygen gave [148,252,253] an orange luminescence band (λ_{max} = 620–640 nm), evidently similar to the red band in ZnS–Cu. The effect of the nature of the activator on the spectral composition of the luminescence of these phosphors, and also the disappearance of these bands at low concentrations of Cu or Ag, suggest a causal relationship between luminescence centres and activator. Although e.s.r. measurements point to the presence of defects of the type $Ag_{Zn}^{\cdot}V_S^{\cdot}$ in these phosphors [252], there is no convincing proof that these are the defects responsible for the luminescence centres. There are some isolated reports [53,254,255] of a weak greenish-blue band (λ_{max} = 480–495 nm) in the luminescence spectrum of ZnS–Ag phosphors, recently confirmed by the work on "quenched" phosphors, in whose spectrum this band is most clearly visible [231]. The similarity in physicochemical behaviour (disintegration of the centres on low-temperature baking) suggests that the "green–blue" Ag centres and the "yellow" Cu centres are alike. The corresponding centres in CdS–Ag give a band with λ_{max} = = 780 nm. [256,257] In the light of what has been said in this and in the previous Sections, we can conclude that, notwithstanding statements to the contrary [97], the luminescence centres formed by silver usually give radiation of shorter wavelength than the corresponding "copper" centres (see Table).

TABLE. *Defects most likely to be responsible for the formation of the luminescence centres in various ZnS phosphors. (The maxima of the corresponding emission bands are shown in brackets).*

Wavelength scale, nm		400	450	500	550	600	650	700
Spectral region		ultraviolet	violet	blue	green	yellow	orange	red
Phosphor	ZnS–Cl	$Cl_i^{\cdot}$ (380-390)	$V_{Zn}Cl_S^{\cdot}$ (450-465)	$V_{Zn}O_S^{\cdot\cdot}$ (510-520)				
	ZnS–Ag	$Ag_{Zn}^{\cdot}$–$Ag_{Zn}^{\cdot}$ (380-395)	$Ag_{Zn}^{\cdot}$ (435-450)	$Ag_{Zn}^{\cdot}$–$Ag_i^{\cdot}$ (480-495)			$Ag_{Zn}^{\cdot}$–$Ag_i^{\cdot}$ (620-640)	
	ZnS–Cu		$Cu_{Zn}^{\cdot}$–$Cu_{Zn}^{\cdot}$ (440-450)	$Cu_{Zn}^{\cdot}$ (515-530)	$Cu_{Zn}^{\cdot}$–$Cu_i^{\cdot}$ (570-590)			$Cu_{Zn}^{\cdot}$---$Cu_i^{\cdot}$ (670-720)

V. "INDIRECT" ACTIVATION AND STRUCTURE OF THE LUMINESCENCE CENTRES

It should be evident from the previous Sections that attempts to explain the great variety of properties of the sulphide phosphors on the assumption of a unique state of the activators in the sulphide lattice (atoms in interstices, ions with an effective charge of -1 at lattice sites, etc.) have proved fruitless. It is also clear that luminescence bands having similar positions in the spectrum are often due to centres produced by defects of different chemical origin, and attempts to attribute them to one and the same centre are groundless. It appears that the wealth of properties of zinc sulphide phosphors depends on the fact that defects, formed by a large number of different impurities and by their combinations with one another and with structural defects, can give rise to luminescence centres, which is not the case with other classes of phosphors. The fundamental cause of this phenomenon is a question that theory must answer.

In the preceding pages we have discussed the chemical nature of the defects responsible for the formation of luminescence centres. But there is another side to the problem under discussion; does the electronic transition responsible for the act of emission occur in the impurity atom (or ion), or does it occur in its immediate vicinity, consisting of atoms of the host material? To solve this problem we must first of all note that the luminescence centres become ionised during the excitation of luminescence. This is shown by the bimolecular nature of the luminescence of ZnS phosphors [258], and by the internal photoeffect which accompanies the luminescence. It was the need to adopt a model which would give a relatively small (about 3 eV) excitation energy for the luminescence centres which caused Seitz [2] to put forward his original hypothesis that the phosphors are activated by free atoms which have penetrated to interstitial sites in the lattice. However, this hypothesis soon came into conflict with the facts, and was displaced by new concepts, according to which the blue luminescence centres in ZnS–Ag and the green luminescence centres in ZnS–Cu are formed by Ag^+ and Cu^+ ions occupying sites of the host lattice. But this

made it necessary to deny that the activator species themselves become ionised, because not only are the ionisation energies of Ag^+ and Cu^+ an order of magnitude higher than those of the corresponding luminescence centres, but they are in the reverse order to the relative quantum energies of the emitted radiation actually found[83,85]. Starting from an ionic model of a crystal phosphor, Klasens[83] suggested that the electronic transitions responsible for the act of emission take place between ions of the main compound. The deficiency of positive charge at a site occupied by a univalent activator assists the removal of electrons from neighbouring S^{2-} ions, and this gives rise to a localised level above the valency band. Even earlier, Leverenz[23] had explained the gradual shift in position of the luminescence band of (Zn, Cd)S phosphors on increasing the concentration of CdS by suggesting that the radiation is emitted by the sulphur atom. Klasens claims support for these views in the fact that replacement of S by Se leads not only to a shift in the luminescence band to longer wavelengths, arising from the smaller width of the forbidden gap, but also to the appearance of a new luminescence band[14,83], which can be ascribed to a perturbed selenide ion. In conformity with the lower electronegativity of Se as compared with S, this band occurs at a longer wavelength than does the corresponding band in the ZnS phosphor. In a similar way the trapping centres can be considered to be Zn^{2+} ions perturbed by neighbouring atoms of the coactivator or by V_S. In agreement with this theory, replacement of Zn^{2+} by Cd^{2+} leads to the appearance of a new trapping level. The small differences in spectral position of the luminescence bands associated with centres of different chemical nature argue in favour of the hypothesis that the electronic processes giving rise to luminescence occur in structural elements of the host lattice. We are now discussing the so-called "indirect activation"[259], which leads to the formation of localised levels which are not characteristic of specific activators.

In the electrostatic approximation the level of S^{2-} adjacent to a defect of charge -1 should lie at a height of $\epsilon = e^2/Kd = 0.74$ eV, where e is the electronic charge, $K = 8.3$ the dielectric constant of ZnS, and $d = 2.35$ Å the interionic distance. Attempts have been made to explain the dependence of the energy level of the centre on the nature of the activator in terms of the polarising effect of the latter, but no rigorous and universally applicable quantitative theory has yet emerged[85]. This has produced a tendency to abandon the ideas of Klasens[47,61]. Thus, Kröger[47] considers that holes localised on excited centres must spend part of their time in the electron shell of an impurity. This point of view is essentially similar to the above-mentioned ideas of Konstantinova-Shlezinger[204], who regards the centres as quasi-molecules. One development of the tendency to explain all the various properties of ZnS phosphors in terms of a single model was Broser's attempt[98] to construct a hydrogen-like model of the luminescence centre. However, the identification of the particular structural elements of the crystal phosphor in which the radiative electronic transitions take place remains an open question.

The experimental material discussed in the preceding Sections provides several illustrations of the similarity between the emission spectra of phosphors containing luminescence centres of entirely different chemical, electrical, and structural nature. This argues in favour of the assumption that the luminescence is caused by electronic transitions in the host material. However, any theory based on this hypothesis must take cognisance of the fact that the bond in ZnS and CdS is predominantly covalent. Therefore the valency electrons taking part in transitions belong not just to sulphur atoms but to both S and Zn (or Cd) atoms. This means that a molecular model of the luminescence centre is a better approximation than an ionic or an atomic model for phosphors of this class. Observations which suggest that molecularly disperse sulphides can luminesce in approximately the region of the spectrum where most of the luminescence bands of normal crystalline sulphide phosphors appear lead to the same conclusion. Thus, according to Weyl[260] and Vargin[261], the yellow luminescence of glasses coloured with cadmium sulphide is due to molecularly disperse CdS, as shown in particular by the absence of a crystalline phase in the glasses with the brightest emission. Gurvich[262,263] found that the dissolution of small amounts of CdS and ZnS in melts of $CdCl_2$, $CdBr_2$, and mixtures of these salts with $ZnCl_2$ produces phosphors having a strong luminescence; this can be explained by electronic transitions in molecules of CdS and ZnS held in the gap between the layers of atoms of the cadmium and zinc halides, which form a layered structure. Several other luminescent systems have been prepared whose ability to emit light can be ascribed to activation by CdS molecules distributed in the bulk or on the surface of the phosphor substrate[260,264,265]. Atoms of Cd (Zn) and S can interact, of course, not only among themselves but also with other neighbouring atoms, but the bond between Cd (Zn) and S is so different in character from all other bonds that we can speak of the formation of CdS and ZnS molecules: this difference accounts for the fact that these molecules are energetically isolated, a necessary condition for the development of luminescence. In a sulphide crystal the bonds between S and Cd (or Zn) atoms adjacent to a defect in the crystal lattice are different, owing to the perturbation caused by the defect, from the bonds in the unperturbed regions of the crystal, and thus we can again use the term molecules or quasi-molecules, formed by the atoms of the sulphide nearest to a defect. Electronic transitions in quasi-molecules of this type, responsible for the act of emission, could be likened to transitions in isolated molecules in a vapour (unfortunately, very little is known about the properties of these molecules[266]) or in solution, for example in the solid solutions discussed above. Since the S–Zn bond is strongly polarised[65,66], the cloud of valency electrons being mainly around the S atom, replacement of Zn by Cd does not have such a marked effect on the luminescence as has replacement of S by Se. This is the case both in normal crystalline sulphide phosphors[83] and in halides activated by sulphides[263]. The relative closeness of a quantum of the characteristic radiation of the majority of centres to the width of the forbidden gap in the sulphide, and the very important close interaction between the electronic processes taking part in the luminescence centres and in the lattice of the host material, are natural consequences of the fact that the phosphor matrix and the luminescence centres are composed of atoms of the same elements. Thus, the capacity for luminescence is embedded, as it were, in the sulphides themselves.

2. Compounds of aluminium hydride with bifunctional amines 655
3. Compounds of aluminium hydride with pyridine 656
4. Alkyl-substituted complexes of aluminium hydride with tertiary amines 657
5. Quaternary ammonium salts of aluminium hydride [quaternary ammonium tetrahydroaluminates] 657

I. INTRODUCTION

Aluminium hydride is one of the least studied but most interesting hydrides and also one of the most interesting in practical respects.

The detailed investigation of aluminium hydride and its complexes can give results of considerable significance for the further development of ideas about the nature of the chemical bond in molecules constructed from atoms of light elements.

Aluminium does not react directly with hydrogen to form the simple hydride AlH_3. Reactions which would yield pure (individual) aluminium hydride by the hydrogenation of aluminium compounds or by exchange reactions with other metal hydrides in the absence of a solvent which is a donor of electrons are still not known. In practice one is usually dealing with solutions or precipitates containing onium complexes of aluminium hydride with oxygen- or nitrogen-containing molecules. When these complexes are sufficiently stable (for example, those with tertiary amines $AlH_3.NR_3$) they can be isolated from the reaction mixture and obtained in an individual state.

The sharp rise in reactivity of the compounds of aluminium in relation to hydrogenating agents in the presence of a solvent which is a donor of electrons is due to additional ionisation of the Al–X bond owing to the effect of an electronic shift in the formation of the onium bond:

Furthermore, complex formation with a solvent stabilises the hydride molecule formed by the reaction:

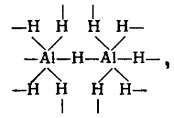
$$AlX_3 + 3MH \rightarrow AlH_3 + 3MX,$$

"clearing" the electron deficiency at the metal atom and hindering polymerisation, which leads to the formation of unstable, insoluble $(AlH_3)_x$.

The valence capacities of aluminium towards hydrogen are not determined uniquely. In alkali metal tetrahydroaluminate complexes† aluminium apparently has a coordination number of six. In support of this assumption there is the absence of isomorphism between $NaAlCl_4$ and $NaAlH_4$. According to Baenziger[1], $NaAlCl_4$ is orthorombic, with tetrahedral $AlCl_4^-$ ions at the lattice sites.

† Termed *alanates* in the Russian, presumably as derivatives of "alane", the name suggested by Wiberg for the AlH_3 unit (Ed. of Translation).

Such "ions" are either absent from the sodium tetrahydroaluminate lattice, being bound in an infinite pattern:



or are so distorted that their departure from tetrahedral symmetry leads to a different type of packing of the molecules in the crystalline lattice. From the formal point of view, octahedral coordination of the hydrogen atoms or ions around the aluminium atoms is entirely possible but the value of this conclusion, drawn on the basis of a comparison of the r_{Al}/r_H ratios with the known criteria for the stability of polyhedra with coordination number four or six, is quite relative, owing to the uncertainty in estimating the radii of the aluminium and hydrogen atoms which are specific for just this type of interaction. On the other hand, a series of derivatives of aluminium hydride are shown in which aluminium exhibits, formally at least, the coordination number of five.

Bis(trimethylamine)alane [2-trimethylamine-aluminium hydride (Ed of Translation)] $AlH_3.2N(CH_3)_3$ and the polymeric *NN'N*-tetramethylethylenediaminealane [*NN'N*-tetramethylethylenediamine-aluminium hydride (Ed. of Translation)] $AlH_3.Me_2N[CH_2]_2NMe_2$ are the only compounds of aluminium hydride for which there have been exhaustive X-ray diffraction investigations[2,3].

The bis(trimethylamine)alane molecule has a trigonal bipyramidal configuration with the hydrogen atoms situated in the equatorial plane. In the linear grouping N–Al–N the interatomic distance d_{Al-N} is 2.18 ± 0.01 Å, that is, a little greater than in aluminium nitride (1.87 Å) and considerably greater than the sum of the covalent radii (1.96 Å).

The configuration of a trigonal bipyramid with the aluminium atom at the centre of the equatorial plane is also retained in the compound of aluminium hydride with *NN'N'*-tetramethylethylenediamine. The interatomic distance d_{Al-N} is 2.195 ± 0.05 Å, and the valence angle N–Al–N is somewhat less than 180°.

It is interesting that in trimethylaminegallane $GaH_3.N(CH_3)_3$, the molecule of which apparently has a configuration[4] identical with that of $BF_3.N(CH_3)_3$, d_{Ga-N} = 1.97 Å, agreeing well with the sum of the covalent radii of Ga and N.

Apparently the increase in the coordination number of aluminium to five or six can be linked either with the participation of the 4*s*- and 3*d*-orbitals in bond formation or with a considerable ionicity of one of the Al–X bonds in the complex. In the latter instance there is some analogy with the so-called "quinquevalent" nitrogen.

II. METHODS OF MAKING ALUMINIUM HYDRIDE AND ITS AMINE COMPLEXES‡

It was mentioned above that there is not yet a method for isolating "pure" unsolvated aluminium hydride from a reaction mixture.

Attempts to obtain it by a "dry" method (without use of a solvent) have been unsuccessful or are of only theoretical significance.

In the direct reaction of metallic aluminium with hydrogen at 1500°, only physical adsorption of the gas takes place.[5] When an aluminium wire is vaporised in an atmosphere of hydrogen at 1100°, a product is formed in which the H:Al ratio fluctuates from 0.19 to 1.02.[5] It is suggested that under these conditions a mixture of aluminium and polymeric aluminium hydride is formed, but the properties of this product differ markedly from those of polymeric aluminium hydride, obtained from ethereal solution — all the hydrogen is lost on heating to -78° whereas the "ordinary" hydride is "stable" up to 105–110°.

The probability of the formation of aluminium hydride under these conditions was shown mass-spectrometrically[6], in which study aluminium hydride monomer was formed at low aluminium concentrations (~ 0.43%) at ~ 1090°, and the formation of the dimeric molecule Al_2H_6 was observed at ~ 1170° and a higher aluminium concentration (~ 1.7%).

On treating an aluminium–cerium alloy (up to 14% Al) with hydrogen, a product is formed which shows a thermal effect at ~ 210–230° on pyrolysis.[7] Decomposition on the walls of the ampoule gives a faint metallic mirror; as cerium hydride decomposes at a much higher temperature, this effect may be connected with the decomposition of aluminium hydride.

The reduction of trimethylaluminium by hydrogen in an electric discharge leads to the formation of aluminium hydride[8,9], but in this instance a mixture of alkylaluminium hydrides and aluminium hydride is obtained.

Methods based on the reduction of aluminium compounds with various reductants in a solvent–electron donor medium have the greatest practical importance for obtaining solutions of polymeric "solvated" aluminium hydride.

1. Reduction of $AlCl_3$ by lithium hydride in ether[10,11]:

$$AlCl_3 + 3LiH \xrightarrow{20^\circ} AlH_3 + 3LiCl.$$

This reaction proceeds in two stages: initially lithium tetrahydroaluminate is formed, which with an excess of aluminium chloride gives aluminium hydride. As a result of the reaction a metastable solution of aluminium hydride in ether is formed, from which on standing the hydride is deposited as a polymer $(AlH_3)_x$.

2. Reduction of aluminium chloride by lithium tetrahydroaluminate in ether[12,13]:

$$AlCl_3 + 3LiAlH_4 \rightarrow 4AlH_3 + 3LiCl.$$

The yield of aluminium hydride here is considerably greater than in the previous method.

3. Reduction of aluminium chloride by calcium or magnesium hydrides with added aluminium in ether.[14] The yield of aluminium hydride is almost quantitative, according to information in the patent.

4. Reaction of aluminium chloride with diethylaluminium hydride in ether[15]:

$$AlCl_3 + 3Et_2AlH \rightarrow AlH_3 + 3AlEt_2Cl.$$

The yield of aluminium hydride is ~ 70% and depends on the time for carrying out the reaction since increasing the duration of the process increased the yield of a side-product of composition Al_2H_5R.

‡ For the latter, see also J.K.Ruff, "Nitrogen Compounds of Boron, Aluminium, Gallium, Indium, and Thallium", Chapter VI of "Developments in Inorganic Nitrogen Chemistry, Vol.1" (Edited by C.B.Colburn), Elsevier, Amsterdam, 1966 (Ed. of Translation).

5. An electrolytic method for obtaining aluminium hydride by the reduction of a saturated solution of sodium tetrahydroaluminate in tetrahydrofuran at a mercury cathode was recently patented.[16] After electrolysis for three hours, the Al:Na ratio was 2.7; it could be taken that the $NaAlH_4$ concentration had decreased and the aluminium hydride had been formed.

All attempts to desolvate aluminium hydride obtained from ethereal solutions have been unsuccessful. On heating, loss of ether molecules does not take place, but the Al–H bond is broken, and when a freshly prepared solution is treated with a large quantity of inert solvent (pentane or ligroin) an etherated product of composition $(AlH_3)_n \cdot (C_2H_5)_2O$, where $n = 2.05-2.30$, is obtained[17].

The isolation of aluminium hydride from the reaction mixture and its stabilisation could be effected by treating it with substances which are stronger donors of electrons than diethyl ether. Such substances are amines forming stable amine complexes, which (unlike the oxonium solvates) are individual substances of constant composition.

---o0o---

The following methods for obtaining complexes of aluminium hydride with amines are possible:

1. Direct reaction of solvated aluminium hydride with amines[18–20].

2. Reaction of an ethereal solution of aluminium hydride with the gaseous amine (trimethylamine)[8,9,12,13,21].

3. The exchange reaction of a simple amine complex of aluminium hydride (for example, $AlH_3.NMe_3$) with more complex amines[22–25].

4. The reaction of lithium tetrahydroaluminate with the amine hydrochloride.[26]

5. Direct reaction of lithium tetrahydroaluminate with the amine in ether[27]; the yield of the complex in this reaction is very small, however.

6. The reaction of aluminium, hydrogen, and amine in tetrahydrofuran under hydrogen pressure with heating.[28]

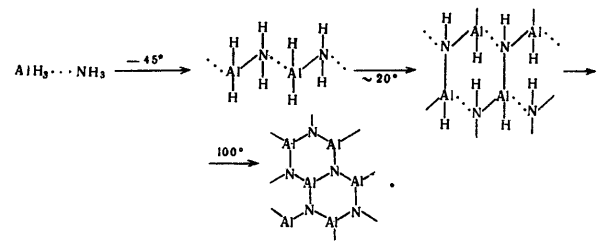
1. Compounds of Aluminium Hydride with Ammonia and Its Derivatives

The study of the reaction of aluminium hydride with ammonia began with attempts to obtain a compound analogous to borazole.[18]

On mixing a solution of aluminium in tetrahydrofuran with dry ammonia in equimolecular proportions at -80° and then heating the mixture, all the intermediate compounds analogous in composition to boron compounds were isolated, but pure alazole was not detected; the explanation given was that aluminium, unlike boron, does not tend to form Al⇄N double bonds, owing to the less electrophilic nature of the "incomplete" 3*p*-orbital.

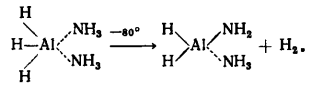
Initially at -80° a voluminous precipitate of composition $AlNH_6$ is formed, which evidently contains alazane $AlH_3 \ldots NH_3$, above -45° one mole of hydrogen is released with the formation of a highly polymeric alazene $(\ldots AlH_2-NH_2\ldots)_x$, which in turn on prolonged heating to room temperature loses a second mole of hydrogen and is converted into a highly polymeric alazyne $(\ldots AlH-NH\ldots)_x$. The formation of aluminium nitride with release of a third mole of hydrogen does not go to completion even on heating to 100°. All the products obtained are insoluble in an excess of the solvent.

In its entirety this process can be represented by the following scheme:



It must be noted that the release of hydrogen from the analogous boron derivatives takes place with much greater difficulty (at higher temperatures)[29,30]. The ease with which hydrogen is released from an aluminium atom was explained by its stronger electronegativity in the hydride compounds of aluminium.[18]

When aluminium hydride in ethereal solution reacts with ammonia in the molar ratio $AlH_3 : NH_3 = 1 : 4$ at -80°, an aminoalane ammine $AlH_2(NH_2).NH_3$ is formed.[18] Here the reaction evidently passes through the stage of formation of aluminium hydride–2-ammonia, $AlH_3.2NH_3$, which at the temperature of the experiment immediately loses one mole of hydrogen (above -30° almost all the hydrogen is lost):



When the reaction is carried out in similar proportions at -50° a white solid of composition $AlH(NH_2)_2$ is obtained after distilling off the excess of ether.

This suggests that diaminoalane is formed by the loss of one mole of hydrogen from aminoalane monoammine:

On heating this compound to room temperature, another mole of hydrogen is released, as a result of which a compound of composition $Al(NH)NH_2$ is formed.

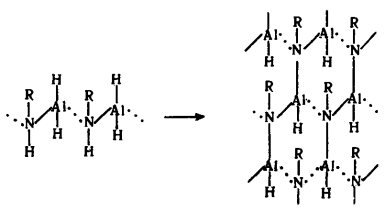
Aminoalane and diaminoalane are intermediate products in the preparation of triaminoalane [aluminium amide, $Al(NH_2)_3$ (Ed. of Translation)], which is formed in the reaction of aluminium hydride with ammonia (in the proportions $AlH_3 : NH_3 = 1 : 4$) at -30°.[13,18] However, under such conditions of carrying out the reaction the theoretical atomic ratio of Al : N = 1 : 3 could not be reached. At best, the ratio Al : N = 1 : 2.84 was attained. On raising the temperature above -30°, triaminoalane decomposes to form aluminium nitride:

Pure triaminoalane is obtained by the reaction of an excess of liquid ammonia with diaminoalane at -50°:[18]

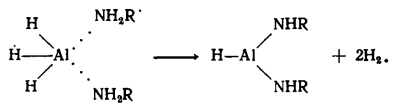
Aluminium hydride in ethereal solutions reacts with methylamine as with ammonia.[18]

When the reaction is carried out with a 1 : 1 molar ratio of the reagents in boiling dioxan a highly polymeric methylalazyne $(AlH-NR)_x$ is formed, and not a trimeric molecule corresponding to *N*-trimethylborazole. The conversion takes place in stages with the formation of *N*-methylalazane (methylamine–alane) $AlH_3 \cdot NH_2R$ and polymeric *N*-methylalazene (methylaminoalane) $(-AlH_2-NHR-)_x$.

When the reaction is carried out at -55° in ether, there is first a white precipitate of methylamine–alane $AlH_3 \cdot NH_2R$, which at -35° releases one mole of hydrogen to form methylaminoalane $AlH_2(NHR)$, converted at room temperature into *N*-methylalazyne with loss of one mole of hydrogen (released only on boiling with dioxan). All the substances thus obtained are high polymers; they are insoluble in ether and benzene and lose hydrogen with difficulty — especially in the last stage, owing to the formation of a complex network structure.



In the reaction of aluminium hydride with methylamine in ether at a reagent molar ratio of 1 : 2 and -55°, a white precipitate of $AlH_3 \cdot 2NH_2R$ is formed[18], which loses two moles of hydrogen at -35° to give bis(methylamino)alane:



Loss of the third mole of hydrogen to form Al(NHR)NR is extremely difficult, owing to the high degree of polymerisation of bis(methylamino)alane.

Bis(methylamino)alane and (methylamino)alane are intermediates in the production of a methyl derivative of triaminoaluminium, tris(methylamino)alane $Al(NRH)_3$,[18] which is a white, highly polymeric substance formed on mixing an ethereal solution of aluminium hydride with an excess of methylamine (~ 1 : 4):

$$[AlH_3] + 3NH_2R \longrightarrow Al(NHR)_3 + 3H_2.$$

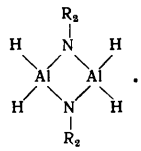
The best result is obtained by cooling the reaction mixture to -50°. The whole reaction scheme is:

$$[AlH_3] + 2NH_2R \longrightarrow AlH_3 \cdot 2NH_2R \xrightarrow{-H_2} AlH_2(NHR) \cdot NH_2R \xrightarrow{-H_2}$$
$$\xrightarrow{-H_2} AlH(NHR)_2 \xrightarrow{+NH_2R} AlH(NHR)_2 \cdot NH_2R \xrightarrow{-H_2} Al(NHR)_3.$$

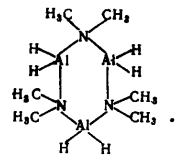
On mixing an ethereal solution of aluminium hydride with dimethylamine in the molar rato $AlH_3 : NHR_2 = 1 : 1$ at -30° and then warming to room temperature, hydrogen is liberated and (dimethylamino)alane AlH_2NR_2 is formed[18]:

$$[AlH_3] + NHR_2 \longrightarrow AlH_2(NR_2) + H_2.$$

This is readily purified by distillation in a vacuum at 40–60°. An ebullioscopic measurement of the molecular weight in ether showed that (dimethylamino)alane is dimeric and its structure evidently corresponds to the formula:



However, a cryoscopic determination of the molecular weight in benzene showed[26] that the degree of association is not 2.16,[18] but 2.99, therefore the formation of a trimeric molecule must be proposed, in which the aluminium atom has a coordination number of four and the association takes place by formation of Al–N bonds (by analogy with boron compounds[31]):



This substance melts without decomposition at 89–90°, is soluble in benzene and ether, and reacts vigorously with water with liberation of hydrogen.

(Dimethylamino)alane can be obtained by reaction of trimethylamine–alane with tris(dimethylamino)alane[32]:

$$2AlH_3 \cdot NMe_3 + (NMe_2)_3Al \rightarrow 3AlH_2(NMe_2) + 2NMe_3$$

and by reaction of lithium tetrahydroaluminate with dimethylamine in equimolecular proportions[27].

(Di-isopropylamino)alane and (diethylamino)alane are obtained in the reaction of the corresponding dialkylammonium chlorides with lithium tetrahydroaluminate[26,32]:

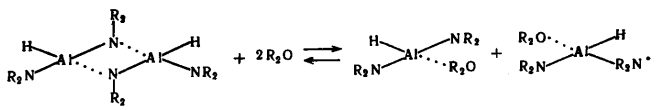
	M.p., °C	Sublimation temp., °C	Degree of association
$[(CH_3)_2CH]_2NAlH_2$	130–131	90	2.16
$(Et_2N)AlH_2$	42	—	2.12

The molecular weights of the two compounds were measured cryoscopically in benzene.

On mixing an ethereal solution of aluminium hydride with dimethylamine in the molar ratio 1 : 2 at -30°, then after the liberation of hydrogen had ceased and distillation under high vacuum at 35–50°, bis(dimethylamino)alane was obtained as colourless crystals[18]:

$$[AlH_3] + 2NHR_2 \rightarrow AlH(NR_2)_2 + 2H_2.$$

According to Wiberg and May[18], bis(dimethylamino)alane melts at 63–65° and dissolves in benzene and ether. An ebullioscopic determination of the molecular weight in ether showed that the substance is partly associated into a dimeric molecule:



Hence it is thought that the introduction of the NR_2 group diminishes the tendency to polymerisation.

Bis(dialkylamino)alanes can be isolated (in high yield) from the reaction of trimethylamine–alane with the appropriate dialkylamines[32,33]:

$$AlH_3 \cdot NMe_3 + 2(Alk)_2NH \rightarrow 2H_2 + HAl(NAlk_2)_2 + NMe_3.$$

Bis(dimethylamino)alane obtained by this method has the same melting point (62°) as the compound described by Wiberg and May[18], however, the degree of its association in benzene is 2.49 (according to these authors, 1.71 in ether). The different degree of association of bis(dimethylamino)alane depending on the solvent can be explained by the formation of an ether addition compound, although it is thought[32] that the bridging bond formed by the Me_3N group is fairly stable.

Bis(dimethylamino)alane is formed also in the reaction of sodium hydride with (dimethylamino)alane[33]:

$$NaH + 2AlH_2NMe_2 \longrightarrow NaAlH_4 + HAl(NMe_2)_2.$$

The introduction of a third R_2N group suppresses the dimerisation of the molecule, according to Wiberg and May[18]; $Al(NR_2)_3$ is monomeric. Tris(dimethylamino)alane is obtained by the reaction of an ethereal solution with dimethylamine and room temperature and molar ratio AlH_3 : NHR_2 = 1 : 4. The substance sublimes in a vacuum at 60–100°, melts without decomposition at 87–88°, and reacts vigorously with water and acids.

The same compound can be obtained by other methods. Ruff[32] proposed two methods of synthesis:

(1) $$H_3Al\cdot NMe_3 + 3HNMe_2 \longrightarrow Al(NMe_2)_3 + NMe_3 + 3H_2,$$

(2) $$LiAlH_4 + 4HNMe_2 \longrightarrow LiAl(NMe_2)_4 + 4H_2,$$

(3) $$3LiAl(NMe_2)_4 + AlCl_3 \longrightarrow 4Al(NMe_2)_3 + 3LiCl.$$

Tris(dimethylamino)alane is also obtained by the reaction of tri-isobutylaluminium with dimethylamine in heptane[34]:

$$(Bu^i)_3Al + 3HNMe_2 \xrightarrow{195^\circ} Al(NMe_2)_3 + 3iso\text{-}C_4H_{10}.$$

And finally Fetter and Bartocha[25] obtained $Al(NMe_2)_3$ by the reaction of trimethylaluminium with tetramethyltetrazene. They proposed the following reaction scheme:

$$3AlMe_3 + 3Me_2HN{=}NHMe_2 \longrightarrow 2Al(Me_2N)_3 + N_2 + 6CH_4.$$

There is a considerable difference in the physical constants of tris(dimethylamino)alane obtained by various methods (see Table 1). The marked difference between the melting points of tris(dimethylamino)alane obtained by Fetter and other authors can only be explained if quite different substances were investigated. The stability of the monomeric form in ether[18,20] and the dimeric form in benzene[32] shows that tris(dimethylamino)alane can form an ether addition compound $Al(NMe_2)_3.O(C_2H_5)_2$.[32]

Tris(dimethylamino)alane reacts without a solvent with anhydrous aluminium chloride[32]; dichloro-(dimethylamino)-alane and chlorobis(dimethylamino)alane are formed:

$$AlCl_3 + 2(Me_2N)_3Al \rightarrow 3(Me_2N)_2AlCl,$$
$$2AlCl_3 + (NMe_2)_3Al \rightarrow 3(Me_2N)AlCl_2.$$

Replacement of the third NMe_2 group taking part in the formation of a nitrogen bridge does not occur.

TABLE 1.

M.p., °C	Molecular weight	Method of determination	Reference
−30	193—199	cryoscopic (cyclopentane)	25
87—88	162	ebullioscopic (ether)	18
87—89	353	cryoscopic (benzene)	32
Not given	320	cryoscopic (benzene)	34

TABLE 2.

Compound	M.p., °C	Sublimation temperature, °C	Degree of association
$(Me_2N)_2AlCl$	55—57	55	1.95
$(Me_2N)AlCl_2$	151	90	2.12

The difference in the reactivity of the bridge and terminal dialkylamino-groups was investigated in the tensimetric titration of dialkylamino-derivatives of aluminium with gaseous boron trichloride[32].

When two moles of boron trichloride are added to one mole of tris(dimethylamino)alane (under conditions such that it is dimeric, that is, a bridge bond is formed), a sharp change in vapour pressure is observed after 15 min; when an excess of boron trichloride (over three moles) is added, the change in vapour pressure occurs after 24 h. This can be explained only by a difference in the reactivity of the NMe_2 groups in tris(dimethylamino)alane.

There are other proofs of the stability of the bridge bonds formed. When (trimethylamino)alane reacts with dimethylamine, trimethylamine is quantitatively replaced by dimethylamine and hence the equilibrium of the reaction is completely displaced in favour of a compound with nitrogen bridges[33].

Tris(di-isopropylamino)alane, unlike tris(dimethylamino)alane, is monomeric[32]. This fact is apparently connected with steric hindrance to dimerisation. The difference between these compounds also appears in the conditions for their preparation — whereas $Al(NMe_2)_3$ is formed rather readily, $Al[(iso\text{-}C_3H_7)_2N]_3$ is considerably more difficult to prepare; this is linked with the necessity of breaking the nitrogen bridges in the intermediate di-isopropylamino-derivatives of aluminium — bis(di-isopropylamino)alane is dimeric.

As mentioned above, tris(dimethylamino)alane is monomeric in ether and this is apparently due to the formation of the ether addition compound $Al(Me_2N)_3.O(C_2H_5)_2$. An attempt was therefore made to obtain an amine complex of tris(di-isopropylamino)alane with trimethylamine and dimethylamine[32].

In the first instance, no reaction was observed; in the second, there was a sudden change in pressure in the system on adding two moles of dimethylamine; apparently an exchange reaction took place instead of the formation of the expected complex:

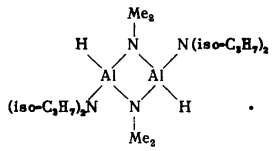
$$2(CH_3)_2NH + [(iso\text{-}C_3H_7)_2N]_3Al \longrightarrow 2(iso\text{-}C_3H_7)_2NH + (Me_2N)_2Al[N(iso\text{-}C_3H_7)_2].$$

However, (di-isopropylamino)bis(dimethylamino)alane was not isolated from the reaction products. Attempts to obtain it by the reaction of di-isopropylamine with dimethylaminoalane led to the replacement of only one hydrogen atom[32]:

$$(iso\text{-}C_3H_7)_2NH + (CH_3)_2N{-}AlH_2 \xrightarrow{36\ h} (CH_3)_2N{-}\overset{H}{\underset{|}{Al}}{-}N(iso\text{-}C_3H_7)_2 + H_2.$$

(Di-isopropylamino)(dimethylamino)alane is a solid which sublimes at 95° and its degree of association (in benzene) is 1.98. Three structural formulae for it are possible

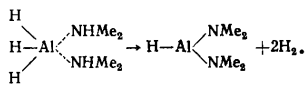
(under the conditions for the formation of nitrogen bridges), the most probable being:



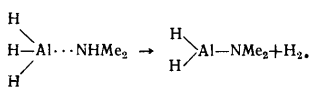
The structural formula with $(iso\text{-}C_3H_7)_2N$ bridge-forming groups is less probable, as the NMe_2 group stabilises the dimer more strongly and the molecule with a bridging bond through this group is rather stable.

As tris(di-isopropylamino)alane is monomeric and all its amino-groups are equivalent, an increase in vapour pressure is observed during tensimetric titration with boron trichloride at the molar ratio $BCl_3 : Al(NPr^i_2)_3 = 3 : 1$.[32]

To conclude this section we will consider the even less-studied bis(dimethylamine)alane and (dimethylamine)alane. Bis(dimethylamine)alane is formed in the reaction of an ethereal solution of aluminium hydride with dimethylamine at -50°.[18] It is of low stability and decomposes at -20° with loss of hydrogen and formation of bis(dimethylamino)alane:



(Dimethylamine)alane can be obtained by the action of dimethylammonium chloride on lithium tetrahydroaluminate at -40°.[26] It exists only up to -10°, above which temperature it loses one mole of hydrogen to form (dimethylamino)alane:



The amine complexes of aluminium hydride with tertiary amines in which the $[AlH_3]$ group of atoms remains unchanged are particularly interesting. Those with trimethylamine have been studied most.

These compounds are readily obtained in the reaction of freshly prepared ethereal solution of aluminium hydride with trimethylamine in the molar ratio 1:1 and 1:2 at room temperature or on coooling[8,9,12,13,20,21]. Another method of preparation is based on the reaction of lithium tetrahydroaluminate with the amine hydrochloride.[26]

Mono(trimethylamine)alane, subsequently called trimethylamine alane, distils readily in a vacuum at 60°/1 mmHg, forming colourless crystals, dissolves readily in ether, benzene, and tetrahydrofuran, reacts explosively with water, and fumes strongly in air. The pure product melts at 76° without decomposition.

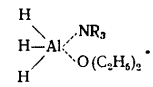
When heated rapidly to 100°, the crystals become opaque, owing to the commencement of the polymerisation of aluminium hydride:

$$x\ AlH_3 \cdot NMe_3 \rightarrow (AlH_3)_x + x\ NMe_3.$$

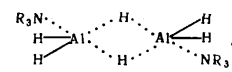
Heating on a naked flame leads to complete decomposition of the compound and the formation of an aluminium mirror:

$$AlH_3 \cdot NMe_3 \rightarrow Al + 1.5H_2 + NMe_3.$$

In determining the molecular weight (ebullioscopic method) in ether, it was found that trimethylamine alane is monomeric, but it is associated in benzene[12,13]; trimethylamine alane vapour is monomeric[35]. This difference in the behaviour of trimethylamine alane depending on the solvent was explained by the unsaturated nature of the four-coordinated aluminium atom — in ether this saturation takes place with the p-electrons of the oxygen atom:



In benzene, this propensity to saturation can be effected by the dimerisation of two molecules of trimethylamine alane with the formation of hydrogen bridges:

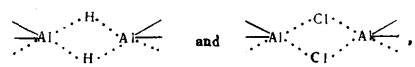


Wiberg's hypothesis of the dimerisation of trimethylamine alane received confirmation in later studies[26,36].

It can also be assumed that association of trimethylamine alane takes place by dipole–dipole interaction in the solution[36-38]. This hypothesis is based on the fact that replacement of hydrogen atoms by chlorine atoms produces a slight change in the degree of association of alane in benzene[37]:

	Degree of association
$AlH_3 \cdot NMe_3$	1.43
$H_2AlCl \cdot NMe_3$	1.32
$HAlCl_2 \cdot NMe_3$	1.46
$AlCl_3 \cdot NMe_3$	1.36

It is improbable that the stability of the rings



would be completely the same. Evidently dipole–dipole interaction is also more probable for trimethylamine alane and for an amine-complex of aluminium chloride in benzene[39].

The investigation of infrared and Raman spectra showed that the symmetry of the trimethylamine alane molecule is C_{3v} and the Al–N vibration frequency is 553 cm^{-1}.[40]

Of the other trialkylamine alanes, triethylamine alane and tri-n-propylamine alane have been obtained and studied[26,42].

Under ordinary conditions triethylamine alane is a transparent liquid, m.p. 18–19°; it is easily distilled in a vacuum at 40°.

On determining the molecular weight of this compound in benzene[26] a considerable difference from Wiberg's data[42] (determination in ether) was found. The degree of association is 1.10 according to Ruff, 1.57 to Wiberg.

With tri-n-propylamine alane steric hindrance completely prevents association into a dimer: it is difficult to distil and can be purified by recrystallisation from hexane at -80°. Its melting point is 80–81°.[26]

Bistrialkylamine alanes can be obtained by various methods which differ little in principle from one another.

When an ethereal solution of aluminium hydride is mixed with trimethylamine (1 : 2), the reaction yields a colourless solution from which, after distilling off the solvent and the excess of amine, bis(trimethylamine)alane is precipitated as a white powder; it readily sublimes in a vacuum at 30–40°/1 mmHg. The same compound can be obtained on adding an excess of trimethylamine to trimethylaminealane[13] or by the action of hydrogen chloride on lithium tetrahydroaluminate followed by addition of trimethylamine[2]:

$$LiAlH_4+HCl \xrightarrow{R_2O} H_2+LiCl+[H_3Al]\cdot R_2O,$$
$$[H_3Al]\cdot R_2O+2NMe_3 \xrightarrow{R_2O} H_3Al\cdot 2NMe_3.$$

Bis(trimethylamine)alane melts at 95° and at 100° it starts to decompose, probably with formation of a polymer of aluminium hydride and liberation of trimethylamine. The compound dissolves readily in ether, benzene, and tetrahydrofuran.

Molecular weight determinations in benzene and ether show that the substance is monomeric in these solvents[26,42]; on comparing the infrared spectra of $AlH_3.2NMe_3$ and $(AlH_3)_2(Me_2N[CH_2]_2NMe_2)_2$ it was noted that the absorption of the Al–H bond in the 5.9 μm region is the same, hence it was assumed that bis(trimethylamine)alane is partly dimerised in the gas phase[23].

Measurements of the polarisation of the molecule in benzene, cyclohexane, and dioxan did not show the presence of a dipole moment which varied in different solvents (1.2 D in benzene, 1.6 D in cyclohexane and dioxan). The existence of a dipole moment for a trigonal bipyramidal model was explained by the high atomic polarisation[38,40].

Ruff and coworkers[33] investigated the conditions for the formation and the stability of other bis(trialkylamine)alanes. The formation constants for these complexes allowed them to construct a series for the stability of alanes as a function of the alkyl group:

$$NR_3=N(CH_3)_3 > N(CH_3)_2CH_2CH=CH_2 > N(CH_3)(C_2H_5)_2 > N(C_2H_5)_3 > N(C_3H_7)_3.$$

The stability of the mixed diaminealanes changes in the sequence:

$$AlH_3\cdot N(CH_3)_3\cdot N(CH_3)(C_2H_5)_2 > AlH_3\cdot N(CH_3)_3\cdot N(C_2H_5)_3 > AlH_3\cdot N(CH_3)_3\cdot N(C_3H_7)_3,$$

that is, the stability of the complexes also depends entirely on the dimensions of the alkyl groups (mixed diaminealanes are more stable than symmetrical ones).

2. Compounds of Aluminium Hydride with Bifunctional Amines

Aluminium hydride in tetrahydrofuran reacts with hydrazine with the formation of aluminium hydrazide $Al(N_2H_3)_3$.[41] This reaction proceeds very slowly in an inert solvent whereas in tetrahydrofuran the yield approaches 94% (the isolation of this compound was carried out in a high vacuum):

$$AlH_3+3N_2H_4 \longrightarrow Al(N_2H_3)_3+3H_2.$$

The mechanism of the reaction between aluminium hydride and hydrazine is not completely clear, but it is possible that the reaction proceeds just as in the reaction of metal amides and metal alkyls with hydrazine, that is, through the formation of the ions $N_2H_3^-$ and $N_2H_5^+$, on account of a shift in the equilibrium of the protolysis of hydrazine:

$$2N_2H_4 \rightleftarrows N_2H_5^+ + N_2H_3^-.$$

The $N_2H_5^+$ ion reacts with a hydrogen ion to form a molecule of hydrazine and a molecule of hydrogen:

$$H^- + N_2H_5^+ \longrightarrow N_2H_4 + H_2,$$

and the $N_2H_3^-$ ion reacts with an aluminium ion to form aluminium hydrazide:

$$Al^{3+} + 3N_2H_3^- \longrightarrow Al(N_2H_3)_3.$$

It is interesting that in this scheme appreciable ionisation of the Al–H bond is proposed.

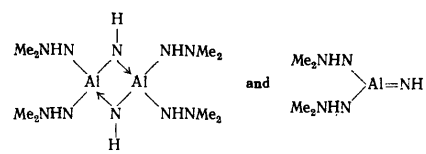
When trimethylaminealane is used instead of aluminium hydride, the reaction yields a white solid, which, when the solvent is removed, explodes at the least vibration[22]; however, this substance has not been identified.

The mechanism of the reaction of trimethylaminealane with alkyl derivatives of hydrazine and the structure of the final products of the reaction are extremely difficult to interpret and are semi-quantitative because most of the products are polymers, have a low vapour pressure, do not distil, and cannot be purified by sublimation. The direction of the reaction depends entirely on the initial proportion of the reagents, the structure of the alkyl hydrazine, and the nature of the solvent.

Methylhydrazine and trimethylaminealane (in hydrocarbon medium) give a white, stable compound[22]. On the basis of the ultimate analysis and infrared spectra of the final products the following reaction scheme was proposed:

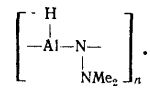
$$n\,H_3Al\cdot NMe_3 + 2n\,H_2NNHMe \longrightarrow \left[\begin{array}{l} NH—NHMe \\ |\quad\quad\quad \\ —Al—NHNMe— \end{array}\right]_n + 3n\,H_2 + n\,NMe_3.$$

1,1-Dimethylhydrazine forms with trimethylaminealane a white crystalline substance which does not sublime in a vacuum and has m.p. 193–194°.[22] Two structural formulae have been proposed for the substance:

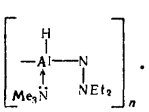


but have not been confirmed by direct experimental data, however.

When 1,1-dimethylhydrazine and trimethylaminealane in the molar ratio $Me_2NNH_2 : AlH_3.NMe_3 = 2 : 1$ react in pentane a substance with the empirical formula $C_2H_7N_2Al$ is obtained[22]. The infrared spectrum agrees best with the polymeric formula:



This structural formula is also supported by the fact that 1,2-diethylhydrazine also reacts with trimethylaminealane[22] only here the trimethylamine molecule is associated with the aluminium atom. As a result of the reaction a viscous substance is formed, the structural formula of which may be:

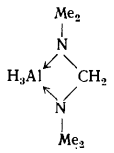


When the reagent ratio is $AlH_3.NMe_3 : Et_2NNH_2 = 1 : 1$, a white, involatile solid is formed, 1,1-diethylhydrazidoalane $AlH_2.NHNEt_2$.[22]

Trimethylhydrazine with trimethylamine–alane forms dimethylaminoalane AlH_2-NMe_2.[22]

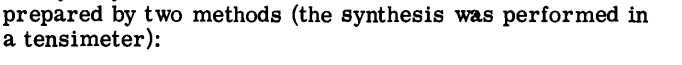
It must be pointed out that freshly prepared aluminium hydride–ether does not react with tetramethylhydrazine[22], although earlier it was thought that it has the same basicity as trimethylamine.

Trimethylamine–alane forms with *NNN'N'*-tetramethylmethylenediamine a cyclic complex which has a sharp melting point (25–26°) and is readily distilled in a vacuum at room temperature[22]. Starting from the NMR spectra and ultimate analysis the following structural formula was advanced for it:



(this complex is evidently partly dimerised in benzene, where its molecular weight is 164–167, against the calculated 132).

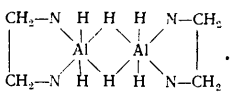
A complex of aluminium hydride with *NNN'N'*-tetramethylethylenediamine has also been obtained[23]. It was prepared by two methods (the synthesis was performed in a tensimeter):



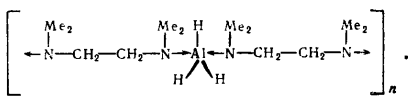
(1) $2LiAlH_4 + Me_2N[CH_2]_2NMe_2 \cdot 2HCl \xrightarrow{Me_2N[CH_2]_2NMe_2} 2H_2 + 2LiCl + 2H_3Al \cdot Me_2N[CH_2]_2NMe_2$,

(2) $AlH_3 \cdot 2NMe_3 + Me_2N[CH_2]_2NMe_2 \longrightarrow 2NMe_3 + AlH_3 \cdot Me_2N[CH_2]_2NMe_2$.

The complex is a white solid which does not decompose on heating to 133° for 24 h. Its vapour pressure at 99.3° and 119.2° is 1.5 and 10.6 mmHg respectively. In measuring the vapour pressure it was found that the product is apparently dimeric and the probable structural formula for it with six-coordinated aluminium atoms was proposed:



However, later investigations[2,3] established the existence of associates with a linear N–Al–N bond:



The same structural formula can be proposed also for the complexes of aluminium hydride with *NNN'N'*-tetramethyl-1,3-propanediamine and 1,4-bis(dimethylamino)but-2-ene[24], since with them aluminium hydride also gives complexes of 1 : 1 composition. *NNN'N'*-tetramethyl-1,3-propanediamine–alane is a white solid with m.p. 136–140°; it distils in a vacuum at 80°/0.05 mmHg. It is obtained by the reaction of trimethylamine–alane with *NNN'N'*-tetramethyl-1,3-propanediamine[24].

The complex with 1,4-bis(dimethylamino)but-2-ene

$$[H_3Al \cdot (Me_2N) \cdot CH_2CH=CHCH_2(NMe_2)],$$

is obtained by reaction with trimethylamine–alane in n-octane[24]. Its m.p. is 150–155° and it distils at 105°/0.05 mmHg. It should be noted that the investigation of these complexes has been qualitative in nature.

Fetter and Moore[24] investigated the reaction of trimethylamine–alane with tetrakisdimethylaminoethylene $[(CH_3)_2N]_2C=C[N(CH_3)_2]_2$ and hexamethylenetetramine. However, here the investigation was purely qualitative: there is no distinct chemical analysis of the product. The authors suggest that the tetrakisdimethylaminoethylene is bonded in a complex with two molecules of aluminium hydride, after which decomposition of the complex occurs (the decomposition products were not determined). The sublimation temperature of the compound is 75°.

With hexamethylenetetramine a stable complex is formed, presumably $AlH_3.(CH_2)_6H_4$, which does not sublime up to 120° and does not melt up to 200°, but above that temperature it decomposes with formation of an aluminium mirror.

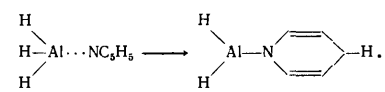
The mechanism of the reaction and the end product of the reaction of trimethylamine–alane with tetramethyltetrazene has been established sufficiently accurately[25]. Tetramethyltetrazene heated in an inert solvent decomposes with formation of tetramethylhydrazine and liberation of hydrogen; however, in the presence of trimethylamine alane the dimethylamino-group does not add to the tetramethylhydrazine but reacts to form dimethylaminoalane:

$$2H_3Al \cdot NMe_3 + Me_2NN=NNMe_2 \rightarrow 2H_2Al-NMe_2 + H_2 + N_2 + 2NMe_3.$$

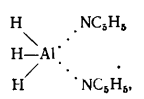
The substance was sublimed at 60°/0.005 mmHg, and then identified by melting point, ultimate analysis and infrared spectra (see above for the physical constants).

3. Compounds of Aluminium Hydride with Pyridine

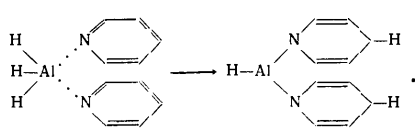
Aluminium hydride reacts in ethereal solution with pyridine in the molar ratio $AlH_3 : NC_5H_5 = 1 : 1$ at -30° with the formation of a white crystalline addition product, $AlH_3.NC_5H_5$.[19] When the latter is heated to room temperature its colour changes from white to yellow. This behaviour is explained by intramolecular rearrangements in which one atom of hydrogen connected with aluminium is introduced into the pyridine ring with formation of a compound with a quinonoid structure:



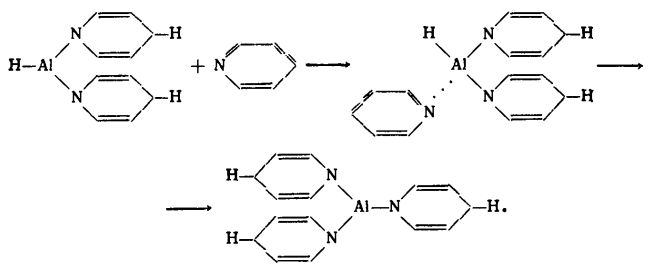
When an excess of pyridine is taken, then aluminium hydride–bis-pyridine is formed under analogous conditions:



which when slowly heated to room temperature gradually changes colour from white to dark red. During this there is considerable heat liberated and the residue melts (60–70°). This change in colour is due to the same intramolecular rearrangement:



Bis(dihydropyridyl)alane is insoluble in benzene, petroleum ether, tetrahydrofuran, chloroform, and does not dissolve in an excess of pyridine. After distilling off the excess of solvent a brownish-red solid of composition $AlH_3.3NC_5H_5$ remains[19]. Hydrolytic decomposition of this compound showed that it does not contain active hydrogen bound to the aluminium atom. Hence bis(dihydropyridyl)-alane and pyridine give tris(dihydropyridyl)alane:



The completeness of the conversion of bis(dihydropyridyl)-alane into tris(dihydropyridyl)alane depends on the reaction time. Both products are sensitive to oxygen.

4. Alkyl-Substituted Complexes of Aluminium Hydride with Tertiary Amines

In addition to the amine complexes of aluminium hydride, a series of complexes is known in which the hydrogen in AlH_3 is partly replaced by alkyl. Such compounds can be prepared as follows:

1. By the reduction of alkylhalides of aluminium with lithium hydride[43,44]:

$$R_2AlHal\cdot NMe_3 + LiH \longrightarrow R_2AlH\cdot NMe_3 + LiCl,$$
$$RAlHal_2\cdot NMe_3 + 2LiH \longrightarrow RAlH_2\cdot NMe_3 + 2LiCl.$$

2. By the alkylation of trimethylamine–alane with dialkylmercury compounds[43,44]:

$$AlH_3\cdot NMe_3 + R_2Hg \longrightarrow R_2AlH\cdot NMe_3 + H_2 + Hg,$$
$$AlH_3\cdot NMe_3 + {}^1/_2R_2Hg \longrightarrow RAlH_2\cdot NMe_3 + {}^1/_2H_2 + {}^1/_2Hg.$$

3. By disproportionations[43,44]:

$$AlH_3\cdot NMe_3 + 2R_3Al\cdot NMe_3 \longrightarrow 3R_2AlH\cdot NMe_3,$$
$$2AlH_3NMe_3 + R_3Al\cdot NMe_3 \longrightarrow 3RAlH_2\cdot NMe_3.$$

4. By alkylation of trimethylamine–alane and dimethylaminoalane with butyl-lithium[44]:

$$AlH_3\cdot NMe_3 + LiC_4H_9 \longrightarrow LiH + C_4H_9AlH_2\cdot NMe_3.$$

The reaction is complicated by a side-reaction:

$$LiH + AlH_3\cdot NMe_3 \longrightarrow LiAlH_4 + NMe_3,$$

which makes control over the stoichiometry of the reaction difficult.

The amine complexes of the alkyl hydrides are extremely sensitive to moisture and oxygen. From the little information which is available about these compounds it can be concluded that the introduction of alkyl groups into the molecule of an amine complex of the hydride stabilises the compound (Table 3).

5. Quaternary Ammonium Salts of Aluminium Hydride [Quaternary Ammonium Tetrahydroaluminates]

A paper recently appeared[45] on a new method of stabilising aluminium hydride by the formation of quaternary ammonium salts of tetrahydroaluminates.

TABLE 3.

Compound	M.p., °C	B.p., °C	Degree of association
$MeAlH_2\cdot NMe_3$	−35	25—26	1.95
$Me_2AlH\cdot NMe_3$	33—35	42—43	1.34
$EtAlH_2\cdot NMe_3$	—	35—40	1.60
$Et_2AlH\cdot NMe_3$	−28	63—65	1.18

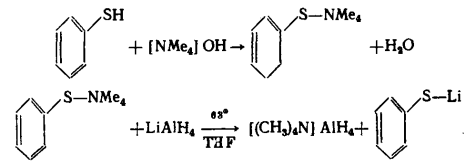
Two salts of this type have been obtained, tri-n-octyl-n-propylammonium tetrahydroaluminate, $[(C_8H_{17})_3(C_3H_7)N].AlH_4$ (I) and tetramethylammonium tetrahydroaluminate $[(CH_3)_4N]AlH_4$ (II).

They are crystalline. (I) melts at 61–63° with decomposition, and is readily soluble in benzene, toluene, and diethyl ether and poorly soluble in pentane and hexane; (II) decomposes at 173° and is not soluble in any of the organic solvents.

Both the compounds, unlike the amine complexes of aluminium hydride, exhibit great stability against hydrolysis: to complete their hydrolysis heating in 6 *N* HCl in sealed tubes for two weeks is necessary. The infrared spectra of these compounds suggest an ionic structure for their molecules. This is also confirmed for (I) by the measurements of electrical conductivity in tetrahydrofuran, which showed that the electrical conductivity of (I) is greater than (approximately twice) that of lithium tetrahydroaluminate.

The ionic character of (II) is confirmed by its insolubility in all organic solvents and by its relatively high decomposition temperature.

Compound (I) is obtained by the reaction of $[(C_8H_{17})_3.(C_3H_7)N]Br$ with lithium tetrahydroaluminate at room temperature in benzene for three days. The pure substance was isolated by treating the filtered solution with pentane. $[(CH_3)_4N]AlH_4$ was obtained by the scheme:



The substance was filtered off, washed with tetrahydrofuran and dried in a vacuum for five hours at room temperature.

---o0o---

The above review shows that attention has so far been mainly directed to problems on the preparation of various derivatives of aluminium hydride. However, insufficient attention has been paid to systematic physicochemical investigation of the substances obtained.

Only two substances have been investigated by X-ray diffraction: bistrimethylamine–alane and *NNN'N'*-tetramethylethylenediaminealane; the structural formulae proposed for the other compounds are based on indirect data and are therefore not very trustworthy.

Most of the complex molecules in solution are either dimeric or trimeric, but the nature of the bonds brought about by dimerisation has been little studied; the data are contradictory and are not based on any reliable experimental evidence; there is hardly any information on the

thermodynamic characteristics of the phase transformations of the various complexes of aluminium hydride, etc.

We therefore consider that future work in the field of the complexes of aluminium hydride will be successful only if physical and physicochemical methods are widely employed.

1. INTRODUCTION

Just as half a century ago, stable radicals continue to play an important part in the development of the theoretical concepts of contemporary chemical science.

The discovery and the wide use of the electron paramagnetic resonance (EPR) method was a powerful tool in the development of this field of chemistry [1-3].

Stable radicals are quite useful in solving many specific problems arising during the course of chemical, physical, and biological experiments.

This class of substances is successfully used in studying the rates of initiation of chain reactions, in catalysis, and in photochemical and quantum-chemical investigations.

After the discovery and study of the phenomenon of dynamic nuclear polarisation, stable radicals with a simple hyperfine spectral structure became used in the construction of high-sensitivity magnetometers and "Maser" type devices.

In recent years several reviews and monographs devoted to free radicals have appeared [4-12], in which little mention has been made of an important class, the paramagnetic derivatives of nitrogen monoxide.

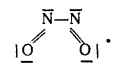
The main focus of the present review is the structure, reactivity, and methods of preparation of the compounds of this class; radiospectroscopic investigations receive less detailed consideration and problems relating to the quantum chemistry of free radicals are not discussed in this review,

2. PARAMAGNETIC NITROGEN OXIDES

The simplest free radical of this series is nitrogen monoxide:

$$\dot{N}=\bar{O}.$$

Despite the presence of a free valency, nitrogen monoxide is considerably less reactive than atomic hydrogen or chlorine and under ordinary conditions it does not dimerise, unless it is present in the liquid (b.p. -151.7°C) or solid (m.p. -163.6°C) states [13-17]. On the basis of spectroscopic investigations of solid nitrogen monoxide it can apparently be ascribed the structure [18-20]:

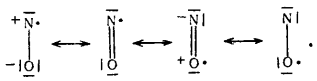


The valence state of nitrogen monoxide can be written as:

$$NO\,[KK\,(N:2s)^2\,(O:2s)^2\,(\sigma 2p)^2\,(\pi 2p)^4\,(\pi^* 2p)^1],$$

where the completely filled orbitals $(\sigma 2p)^2(\pi 2p)^4$ correspond to a triple bond, and $(\pi^* 2p)$ contains an unpaired electron. On transfer of the unpaired electron to the corresponding non-bonding orbital the NO excited species behaves as if it possessed a triple bond [21].

The thermal stability of nitrogen monoxide is so high that it does not decompose appreciably even at 500°. Pauling [22] explains the unusually low level of the ground state of the radical by quantum-mechanical resonance of four structures:



As the two partly ionic structures have approximately equal "weight", the resulting dipole moment of the species should be close to zero. The dipole moment [23] obtained experimentally was in fact very low (μ = 0.16 D).

Nitrogen monoxide can be described by a single formula using Pauling's ideas about a three-electron bond:

$$|N\overset{\cdot}{=}O|\cdot$$

The gain in energy in the formation of such a bond stabilises the species so much that the heat of dimerisation becomes negative [22]. Such a structure for the radical agrees well with the dipole moment and the measured interatomic distance, which is intermediate between the values calculated for double and triple covalent bonds [24]:

N=O	N$\overset{\cdot}{=}$O	N≡O
(1.18 Å)	(1.15 Å)	(1.06 Å)

The cation [25] and anion [26] of nitrogen monoxide have the following structures respectively:

$$[|N\equiv O|]^+\ [|\bar{N}=\bar{O}|]^-.$$

Nitrogen monoxide is a chemically active compound; it is readily reduced in solution to hydroxylamine and ammonia [27]. The gaseous reactions of nitrogen monoxide with chlorine [28,29], bromine [30], and oxygen [31] take place by three-body collisions, through a diamagnetic activated complex, for example:

$$2NO+O_2 \rightarrow [ONOONO] \rightarrow 2NO_2+27\ \text{kcal}.$$

It is interesting that when there is a very large excess of oxygen under these conditions dinitrogen trioxide is formed as the bimolecular reaction:

$$NO+NO_2 \rightarrow N_2O_3+10\ \text{kcal},$$

proceeds much faster than the termolecular reaction [32].

The high-temperature gas reaction of nitrogen monoxide with hydrogen is mainly termolecular [33], but transient states with very short lifetime produced in two-body collisions may occur [34].

Nitrogen monoxide reacts readily with other free radicals [35-38], and hence is not only an indicator [39] but also an effective inhibitor of chain reactions [40,41].

Nitrogen monoxide forms coordination compounds, the nitrosyls, with salts of iron, cobalt, and other transition metals having unpaired *d*-electrons [42-45].

Significantly, in almost all the compounds of nitrogen monoxide the additional covalent bond is formed preferentially with the nitrogen atom [46-48], which is evidence in support of the structure with a free valency at the nitrogen.

In the hyperfine structure (h.f.s.) of the EPR spectrum of nitrogen monoxide there are three transitions between four sublevels. Each line of the rotational-magnetic structure is split into triplets with a separation of ~14.2 Oe between them. Analysis of the h.f.s. parameters of the spectrum also leads to the conclusion that the greater part of the spin density (~60%) is centred on the nitrogen atom [49-52].

Nitrogen dioxide is another stable free radical of this series. The gain in energy on the delocalisation of the unpaired electron does not stabilise it enough to prevent dimerisation into dinitrogen tetroxide [53-57]:

$$2NO_2 \rightleftarrows N_2O_4+13\ \text{kcal}.$$

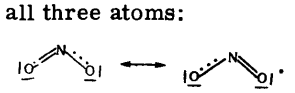
Even in the vapour (b.p. 21°C) nitrogen dioxide is partly dimerised, and in the liquid and solid (m.p. -11°C) states it is a dimer. Only at 150°C is the gas completely dissociated into nitrogen dioxide, which on further heating (~600°C) breaks down into nitrogen monoxide and oxygen [58-60]:

$$N_2O_4 \rightleftarrows NO_2 \rightleftarrows NO+O.$$
$$\uparrow\downarrow$$
$$N_2O_3$$

Sutherland and Penney [61,62] established the structure of nitrogen dioxide [61,62]. They concluded, from an analysis of the absorption bands, that the nitrogen dioxide species is not linear [63]. The molecular parameters of NO_2:

r(N—O)	∠ONO,
1.20 Å	132°

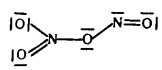
were determined by electron diffraction [64,65]. As the angle ONO is nearer 120° than 90°, it can be approximately assumed that the nitrogen atom is sp^2-hybridised and the σ-bond is formed by the use of the electrons of the molecular orbitals localised between the nitrogen and oxygen atoms. In addition to the ten electron pairs there are another three $2p\pi$-electrons which can form a three-electron bond uniting all three atoms:



The total bond order should therefore be > 1, but < 1.5, which corresponds to a bond length of 1.20 Å. This lies between the values for the normal N–O (1.43 Å) and double N=O (1.16 Å) bonds[66-70].

X-Ray diffraction studies and data from entropy determinations support a symmetrical structure for dinitrogen tetroxide:

Since in such a structure the neighbouring nitrogen atoms have formal charges of the same sign it could be assumed that the unsymmetrical structure

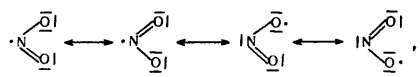


would be more stable.

The chemical properties of dinitrogen tetroxide agree better with the latter structure, as this compound can be used both for diazotisation[71] and for nitration[72].

Nitrogen dioxide is one of the most chemically active of compounds: carbon, sulphur, and phosphorus burn in it. Its free-radical nature is clearly apparent in its reactions of recombination, addition, and initiation[73-76].

Exhibiting a free valency, delocalised at the oxygen and nitrogen atoms:



nitrogen dioxide almost always displays a marked duality of reactivity in its reactions[77,78].

The EPR spectrum of nitrogen dioxide (Fig. 1) is a triplet with a separation of 47.1 Oe between the components. Such an appreciable value for the hyperfine splitting constant is apparently explained by an appreciable contribution of the s-state in the ψ-function of the unpaired electron[79]:

$$\psi = a_1\psi_N(2s) + a_2\psi_N(2p_Z) + b\psi_0(2p_Z).$$

Fig. 1. The EPR spectrum of nitrogen dioxide at 77°K.

In the best resolution of the spectrum into its hyperfine structure there is a large number of components of a rotational-magnetic structure due to independent quanta in the magnetic field of the electron-spin, nuclear-spin, and magnetic moments of the species[50,80]†

3. FREMY'S SALT‡

Over a century ago Fremy obtained a yellow salt of composition $K_2S_2O_7N$, which dissolved in water to give a purple-violet solution[81]. This salt is readily obtained by the action of lead dioxide on an alkaline solution of the corresponding hydroxylimidodisulphate[82]:

$$(KO_3S)_2NOH \xrightarrow[PbO_2]{-H} (KO_3S)_2NO.$$

The initial dipotassium hydroxylimidodisulphate can be obtained by the reaction of sodium nitrite and potassium hydrogen sulphite in aqueous solution[83]. The sodium[84], tetraphenylarsonium[85], and tetraphenylstibonium[86] Fremy salts are also known.

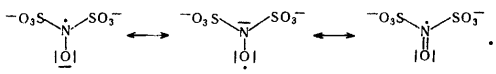
By analogy with dinitrogen tetroxide Fremy ascribed a dimeric structure to the solid salt which breaks down in solution into monomeric anions[87]:

$$(KO_3S)_4N_2O_2 \rightleftarrows 4K^+ + 2ON(SO_3)_2^- .$$

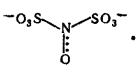
The analogy with nitrogen dioxide is well evident in the reaction of the salt with nitrogen monoxide and the reaction of the resulting addition product with water[88]:

$$(KO_3S)_2NO + NO \rightarrow (KO_3S)_2NONO,$$
$$(KO_3S)_2NONO + H_2O \rightarrow (KO_3S)_2NOH + HNO_2.$$

The bond between the oxygen and nitrogen in the Fremy ion is donor or semipolar, so that the unpaired electron is delocalised between the nitrogen and oxygen atoms of the NO group; the free ion-radical can therefore be described with the aid of several electronic structures:



In a more general form the structure of this radical can be represented with the aid of a formula including a three-electron bond:



The stability§ of Fremy's salt[90-96] in solutions is due to the low level of the ground state of the species which has a three-electron bond[97,98].

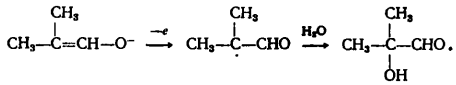
The unusual chemical properties of Fremy's salt permits its use as a selective one-electron oxidant of aromatic amines and phenols[99]. Many *ortho*- and *para*-quinone imines and quinones have been thus obtained in high yields[100-107].

† Ref. 50 is to the EPR spectrum of nitrogen monoxide. Probably Ref. 51 is intended here (Ed. of Translation).]

‡ The anion of Fremy's salt is encountered in the literature under various names: peroxylaminodisulphonate, nitrosyldisulphonate, nitrosodisulphonate, disulphonatonitroxyl, etc.

§ An aqueous solution of Fremy's salt can be kept under ordinary conditions for a few days[89].

Isobutyraldehyde is also smoothly oxidised by Fremy's salt into α-hydroxyisobutyraldehyde, the reaction passing through the stage of single-electron oxidation of the anion of the enol[108]:



The reaction of Fremy's salt with hydrazine and hydroxylamine allows it to be used for the analytical determination of these reagents[109,110]:

$$4(KO_3S)_2NO+N_2H_4 \rightarrow 4(KO_3S)_2NOH+N_2,$$
$$4(KO_3S)_2NO+2NH_2OH \rightarrow 4(KO_3S)_2NOH+N_2O+H_2O.$$

It has been used successfully in weakly alkaline solutions as a photographic developer[111].

A mechanistic analysis of the chemical reactions suggests that almost all the radical reactions of Fremy's salt take place at the oxygen atom of the NO group, in accordance with the imidoxyl electronic structure of this radical:

The EPR spectrum (Fig. 2) of the Fremy anion (in chloroform) is a triplet with components which are equidistant and of the same intensity, the distance between them being ~13 Oe, and the breadth of each < 0.5 Oe.[112-114]. The hyperfine structure of the EPR spectrum agrees well with the theoretical expectation of interaction of the unpaired electron with the nuclear spin of the nitrogen[115]. A detailed study of the fine structure of the EPR spectrum of Fremy's salt[116-118] enabled it to be used for calibrating radiospectrometers[86].
