EVALUATION OF THE HEATS OF MIXING OF SALT SOLUTIONS FROM IONIC CHARACTERISTICS

I.T. Sryvalin, O.A. Esin, and V.G. Korpachev

CONTENTS

Introduction 1

1. Coulombic interaction 1

2. Calculation of other types of interaction 3

3. Comparison with experimental data 5

INTRODUCTION

The study of the laws connecting the properties of solutions and their constituent atoms is the central problem of the theory of solutions [1].

Low-temperature solutions, especially solutions of electrolytes in water and other solvents have been the subject of many papers and reviews relating to the solution of this problem. Very little light has been thrown on this question for salt melts, which have no less scientific and practical importance [2]. In what follows we will consider these systems also. Here we will restrict ourselves only to an analysis of the methods of calculating the heat ΔH or energy Q of mixing of binary solutions, assuming [2] that they are connected by the relation [3]:

$$\Delta H = Q \cdot x_1 \cdot x_2 \qquad (1)$$

where x_1 and x_2 are the mole fractions of the components.

1. COULOMBIC INTERACTION

We will deal only with solutions of salts with a common ion. Grim and Herzfeld [4] and then Tobolsky [5] used Born's method to calculate the ionic lattice energy, in order to find the heats of mixing of solid solutions of the alkali metal halides. It was assumed in this that the lattice parameters in mixed crystals (a) are the sum of those for the pure salts (a_1 and a_2), that is, Vegard's empirical rule is obeyed:

$$a = a_1 + (a_2 - a_1) \cdot x \qquad (2)$$

Then the use of Born's simple formula leads to the following expression for the heat of dissolution:

$$\Delta H \simeq -\frac{U}{2} \cdot \left(\frac{d_1 - d_2}{d_1 + d_2}\right)^2 \cdot x_1 \cdot x_2 = K_e \cdot x_1 \cdot x_2 \qquad (3)$$

where U is the lattice energy of one of the salts (or the mean for the two salts), d_1 and d_2 are the sum of the ionic radii of the first and second salts, and K_e is the energy of mixing.

The minus sign is evidence that the process is endothermic, which agrees qualitatively with the results of Delimarskii and Markov [6], according to which binary solutions of most solid salts show positive departures from Raoult's law.

As regards quantitative agreement, Table 1 shows that the energy of mixing $K_e = 4\Delta H$ calculated by Eqn. (3) is considerably less than that found experimentally (Q_{expt}).

Equation (3) is not applicable to melts, since Vegard's rule does not hold for them. A more suitable assumption here is that of Förland [7], who assumed that ions are rigid spheres and the distances between neighbours of opposite charge are unchanged on mixing the molten salts. He considers that the heat of mixing originates in the circumstance that the energy of the coulombic repulsion between the nearest cations (when the anion is common) in the solution ($X^+-Z^--Y^+$) differs from half the sum of those for the pure salts ($X^+-Z^--X^+$) and ($Y^+-Z^--Y^+$). Neglecting the

TABLE 1. Energy of mixing for solid solutions of certain salts.

$PbBr_2$—$PbCl_2$*	0.4	0.4	0.8	—1.2	17
KBr—RbBr*	0.4	0.4	0.8	0.60	18
RbCl—RbBr*	0.4	0.4	0.8	0.8	18
KCl—KBr*	0.4	0.60	1.00	0.8	18
KCl—RbCl*	0.4	0.4	0.8	0.60	18

influence of subsequent layers, he obtained for an equimolecular melt:

$$\Delta H \simeq \frac{U}{4}\left(\frac{d_1-d_2}{d_1+d_2}\right)^2 \cdot x_1 \cdot x_2 = \frac{U}{4} \cdot \delta^2 \cdot x_1 \cdot x_2 = K_e'' \cdot x_1 \cdot x_2 . \quad (4)$$

Comparison of expressions (3) and (4) which in general are similar in form, shows that the heats of mixing in them differ in sign and also that ΔH for solid solutions is twice that for liquid solutions. Experiment shows that in accordance with Eqn. (4) heat is liberated ($Q_{expt} < 0$) in several instances, namely in the mixing of molten alkali metal halides (see Tables 2 and 3). However, the calculated energies of mixing ($K_e'' = 4\Delta H$) sometimes differ considerably from the experimental values. For molten salts with a common cation the comparison with published data [19,20] shows a still greater discrepancy in the values of Q.

True, in measuring the heats of mixing of molten alkali metal nitrates, Kleppa and Herch [26] found (see Table 4) that they are satisfactorily described by Förland's approximation:

$$\Delta H \simeq x_1 \cdot (1 - x_1) \cdot U \cdot \left(\frac{d_1-d_2}{d_1+d_2}\right)^2 = x_1 \cdot x_2 \cdot U \cdot \delta^2 . \quad (5)$$

This cannot be said about solutions of silver or thallium nitrates with alkali metals nitrates, for which they [27] propose a somewhat different semi-empirical expression:

$$\Delta H = -x_1 \cdot x_2 (140 \cdot \delta^2 - U'' \cdot \delta) . \quad (6)$$

In this, the first term inside the parentheses allows for the electrostatic interaction (coulombic repulsion) and the second, the presence of a covalent constituent in the lattice energy of $AgNO_3$ and $TlNO_3$.

As Table 5 shows, by a suitable choice of the parameter U'' (different for $AgNO_3$ and $TlNO_3$) satisfactory agreement was reached between the values calculated by formula (6) and the experimental data.

Blander [29] made an attempt to improve Förland's equation, by allowing for the coulombic forces being far-acting. However, he was restricted to the solution of only the linear problem for a dilute binary solution of salts with a common anion.

By considering a linear series of n cations of the solvent (at a distance r from one another), in which cations of

another kind are distributed — at a distance $(1+\gamma)r$ from another — he finds the following expression for measurement of the energy of coulombic repulsion:

$$\Delta E = -\frac{e^2}{r}\left[2\sum_1^\infty \frac{1}{n+\gamma}\cdot(-1)^n - (1+2\gamma)\cdot\sum_1^\infty \frac{1}{n+2\gamma}(-1)^n - \left(\frac{1-\gamma}{1+\gamma}\right)\cdot\sum_1^\infty \frac{1}{n}\cdot(-1)^n\right], \quad (7)$$

where e is the charge of an electron.

ΔE is always negative and approximately 40% less in absolute value than that calculated by Förland's formula. As Table 2 shows (K'), the agreement with experiment is not improved.

2. CALCULATION OF OTHER TYPES OF INTERACTION

Some authors [10,30], following Mayer and Born [31,32], used an expression for the lattice energy allowing for the intermolecular interaction:

$$-U = -\frac{\alpha}{r} - \frac{c}{r^6} + B(r), \quad (8)$$

which includes the coulombic, van der Waals, and Born-type (repulsive) interactions. They neglected null energy and multipolar interaction. If the lattice parameters of the pure components and of the equimolecular solution are denoted r_1, r_2, and $r_{1,2}$, then the change in coulombic energy is:

$$\Delta U_{coulomb} = \frac{2\alpha\cdot e^2}{r_{1,2}} - \frac{\alpha\cdot e^2}{r_1} - \frac{\alpha\cdot e^2}{r_2}, \quad (9)$$

where α is the Madelung constant.

By assuming that the distribution of the cationic and anionic sites is random [4], Wallace finds the following relation between the constants of the van der Waals interaction ($c_{i,j}$) of the salts and the overall constant (c) for the solution:

$$c = N_1\cdot N_2\cdot c_{1,2} + N_1\cdot N_4\cdot c_{1,4} + N_2\cdot N_3\cdot c_{2,3} + \frac{1}{2}(N_1^2\cdot c_{1,1} + N_2^2\cdot c_{2,2} + N_3^2\cdot c_{3,3} + N_4^2\cdot c_{4,4} + 2N_1\cdot N_3\cdot c_{1,3} + 2N_2\cdot N_4\cdot c_{2,4}). \quad (10)$$

Here N_1 and N_3 are the ionic fractions of cations 1 and 3, and N_2 and N_4 those of the anions 2 and 4.

According to Mayer and coworkers [31,33], for the alkali metal halides:

$$B(r) = b\cdot c_{i,j}\cdot e^{\frac{r_i+r_j}{\rho}},$$

where r_i and r_j are the ionic radii, $\rho = 0.345\times10^{-8}$ cm, $b = 1\times10^{-12}$ erg; for the cations $c_{i,j} = c_1 = 1.25$; for the anions $c_{i,j} = c_2 = 0.75$, and for particles with opposite charges $c_{i,j} = c_{1,2} = 1.0$.

The potential of repulsion $B(r_0)$ for solid solutions was evaluated with allowance for the interaction of the central ion with z nearest neighbours and z' ions of the following coordination sphere:

$$B(r_0) = \beta_1\cdot e^{-r_0/\rho} + \beta_2\cdot e^{-ar_0/\rho} \quad (11)$$

where

$$\beta_1 = b\cdot z\cdot c_0\cdot\left[N_1\cdot N_2\cdot e^{\frac{r_1+r_2}{\rho}} + N_1\cdot N_4\cdot e^{\frac{r_1+r_4}{\rho}} + N_2\cdot N_3\cdot e^{\frac{r_3+r_2}{\rho}}\right] \quad (12)$$

$$\beta_2 = \frac{b\cdot z'}{2}\left[c_1\cdot\left(N_1^2\cdot e^{\frac{2r_1}{\rho}} + 2N_1\cdot N_3\cdot e^{\frac{r_1+r_3}{\rho}} + N_3^2\cdot e^{\frac{2r_3}{\rho}}\right) + c_2\left(N_2^2\cdot e^{\frac{2r_2}{\rho}} + 2N_2\cdot N_4\cdot e^{\frac{r_2+r_4}{\rho}} + N_4^2\cdot e^{\frac{2r_4}{\rho}}\right)\right] \quad (13)$$

c_0 is the van der Waals constant, taking into account the interaction between ions of opposite charge; c_1 is the same for intercationic, and c_2 that for interanionic, interactions.

The value of r_0 is the equilibrium distance between the nearest neighbours, whereas ar_0 up to the second coordination layer, and r_1, r_2 etc. are characteristic parameters of individual types of ions.

In Eqns. (11)–(13) the interaction between a given pair of ions in a solution is identical with that in the pure salts at corresponding distances.

Table 6 shows the experimental lattice parameters of solid solutions of the NaCl–NaBr, KCl–KBr, and RbCl–KCl binary systems, together with the repulsion constants β and van der Waals constants c, calculated [10] by Eqns. (11)–(13). In this, the equilibrium distances r_0 in the solid solution at 0°K were evaluated with the aid of the Born–Mayer relation:

$$r_0\left(\frac{dU(r_0)}{dr}\right) = \frac{3T}{N\cdot\varepsilon}\left(\frac{dV}{dT}\right)_p, \quad (14)$$

where ϵ is the compressibility.

Furthermore, the values of r_0 were calculated by the additivity rule and appeared (see Table 6) quite close to the experimental values.

The heat of mixing ΔH is expressed by the lattice energies U_1, U_2, and U of the pure salts and solid solution:

$$\Delta H = U - x_1\cdot U_1 - x_2\cdot U_2. \quad (15)$$

In the opinion of Wallace, the change in $B(r)$ is approximately two-thirds of the energy of mixing; the change in the coulombic energy covers most of the rest, and the van der Waals force makes a small contribution.

Table 7 gives the lattice energies, the values of the individual constituents, and their contributions to the heat of mixing, calculated[34] by Eqns. (6)–(15). The calculated values of ΔH are compared with those found experimentally. Although our calculated values do not differ too much from Wallace's values, the relative significance of the various types of interaction is different. The main source of ΔH is the change in the coulombic interaction and not the repulsion forces. Both types of energy are very sensitive to the departure of the lattice parameters from additivity. Values calculated assuming that Vegard's law is applicable are given in parentheses. Here the relative significance of the change in the Born repulsion has increased to about three-quarters of the total energy of mixing. However, in all the systems there are positive departures from Vegard's law. This leads to a relative decrease in the energy of coulombic interaction, and consequently an increase in the positive contribution to the heat of mixing. On the other hand, the Born potential here falls, its contribution decreases, and even the sign changes to positive (at 0°K).

It is interesting to note that the results of the calculation are almost independent of whether we use the equilibrium values of the lattice parameters or assume the applicability of the additivity rule. However, this is correct only when allowance is made not only for the coulombic interaction but also the potential of repulsion.

Comparison with experiment shows a systematic increase in the calculated values of ΔH. Allowance for only one coulombic interaction at 298°K gives the best agreement with experiment, which cannot be said of the data for 0°K.

Wallace's method is apparently not applicable to liquid salts, since there is no long-range order in them. Lumsden[35] considered solutions of molten alkali metal halides with a common anion. He assumes that the energy of mixing is due above all to the asymmetry of the electric field of cations of different kind. The main negative contribution is therefore introduced by the polarisation energy; the increase in van der Waals interaction is a positive term.

Lumsden neglects the change in coulombic energy, which is scarcely proved. The method of calculation proposed by him is scarcely applicable to solutions of salts with a common cation.

The non-polar London forces which act between ions give an energy contribution which is inversely proportional to the distance raised to the sixth power. The forces are short-range, therefore in a mixture with a common anion they can be restricted to the interaction between the nearest cations.

Starting from the simplest geometrical relations, Lumsden finds an expression for the change in the energy of the non-polar interaction for mixing:

$$E_L = K_L \cdot \frac{x \cdot y}{x + y} \qquad (16)$$

Here x and y are the number of moles of the salts X^+Z^- and Y^+Z^-; but the quantity K_L is connected with the constants $c_{i,i}$ by the relation:

$$K_L = 86.5 \cdot \left[\frac{c_{X,X}}{(2r_{X,Z}^2)^3} + \frac{c_{Y,Y}}{(2r_{Y,Z}^2)^3} - \frac{2\sqrt{c_{X,X} \cdot c_{Y,Y}}}{(r_{X,Z}^2 + r_{Y,Z}^2)^3} \right] \qquad (17)$$

We note that the values E_L calculated by Wallace's formulae are considerably less than those for the same salts by Eqn. (17). The main reason for this is the different definition of the constant $c_{i,j}$ for the mixture of salts. Whereas Lumsden assumes that $c_{X,Y}^2 = c_{X,X}\, c_{Y,Y}$, the quantity $c_{X,Y}$ found by formula (10), differs little from the arithmetic mean.

The rule of the geometric mean, true under definite conditions for a series of simple mixtures of dielectrics cannot be unconditionally applicable to ionic solutions. The introduction of formula (10) here is more reasonable.

As is well-known, the geometric mean is always less than the arithmetic mean or equal to it. Therefore the results of the calculations by Eqns. (16) and (17) should

give an increased positive departure in the heat of mixing. Allowance for the asymmetry of the electric field in mixtures with a common anion leads to the following expression for the polarisation energy:

$$E_P = K_P \cdot \frac{x \cdot y}{x + y} \qquad (18)$$

$$K_P = -1060 \cdot N \cdot \alpha \left(\frac{1}{r^3_{X,Z}} - \frac{1}{r^3_{Y,Z}} \right)^2 \qquad (19)$$

In this the molar polarisability $N\alpha$ is expressed in cm^3 but the inter-ion distance $r_{i,j}$ in ångströms (10^{-8} cm).

Table 2 gives the values of the constants K_L and K_P calculated by Lumsden for mixtures of alkali halides with a common anion. In this, the inter-ionic distances were taken from Wyckoff[36], the constants $c_{i,j}$ from Mayer[32], and the data on polarisabilities from Kordes[37]. According to Lumsden, the quantities he obtained agree with the thermal analyses for several binary systems.

Lumsden evidently overestimates the size of the contribution of polarisation in the energy of mixing. The linear model of the solution can hardly be transferred to the three-dimensional without some restrictions†.

It is necessary to consider also the possible revaluation of the role of the London interaction. Use of the geometric mean rule for the constants $c_{i,j}$ leads, evidently, to too high results. On the other hand, allowance for the non-polar interaction, although small, is very important, especially in mixtures with a common cation. In several instances the London forces are the only ones making a positive contribution to the heat of mixing.

As the electron clouds of the ions can be deformed and partially overlap one another, a considerable part of the contribution to the excess energy of the mixture is due not only to the repulsion of particles with charges of the same sign, but also to the change in the interaction of the cation with the anion. The mean distance between them is determined by the minimum free energy — see Eqn. (14) — and should change on mixing.

We will restrict discussion to the formulae mentioned and will not consider those in which the energies of mixing are linked with macroscopic characteristics. This refers in particular to Shimoji's equation[38], in which molecular volumes are introduced instead of the ionic distances.

3. COMPARISON WITH EXPERIMENTAL DATA

To calculate the energies of mixing we used the usual values of the ionic radii, which are compromises between those recommended by various authors. Where possible, directly measured inter-ionic distances were used.

a. Solid Solutions

To calculate the energy by the Wallace method the lattice parameters of the solid solutions must be known. Furthermore, use of this method leads to values of ΔH which are too high (see Table 7). We therefore calculated[34] the energy of mixing with an allowance for the electrostatic interaction after Tobolsky, Eqn. (3), and for the London forces after Lumsden, Eqn. (17). Comparison of values of Q thus calculated with the experimental values (see Table 1) shows very good agreement. For six binary systems marked with asterisks there are only the heats of mixing of the liquid phases. The values of Q in five of these are close to those calculated for the solid solutions. An exception is the $PbBr_2$–$PbCl_2$ system, for which even the signs of the thermal effect are different. As Delimarskii and Markov show[6], this system is a rare exception among solid solutions. They explain[6] the negative departures observed here by the formation of the compound PbClBr.

b. Fused Alkali Metal Halides and Nitrates

Unfortunately, heats of mixing of liquid solutions of alkali halides have not been studied calorimetrically; electrometric data are quite scanty. For comparison there are limited results obtained from the fusion diagrams[35] and from vapour pressures[25,39].

Table 2 contains the values of the contributions of the individual effects to the energy of mixing of salts with a common anion, calculated from Eqns. (4), (7), (17), and (19). The quantities Q found by Lumsden ($K_P + K_L$) do not agree very well with the experimental values. The Förland formula (4) gives a large deviation.

For salts with a common cation the main contribution to Q comes from the coulombic interaction, which decreases the energy of the system, and the dispersion interaction, which increases the potential of the solution. As Table 3 shows, these contributions are approximately the same and compensate one another. As a result the solutions are characterised by small departures from ideality ($\Delta H \simeq 0$). The results of the calculations are close to the available experimental data (see Table 3).

In solutions of salts with a common anion considerable negative departures are observed (see Table 2), connected mainly with the polarisation effect. On the other hand, the role of this effect is small for salts with a common cation.

Precision calorimetric investigations of the thermal effects of mixing of molten nitrates, made at 345–450°C by Kleppa[26] are of special interest for testing the various methods of calculation. Heats calculated with allowance for coulombic (4), non-polar (17), and polarisation (19) effects, and also found by Eqn. (5) are compared with experimental data in Table 4. The best agreement with experiment is obtained if we are restricted only to the polarisation effect. Somewhat worse results are given by the sum of all three constituents (coulombic, London, and polarisation). Eqn. (5) gives approximately the same deviations.

It is unfortunately difficult to solve the problem of the nature of the energy of mixing in molten nitrates, since even allowance for only the coulombic interaction between the nearest cations (5) gives approximately the same thermal effect as the polarisation of anions (ΔH_P).

c. Solutions of Alkali Metal Nitrates and Bromides with Silver and Thallium Salts

In solutions of $AgNO_3$ with alkali metal nitrates (MNO_3) it is observed[27] that there is a gradual change from positive departures (melts with $LiNO_3$ and $NaNO_3$) to negative

† Presumably the author means that the overestimate of the contribution of polarisation is supported only when a two-dimensional model is applied to the (three-dimensional) system (Ed. of Translation).

(KNO_3, $RbNO_3$). Here, as in AgBr–MBr melts [14], the increase in the radius of the M^+ cation leads to an increase in the negative departures from Raoult's law. An analogous dependence was found [27] in $TlNO_3$–MNO_3 melts.

Kleppa and Hersh [27] connect these phenomena with the fact that the lattices of the silver and thallium salts are only partly ionic. The non-coulombic contribution to the lattice energy is thought by them to be ~ 25 kcal for $AgNO_3$ and 15 kcal for $TlNO_3$.

The small changes in volume and energy (entropy) during fusion [40–45] are due to the asymmetric distribution of the electron density around the Ag^+ nucleus. Such a picture also holds true for SiO_2, where the bond between the silicon and the oxygen is very strong and the heat of fusion is small [46].

Förland thinks [40] that the change in energy during mixing is here due to the difference in structure of AgBr and MBr melts. Therefore during mixing one of the compounds or both changes its structure, which promotes an increase in energy. On the other hand, the energy of the solution should decrease, since the Ag^+ polarises Br^- more strongly than the alkali metal cations. Evidence of this is given by the lattice energy of AgBr being greater than that of MBr [47,48]. The absorption of heat during the mixing of AgBr with LiBr and NaBr is due mainly to the structural effects, and the liberation of heat in melts of AgBr with KBr and RbBr is mainly determined by the change in polarisation. It must also be taken into consideration that the tendency of silver salts to complex formation is evidence of the considerable relative significance of the directed bonds.

According to Markov and Delimarskii [6], here the complex-former is usually itself associated. When it passes into the solution, energy is expended in destroying these associates and is liberated as a result of the formation of new complexes with the second component.

The relative influence of these opposing effects is determined in an equimolecular solution of AgBr and MBr by the electrostatic field of the M^+ cation. With strong cations (Li^+) the breakdown of the associate predominates and heat is absorbed. The amount of the latter is determined to a first approximation by the quantity:

$$\delta = \frac{d_{Ag^+} - d_{M^+}}{d_{Ag^+} + d_{M^+}} \qquad (20)$$

On the other hand, with a weak partner (Rb^+) complex formation mainly occurs. The degree to which it takes place also depends on ratio (20), but with the opposite sign.

What has been stated allows the contribution of the directed bonds to the heat of mixing to be represented by the relation:

$$K_c = \Delta U \cdot \left(\frac{d_{M^+} - d_{Ag^+}}{d_{M^+} + d_{Ag^+}}\right) \qquad (21)$$

In this ΔU is the energy due to the existence of directed bonds in the complex-forming salt.

Hence the heat of mixing of salt melts containing strongly polarisable ions has contributions from at least four effects: coulombic, polarisation, intermolecular, and that due to complex formation and the breakdown of the initial associates.

Table 5 compares the heats of mixing calculated by the formula:

$$Q = K_P + K_L + K_e' + K_c \qquad (22)$$

with those found experimentally [14,27] and also with those calculated by the formula (6). The values of ΔU for nitrates (Ag^+ and Tl^+) were taken as -21 and -16 kcal.[27] As for bromides, we found the quantity $\Delta U \simeq -33$ kcal from the difference between the experimental and calculated values of the lattice energy. As Table 5 shows, formula (6) and Eqn. (22) allow the thermal effects of mixing to be evaluated with known accuracy.

d. Energy of Mixing of Halides with Cations of Different Valency

In recent years there have been studies [15,49–62] of the properties of solutions formed by molten $PbCl_2$, $CdCl_2$, $ZnCl_2$, $MgCl_2$, and alkali metal chlorides MCl, and also $PbBr_2$ and $CdBr_2$ with MBr. Some of these results are given in Table 8.

$PbCl_2$–LiCl solutions show small positive departures from Raoult's law. In $PbCl_2$–NaCl melts there are moderate negative departures which increase considerably on going to solutions with KCl or RbCl. The latter are due to the formation of complex ions, as is confirmed by the investigation of electrical conductivity [64–66], surface tension [67,68], viscosity [69], transport number [70,71], and specific and molar volumes [72].

The same regularity is observed in solutions of $CdCl_2$ and $ZnCl_2$ with MCl as in $PbCl_2$ melts.

On going from chloride solutions to the corresponding solutions of bromides there is an increase in the negative departures.

The relationships quoted earlier for evaluating the energy of mixing were developed for solutions of uni-univalent salts, having, for example, a common anion. For melts containing cations of different valency, Eqns. (3), (4), (15), (17) and (19) are inapplicable.

When allowance is made for the difference in the charges of the cations in the derivation of the expression for the contribution from the change in polarisation Eqn. (19) becomes, to a first approximation:

$$K'_P = -1060 \cdot N \cdot \alpha \cdot \left[\frac{2}{(r^{2+})^3} - \frac{1}{(r^+)^3}\right]^2. \quad (23)$$

The energy of mixing found by this formula truly gives the change in Q in AX_2–BX melts. An increase in the radius of the M^+ ion increases the negative departures, whereas an increase in the dimensions of M^{2+} decreases it. The negative departures in bromides under conditions otherwise equal are stronger than in chlorides, since the polarisability of Br is greater than that of Cl. However, the size of the calculated heats of mixing is much higher (see Table 8) than that found experimentally. As the heat of mixing is determined now not by the difference $(r_1 - r_2)$ but by the relation $(\frac{1}{2}r^{2+} - r^+)$, then Eqn. (5) can be used as an empirical formula:

$$\Delta H = -U \cdot \delta_1^2 \quad (24)$$

in which:

$$\delta_1 = \frac{\frac{r^{2+}}{2} - r^+}{d_1 + d_2}$$

Unlike formula (5), it is not based on any physical model of the solution. The quantity U essentially should be close to the arithmetic mean of the lattice energies of the salts. The closest results to experiment are obtained (see Table 8) on taking U = -140 kcal, which is much less than $\frac{1}{2}(U_{AX_2} + U_{BX})$.

An equation analogous to (21) in which the ratio $\delta = \frac{d_1 - d_2}{d_1 + d_2}$ is used instead of $\delta_1 = \frac{\frac{r_1}{2} - r_2}{d_1 + d_2}$ is less convenient. The expression

$$\Delta H = -15 \cdot \delta_1 \quad (25)$$

also, like formulae (23) and (24), does not give (see Table 8) the change in sign of the departures of the solutions from the ideal.

Table 9 gives the experimental results on the thermochemistry of solutions of alkali metal nitrates [27] and carbonates [62] with the corresponding calcium salts. The use of empirical equations (24) and (25) gives somewhat better results than the more well-founded formula (23).

Expressions (22), (5), and (6) poorly describe the experimental results for solutions of the alkaline earth metals (see Table 10). This cannot be said about the chlorides and bromides of other metals.

It is also interesting to note that for oxides and silicates the comparison of calculated values of Q with the published information gives reasonable agreement in general (see Tables 11 and 12).

e. Melts of Reciprocal Salt Systems

Voskresenskaya [78-80] confirmed Kablukov's prediction that the stable pair of salts will be that which corresponds to the liberation of heat during the double decomposition in the solid state. The determination of the direction of the double decomposition from the thermal effects is permissible here, since the sign of ΔZ for the reaction usually changes at temperatures higher than the liquidus. A recommendation has been made [78] for the calculation of the heat of reaction by the lattice energies (U) of the individual salts, found by Kapustinskii's formula:

$$U = 256 \cdot \frac{n \cdot z_1 \cdot z_2}{r_1 + r_2}, \quad (26)$$

where z_1 and z_2 are the charges of the ions.

As our calculations showed, the best agreement is obtained by using the lattice energies found experimentally.

Comparison of the thermal effects of the double decompositions ΔH_R with the heats of mixing of the solutions ΔH with a common ion shows that the former are appreciably greater than the latter. Thus, for LiF–CsF melts the quantity ΔH is 5 kcal, but the heats ΔH_R for the reciprocal systems LiCl + CsF, LiBr + CsF, and LiI + CsF are respectively -9, -13, -15 kcal per mole solution.

To a first approximation the energy of mixing Q of the reciprocal system AX + BY = AY + BX is equal to the sum of those for four systems with a common ion: AX + BX, AY + BY, AX + AY, and BX + BY. Thus Q_R for the system LiI + CsF = LiF + CsI is 15.5 kcal, and the sum of quantities Q for the solutions LiF + CsF, LiF + LiI, LiI + + CsI, and CsF + CsI is 14.8 kcal.

In reactions with ions of different valency the energies of mixing are greater. The differences between the quantities calculated by the Kapustinskii formula and those found experimentally are more significant. As has been shown[78], the experimental values are usually much less than those calculated.

The great difference between calculation and experiment is partly connected with the increase in the fraction of directed bonds in salts of higher valency. It therefore seems desirable to use data on heats of formation. However, there still remains an indeterminacy, connected with the departure of the heat capacity of the components from the Kopp–Neumann law.

It is interesting to note that here also there is a link between the quantities ΔH_R for reciprocal systems and the values of ΔH for their consistuent solutions with a common ion.

All the above shows that the calculation of the energy of mixing from the properties of the individual particles is still in its earliest stages even for such simple systems as ionic melts. We thought it desirable to review these publications in order to draw the attention of investigators to future developments in this important problem.

REARRANGEMENTS INVOLVING THE CLEAVAGE OF N–N OR N–O BONDS AND FORMATION OF A NITRILE GROUP

Yu. A. Naumov and I.I. Grandberg

CONTENTS

1. Introduction 9

2. Nitrile fission of N–N or N–O bonds by electrophilic reagents or metal catalysts 9

3. Nitrile rearrangements produced by nucleophilic reagents 12

4. Structural factors determining the possibility of nitrile rearrangements 16

1. INTRODUCTION

There has been much recent work on rearrangements in which an N–N or N–O bond is broken and a nitrile group formed.

Compounds which can undergo this conversion include substituted aldehyde hydrazones, their cyclic analogues, the 3-unsubstituted pyrazolines and indazoles, and their cyclic and acyclic oxygen analogues, that is, aldoximes and 3-unsubstituted isoxazoles.

The nitrile fission of N–N or N–O bonds is observed under diverse experimental conditions: by the action of salts of complex-forming metals or platinum group metals; in the pyrolysis of hydrochlorides or quaternary salts; in the Hofmann degradation of quaternary ammonium bases; and by the action of nucleophilic reagents. The lack of data on the mechanism of the reaction and the variety of conditions, despite the external similarity of the processes, often hinder their comparison and generalisation.

2. NITRILE FISSION OF N–N OR N–O BONDS BY ELECTROPHILIC REAGENTS OR METAL CATALYSTS†

In 1910 Arbuzov observed[1,2] that heating aliphatic aldehyde phenylhydrazones to 180–200° with catalytic

† Metal catalysts are only formally included in this section, in view of the lack of knowledge of the mechanism of their action and the paucity of experimental material.

amounts of Cu_2Cl_2, $PtCl_2$, or $ZnCl_2$ produces the corresponding nitrile and aniline:

$$R{-}CH{=}N{-}NHC_6H_5 \xrightarrow[t^\circ]{Cu_2Cl_2} R{-}C{\equiv}N + H_2N{-}C_6H_5,$$

that is, fission of the aldehyde phenylhydrazone occurs instead of the normal Fischer indole synthesis. The phenylhydrazones of lower aliphatic aldehydes produce mainly the corresponding indoles, but those of higher aldehydes undergo mainly the nitrile fission.

Somewhat earlier a similar fission was observed by Anselmino [3] in the dry distillation of salicylaldehyde phenylhydrazone, which produces salicylonitrile and aniline together with benzene and ammonia.

In 1921 Maihle [4,5] observed nitrile fission when attempting catalytic hydrogenation of various aliphatic aldehyde phenylhydrazones at 180–190° over nickel.

It has recently been shown [6] that aromatic aldehyde phenylhydrazones also rearrange into amine and nitrile under Arbuzov conditions (Cu_2Cl_2, 220°); this is an exothermic reaction. The reaction is in fact general for compounds R–CH=N–NR′R″; thus diphenylamine and the corresponding nitrile are obtained from benzaldehyde phenylhydrazone (R = R′ = R″ = C_6H_5) and the phenylhydrazones of propionaldehyde and isovaleraldehyde (R = = alkyl, R′ = R″ = C_6H_5). Benzaldehyde benzoylhydrazone, which with phosphoryl(V) chloride under milder conditions disproportionates to benzaldehyde azine and 2,5-diphenyl--1,3,4-oxadiazole [7,8], also undergoes the nitrile rearrangement when heated with copper(I) chloride, yielding benzamide and benzonitrile:

$$C_6H_5CONH{-}N{=}CHC_6H_5 \xrightarrow[t^\circ]{Cu_2Cl_2} C_6H_5CONH_2 + N{\equiv}C{-}C_6H_5.$$

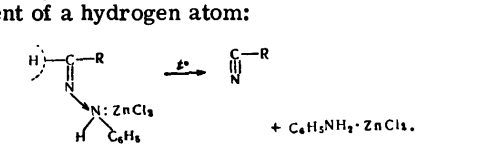
There is only a slight tendency for dialkylhydrazones to decompose with fission of the N–N bond [6]. For example, the decomposition of benzaldehyde dimethylhydrazone (R = C_6H_5, R′ = R″ = CH_3) under Arbuzov conditions (Cu_2Cl_2, 230°) produces benzonitrile in no more than 18% yield, and this falls to 11% if the copper(I) chloride is replaced by anhydrous zinc chloride. Heating heptanol diethylhydrazone at 260° for 4 h in the presence of copper(I) chloride gives only 6% of heptanenitrile and 9% of diethylamine; most of the hydrazone is recovered unchanged [9].

It has not proved possible to obtain an amine and nitrile from aldehyde monoalkylhydrazones, because of their decomposition with evolution of nitrogen [6]; thus when benzaldehyde isopropylhydrazone is heated with copper(I) chloride the double bond is probably displaced and the resulting azo-compound then decomposes, isobutylbenzene and stilbene being obtained:

$$(CH_3)_2CH{-}NH{-}N{=}CHC_6H_5 \longrightarrow (CH_3)_2CH{-}N{=}N{-}CH_2C_6H_5 \longrightarrow$$
$$\longrightarrow (CH_3)_2CH\cdot + N_2 + \cdot CH_2C_6H_5 \longrightarrow (CH_3)_2CHCH_2C_6H_5.$$

The conversion of ketone benzylhydrazones proceeds similarly, but in more complex fashion [10].

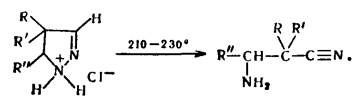
In the fission of aldehyde phenylhydrazones the catalyst ($ZnCl_2$, Cu_2Cl_2, $PtCl_2$) apparently first attaches itself to the more basic nitrogen atom, causing a redistribution of electron density and then cleavage of the N–N bond and displacement of a hydrogen atom:



The amine is often obtained in higher yield than the nitrile, probably because of the formation of the intermediate zwitter-ion $R{-}\overset{-}{C}{=}\overset{+}{N}$, which can polymerise. This, and the influence of the solvent on the reaction when copper(I) chloride is used, indicate that the reaction occurs with heterolytic cleavage of the N–N bond. Benzaldehyde phenylhydrazone produces benzonitrile by the action of copper(I) chloride in very much greater yield in polar solvents than in non-polar; in protic (for example, diethyleneglycol) and aprotic polar solvents (for example, dibutyl phthalate, benzyl benzoate, or diphenyl oxide) the yield is about the same (50–60%), but in non-polar solvents such as 2-methylnaphthalene or liquid paraffin the benzonitrile is obtained in ~ 10% yield [11].

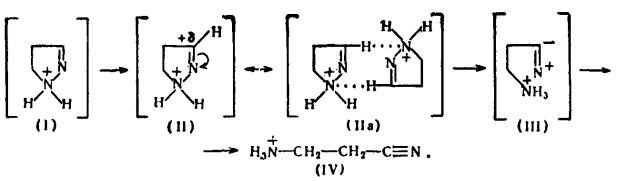
The analogous fission of the N–N bond with formation of a nitrile group is also known in the cyclic analogues of aldehyde hydrazones, the pyrazolines.

In 1962 Grandberg and Potapova found [12] that when heated to 230° 4-ethyl-5-propylpyrazolinium chloride decomposes to yield 3-amino-2-ethylhexanenitrile. This reaction has also been observed [13] with a number of other pyrazolines containing a hydrogen atom in position 3:.



Protonation of the 1-nitrogen atom therefore produces the same rearrangement, with cleavage of the N–N bond, as complex-formation with copper(I) chloride in Arbuzov's experiments. The reaction is highly exothermic, and with large amounts of material can get out of control.

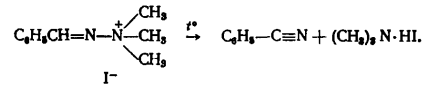
The pyrazolinium cation (I) formed by the acid is considered [13] to undergo a redistribution of electron density:



Because of the positive charge on the 1-nitrogen atom (for this is the salt-forming atom) [14], the electron pair forming the nitrogen–nitrogen σ bond is attracted towards the 1-nitrogen atom, and this causes a displacement of the electrons of the carbon–nitrogen double bond towards the nitrogen atom, leaving a residual positive charge on the 3-carbon atom; thus in the pre-rearrangement state, (II) or (IIa), the bond between the 3-carbon atom and the hydrogen atom is weakened, the the hydrogen is readily lost as a proton. The nitrogen–nitrogen bond is also weakened, because of the strong attraction of the electron pair towards the first nitrogen atom. In the rearrangement step the proton migrates from position 3 to the electron pair associated with the 1-nitrogen atom, and the nitrogen–nitrogen bond finally breaks to form the intermediate (III), which immediately rearranges to the β-aminonitrile cation (IV).

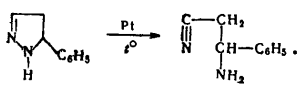
Under the very severe reaction conditions, the resulting β-aminonitriles partially lose ammonia to form αβ-unsaturated nitriles which polymerise during the reaction. These side-reactions greatly reduce the yield of β-aminonitrile, which does not exceed 25%. With 4,4-dimethyl--5-isopropylpyrazoline, where ammonia cannot be lost in this way, the yield reaches 36%.

A reaction similar to the nitrile fission of pyrazolinium chlorides is also possible with aldehyde dialkylhydrazones (when protonation or quaternation occurs on the farther nitrogen atom)[6]; thus pyrolysis of benzaldehyde dimethylhydrazonium chloride at 140° produces an exothermic reaction (the temperature rising to 230°) with the formation of benzonitrile (22%) and dimethylamine (48%), and pyrolysis of benzaldehyde dimethylhydrazone methiodide at 230° yields benzonitrile (21%) and trimethylamine (49%):

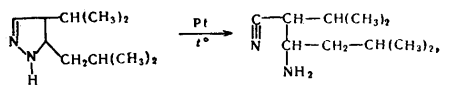


1,1-Dimethylpyrazolinium iodide also produces an aminonitrile when heated at 150° to 180° for a short time, but in low yield[15].

Colloidal platinum also causes rearrangement of 3-unsubstituted pyrazolines into aminonitriles[16]; thus heating 5-phenylpyrazoline to 140° with platinum black gave 3-amino-3-phenylpropanenitrile in 65% yield, instead of the expected mixture of pyrazole and pyrazolidine:



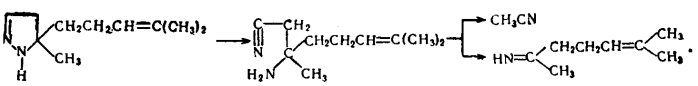
Similarly at 120–140° platinum produced 3-amino-2-isopropyl-6-methylhexanenitrile from 5-isobutyl-4-isopropylpyrazoline:



but the greater part of the material was converted into high-boiling condensation products. With 4-ethyl-5-propylpyrazoline the reaction is exothermic, with evolution of much ammonia, and the main reaction products are resinous materials, probably from polymerisation of the unsaturated nitrile formed.

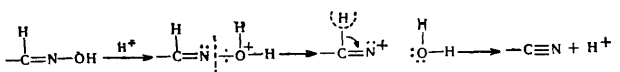
Attempts to carry out the rearrangement using a Raney nickel catalyst have been unsuccessful.

Kizhner has noted[17] that heating 5-isohexenyl-5-methylpyrazoline with platinised alkali gives acetonitrile and a methylheptenone imine in addition to the corresponding cyclopropane hydrocarbon. Apparently this anomalous reaction also passes through the β-aminonitrile stage, and under the severe reaction conditions this decomposes in the way that is known, for example, for Mannich bases[18]:



In addition to the substituted aldehyde hydrazones and pyrazolines, their oxygen analogues the aldoximes also produce nitriles under the action of acidic reagents.

Primarily this is a dehydration of aldoximes to nitriles by means of acids. The mechanism of the reaction is essentially analogous to that considered above for the nitrile fission of substituted aldehyde hydrazones and pyrazolinium chlorides, and may be represented[19]:

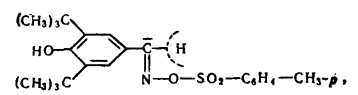


Unlike aldoximes themselves, their *O*-ethers are very stable; they are unaffected by aqueous or alcoholic hydrogen chloride or bromide or by 60% sulphuric acid[20], and like ketoxime *O*-ethers they do not undergo the Beckmann rearrangement[21], which is explained by their inability to form salts[22,23]. However, in the presence of a complex-forming reagent such as boron trifluoride, which can form an oxonium fluoroborate, it has been possible to decompose benzaldehyde oxime *O*-2-cyanoethyl ether into benzonitrile and 2-cyanoethanol[24]:

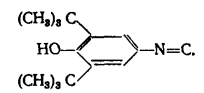
The addition products of aldoximes with methylketen diethyl acetal $CH_3CH_2C(OC_2H_5)_2-O-N=CH-R$ decompose to form $R-C\equiv N$ and $R-N=C$ when boiled in ether with boron trifluoride and mercury(II) oxide[25].

In the course of their comparison of the nitrile rearrangements of oximes and hydrazones, Grandberg and coworkers[6] obtained benzonitrile from benzaldehyde oxime *O*-benzyl ether under Arbuzov reaction conditions (210°, Cu_2Cl_2).

Müller and Narr[26] observed a new type of Beckmann rearrangement from aldoxime *p*-tolylsulphonates such as



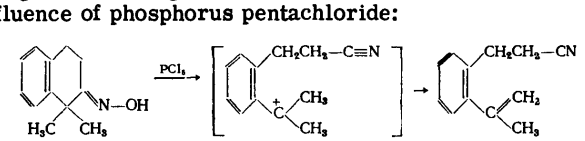
which when prepared in absolute alcohol at -30° gave *p*-toluenesulphonic acid and a 72% yield of the isonitrile



Depending on the mesomeric, inductive, and steric effects of the substituents on the benzene ring, the tolylsulphonates *syn*-Ar–CH=N–OT either ionise at the N–O bond with subsequent rearrangement, leading to formation of the isocyanide ArNC, or lose the proton from the CH-group, giving the nitrile ArCN, or undergo both conversions.

Many investigators have indicated the similarity of the nitrile rearrangements of substituted aldehyde hydrazones[6,16,27] and 3-unsubstituted pyrazolines[6,16] to the Beckmann rearrangement of the second type. This rearrangement is particularly characteristic of α-hydroxyketone oximes, monoximes of certain aliphatic-aromatic α-diketones, aromatic ketoximes containing a tertiary carbon atom in the α-position to the oxime group, and some oximes of cyclic ketones. Information on this rearrangement, which also involves cleavage of an N–O bond and formation of a nitrile, may be found in reviews[28,29].

Conley and Lange[30] recently demonstrated the intermediate formation of carbonium ions in this reaction, using the rearrangement of cyclic ketoximes under the influence of phosphorus pentachloride:

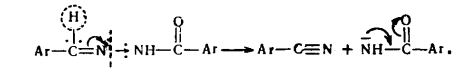


The carbon–carbon bond splits heterolytically, with formation of a carbanion at the carbon atom of the C=N double bond and a carbonium ion at the quaternary carbon atom, the latter being stabilised by elimination of a proton. The overall process is thus similar to a fragmentation reaction[31].

3. NITRILE REARRANGEMENTS PRODUCED BY NUCLEOPHILIC REAGENTS

Naumov and coworkers[11] have established that substituted aldehyde hydrazones also decompose into nitrile and amine when heated to 260–290° with a catalytic amount of solid potassium hydroxide or sodium amide, thus benzaldehyde phenylhydrazone produces benzonitrile and aniline‡. Similarly benzaldehyde diphenyl-, acetyl-, and benzoyl-hydrazones decompose to give benzonitrile with diphenylamine, acetamide, and benzamide respectively. Fission produced by solid alkalis proceeds more smoothly than with copper(I) chloride, but yields are about the same.

The reaction apparently proceeds by β-elimination: the hydroxyl or amido-group attacks the "aldehydic" hydrogen atom, and the deprotonisation increases the polarisation of the nitrogen–nitrogen bond, which when heated splits anionically. The reaction is thus apparently heterolytic:



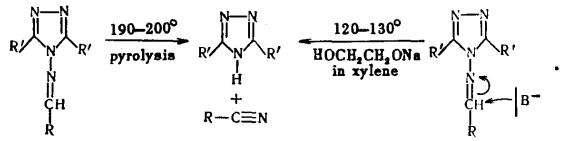
Nitrile fission produced by alkalis is not characteristic of aldehyde mono- or di-alkylhydrazones; as Todd[33] showed, monoalkylhydrazones decompose when heated with solid potassium hydroxide with evolution of nitrogen (as in the Kizhner reaction). On the other hand, benzaldehyde dimethyl- and diethyl-hydrazones are stable to solid alkalis[6,11,33].

A particular conversion of aldehyde phenylhydrazones involving cleavage of the nitrogen–nitrogen bond is the Robev amidine rearrangement. In 1954 Robev found[34,35] that phenylhydrazones of aromatic aldehydes rearrange to amidines when heated to 140–145° with sodium amide in xylene:

Under the reaction conditions the amidine is partially decomposed into aniline and the nitrile, and this reaction goes to completion at a more elevated temperature[36]. Since aromatic amines and nitriles are known to produce *N*-phenylamidines by the action of sodium amide in xylene[37], the amidine rearrangement might have been thought to proceed by initial decomposition of the hydrazone into amine and nitrile followed by reaction between the latter[36,38]; however, it has recently been decisively established[39–43] that the reaction involves homolytic cleavage of the N–N bond, and is not a nitrile fission of the type under review.

Hodgkins and King[44] observed the formation of benzonitrile in the photochemical decomposition of benzaldehyde azine in the presence of benzophenone, and thought it to involve a radical mechanism, the intermediate azine being reduced to benzaldehyde phenylhydrazone which then undergoes the nitrile fission.

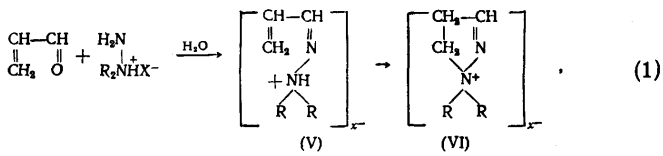
Becker and Timpe have recently found[45] that the azomethines formed from aromatic or heterocyclic aldehydes and 4-amino-1,2,4-triazole decompose into 1,2,4-triazole and the corresponding nitrile when heated to 190–200°. Kinetic studies showed the reaction to be catalysed by bases, and in accordance with this the decomposition temperature in the presence of a base ($HOCH_2CH_2ONa$) is somewhat lower (120–130°) than in pure pyrolysis:



This was proposed as a preparative reaction for various nitriles (other than-aliphatic§), giving yields of up to 85%.

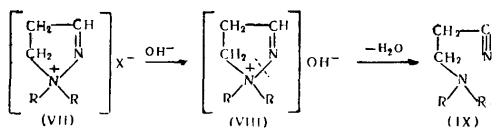
In 1960 Ioffe and Zelenin found[46] that the condensation of acrolein with unsymmetrical dimethyl- or diethyl-hydrazine in the cold in a weakly acid medium gives not the expected unsaturated *NN*-dialkylhydrazones, but β-dialkylaminopropionitriles:

Under the same conditions αβ-unsaturated ketones produce only the stable dialkylhydrazones[47]. In 1962 these workers showed[15,38,48–50] that their formation of β-dialkylaminopropionitriles proceeds by cyclisation of the acrolein and unsymmetrical dialkylhydrazine to produce a pyrazolinium salt:



(1)

followed by decomposition of the quaternary pyrazolinium base (by addition of alkali at room temperature):

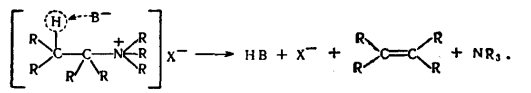


(2)

The structure of the quaternary pyrazolinium salt (VII; R = CH_3) was proved by cross-synthesis from methylhydrazine and acrolein. Addition of 50% NaOH to a concentrated aqueous solution of 1,1-dimethylpyrazolinium iodide causes immediate separation of β-dimethylaminopropionitrile, scheme (2) with R = CH_3, X = I. Several other 1-methylpyrazolinium iodides substituted in positions 1, 4, and 5 decompose analogously[38].

Ioffe and Zelenin concluded that the aminonitrile rearrangement of quaternary pyrazolinium salts proceeds analogously to the Hofmann degradation of quaternary ammonium bases.

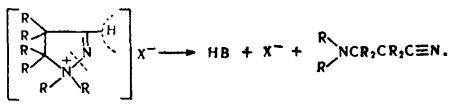
The structural feature characteristic of compounds which undergo this type of rearrangement is the presence of a quaternary nitrogen atom and a hydrogen atom in position 3, that is, in the β-position relative to the quaternary atom. Quaternary ammonium compounds are known to decompose under the action of bases:



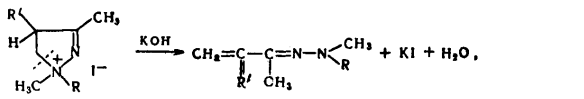
‡ Wolf[32] heated benzaldehyde phenylhydrazone with alcoholic sodium ethoxide at 165° for 20 h and obtained aniline (57%) and benzoic acid (89%). Benzonitrile may have been produced initially.

§ Aliphatic aldehydes give alkylidenebisamines with 4-amino-1,2,4-triazole, and not azomethine derivatives[45].

With quaternary pyrazolinium salts there is an initial abstraction of the proton at the C=N double bond produced by the action of the base (alkali), and then formation of the C≡N bond:

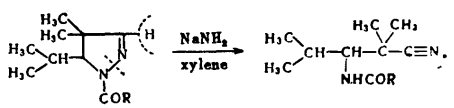


3-Substituted quaternary pyrazolinium salts, for which the aminonitrile rearrangement is impossible, invariably decompose by opening of the ring at the nitrogen–carbon bond, with formation of unsaturated *NN*-dialkylhydrazones[51]:

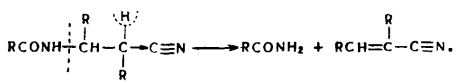


where (R = CH_3 or C_2H_5; R′ = H or CH_3). The reaction is carried out by heating with the solid potassium hydroxide to 130–160°, that is, to a considerably high temperature than is required by the aminonitrile rearrangement. However, these conditions are the same as for the Hofmann degradation of other hydrogenated nitrogen-containing heterocyclic compounds (pyrrolidine, piperidine, etc.)[52,53].

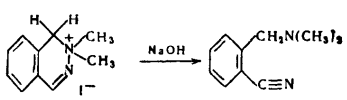
Naumov and coworkers have found[11] that 3-unsubstituted 1-acyl- (including 1-benzoyl- and 1-benzenesulphonyl-) pyrazolines can also produce the corresponding acylaminonitriles when heated with sodium amide in xylene:



If position 4 of the pyrazoline ring carries a hydrogen atom a further degradation becomes possible:



In 1962 Smith and Otremba observed[54] that 2,2-dimethyl-1,2-dihydrophthalazinium iodide is converted into *o*-dimethylaminomethylbenzonitrile by treatment with an aqueous solution of sodium hydroxide:



On the assumption that this is a general reaction for *NNN*-trimethylhydrazinium salts obtained from aldehydes, Smith and Walker studied it in some detail[55], and showed that the quaternary salts derived from the dimethylhydrazones of various aldehydes (aliphatic, aromatic, and unsaturated) are smoothly converted into the corresponding nitriles by treatment with a methanol solution of sodium methoxide

Smith considered his reaction to have an affinity with the base-catalysed conversion of aromatic chloroimines into nitriles:

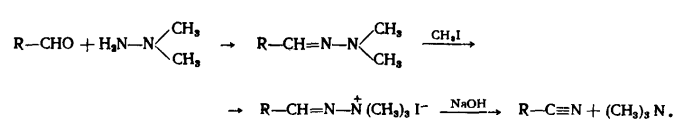
described in 1930 by Hauser and Gillaspie[56], that is, β-elimination occurs, and it differs from the chloroimine reaction only in the group which is eliminated.

Smith and Walker studied the behaviour of quaternary aldehyde hydrazonium salts in aqueous solution. The salts derived from aromatic aldehydes with electron-accepting substituents underwent slow β-elimination when the solutions were boiled for 6–8 h; the trimethylhydrazonium iodides obtained from *o*-nitro-, *m*-nitro-, and *o*-chlorobenzaldehyde gave the corresponding nitriles in yields of 75, 45, and 82% respectively. On the other hand, analogous treatment of benzaldehyde derivatives led to a recovery of 47% of the starting material, together with a mixture of benzaldehyde and benzonitrile. The quaternary *p*-dimethylaminobenzaldehyde hydrazonium iodide also underwent simultaneous elimination and hydrolysis when boiled in aqueous solution. Treatment of benzaldehyde derivatives with 1 *N* NaOH at room temperature caused rapid separation of an oil, which was also a mixture of benzonitrile and benzaldehyde.

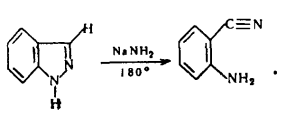
Hauser and coworkers[57] showed the conversion of aromatic chloroimines to nitriles to be of the second order kinetically.

Smith and Walker consider that the elimination reaction shown by the quaternary hydrazonium salts in water alone also proceeds by an E_2 mechanism, the water acting as the base. Under these conditions the elimination can be considered as proceeding by a mechanism similar to that of the decomposition of the trimethyl-2-(*p*-nitrophenyl)-ethylammonium ion to *p*-nitrostyrene in aqueous solution[58]; here electron-withdrawing substituents increase the acidity of the β-hydrogen atom and so facilitate the elimination. With the quaternary hydrazonium salts obtained from unsubstituted benzaldehyde or *p*-dimethylaminobenzaldehyde, the reduced acidity of the β-hydrogen atom enables hydrolysis to complete successfully with the β-elimination reaction. Smith and Walker find these results to be in accordance with those of Hauser and coworkers[57], who obtained relative rates of reaction of 1 : 7.7 : 540 for the sodium hydroxide-catalysed decomposition of chloroimines derived from benzaldehyde, *o*-chlorobenzaldehyde, and *o*-nitrobenzaldehyde.

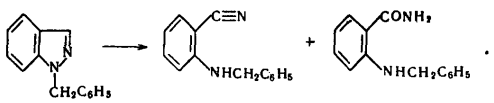
The alkaline fission of quaternary aldehyde hydrazonium salts was described almost simultaneously by other workers also[6,59–61]. It has also been proposed to use this reaction for the preparation of nitriles from aldehydes in yields of 40–80%[59]



Huisgen and coworkers observed[62] the formation of *o*-aminobenzonitrile when indazole is heated to 180° with sodium amide:

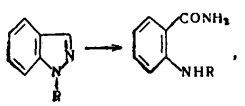


When attempting the amination of certain indazoles with alkali metal amides, Simonov and coworkers found[63] that the action of sodium amide and sodium hydroxide on 1-benzylindazole in xylene causes expansion of the pyrazole ring to a pyrimidine ring, and also ring opening with formation of the amide and nitrile of *N*-benzylanthranilic acid:



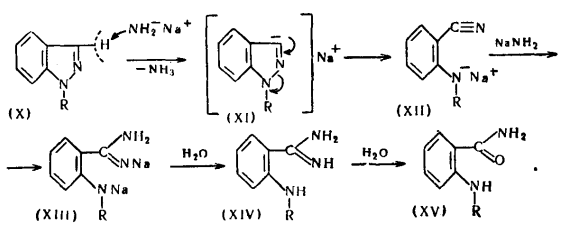
The same result is obtained in a current of ammonia and when thoroughly dry air is passed through the reaction mixture. 1-Benzylindazole reacts very readily with potassium amide in liquid ammonia[65], the main product being the nitrile of *N*-benzylanthranilic acid (67% yield).

The pyrazole ring is also opened when 1-alkylindazoles are heated with sodium amide in xylene in the presence of sodium hydroxide, with the formation of amides of *N*-alkylanthranilic acids in 40–50% yields[66]:



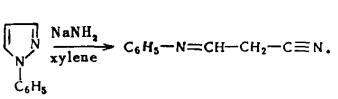
where R = CH_3, C_2H_5, n-C_3H_7 or iso-C_3H_7. Under the same conditions 1-butylindazole yields the nitrile of *N*-butylanthranilic acid in addition to the amide.

The ring is also opened when 1-arylindazoles react with sodium amide in xylene, producing nitriles, amides, or amidines of *N*-phenylanthranilic acid, depending on the structure of the aryl moiety[65]. Apparently[65] there is first a direct nucleophilic attack by the sodium or potassium amide on the hydrogen in position 3 of the pyrazole ring (X) (3-substituted indazoles do not react with sodium amide) with abstraction of a proton, liberation of ammonia and formation of the unstable sodium derivative (XI). After this, or at the same time, there is a redistribution of electron density around the ring, leading to weakening and then cleavage of the N–N bond with formation of the nitrile (XII):

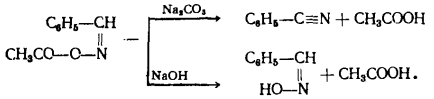


The nitrile (XII) adds on sodium amide at the nitrile group to give the sodium salt of the corresponding amidine (XIII) which, when water is added to the reaction mixture after the reaction, is readily hydrolysed to the amide of the corresponding *N*-substituted anthranilic acid (XV).

Recently Bobrova achieved the opening of the pyrazole ring itself[67]; when 1-phenylpyrazole and certain other 3-unsubstituted pyrazoles are heated with sodium amide in xylene the N–N bond opens to form the corresponding β-iminonitriles:



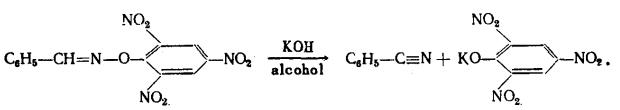
Aldoximes and their derivatives can also undergo nitrile fission of the N–O bond by the action of alkaline substances. Hantsch showed[68] that in addition to alkaline hydrolysis, acetyl β-benzaldehyde oxime can undergo fission of the N–O bond under the action of sodium carbonate in the cold:



Benger and Brady.[69] studied this reaction with many acetylated aromatic β-aldoximes and showed that the nitrile may be formed as follows:

They consider that the deprotonisation under the action of the nucleophilic reagent leads to a redistribution of electron density and rupture of the N–O bond.

Unlike the acetylated oximes, the alkyl *O*-ethers are very stable, and even withstand boiling with 2 *N* NaOH.[20] However, benzaldehyde oxime *O*-2,4-dinitrophenyl ether[70] and benzaldehyde oxime *O*-2,4,6-trinitrophenyl ether[71] decompose to produce benzonitrile when boiled with alcoholic alkali:



In the 1930's it was suggested independently by several workers that when a molecule HX (where X is halogen, acetoxy, etc.) is split off from certain organic compounds by the action of bases a proton is first abstracted, followed by liberation of X with a full octet of electrons. This mechanism was suggested by Drake and McElvain[72] for the removal of hydrogen bromide from ethyl β-bromopropionate in the presence of piperidine, and by Mills[73] for the removal of acetic acid from β-aldoxime acetates in the presence of alkali.

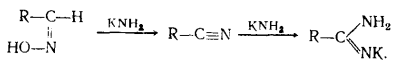
According to Hauser and coworkers[57,74], the removal of hydrogen chloride from aldochlorimines by various bases, and the splitting of benzaldehyde oxime di- and tri-nitrophenyl ethers observed by Brady[70,71], also proceed by the same mechanism.

O-Alkyl ethers of aldoxomes are converted into nitriles by the action of potassium amide in liquid ammonia[75]. The *O*-benzyl ether of α-benzaldehyde oxime decomposes into benzonitrile (some benzamide is also formed) and benzyl alcohol when heated with fused potassium hydroxide[76].

Jordan and Hauser had earlier found[77] that certain *anti*-aldoximes in solution in 2 *N* NaOH at 97–100° are slowly converted into a mixture of the corresponding carboxylic acids and the isomeric *syn*-aldoximes; the latter are also slowly converted into carboxylic acids. It was suggested that the carboxylic acids are formed by hydrolysis of the nitriles produced as intermediates in the dehydration of the *anti*-aldoximes.

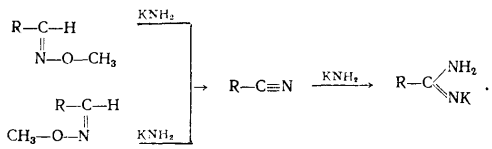
Vermillion and Hauser investigated the action of potassium amide on certain *syn*- and *anti*-aldoximes and their *O*-methyl ethers and acetyl derivatives[75].

After 9 d in a sealed tube with potassium amide in liquid ammonia at room temperature, *anti*-4-methoxybenzaldehyde oxime produces 4-methoxybenzamidine (48%) and 4-methoxybenzamide (15%). Under the same conditions the corresponding *syn*-aldoxime is apparently partly decomposed, but no products were isolated. The formation of the amidine from the *anti*-aldoxime is apparently due to the loss of water with formation of the nitrile, which then reacts with the potassium amide:



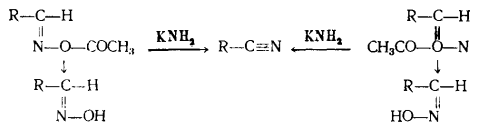
In fact, the nitriles are rapidly converted into amidines in the presence of potassium amide in liquid ammonia. The amides are probably produced by hydrolysis of the amidines, and possibly also directly from the nitriles by reaction with the potassium hydroxide produced by the action of potassium amide with the water split off from the *anti*-aldoximes.

Vermillion and Hauser also found that in the presence of potassium amide in liquid ammonia the *O*-methyl ethers of both *syn*- and *anti*-4-methoxybenzaldehyde oximes split off the elements of methanol to form 4-methoxybenzonitrile, which under the reaction conditions is completely or partially converted into the corresponding amidine:



With reaction for 2 h in the presence of 1.28 equiv. potassium amide, the *anti*-ether is fully decomposed, but the *syn*-ether only partially; the removal of the elements of methanol proceeds more readily from the *anti*-form than from the *syn*-form of the ether, as would be expected. The elimination from the *anti*-ether may be substantially complete within a few minutes. With 3 equiv. of potassium amide, the *syn*-ether is fully decomposed in 4 h, giving the amidine in a yield of ~ 90%.

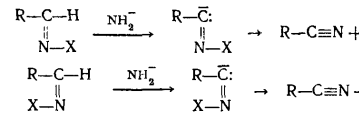
The acetyl derivatives of *syn*- and *anti*-benzaldehyde oximes react with potassium amide in liquid ammonia to form a mixture of the nitrile with the corresponding benzaldehyde oxime:



With reaction for 10 min at -33° *anti*-4-methoxybenzaldehyde oxime acetate gave yields of nitrile and aldoxime of 87% and 4% respectively; the corresponding *syn*-compound gave nitrile and aldoxime yields of 25% and 61% respectively. As would be expected, the yields of nitrile from the *anti*-acetates are higher, and the yields of aldoximes lower, than from the isomeric *syn*-acetates. It is of interest that the *syn*-acetates are not isomerised into the *anti*-forms by the action of potassium amide in liquid ammonia, and consequently the formation of nitriles from the *syn*-acetates is the result of direct removal of the elements of acetic acid, without preliminary isomerisation into the *anti*-acetates.

As compared with sodium hydroxide, which reacts with most *syn*-acetates to form substantially only the *syn*-aldoximes, potassium amide allows more of the β-elimination and less of the hydrolysis, giving a considerable amount of nitrile with *syn*-acetates also.

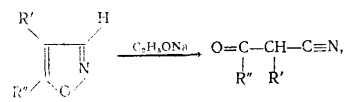
Vermillion and Hauser consider that the loss of HX from *syn*- and *anti*-aldoximes and their *O*-methyl ethers and acetyl derivatives by means of potassium amide is caused by attack by the base on the aldehydic hydrogen, which comes off as a proton; this is followed by the elimination of X as the anion with formation of the nitrile:



The elimination of water from an *anti*-aldoxime in the presence of potassium amide may be represented as follows:

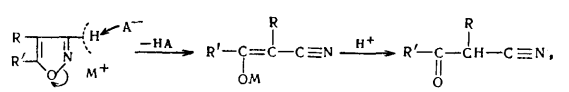
Here the base undoubtedly reacts with the hydroxyl hydrogen to give the aldoxime salt, but this salt is in equilibrium with unchanged aldoxime. This dehydration by means of bases is of particular interest since it proceeds by abstraction of the proton attached to carbon, although this proton is less active than that attached to the oxygen.

The cyclic analogues of the aldoximes — the 3-unsubstituted isoxazoles — can undergo ring-opening to form ketonitriles by the action of nucleophilic reagents, under conditions very similar to those of the aminonitrile rearrangement of quaternary pyrazolinium and aldehyde hydrazonium salts:



where R', R" = H, alkyl, aryl, etc.

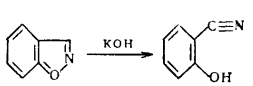
The nucleophilic opening of the isoxazole ring has been much studied[78-80]. Its mechanism involves initial abstraction of a proton from the 3-carbon atom followed by the substantially irreversible isomerisation of the resulting ion into the enolate ion of the end-product[78,80]:



where M = Na, K; A = OH^-, OR^-, NH_2^-.

Pino and coworkers showed that this reaction goes to completion, and is of the first order[81].

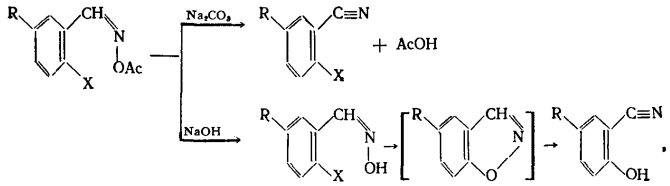
4,5-Benzoisoxazole is particularly unstable towards alkalis; when dissolved in potassium hydroxide it decomposes to salicylonitrile[82]:



The same product is obtained when 4,5-benzoisoxazole is heated[83].

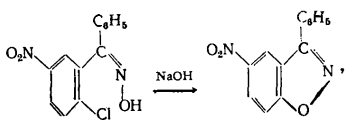
Treatment of the acetyl derivative of 2-chloro-5-nitro-β-benzaldehyde oxime with sodium carbonate eliminates acetic acid, with formation of the corresponding nitrile[84]. The action of sodium hydroxide on this oxime (and on 2-chloro-, 2-bromo- and 2-iodo-β-benzaldehyde oxime[85])

converts it into the nitrile, the halogen atom being replaced by the OH group. The reaction proceeds through the intermediate formation of the 3-unsubstituted nitrobenzoisoxazole, which here is unstable and cannot be isolated:



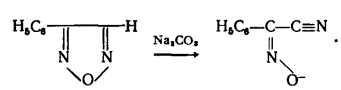
where R = H, NO_2; X = Cl, Br, I.

The action of sodium hydroxide on 2-chloro-5-nitrobenzophenone oxime produces 5-nitro-3-phenylbenzoisoxazole[86]:

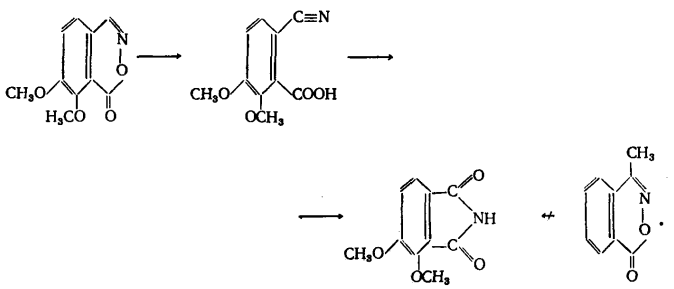


but this does not undergo further rearrangement, since the hydrogen atom in position 3 has been replaced by the phenyl group.

Furazans decompose analogously to the isoxazoles[87], cyanoketoximes being obtained even by the action of sodium carbonate solution:



Brady and coworkers have observed similar reactions in the benzo[*d*]oxazine ring[88]; the anhydride of the oxime of opianic acid forms the nitrile on gentle heating and the imide 3,4-dimethoxyphthalic acid on further heating:



Under comparable conditions 4-methylbenzo[*d*]oxazin-1-one does not give the phthalimide, since the methyl group occupies the position of the hydrogen atom on the C=N double bond, and the formation of the nitrile is impossible.

4. STRUCTURAL FACTORS DETERMINING THE POSSIBILITY OF NITRILE REARRANGEMENTS

As is seen from the material above, the nitrile fission of N–N, N–O, and N–Cl bonds has been observed under very diverse experimental conditions. Most frequently the rearrangement requires the action of a strong nucleophilic reagent, and the part played by such a reagent is clear: it causes deprotonation of the aldehydic carbon atom and so facilitates or induces the reaction.

The nitrile rearrangement occurs only in compounds in which the N–N (or N–O) bond is strongly polarised[11,76]. This polarisation is strongest in compounds containing a quaternary nitrogen atom, such as quaternary pyrazolinium[15,38,48–50], dihydrophthalazinium[54] and hydrazonium salts[6,55,59–61], which are typically ionic compounds carrying a full positive charge on the terminal nitrogen atom of the grouping $-CH=N-\overset{+}{N}\!\!<$. This charge attracts towards itself the pair of σ electrons forming the N–N bond, that is, it induces polarisation of the nitrogen–nitrogen bond, which in its turn produces a considerable shift of the π electrons of the C=N double bond, which leads to increased lability of the proton on the carbon atom:

The deprotonation proceeds readily in aqueous alkaline solution, by the action of the hydroxide ions. As a result of this twofold action (polarisation of the N–N bond and the action of the nucleophilic reagent) nitrile fission proceeds very readily, usually at room temperature.

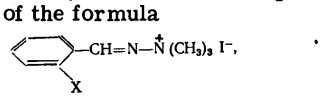
It is of interest to note here that where there is a single action (thermal fission of quaternary hydrazonium or pyrazolinium salts or pyrazolinium chlorides) the reaction requires much more severe conditions[6,12,13,15].

In other instances the necessary polarisation of the N–N bond is produced by including some cationoid activity on the terminal nitrogen atom, by substituting it with electron-withdrawing groups (phenyl, acetyl, benzoyl, etc.) or by increasing this cationoid activity by means of complex-forming agents, or by protonisation.

In particular, for nitrile fission of substituted aldehyde hydrazones of structure $RCH=N-NR'R''$, the substituents R′ and R″ may be groups which facilitate polarisation and cleavage of the N–N bond under the experimental conditions; however, if $R' = R'' = CH_3$, the $+I$-effect of the methyl groups prevents this polarisation (hence benzaldehyde dimethylhydrazone is stable to boiling with solid potassium hydroxide or sodium amide[6,11,33]).

Activation of the $-CH=N-N\!\!<$ (or $-CH=N-O-$) grouping may generally be accomplished in two ways, since the ease with which it dissociates increases (*i*) with the strength of polarisation of the N–N (or N–O) bond, and (*ii*) with the ease of deprotonation of the carbon atom in the β position to the sp^3 nitrogen atom. The former is best achieved by creating the maximum positive charge on the sp^3 nitrogen atom; the influence of this charge is then transmitted through the C=N double bond and facilitates deprotonation of the carbon atom.

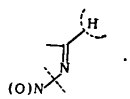
The deprotonation is also facilitated by the introduction of electron-accepting groups near this carbon atom, as in shown, in particular, by the data of Smith and Walker[55] who, as mentioned above, established that quaternary hydrazonium salts of the formula



containing an electron-accepting substituent in the benzene ring (X = NO_2 or Cl), this substituent increasing the acidity of the β-hydrogen atom, form the corresponding benzonitrile even when boiled in aqueous solution. However, the unsubstituted compound, or one containing an electron-donating group such as *p*-dimethylamino, undergo hydrolysis as well as β-elimination, to give a mixture of nitrile and aldehyde.

We have already remarked that the presence of electron-accepting substituents in the benzene ring of aromatic chloroimines also increases the rate of their nitrile fission[57] and, finally, it is known that the introduction of electron-accepting substituents (for example, the nitro-group) into position 4 of the isoxazole ring greatly increases its reactivity towards alkaline reagents[89,90].

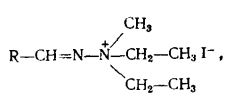
In considering the nitrile fission of oximes and their *O*-substituted derivatives, it must be borne in mind that trans-elimination is the more easily achieved, that is, the *anti*-isomers are the more reactive. We note that in the fission of the pyrazoline, pyrazole, or isoxazole ring, the structure of the heterocycles is such that it is trans-elimination which occurs here also:



The similarity between the nitrile rearrangement of quaternary pyrazolinium and aldehyde hydrazonium salts and the Hofmann degradation of quaternary ammonium bases has been repeatedly remarked[6,11,38,54,61].

Ioffe and coworkers have noted[51,61] that although the aldehyde hydrazonium salts which they investigated contained two ethyl groups (they used diethylhydrazones), which are the most readily removed in the Hofmann degradation, they never observed the formation of ethylene; consequently, the nitrile formation proceeds much more readily than the Hofmann decomposition with elimination of the β-hydrogen atom in the structure $CH_3-CH_2-\overset{+}{N}<$.

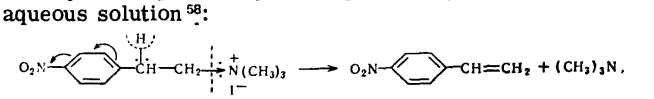
In compounds of the structure



the positive charge on the quaternary nitrogen atom causes strong polarisation of the $C-\overset{+}{N}$ bonds and the $N-\overset{+}{N}$ bond. Naturally, insofar as the molecule is potentially able to undergo either nitrile formation or Hofmann degradation, the β-elimination will occur in the direction in which the β-hydrogen atom is most readily removed. Clearly, the effect of the positive charge on the nitrogen atom is much more readily transmitted across the C=N double bond to the aldehydic hydrogen atom than to the β-hydrogen atoms of the ethyl groups, and this is why the nitrile rearrangement is the reaction that occurs here, and, for the same reasons, why quaternary pyrazolinium salts carrying β-hydrogen atoms in both position 3 and position 4 undergo nitrile formation and not Hofmann degradation.

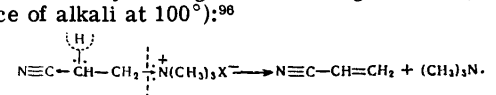
Even electron-accepting groups (nitrile or phenyl) in the β position of the ethyl radical in quaternary *N*-ethylpyrazolinium salts do not facilitate the Hofmann degradation of the C–N bond; here also the pyrazoline ring opens, with formation of β-dialkylaminopropionitriles[91].

Nevertheless, instances are known where the Hofmann degradation of quaternary ammonium bases proceeds as readily as the aminonitrile rearrangement, when the structure of the compounds is such that elimination of the β-hydrogen atom is facilitated. Thus salts of quaternary ammonium bases containing the phenylethyl group decompose when heated with aqueous alkali[92-94]. Moreover, according to von Braun[95], steam distillation of trimethyl-(2-phenylethyl)ammonium hydroxide causes it to decompose almost quantitatively to give styrene. However, aqueous solutions of trimethyl-(3-phenylpropyl)ammonium and other ammonium hydroxides in which the phenyl radical is further removed from the β-hydrogen atom can be evaporated on a water-bath with no sign of decomposition. Finally, trimethyl-2-(*p*-nitrophenyl)ethylammonium iodide readily decomposes to produce *p*-nitrostyrene even in aqueous solution[58]:

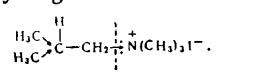


This is because of the influence of the *p*-nitrophenyl group adjacent to the β-carbon atom; the inductive and electromeric effects of this group both act in the same sense, greatly facilitating elimination of the β-hydrogen atom.

In quaternary ammonium salts derived from β-dialkylaminopropionitriles, removal of the β-hydrogen atom is facilitated by the inductive effect of the nitrile group; these salts readily undergo Hofmann degradation (in the presence of alkali at 100°):[96]



On the other hand, if the β-carbon atom carries alkyl groups, the rate of this reaction decreases[97], since the +*I*-effect of such groups compensates for the inductive effect of the positively charged nitrogen atom, and hinders elimination of the hydrogen atom:



Here, hydrolysis competes successfully with the β-elimination in an aqueous alkaline medium, so that the Hofmann degradation of such quaternary ammonium salts is usually carried out by heating with silver oxide or solid alkali.

The influence of inductive and electromeric factors on elimination reactions has been investigated by Hughes and Ingold[58,98]. An analogous analysis of the influence of structural factors provides an understanding of the possibility and varying ease of accomplishment of nitrile rearrangements.

I. INTRODUCTION

In recent years there has been a great development of the chemistry of aliphatic nitro-compounds. The improvement of old and the discovery of new methods of synthesis has led to a sharp increase in the number of nitro-products that have become readily available; some of these are already produced on the industrial scale.

The nitroalkanes, which are now manufactured in tens of thousands of tons a year, are used as starting materials in the production of many aliphatic nitro-compounds.

In this connection, the attention of chemists has been increasingly attracted to the possibility of using nitro-derivatives of the aliphatic series for the needs of industry and agriculture, both directly and as a relatively cheap chemical material for the synthesis of various products with important applications.

Reduction occupies a special position in the chemical transformations of nitro-compounds. There is no need to dwell on the tremendous importance of this reaction in the aromatic series. However, the reduction of aliphatic nitro-compounds has been studied in a less detailed manner and the literature on this question has not been specially systematised. Isolated information on some particular problems may be found in a number of monographs and review articles on the nitro-compounds[1-7].

Since the question of the reduction of nitro-compounds containing other functional groupings in addition to the nitro-group is of fundamental chemical and pratical interest, only examples of selective reduction of aliphatic functional nitro-compounds will be considered in this review. This question is considered in two aspects. Thus, in the first part the reduction of the nitro-group to the amino-group without change of other functions is considered, and in the second the reduction of functional groups without changing the nitro-group.

It was not our purpose to produce an exhaustive review of all instances of selective reduction of nitro-compounds, and the material of the review has been selected in such a way as to illustrate the use of various reducing agents or catalysts, suitable for the selective (in the above sense) reduction of functional aliphatic nitro-derivatives.

II. SELECTIVE REDUCTION OF THE NITRO-GROUP IN ALIPHATIC NITRO-COMPOUNDS WITH OTHER FUNCTIONAL GROUPS

1. Reduction of Nitro-Alcohols to Amino-Alcohols

Of all aliphatic nitro-compounds, the reduction of the nitro-alcohols has been most fully studied. The leading motive of many investigations in this field is the wide use

of amino-alcohols in a number of branches of industry and also their great importance as physiologically active compounds.

The selective reduction of nitro-alcohols does not present particular difficulties, because the hydroxyl group is inert to the action of the majority of chemical reagents usually employed for reducing the nitro-group.

Hydrogenation with Raney nickel is one of the main methods of selectively reducing nitro-alcohols. Change of temperature between 30° and 100° and of pressure between 1 and 130 atm has no material effect on the yields of amino-alcohols [8-20]; however, carrying out the hydrogenation in the presence of carbon dioxide leads to a significant increase in the yield of amino-alcohols [11,14]. In an acid medium, as a rule, the hydrogenation of the nitro--group is not accompanied by side-reactions. On the other hand, when the reaction is carried out in an alkaline medium, the reduction is frequently accompanied by side--reactions connected with the instability of nitro-alcohols under these conditions. Thus in the reduction of 2-methyl--2-nitropropan-1-ol with Raney nickel in liquid ammonia, Johnson separated 1,2-diamino-2-methylpropane, the appearance of which the author explains by the exchange of a hydroxyl group of the reduced alcohol for an amino--group [21]. Moreover, in an alkaline medium methyl groups are easily eliminated from tertiary carbon atoms. For example, in the reduction of 2-ethyl-2-nitropropan-1,3--diol, 2-aminobutanol and methanol are formed [22]. In an acid medium the reaction proceeds normally and leads to the formation of 2-amino-2-ethylpropan-1,3-diol.

In a number of papers the reduction of nitro-alcohols (monohydroxy- and polyhydroxy-) to amino-alcohols in the presence of platinum oxide [23-25] and palladium [26-29] is described. Usually the yield of amino-alcohols is 80–95%. The process is best carried out in an acid medium.

Fundamental information on the selectively catalytic hydrogenation of nitro-alcohols is collected in Table 1.

There are many papers on the reduction of nitro-alcohols by chemical reagents. The reduction of nitro-alcohols with nascent hydrogen has been studied in great detail. Various combinations of metals and acids have been proposed as a source of hydrogen (for example, Fe + H_2SO_4, HCl, or H_3PO_4 [10,30,31]; Zn + HCl [14]; $SnCl_2$ + HCl [15]).

TABLE 1.

Initial nitro-alcohol	Catalyst*	Hydrogenation conditions (temp., H_2 pressure)	Solvent	Yield of amino--alcohol, %	Ref.
2-Methyl-2-nitropropan--1-ol	Ni/Re	70°; 30–35 atm	water–methanol	95.8	9
2-Nitro-1-phenylpropan--1-ol	Ni/Re	50–70°; 20–120 atm; CO_2	alcohol	87.45 (no CO_2)	14
1-Cyclohexyl-2-nitro-ethan-1-ol	Ni/Re	25–35°; 4–6 atm; CO_2	–	91	16
$CH_2OH-C(NO_2)CH_2OH$ | C_nH_{2n+1}	Ni/Re	125°; 1–135 atm	water–methanol	–	18
1,4-Dinitrobutan-2,3-diol	Ni/Re	40–80°; 200 atm	dioxan	–	19
1-Deoxy-1-nitro-D--*manno*-D-galaheptanol	Ni/Re	20°; 1 atm	–	90	16
1,4-Dideoxy-1,4-dinitro-neoinositol	Ni/Re	20°; 1 atm	acetic acid–dimethylform-amide	89.6	20
2-Nitrooctadecan-1,3--diol	PtO_2	20°; 1 atm	acetic acid	71	24
3-Nitropentan-2,4-diol	5% Pd on $BaSO_4$	20°; 1 atm	H_2O + pyridine	86.5	28
2-Nitropropan-1,3-diol	Pd on $BaSO_4$	20°; 1 atm	in the presence of COOH–COOH	93	2,9

* Ni/Re presumably denotes Raney nickel (Ed. of Translation).

Evidently, the action on β-nitro-alcohols of iron in sulphuric acid at a pH of 3–3.5, and the use of 1–1.1 equivalents of acid for each nitro-group give the most favourable conditions for the reduction of β-nitro-alcohols by this method; the yields of amino-alcohols is 92–98%.

Lower β-amino-alcohols (C_3–C_5) are conveniently obtained by the action of aluminium in weak acid on nitro--alcohols [32]; the yield varies between 50 and 70%. The method is particularly recommended for nitro-alcohols sensitive to strong alkalis and acids, but the effectiveness of the method is greatly reduced in the reduction of higher nitro-alcohols (>C_5).

The reduction of β-nitro-α-phenyl-alcohols to the corresponding amino-derivatives by sodium amalgam [33] and lithium tetrahydroaluminate [34] has also been described.

As has been shown by the investigations of Jenny and Druey [35], and also by Grob and Gadient [36], lithium tetrahydroaluminate, or zinc and hydrochloric acid, or aluminium and acetic acid may be used for the simultaneous reduction of nitro-groups and multiple carbon bonds in higher aliphatic unsaturated nitrodiols. The yields of saturated amino-alcohols vary between 40 and 70%. According to Takagi and coworkers [37], ammonium amalgam reduced nitrodiols to hydroxylaminodiols [37].

Examples are known of the selective electrochemical reduction of nitro-alcohols and diols [17,38]. The authors used a lead cathode and dilute sulphuric or hydrochloric acid as electrolytes. The yield of amino-derivatives was 75–94%.

2. Reduction of Alkyl Ethers of Nitro-Alcohols to Alkyl Ethers of Amino-Alcohols

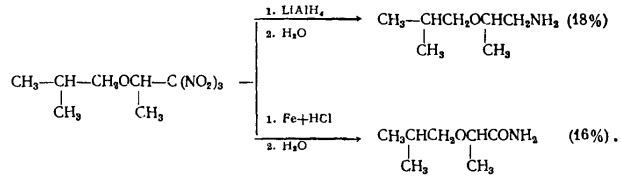
The alkoxy-group in the β-position to the nitro-group is much more stable than the hydroxyl group. Thus, when lithium tetrahydroaluminate acts on β-nitro-α-phenyl-alcohols the carbon–carbon bond is ruptured, but when the analogous alkoxy-compounds are reduced with this reagent, the corresponding β-alkoxy-β-phenylamines are formed in quantitative yield [34].

It is very easy to reduce 1-alkoxy-2-nitro-1-phenyl-alkanes by zinc in organic acids. For example, by using zinc and formic acid, it is possible to obtain β-amino--ethers in ~90% yield [39]. Lambert and coworkers, who made a detailed study of the action of various reducing agents on lower aliphatic β-nitro-ethers, showed that the highest yields of amino-ethers are obtained by catalytic hydrogenation [40]:

$$C_2H_5OCH_2CH_2NO_2 \xrightarrow[20°,\ 100\ atm,\ alcohol]{H_2/PtO_2} C_2H_5OCH_2CH_2NH_2 \quad (52\%),$$

$$CH_3CH(NO_2)CHCH_3 \xrightarrow[50°,\ alcohol]{H_2,\ Raney\ Ni} CH_3CH(NH_2)CHCH_3 \quad (50\%).$$
$$\quad\quad\quad

Schechter and Cates reduced isobutyl 1-trinitromethylethyl ether to the corresponding amine by the action of lithium tetrahydroaluminate, and to α-isobutoxypropionamide by the action of iron in hydrochloric acid[42].



3. Reduction of Nitro-Ketones and Nitro-Aldehydes to Amino-Ketones and Amino-Aldehydes

The presence of a carbonyl group in nitro-compounds makes selective reduction of the nitro-group difficult, because many hydrogenation catalysts and chemical reagents (for example, lithium tetrahydroaluminate) first reduce the carbonyl group. Moreover, reduction is often accompanied by cyclisation through the carbonyl group of the amino-ketones and -aldehydes formed.

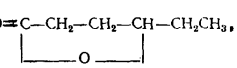
Using 4-keto-6-nitrohexanoic acid (II) and its esters as examples, Moldenhauer[43] and Grundmann[44] showed the possibility of selectively reducing the nitro-group in β-nitro-ketones. When (II) was hydrogenated with palladium on charcoal in hydrochloric acid under normal conditions, the yield of amino-acid reached 96.4%.[44]

$$\underset{\text{(II)}}{CH_2(NO_2)CH_2CO[CH_2]_2COOH} \rightarrow \underset{\text{(III)}}{CH_2(NH_2)CH_2CO[CH_2]_2COOH}.$$

However, hydrogenation of (II) with palladium on barium sulphate in acetic acid leads to (III) in lower yield (67%).

The authors point out the instability in an alkaline medium of compounds containing the β-amino-ketone grouping.

The possibility of selectively reducing the nitro-group in esters of (II) has also been studied and it has been shown that it may be effected by hydrogenation with 5% palladium on charcoal in water[43]. The yield of the corresponding esters of the amino-keto-acid mounted to ~30%. The use in this reaction of Raney nickel as hydrogenation catalyst at low hydrogen pressures leads to the formation of (III) in 20% yield, but at a pressure of 100 atm and a temperature of 225–240° the lactone



is formed in 33.7% yield[44].

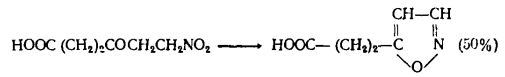
Hydrogenation of (II) with platinum dioxide in water brings about reduction of the keto-group as well as the nitro-group and leads to 6-amino-4-hydroxyhexanoic acid[43].

When palladium on aluminium oxide is used as catalyst, deamination of the reduction products occurs[43]:

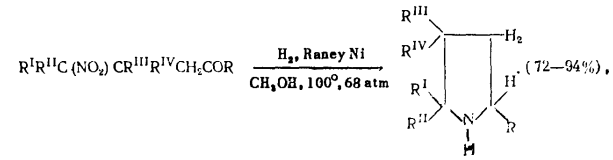
$$CH_2(NO_2)CH_2CO(CH_2)_2COOR \longrightarrow CH_3CH_2CO(CH_2)_2COOR \quad (20\text{–}30\%)$$

where R = H or alkyl.

When lithium tetrahydroaluminate acts on (II), all the functional groups are reduced[43]. Reduction of (II) with tin(II) chloride in hydrochloric acid leads to the formation of an isoxazole ring[45]:



According to Kloetzel[46], on reduction γ-nitro-ketones undergo ring closure to pyrrolidine rings:

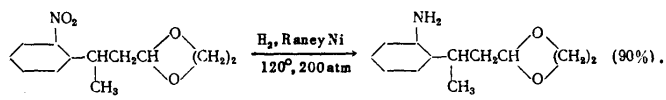


where R, R^I, R^{II}, R^{III}, R^{IV} = H or alkyl.

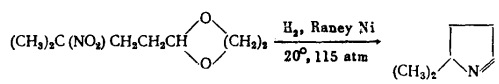
In connection with the difficulties arising in the direct reduction of nitro-ketones and nitro-aldehydes, it is useful to first protect the keto-group by the formation of acetals. Losanitsch[47] has described the reduction of the nitro-group in β-nitroacetals by sodium in boiling alcohol:

$$NO_2CH_2CH(OC_2H_5)_2 \longrightarrow NH_2CH_2CH(OC_2H_5)_2 \quad (\sim 50\%).$$

However, when acetals of γ-nitro-ketones are reduced, the final product largely depends on the structure of the initial nitro-acetal. Thus, in particular, reduction of the acetal† of ethylene glycol and γ-(2-nitrocyclohexyl)butyraldehyde is not accompanied by cyclisation of the final product[48]:



On the other hand, hydrogenation of the acetal‡ of ethyleneglycol and γ-methyl-γ-nitrovaleraldehyde is accompanied by cyclisation[49]:



4. Reduction of Nitro-Acids and Their Derivatives to Amino-Acids and Derivatives

The tremendous practical interest in the selective reduction of the nitro-group in α-nitro-acids and their derivatives as a method of synthesis of α-amino-acids should be mentioned.

The world demand for some amino-acids now reaches some hundreds of thousands of tons per year; for this reason at the present time intensive searches are being

† 2-[2-(2-Nitrocyclohexyl)propyl]-1,3-dioxolane (Ed. of Translation).

‡ 2-(3-Methyl-3-nitrobutyl)-1,3-dioxolane (Ed. of Translation).

made for cheap chemical materials which could be used in their synthesis. In particular, great attention has been paid to the possibility of using nitromethane for this purpose. Nitroacetic esters can easily be obtained from nitromethane, and from these the synthesis of many amino-acids can be effected. Thus, glycine was obtained by the reduction of nitroacetic ester on Raney nickel[50].

In a general way the synthesis of α-amino-acids from nitromethane may be represented by the following scheme:

$$CH_3NO_2 \rightarrow CH_2NO_2COOR' \rightarrow RCH(NO_2)COOR' \rightarrow RCH(NH_2)COOH,$$

where R = alkyl, or substituted alkyl; R′ = CH_3 or C_2H_5. Using this scheme, Weisblat and coworkers[51] synthesised DL-tryptophan and leucine.

In recent years the selective reduction of α-nitro-acids obtained from nitroacetic ester has been studied in detail by Belikov and coworkers[52-54]. In particular, in a study of the hydrogenation of methyl esters of α-nitro-αβ-unsaturated acids with Raney nickel in methanol, it was shown that sometimes there is first addition of the elements of the solvent through the activated double bond, which is probably catalysed by traces of alkali present in the catalyst[52]:

$$CH_3CH{=}C(NO_2)COOCH_3 \xrightarrow{CH_3OH} CH_3CHCH(NO_2)COOCH_3 \rightarrow$$
$$\rightarrow \underset{55^\circ,\,75\ atm}{\xrightarrow{H_2}} CH_3CHCH(NH_2)COOH \quad (41\%).$$
$$\quad OCH_3 \qquad\qquad\qquad\quad OCH_3$$

Esters of sterically hindered α-nitro-acids are normally reduced under these conditions:

$$(CH_3)_2CH{-}CH{=}C(NO_2)COOCH_3 \xrightarrow[50^\circ,\,68\ atm]{H_2,\,CH_3OH} (CH_3)_2CHCH_2CHCOOCH_3 \quad (61\%).$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad NH_2$$

Another example is the synthesis of proline from nitroacetic ester[54]:

$$CH_2NO_2COOCH_3 \xrightarrow{CH_2{=}CH{-}CHO} HCCH_2CH_2CH(NO_2)COOCH_3 \rightarrow$$
$$\rightarrow (CH_3O)_2CHCH_2CH_2CH(NO_2)COOCH_3 \xrightarrow[2.\ H_2O]{1.\ H_2/PtO_2} \text{(proline)}$$

Reduction of α-nitro-acids or their derivatives to amino-acids with the aid of chemical reagents is carried out much less frequently; as a rule, the amino-acids are obtained in a lower yield than by catalytic hydrogenation. Information on the reduction of nitro-acids and their derivatives is given in Table 2.

Sometimes the hydrogenation of nitro-acids is accompanied by side reactions. Thus, the reduction of esters of dibasic γ-nitro-acids on platinum oxide or Raney nickel leads to lactams[61] and other cyclic products[62]:

$$CH_3OOC(CH_2)_2CH(CH_2)_2COOCH_3 \xrightarrow[25^\circ,\,2\text{–}3\ atm]{H_2,\,PtO_2} (CH_2)_2{-}COOCH_3$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad CH{-}NH\diagdown C{=}O$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad CH_2{-}CH_2\diagup$$
$$\qquad\qquad\qquad\quad NO_2$$
$$\xrightarrow[275^\circ,\,250\text{–}350\ atm]{H_2,\ Raney\ Ni} \text{(pyrrolidine)} \quad (57\%).$$

When the ethyl 3,4-dehydro-5-nitrohexanoate is hydrogenated on Raney nickel at high temperatures and pressures, caprolactam is obtained instead of ethyl 6-amino-hexanoate[62].

Isolated information on the reduction of nitro-acids containing other functional groups is given in preceding and subsequent parts of Section II (see pp. 21,23).

5. Reduction of Nitro-Nitriles to Amino-Nitriles

The selective reduction if the nitro-group in nitro-nitriles to the amino-group is of considerable interest, since in the end it opens the way to the synthesis of amino-acids.

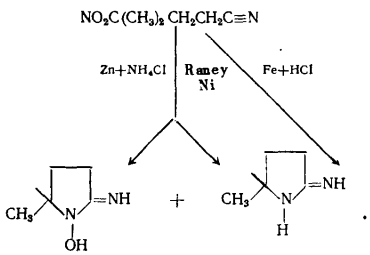
Using nitro-t-butyl cyanide as an example, Buckley and coworkers[63] showed that the selective reduction of β-nitro-nitriles is usefully carried out with iron in dilute hydrochloric acid. The yield of amino-t-butyl cyanide was 65%. When the starting material and other β-nitro-nitriles were catalytically hydrogenated (Raney nickel, palladium on calcium carbonate), instead of amino-nitriles the authors obtained amino-acid amides, diamines, and other secondary products.

As Buckley and Elliott showed[64], when γ-nitro-nitriles are reduced both by chemical and catalytic methods amino-nitriles are generally not obtained. Instead of them,

TABLE 2.

Initial nitro-acid or its derivative	Reducing agent or hydrogenation catalyst	Reaction conditions	Solvent	Reduction product	Yield, %	Ref.
Ethyl β-indolyl-α-nitropropionate	Raney Ni	100°, ~100 atm	alcohol	DL-tryptophan	50	55
Diethyl α-nitroglutarate	Raney Ni	100°, 150 atm	alcohol	DL-glutamic acid	–	56
$(CH_3O)_2CH(CH_2)_2CHCOOCH_3$ (NO₂)	skeleton Ni	70°, 62 atm	absolute methanol	$(CH_3O)_2CH(CH_2)_2CHCOOCH_3$ (NH_2)	75	54
Ethyl αα-dimethyl-β-nitropropionate	Raney Ni	90°, 95 atm	water + $Ba(OH)_2$	β-amino-αα-dimethylpropionic acid	65	57
$(CH_3)_2C(NO_2)(CH_2)_2$–CONRR′	Raney Ni	125°, 68 atm	–	$(CH_3)_2C(NH_2)(CH_2)_2CONRR'$	45–89	58
Methyl β-hydroxy-α-nitrobutyrate	5% Pd/C	20°, 40–50 atm	acetic acid	DL-threonine	74	53
$CH_3CH{=}C(NO_2)COOCH_3$	PtO_2	5°, 1 atm	ethyl acetate	$CH_3CH_2CH(NH_2)COOCH_3$	63	53
γ-Nitropentanoic acid	PtO_2	20°, 1 atm	alcohol	γ-aminopentanoic acid	98	59
$(CH_3O)_2CH(CH_2)_2CHCOOCH_3$ (NO_2)	PtO_2	20°, 60 atm	70% CH_3COOH	DL-proline	65	54
Ethyl β-indolyl-α-nitropropionate	Fe + HCl	20°	–	DL-tryptophan	25	55
Ethyl nitromalonate	Zn + CH_3COOH	50–80°	$(CH_3CO)_2O$	$CH_3CONHCH(CO_2C_2H_5)_2$	30	60

mixtures of the corresponding *N*-hydroxy-5-iminopyrrolidines and 5-iminopyrrolidines are obtained. For example:



6. Reduction of Nitro-Amines to Polyamines

Information in the literature relates to the reduction of β-nitro-amines, products readily obtained by the Mannich reaction from nitro-compounds, formaldehyde, and amines. The most selective reduction of the nitro-group in nitro--amines should, of course, not present any difficulties. However, in selecting the reaction conditions it should be noted that the process is often complicated by side-reactions which are connected with the instability of the initial compounds and to a large degree depend on the structure of the latter, the pH the medium, and other factors.

Johnson[65] reduced a series of β-nitro-amines on Raney nickel at 30–50° and a hydrogen pressure of 70 atm in methanol; the yield of diamines was 65–80%. A few other papers have been published on the selective reduction of nitro-amines and nitro-diamines on Raney nickel under similar conditions[66,67,70–72]. However, Senkus hydrogenated *NN*-diisopropyl-2-methyl-2-nitropropylamine under the same conditions and obtained a mixture of lower amines instead of the diamine[69]. The author explains this result by the instability of the initial nitro-amine. Some β-nitro-amines may be reduced to diamines by the action of tin(II) chloride in hydrochloric acid at 0° in yields of ~30%.[68]

When esters of α-nitro-β-alkylamino-acids are catalytically hydrogenated, esters of the αβ-diamino-acids are not obtained; the bond between the α- and β-carbon atoms is ruptured[70]:

$$\begin{matrix}RCH{-}CH(NO_2)COOR'\\ \quad\quad|\\ \quad\quad NHR'\end{matrix} \xrightarrow[PtO_2]{H_2} RCH_2NHR' + CH_2(NH_2)COOR'.$$

Dornow and Gellrich[34] observed similar cleavage of the initial α-nitro-β-alkyl aminoester under the action of lithium tetrahydroaluminate:

$$\begin{matrix}Cl{-}C_6H_4{-}CHCH(NO_2)COOC_2H_5\\ \quad\quad\quad\quad|\\ \quad\quad\quad\quad NHC_6H_5\end{matrix} \xrightarrow{LiAlH_4} Cl{-}C_6H_4{-}CH_2NHC_6H_5 + CH_3NH_2CH_2OH.$$

Obviously, this reaction is general for all β-nitro-amines in which the nitro-group is on the carbon atom connected to the ester grouping.

The reduction of the nitro-group in *N*-nitro-amines has been studied in the literature with nitroguanidine as an example. The catalytic reduction has been described of nitroguanidine to aminoguanidine with the aid of Raney nickel[71], platinum oxide[71,72], sodium with the addition of ammonium chloride in liquid ammonia[73], zinc dust[74–76], titanium trichloride[77,78]; an electrolytic method has also been used[79,80].

Moreover, it has been shown that nitroguanidine can be converted into nitrosoguanidine[71,81].

There are also reports on the electrolytic reduction of nitrourea to semicarbazide on a platinum cathode[82].

7. Reduction of Halogeno-Nitro-Compounds to Halogeno--Alkylamines

Catalytic hydrogenation is generally used for the selective reduction of the nitro-group in γ-fluoronitroalkanes. In particular, Cook smoothly reduced 2-heptafluoropropyl--1-nitrobutane to the corresponding amine under mild conditions (20°, 4 atm) with the aid of Adams' catalyst[83]. In the same paper it is shown that selective hydrogenation of the nitro-group in fluoronitroalkanes, including those containing hydroxyl groups in the β-position to the nitro-group, can be effected with the aid of Raney nickel. It has also been noted that lithium tetrahydroaluminate in the reduction of the nitro-group and some other functions does not generally affect the C–F bond and permits the preparation of the corresponding polyfluoroamines in good yield.

The reduction of monochloro-β-nitroalkanes is most efficiently carried out with tin(II) chloride in hydrochloric acid[88]. Under these conditions 2-chloro-3-methyl-1--nitrobutane gave the corresponding β-chloroamine in 57% yield. However, when the starting compound is hydrogenated on Raney nickel, a mixture of amines and hydroxylamines difficult to separate is formed.

As already mentioned, β-alkoxy-γ-trichloronitroalkanes[41] and γ-trichloro-β-hydroxynitroalkanes[15] may also be selectively reduced to amines in high yields (50–70%) by tin(II) chloride and hydrochloric acid.

3-Amino-1,1,1-trichloropropan-2-ol was obtained[85] by the reduction of 1,1,1-trichloro-3-nitropropan-2-ol on Raney nickel at room temperature and pressures up to 10 atm. However, at a higher pressure (50 atm) and increased temperature (106°), one chlorine atom may be reduced in addition to the nitro-group[15]:

$$CCl_3CH(OH)CH_2NO_2 \xrightarrow[\text{in HCl}]{H_2} CHCl_2CH(OH)CH_2NH_2\cdot HCl \quad (34.7\%).$$

In the light of these results, it may be concluded that Raney nickel is unsuitable for the selective reduction of the nitro-group in γγγ-trichloronitroalkanes.

8. Selective Reduction of Nitro-Groups in Aliphatic Sulphur-Containing Compounds

Several papers have been published on the selective reduction of the nitro-group in β-nitroalkyl sulphides[86], β-nitroalkyl sulphones[86,87] and β-nitrosulphonic acids[88] by hydrogenation of the initial compounds in methanol on Raney nickel at room temperature, or slightly higher, and at atmospheric or higher hydrogen pressure. In a number of cases the corresponding amines are obtained in close to quantitative yield.

Gold and coworkers made a detailed study of the reduction of the nitro-group in salts of β-nitrosulphonic acids of the type $CH_2(NO_2)CHRSO_3H$ (R = H, CH_3, C_6H_5); $CH(NO_2)R{-}CH_2SO_3H$ (R = H, CH_3, C_2H_5); $CH(NO_2)(C_2H_5)CH(C_3H_7)SO_3H$.[89] The authors consider that the most efficient conditions of hydrogenation of the initial salt are with Raney nickel in

water at 30° and low pressures; the yield of β-aminosulphonic acids is greater than 90%. At increased hydrogenation temperature there is a reduction in the yield of β-aminosulphonic acids. Reduction of the above-mentioned compounds may also be carried out by iron in water in the presence of catalytic quantities of hydrochloric acid (the yield of β-aminosulphonic acids is greater than 80%), and also electrolytically on a lead cathode with 15% sulphuric acid as an electrolyte (the yield of β-aminosulphonic acids is 60%).

The reduction of 1-nitroethyl *p*-tolyl sulphide (IV) and sulphone (V) proceed anomalously[90]. When treated with Raney nickel or Adams' catalyst, (IV) is recovered unchanged, but (V) gives a mixture of products:

$$p\text{-}CH_3C_6H_4SO_2CH(NO_2)CH_3 \xrightarrow[\text{Raney Ni}]{H_2} \begin{cases} p\text{-}CH_3C_6H_4SO_2C(NOH)CH_3 & \text{(VI) (10\%)} \\ p\text{-}CH_3C_6H_4SO_2NH_4 & \text{(28\%)} \\ p\text{-}CH_3C_6H_4SO_2H & \text{(50\%).} \end{cases}$$
(V)

When (IV) is treated with lithium tetrahydroaluminate, (VIa) is obtained in low yield:

$$p\text{-}CH_3C_6H_4SCH(NO_2)CH_3 \xrightarrow{LiAlH_4} p\text{-}CH_3C_6H_4S\overset{\overset{NOH}{\|}}{C}CH_3 \quad (14\text{—}16\%).$$
(IV) (VIa)

It should be emphasised that the reduction of aliphatic nitro-compounds with lithium tetrahydroaluminate is hardly mentioned in the literature. From this point of view the example given here is of undoubted interest.

9. Reduction of Nitro-Alkynes to Amino-Alkynes

The selective reduction of the nitro-group in aliphatic acetylene nitro-diols is described in papers by Jenny[35] and by Grob[36]

$$R\text{—}C{\equiv}CCH(OH)CH(NO_2)CH_2OH \rightarrow R\text{—}C{\equiv}C\text{—}CH(OH)CH(NH_2)CH_2OH,$$
(VII, *a—f*) (VIII, *a—f*)

(*a*) R = n-C_6H_{17}; (*b*) R = n-$C_{10}H_{21}$; (*c*) R = n-$C_{12}H_{25}$; (*d*) R = n-$C_{14}H_{29}$; (*e*) R = $C_{16}H_{33}$; (*f*) R = $C_{18}H_{37}$.

With the action of zinc and hydrochloric acid on (VII, *c*), the yield of (VIII, *c*) amounted to 72%. When (VII, *f*) was reduced by aluminium in ether with the addition of a little water and acetic acid at room temperature, the yield of (VIII, *f*) did not exceed 45%. Aluminium amalgam was found to be unsuitable for the reduction of (VII). Hydrogenation of (VII) with palladium on lead carbonate, with palladium on carbon, or with lithium tetrahydroaluminate involves the triple bond§.

By the action of zinc or aluminium in acid on optically active (VII, *f*), the authors obtained (VIII, *f*) in optically active form.

10. Reduction of Nitro-Alkenes to Amino-Alkenes

There is evidently no general method for the selective reduction of the nitro-group in nitro-alkenes. The selection of the reducing agent and the reaction conditions depends entirely on the structure of the initial nitro-alkene. It is entirely understandable that special difficulties should be encountered in attempts to reduce the nitro-group without affecting the double bond in α-nitro-alkenes. The instability of the corresponding amino-derivatives considerably complicates the study of this reaction. However, even with exhaustive reduction of α-nitro-alkenes, it is necessary to choose carefully the reducing agent and the conditions of the reaction, since frequently oximes are obtained as the final product of the expected alkylamines. Thus, when aluminium and amalgam[91], zinc dust in an alkaline medium[92], or iron filings in hydrochloric acid[93] acts on α-nitro-alkenes only the oximes of the corresponding aldehydes and ketones are obtained. Ammonium sulphide reduces α-nitro-alkenes to acid amides[94]. When hydride reducing agents, for example, lithium tetrahydroaluminate, act on α-nitro-alkenes the double bond is first reduced[83]. The same result was obtained in attempts at selective electrolytic reduction[84].

Until recently only one α-nitro-unsaturated compound (ethyl β-methyl-α-nitrocrotonate) had been described in which the nitro-group had been successfully reduced selectively:

$$(CH_3)_2C{=}C\text{—}COOC_2H_5 \rightarrow (CH_3)_2C{=}C(NH_2)COOC_2H_5 \text{ or } (CH_3)_2C{=}C(NHCOCH_3)COOC_2H_5.$$
(IX) (X) (XI)

Obviously, the stability of the C=C bond in (IX) to reduction is related to the steric hindrance caused by its substituents.

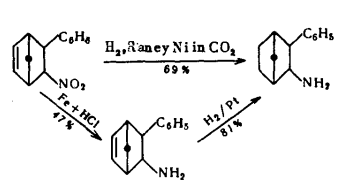
Bouveault[95] obtained (X) in 60–62% yield by the action of aluminium amalgam in ether on (IX), having shown that acid and alkaline reagents were not suitable for the selective reduction of (IX). However, these results were not confirmed by the later work of Süs, who only obtained the acetyl derivative (XI).[96] Moreover, he showed that the catalytic reduction of (IX) on Raney nickel at 70° and 50 atm in the presence of acetic anhydride leads to (XI) in over 90% yield[97].

In recent years Kuhn proposed a reducing agent which apparently can be used for the selective reduction of the nitro-group in α-nitro-alkenes[98]. According to the author, hydrazine in the presence of catalytic platinum or palladium is a very effective reducing agent for nitro- and nitrate-groups, and it does not affect the carbon–carbon double bond. In particular, 2-amino-1-phenylprop-1-ene can be obtained from 2-nitro-1-phenylprop-1-ene. Replacement of the platinum or palladium by nickel reduces the effectiveness and selectivity of the reagent and leads to hydrogenation of the double bond.

The selective reduction of the nitro-group in β-nitro-alkenes has not been described in the literature.

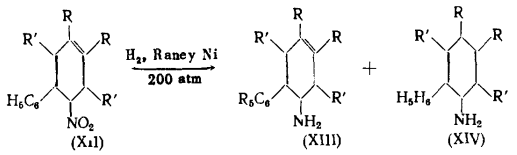
Work on the reduction of the nitro-group in γ-nitro-alkenes does not permit of any general recommendations on the choice of reducing agent.

Parham and coworkers[99] studied the reduction of 3-nitro-2-phenylbicyclo[1,2,2]hept-5-ene by various agents, and they showed that only iron in hydrochloric acid has a selective action:



§ For more details see the next Section.

As the results of the work show, catalytic methods do not permit the selective reduction of the nitro-group in this γ-nitro-alkene. However, Nightingale and Tweedie[100], who studied the hydrogenation of some phenylnitrocyclohexenes on Raney nickel, obtained different results:



(XII) (XIII) (XIV)

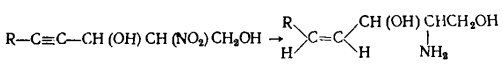
a, R = R′ = H; *b*, R = CH_3, R′ = H; *c*, R = H, R′ = C_6H_5.

The authors found that in (XII, *a–c*), at low temperature and with Raney nickel as catalyst, the nitro-group is first reduced and then the double bond. Thus, at 26° (XII, *a*) gives an almost quantitative yield of (XIII, *a*).

The introduction of methyl groups still further hinders the reduction of the double bond, which in (XII, *b*), for example, cannot be reduced at a temperature below 165°. The introduction of phenyl radicals hinders the reduction of both functional groups; therefore (XII, *c*) is reduced more slowly than (XII, *a*).

The use of other reagents for the selective reduction of (XII, *a–c*) gives less satisfactory results. Thus, when tin(II) chloride and hydrochloric acid in alcohol act on (XII, *a*) the unsaturated amine (XIII, *a*) is formed in 50% yield; however, under the same conditions (XII, *b*) gives a complex mixture of products. The authors also do not recommend zinc in acetic acid of iron(II) sulphate for the selective reduction of the nitro-group in these compounds.

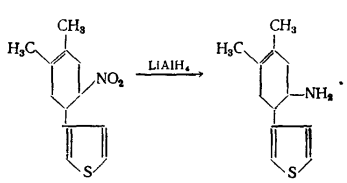
The most effective catalytic method for the selective reduction of unsaturated nitro-compounds uses Lindlar catalyst (palladium on lead carbonate). With the aid of this, Jenny and Druey[35] obtained a series of *cis*-unsaturated aliphatic amines:



R = n-C_8H_{17}; n-$C_{10}H_{21}$; n-$C_{12}H_{25}$; n-$C_{14}H_{29}$; n-$C_{16}H_{33}$.

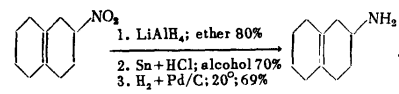
When lithium tetrahydroaluminate was used as a reducing agent, the corresponding *trans*-unsaturated amines were obtained.

In some γ-nitro-alkenes lithium tetrahydroaluminate reduces only the nitro-group, but in others it reduces both the nitro-group and the double bond. Thus, Nightingale and coworkers[101] described the selective reduction by lithium tetrahydroaluminate of the nitro-group in 1,2-dimethyl-4-nitro-5-thien-3-ylcyclohex-1-ene:

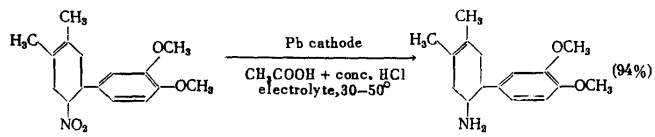


On the other hand, Dornow and Gellrich[34] showed that 3-hydroxy-4-nitro-1-phenylbut-1-ene cannot be selectively reduced with lithium tetrahydroaluminate:

Obviously, the possibility of selectively reducing the nitro-group in γ-nitro-alkenes largely depends on the structure of the initial compound. If the double bond is screened and not activated by other substituents, it is not affected by many reducing agents. For example, Bailev and Golden reduced 2-nitro-9,10-octalin and 2-amino-9,10-octalin by three different methods[102]:



A successful electrochemical method for the selective reduction of γ-nitro-alkenes has been described[103]:



11. Reduction of Nitro-Groups in Compounds with Other Functional Groups

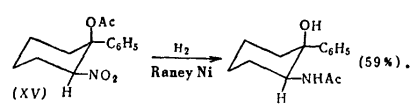
In this section we shall give some examples of the selective reduction of nitro-groups in functional compounds not considered in previous Sections.

There are two United States patents on the reduction of the nitro-group in nitrodioxans. Morey described a method for the preparation of substituted 5-amino-1,3-dioxans:

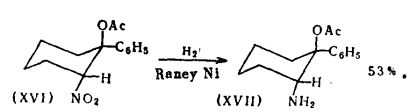
by the catalytic reduction of the corresponding nitro-compounds[104]. The catalyst is not indicated in the patent.

Senkus obtained substituted 5-amino-1,3-dioxans by the catalytic hydrogenation of 5-nitro-1,3-dioxans on Raney nickel at 25° and 130 atm in methanol[105]. The author notes the insecticidal activity of the products obtained.

Interesting information on the reduction of acetates of the stereoisomeric 2-nitro-1-phenylcyclohexan-1-ols and 2-nitro-1-phenylcyclopentan-1-ols is contained in a paper by Bordwell and Garbisch[106]. These workers showed that the reduction of 1-acetoxy-*cis*-2-nitro-1-phenylcyclohexane on Raney nickel is accompanied by transacylation and leads to 2-acetamino-1-hydroxy-1-phenylcyclohexane:

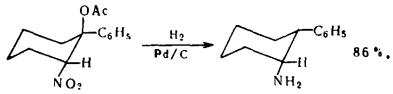


Reduction of the *trans*-isomer proceeds normally:



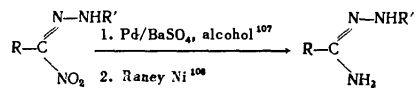
When (XVI) is electrolytically reduced on a platinum cathode at 50°, (XVII) is also formed. Hydrogenation

of (XVI) on palladium is accompanied by elimination of the acetyl group:



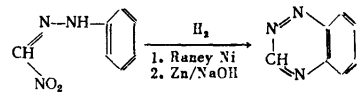
Analogous results were obtained with 1-acetoxy-2--nitro-1-phenylcyclopentenes.

There are hardly any examples in the literature on the selective reduction of aliphatic α-substituted nitro-compounds. Generally, reduction of such compounds proceeds in a complex manner[90]. However, a few instances are known of the selective reduction of hydrazones of alkyl- or aryl-nitroformaldehydes to the corresponding amidrazones[107,108]:



where R = alkyl or aryl.

If R = H and R' = phenyl, the reaction does not stop at the amidrazone stage and leads to triazines[108]:



However, it was not possible to separate the amidrazone as an intermediate product.

Table 3 shows the applicability of various reducing agents to the reduction of the nitro-group in aliphatic nitro--compounds with other functional groups.

Table 3 makes clear the field of application of a given reducing agent for the selective reduction of nitro-compounds; it also shows to what extent the reduction of various classes of nitro-compounds has been studied.

Raney nickel is the most widely used catalyst for the reduction of various nitro-compounds with other functional groups. The reaction is carried out over a wide range of temperature and pressure and, as a rule, in polar solvents (generally alcohols, water, or acetic acid). Other hydrogenation catalysts have not the same general importance; however, of these palladium on lead acetate should be mentioned; hydrogenation on this catalyst does not effect the double bond.

In work with catalysts other than Raney nickel, low pressures and temperatures close to room temperature are used.

Of chemical reducing agents, iron filings and iron(II) salts should be mentioned; with these the reduction usually proceeds in the presence of catalytic quantities of protons:

$$R{-}NO_2 + 3\,Fe + 4\,H_2O \xrightarrow{H^+} R{-}NH_2 + 3\,Fe(OH)_2,$$

or

$$R{-}NO_2 + 2\,Fe + 4\,H_2O \xrightarrow{H^+} R{-}NH_2 + 2\,Fe(OH)_3$$

This permits reduction with iron to be carried out in weakly acid, almost neutral, solution[109].

In spite of the selectivity of tin and tin(II) chloride in hydrochloric acid (they do not attack multiple C–C bonds), they generally give lower yields than catalytic methods and the reduction is sometimes complicated by side-reactions¶.

The use of lithium tetrahydroaluminate, which, as a rule, readily reduces the aliphatic nitro-group to the amino-group, is largely affected by the interaction of this agent with many functional groups (carbonyl, carboxyl, ester, nitrile, triple bond, etc.).

It is of interest to note that when optically active nitro--compounds are reduced with lithium tetrahydroaluminate, optically active amines are obtained[110].

Aluminium amalgam and zinc dust are extremely weak reducing agents. In reduction with zinc in an acid solution, it is sometimes useful to employ copper-coated or amalgamated zinc[111,112].

Until recently the possibility of selectively reducing nitro-groups in aliphatic compounds by such reagents as hydrazine with the addition of platinum or palladium, titanium sulphate[113], NH_4–Hg amalgam[114], etc. was not considered. However, these agents reduce the nitro--group in aromatic nitro-compounds extremely rapidly and easily.

The electrochemical method has also not been sufficiently used for the selective reduction of nitro-groups in polyfunctional aliphatic compounds.

III. SELECTIVE REDUCTION OF FUNCTIONAL GROUPS IN NITRO-COMPOUNDS

There is relatively little information in the literature on the selective reduction of functional groups in nitro--compounds. This may be explained by the difficulty of this problem, since the nitro-group is one of the functions most sensitive to reduction, and also by the fact that the object of the majority of workers is to find conditions for the reduction of the nitro-groups in order to synthesise the corresponding amines, oximes, or alkylhydroxylamines.

¶ This applies to a greater extent to aromatic nitro-compounds.

In recent years, in connection with the increasing part played by nitro-compounds in industrial practice and theoretical investigations, the attention of chemists has been more and more attracted to the possibility of synthesising nitro-products (mainly nitroalkanes, nitro-alcohols, and nitro-amines) by the selective reduction of the corresponding polyfunctional compounds.

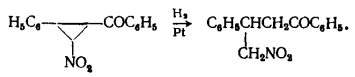
The material in this part of the review is grouped according to general methods of reduction, catalytic, chemical, and electrochemical.

1. Catalytic Reduction of Functional Groups in Nitro--Compounds

Multiple carbon–carbon bonds can usually be easily reduced by catalytic hydrogenation. This obviously explains why most work on the catalytic reduction of polyfunctional nitro-compounds has been done on the reduction of nitro-alkenes.

As early as 1917, work was carried out on the reduction of the double bond conjugated with a nitro-group; this work was done on the nitrostyrenes. Sonn and Schellenberg observed that when nitrostyrenes are hydrogenated on platinum black or colloidal palladium in alcohol at room temperature, selective reduction of the double bond occurs[115]. However, instead of the desired phenylnitroethanes, products formed by the addition of phenylnitroethane to unreduced nitrostyrene were obtained.

Similar results were obtained somewhat later by Kohler and Drake, who showed, moreover, that Kelber nickel cannot be used as a catalyst for the selective reduction of α-nitro-alkenes because the rate of reduction of the nitro--group is similar to the rate of reduction of the double bond[116]. These workers opened the cyclopropane ring of 3-benzoyl-1-nitro-2-phenylcyclopropane without affecting the carbonyl or nitro-group:

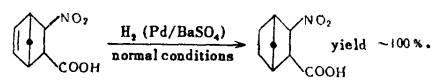


Hurd developed a satisfactory method of selective hydrogenation, not accompanied by dimerisation, for 1-aryl-2--nitroalk-1-enes[117]. He carried out the reduction at 15–40° on platinum or palladium in water, alcohols, ketones or aromatic hydrocarbons and obtained the corresponding 1-aryl-2-nitroalkanes in 25–60% yield. The author noted ketones or oximes as possible secondary products.

It is much easier to reduce a double bond not conjugated with a nitro-group. For this it is expedient to use platinum dioxide in acetic acid at room temperature. Examples are known of the successful selective reduction of the C=C bond with the aid of this catalyst in nitro-alkenes[118], phenylnitrocyclohexenes[119,120] nitronorbornylenes[121] and other nitro-cyclenes of the terpene series[122]. Raney nickel is less suitable for the selective hydrogenation of the double bond, since in a number of instances the double bond is reduced on this catalyst only after reduction of the nitro--group[100].

It should be mentioned that the structure of the nitro--compound undergoing reduction frequently affects the nature of the products of catalytic hydrogenation. Thus, Young and Snyder succeeded in hydrogenating the phenyl ring of ethyl 3-(2-nitrobutyl)indole-2-carboxylate without affecting the nitro- or the ester group[123]. The catalyst was 30% palladium on charcoal, and the reaction was carried out at room temperature under a hydrogen pressure of 3 atm in acetic acid. The authors consider that the course of this reaction is explained by a combination of steric and electronic factors that protect the nitro-group in this compound. It is also known that the double bond conjugated with the nitro-group can be selectively reduced in 1,2-dideoxy-1-nitro-D-*arabo*-hexitoltetraacetate, the molecule of which contains several ester groups[124]; the reaction was carried out on palladium black in absolute alcohol under normal conditions.

Recently Yur'ev and coworkers[125] described the selective reduction of 2-nitro-3,6-*endoxo*-Δ^4-tetrahydrobenzoic acid in acetone with palladium on barium sulphate:



There are no references whatever in the literature on the possibility of the catalytic selective reduction of carbonyl-containing functional groups in aliphatic nitro-compounds.

On the contrary, as is shown in Section II, in a number of instances the nitro-group is first reduced[44]. Catalytic reduction of the sulpho-group is also impossible in the presence of a nitro-group[88].

The examples given therefore exhaust all information on the catalytic selective reduction of functional groups in aliphatic nitro-compounds. It is clearly obvious that this method is not general, and in effect can only be used for the reduction of multiple bonds in nitro-alkenes; even here the reaction is sometimes complicated by the formation of secondary products. It should also be noted that the catalytic hydrogenation of functional groups in polynitro-compounds is not described in the literature, and it may be supposed that this would be a still more complicated process.

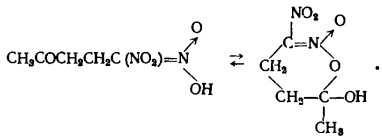
2. Chemical Reduction of Functional Groups in Nitro--Compounds

As is shown in Section II, reduction by atomic hydrogen, obtained by the interaction of metals with acids and alkali metals with alcohols, is one of the most widely used methods for the chemical reduction of the nitro-group and cannot be used for the selective reduction of functional groups in nitro-compounds. In the same way, chlorides of metals of variable valency which react with the nitro--group must also be excluded.

In the past decade the method of chemical reduction with complex hydrides of the alkali and alkaline earth elements has been widely developed. This method was very promising for the selective reduction of functional groups in nitro--compounds, because of the relative stability of nitro--groups to hydride anions. Moreover, at present there is a great selection of hydride reducing agents with the most diverse sensitivity to a number of functional groups.

Shechter[126] showed that nitro-ketones and nitro-aldehydes may be reduced in good yield to nitro-alcohols with sodium tetrahydroborate in aqueous-methanolic solution at pH 3–10.5. and a temperature from 0° to 25°. 1,1-Dinitropentan-4-one formed an exception; even with a considerable excess of reducing agent this gave a low yield of

nitro-alcohol. The author explains this by the existence of the initial compound as an equilibrium mixture:



Shechter suggests that sodium tetrahydroborate is particularly useful for the selective reduction of the most labile nitro-ketones and nitro-aldehydes. He also recommends the reduction of the carbonyl group in more stable nitro-ketones and nitro-aldehydes by aluminium isopropoxide† in isopropyl alcohol or toluene (for more "acid compounds"); aldehydes are reduced more rapidly than ketones, and the yields of nitro-alcohols are connected in the following manner with the nature of the nitro-group in the initial compounds:

$$t\text{-}NO_2 > s\text{-}NO_2 > primary\text{-}NO_2.$$

It is known that at room temperature lithium tetrahydroaluminate reduces the nitro-group in nitro- [36,58] and polynitro-compounds [42]. However, it has beenshown by Feuer and Kucera [129] that in ether at -30° and -60° this is a stronger reducing agent than sodium tetrahydroborate and may be used for the selective reduction of esters containing secondary and tertiary nitro-groups and even *gem*--dinitro-groups. The yields of nitro-alcohols are 53–76%. Hence, Shechter [126] and Feuer [129] have developed a new method of obtaining nitro-alcohols, greatly extending the range of these compounds, which are of practical interest.

In 1963, Gold and Klager published a paper on the reduction with sodium tetrahydroborate of the chlorides of a number of nitro-acids, including trinitrobutyric acid [130]; the corresponding nitro-alcohols were always obtained (see Table 4).

The authors also describe the reduction of some ketones containing $C(NO_2)_3$ groups, but they do not give yields, constants of the alcohols obtained, or experimental methods:

$$C(NO_2)_3CH_2CH_2COCH_3 \xrightarrow{NaBH_4} C(NO_2)_3CH_2CH_2CH(OH)CH_3,$$

$$C(NO_2)_3CH_2CH_2COCH_2OH \xrightarrow{NaBH_4} C(NO_2)_3CH_2CH_2CH(OH)CH_2OH.$$

TABLE 4.

Initial acid chloride	Alcohol obtained	Yield, %
$CH_3—C(NO_2)_2(CH_2)_2COCl$	$CH_3C(NO_2)_2(CH_2)_3CH_2OH$	63
$CH_3—C(CH_3)NO_2(CH_2)_2COCl$	$CH_3C(CH_3)NO_2(CH_2)_2CH_2OH$	70
$C(NO_2)_3(CH_2)_2COCl$	$C(NO_2)_3CH_2CH_2CH_2OH$	65
$CH_3C(NO_2)_2CH_2N(NO_2)CH_2COCl$	$CH_3C(NO_2)_2CH_2N(NO_2)CH_2CH_2OH$	82
$(NO_2)_2C(CH_2CH_2COCl)_2$	$(NO_2)_2C(CH_2CH_2CH_2OH)_2$	50
$(NO_2)_2C[CH_2C(NO_2)_2CH_2CH_2COCl]_2$	$(NO_2)_2C[CH_2C(NO_2)_2CH_2CH_2CH_2OH]_2$	63
$(NO_2)HC[CH_2C(NO_2)_2CH_2CH_2COCl]_2$	$NO_2CH[CH_2C(NO_2)_2CH_2CH_2CH_2OH]_2$	85
$N(NO_2)—[CH_2C(NO_2)_2CH_2CH_2COCl]_2$	$N(NO_2)[CH_2C(NO_2)_2CH_2CH_2CH_2OH]_2$	85

† It should be mentioned that isolated instances of selective reduction of the carbonyl group in nitrocyclopropyl ketones had previously been known [127,128]. However, the authors of these papers did not aim at developing a general method of preparing nitro--alcohols.

Recently, a number of patents appeared on the preparation of the latter polynitrodiol from hydroxymethyl 3,3,3--trinitropropyl ketone with the aid of sodium tetrahydroborate. [131-134] The authors point out that this diol may be used as an intermediate in the synthesis of components of solid rocket propellents.

Ioffe and coworkers [135] showed that a solution of diborane in tetrahydrofuran (THF) may be used for the reduction of aliphatic mononitro-acids:

$$CH_2NO_2CH_2COOH + B_2H_6 \xrightarrow{THF} (NO_2)CH_2CH_2CH_2OH.$$

Diborane in tetrahydrofuran is also suitable for the reduction of esters of nitro-acids, but the presence of such electronegative substituents as nitro-groups sharply reduces the rate of reduction of the ester group.

Alkali metal tetrahydroborates (for example, sodium tetrahydroborate or sodium hydrotrimethoxyborate), which are reducing agents of the nucleophilic type, may be used very successfully also for the preparation of nitroalkanes and conjugated nitroalkenes [136], since the influence of the nitro-group ensures the possibility of nucleophilic attack of the BH_4^- and $BH(OCH_3)_3^-$ anions on the double bond. According to Shechter, the reduction mechanism includes nucleophilic attack of the relatively positive carbon atom of the C=C group of the conjugated nitro-alkene. Evidently, the initially formed metal trihydro(monoalkanenitronato)-borate Li or $Na(R_2CHCR'{=}NO_2)BH_3$ enters into further reactions giving a metal tetrakis(alkylnitronato)borate which is converted into the nitroalkane after hydrolysis. The course of the reactions may be represented by the following equations:

$$R_2C{=}CR'NO_2 + NaBH(OCH_3)_3 \rightarrow R_2CHCR'NO_2Na + B(OCH_3)_3,$$

or

$$4R_2C{=}CR'NO_2 + BH_4^- \xrightarrow[Na^+]{Li^+} [(R_2CHCR'{=}NO_2)_4B]^-.$$

The yield of nitroalkanes is 50–80%. The introduction of electronegative substituents, which increase the electron deficiency of the double bond, accelerates reduction. For this reason, the reaction with sodium and lithium tetrahydroborates is suitable for the selective reduction of conjugated fluoronitroalkenes (for example, 4,4,5,5,6,6,6-heptofluoro-2-nitrohex-2-ene). The reduction of nitroalkenes is usefully carried out at the lowest possible temperatures (-50°, -70°); the alkene is added to the metal tetrahydroborate to reduce the dimerisation side reaction:

$$R_2CHCR'{=}NO_2^- + R_2C{=}CR'NO_2 \rightarrow R_2CHCR'(NO_2)CR_2CR'{=}NO_2^-.$$

The reduction of sterically hindered nitroalkenes (for example, 3-nitrohept-4-ene) cannot be fully effected even at 0°. The reaction with such alkenes is carried out at room temperature.

The C=C bond in conjugated nitroalkenes may be reduced in the presence of ester groups by means of alkali tetrahydroborates [136]. In particular, the double bond in 1,2-dideoxy-1-nitro-D-*arabo*hexitol tetraacetate has been reduced with sodium tetrahydroborate [136]; the yield of product was 55–65% (for the catalytic reduction see Sowden and Fischer [124].) It has also been observed that, because of the strong inductive effect, closely situated nitro-groups activate ester groups to such an extent that they are reduced by metal tetrahydroborates [136]. Both sodium tetrahydroborate and sodium hydrotrimethoxyborate successfully reduce 2-nitrobutyl acetate at 3–5° to the corresponding alcohol, although generally under these conditions these reagents do not affect the ester gruup.

Cook and coworkers[83] showed that α-nitro-alkenes (including those containing fluorine) may be reduced to fluoronitro-alkanes in 35–55% yield by the action of lithium tetrahydroaluminate in anhydrous ether at -50°. Shechter and coworkers, who studied this reaction, also observed that it proceeds smoothly at temperatures below -40° after addition of lithium tetrahydroaluminate to the alkene undergoing reduction[136]. If the reagents are mixed in a different order, polymerisation occurs.

There are some very interesting results on the chemical reduction of the halogen in α-halogenonitro-compounds. In 1893, Duden showed that dibromodinitromethane is reduced to dinitromethane in 70–80% yield by the action of arsenic trioxide in potassium hydroxide solution[137]. Similar results are obtained by treatment of dibromodinitromethane with aqueous ammonia solution of hydrogen sulphide. Somewhat later, Pratt observed that the halogen in nitromethane derivatives can be reduced by an alkaline solution of hydrazine[138]‡:

$$CX(NO_2)_3 + NH_2{-}NH_2 \xrightarrow{KOH} CH(NO_2)_3,$$

$$RCHBrNO_2 + NH_4{-}NH_2 \xrightarrow{KOH} RCH_2NO_2,$$

$$CBr_2(NO_2)_2 + NH_2{-}NH_2 \xrightarrow{KOH} CHBr(NO_2)_2,$$

$$CCl_3NO_2 + NH_2{-}NH_2 \xrightarrow{KOH} CCl_2H(NO_2),$$

where X = Cl or Br, R = H or C_6H_5.

Iffland proposed the reduction of α-bromonitro-compounds of the aliphatic and alicyclic series to the corresponding nitro-alkanes (yield 15–80%) by sodium tetrahydroborate in aqueous methanol solution[139,140]. Although ordinary halogenoalkanes are inert to sodium tetrahydroborate, the reduction of α-bromonitro-compounds becomes possible, evidently because of the strong inductive effect of the nitro-groups, which facilitates nucleophilic attack of the tetrahydroborate anion on the carbon atom carrying the halogen and the nitro-group. As a result of his investigations, Iffland[139,140] proposed a new method of preparing nitroalkanes from the corresponding carbonyl compounds:

$$R_2C{=}O \rightarrow R_2C{=}NOH \xrightarrow{\text{bromosuccinimide}} \left[\begin{array}{c} Br \\ | \\ R_2{-}C{-}N{=}O \end{array}\right] \rightarrow$$

$$\rightarrow R_2CBrNO_2 \xrightarrow{NaBH_4} R_2CHNO_2.$$

Klager has described the reduction of αα-tetrabromodinitro-compounds by sodium tetrahydroborate[141]:

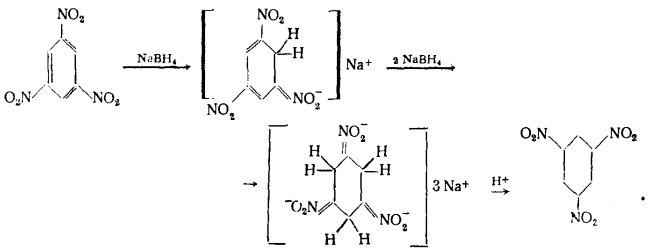
$$CBr_2NO_2CH_2CH_2CBr_2NO_2 \xrightarrow{NaBH_4} CH_2NO_2CH_2CH_2CH_2NO_2.$$

Thus, α-halogenonitro-alkanes may be reduced in several ways to nitro-alkanes. However, as has been shown in Section II.7, only the nitro-group is usually reduced in other halogenonitro-compounds.

Although the present review is concerned with aliphatic nitro-compounds, the work of Severin and Schmitz should be briefly mentioned[142-147]; they showed that the aromatic ring in polynitrobenzenes could be selectively reduced with sodium tetrahydroborate.

‡ It is interesting to note that aromatic nitro-groups, in contrast to aliphatic, are readily reduced by hydrazine.

The alkali tetrahydroborates are, as a rule, inert to aromatic systems, but because of the strong electron-acceptor activity of the nitro-groups, BH_4^- can attack the carbon atoms of the ring, for example:



More detailed information on this question is given in the literature[142-147].

It can be concluded from the material discussed here that the use of complex metal hydrides has substantially extended the possibility of selectively reducing functional groups in nitro-compounds; in particular it has, for the first time, permitted the preparation of a large number of nitro-alcohols from the corresponding carbonyl-containing compounds.

3. Electrochemical Reduction of Functional Groups in Nitro-Compounds

The only work on the selective reduction of functional groups in aliphatic nitro-compounds by an electrochemical method is that of Mairanovskii and coworkers[148], who investigated α-halogenonitroalkanes. These workers found that the effect of the nitro-groups facilitates the polarographic reduction of the C–Hal bond, and the wave corresponding to this process precedes the wave corresponding to the reduction of the nitro-group. This order of the waves was observed for mononitro-, dinitro-, and trinitro-alkanes containing chlorine, bromine, or iodine in the α-position to the nitro-groups.

There is some indirect information indicating the possibility of selectively reducing the carbonyl group in nitro-compounds by an electrochemical method. Shikata and Tacho established that the reduction potentials of ketones, azo-, and nitro-compounds are proportional to the electronegativity of the substituents linked to the group undergoing reduction[149]. Obviously, it should be possible to select substituents such that their carbonyl group is reduced by an electrochemical method before the nitro-group. However, there is no information on this question in the literature

---o0o---

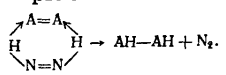
In conclusion, some hydrogenation catalysts will be briefly discussed that do not reduce the nitro-group, and also reagents that weakly react (or do not react at all) with the nitro-group, but are capable of reducing some functional groups. However, these have not yet been used for the selective reduction of polyfunctional nitro-compounds.

According to Japanese workers, the hydrogenation of 1-nitropropane on a catalyst of metal formates (for example, Ni and Zn, or Zr and V formates) is difficult[150].

A silk–palladium catalyst, generally used for the hydrogenation of multiple bonds in alkenes, aldehydes and nitriles, has similar properties[151].

Broadbent and Johnson[152] recently described a catalyst based on rhenium oxide ($Re_2O_7.3C_4H_8O$) with a wide spectrum of activity. It can be used for readily hydrogenating aromatic systems, but it also reduces carbonyl and carboxyl groups to alcohols groups, and nitriles to amines; this catalyst is inert to aliphatic nitro-compounds (for example, 2-nitropropane) and reduces aromatic nitro-compounds (for example, nitrobenzene) with difficulty. However, m-nitroacetophenone is very inert to its action, and, thus, the introduction of the nitro-group may render the carbonyl group and the atomatic nucleus passive.

Diimide readily reduces symmetrical multiple bonds (C=C, C≡C, N=N, O=O, etc.) with which it apparently forms a transition complex[153,154]:



→ AH—AH + N_2.

However, the formation of such a complex with two unlike charged atoms is difficult, and therefore the reduction of groups of the type C=N, NO_2, C≡N, S=O, and C=O proceeds much more slowly. In particular, nitroethane is comparatively stable to the action of azodiimide[153].

It should be noted that some nitro-compounds are not affected by calcium hydride[155].

Some neutral complexes of borine and alkylborines that do not react with the nitro-group should also be mentioned[156]; these have hardly been used for the reduction of polyfunctional aliphatic nitro-compounds.

POLYMER SYNTHESIS BY CYCLIC POLYMERISATION

S.G. Matsoyan

CONTENTS

I. Introduction 32

II. Synthesis of carbocyclic polymers 32
1. Polymerisation of non-conjugated dienes 32
2. Polymerisation of unsaturated compounds of other types 35

III. Synthesis of heterocyclic polymers 35
1. Polymerisation of non-conjugated systems containing a hetero-atom 35
2. Polymerisation of compounds of other types 38

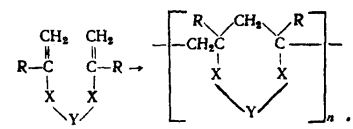
IV. Synthesis of cyclic copolymers 39

I. INTRODUCTION

In connection with studies on the synthesis of polymers with valuable technical properties, in particular high thermal stability, there has been a considerable increase of interest in recent years in polymeric compounds containing cyclic groupings in the main chain [1-3]. At the present time extensive experimental data have been accumulated on the synthesis of various cyclic polymers, their structure, and their properties.

When the information available in the literature is generalised and systematised, it becomes clear that introduction of cyclic groupings, carbocyclic and heterocyclic units, into the main polymer chain can be achieved in three principal ways: by cyclic polymerisation, polycondensation, and chemical modification of polymeric compounds. Cyclic polymerisation can in turn be subdivided into two classes according to the mode of formation of the rings: chain polymerisation and stepwise polymerisation. The latter class includes polymerisation by the Diels-Alder reaction [4], thermal polymerisation of allene hydrocarbons [5], and others.

In the present review only cyclic polymers obtained by cyclic chain polymerisation are considered. In the field of cyclic polymerisation the so called intermolecular-intramolecular polymerisation of non-conjugated dienes has at present undergone the greatest development [6]. This type of cyclic polymerisation was discovered as a result of studies by several investigators [7-11], in particular Butler and coworkers [12,13]. It consists essentially in intramolecular ring closure of non-conjugated dienes, in particular 1,6-dienes, with simultaneous intermolecular chain growth, according to the following general mechanism:

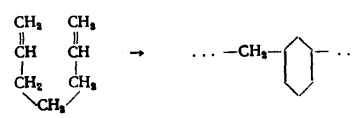


The polymerisation of other unsaturated systems, cyclodiene, triene, and vinylacetylene compounds and bifunctional compounds (dialdehydes, diepoxides) has also been investigated, using all known methods of initiation, with the aim of synthesising cyclic polymers. It was established that cyclic units in the polymer chain can form by intramolecular cyclisation of the monomer and interaction of two or several monomeric units of various types. For this reason, we shall give the name cyclic polymerisation to any type of polymerisation which leads to the introduction into the main polymer chain of cyclic groupings, regardless of the structure and nature of the monomer.

II. SYNTHESIS OF CARBOCYCLIC POLYMERS

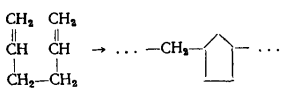
1. Polymerisation of Non-Conjugated Dienes.

A. Polymerisation of diene hydrocarbons. Marvel and Stille [14] were the first to show the possibility of the cyclic polymerisation of non-conjugated diolefins under the influence of complex metal alkyl catalysts. A solid, benzene-soluble polymer with cyclohexane rings in the chain, melting at 210-230° and having an intrinsic viscosity $[\eta] = 0.2-0.4$, was obtained from hepta-1,6-diene under the action of the $Al(iso\text{-}C_4H_9)_3$-$TiCl_4$ catalytic system:



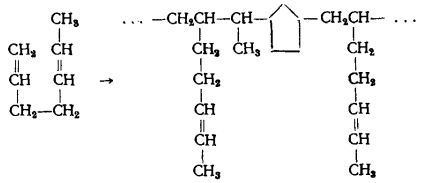
Rigid rubberlike polymers, the degree of cyclisation in the soluble fraction of which reaches 87%, are obtained under similar conditions from hexa-1,5-diene and 2,5-dimethylhexa-1,5-diene. Recently Makowski et al. [15] obtained in

the presence of aluminium triethyl and titanium tetrachloride a crystalline polyhexa-1,5-diene consisting of 1-methylene-3-cyclopentyl units:

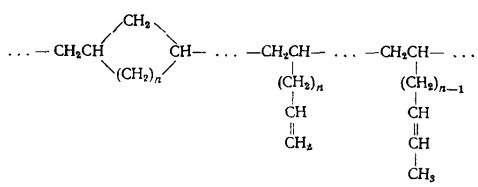


Its melting range extended to 146° and its intrinsic viscosity $[\eta]$ ranged up to 2.

The thermal stability of the cyclic polymers of hexa--1,5-diene, 2-methylhexa-1,5-diene, and hepta-1,6-diene was investigated by Anderson [16]. In the polymerisation of hepta-1,5-diene in the presence of aluminium triethyl and titanium tetrachloride a transparent rubberlike soluble product, consisting on average of 13 monomer units, was obtained [17]. It was established that the polymer contains units of two types in proportions of about 1 : 2: five--membered rings and branched groups with an internal double bond.



Marvel and Garrison [18] synthesised and studied the cyclic polymerisation of di-olefinic hydrocarbons with a long chain in the presence of Ziegler type catalysts. The degree of cyclisation of the soluble fraction of the polymers depends on the size of the rings formed (Table). The authors represent the structure of these polymers in the following way:

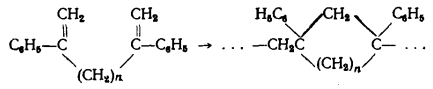


Field [19] studied the thermal polymerisation of 2,6-diphenylhepta-1,6-diene in the presence of free-radical initiators and anionic and cationic catalysts. According to his data, the polymerisation proceeds by a cyclic mechanism regardless of the method of initiation and leads to the formation of a polymer with six-membered rings in the chain. Using the method developed by Field, Marvel and Gall [20,21]

TABLE. Degree of cyclic polymerisation of di-olefins.

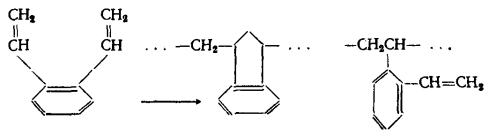
n in $CH_2=CH\diagdown\diagup(CH_2)_n$	Number of ring atoms	% of cyclic units in the soluble fraction of polymers	n in $CH_2=CH\diagdown\diagup(CH_2)_n$	Number of ring atoms	% of cyclic units in the soluble fraction of polymers
4	7	25	9	12	11
5	8	9	11	14	15
6	9	6	12	15	15
7	10	10	14	17	4
8	11	11	18	21	8

synthesised several phenyl-substituted diene hydrocarbons and studied their capacity for cyclic polymerisation:



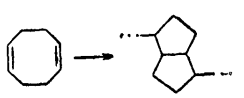
where n = 2, 3, 4.

In the radical polymerisation of *o*-divinylbenzene [22] in benzene solution a soluble polymer (melting at 400° with decomposition) whose degree of cyclisation varied markedly with the reaction temperature and monomer concentration, was obtained. A kinetic equation for the calculation of the proportions of cyclic and vinyl polymerisation was derived.



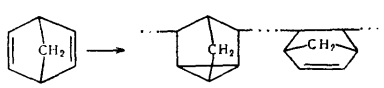
Many investigators used cyclic polymerisation to prepare polymers with bicyclic bridge units. Ball and Harwood [23] obtained from 1,4-dimethylenecyclohexane under the action of gaseous boron trifluoride a soluble polymer (yield 85%, $[\eta]$ = 0.07) which does not melt up to 250°. The repeating unit in this polymer is methylene-1,4-bicyclo-[2,2,1]heptane:

In the polymerisation of *cis,cis*-cyclo-octa-1,5-diene [24] under the action of the Ziegler catalyst a polymer (m.p. 100–180°, $[\eta]$ = 0.02–0.04) with a unit structure similar to bicyclo[3,3,0]octane was obtained:

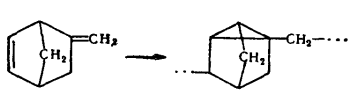


In the attempted preparation of a bridge-type polymer from cyclohexa-1,4-diene under similar conditions only rearrangement with formation of polycyclohexa-1,3-diene was observed.

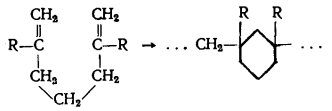
According to Zutty's data [25], in the presence of a free--radical initiator bicyclo[2,2,1]hepta-2,5-diene is converted into a low-molecular-weight soluble polymer containing both 3,5-disubstituted nortricyclene units and 5,6-disubstituted bicyclo[2,2,1]hept-2-ene units in the chain:



Bridge polymerisation [26] of 2-methylenenorborn-5-ene in the presence of aluminium tribromide leads to the formation of a polymer (m.p. 150–160°, $[\eta]$ = 0.3) whose units are produced by opening of both double bonds in the monomer with simultaneous formation of a bridge bond:

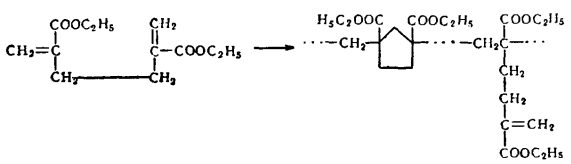


B. Polymerisation of substituted hepta--1,6-dienes, hexa-1,5-dienes, and penta--1,4-dienes. Marvel and Vest[27,28] studied the cyclic polymerisation of $\alpha\alpha'$-dimethylenepimelic acid and its methyl and ethyl esters, nitrile, and amide in the bulk, in solution, and in emulsion; in most cases soluble polymers were obtained, melting in the range 125–300° and having $[\eta] = 0.14–0.73$:

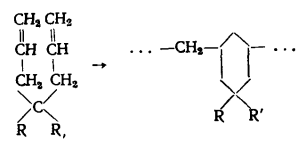


where R = COOH, $COOCH_3$, $COOC_2H_5$, CN, and $CONH_2$.

With the aim of synthesising soluble polymers having a high molecular weight, Milford[29] made a detailed study of the conditions of the cyclic polymerisation of the methyl ester and nitrile of $\alpha\alpha'$-dimethylenepimelic acid; on ultraviolet irradiation in solution in tetramethylenesulphone at 20° in the presence of benzoin as the photo-initiator, the corresponding cyclic polymers were obtained in 74–80% yield with $[\eta] = 2.03$ and 1.2 respectively. Radical polymerisation of 2,5-dicarbethoxyhexa-1,5-diene[28] in benzene solution leads to the formation of a cyclic polymer (m.p. 110–120°, $[\eta] = 0.21$) containing up to 10% of open-chain units:

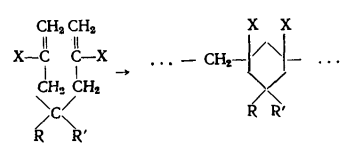


Matsoyan and his coworkers[30-32] studied the capacity for cyclic polymerisation of a number of 4-substituted hepta-1,6-dienes in the presence of radical initiators. The cyclic structure of the polymers obtained was demonstrated by chemical and spectroscopic methods:



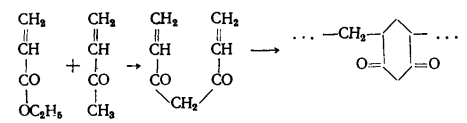
where R = H, R′ = COOH, $COOC_2H_5$, $COOC_6H_5$, $CONH_2$, $CON(CH_3)_2$, $CONHC_6H_5$, $COCH_3$, OH, $OCOCH_3$, $OCOC_6H_5$, Cl, CN; R = R′ = $COCH_3$; R = R′ = $COOC_2H_5$; R = $COCH_3$, R′ = $COOC_2H_5$; R = COOH, R′ = CN; R = $COOC_2H_5$, R′ = = CN.

These workers investigated the effect of the nature of the substituents (in positions 2, 4, and 6) on the cyclic polymerisation of substituted hepta-1,6-dienes[30-33]; the presence of methyl groups in positions 2 and 6 retards cyclic polymerisation while the presence of chlorine atoms sharply accelerates it. Under conditions of cyclic polymerisation 2,6-dichloro-4-substituted hepta-1,6-dienes undergo up to 70% dehydrochlorination:



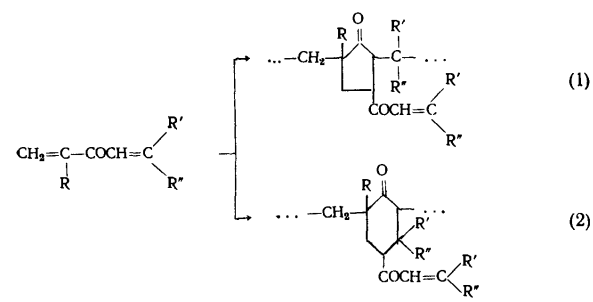
where X = CH_3 and R = R′ = $COOC_2H_5$; R = H, R′ = CN; R = $COOC_2H_5$, R′ = CN; R = COOH, R′ = CN; or X = Cl and R = R′ = $COOC_2H_5$; R = H, R′ = COOH; R = $COCH_3$, R′ = $COOC_2H_5$.

The mechanism of the cyclic polymerisation of some of the 4-substituted hepta-1,6-dienes described above was also studied by other investigators[34,35]. Jones[36] showed that in the Claisen condensation of ethyl acrylate with methyl vinyl ketone in the presence of sodium methoxide, a soluble coloured polymer (M = 2000) melting at 190° is formed instead of the expected diacryloylmethane. The author suggests that the actual product is a cyclic polymer of diacryloylmethane:



Somewhat later[37] in a detailed study of the condensation product described by Jones it was found that it is a copolymer of methyl vinyl ketone and diacryloylmethane. Bloomfield[38] synthesised the monomeric diacryloylmethane by the pyrolysis of the diene reaction adduct[39] and found that under the conditions used by Jones diacryloylmethane forms an insoluble three-dimensional polymer. However, later Marvel and coworkers[40] succeeded in obtaining in the presence of sodium methoxide at -75° a cyclic homopolymer of diacryloylmethane as a light yellow powder soluble in dimethylformamide.

Matsoyan and coworkers[41-43] showed that radical polymerisation of 1,4-dienes, substituted divinyl ketones, leads to the formation of solid soluble polymers containing cyclopentane or cyclohexane rings, depending on the structure of the monomers, instead of the expected four-membered rings; the polymer unit is formed by the cyclisation of two monomer molecules. The polymerisation of β-methylvinyl, di-(β-methylvinyl), β-t-butylvinyl, β-methylvinyl, α-methylvinyl β-methylvinyl, and ββ-dimethylvinyl α-methylvinyl ketones proceeds according to reaction (1), while dienes containing allyl groupings of the type $-COCH=CR-CH_2-$, β-ethylvinyl vinyl, β-n-propylvinyl vinyl, β-ethylvinyl β-methylvinyl, di-(β-ethylvinyl), and ββ-pentamethylene-vinyl vinyl ketones form polymers according to reaction (2):



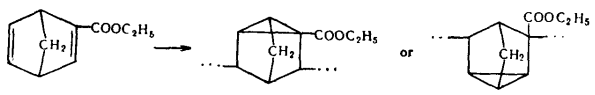
(1)

(2)

Arbuzova and Mosevich[44] obtained a soluble polymer ($[\eta] = 0.054$) with a cyclopentane ring in the chain by prolonged heating of dibenzylideneacetone at 130° in the presence of benzoyl peroxide.

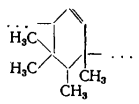
Radical polymerisation of 2-ethoxycarbonylbicyclo-[2,2,1]hepta-2,5-diene[45] yielded a soluble saturated polymer

with a vitrification temperature of 220° ([η] = 1.32–1.92). The principal structural units of this polymer are nortricyclenes:



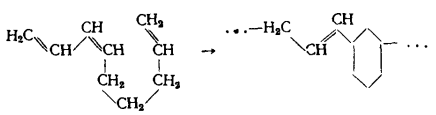
2. Polymerisation of Unsaturated Compounds of Other Types

Following the publication of studies on the cyclic polymerisation of non-conjugated dienes, reports appeared on the synthesis of carbocyclic polymers from unsaturated compounds of other types. Jones [46] studied the structure of soluble polymers of 2,6-dimethylocta-2,4,6-triene (allo-ocimene), whose polymerisation in the presence of cationic catalysts [47] has been known for a long time. On the basis of the data obtained and the known fact of the ease of cyclisation of allo-ocimene into α- and β-pyronenes [48,49], Jones suggested the following cyclic structure for polyallo-ocimene:

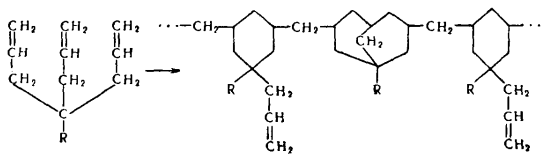


Marvel and coworkers [50,51] polymerised allo-ocimene under the action of anionic and cationic catalysts and made a detailed study of the structure of the polymers obtained. They found that the polymerisation of allo-ocimene proceeds mainly according to the usual linear mechanism, the degree of cyclisation being slight.

Butler and Brooks [52,53] showed that the polymerisation of triene hydrocarbons, *trans*-nona-1,3,8-triene, *cis*-nona-1,3,8-triene, and octa-1,3,7-triene, under the influence of aluminium triethyl and titanium tetrachloride leads to the formation of cyclic polymers as a result of simultaneous 1,2 and 1,4 intramolecular addition and chain growth:

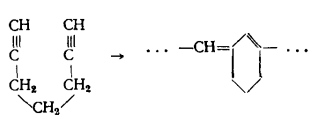


Matsoyan et al.[54] showed that, on radical polymerisation of branched trivinyl compounds such as triallylmethane derivatives, there is both monocyclic and bicyclic chain growth in proportions of 1 : 2:

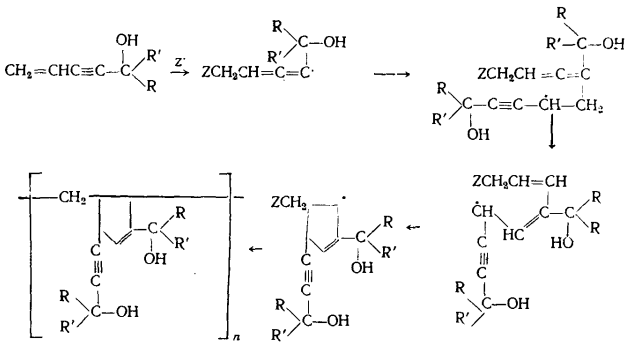


where R = OH, $OCOCH_3$, CN, $CONH_2$.

Stille and Frey [55] applied the cyclic diene polymerisation to hepta-1,6-diyne, octa-1,7-diyne, and nona-1,8-diyne. The polymers obtained in the presence of the Ziegler catalyst were brown or black in colour, which is probably due to double bond conjugation in the polymer chain:



Despite the view expressed in the literature [56], Matsoyan and coworkers [57–60] showed that the polymerisation of ethynylvinyl carbinols, both spontaneous and initiated, proceeds according to a chain mechanism and leads to the formation of high-molecular-weight soluble linear polymers, which are not cross-linked and are completely stable even on heating. According to the mechanism proposed [61,62], cyclic polymerisation of vinylacetylenic alcohols occurs as follows:



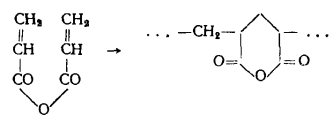
where R and R′ are aliphatic, alicyclic, aromatic and heterocyclic residues.

The kinetics of the cyclic polymerisation of ethynylvinyl carbinols have been studied [63,64]. Carbocyclic polymers of similar structure were obtained from ether derivatives of ethynylvinyl carbinols [65,66]. The possibility of the formation of linear-cyclic polymers from alicyclic [67] and aromatic [68,69] ethynylvinyl carbinol and also certain other vinylacetylenic compounds [70,71] has likewise been demonstrated. The dielectric properties of the cyclic polymer of dimethylvinylethynyl carbonil were studied by Kocharyan et al.[72]

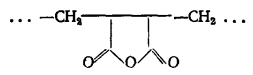
III. SYNTHESIS OF HETEROCYCLIC POLYMERS

1. Polymerisation of Non-Conjugated Systems Containing a Hetero-Atom

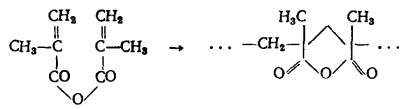
A. Polymerisation of oxygen-containing dienes. The formation of oxygen-containing heterocyclic polymers was first observed by Simpson and coworkers [7,9] in a study of the polymerisation of diallyl carbonate, oxalate, malonate, succinate, phthalate, glutarate, isophthalate, adipate, azelate, and sebacate, and also dimethylallyl carbonate and phthalate. It was found that the capacity of these esters for cyclisation does not always depend on the size of the ring formed (from eight- to seventeen-membered), although it might have been expected that the degree of cyclisation would decrease as the distance between the two allyl groups of the monomer increases. In order to obtain six-membered oxygen-containing heterocyclic polymers, Crawshaw and Butler [73] investigated almost simultaneously with Jones [74] the polymerisation of acrylic anhydride in the bulk and in solution using radical initiators and polymerisation regulators. The authors found that the chain units of the soluble polymers obtained consist of the anhydride of 5-methyleneglutaric acid:



Later Mercier and Smets [75,76] studied the kinetics of the cyclic polymerisation of acrylic anhydride and the structure of the polymer formed as a function of reaction temperature. At 115° and above the polymerisation leads to the formation of five-membered anhydride units in the chain:



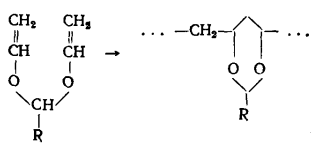
A cyclic polymer of methacrylic anhydride (m.p. 200°, $[\eta]$ = = 0.6–0.8) was obtained by Bresler et al.[77] in the radical polymerisation of the monomer in dimethylformamide:



The same polymer was synthesised by the authors by thermal dehydration of polymethacrylic acid.

In a study of the kinetics of the cyclic polymerisation of methacrylic anhydride Gibbs and Murray[78] found that the effective activation energy for the process is 23 kcal mole^{-1}. In order to confirm that the polymerisation of acrylic and methacrylic anhydrides proceeds accordingly to an intermolecular-intramolecular mechanism, Miyake[79] made a detailed study of the infrared spectra of the polymers. The stereochemical configuration of the cyclic polymers of the anhydrides of the unsaturated acids was determined[80–82]; it was shown by nuclear magnetic resonance that the poly(methyl methacrylate) obtained from the cyclopolymer of methacrylic anhydride has a stereoregular structure.

Matsoyan and Avetyan[83,84] demonstrated the possibility of obtaining acetals of poly(vinyl alcohol) directly from the monomers by the cyclic polymerisation of divinyl acetals. Later this reaction was used to prepare a wide variety of aliphatic[85–90], aromatic, and heterocyclic[91–95] poly(vinyl acetals):

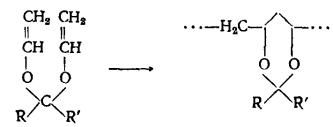


where R = H, CH_3, C_2H_5, C_3H_7, iso-C_3H_7, iso-C_4H_9, C_5H_{11}, C_6H_{13}, $CH_3O(CH_2)_2$, $C_2H_5O(CH_2)_2$, $C_3H_7O(CH_2)_2$, $ClCH_2CH_2O(CH_2)_2$, C_6H_5, 2-$CH_3C_6H_4$, 3-$CH_3C_6H_4$, 4-$CH_3C_6H_4$, 2,4-$(CH_3)_2C_6H_3$, 2,5-$(CH_3)_2C_6H_3$, 3,4-$(CH_3)_2C_6H_3$, 2,4,6-$(CH_3)_3$-C_6H_2, 2-$CH_3OC_6H_4$, 3-$CH_3OC_6H_4$, 4-$CH_3OC_6H_4$, 2-$C_2H_5OC_6H_4$, 2-$C_3H_7OC_6H_4$, 2-iso-$C_3H_7OC_6H_4$, 2-$C_4H_9OC_6H_4$, 2-iso-C_4H_9-OC_6H_4, 2-$C_5H_{11}OC_6H_4$, 2-iso-$C_5H_{11}OC_6H_4$, 2-ClC_6H_4, 3-ClC_6H_4, 4-ClC_6H_4, α-$C_{10}H_7$, α-C_4H_3O.

The polymerisation of divinyl acetals occurs in the bulk and in solution in the presence of radical iniators and under the influence of ionic catalysts. It was found that in the cyclic polymerisation the steric configuration and the presence of an axis of symmetry in the monomeric divinyl acetal molecules are important.

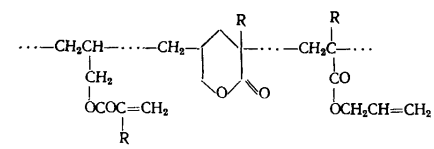
Arbuzova and coworkers[96–100] also studied the polymerisation of divinyl acetals; they obtained the cyclic polymers of the divinyl acetals of formaldehyde, acetaldehyde, propionaldehyde, butyraldehyde, and benzaldehyde. Sultanov and Arbuzova[101,102] established that, in contrast to divinyl acetals, allyl vinyl acetals and diallyl acetals give polymers in low yield, in which the fraction of cyclic units is small. It is interesting to note that ionic polymerisation of the divinyl acetals of formaldehyde[90,103] leads to the formation of only the cross-linked polymer, regardless of the reaction conditions.

The polymerisation of divinyl ketals [104], like that of divinyl acetals, leads to the formation of cyclic polymers containing, 1,3-dioxan rings:



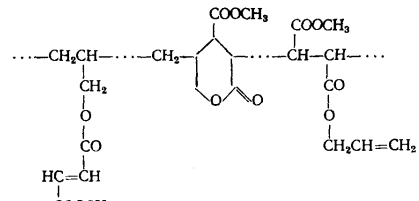
where R = R′ = CH_3; R = CH_3, R′ = C_2H_5; R,R′ = $(CH_2)_5$; R = R′ = C_6H_5.

The degree of cyclisation of asymmetric dienes, for example allyl esters of $\alpha\beta$-unsaturated acids, is as a rule low. Gindin et al.[105] indicated, in a discussion on the structure of the soluble polymers of allyl acrylate, the possibility that they have a cyclic structure. Several other workers[106–108] also obtained soluble polymers of allyl acrylate and allyl methacrylate, but the structre of the latter was not established. Schulz et al.[109] showed that, depending on the concentration of allyl acrylate in solution, the polymer contains at least 31% of six-membered lactone rings. In the radical polymerisation of allyl acrylate and allyl methacrylate[33] in dilute benzene solutions (5–10%) the yield of soluble polymers reaches 85%. By virtue of their considerable content of cyclic units, these polymers are relatively heat-resistant; the open-chain units contain both acryloyl and allyl bonds:



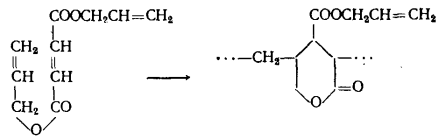
where R = H, CH_3.

The ionic polymerisation of allyl acrylate [110] under the influence of butyl-lithium proceeds exclusively at the acrylic double bond with formation of a non-cyclic polymer (m.p. 86–90°). Barnett et al.[111] studied the radical polymerisation of methyl allyl, methy-but-2-enyl, and methyl but-3-enyl esters of maleic and fumaric acids and found that the degree of cyclisation in the polymers obtained ($[\eta]$ = 0.036–0.072) amounted to 23–60%. The authors believe that the possible cyclic units are six- or seven-membered lactone rings (in the case of but-3-enyl esters) and therefore the structure of poly(methyl allyl fumarate), for example, is represented as follows:

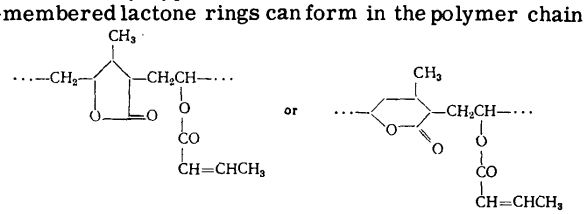


In the radical polymerisation of monoallyl esters of maleic and citraconic acids Arbuzova et al.[112] obtained cyclic polymers with a structure similar to that indicated

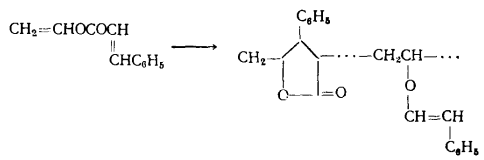
above. It was established that in the first stage of polymerisation of diallyl maleate [113] a soluble polymer is formed preferentially by a cyclic mechanism:



Rostovskii and Barinova [114] studied the radical polymerisation of vinyl crotonate in solution and obtained a soluble polymer ($[\eta] = 0.31$) containing about 50% of double bonds of the crotyl type. In their view both five-membered and six-membered lactone rings can form in the polymer chain:



In the polymerisation of vinyl *trans*-cinnamate in benzene solution in the presence of azoisobutyric acid dinitrile van Paesschen et al. [115] obtained a soluble polymer (yield 22–40%) which contained 80–85% of γ-lactone units and 15–20% of open-chain units:

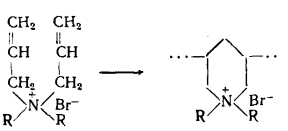


Roovers and Smets [116] studied the kinetics of the cyclic polymerisation of this monomer.

Barnett and Butler [117] investigated the polymerisation of allyl, β-methylallyl, γ-methylallyl, and propargyl vinylacetates and crotonates. The results showed that only allyl and β-methylallyl crotonates are converted into solid polymers (yield 10%, $[\eta] = 0.039–0.046$) with a degree of cyclisation of 25 and 31% respectively.

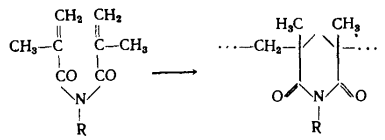
The cyclic polymerisation of non-conjugated oxygen-containing dienes was also investigated using the dimethacrylates of ethylene glycol and diethylene glycol as examples [118]. In contrast to the diallyl ester, the di-2-chloroallyl ester [33] readily forms a cyclic polymer which undergoes extensive dehydrochlorination as a result of the cyclisation of the monomer under the polymerisation conditions.

B. Polymerisation of nitrogen-containing dienes. The intermolecular-intramolecular polymerisation of non-conjugated dienes was in fact first used for the preparation of nitrogen-containing heterocyclic polymers. In their investigation of the radical polymerisation of unsaturated quaternary ammonium compounds Butler and coworkers [119–125] found that diallyldialkylammonium salts [12,13] form water-soluble polymers containing piperidine rings in the main chain:

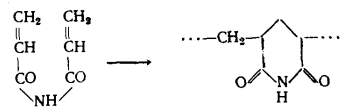


where R = H, CH_3, C_2H_5.

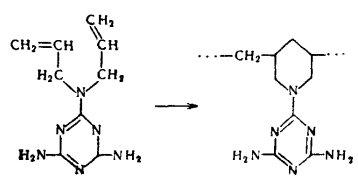
Sokolova and Rudkovskaya [126,127] synthesised six-membered nitrogen-containing polymers by the cyclic polymerisation of *N*-methyl- and *N*-ethyl-dimethacrylamides:



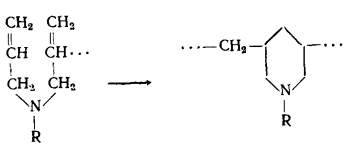
where R = CH_3, C_2H_5. In the polymerisation of *N*-acryloylacrylamide [128] a soluble polymer was obtained, whose chain units were identical with glutarimide:



Gibbs and van Densen [129] described cyclic polymerisation in the solid phase. On γ-irradiation (from a cobalt-60 source) of crystalline *NN*-diallylmelamine at room temperature, an acid-soluble polymer with a decomposition temperature of 250° and a molecular weight of 10 000–20 000 was obtained:



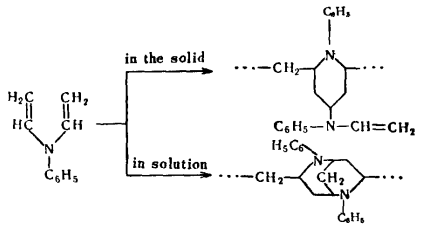
Matsoyan and coworkers [130] showed that introduction into diallylamine of polar substituents whose electron-acceptor group is lined directly with the nitrogen atom results in *N*-substituted diallylamine exhibiting a tendency towards radical polymerisation with formation of cyclic polymers containing piperidine rings:



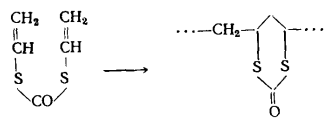
where R = CN, HCO, CH_3CO, C_2H_5CO, $ClCH_2CO$, CH_3OCO, C_2H_5OCO, C_6H_5CO, 4-$NO_2C_6H_4CO$, $C_6H_5SO_2$, 4-$CH_3C_6H_4SO_2$, $CSNHC_6H_5$. It was established that the capacity of *N*-substituted derivatives of di(methylallyl)amine [131] for cyclic polymerisation is much lower than that of the corresponding *N*-substituted diallyl derivatives. Similar cyclic polymerisation of *N*-diallyl compounds has been described by Ostroverkhov et al. [132]. In the polymerisation of allyl and ethyleneglycol esters of *N*-vinylcarbamic acid [109], *N*-allylacrylamide, and *N*-allylmethacrylamide [133] nitrogen-containing cyclic-linear polymers are also formed.

Chang and Price [133] described the synthesis of *NN*-divinylaniline and studied its polymerisation with the aid of an free-radical initiator. It was found that the polymeric unit forms as a result of the cyclisation of two *NN*-divinylaniline molecules and, depending on the method

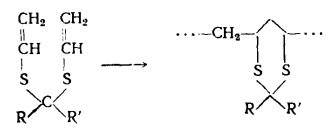
of polymerisation, the reaction leads to the formation of monocyclic or bicyclic units:



C. Polymerisation of dienes containing sulphur, silicon, phosphorus, and other elements. Ringsdorf and Overberger [134] studied the conditions of the polymerisation of *SS*-divinyl dithiocarbonate in the presence of a free-radical initiator and found that in dilute solutions a soluble cyclic polymer with a softening temperature of 300–310° is formed; a non-cyclic polymer obtained from the same monomer softens at 40–80°:



In the polymerisation of divinyl thioacetals and divinylmercaptans Matsoyan and Saakyan [135,136] obtained the sulphur analogues of polyvinylacetals in the form of elastic rubberlike substances. On hydrolysis these cyclic polymers converted into polyvinylmercaptan and on oxidation into the corresponding sulphones:

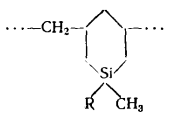


where R = R′ = H; R = H, R′ = CH_3; R = H, R′ = C_3H_7; R = R′ = CH_3. Ringsdorf and Overberger [137] also reported the cyclic polymerisation of the divinyl thioacetal of formaldehyde.

In contrast to diallyl sulphide and diallylsulphone, di-2-chloroallyl sulphide and di-2-chloroallylsulphone [33] are capable of polymerising in the presence of radical initiators with formation of cyclic sulphur-containing polymers which are extensively dehydrochlorinated under the reaction conditions.

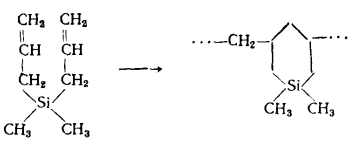
The possibility of the polymerisation of dialkenylsilanes in the presence of peroxide initiators was demonstrated by Korshak, Petrov, and coworkers [138–140]. The kinetics of the polymerisation of diallyldimethylsilane in the presence of t-butyl peroxide at 120–150° were investigated by Mikulasova and Hrivik [141]. Topchiev [142] demonstrated the possibility of the polymerisation of diallydimethylsilane and diallylmethylphenylsilane under the action of Ziegler type catalysts, but the structure of the products obtained, predominantly liquid, was not established.

Independently of Bogomol'nyi [144], Kolesnikov and coworkers [143] studied the polymerisation of diallyl derivatives of silicon. Under the action of the catalytic system $Al(C_2H_5)_3$–$TiCl_4$, diallyldiethylsilane gives a tetramer with six-membered cyclic units. Under similar conditions diallyldimethyl- and diallylmethylphenyl-silanes give rubber-like polymers, in the soluble fraction of which cyclic units with the following structure predominate:



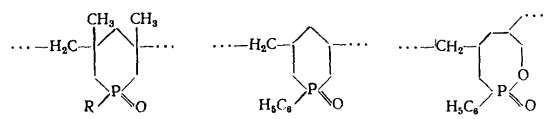
where R = CH_3, C_6H_5.

In a study of the polymer of diallyldimethylsilane obtained under the action of the $Al(iso\text{-}C_3H_7)_3$–$TiCl_4$ system, Marvel and Woolford [145] showed that the degree of cyclisation of the monomeric units in the polymer chain is 94%:



Butler and Stackman [146] studied the polymerisation of diallyldimethyl- and diallyldiphenyl-silanes with the aid of complex methal alkyl catalysts and obtained solid cyclic-linear polymers with m.p. 80–150° and $[\eta]$ = 0.065–0.13.

Berlin and Butler [147,148] studied the possibility of the cyclic polymerisation of phosphorus-containing non-conjugated dienes. They obtained soluble polymers (m.p. 85–185°, $[\eta]$ = 0.026–0.01) with a low content of residual double bonds on radical polymerisation in the solid state of methyl-, ethyl-, and dimethylallyl phenyl phosphine oxide, diallylphenyl phosphine oxide, and allyl phenyl allylphosphonate. The polymerisation proceeds by a cyclic mechanism with formation of phosphorus-containing heterocyclic polymers:

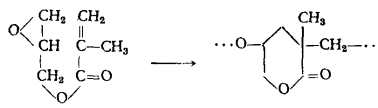


where R = CH_3, C_2H_5, C_6H_5. Unfortunately the structure of the soluble polymers of divinyl, diallyl and di(methylallyl) esters of various phosphorus acids has not been investigated, but is probably cyclic.

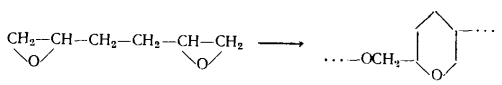
The synthesis of heterocyclic polymers from non-conjugated dienes containing other hetero-elements has been described in the literature — symmetrical diallyl compounds [143,149,150] in which the allyl groups are linked to the atoms of the following elements: Ge, Sn, Se, Ti, As, Pb, Zn, and others.

2. Polymerisation of Compounds of Other Types

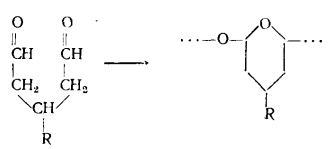
Arbuzova and coworkers [151,152] discovered the formation of a new type of cyclic polymers, from the glycidyl esters of acrylic and methacrylic acids. According to their data, both the epoxy-ring and the double bond of the monomer participate in ionic polymerisation [boron trifluoride etherate, aluminium trichloride], in contrast to radical polymerisation, with formation of cyclic units in the main polymer chain:



Stille and Culbertson [153] found that, under the action of the catalytic system PF_5–H_2O or $Zn(C_2H_5)_2$–H_2O, 1,2,5,6-diepoxyhexane polymerises with formation of a soluble polymer consisting of tetrahydropyran structural units:

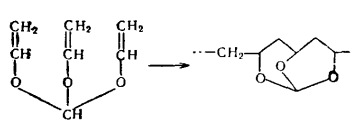


Under similar conditions 1,2,4,5-diepoxypentane yields insoluble polymers. A number of investigators have applied cyclic diene polymerisation to dialdehydes. In the polymerisation of glutaric aldehyde [154,155] in the solid state without initiator or in solution (in toluene) under the influence of various catalysts [$BR_3.(C_2H_5)_2O$, $Al(iso\text{-}C_3H_7)_3$, and others] soluble polymers with a small content of aldehyde groups are obtained. Infrared spectra of polyglutaraldehyde and also the polymers of β-methyl- and β-phenyl-glutaric aldehyde [156] show that the polymerisation involves intermolecular-intramolecular interaction of the two carbonyl groups of the monomers with formation of tetrahydropyran rings in the polymer chain:

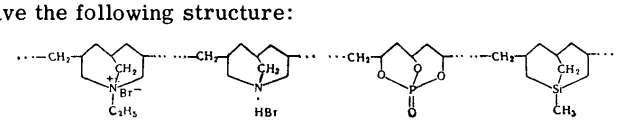


where R = H, CH_3, C_6H_5.

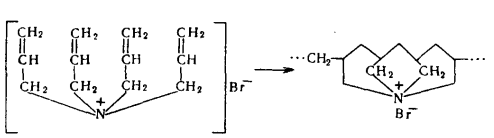
Matsoyan and coworkers [54] polymerised trivinyl orthoformate in solution in the presence of radical initiators and obtained a soluble bicyclic polymer (m.p. 250–260°) which is an ester derivative of poly(vinyl alcohol) and orthoformic acid:



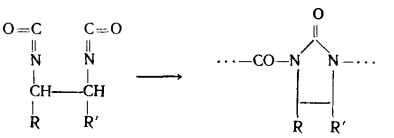
The possibility of the formation of nitrogen-, silicon-, and phosphorus-containing bicyclic polymers from branched trivinyl compounds has been demonstrated with triallylethylammonium bromide [157], triallylammonium bromide [54], trivinyl phosphate [54], and triallylmethylsilane [157] as examples. The chain units of the soluble polymers obtained have the following structure:



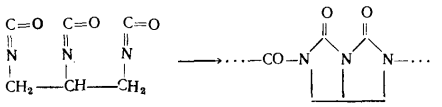
Trifan and Hoglen [157] have indicated that in the polymerisation of tetra-allylammonium bromide in dilute aqueous solution in the presence of t-butyl hydroperoxide (0.3%) a soluble polymer with tricyclic units in the main chain is formed:



King [158] polymerised aliphatic 1,2-diisocyanates in dimethylformamide solution in the presence of sodium cyanide and obtained cyclic-linear polymers between 290° and 365° and soluble in sulphuric acid, nitromethane, etc. According to his data, the cyclic polymerisation proceeds as a result of intermolecular-intramolecular interaction between the two nitrogen–carbon double bonds in the monomer:



where R = R′ = H; R = H, R′ = CH_3; R, R′ = $(CH_2)_4$. Under similar conditions glyceryl triisocyanate yields a bicyclic polymer melting at 365–400°:

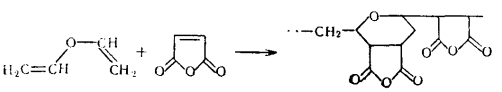


IV. SYNTHESIS OF CYCLIC COPOLYMERS

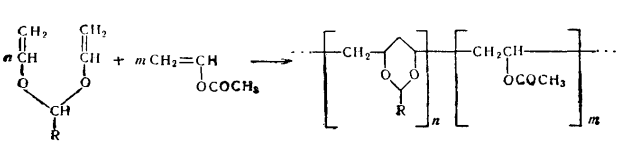
Even before the discovery of the cyclic polymerisation of non-conjugated dienes, the copolymerisation of vinyl monomers with isolated dienes was known; this reaction is widely used in the manufacture of cross-linked polymeric materials and cast articles.

Milford [29] studied the radical copolymerisation of 2,6-di(methoxycarbonyl)hepta-1,6-diene with acrylonitrile in solution and found that, when the concentration of the monomer mixture in the system is not higher than 10%, soluble linear copolymers with substituted cyclohexane rings in the chain are formed.

Butler [159] described the cyclic copolymerisation of vinyl ether, divinyl sulphone, and dimethyldivinylsilane with maleic anhydride, diethyl maleate, dimethyl fumarate, and vinyl acetate. Using vinyl ether and maleic anhydride as an example, Butler represents the formation of cyclic polymers in the following way:

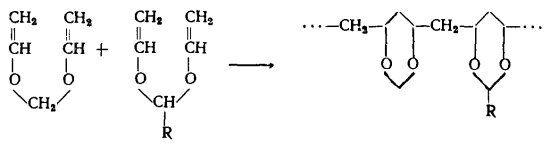


Matsoyan and coworkers [160–163] showed that the radical copolymerisation of the divinyl acetals of formaldehyde, acetaldehyde, butyraldehyde, isobutyraldehyde, and isovaleraldehyde with vinyl acetate proceeds by a cyclic mechanism; in the copolymer the divinyl acetal units form 1,3-dioxan rings. It was found that, whatever the molar proportions of the components and whatever the degree of the reaction, this type of copolymerisation leads to the formation of azeotropic copolymers, whose compositions are identical with those of the initial mixtures:

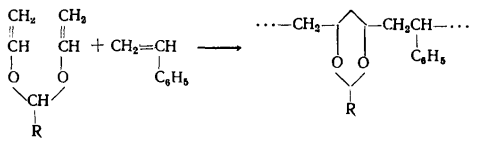


The possibility of cyclic copolymerisation of two diene monomers, forming rings on polymerisation, has been demonstrated [85] using the copolymerisation of the divinyl

acetal of formaldehyde with the divinyl acetals of acetaldehyde and butyraldehyde as examples[85]:

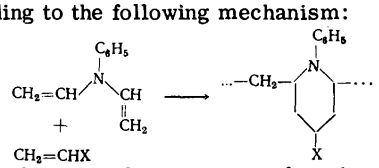


The copolymerisation of aliphatic divinyl acetals with styrene in the presence of benzoyl peroxide leads to the formation of the corresponding cyclic copolymers[164]. This reaction makes it possible to introduce simply and conveniently divinyl acetal units into the polystyrene chain:



Cyclic copolymers of similar structure were also obtained in the copolymerisation of the divinyl acetals of formaldehyde, acetaldehyde, and butyraldehyde with 2-methyl-5--vinylpyridine[165]. The possibility of cyclic copolymerisation of the divinyl acetal of butryaldehyde with monomers incapable of homopolymerisation — dimethylcrotonoyl carbinol and dimethylcrotonoylmethyl acetate — has been investigated[165]. It was found that in the presence of the cyclic divinyl butyraldehyde acetal these monomers are capable not only of copolymerisation but also of homopolymerisation.

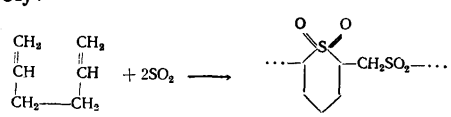
According to the data of Chang and Price[133], the copolymerisation of *NN*-divinylaniline, divinyl sulphone, and vinyl ether with styrene, *p*-methylstyrene, methyl methacrylate, etc. leads to the formation of six-membered cyclic groupings, each comprising one molecule of the diene and the vinyl component. Thus the cyclic copolymerisation of *NN*-divinylaniline with a vinyl monomer proceeds according to the following mechanism:



In a study of the copolymerisation of methacrylic anhydride with methyl methacrylate, styrene, acrylonitrile, etc. Hwa and Miller[166] found that soluble cyclic-linear copolymers are formed only when the reaction mixture is very dilute and when the degree of reaction is low. They showed that the usual equations for a binary system of vinyl monomers are applicable in the calculation of the composition of the cyclic copolymer when the degree of cyclisation of the non-conjugated diene component is relatively complete.

Michelotti[167] reported the possibility of cyclic copolymerisation of diallyl-2,3-epoxypropylamine with styrene.

Stille and Thomson[168] showed that the copolymerisation of hexa-1,5-diene with sulphur dioxide leads to the formation of a cyclic copolymer containing pentamethylene sulphone rings; the ratio of the initial components in the soluble part of the copolymer (m.p. 320–350°) is 1 : 2 respectively:



Roovers and Smets[116] established that the copolymerisation of vinyl *trans*-cinnamate with vinyl acetate, vinylpyrrolidone, methyl methacrylate, and styrene results in chain growth of the vinyl type due to the ester group of the diene as well as the cyclisation of the diene monomer into γ-lactone rings.

Avetyan et al.[169] showed that, in addition to the usual vinyl copolymerisation, cyclisation with formation of cyclopentanone rings in the main copolymer chain proceeds in the radical copolymerisation of isopropenyl propenyl ketone and isobutenyl vinyl ketone with acrylonitrile, vinylidene chloride, and 2-methyl-5-vinylpyridine. In the presence of radical initiators dibenzylideneacetone and maleic anhydride form an unsaturated cyclic-linear copolymer[44]. Matsoyan and Morlyan[170] studied the copolymerisation of ethynyldimethylvinyl carbinol with styrene, acrylonitrile, vinylidene chloride, methyl methacrylate, and vinyl acetate in the presence of benzoyl peroxide. They showed that the fraction of the copolymer consisting of the ethynyldimethylvinyl carbinol units contains cyclic units, like the homopolymers of ethynylvinyl carbinol[62,63].

---o0o---

The foregoing review shows that cyclic polymerisation constitutes a new and rapidly developing field in polymer chemistry. Cyclic polymerisation makes it possible to prepare fundamentally new types of polymeric compounds with a wide variety of cyclic groupings in the chain, which were previously unobtainable; for this reason, synthesis of polymers and copolymers by cyclic chain polymerisation has been attracting recently the attention of a wide circle of investigators. There is no doubt that in future still further varieties of cyclic polymerisation will be discovered and that this method of synthesising polymeric compounds is one of the important means of obtaining polymers with valuable technical properties.

THE SYNTHESIS OF MACROMOLECULAR COMPOUNDS BY RADIATION POLYMERISATION

V. S. Ivanov

CONTENTS

Introduction 43
1. Radiation polymerisation of alkenes 44
2. Alkadienes 45
3. Halogeno-derivatives of alkenes and alkadienes 46
4. Unsaturated carboxylic acids and their derivatives 47
5. Vinyl esters and ethers 48
6. Vinyl derivatives of carbocyclic compounds 48
7. Vinyl derivatives of heterocyclic compounds 49

INTRODUCTION

At the present time, polymerisation is initiated chiefly by chemical methods in which the monomers or their solutions are treated with initiators for polymerisation taking place by a radical mechanism, or catalysts for ionic polymerisation. The use of thermal and photochemical method of initiation is limited — for the first because of the unfavourable conditions for the development of chains at elevated temperatures and the secondary processes which take place, and for the second because of the low efficiency and the complexity of the technological layout, associated chiefly with the influence of the optical properties of the medium on the course of photochemical reactions.

Recently, the attention of many research workers has been drawn to a new method of polymerisation — radiation polymerisation — in which the chain process is initiated by the action of ionising radiation. The first observations of the formation of polymeric (resinous) substances under the influence of the radiation from radium and radon were made at a very early date, but the development of radiation polymerisation as an independent branch of the chemistry of macromolecular compounds is a recent phenomenon. It appears that in a few years this new method will be recognised as an effective industrial method for the synthesis of certain polymeric products.

Problems of radiation polymerisation have been examined in a number of general papers and reviews[1-17], which give data characterising chiefly the fundamental features of the method, in particular the mechanism of radiation-chemical initiation, the influence of various factors (including such specific factors as the dose and dose rate) on the reaction rate, sensitisation in multicomponent systems, polymerisation in inclusion compounds, etc. Special reviews devoted to radiation polymerisation in the solid phase[18-23] and a review of the patent literature[24] have been published. No systematic review of data on the use of radiation-chemical initiation for the polymerisation of various monomers according to classes has

been published, however. The aim of the present work is to fill this gap.

Radiation polymerisation has a number of advantages over other methods for the preparation of polymers.

1. It makes it possible to obtain polymeric products based on monomers whose polymerisation under ordinary conditions either does not take place at all or can be achieved only with considerable difficulty. Such monomers include, in particular, certain fluorine-containing monomers which give valuable heat-resistant and chemically stable polymers of practical importance[14], monomers with a symmetrically-substituted double bond[25-27], and allyl monomers[28].

2. Radiation polymerisation is the simplest and most effective method for polymerising monomers in the solid phase[14], and also in channel[29] and layer[30] inclusion compounds.

3. The radiation method makes it possible to obtain highly pure polymers containing no residual initiators, catalysts, or other auxiliary polymerisation agents, whereas this is unavoidable in polymerisation by the usual methods[2]. These impurities are often responsible for a significant deterioration in the operational properties of the polymers; this is of particular importance for polymers used in radio-electronics and medicine, where these impurities have a harmful influence[31].

4. With radiation initiation, polymerisation can be carried out at reduced temperatures, at which the conditions of chain growth are favourable for the formation of macromolecules with only minimal degrees of branching; this leads to an improvement in the properties of the polymeric materials[2].

5. Radiation polymerisation takes place more smoothly than ordinary polymerisation and enables the reaction rate to be regulated[2]. In "material" initiation the rate decreases as the initiator (or catalyst) is used up, and with an exothermic process increase in temperature leads to an increased rate of dissociation of the initiator, resulting in a change in the rate of the process[9]. With radiation initiation, however, analogous increase in temperature has almost no influence on the concentration of radicals or ions initiating the polymerisation, since this concentration is determined chiefly by the intensity of the irradiation (dose rate). By varying the latter, it is possible to polymerise monomers with appreciable quantities of inhibiting additives, whose action is suppressed[2].

6. The radiation method sometimes makes it possible to produce polymer manufactured parts "in situ" in construction where access is difficult ("imprinting" linings, one-piece parts, etc.)[31].

7. Radiation polymerisation in certain instances makes it possible to obtain finished textile fibres in a single operation by irradiating the crystalline monomer[32].

The use of radiation-chemical initiation naturally involves a number of difficulties, of which the following may be noted: special requirements have to be satisfied in the design of the apparatus, associated with the use of penetrating radiation (safety precautions), and also with the need, in most instances, to create in the reaction zone a field with uniform radiation density; the possibility of secondary processes and side-reactions: cross-linking or degradation of the resulting polymers and radiolysis of the monomers.

These difficulties are not insuperable, however. It appears to be possible to find solutions to the engineering and technological problems and to choose reaction conditions which will satisfy the requirements made of the apparatus and will make it possible to carry out the process with maximal rate of polymerisation and relatively low yields of side products. Sometimes it is possible in principle to make the process continuous, with removal of the resulting polymer from the irradiation zone. In individual instances it is possible to make use of the cross-linking of the resulting polymer and to combine the preparation of the polymer and its vulcanisation in a single process. It should also be noted that the radiolysis products contaminating the finished polymer do not lead to a deterioration in its electrophysical properties, although they may sometimes have a plasticising action.

We shall examine the results of published work on the use of ionising radiation for the synthesis of polymeric products from monomers of different type. The problems of radiation copolymerisation, including graft copolymerisation and telomerisation, are not examined here, since they are of independent interest. The monomers are grouped according to the usual classification of organic compounds with allowance for the nature of the structural elements by which polymerisation is brought about.

1. RADIATION POLYMERISATION OF ALKENES

Ethylene, depending on the polymerisation conditions, forms products with different molecular weights, from liquid oils and waxy substances to hard plastics with a fairly high degree of crystallinity[1]. Macromolecular products are obtained only under pressure (~ 300–400 atm), but this pressure is much lower than the pressures used in the production of ordinary "high pressure" polyethylene (1500–3000 atm at 150–250°). The properties (density, degree of crystallinity, degree of branching) of "radiation" polyethylene are similar to those of polyethylene obtained at low pressures. It has excellent dielectric properties including, in particular, low dielectric loss at high frequencies[1]. To give ordinary "low pressure" polyethylene these properties, special purification of the polymer from traces of catalysts is necessary. The cost of low-pressure polyethylene purified in this way is 1.5–2 times greater than the cost of radiation polyethylene. The radiation process is free from the danger of explosion, is readily controlled, and takes place at low temperatures[33] with values of G up to 1 130 000 (at 200° and 850 atm)[34]. Economic calculations show that when fuel elements are used, the radiation method for preparing polyethylene can compete with ordinary methods[35]. The requirements to be satisfied by the chief technological characteristics of apparatus for the radiation polymerisation of ethylene on the industrial scale have been formulated[36]. The polymerisation of ethylene under the influence of γ-radiation is carried out from the gaseous phase[37-41] and in liquid medium[24,42]. Study of the heterogeneous polymerisation of ethylene[43,44] under a pressure of 300–400 atm at temperatures below the melting point of polyethylene (25°) showed that the process takes place in the kinetic range[45]. The radiation polymerisation of ethylene in solutions has been studied[41,46], but here products with molecular weight not exceeding 40 000 are formed. In aqueous solutions in

the presence of Ag salts the radiation yield G reaches 60 000 molecules per 100 eV.[47] Irradiation of ethylene in the solid state (-196°) in a Van de Graaf electrostatic generator (3 MeV) gives a negligibly low yield of polymer (G = 2.5). The results of experiments on the irradiation of a mixture of ethylene and deuteroethylene lead to theories of an ion-molecular mechanism[48].

The molecular weight of radiation polyethylene may reach 800 000[41] and even 1.5 million.[53] The polymer has a higher density (0.945–0.975 g cm^{-3}) and crystallinity than high-pressure polyethylene but its tensile strength is about the same. The macromolecular chain of radiation polyethylene has a low degree of branching[49].

Of particular interest is the polymerisation of ethylene on Ziegler catalysts — halides of Ti, V, Cr, Co, Fe, Zr, etc. — in which the part of cocatalyst is played by the ionising radiation. A solution of the metal halide (for example, a solution of $TiCl_4$ in heptane) is irradiated at low temperature, after which gaseous ethylene is passed through the irradiated solution; under these conditions the ethylene polymerises. Studies of this type are directed towards an investigation of the role of the components and the mechanism of action of the Ziegler–Natta catalysts[50–52]. The action of γ-radiation on a mixture of ethylene and carbon dioxide at temperatures from -78° to +204° gives liquid and paste-like polymers of carboxylic acids with a linear carbochain structure and molecular weight up to 660 ($G_{-C_2H_4} \simeq$ 310 molecules per 100 eV).[53] The radiation-catalytic method has been used to prepare higher carboxylic acids with m.p. 121–123° and M = 3000.[54]

The polymerisation of propene at pressures up to 160 atm, temperatures from -75° to +200° and a dose rate of 400 r s^{-1} gives oily products with low molecular weights in the range 112–200 (G varies in the range 800–4400 molecules per 100 eV).[55] Work has also been carried out on the radiation polymerisation of propene at high pressures of 5000–17 000 atm and 21–83°.[56,57] The maximal degree of polymerisation reached 75 and the values of G reached 108 000. The results obtained indicate that this process takes place by a radical mechanism[56]. Radiation polypropene is soluble in benzene at room temperature.

2-Methylpropene is a convenient material for studying the cationic mechanism of radiation polymerisation[58–69]. 2-Methylpropene does not polymerise at 0° and higher temperatures. Polymerisation from the gaseous phase gives only low-molecular-weight products[70]. At low temperatures (-78°) in the presence of electron-accepting solid additives or solvents, 2-methylpropene gives a polymer with high molecular weight and the same properties as that obtained by ordinary polymerisation. The influence of the purity of the monomer on the yield and molecular weight of radiation polyisobutene [poly-(2-methylpropene) (Ed. of Translation)] has been established[55]. Oxygen and more particularly water have an inhibiting influence. G may be increased to 2 million by polymerisation under sterile conditions in the presence of specially treated zinc oxide[12]. A polymer with M = 3.759 million was obtained at -110° and a dose of 24 Mrad.[67]

The radiation polymerisation of higher alkenes — pentenes[71], hex-1-ene[72], n-heptene (in the presence of $TiCl_4$)[73], oct-1-ene[72–74], oct-2-ene, 2,2,4-trimethylpent-2-ene[74], 2,4,4-trimethylpent-1-ene[75,76], and hexadec-1-ene[77] — leads to the formation, for the most part, of liquid and viscous polymers of low molecular weight.

2. ALKADIENES

Diene hydrocarbons are polymerised with low radiation-chemical yields. The radiation polymerisation of butadiene "in bulk"[78–80] at temperatures from 0° to -196° gives a polymer containing the same relative quantities of *cis*-1,4-, *trans*-1,4-, and 1,2-linkages as the product obtained by the cationic mechanism. This indicated that at low temperatures the radiation polymerisation of butadiene also takes place by a cationic mechanism[79]. In all instances, including those where halogen-containing solvents were used[81] (apart from one[78], where the degree of conversion was very small), low-molecular-weight viscous polymers are formed. Channel polymerisation in urea complexes leads to the 1,4-*trans*-structure with m.p. 135°.[82]

A method has been described in a patent[83] for preparing macromolecular polybutadiene ($[\eta]$ = 1.8) at +40° and a dose of 0.5 Mr in an emulsion; the product has the microstructure: 1,4-*trans* 57%, 1,4-*cis* 20%, and 1,2 23%. A polymer with M = 100 000 was obtained by irradiation in nitromethane at -100°.[84]

The radiation polymerisation of isoprene "in bulk" gives viscous polymers[85–88]. As for butadiene, the possibility of polymerisation at low temperatures by an ionic mechanism has been demonstrated[85,87]. The microstructure (at 20°) includes up to 8% 1,2- and 3,4-linkages and up to 84% 1,4-linkages, including 15% 1,4-*cis*-linkages. The concentration of 1,4-*cis*-linkages increases to 36.4% with increase in temperature to 40°. Irradiation in the presence of $TiCl_4$ increases the rate of the process, which takes place by a cationic mechanism[89]. The sensitisation of the polymerisation of isoprene by carbon tetrachloride has been studied[86,90]. The radiation polymerisation of isoprene in clathrate complexes with 4,4'-dihydroxytriphenylmethane gives a polymer with a ratio of *cis*-1,4- to *trans*-1,4-linkages equal to 1 : 9, with almost complete absence of the 1,2- and 3,4-structures[91]. A polymer with M = 200 000 was obtained by irradiating isoprene in a Van de Graaf generator at -100°.[84]

Piperylene "in bulk" under the influence of radiation also forms a viscous polymer with $G \simeq$ 20–30 molecules per 100 eV. The sensitisation of its radiation polymerisation by noble gases (argon and krypton) and also by carbon tetrachloride has been noted. The decreased concentration of double bonds in the polymer is due to possible cyclisation[92].

The microstructure of the polymer, studied by infrared spectroscopy[92,93] and ozonisation[93], consists chiefly of the 1,4- and 1,2-*trans*-linkages (64–67%). The concentration of 1,2-linkages is 17.4% and that of 3,4-linkages (vinyl group) is 3–6.5%. "Channel" polypiperylene, prepared in the complex with urea[94], is more regular and contains no 3,4- or *cis*-linkages.

2,3-Dimethylbuta-1,3-diene and cyclohexa-1,3-diene give high-melting crystalline polymers with the *trans*-structure when their complexes with thiourea are irradiated[29,95,96]. Ammonia has a marked inhibiting action on the polymerisation of cyclopenta-1,3-diene at -78°;[97,98] this may be due to the transfer of a proton from the hydrocarbon ion to NH_3 and also to aminolysis of carbonium ions[99]; methylene dichloride has a marked sensitising influence on the polymerisation[100].

In the irradiation of dienes, polymerisation is accompanied to some extent by radiolysis[101]. It has been suggested that

the radiolysis products may inhibit the polymerisation.

3. HALOGENO-DERIVATIVES OF ALKENES AND ALKADIENES

Of the halogeno-derivatives of the alkenes, the fluoroalkenes have been most extensively studied. Tetrafluoroethylene is one of the monomers most readily polymerised under the influence of radiation. The radiation polymerisation yield is exceptionally high and reaches 800 000 molecules per 100 eV; the organisation of an industrial process for the radiation polymerisation of Fluoroplast can thus be regarded as one of the first tasks in radiation technology. The radiation polymerisation of tetrafluoroethylene takes place from the gaseous phase [102,103], "in bulk", in chloroform [102,104], in aqueous medium [104], at low temperature in the liquid phase [105], and in the solid phase [106-108]. A post-effect is observed [102,104]. The radiation polymerisation of trifluorochloroethylene "in bulk" has been studied over a wide range of dose rate and temperature [104,109,110]. The polymerisation was first studied by Lazar [111]. The polymer forms a solid phase insoluble in the monomer. G reaches values of 10 000 molecules per 100 eV. In halogen-containing solvents ($CHCl_3$, CCl_4, $CFCl_2-CF_2Cl$), polymers with melting point of the crystalline phase in the range 80–200°, have been obtained [112] depending on the dose rate. The polymerisation takes place by a radical mechanism and gives a product of the Fluoroplast-3 type. A post-effect is observed. Vinylidene difluoride also polymerises under the influence of γ-radiation [113-115]. The rate of polymerisation decreases in the order: tetrafluoroethylene–vinylidene difluoride–trifluorochloroethylene [114]: the corresponding values of G (molecules of monomer per 100 eV) are 10^6, 10^5, and 10^4. The marked induction effect is due to contaminants, particularly oxygen [114]. The activation energy (6–8 kcal mole^{-1}) and dose rate exponent (0.6) indicate a radical mechanism. Complete conversion of the monomer requires a dose of 24 Mr. Radiation polymerisation of vinyl fluoride at a dose rate of 34 r s^{-1} leads to the formation of waxy products. A radical mechanism is indicated [116]. $G \simeq 10^3$ molecules per 100 eV. [115] C_3-Fluoroalkenes with different degrees of fluorination and the monomer $CH_2=C<^{CF_3}_{CF_3}$, under the influence of radiation, form polymers with M = 510–800 in the form of viscous liquids and wax-like products with G = 9–350 molecules per 100 eV. [117] Perfluoropropene, [118,119] perfluoro-2-methylpropene, [119] and perfluoropentylpropene [119] form oligomers at extremely high doses (~200–600 Mr). These liquid "radiation" fluoropolymers can be used as heat-resistant lubricants. Irradiation of n-perfluorohept-1-ene under a pressure of 10 000–15 000 atm gives a solid polymer with M = 5000. [120] The highest degree of polymerisation, equal to 76 ± 8, was observed at a pressure of 17 000 atm, 189°, and dose rate 0.0027 Mrad h^{-1}. [56] It should be emphasised that for most of the fluorinated monomers examined, radiation polymerisation provides the only possible method of conversion into polymers.

Vinyl chloride in the gaseous phase has been polymerised by α-particle bombardment [121,122] with the formation of liquid and solid polymers and radiolysis products — hydrogen and methane. The polymer formed under the influence of γ-radiation consists of a white powder which swells readily in the reaction medium, and on further irradiation forms a red solid monolithic material. Oxygen inhibits the polymerisation [123,124] but mercury at 10–95° sensitises it [123]. At a pressure of 1.5 atm and room temperature, $G \simeq 900$ molecules per 100 eV. In the liquid phase ("in bulk") at room temperature a polymer analogous to that obtained by ordinary polymerisation is formed [78,125-128]. The kinetics of polymerisation are typical of those for a hetero-phase process [127,129]. A post-effect is observed. "In bulk" at -20° with a dose of 0.2–0.5 Mrad, a product with glass point 100° is formed (with "material" initiation, the glass point of the polymer is 75–80°) [127]. Radiation poly(vinyl chloride) has not only an increased heat resistance, but also a high purity, which distinguishes it from the polymers obtained by the usual methods [125,130]. It may find application in fields where prolonged stability to high temperatures is required [1]. There are patents on the continuous production of poly(vinyl chloride) with initiation by γ-radiation [125,131]. Vinyl chloride polymerises in the vitreous state in a solid dispersion (mineral oil, etc.) [132]. Polymerisation of the monomer itself in the solid phase is not observed, however [133,134].

Channel polymerisation of vinylidene dichloride (complex with thiourea) [95] gives a brown polymer identical with that obtained in the usual way. No polymerisation of vinylidene dichloride is observed in the solid phase at -196° under the influence of γ-radiation [18]. The formation of polymeric products by the γ-irradiation of *cis*- and *trans*-1,2-dichloroethylenes has been studied [26,135]. Only the *trans*-isomer forms solid polymers. The total radiation yield for *trans*-1,2-dichloroethylene amounts to 204–239 molecules per 100 eV; the concentration of solid polymer in the polymeric products reaches 24.8%. For *cis*-1,2-dichloroethylene, G = 134–138. Trichloroethylene and tetrachloroethylene have values of G (molecules per 100 eV) equal to 31–34 and 9 respectively [26]. Liquid and waxy oligomers are formed from trichloroethylene. Thus increase in the number of chlorine atoms in the ethylene molecule leads to an increase in the stability of the monomer towards radiation.

Vinyl iodide in the pure state or in concentrated solutions does not polymerise under the influence of X-rays. In solutions in CCl_4 (concentration less than 80%), $CHCl_3$ (concentration less than 60%), and CH_2Cl_2 (concentration less than 45%), however, it forms solid white polymers which are stable in air in diffused light for a period of two months; the temperature of decomposition in a vacuum is 97°. [136]

Perfluorobutadiene at a dose of 225.6 Mr forms an oligomer in 55% yield [40,119] and 4-chlorodecafluorohepta-1,6-diene forms a polymer with 100% conversion at 150°, a pressure of 1 atm, and a dose rate of 0.2 Mrad h^{-1} with irradiation for 71 h. The low characteristic viscosity of the polymer (0.09) can be increased to 0.60 by carrying out the polymerisation at a dose rate of 0.003 Mrad h^{-1} for 113 h at 147° and a pressure of 13 600 atm; [56] here a solid product is formed.

When irradiated "in bulk", Chloroprene [2-chlorobuta-1,3-diene (Ed. of Translation)] forms a cross-linked product (μ-polymer). Formation of soluble α-poly(chloroprene) is achieved by the addition of stabilisers which regulate the molecular weight and the process of structure formation [137,138]. The properties of the radiation elastomer are similar to those of GN Neoprene [137]. 2,3-Dichlorobuta-1,3-diene in its complex with urea and thiourea is polymerised completely in an electron

beam (800 keV, dose rate 2.3×10^5 r s^{-1}) in several seconds with the formation of a highly crystalline *trans*--1,4-polymer with regular structure[82,95].

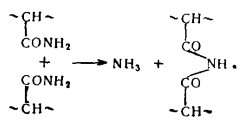
4. UNSATURATED CARBOXYLIC ACIDS AND THEIR DERIVATIVES

Acrylic, methacrylic, and butadiene-1--carboxylic acids polymerise under the influence of γ-radiation in the solid phase[133,134,139]. In the case of acrylic and methacrylic acids at -18° the polymerisation is very rapid (rate of conversion 400% h^{-1})[133]. Butadiene-1--carboxylic acid polymerises spontaneously and forms a cross-linked product[139]. Its closest homologue — sorbic acid — undergoes 1,4-polymerisation in the solid phase and in solvents by a radical mechanism yielding amorphous soluble polymers with $[\eta]$ up to 1.0.[140] Potassium, sodium, and lithium acrylates and methacrylates, rubidium and calcium acrylates, and barium methacrylate also polymerise in the solid phase[18,141,142]. The difference in the crystalline structure of the monomers determines their relative rates of polymerisation. Marked differences are observed between the ease of polymerisation of the hydrated salts and the anhydrous forms. For example, at a dose of 0.8 Mrad under identical conditions, the conversion of barium methacrylate dihydrate amounts to 55%, while that of the anhydrous monomer is 1%.[142] The sodium, potassium, and barium butadiene-1-carboxylates are fairly stable to γ-radiation[139].

The polymerisation of methyl acrylate "in bulk", initiated by γ-radiation, is very rapid at room temperature and is accompanied by a marked gel-effect[78,143]. Polymerisation in an atmosphere of air (dose 40 Mr) gives a colourless transparent elastomer. Its density is 25% greater than that of the ordinary polymer. The increase in weight of a specimen immersed in water for 24 h is 0.4%.[40] Very slight sensitisation is observed in CCl_4 solution[144]. Polymerisation takes place by a radical mechanism at -78° in polar solvents[145]. Almost no polymerisation takes place in the solid phase (at -78° and -196°)[18]. Ethyl acrylate polymerises readily at low temperatures[12] and in an emulsion at 25°.[146] Methyl methacrylate (MMA) has been studied fairly systematically. For polymerisation "in bulk" the degree of conversion and molecular weight of the polymer are increased at higher temperatures. The gel-effect is very marked and is appreciable even at a degree of conversion equal to 2%.[78] The polymerisation of MMA has been studied in the presence of solid additives[147-149] and in various solvents: methyl acetate[150-152], ethyl acetate[150], carbon tetrachloride[150-153], benzene[78,150-152], its mixture with acetone[154], methanol[78], isopropylamine[155], and dimethylformamide[156]. The rate is decreased in benzene, whereas sensitisation is observed in CCl_4, $CHCl_3$, and dioxan[157]. Special technological apparatus has been developed and tested under different conditions[158], indicating an attempt to introduce a radiation method for the polymerisation of MMA. The monomer itself does not polymerise in the solid phase[18,156] but polymerisation can be achieved by adding alkanes[132,156]. A kinetic study has been made of the radiation polymerisation of cetyl methacrylate in the liquid and solid phases[159-161]. The rate of polymerisation of the crystalline monomer is fairly high initially and decreases with increase in the degree of conversion, indicating degeneration of the autocatalytic nature of the polymerisation in the solid phase[162]. The degree of polymerisation at 60° reaches about 30 000.

Diacrylates and dimethacrylates (octamethylene diacrylate, ethylene dimethacryalte, and octamethylene dimethacrylate) are polymerised under the influence of fast electrons (800 keV)[163]. The polymerisation of octamethylene dimethacrylate has been studied in more detail than that of the others. Its rate at room temperature is 45 times that of the polymerisation of MMA. A crosss-linked polymer in the form of a gel is produced in several seconds. Since the diffusion of the growing chains in such a short time interval is almost negligible, the shape of the resulting polymer reproduces exactly the geometry of the electron beam falling on the monomer[1]. 2,2,3,3,4,4,4-Heptafluorobutyl acrylate at a dose of 220 Mfer is converted completely into a cross-linked rubber-like polymer which softens and undergoes degradation at 150°.[119] Here the polymerisation takes place at both the C=C and the C=O bonds.

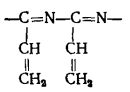
The radiation polymerisation of acrylamide in aqueous solutions has been studied[164,165]. Irradiation of solutions with a monomer concentration greater than 10% gives cross-linked products with liberation of ammonia, apparently as a result of reaction between the chains with the formation of an imide bridge



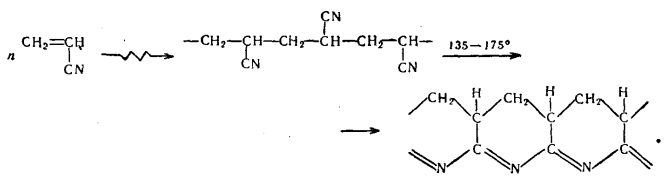
Acrylamide polymerises readily in the solid phase[133,134,166-175]; under pressure the rate increases close to the melting point of the monomer[176,177]. It is suggested that the solid-phase polymerisation takes place by a radical mechanism[178,179]. Methacrylamide also polymerises in the solid phase[168,175,180]. The yield of polymer is much greater for irradiation in air at 32° than for irradiation in nitrogen[181]. Post-polymerisation is observed[180]. *N*-Arylmethacrylamides (the *o*-chloro-, *o*-butyl-, and *o*-ethoxy-derivatives) also polymerise in the solid phase at 20° ± 3°.[180] The solid-phase polymerisation of the *N*-phenyl- and *p*-biphenylylene-derivatives was observed directly in an electron microscope under the initiating influence of the electron beam[182].

Detailed studies have been made of the radiation polymerisation of acrylonitrile "in bulk"[183-186] and in various solvents: dimethylformamide[156,187-191], triethylamine[187,192], isopropylamine, acetone, toluene[87], ethyl chloride, acetonitrile[58,192], butyronitrile[192], methanol[1], and water[193-195]. In polymerisation "in bulk" the polymer separates in the form of aggregates of particles[78]. A clearly defined post-effect is observed. In polymerisation in aqueous solutions under the influence of γ-radiation, a number of sulphates exhibit an inhibiting influence[195]. The addition of substances with electron-acceptor character (ethyl chloride, ethyl acetate, acetonitrile, and butyronitrile) to a solution of acrylonitrile in triethylamine at -78° inhibits polymerisation but the addition of substances with electron-donor character (pyridine)[192] or the addition of semiconducting oxides of the *p*-type[147,148], accelerate the polymerisation. It has been shown that the radiation polymerisation of acrylonitrile may take place both by a radical mechanism and by an ionic mechanism; these mechanisms predominate in the ranges of elevated and reduced temperatures respectively[196]. A patent[197] has proposed that the efficiency of radiation polymerisation be

increased by using a platinum electrode in contact with the polymerisation system to remove the electrons which accumulate during irradiation. In this way the yield of polyacrylonitrile is increased from 6.5% to 19.6% for a dose of 7.3 Mr and a dose rate of 0.09 Mr h^{-1}. In the opinion of Japanese authors[198], the polymerisation of acrylonitrile in liquid ethylene gives a product which contains, in addition to polyacrylonitrile with ordinary structure, chains with the following structure:



A post-effect is observed in the solid-phase polymerisation of acrylonitrile[156,175,196,198-207]. The molecular weight of the polymer reaches 200 000 or more. Polyacrylonitrile obtained at temperatures from -94° to -196° is a syndiotactic polymer; on thermal treatment the $-C\equiv N$ group is readily converted into the $-C=N-$ group[208]:



At a dose of ~200 Mr perfluoroacrylonitrile forms a polymer with low molecular weight in 20% yield[119]. The behaviour of methacrylonitrile is analogous to that of acrylonitrile[209]. In the solid phase at low temperature, the polymer is formed, in the opinion of the authors, by opening of the double carbon–carbon and triple carbon–nitrogen bonds[210]. It is suggested that the product is a syndiotactic polymer whose $-C\equiv N$ groups, unlike the analogous groups of the acrylonitrile polymer, are converted into $-C=N-$ groups without the use of elevated temperatures, apparently due to the influence of the methyl group[208].

5. VINYL ESTERS AND ETHERS

The radiation polymerisation of vinyl acetate is extremely sensitive to traces of contaminants. The polymerisation "in bulk" has been studied under conditions of initiation by γ-radiation[78,150] and in a reactor with filtered-neutron irradiation[211]. Studies have been made of the influence of 70 different additives, of which the most effective were found to be acids and their anhydrides[212]. It was established that the molecular weight of the polymer decreases with increase in temperature[213]. A patent[214] has proposed a method for carrying out the polymerisation in different solvents using various radiation sources with subsequent hydrolysis of the polymer to poly(vinyl alcohol). Study of the polymerisation in the solid phase with irradiation by 1.6 MeV electrons showed that the reaction rate is much less than that in the liquid phase; the rate of polymerisation of the solid monomer in the vitreous state is greater by one order of magnitude than that in the crystalline state[203,204]. It has been shown that the polymerisation takes place only in the beam; there is no post-effect. Vinyl stearate[133] and octadecyl vinyl ether[215] are polymerised under the influence of ^{60}Co γ-radiation above and below the melting point.

The polymerisation of pentafluorophenyl trifluorovinyl ether and phenyl trifluorovinyl ether was achieved only by using radiation initiation (γ-radiation) under a pressure of 12 000–14 000 atm at 100–103°.[56] The radiation polymerisation yield for a dose rate of 0.003 Mrad h^{-1} is 283 molecules per 100 eV for the first and 1190 molecules per 100 eV for the second.

6. VINYL DERIVATIVES OF CARBOCYCLIC COMPOUNDS

The radiation polymerisation of styrene "in bulk" has been studied under conditions of initiation by γ-radiation[216,217]. The polymer formed by complete conversion has a higher heat resistance than the ordinary polymer[2]. Polymerisation "in bulk" by radiation from an atomic reactor (neutron irradiation filtered with cadmium foil) shows a low degree of conversion (0.79% after 60 min)[211]. Macromolecular radiation polystyrene with an average molecular weight of 70 000 was obtained by Abkin and coworkers by the polymerisation of styrene in ethyl chloride solution at -78°.[61,218] The efficiency of the ionic polymerisation of styrene is increased in solvents with high dielectric constant (methylene dichloride)[219,220], in the presence of SiO_2 and other mineral additives at -78°.[221-223] Bromoform is an extremely effective sensitiser[224]; white phosphorus accelerates the polymerisation slightly[225]. The radiation polymerisation of styrene in the presence of the initiator benzoyl peroxide has also been studied[226]; the rate of polymerisation is ten times the value calculated assuming additivity, indicating effective transfer of excitation energy from the styrene to the benzoyl peroxide. Data have been obtained indicating an ionic mechanism for the polymerisation of styrene under ordinary conditions[227] and a radical mechanism in the solid phase (vitreous state in mineral oil)[132]. It has been shown that the polymerisation of styrene and 2,4-dimethylstyrene takes place simultaneously by ionic and radical mechanisms[228,229].

α-Methylstyrene at room temperature forms low-molecular-weight polymers with an exceptionally low rate of polymerisation[230]; the author considers that the polymerisation takes place by a radical mechanism. At -78° the reaction takes place by an ionic mechanism[59]. The anhydrous monomer gives a polymer with degree of polymerisation 15–45 and G = 8000 molecules per 100 eV.[231] Macromolecular poly-(α-methylstyrene) (average molecular weight 50 000) is formed by the action of γ-radiation at 25° and a pressure of 10 000 atm (G = 18 molecules per 100 eV)[129]. In solution, m- and p-methylstyrenes polymerise by a radical mechanism at 25° and by a cationic mechanism at -65°.[232]

p-Acetamidostyrene polymerises instantly under the influence of γ-radiation in the solid phase; this may be of practical importance for the production of textile fibres in a single operation by irradiation of the crystalline monomer[32].

β-Pinene also polymerises under the influence of radiation[231,233,234]. Traces of water decrease the rate of the process considerably. When the β-pinene is dried the values of G increase to 370–1055 molecules per 100 eV.[231] Attention has been drawn to the need to purify the monomer not only from traces of moisture but also from oxygen. Irradiation of the liquid monomer with a dose of ~4 Mrad gives a solid polymer in 45% yield; this is precipitated during the polymerisation and is stable at 230° in a vacuum. The polymerisation apparently involves opening of the double bond and it is suggested that elements of a camphene structure may be formed by rearrangement. Data

obtained by infrared spectroscopy and NMR also indicate the presence of unsaturated groups in the microstructure[233].

7. VINYL DERIVATIVES OF HETEROCYCLIC COMPOUNDS

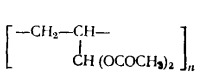
The radiation polymerisation of vinylpyrrolidone has been carried out in aqueous, alcoholic, and chloroform solutions[1]. Poly(vinylpyrrolidone) is important in medicine (blood plasma substitute). It can also be used in the dyestuffs industry, for cosmetics, and for other purposes. Advantages of its production by radiation polymerisation include the slightly narrower molecular-weight distribution and the possibility of organising a continuous process[1,9]. Vinylpyrrolidone also polymerises in the solid phase[18,235]. The radiation polymerisation of *N*-vinylcarbazole[133,154,236,237], *N*-vinylcaprolactam[159,238], *N*-vinylsuccinimide[159,238-241], and *N*-vinylphthalimide[18] has been carried out in the liquid and solid phases. According to data obtained by thermal analysis, the last two monomers in the solid phase polymerise autocatalytically and explosively. For the solid-phase polymerisation and post-polymerisation of *N*-vinylsuccinimide, two alternatives have been observed, differing in their dependence on the temperature, dose rate, and dimensions of the specimen: that involving a uniform thermal polymerisation stage and that involving thermal explosion[160]. The rate of polymerisation of *N*-vinylcarbazole changes little on going from the solid phase to the liquid phase[237]. The polymerisation of *N*-vinylcaprolactam in the solid phase is very slow, whereas the process is rapid in the supercooled state[160]. *N*-Vinylpyridinium salts also polymerise under the influence of ^{60}Co γ-radiation in solution (water of dimethylformamide) and in the solid phase[242,243]. The polymers are amorphous and in aqueous solution have the properties of a polymeric electrolyte. It is suggested that the reaction in the liquid and solid phases takes place by a radical mechanism.

It should be emphasised that the polymerisation of this group of monomers involves the double bond of the vinyl group, the heterocycle being preserved.

8. ALLYL MONOMERS

Allyl derivatives, with the exception of allylsilanes and allyl hydrocarbons do not polymerise under ordinary conditions. Only a few form oligomers. In this case radiation initiation is the only means of obtaining polymers. The action of γ-radiation has made it possible to obtain macromolecular products from allyl alcohol, allyl chloride and bromide, allyl acetate, allyl ethyl ether, allylamine, allyl nitrile, and other monomers[28,244-246]. The polymerisation takes place by opening of the double carbon–carbon bond, but with allyl nitrile, the nitrile functional group also takes part. The radiation-chemical yield is low (up to 50 molecules per 100 eV). Despite the large doses used (up to 10^9 r g^{-1}), almost, no radiolysis of the monomers or cross-linking of the polymeric products takes place, however[28].

Allylidene diacetate polymerises when irradiated "in bulk".[247] The polymer

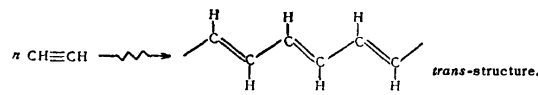


consists of a white powder with molecular weight up to 2750 and m.p. 130–140°; it is soluble in the monomer, acetone, benzene, and dioxan. It can be hydrolysed.

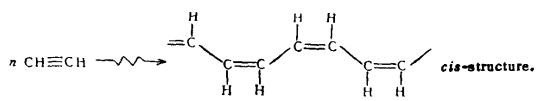
9. ALKYNE MONOMERS

The polymerisation of acetylene and its homologues gives polyvinylenes — structures with a conjugated system of double bonds. These substances have a high heat resistance and electrical conductivity.

The influence of α-radiation on gaseous acetylene was one of the first examples of radiation polymerisation to be observed. The resulting insoluble yellow powder is similar to cuprene, but subsequent electron-microscope study showed that it differs from cuprene and the name "alprene" was proposed for the product[248,249]. Benzene is formed in addition to the solid polymer ($G_{polymer}$ = 60 molecules per 100 eV and $G_{benzene}$ = 5.1 molecules per 100 eV). The polymerisation of acetylene also takes place under the influence of β-radiation from tritium[250]. Sensitisation of the polymerisation in gaseous medium by noble gases has been observed when α-radiation from radon[251,252] and X-rays[253,254] were used. The radiation polymerisation of acetylene in the liquid and solid phases has also been studied[208,210,255,256]. The possibility of formation of a polymer with regular structure has been noted (*trans*--configuration for irradiation of acetylene in the solid state):



trans-Polyacetylene is insoluble and is dark red. To explain the solid-phase polymerisation, the authors suggest an "electronic polymerisation" mechanism[257] (see Section 12 below). In the liquid phase, in the authors' opinion, the polymerisation takes place by a cationic mechanism with the formation of a *cis*-structure[256]:

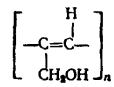


cis-Polyacetylene is soluble and brown.

Phenylacetylene polymerises under the influence of electrons (1.5 MeV) in an atmosphere of air and in a vacuum[258-262]. The value of G is low: 9 molecules per 100 eV. The number-average molecular weight of the polymer is 1100. Atmospheric oxygen accelerates the polymerisation and the yield increases by a factor of 1.5–2. Radiation poly(phenylacetylene)[260] is yellow--orange and soluble in acetone, benzene, esters, and carbon tetrachloride. It is insoluble in petroleum ether and alcohol. The purified product melts at 170–190°. Atmospheric oxygen does not influence the polymerisation of hex-1-yne and cyclohexylacetylene[259], unlike phenylacetylene.

The polymerisation of perfluorobut-2-yne (^{60}Co γ-radiation, dose rate 0.36 Mr h^{-1}, duration of irradiation 67 h) leads to the quantitative formation of a heat-resistant solid white polymer which is not attacked or even wetted by boiling concentrated sulphuric acid, concentrated nitric acid, or 50% sodium hydroxide solution. The polymer is

insoluble in ether, CCl_4, methanol, benzene, and other common solvents[263]. Thermographic analysis shows that its decomposition in nitrogen begins at 425° and that the point of 50% degradation is 75 deg higher than for poly(tetrafluoroethylene). The rate of polymerisation of prop-2-ynyl bromide and prop-2-ynyl alcohol is unaffected by the presence of air[261]. The prop-2-ynyl alcohol polymer is a dark red product with structural unit[208,210]:



Macromolecular products are obtained by the radiation polymerisation of 2,2-dimethyltrimethylene dipropiolate and acetylenedicarboxylic acid[264].

10. CARBONYL COMPOUNDS

Characteristic features of the radiation polymerisation of aldehydes involving opening of the C=O bonds are the very high rates and the consequent use of extremely small doses. According to a patent taken out by a Japanese firm, anhydrous formaldehyde, emulsified at -16° in n-hexane solution, polymerises under the influence of ^{60}Co γ-radiation at a dose rate of 900 r h^{-1}.[265] According to another patent[266], absolutely anhydrous liquid formaldehyde (m.p. -118°) at -30° and -100° and high dose rates of 10^2–10^8 r h^{-1} forms a polymer which is more stable than that obtained by ordinary polymerisation. Under the influence of γ-rays and X-rays, the polymerisation in the solid phase[267–269] develops satisfactorily at temperatures from -75° to -196° at very small doses (less than 2000 r); this requires extremely low-power sources. Explosive polymerisation was observed at lower temperatures. The values of G are exceptionally high and amount to 5.4×10^6 molecules per 10 eV; $[\eta]$ for the polymer is 3.5–4.0.[269] Comparison of the polymerisation of acetaldehyde in the liquid[270,271] and solid[270,272,273] phases showed that, as for formaldehyde, the process takes place readily in the solid phase and the product is a rubber-like polymer with high molecular weight (up to 1.5 million). In the liquid phase a polymer with M = 140 000–500 000 is formed. No post-effect is observed. In the solid phase the radiation polymerisation takes place by a mechanism involving propagation through the crystal lattice[272]. Radiation polyacetaldehyde is apparently as unstable as the polymer obtained by ordinary polymerisation. Propionaldehyde at -196°, at a dose of 0.57 Mr and a dose rate of 4750 r × × min^{-1} (X-rays) gives an elastomer (degree of conversion 3%) extremely similar to radiation polyacetaldehyde[267,270,271]. The polymerisation of acrolein[274–276] "in bulk" gives an extensively cross-linked (by polymerisation at the C=C and C=O bonds) vitreous polymer insoluble in aqueous sulphuric acid solution. The rate of polymerisation is increased in solutions, particularly aqueous solutions. The product is a polymer which is soluble in sulphuric acid and contains reactive aldehyde groups[274]. The same effect is achieved by polymerisation "in bulk" at -78°.[276] Radiation polymerisation in aqueous medium leads to the formation of a water-insoluble polymer[277]. The γ-irradiation of chloral at a dose rate of 0.068 r h^{-1} at low temperatures gives a colourless solid polymer[278].

The γ-irradiation of dimethylformamide with ^{60}Co at low temperatures gives a polymer in the form of a reddish orange oil, immiscible with water[279]. The polymerisation apparently involves opening of the C=O bonds.

Acetone has been polymerised in the solid phase at -136° and -196° under the influence of γ-radiation[280]. The yield of polymer is 0.1–1% and G amounts to 30–500 molecules per 100 eV. The polymer is a yellow unstable elastomer. Data obtained by infrared spectroscopy indicate the presence of polyether units (–O–C–O–). Chloroacetone and bromoacetone have also been polymerised in the solid phase[280]. For chloroacetone at -78°, G = 8.4 molecules per 100 eV. For bromoacetone under the same conditions, G = 470 molecules per 100 eV. The polymerisation of methyl vinyl ketone "in bulk" at temperatures from 22° to -78° takes place by a radical mechanism with monomolecular termination[281].

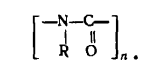
11. NITRILES OF SATURATED CARBOXYLIC ACIDS

Polymerisation of nitriles at the triple bond should give hetero-chain polymers with a conjugated system of bonds

These polymers have a high heat-resistance and semiconductor properties[282]. The radiation polymerisation of acetonitrile[208,261,283] takes place by an anionic mechanism, as established by comparison of radiation polyacetonitrile with polymers obtained using cationic and anionic catalysts and by radical polymerisation. The polymers (dark brown adhesive or elastic products) are formed with low values of G (10–50 molecules per 100 eV). The degree of polymerisation is also low (~10–50). The acetonitrile polymer is soluble in the monomer and in dimethylformamide. The infrared spectrum of radiation polyacetonitrile indicates the presence of C=N–C=N and N=C=N bonds. According to data given in a patent[284], G for the polymerisation of acetonitrile at a dose of ~4.35 Mr and a dose rate of 0.0195 Mr h^{-1} has the values (molecules per 100 eV) 8.4 and 12.6 at 20° and -78° respectively. The radiation polymerisation of propionitrile, isobutyronitrile[208,283], and n-butyronitrile[208] in the solid phase has been observed. Experiments with the addition of ethylene showed that it acts as a sensitiser[208]. The results of the radiation polymerisation of propionitrile, butyronitrile, and benzonitrile in the liquid and solid phases[284] are analogous to the results obtained in the polymerisation of acetonitrile.

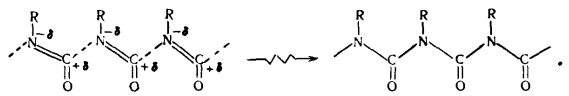
12. ISOCYANATES

It is suggested that in the radiation polymerisation of isocyanates[285,286], as in the case of "material" initiation, the polymers are formed by opening of the N=C bonds with units:



Methyl and phenyl isocyanates in the liquid and solid phases give amorphous polymers[286]. Polymethyl isocyanate is a white solid, melting with decomposition at 210°.[285] Butyl isocyanate forms an amorphous polymer in the liquid phase and a crystalline stereoregular polymer at low temperature in the solid phase[286]. The rate of polymerisation is much higher in the solid phase

than in the liquid phase. It is assumed that at low temperature with radiation initiation, stereospecific polymerisation takes place, as happens under analogous conditions for acrylonitrile, methacrylonitrile[208], and acetylene[208,255]. The process takes place by an anionic mechanism in the liquid phase. To explain the process taking place in the solid phase, the authors introduce the so-called "electronic" mechanism of polymerisation, with the assumption that here the process is neither ionic nor radical[286]. These ideas are essentially based on the concept previously put forward in principle by Semenov[287]. The Japanese authors emphasise the importance of the electronic state of the crystal as a whole at low temperature, pointing out the strong electronic interaction between the molecules of the monomer in the crystalline state:



From this examination of the electronic state, in the authors' opinion, it follows that the monomer in the crystal at low temperature is present in an excited state produced by the strong collective interaction. Under the influence of ionising radiation the ordered molecules give corresponding macromolecular compounds.

13. CYCLIC MONOMERS

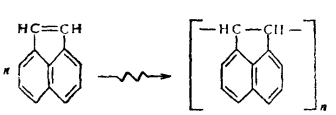
The polymerisation of this group of monomers is brought about either by opening of the ring or at an unsaturated bond in the ring.

Among the carbocyclic compounds, the aromatic hydrocarbons and acenaphthylene are noteworthy. The formation of polymers by the irradiation of benzene has been noted[288-291]. The value of G for the polymerisation is negligibly small (0.76 [288] or 0.91 [290]). The polymeric products are unsaturated yellow oils with M = 250–530. It has been suggested that the polymers are formed by opening of the benzene ring when benzene is irradiated in the liquid and solid phases[210,280]:

$$-CH=CH-CH=CH-CH=CH- \quad [210, 280].$$

As for benzene, irradiation of toluene produces a polymer with low radiation yield (0.92 molecules per 100 eV)[288]. The formation of a *p*-xylene polymer on irradiation in a reactor (yield 8%) has been noted[291]. Polynuclear aromatic hydrocarbons (biphenyl, terphenyl, etc.) are extremely stable to radiation and on prolonged irradiation form only traces of polymers[292]. Their stability to radiation increases and their tendency to polymerise decreases with increase in the number of aromatic rings in the molecule.

The polymerisation of acenaphthylene takes place under the influence of X-rays in the solid phase in an atmosphere of air or nitrogen and in a vacuum[293]:

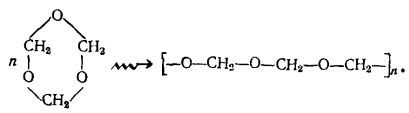


For irradiation in the liquid phase at 125° with a dose of 1.6 Mr the yield is 51.7%. The polymer is a white or yellow solid amorphous product with molecular weight 606 000. Thermal analysis shows no change in the polymer on heating in an atmosphere of air or nitrogen to 350°.

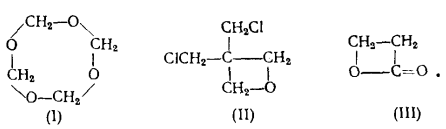
Study of the radiation polymerisation of heterocyclic compounds, particularly in the solid phase, has led to important results.

Sylvan (2-methylfuran) is relatively stable to radiation because of its conjugated system of double bonds: the pure monomer is not polymerised even at doses of 25 Mr.[294] The addition of 30–40 rel.% CCl_4 or $CHCl_3$ at doses above 5 Mr leads to the formation of resinous products (yield 70–80 wt.%) which are soluble in acetone and give lacquer coatings[294]. The formation of a polymer from furfuryl alcohol under the influence of ^{60}Co γ-rays has been reported[295].

Trioxan (m.p. 62°) polymerises readily in the solid state under the influence of γ-radiation or electrons with the formation of poly(oxymethylene)[296-302]:



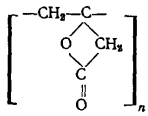
At a dose of 0.44 Mr for polymerisation in the liquid phase at 80° the yield of polymer is ~ 1%, whereas in the solid phase it increases to 16% at 50° and to 22% at 55°.[19] The degree of conversion of the monomer increases when it is subjected to high pressure before irradiation[302]. The polymerisation takes place more readily in large single crystals than in fine crystals[296] and the polymers have a higher melting point (198° and 186° respectively)[303]. The post-polymerisation has been noted and studied[302,304-306]. Radiation poly(oxymethylene) prepared from trioxan has a higher melting point and better heat resistance than the polymer from formaldehyde[297]. Microscope studies show that this product, like the radiation polymers from 3,3-bischloromethyloxacyclobutane, β-propiolactone, and diketen described below, can be obtained in the form of fibres. The sulphur-containing analogue of trioxan — trithian — forms polythioformaldehyde under the influence of γ-radiation at room temperature at doses up to 10 Mrad with subsequent heating at 180° (35 deg below the melting point of trithian)[307-309]. Tetraoxan (tetraoxymethylene) (I) (m.p. 120°) in the form of single crystals was exposed to ^{60}Co γ-radiation at a dose of 0.45 Mr at 80° and gave poly(oxymethylene) in 94% yield[310,311].



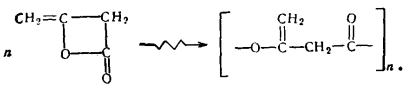
(I) (II) (III)

3,3-Bischloromethyloxacyclobutane (3,3-bischloromethyloxetan) (II) — the monomer of "Penton" — forms a polymer with linear structure[296,297,312]. The yield is greater from a large single crystal than from fine crystals[296,297]. Post-polymerisation has been noted[304,312]. The monomer polymerises only in the solid state (from 16° to -78°). The melting point of the polymer is 171–176°, that is 8–10 deg higher than for polymerisation with BF_3.[313] The solid-phase polymerisation of 3,3-bisbromomethyloxacyclobutane and 3,3-bisiodomethyloxacyclobutane has also been studied. The chlorine-containing monomer is the most reactive and the reactivity of the iodine derivative is very low (Cl > Br ≫ I).[314]

Of the lactones, β-propiolactone (III) polymerises in the solid phase with opening of the ring under the influence of γ-rays and electrons. The yield at -78°, a dose of 143 000 r, and a dose rate of 9000 r h^{-1} is 13.2% from a large single crystal and 10.9% from fine crystals[296,297]. Data characterising the kinetics of polymerisation indicate an ionic mechanism[315]. The polymer obtained from single crystals shows a high orientation of the crystalline regions[303,310]; its crystallinity and melting point are higher than those of the polymer obtained by ordinary polymerisation with ionic catalysts. With chemical initiation, diketen is capable of polymerising either at the $CH_2=C<$ bond in the case of radical initiation with the formation of a polymer of the vinyl type



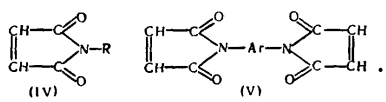
or with opening of the ring under the influence of ionic catalysts with the formation of polymeric products of the ester type. In radiation polymerisation in the solid state, a polymer of the polyester type is formed[296,297]:



The radiation polymer has a higher melting point and better crystallinity than the polymers obtained using ionic catalysts[297].

Maleic anhydride polymerises under the influence of ^{60}Co γ-radiation "in bulk" and in solution in benzene and acetic anhydride. In the latter at a dose of 40 Mr and a dose rate of 0.195 Mr h^{-1} the degree of conversion reaches 90%.[27] The polymerisation apparently involves opening of the double carbon–carbon bond in the ring.

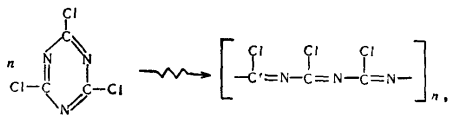
The imides of maleic acid (maleimides) polymerise readily in the solid phase. Studies have been made of the polymerisation, under the influence of ^{60}Co γ-radiation, of various *N*-substituted monomaleimides (IV) and dimaleimides (V):



(IV) (V)

N-phenylmaleimide[316–320], *N*-*p*-tolylmaleimide, *N*-2,4-dimethylphenylmaleimide, *N*-benzylmaleimide[320], *N*-carbamylmaleimide[320,321], *NN'*-*p*-phenylenedimaleimide, and *NN'*-4,4'-biphenylylenedimaleimide[322,323]. The degree of conversion is high close to the melting point of the monomers, for example up to 95% at a dose of up to 3 Mrad for *N*-*p*-tolylmaleimide[320]. The solid-phase polymerisation at 20° is sensitised by solid trichloroacetic acid[318–320] and liquid trifluoroacetic acid[320]. The monomaleimides form soluble polymers[316–321] with softening temperatures from 168° for *N*-benzylmaleimide to 330° for *N*-2,4-dimethylphenylmaleimide[320]. Polymerisation takes place at the C=C bonds with preservation of the imide rings in the chain[318–320]. The dimaleimides form heat-resistant insoluble polymers[322,323].

The triazine derivative cyanuric chloride (the chloride of cyanuric acid), a crystalline substance with m.p. 154°,



is polymerised in the solid phase under the influence of γ-radiation[324]. The yield of polymer is 70% at 16°, a dose rate of 0.03 Mr h^{-1}, and a dose of 14 Mr. Opening of the triazine ring was confirmed by infrared spectroscopy. The polymer is soluble in dimethylformamide and does not melt below 260°.

Of the heterocyclic spiro-compounds, dioxaspiro-[3,3]heptane has been studied. It polymerises in the solid phase with the formation of an amorphous, insoluble, and infusible polymer, but the rate of polymerisation is lower than in the case of trioxan and 3,3-bischloromethyloxetane. Air sensitises the polymerisation under the beam and the post-effect[325].

14. ORGANOELEMENTAL MONOMERS

These monomers can in turn be divided into cyclic, vinyl, and allyl monomers. The formation of the macromolecular chains is here analogous to that for the corresponding groups of monomers previously examined.

Hexamethylcyclotrisiloxane polymerises in the solid phase under the influence of fast electrons (800 keV)[326] or ^{60}Co γ-radiation[327] by different mechanisms corresponding to its two crystalline modifications[328]. The polymerisation product at doses below 0.5 Mr, a dose rate of 0.05–0.25 Mr h^{-1}, and a temperature of 40° is a soluble polymer, whose infrared spectrum is analogous to that of linear polysiloxane[327]. It is suggested that the polymerisation takes place with opening of the ring according to an ionic mechanism, since this monomer is not polymerised with radical initiators[327]. The post-polymerisation has been studied[306]. Octamethylcyclotetrasiloxane polymerises in a very narrow temperature range in the solid phase close to the melting point of the monomer[329,330]. Heptamethylvinylcyclotetrasiloxane is polymerised in the liquid and solid phases. The polymerisation in the latter takes place at the vinyl groups to give fibrous polymers soluble in benzene[331]. The radiation polymerisation of allyldiethylsilane, allylethylphenylsilane, allyldiphenylsilane, diallylethylsilane, and triallylsilane has been studied[332,333]. The ease of polymerisation increases in the order given, due to the increase in the number of allyl groups and in the monoallylsilanes the activity of the monomers increases with the introduction of phenyl groups into the molecules. The polymerisation takes place at the double bond of the allyl group by a radical mechanism. Di- and tri-allylsilanes form cross-linked products by polymerisation "in bulk"; polymerisation of diallylsilanes in 20% benzene solution gives soluble polymers[334]. The latter are also obtained from the divinyl-derivatives[335,336] and trivinyl-derivatives[336,337].

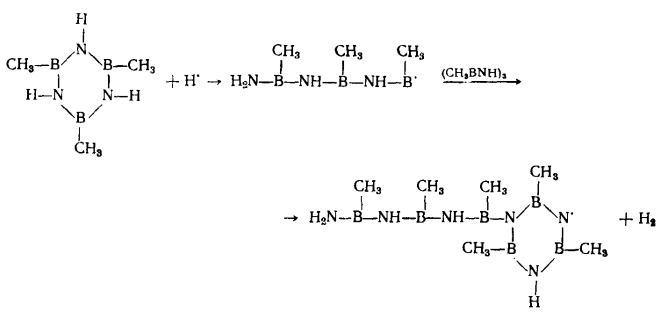
The radiation polymerisation of diethylvinylphosphine oxide and diphenylvinylphosphine oxide gives polymers with molecular weight 30 000–60 000 in

80–90% yield[338–340]. The molecular weight of the polymers obtained from these monomers by usual polymerisation methods does not exceed 3000–4000.

The study of the solid-phase polymerisation of the two polymorphic modifications of tributylvinylphosphonium bromide is of interest[341]. Under the influence of X-rays at temperatures from 30° to -80° and a dose rate of 0.28 Mrad h^{-1}, the radiation yield for 50% conversion varied in the range (molecules of monomer per 100 eV) 1147–9872, depending on temperature. An unusual effect was shown by atmospheric oxygen, which inhibits the polymerisation at 30° and -80° but sensitises the polymerisation at 0°. The polymer is amorphous, soluble in water, and hygroscopic. Its weight-average molecular weight is 50 000–96 000, glass point 5–16°, and heat resistance 340–396° (in air) or 396–411° (in nitrogen). Tributylvinylphosphonium iodide also polymerises in the solid phase under the influence of X-rays[342].

The radiation polymerisation of vinylsulphonamide has been studied in the liquid and solid phases[343,344]. The process is extremely rapid: at a dose rate of 0.25 Mr h^{-1} and 22° the rate of conversion of the monomer amounts to 75% h^{-1}, whereas for other monomers the rate is 1–17% h^{-1}.

Among the organoboron monomers, the polymerisation of the borazoles has been studied. *BB'B"*-Trimethylborazole was irradiated in an electron accelerator (800 keV) and in an X-ray apparatus (800 kV, 200 mA)[345]. The polymer is a transparent resin with a low degree of polymerisation, readily soluble in benzene. A scheme of polymer formation by a radical mechanism has been proposed. The authors assume the formation of linear macromolecules from borazole rings and in some instances opening of the rings to form linear units, which may alternate with the rings in the chain:



BB'B"-Triphenylborazole and *BB'B"*-triphenyl-*NN'N"*-trimethylborazole (the latter on irradiation in the solid phase) form polymers which are insoluble in benzene but soluble in cresol. The polymers are brown powders which do not melt up to 300°.[345] Analogous polymerisation is undergone by the phosphorus-containing analogue of borazole — the cyclic dimethylphosphineborine trimer. The molecular weight of the polymer is 5200.[346]

15. INORGANIC MONOMERS

The polymer of dichlorophosphazene or so-called "inorganic rubber" has high heat resistance. With irradiation by electrons (4 MeV) the cyclic oligomers of dichlorophosphazene are more stable; the oligomers with an open chain polymerise more readily[347]. The polymerisation of the trimer has been described; in an electron accelerator (1–1.2 MeV) in an atmosphere of air at 130° the trimer can be completely polymerised to a sticky rubber-like mass containing a trace of the tetramer[348]. In the polymerisation of dichlorophosphazene in the solid phase at 100° under the influence of X-rays (dose rate 1.2 Mr h^{-1}) a degree of conversion of 10% is reached in 40 h.[349] The tetramer does not polymerise under the influence of γ-radiation either in the solid or in the liquid phase[350]. On irradiation of the trimer in the solid phase the rate of polymerisation increases with increase in temperature to the melting point but above this temperature it decreases to almost zero[350]. In the polymerisation of dicyan (cyanogen) $(CN)_2$ from the gaseous phase, it was found that argon, krypton[253], and xenon[253,351] have a sensitising influence. Analogous studies were carried out with hydrogen cyanide[253]. A carbon disulphide polymer was previously obtained by thermal polymerisation at 185° and a pressure of about 55 000 atm[352]. Infrared spectroscopy indicated that the solid black polymer had the microstructure

The action of ^{60}Co γ-radiation gives a brown product at a pressure of 1 atm and a black product at high pressures (up to 15 000 atm). The polymer is insoluble in the monomer but swells in it. The yields of polymer are very low. The maximum yield of 4.1% (G = 1.5) was obtained at a dose of 400 Mr, a dose rate of 3.2 Mr h^{-1}, a temperature of 98° and a pressure of 10 000 atm.[120,352] It is reported that carbon monoxide forms a polymer under the influence of ionising radiation[34].

6. New dehydrogenation reactions 71

1. INTRODUCTION

The annual world production of buta-1,3-diene (divinyl), the most important monomer for the synthesis of many types of rubber, has long exceeded one million tons; the greater part of the butadiene is at present obtained by the catalytic dehydrogenation of n-butane and n-butene[1].

As a result of studies of the catalytic dehydrogenation of butane and butene, begun as early as the nineteen-thirties in the USSR and other countries, large factories were constructed in the USA during the Second World War for the production of butadiene by the single-stage dehydrogenation of butane in a vacuum, by the dehydrogenation of butene in the presence of water vapour†, and also by the two-stage dehydrogenation of butane according to the scheme: butane → butene → butadiene[1]. In the post-war years, several synthetic rubber factories were constructed in the USSR for the production of butadiene by the two-stage dehydrogenation of butane.

Because of their great practical importance, the dehydrogenation processes have been studied for many years in this country and abroad. The aim of studies of the dehydrogenation reactions is not limited to the solution of applied problems, however; the results of these studies have made an important contribution to the theory of heterogeneous catalysis. In particular, Balandin's multiplet theory of catalysis was developed in a study of the mechanism and kinetics of dehydrogenation reactions.

The number of papers devoted to the study of the dehydrogenation of hydrocarbons amounts to several hundred. The most detailed reviews are those of Kearby[2] and Lyubarskii[3]; the first of these covers the literature up to 1953, gives the equilibrium degrees of dehydrogenation at different temperatures, and describes industrial catalysts and methods of dehydrogenation; the second covers the literature up to 1957, describes in considerable detail the results of the development of catalysts for the dehydrogenation of alkanes, and gives data on the rate of dehydrogenation of butane, butene, and isopentane, obtained in the Karpov Physicochemical Institute.

The aim of the present paper is to review the accumulated material on the chemistry of the reactions taking place in the catalytic dehydrogenation of butane and butene, and on the equilibria and kinetics of these reactions.

2. REACTIONS TAKING PLACE IN THE DEHYDROGENATION OF BUTANE AND BUTENE

In the catalytic dehydrogenation, many side reactions take place in addition to the main reactions involving the conversion of butane into butene and of butene into butadiene[4-6].

1. The main reactions are evidently:

$$n\text{-}C_4H_{10} \rightleftharpoons CH_3.CH_2.CH{=}CH_2 + H_2, \quad (1a)$$

$$n\text{-}C_4H_{10} \rightleftharpoons cis\text{-}MeCH{=}CHMe + H_2, \quad (1b)$$

$$n\text{-}C_4H_{10} \rightleftharpoons trans\text{-}MeCH{=}CHMe + H_2, \quad (1c)$$

or, overall,

$$n\text{-}C_4H_{10} \rightleftarrows n\text{-}C_4H_8 + H_2, \quad (1)$$

where $n\text{-}C_4H_8$ represents the equilibrium mixture of n-butene isomers;

$$EtCH{=}CH_2 \rightleftharpoons C_4H_6 + H_2, \quad (2a)$$

$$cis\text{-}MeCH{=}CHMe \rightleftharpoons C_4H_6 + H_2, \quad (2b)$$

$$trans\text{-}MeCH{=}CHMe \rightleftharpoons C_4H_6 + H_2, \quad (2c)$$

or, overall,

$$n\text{-}C_4H_8 \rightleftarrows C_4H_6 + H_2. \quad (2)$$

Let us now examine the side reactions.

2. The cracking of $n\text{-}C_4H_{10}$ in general cannot be described by a single stoichiometric equation, since the stoichiometric coefficients (and possibly even the composition of the reaction products) may depend on the temperature, degree of decomposition, and type of catalyst; these problems have been little discussed in the literature, however. It is stated[7] that the thermal cracking of $n\text{-}C_4H_{10}$ at 520°C and a degree of transformation up to 25% is described by the following reactions, which can be regarded as primary reactions:

$$15\ n\text{-}C_4H_{10} \rightarrow 10\ C_3H_6 + 10\ CH_4, \quad (3a)$$

$$\rightarrow 4\ C_2H_4 + 4\ C_2H_6, \quad (3b)$$

$$\rightarrow n\text{-}C_4H_8 + H_2, \quad (3c)$$

(that is, $15n\text{-}C_4H_{10} \rightarrow 10C_3H_6 + 10CH_4 + 4C_2H_4 + 4C_2H_6 + n\text{-}C_4H_8 + H_2$).

3. The cracking of $n\text{-}C_4H_{10}$ during its catalytic dehydrogenation to butene on one of the catalysts[5] takes place according to the equation

$$n\text{-}C_4H_{10} \rightarrow 0.12H_2 + 0.49CH_4 + 0.39C_2H_4 + 0.38C_2H_6 + 0.49C_3H_6 + 0.01C_3H_8 + 0.12C_4H_8, \quad (3d)$$

but on the catalyst used in the USSR it is described approximately by the equation[6]

$$n\text{-}C_4H_{10} \rightarrow 0.62CH_4 + 0.13C_2H_4 + 0.44C_2H_6 + 0.04C_3H_6 + 0.2C_3H_8 + 0.3(C_5+). \quad (3e)$$

† The use of water vapour achieves three results: the partial pressure of $n\text{-}C_4H_8$ is reduced, displacing the equilibrium towards the formation of C_4H_6, the necessary heat is supplied, and the deposited "carbon" is removed.

4. The cracking of $n\text{-}C_4H_8$. A characteristic feature of the primary reactions involved in the thermal cracking of $n\text{-}C_4H_8$ is their much greater variety. Analysis of published data[8-14] indicates that at temperatures up to 600°C and small degrees of transformation in the thermal decomposition of but-1-ene and but-2-ene, the products are H_2, CH_4, C_2H_4, C_2H_6, C_3H_6, C_3H_8, C_4H_6, and liquid hydrocarbons. The highest thermal stability is shown by but-2-ene.[13] The following can be regarded as the primary reactions in the thermal decomposition of $n\text{-}C_4H_8$:

$$n\text{-}C_4H_8 \rightleftarrows C_4H_6 + H_2, \quad (4a)$$
$$n\text{-}C_4H_8 + H_2 \rightarrow C_2H_4 + C_2H_6, \quad (4b)$$
$$n\text{-}C_4H_8 \rightarrow 2\,C_2H_4, \quad (4c)$$
$$n\text{-}C_4H_8 + H_2 \rightarrow CH_4 + C_3H_6, \quad (4d)$$
$$3n\text{-}C_4H_8 \rightarrow CH_4 + C_3H_6 + C_8H_{14}. \quad (4e)$$

The greater part of the $n\text{-}C_4H_8$ decomposes according to reaction (4d). It is suggested[5] that the cracking of $n\text{-}C_4H_8$ in its dehydrogenation on one of the catalysts (in the presence of water vapour) takes place according to the equation

$$n\text{-}C_4H_8 \rightarrow 0.25H_2 + 0.27CH_4 + 0.15C_2H_4 + 0.31C_3H_6 + 0.5C_4H_6 + 0.08 + 0.08(C_5+) + 0.1C. \quad (4)$$

5. Transformation of butadiene. The main reaction of C_4H_6 at 400–700°C and atmospheric pressure is its dimerisation[15] and this reaction is apparently the primary reaction:

$$2\,C_4H_6 \rightleftarrows C_8H_{12}. \quad (5a)$$

In the presence of dehydrogenation catalysts, this reaction is accompanied by the decomposition of butadiene (or its dimer) with the formation of lighter hydrocarbons and carbonaceous deposits ("carbon"); the following equations were found for two different catalysts for the dehydrogenation of $n\text{-}C_4H_8$:

According to the data of Beckberger and Watson[5]

$$C_4H_6 \rightarrow 0.56CH_4 + 0.07C_2H_4 + 0.58C_3H_6 + 1.49C, \quad (5b)$$

according to our data[16]

$$C_4H_6 \rightarrow 0.098CH_4 + 0.024C_2H_4 + 0.017C_3H_6 + 0.68C_4H_8 + 1.08C. \quad (5c)$$

The last equation was obtained[16] on the basis of the composition of the products of the decomposition of C_4H_6 on passage over a catalyst at 560–600°C and molar ratio $C_4H_6 : H_2O = 1 : 10–1 : 30$.

6. Isomerisation of $n\text{-}C_4H_{10}$ and $n\text{-}C_4H_8$. The following reactions are observed in the catalytic dehydrogenation

$$n\text{-}C_4H_{10} \rightleftharpoons iso\text{-}C_4H_{10}, \quad (6a)$$
$$n\text{-}C_4H_8 \rightleftharpoons iso\text{-}C_4H_8. \quad (6b)$$

7. Reactions of water vapour. In the dehydrogenation of butene in the presence of water vapour (the usual industrial conditions) the "carbon" formed on the catalyst — for example, according to reactions (5b) or (5c) — reacts with water vapour. It is assumed[17] that the following reactions take place in the interaction between water vapour and carbon (in particular during its gasification):

$$C + H_2O \rightleftarrows CO + H_2, \quad (7a)$$
$$C + 2H_2O \rightleftarrows CO_2 + H_2, \quad (7b)$$
$$CO_2 + H_2 \rightleftarrows CO + H_2O, \quad (7c)$$
$$C + 2H_2 \rightarrow CH_4, \quad (7d)$$

and a number of others. Two generally similar equations have been given for the reaction of water vapour with "carbon" deposited in the catalytic dehydrogenation of $n\text{-}C_4H_8$; one of these is[5]

$$H_2O + 0.512C \rightarrow 0.488CO_2 + 0.024CO + H_2, \quad (7e)$$

and the other is[16]

$$H_2O + 0.5068C \rightarrow 0.4931CO_2 + 0.0137CO + H_2. \quad (7f)$$

8. Reduction of the oxides of the catalyst. As shown below, many of the catalysts used in industry for the dehydrogenation of butane and butene contain the oxides of metals with variable valency — chromium and iron. The higher-valency oxides formed during their regeneration, that is, in the high-temperature calcination in a current of oxygen-containing gas, are converted into lower-valency oxides during the dehydrogenation in a reducing medium. For example[18],

$$CrO_3 \xrightarrow{C_nH_m} Cr_2O_3 + H_2O + CO_2 + CO,$$

and similarly for iron oxide

$$Fe_2O_3 \xrightarrow{C_nH_m} Fe_3O_4 \rightarrow FeO + H_2O + CO_2 + CO$$

Reduction may also be brought about by the hydrogen formed in the dehydrogenation, but analysis of the products[18,19] indicates that, for example, the CrO_3 in the aluminium–chromium catalyst is reduced chiefly by hydrocarbons. Other views have been put forward regarding the chemistry of the reduction of aluminium–chromium catalysts (with added potassium oxide); for example, it is suggested[20] that K_2CrO_4 is formed in the regeneration and that the following reaction takes place during dehydrogenation

$$2\,K_2CrO_4 + 2\,Al_2O_3 \xrightarrow{H_2} 4\,AlOOK + Cr_2O_3 + H_2O.$$

9. Reactions during the regeneration of the catalysts. The chief reactions in the regeneration of dehydrogenation catalysts are the combustion of the carbonaceous deposits and the change of the oxides of the catalysts from a lower valency to a higher valency. In particular, it has been shown[18,21-25] that in the regeneration of chromium and aluminium–chromium catalysts, Cr_2O_3 is converted into CrO_3; in addition, solid solutions of oxygen in chromium oxide may be formed.

10. Reactions leading to the formation of carbonaceous deposits. Important reactions in the dehydrogenation of butane and butene are those leading to the formation of carbonaceous deposits, which contain an appreciable quantity of hydrogen in addition to carbon[26] and which would be more correctly called tarry deposits. There are grounds for assuming[6,26-28] (the nature of the change in the composition of the carbonaceous deposits with change in the dehydrogenation conditions, and the formation of benzene, toluene, styrene, and other aromatic and cyclic hydrocarbons as side-products) that the so-called "carbon" deposited on the catalyst is formed not according to reactions (5b) or (5c) but according to the scheme:

$2C_4H_6 \rightarrow$ (vinylcyclohexene) $\rightarrow$ ... (polycondensation, dehydrogenation, cracking) ... $\rightarrow$ polycyclic hydrocarbons $\rightarrow$ ("tars" or "carbons").

11. Other reactions. The above list does not exhaust all the reactions taking place in the dehydrogenation of butane and butene, but these are the most important[6]. Other reactions which evidently take place in the dehydrogenation of n-C_4H_{10} and n-C_4H_8 are the dehydrogenation of the iso-C_4H_{10} formed by the isomerisation of n-C_4H_{10}, and the cracking of iso-C_4H_{10} and iso-C_4H_8, but the part played by these reactions is slight.

3. REACTION EQUILIBRIA

The equilibrium constant for the chemical reaction is calculated from the familiar equation

$$RT\ln K_{pT} = -\Delta G^\circ_T = -\Delta H^\circ_T + T\Delta S^\circ_T,$$

and the degree of transformation x is related to K_p by an equation which depends on the form of the stoichiometric equation for the reaction. Methods for calculating the thermodynamic quantities and their values at different temperatures have been described in a number of familiar works[29-32], so that here we shall give for most reactions only the final equations for calculating the values of $\log K_p$ and the necessary data confirming the applicability of these equations; for some reactions we shall give the most reliable tabulated data.

1. The reaction n-$C_4H_{10} \rightleftarrows$ n-$C_4H_8 + H_2$. The experimental and calculated data on the equilibrium for the dehydrogenation reaction have been reviewed[29].

Comparison of the values of K_p and x calculated on the one hand[2,6] from the latest and now generally accepted thermodynamic data, and on the other hand[6] from the empirical equations proposed by various authors, shows that the most satisfactory equations are those of Korobov and Frost[33]:

$$\begin{aligned}\log K_{p_1-a} &= \frac{-6586}{T} + 6.685,\\ \log K_{p_1-b} &= \frac{-6209}{T} + 6.639,\\ \log K_{p_1-c} &= \frac{-5992}{T} + 6.112.\end{aligned} \qquad (1)$$

The equilibrium constant for the overall reaction (1) is:

$$K_{p_1} = K_{p_1-a} + K_{p_1-b} + K_{p_1-c},$$

and the degree of transformation is

$$x_1 = \left(\frac{K_{p_1}}{K_{p_1} + P_{total}}\right)^{0.5}.$$

In the range 760–900°K, more accurate values of K_{p_1} are obtained from the equation[6]:

$$\log K_{p_1} = \frac{-30\,500}{4.575T} + 7.574. \qquad (2)$$

The values of K_p and x_1 calculated from Eqns. (1) and (2) are compared in Table 1 with the calculated values obtained[2] from thermodynamic data[32].

When side reactions take place simultaneously, the equilibrium degrees of dehydrogenation will differ from the values given in Table 1. When only the reaction $C_4H_{10} \rightleftarrows C_4H_8 + H_2$ takes place and the degree of dehydrogenation is x_1, the partial pressures of the components are:

$$P_{C_4H_{10}} = \frac{1-x_1}{1+x_1}P_{total}, \qquad P_{C_4H_8} = P_{H_2} = \frac{x}{1+x}P_{total}.$$

TABLE 1. Equilibrium constants and equilibrium extents to which reaction (1) takes place at $P_{total} = 1$ atm.

T, °K	According to Eqn. (1)		According to Eqn. (2)		Calculations from thermodynamic data (Ref. 32)	
	K_{p_1}	x_1	K_{p_1}	x_1	K_{p_1}	x_1
760	0.0563	0.231	0.057	0.23	0.063	0.235
780	0.0945	0.296	0.106	0.31	0.105	0.309
800	0.1454	0.356	1.179	0.39	0.174	0.389
820	0.2258	0.433	0.282	0.47	0.282	0.47
840	0.3403	0.504	0.429	0.55	0.429	0.55
860	0.5069	0.580	0.667	0.63	0.667	0.63
880	0.7407	0.652	1.00	0.71	1.00	0.71
900	1.063	0.720	1.630	0.79	1.480	0.78

Substituting these values in the equation $K_{p_1} = \frac{P_{C_4H_8}P_{H_2}}{P_{C_4H_{10}}}$, we obtain

$$x_1 = \left(\frac{K_{p_1}}{K_{p_1} + P_{total}}\right)^{0.5}.$$

When side-reactions take place, the total number of reaction products is not $1 + x_1$ but α_1; since some of the n-C_4H_8 formed is used up in secondary reactions, the number of moles of n-C_4H_8 becomes equal to $x_1\gamma_1$ (where γ_1 is the selectivity of the dehydrogenation), and the quantity of hydrogen increases to $x_1\gamma_1\beta_1$, where β_1 is a coefficient for the excess of hydrogen, equal to $P_{H_2}/P_{C_4H_8}$. Substituting these values in the equation for the equilibrium constant, we obtain

$$x_1 = \frac{-K_{p_1}\alpha_1 + \sqrt{K_{p_1}\alpha_1(4\gamma_1^2\beta_1 P_{total} + K_{p_1}\alpha_1)}}{2\gamma_1^2\beta_1 P_{total}}.$$

2. The reaction n-$C_4H_8 \rightleftarrows C_4H_6 + H_2$. Fairly accurate values of K_{p_2} and x_2 can be found from the equations[5]

$$\log K_{p_2} = \frac{-28\,000}{4.575T} + 5.70121, \qquad (3)$$

or[6]

$$\log K_{p_2} = \frac{-30\,500}{4.575T} + 6.33, \qquad (4)$$

as can be seen from Table 2, which gives the values of K_{p_2} and x_2, calculated[6] from these equations and found[2] from thermodynamic data[32].

The equation giving the dependence of x on K_p shows that with decrease in the total pressure (on dilution with an inert gas) the equilibrium degrees of dehydrogenation of butane and butene increase; the influence of reduced pressure is shown below for reaction (2):

	$P = 1$ atm						
T, °K	800	820	840	860	880	900	920
x_2	0.10	0.127	0.158	0.194	0.234	0.28	0.329
	$P = 0.1$ atm						
x_2	0.304	0.375	0.45	0.53	0.608	0.678	0.74
	$P = 0.05$ atm						
x_2	0.41	0.496	0.582	0.663	0.734	0.793	0.84

TABLE 2. Equilibrium constants and equilibrium extents to which reaction (2) takes place at P_{total} = 1 atm.

T, °K	According to Eqn. (3)		According to Eqn. (4)		Calculations (Ref. 2) according to published data (Ref. 32)

The equilibrium degree of dehydrogenation with allowance for side-reactions‡ is here equal to[6]:

$$x_2 = \frac{-K_{p_2}(\lambda+\alpha_2)+\sqrt{K_{p_2}^2(\lambda+\alpha_2)^2+4K_{p_2}(\lambda+\alpha_2)(P_{total}\gamma_2^2\beta_2)}}{2\gamma_2^2\beta_2 P_{total}}.$$

Equilibrium for the Dehydrogenation of Butane-Butene Mixtures. In the single-stage method for the preparation of butadiene, a butane–butene mixture is dehydrogenated (at reduced pressure). The term "single-stage" is a technological description (the process takes place in a single reaction vessel and only n-C_4H_{10} is used up), but in actual fact the reaction takes place[34] according to the scheme

$$\text{n-}C_4H_{10} \rightarrow \text{n-}C_4H_8 \rightarrow C_4H_6.$$

The equilibrium degrees of dehydrogenation of a n-C_4H_{10} + n-C_4H_8 mixture in the presence of an inert diluent were first calculated by Bogdanov[35]. The calculation of the equilibrium composition in the dehydrogenation of n-C_4H_{10} + n-C_4H_8 at reduced pressure can be approached as follows[6]. Let us assume that n-C_5H_{10} : n-C_4H_8 = m : n and that $m + n = 1$. Let y_1 and y_2 be the numbers of moles of n-C_4H_8 and C_4H_6 formed. The equilibrium mixture will then contain the following numbers of moles:

$$\text{n-}C_4H_{10} = m - y_1;\ \text{n-}C_4H_8 = n + y_1 - y_2;\ C_4H_6 = y_2;\ H_2 = y_1 + y_2,$$

and a total of $1 + y_1 + y_2$ moles.

The partial pressures are

$$P_{C_4H_{10}} = \frac{m-y_1}{1+y_1+y_2}P_{total};\quad P_{C_4H_8} = \frac{n+y_1-y_2}{1+y_1+y_2}P_{total};$$

$$P_{C_4H_6} = \frac{y_2}{1+y_1+y_2}P_{total};\quad P_{H_2} = \frac{y_1+y_2}{1+y_1+y_2}P_{total}.$$

‡ $\lambda = H_2O/C_4H_8$ mole mole^{-1}.

The equilibrium constant for the reaction

$$\text{n-}C_4H_{10} \rightleftharpoons \text{n-}C_4H_8 + H_2,$$

is

$$K_{p_1} = \frac{(n+y_1-y_2)(y_1+y_2)}{(1+y_1+y_2)(m-y_1)}P_{total},$$

and the equilibrium constant for the reaction

$$\text{n-}C_4H_8 \rightleftarrows C_4H_6 + H_2,$$

is

$$K_{p_2} = \frac{(y_1+y_2)y_2}{(1+y_1+y_2)(n+y_1-y_2)}P_{total}.$$

Dividing the first equation by the second and introducing the symbols $\frac{n+y_1}{y_2} = a$ and $\frac{1}{y_2} = b$, we obtain

$$b = \frac{(1+a)P_{total}-K_{p_2}(a^2-1)}{K_{p_2}m(a-1)+nP_{total}}, \quad (5)$$

$$b = \frac{K_{p_2}(a-1)^2}{K_{p_1}} + a. \quad (6)$$

This system can be solved graphically. For this purpose, Eqn. (6) is used to construct curves giving the dependence of b on a for different temperatures; points are plotted on the resulting graph in accordance with Eqn. (5) (separately for each temperature and pressure). The equilibrium compositions calculated[6] in this way for the dehydrogenation of a n-C_4H_{10} + n-C_4H_8 mixture are given in Table 3.

Thus industrially acceptable yields of butadiene can be achieved at a temperature above 570°C and a pressure less than 125 mmHg at a concentration of n-C_4H_8 in the original mixture not less than 30%.

3. Cracking of n-C_4H_{10}. The results of calculations[36] of the equilibrium composition of the products obtained when only the primary reactions (3a)–(3c) take place indicate that under the conditions of dehydrogenation of n-C_4H_{10} (500–600°C) its equilibrium degree of cracking amounts to about 70–75%.

TABLE 3. Equilibrium n-C_4H_{10} + n-C_4H_8 + C_4H_6 composition for dehydrogenation of n-C_4H_{10} + n-C_4H_8 mixture.

Original n-C_4H_{10} + + n-C_4H_8 mixture	T, °K	P_{total} = 760 mmHg			250 mmHg			125 mmHg			95 mmHg

4. Cracking of $n\text{-}C_4H_8$. The equilibrium extents to which the primary reactions involved in the cracking of $n\text{-}C_4H_8$ take place can be calculated from the equations:

$$x_{4b} = \frac{(K_{p_{4b}})^{0.5}}{1+(K_{p_{4b}})^{0.5}}; \quad x_{4c} = \left(\frac{K_{p_{4c}}}{K_{p_{4c}}+4}\right)^{0.5};$$

$$x_{4d} = \frac{(K_{p_{4d}})^{0.5}}{1+(K_{p_{4d}})^{0.5}}; \quad x_{4e} = \frac{\sqrt[3]{K_{p_{4e}}}}{1+\sqrt[3]{K_{p_{4e}}}},$$

while that for reaction (4) can be found graphically. Calculations[6] from thermodynamic data[29] showed that in the range 520–630°C reactions (4), (4b), and (4e) are almost completely displaced to the right; the degree of transformation according to reaction (4d) varies from 94.7% to 92.3% and the degree of transformation according to reaction (4c) varies from 46.6% to 80.8%.

5. Transformation of C_4H_6. The temperature dependence of the equilibrium constant for the dimerisation of C_4H_6 is given by the equation[5]:

$$R\ln K_{p_{5a}} = \frac{-34\,825}{T} + 5.968 + 11.0755\log T + 10^{-4}T - 1.288\times10^{-6}T^2.$$

The equilibrium degrees of dimerisation, calculated[6] from the equation

$$x_{5a} = \left[1 - \frac{1}{(1+4K_{p_{5a}})^{0.5}}\right],$$

are given in the following table

T, °K	800	820	840	860	880	900
x_{5a}	0.891	0.861	0.818	0.767	0.707	0.633

The cracking reactions (5b) and (5c) at 500–600°C are almost completely displaced to the right.

6. Isomerisation reactions. Equations for calculating the equilibrium constants for the isomerisation reactions in the gaseous phase are summarised in Table 4.

All these equations show satisfactory agreement with calculations using the latest thermodynamic data.

TABLE 4. Equations for the temperature dependence of the equilibrium constants of the isomerisations (in the gaseous phase).

Reaction	Equation	Temp. range, °C	Ref.
$n\text{-}C_4H_{10} \rightleftarrows Me_2C{=}CH_2$	$\log K_{p_{4a}} = \frac{358+93}{T} - 0.802+0.055$	—	33
	$\log K_{p_{4a}} = \frac{2318}{4.575T} - 0.929$	150	37
$n\text{-}C_4H_8 \rightleftarrows Me_2C{=}CH_2$	$\log K_{p_{4b}} = \frac{304}{T} - 0.528\pm0.020$	265—426	38
$EtCH{=}CH_2 \rightleftarrows MeCH{=}CHMe$	$\log K_p = \frac{619.3}{T} - 0.335$	200—380	39
$EtCH{=}CH_2 \rightleftarrows$ *cis*-$MeCH{=}CHMe$	$\log K_p = \frac{387}{T} - 0.393$	200—380	39
$EtCH{=}CH_2 \rightleftarrows$ *trans*-$MeCH{=}CHMe$	$\log K_p = \frac{606}{T} - 0.524$	200—380	39

With increase in temperature the equilibrium is displaced towards the formation of $n\text{-}C_4H_8$; the equilibrium composition of the $n\text{-}C_4H_8$ mixture changes little with temperature[40]:

T, °K	800	820	840	860	880	900
$EtCH{=}CH_2$	0.303	0.312	0.32	0.328	0.336	0.344
cis-$MeCH{=}CHMe$	0.297	0.294	0.292	0.289	0.288	0.285
trans-$MeCH{=}CHMe$	0.40	0.394	0.388	0.383	0.376	0.371

7. Reactions of water vapour. The equilibrium constants for reactions (7a) to (7d) can be calculated using the following simplified equations[17]:

$$\log K_{p_{7a}} = \frac{-6830}{T} + 1.75\log T + 2.5, \quad (7a)$$

$$\log K_{p_{7b}} = \frac{-4300}{T} + 1.75\log T + 0.8, \quad (7b)$$

$$\log K_{p_{7c}} = \frac{-2150}{T} + 2.3, \quad (7c)$$

$$\log K_{p_{7d}} = \frac{-8919}{T} + 9.01. \quad (7d)$$

The equilibrium extents to which all these reactions take place increase with temperature and, for example, amount to 50–60%[33] at 600°C and stoichiometric ratio of the reacting substances; under the conditions of the dehydrogenation of butene, however, because of the large excess of water vapour (and also hydrogen) relative to the quantity of "carbon" on the catalyst, the equilibria for reactions (7a), (7b), (7c), (7e), and (7f) are almost completely displaced to the right.

It is impossible to examine the equilibria for the oxidation or reduction of the metal oxides usually present in dehydrogenating catalysts, since usually the form of compound in which the oxides are actually present in the catalyst and the reactions involved in the conversion of the metal from one valency state to another are still unknown.

4. CATALYSTS

There have been many attempts to use different combinations of oxides as catalysts for the dehydrogenation of alkanes, particularly butane, but only the aluminium–chromium oxide catalysts promoted with potassium oxide have found industrial application[2]. The optimal concentration of Cr_2O_3 in catalysts for the dehydrogenation of $n\text{-}C_4H_{10}$ to $n\text{-}C_4H_8$ is apparently close to 10%.[2] Many properties of these catalysts (the optimal concentration of chromium oxide, the influence of promoting additives, methods of preparation, the porous structure of the Al_2O_3 and the catalysts, the influence of the catalyst particle size, the degree of dispersion of the chromium oxide, and the relationship between the catalytic activity and the electrical conductivity) have been described in detail[3]. A characteristic property of aluminium–chromium catalysts is their sensitivity to the poisoning effect of water; thus in the dehydrogenation of isobutane the activity of the catalyst begins to decrease at a concentration of water vapour in the original gas greater than 1 mg litre^{-1}, but the activity also decreases with decrease in the moisture content of the isobutane (below 1 mg litre^{-1}).[41] This feature (the decrease in activity in the total absence of water) has unfortunately not yet been explained. An extremely important feature of aluminium–chromium catalysts is the change in their activity during dehydrogenation; the yield of butene[19] increases sharply in the first few minutes after regeneration, reaches a maximum (see

Fig. 1§), and then decreases¶. The reduced activity in the first minutes is attributed[16] to poisoning of the catalyst by the water formed by the reaction of the excess (relative to Cr_2O_3) of oxygen with the hydrocarbons. The activity of the catalyst increases as this excess of oxygen is used up and the water (and also CO_2) is desorbed. The decrease in the activity of the catalyst after the maximum is usually attributed to an increase in the deposition of carbon, although this is unlikely to be the only cause.

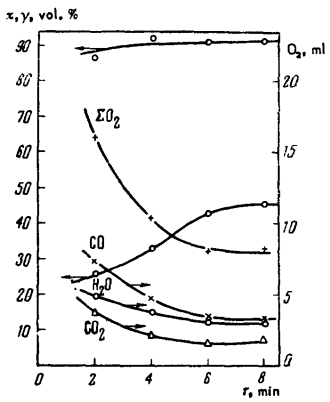

Fig. 1. Change in the yield of n-C_4H_8, selectivity, and quantity of combined oxygen during dehydrogenation of butane for 8 min at 570° and a space velocity of 1000 h^{-1}:
x — yield of n-C_4H_8; γ — selectivity;
O_2 — quantity of oxygen in H_2O, CO_2, and CO;
ΣO_2 — total quantity of O_2; τ — duration of dehydrogenation.

Many papers have been devoted to the study of the influence of the oxidation and reduction of aluminium–chromium[18,22,24,25,43] and also chromium[44–46] catalysts on their activity in dehydrogenations (of butane or cyclohexane). In most of this work it has been shown unambiguously that after reduction (with sufficient desorption of water) the activity of the catalysts increases†; if, however, the desorption of the water formed during the reduction is inadequate, the activity of the catalyst may even decrease as a result.

The compositions of the industrial catalysts for the dehydrogenation of butene are more varied than those of the catalysts for the dehydrogenation of butane; the compositions and properties of these catalysts are given in Table 5.

At present, the chief catalyst used in Canada and Britain is Dow-B, and the chief catalysts used in the USA are Shell-205, Dow-B, and Phillips-1490.[47] The chief advantages of the Shell catalysts are: prolonged operation without regeneration, low dilution with water vapour, durability, and mechanical strength; a disadvantage of the catalysts is their low selectivity[48]. High yields and selectivity are the chief advantages of the catalyst Dow-B,[49] although this catalyst also has many disadvantages (sensitivity to poisoning by most oxides and metals, higher yields of carbonyl compounds and alkynes, and shorter operational life[48]).

Method of dehydrogenation may be mentioned briefly. Three methods for dehydrogenating butane to butene are known[50–55]: in tubular periodic-action reactors with external heating and immobile catalyst, in assemblies with moving catalyst spheres, and in assemblies with a fluidised bed of fine catalyst particles.

In all countries the dehydrogenation of butene on the industrial scale is carried out in reactors without external heating on an immobile catalyst[1]. The single-stage dehydrogenation of butane to buta-1,3-diene is carried out[1] at reduced pressure in a system of reactors, each of which

§ An earlier paper[19] gave data on the change in the yields only at 505°; analogous data have been obtained at 570° and 590°.

¶ The same relationships were observed in the dehydrogenation of isopentane[42,114].

† An increase in the activity of the aluminium–chromium catalyst as a result of its reduction by hydrogen was also observed[42] in the dehydrogenation of pentane and isopentane.

TABLE 5. Composition and properties of some industrial catalysts for the dehydrogenation of butene*.

Catalyst (firm's designation)	Composition, %	Conditions of use (in industrial reactors)	Characteristics		References
			yield of C_4H_8, mole %	selectivity, mole %	
No. 1707	72.4MgO + 4.6CuO + 18.4Fe_2O_3 + 4.6K_2O	630°, space velocity (with respect to C_4H_8) 400 h^{-1}, dilution to molar ratio $C_4H_8:H_2O$ = 1 : 10, duration of dehydrogenation 1 h, duration of regeneration 1 h	20.2	73	1, 47
Shell-105	90Fe_2O_3 + 4Cr_2O_3 + 6K_2CO_3	620°, space velocity 400 h^{-1}, dilution to molar ratio 1 : 10, duration of dehydrogenation without regeneration about one week	19–20.3	69–72	1, 2, 47, 48
Shell-205	same as Shell-105, but with higher K_2CO_3 content	621–677°, space velocity 500 h^{-1}, dilution to molar ratio 1 : 8, dehydrogenation for 24 h, regeneration for 1 h	19.5–20.5	73–75	1, 2, 47

Dow-B	$Ca_3Ni(PO_4)_2$ stabilised with 2% Cr_2O_3 on carrier	593–677°, space velocity 125–175 h^{-1} dilution to molar ratio 1 : 20, dehydrogenation for 15–30 min, regeneration for 15–50 min	42.5–49.5	90–94**	49, 94

* See also Ref. 94.

** Maximal yield and selectivity.

is periodically switched over to dehydrogenation, regeneration, and preliminary operations (blow-through, evacuation, etc.). In the dehydrogenation the temperature of the catalyst (mixed with inert packing) is reduced by 15–20 deg and this supplies the heat required for the process. The operational conditions are chosen in such a way that the heat of dehydrogenation is equal to the heat of regeneration[47,56]. Many sources point out the need to purge the catalyst with hydrogen after regeneration[57].

5. REACTION RATES

The study of the rates of the reactions taking place in the dehydrogenation of n-C_4H_{10} and n-C_4H_8 involves many difficulties associated with the complexity (large number of reactions) and non-steady nature (change in activity during a single cycle) of the process.

An outstanding contribution to the study of the mechanism and kinetics of the catalytic dehydrogenation of organic compounds has been made by the work of Balandin and his school. On the basis of the principles of the multiplet theory of catalysis, he developed the mechanism of dehydrogenations[58,59], proposed a general equation for the rate of dehydrogenation of organic compounds[60,61], made a detailed study of the rate of dehydrogenation of n-C_4H_8 on chromium and mixed oxide catalysts[62–65], obtained general relationships[66] for the dehydrogenation of n-C_4H_{10}, and studied the dehydrogenation[67–69] of n-C_4H_{10} + n-C_4H_8 mixtures. Important studies of the kinetics of the dehydrogenation of n-C_4H_{10} and n-C_4H_8 have been carried out by Kagan, Lyubarskii, Pshezhetskii, and their coworkers[3]. Let us now examine the equations for the rates of individual reactions.

Rate of Dehydrogenation

The reaction n-$C_4H_{10} \rightleftharpoons$ n-$C_4H_8 + H_2$. The equations at present known for the rate of dehydrogenation of n-butane to butene are given in Table 6.

TABLE 6. Equations for the rate of dehydrogenation of n-C_4H_{10} to n-C_4H_8 over aluminium–chromium catalysts.

No.	Rate equations	Temperature range, deg	Apparent activation energy E_1, kcal mole^{-1}	Refs.
1	$\frac{dx_1}{d\tau} = k_d \exp\left(h - \frac{1}{RT}\right) E_1 \cdot \frac{P_1}{\Sigma z_r \cdot P_r}$	—	—	59,60
2	$-\frac{dP_1}{d\tau} = \frac{k_1 P_1}{1 + k_1/k_2 P_1 + k_3/k_4 P_2}$	260–500	—	70
3	$-\frac{dC_1}{d\tau} = k_1 \frac{C_1}{C_2^{0.5}} - k_{hydr} C_2^{0.5} \cdot C_3$	460–500	40.0±1.0	71,72
4	$\ln \frac{D}{D-M} = a\tau^b$	500–550	—	73
5	$\frac{dx_1}{d(W/F)} = \frac{k_1 (P_1 - P_2 P_3/Kp)}{(1 + k_1' P_1 + k_2' P_2 + k_3' P_3)^3}$	570 480–550	36.0 43.9	4 53
6	$\frac{dx_1}{d(W/F)} = k_1 \frac{P_1}{P_2^{0.5}} \left(1 - \frac{P_2 P_3}{K_p P_1}\right)$	510–550	41.4±2.2	83,115

Note. According to data[116] obtained in a flow-circulation assembly, the rate of dehydrogenation of n-C_4H_{10} on a reduced aluminium–chromium–potassium catalyst at 525–570° is described by the equation

$$k_1 P_1 \left(1 - \frac{P_2 P_3}{K_p P_1}\right), \quad E = 46 \pm 3 \text{ kcal mole}^{-1}.$$

In these equations, the left-hand side gives expressions for the rate of dehydrogenation; P_1, P_2, P_3, and P_4 are the partial pressures of n-C_4H_{10}, n-C_4H_8, H_2, and C_4H_6 respectively; C_1, C_2, C_3, and C_4 the concentrations of the reagents (in the same order as in the case of P_i); $k_d = \frac{k_0 \alpha}{h - 1/RT}$, in which k_0 is a constant, and h and α the coefficients in the function for the distribution of the active centres of the catalyst with respect to activation energies $\Phi(E) = \alpha \exp(hE)$; z_r the relative adsorption coefficients for the reacting substances, and P_r their partial pressures; k_1, k_2, and k_3 — in Eqn. (2) — the rate constants for the elementary reactions (formation and decomposition of the surface radical) or, in Eqn. 5 (with primes) the constants of the adsorption equilibrium for n-C_4H_{10}, n-C_4H_8, and H_2; k_1 — in Eqns. (3), (5), and (6) — the rate constant; W the weight of catalyst; F the rate of supply of butane; x_1 and M the degrees of dehydrogenation; D the maximum degree of dehydrogenation attainable on a given catalyst at a given temperature; τ the duration of contact, and a and b coefficients.

Equation 1 was proposed by Balandin, who claims[61] that it expresses the rate of dehydrogenation of hydrocarbons, alcohols, and amines over metallic and oxide catalysts at pressures which are not too low and at a distance from equilibrium. This equation is readily transformed into Frost's equation[75] for monomolecular irreversible reactions. Let us demonstrate this. For a given catalyst, the quantity $k_d \exp(h - 1/RT).E = \varphi(T) = K$. Replacing the partial pressures by the degree of dehydrogenation x_1 and integrating from 0 to x_1, we obtain

$$k\tau = \int_0^{x_1} \frac{\frac{1-x_1}{1+x_1} z_1 + \frac{x_1}{1+x_1} z_2 + \frac{x_1}{1+x_1} z_3}{\frac{1-x_1}{1+x_1}} dx = \int_0^{x_1} \left[z_1 + (z_2 + z_3) \frac{x_1}{1-x_1} \right] dx_1 = (z_2 + z_3) \int_0^{x_1} \left(\frac{z_1}{z_2 + z_3} + \frac{x_1}{1-x_1} \right) dx_1,$$

from which

$$\frac{K}{z_2 + z_3} \tau = \frac{z_1}{z_2 + z_3} x_1 - \ln(1 - x_1) - x_1 = \ln \frac{1}{1-x_1} - \left(1 - \frac{z_1}{z_2 + z_3}\right) x_1.$$

Introducing the symbols

$$\frac{K}{z_2 + z_3} = k_1 \text{ and } 1 - \frac{z_1}{z_2 + z_3} = \beta,$$

we obtain

$$k_1 \tau = \ln \frac{1}{1-x_1} - \beta x_1.$$

An analogous transformation[106] in more general form was given earlier[59,61].

Equation 2 (Pshezhetskii, Lyubarskii, and coworkers) is analogous in form to the first equation of Balandin, but the coefficients of the equations (for the partial pressures of the reagents) are interpreted in different ways. According to Pshezhetskii, Lyubarskii, and coworkers[70], these coefficients give the ratio of the rate constants of the elementary stages of the reaction; according to Balandin[60,61], these coefficients are the relative constants of the adsorption equilibrium for the reagents, as confirmed by the much higher value of the constants for the adsorption equilibrium compared with the value of the dehydrogenation rate constant[76].

The equation of Pshezhetskii and Lyubarskii is also readily transformed into Frost's equation. Integration of this equation gives[70]:

$$\left(\frac{k_1}{k_2}-\frac{k_3}{k_4}\right)P_1^0\alpha-\left(1+\frac{k_3}{k_4}\right)P_1^0\ln(1-\alpha)=\frac{k\omega}{V},$$

where P_1^0 is the initial partial pressure of C_4H_{10}, $\alpha = \frac{P_1^0 - P_1}{P_1}$ the degree of transformation; V the rate of flow of gas, and ω the free volume of the catalyst. Dividing both sides of the equation by $\left(1+\frac{k_3}{k_4}P_1^0\right)$ and introducing the symbols

$$\frac{\left(\frac{k_1}{k_2}-\frac{k_3}{k_4}\right)P_1^0}{1+\frac{k_1}{k_2}P_1^0}=-\beta \text{ and } \frac{k_1}{1+\frac{k_3}{k_4}P_1^0}=K,$$

we obtain

$$K\frac{\omega}{V}=\ln\frac{1}{1-\alpha}-\beta\alpha.$$

The value of β here is in fact negative, since[70] $\frac{k_3}{k_4} \gg \frac{k_1}{k_2}$ (for example[70], at 500°, $k_1/k_2 = 3.8$ and $k_3/k_4 = 100$).

Equations 1 and 2 are applicable only for low degrees of dehydrogenation, since they make no allowance for the back reaction.

Equation 3 (Lyubarskii and Pshezhetskii) is an empirical equation; it makes allowance for the reverse reaction of hydrogenation[72] and is more conveniently written in the form (retaining the symbols used in the original[72]):

$$w=k_1\frac{C_1}{C_2^{0.5}}\left(1-\frac{C_2C_3}{K_CC_1}\right),$$

since $k_1/k_{hydr} = K_C$ is the equilibrium constant. In this form the equation is applicable up to equilibrium.

Equation 4 (Obolentsev and coworkers[73]) is of characteristic form‡ and is also distinguished by the fact that as $\tau \to 0$ the reaction rate also tends to 0; the existence of an induction period for this example is difficult to explain although for the thermal dehydrogenation of ethane the form of the kinetic curve apparently indicates the existence of an induction period[78].

Equation 5 was derived, on the basis of a general method[79], from the Langmuir isotherm. In the derivation it was assumed[4] that the dehydrogenation involves two active centres; the equation makes allowance for the back reaction.

Equation 6[6,74,115] is analogous to the Lyubarskii–Pshezhetskii equation. Some of the data for its derivation are given in Figs. 2 and 3§. The experiments were carried out in a flow assembly with an immobile catalyst layer (particle size 0.7 mm) at maximal activity. In the range 510–550°C, the apparent activation energy is 41.4 ± ± 2.2 kcal mole^{-1}, and in the range 550–570°C E = 15.7 ± ± 0.7 kcal mole^{-1}.[83,115] The observed decrease in the value of E here is due to retardation by internal diffusion.

The establishment of the kinetic relationships for dehydrogenation in a fluidised catalyst bed is extremely important. From the general relationship[80] it follows that

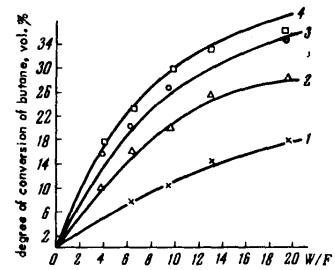

Fig. 2. Dependence of the degree of conversion of n-C_4H_{10} on the rate of supply and temperature (°C): 1) 510°; 2) 530°; 3) 550°; 4) 570° (atmospheric pressure).

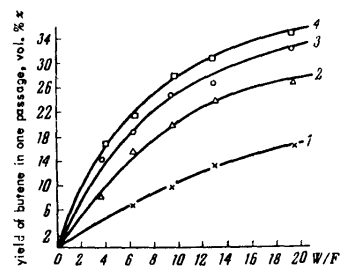

Fig. 3. Dependence of the yield of n-C_4H_8 on the rate of supply of butane and temperature (for numbering see Fig. 2).

the degree of dehydrogenation in a reactor containing a fluidised bed is less than that in a reactor containing an immobile layer, and that this difference increases with increase in the linear velocity and decrease in the particle size of the catalyst in the fluidised bed; this is due to the fact that some of the gas slips through the fluidised bed in the form of bubbles[74]. The rate of dehydrogenation in this reactor¶ is given by an equation of the same type, with the introduction of a coefficient φ which makes allowance for the change in the reaction rate as a result of the fact that some gas slips through[74]:

$$\frac{dx_1}{d(w/F)}=\varphi k_1\frac{P_1}{P_2^{0.5}}\left(1-\frac{P_2P_3}{K_pP_1}\right),$$

in which

$$\varphi=\left[1-\left(\frac{w-w_{cr}}{w}\right)^2\right]^{0.5},$$

where w is the linear velocity of the gas in the reactor and w_{cr} the rate of the start of formation of the fluidised bed; other conditions being equal, w_{cr} depends on the particle size[6].

The reaction n-$C_4H_8 \rightleftharpoons C_4H_6 + H_2$. The published kinetic equations for this reaction are given in Table 7; the symbols are the same as those used earlier. It can be seen that some of the equations in Table 7 are

‡ An equation of this type was justified by Kazeev[77].

§ The experimental data are given in detail elsewhere[6].

¶ The results of the dehydrogenation of n-C_4H_{10} in a fluidised bed in small experimental assemblies have been described by Aliev et al.[95]

TABLE 7. Equations for the rate of the reaction $n\text{-}C_4H_8 \rightleftharpoons C_4H_6 + H_2$ over various oxide catalysts.

No.	Equations	Catalyst	Conditions	E_a, kcal mole^{-1}	Refs.
1	$\frac{dx_2}{d\tau} = \frac{k_2 C_2}{C_2 + z_3 C_3 + z_4 C_4}$	chromium, chromium oxide	pressure 180–350 mmHg, 535–559°C 550–600°C	34.34–34.14 26.26–27.93	63
2	$\frac{d(H_2)}{d\tau} = \frac{104.5\,[C_4H_8]}{[C_4H_8] + 9.5\,[C_4H_6] + 0.82\,[H_2]}$	ditto	dilution to molar ratio $n\text{-}C_4H_8 : H_2O = 1:10$, 560°C	19.1	64
3	$-\frac{dP_2}{d\tau} = \frac{k_2 P_2}{1 + k_2/k_3 P_2}$	aluminium–chromium	dilution with nitrogen, $P_2 = 0.1$–0.3 atm, 450–500°C	27±1	70

similar in form to the equations for the rate of dehydrogenation of $n\text{-}C_4H_{10}$; only equations 5 and 7 make allowance for the reverse hydrogenation reaction.

Equations 1 and 2 (Balandin, Bogdanov, and coworkers[63,64]) are identical; the numerical coefficients are given for 560° and P_{total} = 180–350 mmHg. The difference between equation 3 (Pshezhetskii and coworkers[70]) and Balandin's equation is in a term making allowance for retardation by the reaction products. Shcheglova and Pshezhetskii[81] did not detect this retardation, apparently because of differences in the experimental procedures: in the study of the retarding influence of C_4H_6 its concentration in the original mixture[81] did not exceed the quantity formed by dehydrogenation of pure $n\text{-}C_4H_8$; in the work by Balandin and coworkers[63,64], the quantity of C_4H_6 added was 3–10 times greater than the quantity of C_4H_6 formed. It should be emphasised that in these experiments of Balandin and coworkers[63], as in the dehydrogenation of butane[62], a decrease in the value of E with increase in temperature was observed.

Equation 5 is completely analogous to the corresponding equation for the rate of dehydrogenation of butane, so that all that was previously said regarding this equation is applicable to the equation for the rate of dehydrogenation of $n\text{-}C_4H_8$.

Equation 6[82] was derived from experimental data obtained on a large-scale assembly in a tubular reactor with 8 litres of catalyst. It appears that some methodological factors associated with this are responsible for the unusual order of the reaction.

Equation 7 is applicable for a catalyst with maximal activity[6,16]. In fact, the activity of the industrial catalyst for which this equation was obtained does not remain constant throughout the operational period; the time dependence of the rate constants for the dehydrogenation of $n\text{-}C_4H_8$, calculated[6] from published data[16], is shown in Fig. 4. The temperature dependence of the maximal values of k_2 is given by the equation[16]:

$$\log k_2 = \frac{-24\,800}{4.575T} + 5.03,$$

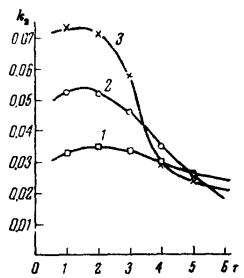

Fig. 4. Time dependence of the rate constants for the dehydrogenation of $n\text{-}C_4H_8$:
1) 580°; 2) 600°; 3) 620°; τ = duration of dehydrogenation, h.

and for any value of the time within the operational period from 1 h to 6 h the values are given by the equations[6] (for example, for 600°):

$$\text{from 1 h to 4 h, } k_\tau = k_2 \times 0.9924\tau^{0.062} \exp(-0.0109\tau^{2.5}),$$
$$\text{from 4 h to 6 h, } k_\tau = k_2 \times 5.97\tau^{-1.88}.$$

It is assumed[16] that the change in the activity of the dehydrogenation catalyst is due to a change in chemical composition under the influence of the reaction medium.

Dehydrogenation of butane–butene mixtures at reduced pressure. No mathematical description of the rate of dehydrogenation of $n\text{-}C_4H_{10}$ + + $n\text{-}C_4H_8$ mixtures at reduced pressure (that is, the rate of the single-stage dehydrogenation) has yet been published, but a number of papers have described fairly clearly the main regular features of this process.

On an aluminium–chromium catalyst, the rate of the reaction $n\text{-}C_4H_{10} \rightleftharpoons n\text{-}C_4H_8 + H_2$ is greater[67,70] than the rate of the reaction $n\text{-}C_4H_8 \rightleftharpoons C_4H_6 + H_2$. According to the data of Pshezhetskii et al.[70] the difference in the rates of these

reactions decreases with temperature and at 500°C $w_1 : w_2 = 2.7$; according to the data of Shcheglova and coworkers[67] the rate of the first reaction at 600°C is almost six times the rate of the second reaction. The establishment of the fact that the reactions involved in the formation of C_4H_6 from n-C_4H_{10} take place in succession is extremely important. It has been established[34] using ^{14}C that in the dehydrogenation of n-C_4H_{10} + n-C_4H_8 on an aluminium–chromium catalyst at 600°C and P_{total} = = 250 mmHg the rate of the reaction n-$C_4H_8 \rightarrow C_4H_6 + H_2$ is approximately twenty-five times the rate of the reaction n-$C_4H_{10} \rightarrow C_4H_6 + 2H_2$. From this work[34] it also follows that the rate of dehydrogenation of n-C_4H_{10} to n-C_4H_8 is smaller than the rate of dehydrogenation of n-C_4H_8 by a factor of about 2.5; the reasons for the discrepancy between these and other data[67,70] are not clear.

General relationships describing the influence of temperature, volume rate, pressure, and composition of the original n-C_4H_{10} + n-C_4H_8 mixture on the yield of butadiene and the selectivity of the process have been published[84,85]. They may be summarised as follows. Under the conditions studied[85] the yield of C_4H_6 increases with increase in temperature, increase in the concentration of n-C_4H_8 in the original mixture, and decrease in pressure. When the catalyst is purged for a short period with hydrogen after regeneration, the yield and selectivity increase appreciably (by 10–15%); the selectivity also increases with increase in the volume rate and with decrease in the temperature or pressure. An important characteristic of the process is the ratio of the quantities of n-C_4H_8 in the reaction products and in the original mixture. If this ratio is equal to unity, the butene is not used up and the process can be regarded as a single-stage process in the sense that only butane has to be added to the butane–butene mixture returned for recycling. This parameter, called the degree of single-stage character, increases with decrease in the concentration of butene in the original mixture, with decrease in the volume rate, with decrease in temperature, and with increase in pressure; purging of the catalyst with hydrogen also increases the degree of single-stage character (by 15–20%). Moreover, all the characteristics of the process also depend on the duration of the dehydrogenation[85]: the yield of butadiene at first increases, passes through a maximum, and then decreases†; the selectivity increases continuously and the degree of single-stage character decreases.

Reactions involved in the cracking of n-C_4H_{10} and n-C_4H_8. The catalytic and thermal cracking of hydrocarbons obeys a first-order equation. For n-butane the rate constant of the thermal decomposition (for a degree of transformation 7–9%, when secondary reactions can be neglected) is determined from the equation[86]:

$$\log k_c = \frac{-73\,900}{4.575T} + 17.05.$$

According to other data[87], for all straight-chain alkanes from C_3 to C_{10}, the activation energy of the primary thermal decomposition has an average value of 63 kcal mole^{-1}. According to more recent data[88], for n-C_4H_{10} E = = 58.7 kcal mole^{-1}; the same value was obtained in recently published work[89] in which the order of the reaction involved in the thermal decomposition of n-C_4H_{10} was found to be 3/2.

The rate of the cracking of butane in its catalytic dehydrogenation has been examined by a few authors[4,6,53]. It has been assumed[4] that the rates of the cracking of n-C_4H_{10} and n-C_4H_8 under dehydrogenation conditions are approximately equal; the cracking reaction is homogeneous and of first order. Since the kinetic data were obtained[4] for a single temperature (571°C) the equation obtained by Paul and Marek[86] is used for the cracking rate constant, although it is pointed out that the rate of cracking in the presence of an aluminium–chromium catalyst is slightly greater than the rate of thermal cracking (but by a factor of not more than 5–10). It is considered[5] that in the dehydrogenation of butene on catalyst No. 1707 the cracking of butane is also a first-order thermal reaction

$$\log k_c = \frac{-60\,000}{4.575T} + 15.2734,$$

the rates of the cracking of n-C_4H_{10} and n-C_4H_8 being approximately equal. The same assumption, made by Tyuryaev[6], is justified by the fact that on the highly selective catalyst used[6] only a comparatively small quantity of butane and butene decompose by cracking reactions (not more than 15% of the total butane reacting). With these assumptions, the rate of cracking is[83]:

$$\frac{dx_c}{d(W/F)} = k_c \frac{P_{C_4H_{10}} + P_{C_4H_8}}{P_{H_2}}.$$

For the dehydrogenation of butane on this catalyst[83,115]:

$$\log k_c = \frac{-40\,000 + 3600}{4.575T} + 7.0 \pm 1.0.$$

For dehydrogenation on another catalyst[53] the rate of cracking was given approximately by the equation

$$\frac{dx_c}{d(W/F)} = k_c(P_{C_4H_{10}} + P_{C_4H_8}), \text{ and } \log k_c = \frac{-38\,300}{4.575T} + 8.06.$$

Comparison of the cracking rate constants from this equation and from the equation for thermal cracking[87,88], shows that the rate of cracking increases slightly in the presence of the dehydrogenating catalyst.

There are very few papers on the thermal cracking of n-butene. The cracking of MeCH=CHMe has been studied in detail[8]. At 570–700°C and a degree of transformation in the range 5–12%, the rate of decomposition is described approximately by a first-order equation:

$$\log k_c = \frac{-53\,000 + 900}{4.575T} + 11.40.$$

The rate of the cracking of butene during its dehydrogenation on catalyst No. 1707 was mentioned above[5]; on another industrial catalyst[16] the cracking of n-C_4H_8 is negligibly small so that the study of this reaction is of no particular interest.

The decomposition of butadiene is an important reaction in the dehydrogenation of butene[5,6,63,90]. Work on the rate of thermal transformation of C_4H_6 has been reviewed[91]. The chief reaction involved in the thermal transformation of C_4H_6 at 400–700°C and atmospheric pressure[15] is polymerisation; the reaction is of second order with E = 28 kcal mole^{-1} and

$$\log k = \frac{-6400}{T} + 7.3 \pm 0.04.$$

† On the specimen studied[85], the yields of C_4H_6 were:

duration of dehydrogenation, min:	5	7	10	13
yield of C_4H_6 in one passage, mole %:	18	19	17	16

At reduced pressure[91,92], the chief reaction in the transformation of butadiene is dimerisation; the reaction is of second order[91] with

$$\log k = \frac{-26\,800}{4.575T} + 11.14.$$

In the dehydrogenation of n-C_4H_8 on catalyst No. 1707[5] (with dilution by water vapour) decomposition of the butadiene formed involves chiefly catalytic cracking (5b) and thermal dimerisation; the rate of the first reaction is

$$r = \frac{kP_{C_4H_6}}{(1 + k_{C_4H_6}P_{C_4H_6} + k_{H_2}P_{H_2} + k_AP_A)^2},$$

with

$$\log k = \frac{-5000}{4.575T} + 0.2385,$$

(the subscripts A denote aromatic compounds). The dimerisation is a second-order reaction with

$$\log k = \frac{-25\,000}{4.575T} + 8.0632.$$

The dimer may also undergo cracking[5] with the formation of H_2, CH_4, C_2H_4, C_2H_6, and toluene; this reaction is a thermal reaction of first order, with

$$\log k = \frac{-31\,000}{4.575T} + 6.0323.$$

In the dehydrogenation of n-C_4H_8 on an industrial catalyst the cracking of C_4H_6 according to Eqn. (5c) is described by an equation of the same type[90] as that given by Beckberger and Watson[5] (with the exception of the term k_AP_A), or by the simpler equation[6]:

$$\frac{dx}{d(W/F)} = \frac{kP_{C_4H_6}}{(1 + aP_{C_4H_6})^2}.$$

The constants in these equations naturally depend on the form of equation used[6,90]. The activity of the catalyst with respect to the cracking reaction decreases during the operational period[90]. The time dependence of the rate constant is shown in Fig. 5; the curves are described by the equation

$$k_\tau = k\exp(-0.429\tau^{0.613}),$$

where τ is the duration of the operational period and k the rate constant for τ = 1 h.

Rate of carbon formation. As can be seen from Section 2, the quantity of "carbon" deposited on the catalyst in the dehydrogenation of n-butene is determined by the rate of decomposition of C_4H_6, for example, according to reactions (5b) or (5c); carbon formation in the dehydrogenation of n-butane must be regarded as an independent process[26]. Only one paper[26] has been published on the kinetics of carbon deposition on an aluminium-chromium catalyst in the dehydrogenation of n-C_4H_{10}; other papers[50,96,97] merely record the fact that "carbon" is formed or give values for the extent of carbon deposition on the catalyst under specific dehydrogenation conditions. The quantity of "carbon" formed in the dehydrogenation of butane is independent of the particle size of the catalyst and the volume rate of supply of butane and is determined by the equation[26]: $C_C = A\tau^{0.684}$, where C_C is the quantity of "carbon" as a percentage of the weight of catalyst, and τ the duration of dehydrogenation or the time for which the catalyst is present in the reactor, min‡,

$$\log A = \frac{-6620}{T} + 6.57.$$

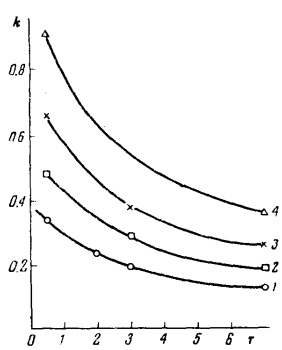

Fig. 5. Time dependence of the rate constants for the transformation of C_4H_6: 1) 560°; 2) 580°; 3) 600°; 4) 620°.

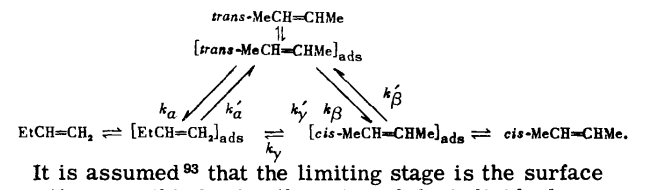
The kinetic equation obtained[26] is analogous in form to equations found earlier for the rate of carbon formation in the cracking of petroleum products on an aluminosilicate catalyst[98] or in the dehydrogenation of cyclohexane on an aluminium–molybdenum catalyst[99].

The isomerisation of n-C_4H_{10} and n-C_4H_8. Although isomerisation in the dehydrogenation of n-butane and n-butene has been reported many times[47,73], there are no quantitative data on the rates of the reactions n-C_4H_{10} ⇌ iso-C_4H_{10} and n-C_4H_8 ⇌ $Me_2C{=}CH$ in the presence of dehydrogenating catalysts. The rate of the isomerisation $EtCH{=}CH_2$ ⇌ *trans*-MeCH=CHMe ⇌ *cis*-MeCH=CHMe on an aluminium–chromium catalyst has been studied in detail[93]. The following reaction mechanism has been proposed:



It is assumed[93] that the limiting stage is the surface reaction; on this basis, the rates of the individual reactions are:

$$-\frac{dP_1}{d\tau} = \frac{dP_t}{d\tau} + \frac{dP_c}{d\tau} = \frac{k_\alpha K_1P_1}{1+K_1P_1} + \frac{k'_\gamma K_1P_1}{1+K_1P_1},$$

$$-\frac{dP_c}{d\tau} = \frac{dP_1}{d\tau} + \frac{dP_t}{d\tau} = \frac{k_\gamma K_cP_c}{1+K_cP_c} + \frac{k'_\beta K_cP_c}{1+K_cP_c},$$

$$-\frac{dP_t}{d\tau} = \frac{dP_c}{d\tau} + \frac{dP_1}{d\tau} = \frac{k_\beta K_tP_t}{1+K_tP_t} + \frac{k'_\alpha K_tP_t}{1+K_tP_t}.$$

In these equations, P represents the partial pressures and K the adsorption equilibrium constants; the subscripts 1, c, and t refer to $EtCH{=}CH_2$, *cis*-MeCH=CHMe, and *trans*-MeCH=CHMe, and k and k' are the rate constants for the forward and back reactions. The following values were found for the activation energies (kcal mole^{-1}):

for $EtCH{=}CH_2$ ⇌ *trans*-MeCH=CHMe, E = 7.9;

for $EtCH{=}CH_2$ ⇌ *cis*-MeCH=CHMe, E = 5.0;

and for *trans*-MeCH=CHMe ⇌ *cis*-MeCH=CHMe, E = 12.6.

‡ According to data[117] published after the present manuscript was submitted, $C_C = A + B\tau$.

In the dehydrogenation of n-butane, the isomeric composition of the mixture of n-butenes obtained[6,50] is close to the equilibrium composition. The part played by skeletal isomerisation of n-C_4H_{10} and n-C_4H_8 in the dehydrogenation is small[6].

The reaction of water vapour with "carbon". Reactions (7e) and (7f), observed in the dehydrogenation of n-C_4H_8 (with dilution by water vapour), is of zeroth order both with respect to H_2O and with respect to the concentration of carbonaceous deposits on the catalyst[5,6];

$$\log k = \frac{-39\,000}{4.575T} + 5.09375, \text{ according to Beckberger and Watson (Ref. 5),}$$

or

$$\log k = \frac{-41\,600}{4.575T} + 8.02475, \text{ according to Tyuryaev (Ref. 6).}$$

The zeroth order with respect to water is attributed[6] to the very large excess of water vapour, and the order with respect to "carbon" probably depends on the reaction mechanism. The rate constant decreases with time[6] (see Fig. 6).

Reaction involved in the regeneration of the catalysts. Despite the importance of this question, the rate and chemistry of the processes taking place in the regeneration of dehydrogenating catalysts have been insufficiently studied. Thermograms have been obtained[23,101] for the regeneration of chromium catalyst specimens on which carbon was deposited during the decomposition of alcohols and dehydrogenation of cyclohexane; combustion of the carbonaceous deposits began at 240°. It was established[23,102] that the carbonaceous deposits contain components richer in hydrogen ("tars") and components with low hydrogen content ("coke").

The rate of combustion of carbonaceous deposits in the regeneration of aluminium–chromium catalysts has been little studied[6,100,103]. In the kinetic range (300–350°)[103] the combustion is of second order with respect to "carbon" and of first order with respect to oxygen, that is, $-\frac{dc}{d\tau} = kc^2P_{O_2}$, and E = 31.1 kcal mole^{-1}. The rate constant depends on the composition of the carbonaceous deposits: the value of k decreases with decrease in the hydrogen content; on the other hand, the hydrogen content of the carbonaceous deposits decreases with increase in the deposition of carbon on the catalyst. The rate of regeneration of aluminosilicate cracking catalysts obeys the same equation[104]; the value of E here is similar (26.6 kcal × × mole^{-1}).

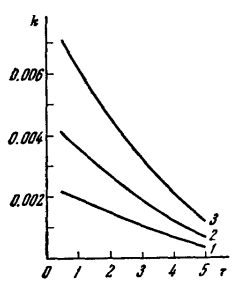


Fig. 6. Change in the rate constants for the reaction of water vapour with "carbon":
1) 560°; 2) 580°; 3) 600°.

In the regeneration of a catalyst for the dehydrogenation of butane in a fluidised bed[100] at 600–650°, the combustion takes place in the outer-diffusion range; the reaction rate is given by an equation of the same type

$$-\frac{dc}{d\tau} = k_d c^2 P_{O_2},$$

where k_d is the apparent rate constant, which depends on the rate of diffusion

$$\log k_d = \frac{-2800}{4.575T} + 0.14 \text{ or } k_d = 0.0482(T/273)^{1/2}.$$

The rate of oxidation of an aluminium–chromium catalyst during regeneration is given by an equation of the form $C = A\tau^n$ where C is the CrO_3 concentration, wt.%, A the temperature coefficient, and τ the duration of the regeneration, min.[6,100] For the catalyst specimen studied[6,100], the reaction takes place in the kinetic range up to 550°C, after which diffusion retardation is observed; in the kinetic range, n = 0.098 and $\log A = \frac{-815}{T} + 0.766$.[6] An interesting feature is that integration of the equation proposed[105] for the rate of reduction of MoO_3 to MoO_2 during treatment of an aluminium–molybdenum catalyst with hydrogen, $\frac{1}{W_0}\frac{dW}{d\tau} = -a\tau^{-b}$, gives an equation of the same form with approximately the same exponents§.

The relationship between the activity and the concentration of sexivalent chromium after regeneration has been studied by a number of workers[18,22,24,25].

Rate of desorption of water. The change in the water content with time during regeneration of the catalyst for the dehydrogenation of n-butane is described satisfactorily by the equation[6,100]: $q/q_0 = A_1\tau^{0.61}$, where q_0 is the initial or equilibrium concentration of H_2O on the catalyst and q the concentration of H_2O, wt.%, at time τ, min.

The desorption rate constant also depends on the initial water content[6,100]:

for q_0 = 0.2–0.4 mg g^{-1}

$$\log A_1 = -\left(\frac{800}{T} + .49\right);¶$$

for q_0 = 0.1–0.2 mg g^{-1}

$$\log A_1 = \frac{-1680}{T} + 0.65;$$

for $q_0 < 0.1$ mg g^{-1}

$$\log A_1 = \frac{-3400}{T} + 2.61.$$

This relationship is attributed[6] to the fact that part of the water is adsorbed physically on the catalyst and part is

§ $\frac{dW}{W_0} = -a\tau^{-b}d\tau\frac{W}{W_0} = \frac{a}{1-b}\tau^{1-b}$. According to John and co-workers[105], b = 0.904, that is, $1 - b$ = 0.096 (compare with n = = 0.098).

¶ Misprint in Russian text (Ed. of Translation).

chemisorbed; on heating, the physically adsorbed water is desorbed first (with a smaller thermal effect). The magnitude of the apparent activation energy for the removal of chemisorbed water should be close to the activation energy of chemical reactions. This is confirmed by the results obtained[6]; from the last equation it follows that E = = 15.6 kcal mole^{-1}. With increase in the extent of the heat treatment of the catalyst, its activity for the dehydrogenation of butane increases[100].

There are no published data on the kinetics of carbon decomposition, combustion of carbonaceous deposits, and oxidation of catalysts for the dehydrogenation of butene.

6. NEW DEHYDROGENATION REACTIONS

The dehydrogenations examined up to the present are reversible; the yields of butene or buta-1,3-diene usually do not exceed 80% of the equilibrium degrees of dehydrogenation. This means that in the two-stage dehydrogenation the yields (of n-C_4H_8 in the first stage and of C_4H_6 in the second stage) cannot exceed about 45% and that the yield of C_4H_6 in the single-stage dehydrogenation of butane in a vacuum can at best reach 20%. Thus the scope of ordinary dehydrogenation methods is clearly limited.

Recent years have seen the discovery of other dehydrogenation reactions in which the hydrogen is bound in the form of water, for example[107]:

$$n\text{-}C_4H_8 + \tfrac{1}{2}O_2 \rightarrow C_4H_6 + H_2O.$$

These reactions, which may be called oxidative dehydrogenation reactions, are displaced almost completely to the right. On the basis of published data[107-113], these dehydrogenation reactions can be divided into three groups.

1. Dehydrogenation of alkenes on oxide catalysts in the presence of oxygen[107,108]. The reaction is carried out at 450–540° at a volume rate of supply of n-C_4H_8 equal to 200–600 h^{-1} with dilution by water vapour. In a reactor with an immobile layer of catalyst[107] (a mixture of oxides of metals from Groups V and VI of the Periodic System) the yield of C_4H_6 reaches 50% and the selectivity is about 90%. The chief side-reaction is extensive oxidation of the hydrocarbons (to CO_2 and CO); almost no hydrogen is present. In a reactor with a fluidised catalyst bed the yield of C_4H_6 could be increased[108] to 70% without loss of selectivity. It is reported[109] that catalysts based on bismuth tungstate, bismuth molybdate, and bismuth phosphate are active for the oxidative dehydrogenation of butene.

2. Dehydrogenation of alkanes to alkadienes in the presence of iodine[110,111,113]. The process is described by the following equations[110]

$$n\text{-}C_4H_{10} + 2I_2 \rightleftharpoons C_4H_6 + 4HI,$$
$$2HI + MO \rightarrow H_2O + MI_2,$$
$$MI_2 + \tfrac{1}{2}O_2 \rightarrow MO + I_2.$$

MnO_2 has been used as metal oxide[111]. The reaction is carried out at 520–550° at a molar ratio $C_4H_{10}:I_2$ = 1 : 1.43 in the presence of metal oxides which readily absorb the HI formed. The use of the oxides achieves two results: displacement of the dehydrogenation equilibrium to the right and regeneration of iodine. The quantity of iodine required[110] can be decreased by adding oxygen to the reaction mixture to bring about "internal regeneration" of iodine:

$$2HI + \tfrac{1}{2}O_2 \rightarrow I_2 + H_2O.$$

A C_4H_6 yield of 52% has been achieved[110] with a selectivity of 75%.

3. Dehydrogenation of alkanes on solid catalysts in the presence of oxygen. A number of patents[112] show that it is possible to carry out the reaction

$$n\text{-}C_4H_{10} + O_2 \rightarrow C_4H_6 + 2H_2O.$$

The catalysts consist of a mixture of metal oxides (for example, 97.5 Fe_3O_4 + 2.5 LiOH) or a mixture of metal halides (for example, 2.08 KBr + 1.09 r.e.e. chlorides + + 0.82 AgBr on α-Al_2O_3). In the first the original mixture (in moles): n-C_4H_{10} + 15H_2O + 0.85O_2 + 0.07I_2 + + 0.115Cl_2 is passed over a catalyst at 575°C and a liquid C_4H_{10} volume rate of 0.5 h^{-1}. Under these conditions the yield of C_4H_6 is 54% and the selectivity 66%.

Passage of a mixture with C_4H_{10} : air : I_2 : H_2O = 1 : 4.76 : : 0.04 : 2.9 (in moles) at 500°C over a catalyst of the second type gives a C_4H_6 yield of 48.7% and selectivity 79.1%.

Oxidative dehydrogenation reactions open up new possibilities for the preparation of alkadienes; the study of these reactions is of considerable scientific interest.

THE ABSOLUTE RATE CONSTANTS OF THE ELEMENTARY STAGES OF RADICAL POLYMERISATION

A. F. Revzin

The elementary stages in a polymerisation radical chain reaction can in most cases be summarised as follows:

$$M \rightarrow M^{\cdot}, \quad (1)$$

$$M^{\cdot} + M \xrightarrow{k_p} MM^{\cdot}, \quad (2)$$

$$2M^{\cdot} \xrightarrow{k_t} P. \quad (3)$$

Reaction (1) is initiation, that is, formation of radicals from inactive molecules of the monomer M, reaction (2) is propagation of the reaction chain, leading to growth of the polymeric radical, and reaction (3) leads to the formation of the final reaction product — inactive polymer — and termination of the reaction chain.

Kinetic study of the polymerisation scheme (1) shows that for long reaction chains the dependence of the steady-stage reaction rate V_{st} on the elementary constants is given by the equation

$$V_{st} = I^{1/2} \frac{k_p}{k_t^{1/2}} [M]. \quad (4)$$

Thus the quantity $k_p/k_t^{1/2}$ can be determined from the reaction rate if the rate of initiation I is known. Methods for measuring rates of initiation have been described in detail[1]. $k_p/k_t^{1/2}$ can also be determined[2] from the dependence of the length of the polymer chain on the rate of polymerisation, given by the equation

$$\frac{1}{P_n} = \frac{k_M}{k_p} + \frac{k_t}{k_p^2} \frac{V_{st}}{[M]^2}, \quad (5)$$

where P_n is the number-average degree of polymerisation, usually determined from the viscosity of the polymer solutions, and k_M is the rate constant for chain transfer via the monomer. Schulz and coworkers[3] proposed equations which can be used to calculate the value of $k_p/k_t^{1/2}$ directly from the viscosity-average degree of polymerisation P_η. The value of $k_p/k_t^{1/2}$ can also be found by measuring the intensity of light scattering in the reaction vessel during the polymerisation[4].

The individual absolute values of the constants k_p and k_t cannot, however, be determined on the basis of Eqns. (4) or (5) alone. An additional equation relating these quantities depends on kinetic measurements of the lifetime of the radicals under non-steady reaction rate conditions.

There are several methods for making non-steady kinetic measurements. In the case of photochemical initiation, the absolute values of the elementary reaction rate constants can be found by intermittent illumination using a rotating sector. An interesting modification of this method has been proposed[5] for studying reactions in a flow system, initiated by γ-radiation; the glass tube used as reaction vessel was wound in a spiral round a ^{60}Co source placed in a lead cylinder with a longitudinal opening. The extensive use of the intermittent-illumination method for studying chain reactions began about 1945.

The theory of the method has been described in detail[1,6]. The practical details are as follows: measurements are made of the steady-state rates with continuous illumination V_{st} and with the rotating sector V_{int} with light–dark interval T chosen in such a way that V_{int}/V_{st} lies in the range 0.50–0.708. The graph giving the theoretical dependence of V_{int}/V_{st} on T/τ is then used to find T/τ and hence the lifetime of the free radicals τ. This is related to the constants k_p and k_t by the equation

$$\frac{k_p}{k_t} = \frac{\tau V_{st}}{[M]}. \qquad (6)$$

The method of intermittent illumination does not require a specially sensitive procedure and is simple in operation, but its accuracy is low compared with other methods.

A modified rotating-sector method combined with dilatometric recording of the steady-state rate has been used[7]. These measurements are made at low degrees of conversion, and in the authors' opinion they give better agreement between the theoretical curves and the experimental points than the ordinary rotating-sector method.

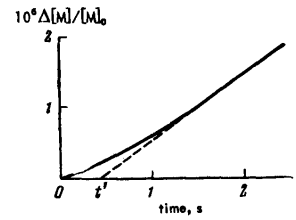
The method of initial non-steady kinetics is based on the determination of the lifetime of the radicals during the establishment of the steady state. The modern form of the theory of this method was put forward by Burnett[8]. The Figure gives the experimental curve for the kinetics of styrene polymerisation and shows clearly the initial non-steady section. The intercept cut off on the time axis by producing the subsequent steady-state section is $t' = \tau \ln 2$. If τ is known, k_p/k_t can be calculated from Eqn. (6).

These equations refer to quadratic chain termination. It follows from Eqn. (4) that the steady-state rate of polymerisation here is proportional to the square-root of the rate of initiation or, for photochemical initiation, the square root of the incident light intensity. Thus the applicability of Eqn. (4) is verified experimentally from the dependence of the reaction rate on the intensity of illumination. Deviations from the degree of the dependence $n = 0.5$ show that the bimolecular chain termination is accompanied by monomolecular chain termination (with respect to the radical heading the chain), for example, on an impurity X

$$P + X \rightarrow \text{products}. \qquad (7)$$

In the range $n = 0.5$–0.6, the corrections to the values of k_p and k_t, determined on the assumption that n is equal to exactly 0.50, do not exceed 20%,[9] that is they lie within the limits of the usual accuracy of the determination of kinetic constants. Methods have been proposed for determining these corrections.

Various methods have been proposed for recording the kinetic curve in the initial non-steady stage; these are in



Initial non-steady kinetics for the polymerisation of styrene[11].

fact based on measurement of the increase in temperature in the reaction vessel as a result of the exothermic reaction in the time interval in which it is possible to neglect the loss of heat from the reaction vessel to the thermostat liquid, that is, under so-called pseudo-adiabatic conditions. In the first experiments[10,11], the change in the dielectric constant of the reaction mixture and the change in the refractive index of the liquid were recorded[12]. The increase in temperature was also recorded directly by means of a thermocouple[13] or thermistors[14]. Bengough[15] developed a dilatometric method for recording non-steady kinetics. A method for determining the value of k_p/k_t from light scattering measurements was recently proposed[16].

Study of the initial non-steady kinetics has the indisputable advantage that with the short time interval for a single measurement it is possible to carry out a large number (up to 20) separate measurements on the same specimen, with an appreciable increase in accuracy. The accuracy of the determination of τ does not exceed 0.1 s, however, and this restricts the applicability of this method, particularly to reactions where the lifetime of the radicals is less than 0.5–0.7 s.

Another group of methods for measuring non-steady kinetics involves the study of reactions after photochemical initiation is stopped. These do not differ in principle from the methods described above, but they exhibit certain characteristic methodological features. In most of them, the rate of the spontaneous thermal reaction is taken into account. To record the reaction rate, Bamford and Dewar[17,18] proposed a viscosimetric method based on the determination of the number-average degree of polymerisation by measurement of the viscosity of the resulting polymer during and after photochemical initiation. Details of the method have been given in a review[19] and a monograph[1]. A modification of the method, which makes it possible to determine the constants directly from the viscosity-average degree of polymerisation and also makes allowance for monomolecular termination, was recently proposed by Okamura and coworkers[20]. The viscosimetric method is rather tedious, involves the solution of cumbersome equations, and has a low accuracy. A method has also been described for determining the chain-growth constant by measuring the rate of emulsion polymerisation under certain conditions[21].

The photochemical after-effect[22] has also been used in the dilatometric determination of polymerisation constants. Benson and North[23] examined some experimental complications associated with the dilatometric measurements (loss of heat from the dilatometer, heating of the reaction mixture as a result of illumination, absence of thermal initiation, presence of monomolecular chain termination, etc.).

We developed a method[24] for determining the value of k_p/k_t from the non-steady kinetics of the photochemical after-effect by measuring the increase in temperature in the period of pseudo-adiabatic conditions. When a slow background reaction, which may be a thermal reaction or a reaction brought about specially by means of constant weak illumination, is taking place in a system, it is found that when the illumination (main initiation) is switched off after a steady-state rate has been attained, the quantity of substance ΔM_{qu} which has reacted when the reaction is quenched is given by the equation

$$\Delta M_{qu} = k_p n_0 [M](t-\theta) + \frac{k_p}{k_t}[M]\ln\left(\frac{1-q^{-2k_t n_0(t-\theta)}}{1-q}\right), \quad (8)$$

where n_0 is the steady-state concentration of radicals resulting from the background reaction, θ the moment at which the illumination is switched off, and $q = (V_{st} - V_0)/(V_{st} + V_0)$, where V_{st} and V_0 are the steady-state rates of the photoinitiation and the background reaction.

If the reaction vessel in which the background reaction takes place is brought into thermal equilibrium with a thermostat, the increase in temperature for the subsequent switching-on and switching-off of the illumination (main initiation) will be determined by the second term on the right-hand side of Eqn. (8). The total quantity of substance converted at the quenching of the photoinitiated reaction is obtained for $t \to \infty$:

$$\Delta\Delta M = -\frac{k_p}{k_t}[M]\ln\frac{2V_0}{V_{st}+V_0}. \quad (9)$$

This equation can be used to find k_p/k_t.

It can be seen that in the photochemical after-affect method, unlike the initial non-steady kinetics method, we record not the duration of the non-steady state, but the quantity of substance converted, which is proportional to the increase in temperature. This quantity is usually determined with a higher accuracy than the duration of the non-steady state. Independent determination of V_0 and V_{st} by the dilatometric method also increases the accuracy of the determination of k_p/k_t.

The method also makes it possible to carry out measurements where no purely thermal reaction takes place in the system.

An expression identical to (9) was obtained by Bateman and Gee[25] for the quantity of oxygen absorbed at quenching of the photoinitiated oxidation.

Most of the methods for determining the rate constants of the elementary stages of radical polymerisation involve the use of complex highly sensitive instruments, which represent the limits of measuring techniques at the present stage of their development. Methods involving the simpler dilatometric measurements give less reliable results. Almost all methods involve the accurate recording of the start or finish of the photochemical reaction. This feature imposes an additional restriction on the range of materials for which the constants can be measured. This difficulty can apparently be avoided by using a recently-proposed method[26] in which a solution of rapidly-decomposing initiator is sprayed into the monomer, with efficient mixing.

Data on the determination of rate constants for radical polymerisation up to 1958 were collected and critically reviewed by Bagdasar'yan[1]. The present paper will examine chiefly work published in the last five years (up to March 1964), including earlier data for the sake of completeness where necessary.

Sometimes only the overall rate of polymerisation was determined, and information even on the magnitude of $k_p/k_t^{1/2}$ can be obtained from these data only by additional calculation; if the thermal initiator, its concentration, and, most important, the rate of decomposition and efficiency of initiation, determined by an independent method, are known, it is possible to calculate the rate of initiation and the value of $k_p/k_t^{1/2}$. The kinetic behaviour of a number of monomers on polymerisation does not correspond to the kinetic scheme of reactions (1)–(3), and if a new reliable scheme is not proposed, calculation of the constants for these monomers is impossible. Data for individual monomers are given below.

Styrene. Analysis of the most reliable data leads[1] to the following values for the constants† for styrene polymerisation

$$k_p/k_t^{1/2} = 380\exp(-6500/RT), \quad (10)$$

$$k_p = 9.35\times10^6\exp(-7250/RT), \quad (11)$$

$$k_t = 7.1\times10^8\exp(-1500/RT). \quad (12)$$

The values of $k_p/k_t^{1/2}$ recently obtained from the length of the polymer chains[20,27-29] are almost the same as those calculated from Eqn. (10). Henrici-Olivé and Olivé[29], on the basis of their measurements and published data, obtained the expression

$$k_p/k_t^{1/2} = 135\exp(-5700/RT), \quad (13)$$

which is almost the same as (10). Moreover, in these experiments attention was directed to the part played in chain termination by the primary radicals formed by decomposition of the initiator. It was shown[20,27] that at low concentrations of the usual initiators (azoisobutyronitrile, benzoyl peroxide) relative to the monomer, the recombination of the primary radicals with polymeric radicals can be neglected, but with an initiator such as phenylazotriphenylmethane, which gives stable triphenylmethyl radicals with low activity, it is necessary to make allowance for termination by primary radicals even at an initiator concentration of 10^{-4} M.[28] An important part is also played by primary radicals in chain termination for initiation of styrene polymerisation by the thermal decomposition of the polymeric peroxides of dibasic organic acids[30].

The value of k_p at 40°, determined by Burnett and Lehrle[31] by the emulsion polymerisation method is only 14% lower than the value calculated from Eqn. (11).

Methyl methacrylate. On the basis of a thorough critical analysis of a large amount of experimental data, Bagdasar'yan[1] obtained the following equations for the constants for methyl methacrylate polymerisation

$$k_p/k_t^{1/2} = 95\exp(-4500/RT), \quad (14)$$

$$k_p/k_t = 1.35\times10^{-2}\exp(-4300/RT). \quad (15)$$

Recent years have seen the appearance of a fairly large number of papers devoted to the kinetics of the polymerisation of methyl methacrylate; studies have been made not only of the initial stage of polymerisation, but also of the kinetics at high degrees of conversion and in solvents with

† The values for all the constants are given in mole litre^{-1} s^{-1}.

different viscosities. These data will be discussed later. The results of the determination of the kinetic constants at very low degrees of conversion are compared in Table 1 with the values obtained from Eqns. (14) and (15).

Schulz and coworkers[3] found that in the polymerisation of methyl methacrylate in benzene solution at 30–80° the equation

$$k_p/k_t^{1/2} = 53\exp(-4200/RT), \quad (16)$$

is satisfied.

It can be seen from the above data that the results of recent work show good agreement with Eqns. (14) and (15); the deviation from these equations is determined by the accuracy of the measurements. Values of $k_p/k_t^{1/2}$ were determined[27,34] viscosimetrically from the relationship between molecular weight and characteristic viscosity for non-fractionated polymers, and this method has been supplemented[3] by initiation by means of an initiator labelled with ^{14}C and by determination of the molecular weight of individual fractions by an osmotic method. The rate of initiation has been determined using ^{14}C [33] and from the rate of the reaction of radicals from the initiator azocyclohexane-1,1′-carbonitrile with diphenylpicrylhydrazyl in chloroform solution[32]. The ratio $k_p/k_t^{1/2}$ was determined from the initial non-steady kinetics using a thermocouple[32,33] and dilatometrically from the photochemical after-effect[34,35].

The ratio of the rate constants for chain termination by disproportionation k_{dis} and by recombination of the radicals k_{rec} was also determined[3]

$$\log(k_{dis}/k_{rec}) = 2.89 - 1000/T, \quad (17)$$

which gives for the difference in the energies of activation $E_{dis} - E_{rec} = 4.6$ kcal mole^{-1}. From Eqn. (17) at 60°, $k_{dis}/k_{rec} = 0.78$, which, although it differs from the accepted[1] value of 0.67, produces a change of only 4–5% in the calculated value of $k_p/k_t^{1/2}$. Determination of k_{dis}/k_{rec} from the quantity of radioactive initiator fragments in the polymer gave the value 1.35 at 60°.[36]

North and coworkers[37] studied the polymerisation of methyl methacrylate in the range from -60° to -20° in ethyl acetate solution. The reaction was initiated by ethylsilver, whose rate of decomposition was used to calculate the rate of initiation. The kinetics of the polymerisation are described by the equation;

$$V = 1.7\exp(-5100/RT)\,[\mathrm{MMA}]^{3/2}\,[\mathrm{AgC_2H_5}]^{1/2}.$$

Extrapolation of Eqn. (17) shows that at these low temperatures, termination takes place chiefly by the recombination of radicals. The values of $k_p/k_t^{1/2}$ determined with this assumption from the length of the polymer chains are greater by a factor of 2.5 than the value expected from Eqn. (14). It is suggested that ethylsilver forms a complex with methyl methacrylate. The reaction is initiated by the reverse decomposition of this complex to metallic silver and a free radical.

Atkinson and Cotten[22] studied the polymerisation of methyl methacrylate in aqueous solution at 25° and obtained the values $k_p = 75$ litre mole^{-1} s^{-1} — Eqns. (14) and (15) give $k_p = 252$ — and $k_t = 1.8 \times 10^4$. Although k_p does not differ greatly from the usual value, the rate of termination in water is greater by three orders of magnitude than that in organic systems.

Ethyl methacrylate. In the range 35–100°, for polymerisation "in bulk" with azoisobutyronitrile initiator, the viscosimetric method gave the value[38] $k_p/k_t^{1/2} = 77.6\exp(-4220/RT)$. The degree of polymerisation was determined from the characteristic-viscosity relationship for fractionated polymers.

n-Propyl methacrylate. The rotating sector method at 30°[39] gave $k_p/k_t = 0.070$, $k_p = 467$, and $k_t = 4.5 \times 10^7$. The rate of initiation was determined from the diphenylpicrylhydrazyl consumption.

n-Butyl methacrylate. $k_p/k_t^{1/2} = 0.116$ at 30°[39] and 0.196 at 60°.[40] The last value was determined without allowance for k_{dis}/k_{rec}, but differs from the value calculated from the rate of decomposition of the initiator by only 15–30%. From these two points, $k_p/k_t^{1/2} = 50\exp(-3500/RT)$. At 30° "in bulk" $k_p/k_t = 3.62 \times 10^{-5}$ [39] and in ethyl acetate solution $k_p/k_t = 9.1 \times 10^{-5}$.[35] Making use of the value of $k_p/k_t^{1/2}$, we have $k_p = 147$–362 and $k_t = (1.0$–$1.6) \times 10^7$.

Isobutyl methacrylate. Khanna and coworkers[38] obtained the value $k_p/k_t^{1/2} = 55.3\exp(-4000/RT)$. The value obtained at 60°[40] is $k_p/k_t^{1/2} = 0.180$, which is only 14% less than that found by Khanna and coworkers[38] by the same method. In ethyl acetate solution at 30°, $k_p/k_t = 9.1 \times 10^{-5}$,[35] which with the above data gives $k_p = 109$ and $k_t = 1.2 \times 10^7$ at 30°.

t-Butyl methacrylate. Grant and Grassie[41] found for the polymerisation "in bulk" and in benzene solution at 20–90° the value $k_p/k_t^{1/2} = 0.0955$ at 25° and $E_p - \frac{1}{2}E_t = 3.85$ kcal mole^{-1}. The value of $k_p/k_t^{1/2}$ was determined viscosimetrically from the length of the polymer chains; it was assumed that $k_{rec} = 0$. The rotating-sector method gave $k_p/k_t = 6.5 \times 10^{-3}\exp(-3300/RT)$, so that $E_p = 4.4$ kcal mole^{-1} and $E_t = 1.1$ kcal mole^{-1}; at 30°, $k_p = 410$ and $k_t = 1.4 \times 10^7$.

Comparison of the data for the butyl methacrylates shows that the rotating-sector method gives a value for k_p which is 2–4 times that given by the dilatometric method of Benson and North[34]. It is difficult to give preference to either set of data, particularly since the determination of $k_p/k_t^{1/2}$ and k_p/k_t by the rotating-sector

TABLE 1. Values of k_p and k_t for methyl methacrylate.

* In ethyl acetate solution.

** In toluene solution.

method was carried out "in bulk" and the determination of k_p/k_t by the dilatometric method was carried out in the less viscous ethyl acetate solution.

Nonyl methacrylate. The value $k_p/k_t^{1/2} = 24.3 \exp(-2590/RT)$ has been obtained[38] (the structure of the nonyl group is not indicated). The value $k_p/k_t = 1.8 \times 10^{-4}$ was obtained for 3,5,5-trimethylhexyl methacrylate in ethyl acetate solution at 30°.[35] If we assume that the same substance was studied in the two instances and neglect the difference in viscosity, calculation gives $k_p = 620$ and $k_t = 3.45 \times 10^6$ for 30°. The value of k_p is evidently several times too high.

Cetyl methacrylate. The viscosimetric method (by analogy with other methacrylates it was assumed that $k_{rec} = 0$) in the range 50–80° gave the expression[42] $k_p/k_t^{1/2} = 42.3 \exp(-2500/RT)$, which on extrapolation to 30° gives $k_p/k_t^{1/2} = 0.69$. Dobó and Friese[43] by rough calculation obtained $k_t = 3 \times 10^6$ at 24°, from which $k_p = 98$ at 30°.

A detailed study has been made, for the polymerisation of alkyl methacrylates, of the influence of viscosity on the magnitude of the polymerisation rate constants, noted by Bengough and Melville[44] in a study of the polymerisation of vinyl acetate at high degrees of conversion. North and coworkers[34,35] studied this effect by carrying out the polymerisation at a low degree of conversion in solvents with different viscosities, and found that for methyl methacrylate the value of k_t/k_p is inversely proportional to the viscosity throughout the entire range of viscosity studied $\eta = 0.42$–1000 cP, the lower value being less than the viscosity of the monomer. The value of k_t/k_p is proportional to $\eta^{-0.8}$ for butyl methacrylate and to $\eta^{-0.735}$ for nonyl methacrylate. Subsequently, like a number of other authors and following published conclusions[32,33,39], we shall assume that the chain-growth constant for alkyl methacrylates is independent of the viscosity and the length of the side chain (thus in the analysis it is sometimes more convenient to use the reciprocal k_t/k_p instead of the usual ratio k_p/k_t). The dependence of the termination rate constant on the length of the side-chain or the solvent, however, is evidently determined by the change in the rate of diffusion of the polymeric radicals and not by polar or steric effects, as has been suggested[27,38].

Since the values of k_t/k_p were given[34,35] for a low viscosity and the values of $k_p/k_t^{1/2}$ were determined "in bulk"[38], the individual rate constants calculated above from these data give merely an indication of the order of magnitude and have no claim to accuracy. It would be of interest to compare the constants obtained at the same viscosity. For this it is necessary to know the viscosity of each monomer, but we have been unable to find this information, apart from data[42] for the viscosity of methyl methacrylate (0.34 cP) and cetyl methacrylate (3.18 cP) at 70°. Calculation based on some rather arbitrary assumptions[45] gives values (Table 2) which reveal certain trends. It is evident that discussion of the influence of structure on the rate of termination for a system where it is determined by diffusion for some substances and lies in the kinetic range for other substances can lead to incorrect conclusions. As far as the values of the constants are concerned, Table 2 shows that at constant viscosity the decrease in the termination rate constant with increase in the dimensions of the ester group is irregular: with increase in the number of carbon atoms from 1 to 4 the termination rate constant decreases by a factor of 4–5,

TABLE 2. Dependence of the rate constants for the polymerisation of alkyl methacrylates on viscosity at 30° (approximate calculation).

Methacrylate	Viscosity of monomer, cP (estimated)	k_p		$10^{-7}k_t$	
		for η = 0.42 cP	"in bulk"	for η = 0.42 cP	"in bulk"
Methyl	0.42	270	270	2.5	2.5
n-Propyl	0.96	220	—	2.1	—
n-Butyl	1.23	62	93	0.68	0.065
Isobutyl	1.23	51	—	0.56	—
Nonyl	2.58	170	130	0.010	0.014

whereas further increase up to 9 leads to an increase in the constant by a further factor of 50–60. For a group of medium size (butyl) change in viscosity has a significant influence on the rate of termination, whereas for the bulky nonyl group the viscosity of the surrounding medium is no longer important.

Atherton and North[46] showed that for the copolymerisation of methyl methacrylate and vinyl acetate at 30° and 60° the termination is also determined by diffusion of the polymeric radicals.

According to North[34,35] diffusion termination takes place in three stages. The first stage involves the translational diffusion of two macroradicals into a position in which some segments of each chain are brought into contact. In the second stage, rearrangement or segmental diffusion takes place so that the ends of the two radicals approach sufficiently closely to one another for the third stage — chemical interaction — to take place. This scheme can be represented as follows:

$$P_A^{\cdot} + P_B^{\cdot} \rightarrow [P_A^{\cdot} \ldots P_B^{\cdot}], \quad (18)$$

$$[P_A^{\cdot} \ldots P_B^{\cdot}] \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [P_A : P_B], \quad (19)$$

$$[P_A : P_B] \xrightarrow{k_2} \text{products}. \quad (20)$$

It was shown[34] that the first stage is not the limiting stage. A model was proposed for the polymeric radical[35], in which the end of the chain is regarded as a cylinder whose axis coincides with the main C–C axis of the polymer chain and whose radius is determined by the dimensions of the lateral groups. From the dependence of the reaction rate on the size of the alkyl groups it was shown that the model corresponds to the experimental data. On the basis of scheme (18)–(20), Guertin[47] derived equations relating the rate of the individual stages to the rate and degree of polymerisation and also to the rate of initiation I, and obtained by calculation from the experimental data for methyl methacrylate[46] the values $k_{-1}/k_2\eta = 0.16$ P and $I\eta/k_1 = 9.16 \times 10^{-18}$ mole^2 P^{-1}.

Examination of these "hyper-elementary" stages became possible only as a result of the development of kinetic experiment and demonstrates how the fine effects of a chemical reaction can be revealed by modern methods.

Glycidyl methacrylate $CH_2-CHCH_2O-\underset{\underset{O}{\|}}{C}-\underset{\underset{CH_3}{|}}{C}=CH_2$.

The length of the polymer chains was determined[48] for polymerisation "in bulk" in the range 40–80°; the value of $k_p/k_t^{1/2}$ was also calculated from the rate of decomposition of the initiators. It was found that $k_{dis}/k_{rec} = 2.7$ and $k_p/k_t^{1/2} = 52.6 \exp(-3800/RT)$, which for 30° gives $k_p/k_t^{1/2} = 0.095$. The same authors[48], on the basis of the assumption that k_p/k_t is proportional to $k_p/k_t^{1/2}$ and

that E_t = 400 kcal mole^{-1}, obtained for glycidyl methacrylate, by comparison with the value of k_p/k_t for methyl methacrylate, the values $k_p = 4.13 \times 10^5 \exp(-4000/RT)$ and $k_t = 6.17 \times 10^7 \exp(-400/RT)$. From the data of Arbuzova and Efremova[49] for polymerisation "in bulk" at 70° with benzoyl peroxide initiator, it follows that the rate of polymerisation is approximately proportional to the square root of the initiator concentration. Assuming that the rate constant for the decomposition of benzoyl peroxide is 9.60×10^{-6} s^{-1} and that the efficiency of initiation is 0.8,[1] we obtain by calculation $k_p/k_t^{1/2} = 0.242$.

Benzyl methacrylate. Calculation by the same method from Majer's data[50] gives $k_p/k_t^{1/2} = 0.0338$ at 60° and 0.0362 at 70°.

Methyl acrylate. Data from recent papers, published simultaneously, which give the constant determined by the rotating-sector[51] and dilatometric[52] methods, differ little: $k_p = 1.45 \times 10^6 \exp(-4700/RT)$[51] and k_t = $= 3.55 \times 10^8$ [51] and 6.5×10^6.[52] In one[51] it was assumed that $k_{rec} \simeq 0$, and in the other[52] the rate of initiation was determined from the rate of consumption of diphenylpicrylhydrazyl. The determinations using diphenylpicrylhydrazyl apparently gave slightly high values for $k_p/k_t^{1/2}$.[41]

Butyl acrylate. Melville and coworkers[13,53], from initial non-steady kinetics using a thermocouple, recently obtained the value $k_p/k_t = 6.2 \times 10^{-5}$ at 25°. Benson and North[34], using the dilatometric method at 30°, obtained $k_p/k_t = 12.5 \times 10^{-4}$ "in bulk" (this result coincides with the earliest determination for butyl acrylate[53]) and 8.33×10^{-4} in ethyl acetate solution. Having determined the rate of initiation in separate experiments from the rate of consumption of diphenylpicrylhydrazyl, Bengough and Melville[53] obtained $k_p = 2100$ and $k_t = 3.3 \times$ $\times 10^8$ at 25°. These figures are greater, by factors of 4 and 400 respectively, than those adopted[1] on the basis of the values of $k_p/k_t^{1/2}$ found by other methods. For the activation energy it was found by $E_p - \frac{1}{2}E_t = 3.8$ kcal $\times$ $\times$ mole^{-1}. It is difficult to give preference to any of the data for butyl acrylate.

Methyl α-cyanoacrylate. For radical polymerisation with azoisobutyronitrile at 60°, $k_p/k_t^{1/2}$ = = 0.145 [55]; 100% efficiency of initiation was assumed in the calculations.

Vinyl chloride. Supplementary to earlier[1] contradictory results, Bengough and coworkers[7] obtained $k_p/k_t = 7.1 \times 10^{-7}$ at 25°, which is smaller by a factor of 10 than the value found by Burnett and Wright[56] by the rotating-sector method.

Vinyl acetate. Recent results[15,57-59] show good agreement with the equations adopted earlier[1]: $k_p = 1.13 \times$ $\times 10^6 \exp(-4200/RT)$ and $k_t = 3.12 \times 10^7$. The rate of polymerisation of vinyl acetate changes in a complex fashion with increase in the degree of conversion[44,60] and increases with increase in the viscosity of the solvent[46]. It was established[60] that in polymerisation "in bulk" the rate of diffusion of the macroradicals begins to exert a significant influence on the value of k_t from a degree of conversion equal to 2%, whereas k_p remains unchanged up to 50% conversion.

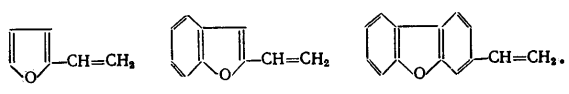
Vinyl benzoate. For polymerisation "in bulk", $k_p/k_t^{1/2} = 0.0255$ at 60° [61] and 0.14 at 79.6°.[62] The first figure[61] is more reliable, since the molecular weights were determined by an osmometric method and the length of the polymer chain was determined using an initiator labelled with ^{14}C. In the second case[62] the molecular weight was determined from the viscosity of solutions of the polymers from the formula for fractionated polymers, without appropriate corrections.

1-Vinylnaphthalene. The value $k_p/k_t^{1/2}$ = $= 3.92 \times 10^2 \exp(6150/RT)$ was obtained[63] from the dependence of the rate of polymerisation "in bulk" at 50–70° on the concentration of azoisobutyronitrile, with allowance for its rate of decomposition. The constant for chain transfer via the monomer is very high, $k_M = 0.03$. Naphthalene, which generally speaking reacts more readily with radicals than benzene, is activated further by the vinyl group.

Isopropenyl methyl ketone $CH_3-\overset{\overset{O}{\|}}{C}-\overset{\overset{CH_3}{|}}{C}=CH_2$.

For polymerisation "in bulk" and in toluene solution with benzoyl peroxide at 80°, from the length of the polymer chains, $k_p/k_t^{1/2} = 0.0278$.[64]

2-Vinylfuran, 2-vinylbenzylfuran, and 2-vinyldibenzylfuran



Calculation from the graphs given by Andreeva and Koton[65] on the assumption that Eqn. (4) applies (the dependence of the rate on the concentration of monomer and benzoyl peroxide initiator has not been determined experimentally) gives for polymerisation "in bulk" and in solution at 80–100° the values $k_p/k_t^{1/2} = 0.001$–0.0025 for 2-vinylfuran, 0.004–0.008 for 2-vinylbenzylfuran, and 0.006–0.021 for 2-vinyldibenzylfuran.

2-Vinylpyridine. For the rate of polymerisation with azoisobutyronitrile at 50–90°, the equation $V = 1 \times$ $\times 10^9 \exp(-2400/RT)$ s^{-1} has been obtained[66]. Calculation of the rate of initiation with the usual assumptions gives $k_p/k_t^{1/2} = 0.088$ at 50° and 0.281 at 90°, and $E_p - \frac{1}{2}E_t$ = = 5.2 kal mole^{-1}; extrapolation to 25° gives $k_p/k_t^{1/2}$ = = 7.4×10^{-3}. This calculation gives a value which differs from those for other vinylpyridines at 25° by a factor of only 3–4.

4-Vinylpyridine. Using the viscosimetric method at 25°, Onyon[67] obtained the values $k_p = 12$, $k_t = 3 \times 10^6$, and $k_M = 8 \times 10^{-3}$. The value $k_p/k_t = 1.9 \times 10^{-5}$ was obtained for polymerisation "in bulk" and in ethanol solution from the adiabatic increase in temperature[68]. The difference between these data and Onyon's data (0.4×10^{-5}) is apparently due to the low accuracy of the viscosimetric method for determining the values of k_p and k_t.

2-Methyl-5-vinylpyridine. The polymerisation was carried out[69] in benzene solution at 60–80° with azoisobutyronitrile and benzoyl peroxide. The rate is proportional to the square root of the initiator concentration. Calculation from the graphs gives values of $k_p/k_t^{1/2}$ which differ slightly for each initiator: 0.031 and 0.042 at 80° and 0.020 and 0.034 at 60°; extrapolation to 25° gives the

values 0.008 and 0.021. At 25°,[68] $k_p = 47$, $k_t = 3.5 \times 10^6$, and $k_M = 3.9 \times 10^{-3}$. In the determination of $k_p/k_t^{1/2}$ and k_M, the length of the polymer chains was calculated from the viscosity using a formula recalculated for the non-fractionated polymer with allowance for termination by chain transfer.

N-Vinylurethane[70]. The degree of polymerisation at 60° with azoisobutyronitrile was determined by an osmometric method. If it is assumed that $k_{rec} = 0$, the efficiency of initiation is $f = 0.59$ and $k_p/k_t^{1/2} = 0.52$ (if it is assumed that $k_{rec} > 0$, the value of f increases; for this initiator, however, f very rarely exceeds 0.6).

Acrylonitrile. The early data[1] are extremely contradictory. The value of k_p at 60° varies in the range 425–1960, and $k_t = 1.2 \times 10^7 - 7.8 \times 10^8$. For a long time it was assumed[71] that termination takes place by disproportionation of the polymeric radicals, but Bailey and Jenkins[72] showed, using tracer methods, that the chains are terminated by recombination of the radicals. Bengough[7] obtained the value $k_p/k_t = 3.4 \times 10^{-6}$ by a combined method in dimethylformamide solution at 25°, and the values $k_p = 52$ and $k_t = 5.0 \times 10^6$ by the thermocouple method "in bulk"[73] at a degree of conversion less than 0.1%, when the polymer has not yet precipitated from its solution in the monomer. These data show satisfactory agreement with our results[68] for dimethylformamide solution: $k_p = 2.35 \times 10^5 \exp(-6400/RT)$, $k_t = 1.8 \times 10^6$, and $E_t \simeq 0$.

The polymerisation of acrylonitrile in dimethylformamide was also studied by the rotating-sector method with initiation by γ-rays[74]. The reaction rate depends on the intensity of irradiation to the power 0.60. The Arrhenius relationship is observed in the range 0–60°; the values found were $E_p = 3.88$ kcal mole^{-1} and $E_t = 3.70$ kcal mole^{-1}. The results for 60°, $k_p = 660$ and $k_t = 8.65 \times 10^7$, agree with earlier data, within the limits of experimental error.

Comparison of the rates of the elementary stages of the polymerisation of nitrogen-containing monomers and styrene at 25° (Table 3) shows that the influence of the free electron pair of the nitrogen is the same for direct conjugation with the C=C double bond in acrylonitrile and for the transfer of this influence through the system of conjugated aromatic bonds in the vinylpyridines. The difference of one order of magnitude in the rates of chain termination indicate a sharp difference in the properties of the polystyrene radical compared with the polyacrylonitrile and polyvinylpyridine radicals. It is possible that the greater mobility of the polystyrene radical brings about more rapid segmental diffusion, compared with the relatively rigid polyacrylonitrile and polyvinylpyridine radicals.

Methacrylamide. For photopolymerisation in aqueous solution, initiated by H_2O_2, at 10–40°, the rotating-sector method[75] gave $k_p = 4 \times 10^5 \exp(-3700/RT)$ and $k_t = 1.3 \times 10^{10} \exp(-4000/RT)$. In the calculation of the rate of initiation, the quantum yield was taken as 0.87, by analogy with the reaction for acrylamide.

Esters of vinylphosphonic acid $CH_2=CH-PO(OR)_2$ were polymerised[76] at 50° with 2 mole % benzoic acid. The kinetic curves were used to calculate the values of $k_p/k_t^{1/2}$ for different esters: methyl 0.23, ethyl 0.14, n-propyl 0.23, isopropyl 0.12, n-butyl 0.36, isobutyl 0.22, and isopentyl 0.34.

TABLE 3.

	Acrylonitrile	4-Vinylpyridine	2-Methyl-5-vinylpyridine	Styrene
k_p	51		47	44
k_t	$1.8 \cdot 10^8$		$3.5 \cdot 10^8$	$4.0 \cdot 10^7$
$\frac{k_p}{k_t}$	$2.8 \cdot 10^{-5}$	$1.9 \cdot 10^{-5}$	$1.3 \cdot 10^{-5}$	$1.1 \cdot 10^{-6}$

Ethylene. The kinetics of the radical polymerisation of ethylene under the influence of suitable initiators under pressure in the liquid phase or in solution have been studied only recently. For polymerisation "in bulk" at a pressure of 40 atm under the influence of the photochemical decomposition of dimethyl azoisobutyrate at 0°, the viscosimetric method[77] gave the value $k_p/k_t^{1/2} = 5.2 \times 10^{-4}$. It was assumed that $k_{dis} = 0$. The efficiency of the initiation was found to be only 0.05. For polymerisation in t-butyl alcohol[78] under the influence of diethyl peroxydicarbonate at 60° and ~50 atm, $k_p/k_t^{1/2} = 0.0182$. The initial rate depends on the concentration of initiator to the power 0.5. An independent method gave for the rate constant for the decomposition of the initiator in ethylene $k_{decomp} = 5 \times 10^{17} \exp(-33\,000/RT)$. The number-average molecular weight was determined ebulliometrically: the efficiency of initiation was close to 1.

Laita[79,80] obtained the values $k_p = 470$ and $k_t = 1.05 \times 10^9$ by the rotating-sector method at 83° in benzene solution; termination takes place by disproportionation of the radicals. Monoradical termination at initiator also takes place in the system with a rate constant of 185. The rate of initiation for the photodecomposition of azomethane was determined by the inhibition method and also from the number-average molecular weight of the polymer. The polymerisation at high pressures (750–2500 atm) was studied[81] in propane solution at 129° with di-t-butyl peroxide initiator. The rate of polymerisation is approximately proportional to the pressure and to the square root of the initiator concentration. With the assumption that the rate of decomposition of the initiator is independent of the pressure and that the efficiency of initiation is equal to 1, the values found for $k_p/k_t^{1/2}$ were 0.22 at 750 atm and 0.73 at 2500 atm.

Rabel and Ueberreiter[82] studied the polymerisation of ethylene "in bulk" for the photodecomposition of the same initiator at -20°. With the assumption that chain termination takes place by disproportionation, calculation by the method proposed by Schulz and coworkers[3] from the dependence of the viscosity-average degree of polymerisation on the reaction rate gave the value $k_p/k_t^{1/2} = 8.7 \times 10^{-4}$. The rotating-sector method gave $k_p/k_t = 4.1 \times 10^{-8}$. These values give $k_p = 18.6$ and $k_t = 4.55 \times 10^8$. Marked deviations have been observed[79,80,82] from the power $n = 0.50$ for the dependence on the intensity of initiation (up to $n = 0.76$); corrections were introduced by the method proposed by Burnett and Wright[83].

The data given for the constants for the elementary stages of the polymerisation of ethylene are contradictory. The values of $k_p/k_t^{1/2}$ from different papers do not lie on the Arrhenius straight line. This is apparently due to the low solubility of polyethylene in the monomer and also to the necessity to work under considerable pressures, different for different temperatures, in the determintion

of the constants "in bulk". The value of $k_p/k_t^{1/2}$ shows a marked pressure dependence at 750–2500 atm,[81] and it is not excluded that the dependence on pressure is preserved even at 20–60 atm. The nature of the solvent used in a number of experiments also appears to influence the value obtained for the constants.

Isoprene. The radical polymerisation of isoprene, like that of ethylene[78] (see above), stops at low degrees of conversion x as a result of consumption of the initiator. Treatment of these limiting conversion phenomena ("dead end") gives the equations[84]

$$-\ln(1-x_\infty)=2k_p\left(\frac{f(I)_0}{k_t k_{decomp}}\right)^{1/2}$$

and

$$\frac{\ln(1-x)}{\ln(1-x_\infty)}=1-e^{-\frac{k_{decomp}t}{2}},$$

which can be used to find the rate constant for the decomposition of the initiator k_{decomp} from the polymerisation kinetic curves. If the efficiency of initiation f is found by an independent method, the above equations can be used to determine $k_p/k_t^{1/2}$.

For the polymerisation of isoprene[85] "in bulk" at 60–90°, this method gave $k_p/k_t^{1/2} = 1\times10^4\exp(-9800/RT)$. Taken with the value $k_p = 1.2\times10^8\exp(-9800/RT)$, determined by emulsion polymerisation[86], this gives $k_t = 1.34\times\times10^8$.

2,3-Dimethylbuta-1,3-diene. Emulsion polymerisation in the range 5–60°[87] gave the value $k_p = 8.9\times\times10^7\exp(-7000/RT)$.

Maleic anhydride. The rate of free-radical polymerisation[88] "in bulk" at 74.5° with benzoyl peroxide is directly proportional to the square root of the initiator concentrations. The length of the polymer chains gives the value $k_p/k_t^{1/2} = 0.0092$.

The reactions of telomerisation and the addition of radicals across the double bond of vinyl compounds are similar to polymerisation reactions. In recent years a number of kinetic studies have been made of the reactions involved in the addition of bromotrichloromethane to certain monomers and various compounds containing a double bond. The method used to determine the rates of the elementary steps in these reactions is basically the same as that used for polymerisation reactions. Photochemical reactions involving CCl_3Br are convenient since no sensitising agent is required. CCl_3Br decomposes to $CCl_3^\cdot$ and $Br_3^\cdot$ radicals under the influence of ultraviolet light.

The photochemical addition of bromotrichloromethane to vinyl compounds (denoted M) with the formation of the 1:1 adduct involves the following elementary steps[89]:

$$CCl_3Br+h\nu \xrightarrow{I} CCl_3^\cdot + Br^\cdot \quad (22)$$

$$CCl_3^\cdot + M \xrightarrow{k_2} CCl_3M^\cdot \quad (23)$$

$$CCl_3M^\cdot + BrCCl_3 \xrightarrow{k_3} CCl_3MBr + CCl_3^\cdot \quad (24)$$

$$CCl_3^\cdot + CCl_3^\cdot \xrightarrow{k_4} C_2Cl_6 \quad (25)$$

$$CCl_3^\cdot + CCl_3M^\cdot \xrightarrow{k_5} \text{products} \quad (26)$$

$$CCl_3M^\cdot + CCl_3M^\cdot \xrightarrow{k_6} \text{products} \quad (27)$$

Kinetic analysis of the scheme by the method of quasi-steady states gives the equation

$$V_{st} = -\frac{d[M]}{dt} = \frac{k_2 I^{1/2}[M]}{k_4^{1/2}} \times \frac{1}{\sqrt{1+\frac{k_6}{k_4}\left(\frac{k_2}{k_3}\right)^2\left[\frac{[M]}{[CCl_3Br]}\right]^2+\frac{k_2k_5[M]}{k_3k_4[CCl_3Br]}}}, \quad (28)$$

which becomes Eqn. (4) with $k_p = k_2$ and $k_t = k_4$, if $\alpha = [M]/[CCl_3Br]$ is sufficiently small. The steady-state rate can also be expressed in terms of the CCl_3Br concentration and then the expression, analogous to (29), becmes Eqn. (4) with $k_p = k_3$ and $k_t = k_6$ if $1/\alpha$ is sufficiently small. Thus the values of k_2 and k_4 are determined in experiments with an excess of CCl_3Br and k_3 and k_6 are determined in an excess of M. The applicability of Eqn. (4) here is determined experimetanlly from the linear dependence of the steady-state rate on the concentration of M or CCl_3Br respectively, and also from the dependence of V_{st} on the square root of the intensity of illumination.

The reaction of CCl_3Br with cyclohexene. Melville and coworkers[90] obtained the following values for the constants in a large excess of CCl_3Br at 30–50°: $k_2 = 4\times10^5\exp(-3400/RT)$, $k_4 = 1\times10^8$, and $E_4 = 0$. The ratio k_2/k_4 was determined by the rotating-sector method and the rate of initiation was found from the rate of consumption of the inhibitor tetrachloro-*o*-quinone.

These determinations were repeated[24] at 25° from the adiabatic increase in temperature and the value $k_2/k_4 = 2.1\times10^{-5}$ was obtained. The effective activation energy for the photochemical reaction $E_2 - \frac{1}{2}E_4 = 3.5$ kcal, which agrees with Melville's data. The determination of the rate of initiation by the usual method involving the introduction of an inhibitor into the photoinitiated reaction may lead to errors, since tetrachloro-*o*-quinone absorbs light strongly even at the low concentrations required for measurement of the rate of initiation. The value $k_2/k_4^{1/2} = 0.87\times10^{-2}$ was obtained at 60° from the rate of decomposition of inhibitor in the reaction initiated by the thermal decomposition of azoisobutyronitrile, and agreed with the value calculated from the rate of decomposition of the initiator for $f = 0.40$. The activation energy can be used to calculate $k_2/k_4^{1/2}$ at other temperatures. The values $k_2 = 1100$ litre mole^{-1} s^{-1} and $k_4 = 0.52\times10^8$ litre mole$^{-1}\times\times$ s^{-1} were obtained in this way. That the values of $k_2/k_4^{1/2}$ determined by Melville and coworkers[90] and by Bagdasar'yan and Revzin[24] differ by a factor of six is evidently due to some inaccuracy in the former determination[90] (see our paper[24] for more detail).

It was shown[91] that the reaction of CCl_3Br with cyclohexene involves not only the addition of the $CCl_3^\cdot$ radical across the double bond but also the removal of an α-hydrogen atom:

$$CCl_3^\cdot + C_6H_{10} \xrightarrow{k_7} CHCl_3 + C_6H_9^\cdot \quad (29)$$

The ratio k_2/k_7 was recently determined[92] for a number of hydrocarbons. For cyclohexene, $k_2/k_7 = 1.20$ at 78° and 1.85 at 40°. From these two points, $E_2 - E_7 = -2.5$ kcal$\times\times$ mole^{-1}, so that $E_7 = 6.0$ kcal mole^{-1}. Extrapolation to 25° gives $k_2/k_7 = 2.28$, that is $k_7 = 483$ litre mole^{-1} s^{-1}‡.

‡ Bagdasar'yan and Revzin[24] give slightly different figures for k_2 and k_7, since the experimentally-determined value of k_2 was erroneously taken[24] as the sum of the rate constants for reactions (23) and (29). This point was brought to our attention by A.N. Pravednikov.

For an excess of cyclohexene, Melville and coworkers[93] obtained the values $k_3 = 63.8$, $E_3 = 4.5$ kcal mole^{-1}, $k_7 = 4 \times 10^7$, and also $k_5 = 5.7 \times 10^8$. The activation energy for termination $E_6 = E_5 \simeq 0$.

The reaction of CCl_3Br with hept-1-ene was studied[24] at different reagent ratios in the range 15–40°. The rate of initiation in an excess of CCl_3Br was assumed to be the same as in the reaction with cyclohexene, and the rate of initiation in an excess of hept-1-ene was calculated at 60° from the rate of the thermal decomposition of the initiators. The adiabatic increase in temperature gave the values $k_2 = 2.3 \times 10^9 \exp(-7000/RT)$, $k_3 = 2.48 \times 10^8 \exp(-8500/RT)$, $k_4 = 1.38 \times 10^8$, and $k_6 = 1.03 \times 10^6$ litre mole^{-1} s^{-1}; $E_4 = E_6 \simeq 0$.

A curious feature is the anomalously low value, which is difficult to explain[95], of the rate constant for addition to cyclohexene shown both by the $CH_3^\bullet$ radical and by the $CCl_3^\bullet$ radical. The rate of removal of hydrogen from cyclohexene, however, is apparently quite "normal": by extrapolating k_2 for cyclohexene to 77.8° and making use of the value $k_2/k_7 = 1.20$ for this temperature[92], we obtain for cyclohexene $k_7 = 2200$; similar calculations for hept-1-ene give the value $k_7 = 2400$. Thus the difference in the rates of removal of hydrogen k_7 by the $CCl_3^\bullet$ radical from cyclohexene and hept-1-ene is insignificant and confirms the observation, found for other radicals, that the reactivity of secondary hydrogen atoms is approximately the same for all alkenes and cycloalkenes.

For the reaction of CCl_3Br with n-butyl vinyl ether[94], $k_2 = 3.16 \times 10^{10} \exp(-7700/RT)$, and for the reaction of CCl_3Br with phenyl vinyl ether, $k_2 = 2.0 \times 10^4$ at 25° (the value of k_4 was taken as 1.0×10^8).

The value $k_2 = 3240$ litre mole^{-1} s^{-1} has been reported[92] for the addition of $CCl_3^\bullet$ to methylallyl acetate at 30°; the activation energy for this reaction is 7.74 kcal mole^{-1}.

For the addition to vinyl acetate the rotating-sector method[93] gave $k_2 = 1120$ at 30° and $E_2 = 6.1$ kcal mole^{-1} in the same laboratory; later, Bengough and Thomson[96] determined the rate of initiation from the rate of consumption of diphenylpicrylhydrazyl or from the duration of the induction period in different solutions at 25° and obtained the value $k_2 = 795$–2410, depending on the method used to determine I. These small values for vinyl acetate are even more surprising than those for cyclohexene, since the rate of addition of $CCl_3^\bullet$ to other rapidly polymerising monomers (styrene, methyl methacrylate) is greater by approximately one order of magnitude. The telomerisation of bromotrichloromethane with a large excess of vinyl acetate[97] leads to the formation of telomers containing different numbers of monomer units for every CCl_3 group. From their data[97], the authors concluded that the value obtained by Melville and coworkers[93] for the rate constant for the removal of the Br atom from CCl_3Br by the $CH_3COOCHCH_2CCl_3^\bullet$ radical at 30°, $k = 2740$, is clearly too low. For other substances with different structure, including active monomers (see below), however, this quantity has values in the range 13–400, that is, the value of k_3 for vinyl acetate is greater by one order of magnitude than the values for other substances.

Robb and coworkers studied the mechanism and kinetics of the photochemical telomerisation of bromotrichloromethane with styrene[98,99] and methyl methacrylate[100]. The rate of initiation was determined from the duration of the induction period in the presence of diphenylpicrylhydrazyl, and the lifetime of the free radicals was determined by the rotating-sector method. The reaction rate is proportional to the square root of the intensity of illumination.

The following values were found for the rate constants of the dimeric and trimeric teloradicals at 30°:[99]

	k_a	k_p	k_t
$[(C_6H_7)_2CCl_3]^\bullet$	$4.4 \cdot 10^3$	56.8	$5 \cdot 10^8$
$[(C_6H_7)_3CCl_3]^\bullet$	$4.3 \cdot 10^3$	1.56	$1.6 \cdot 10^8$

The symbols for the constants have their usual significance: k_3 is the constant for the removal of a bromine radical from CCl_3Br, k_p the constant for the addition to a molecule of monomer, and k_t the constant for recombination of the radicals. When the number of monomer units in the telomer chain is greater than or equal to 4, the value of k_p again increases to the usual value for the polymerisation of styrene.

For the reaction of methyl methacrylate with trichlorobromomethane[100], the rate constants for the telomeric radicals $[(MMA)_nCCl_3]^\bullet$ at 30° have the following values:

n	k_a	k_p
3	13.3	160
4	8.34	37.9
5	330	281

The termination rate constant $k_t = 1.6 \times 10^7$ is independent of the value of n.

Thus the systems studied show a minimum reactivity for the trimer for styrene and the tetramer for vinyl acetate (according to the data of Bengough and Thomson[97], examined critically by Robb and Senogles[100]) and methyl methacrylate. The same phenomena were observed in the telomerisation of esters of acrylic acid with lower thiols[101]. The reduced reactivity of the trimers and tetramers was attributed to the fact that, as a result of the steric conditions here, the CCl_3 (or SH) group attached to the first unit is in direct proximity to the C atom carrying a free valency, and reacts with it. Moreover, the influence of the CCl_3 group on the activity of the radical decreases with increase in the length of the telomeric radical chain. The reactions of telomers show particulary clearly that the rate constants for propagation and termination of the chain, determined in polymerisation, refer, strictly speaking, only to the reactions of sufficiently large polymeric radicals containing more than four units. In polymerisation reactions, the difference in the rates of reaction for 2- and 3-unit or longer polymeric radicals is smaller, however, than that for telomerisation reactions.

FEATURES OF THE KINETICS OF CHEMICAL REACTIONS OF HIGH-MOLECULAR-WEIGHT COMPOUNDS

I.A. Tutorskii, S.V. Novikov, and B.A. Dogadkin

CONTENTS

I. Introduction 83

II. Influence of the inclusion of a functional group in a polymeric chain on the kinetic parameters for the reactions of this group 83

III. Influence of the interaction of functional groups in a polymeric chain on the reaction kinetics 84

I. INTRODUCTION

The study of the kinetics of homogeneous reactions of macromolecules has recently received much attention from several investigators [1-37]. The interest in this problem is due to the search for ways of controlling the chemical changes in polymers and of carrying out directed reactions to obtain chemical derivatives with desired properties.

By comparing the kinetic parameters of reactions of functional groups included in the polymer chain with the analogous parameters of the same groups in low-molecular-weight compounds, it is possible to suggest a series of factors which lower the pre-exponential term of the Arrhenius equation for large molecules [1]. Firstly, from the kinetic theory, with increase in the dimensions (mass) of the molecule the rate of the Brownian movement of the molecules falls. Secondly, the high viscosity of the polymeric solutions decreases the number of collisions of the reacting groups. Thirdly, there is the great steric factor due to the screening of the functional groups by coiling of the polymeric chains.

When there is regular attention of the functional groups in the polymeric chain, the interaction of neighbouring groups (of two which have not reacted or which have reacted with those which have not yet entered into reaction, etc.) can affect the energy of activation.

This review shows the influence of the inclusion of a functional group in a polymeric chain and the interaction of regularly alternating functional groups on the kinetic parameters of reactions of macromolecules.

II. INFLUENCE OF THE INCLUSION OF A FUNCTIONAL GROUP IN A POLYMERIC CHAIN ON THE KINETIC PARAMETERS FOR THE REACTIONS OF THIS GROUP

There are many experimental results which show that the inclusion of a functional group in a polymeric chain does not significantly change either the activation energy or the pre-exponential term of the Arrhenius equation for reactions of this group with low-molecular-weight agents. Thus, Fuoss and coworkers [2], in studying the formation of quaternary salts of poly(vinylpyridine) and low-molecular pyridine compounds obtained the following constants for reaction rates and activation energies (Table 1).

The reaction was effected in tetramethylene sulphone; the alkyl halide used was n-butyl bromide.

TABLE 1. Kinetic parameters of the Menshutkin reaction for poly(vinylpyridine) and low-molecular-weight pyridines.

	$10^3 K_2$			E_a
	25°	50°	75°	
Pyridine C_5H_5N	0.463	3.70	23.1	16.04
4-Isopropylpyridine $C_3H_7C_5H_4N$	0.904	6.95	39.7	15.6
Poly(vinypyridine) (first stage of reaction)	0.64	5.4	29.4	15.7
4-Picoline $CH_3C_5H_4N$	0.83	6.58	40.1	15.95

Table 1 shows that the inclusion of pyridine in the polymeric chain affects neither the activation energy nor the reaction rate constant. Analogous results were obtained when propylene carbonate [4 methyl-1,2-dioxolan-2-one (Ed. of Translation)][3], 2,4-dimethylsulpholane [2,4-dimethyltetramethylene sulphone (Ed. of Translation)][4] or a mixture of propylene carbonate and diphenyl ether [5] was used as solvent.

Loucheux and Banderet[6] investigated the kinetic parameters of the reactions of macromolecules with one or several groups. In the range of functional group concentrations from 10^{-6} to 10^{-8} (per 1 cm^3) the rate of reaction of monoanhydride with aniline is the same for both the functional group of a macromolecule and the low-molecular-weight anhydride. The rate of reaction is independent of the viscosity of the solution even beyond the gelling point.

Moens and Smets[7] found that the rate constants and the Arrhenius parameters for the alkaline hydrolysis of poly(diethylacrylamide) were identical with those for diethyl isobutyramide (Table 2).

TABLE 2. Alkaline hydrolysis of amides.

	$10^4 K_{1,OH}$, s^{-1}			E_a	$\log PZ$
	60°	70°	80°		
Poly(diethylacrylamide)	0.14	0.415	1.15	22.05	9.47
Diethylisobutyramide	0.20	0.51	1.24	21.70	9.07

In the alkaline hydrolysis of amides[8] the Arrhenius parameters for polyacrylamide and isobutyramide are identical (E_a = 14.16 kcal $mole^{-1}$ and $\log PZ$ = 5.63 for the first stage of the hydrolysis of polyacrylamide and E_a = 14.2 kcal $mole^{-1}$ and $\log PZ$ = 5.56 for the hydrolysis of isobutyramide).

Similar results are obtained in the acid of poly-(*N*-ethylacrylamide) and *NN'*-diethylisobutyramide: the activation energy for the first is 24.6 kcal $mole^{-1}$ and the number of effective collisions was characterised by $\log PZ$ = 9.49; for the model low-molecular-weight compound E_a = 23.7 kcal $mole^{-1}$ and $\log PZ$ = 9.20.

Conix and Smets[9] obtained the following results in the hydrolysis of low- and high-molecular-weight lactams (Table 3).

TABLE 3. Hydrolysis of lactams.

	E_a, kcal $mole^{-1}$	$\log PZ$
Poly-(*N*-vinylpyrrolidone)	25±1	11.7
N-Isopropyl-2-methylpyrrolidone	27±0.5	12.3
Copolymer of vinylpyrrolidone and maleic acid (68 : 32)	16±1	6.3
Pyrrolidone-*N*-acetic acid	17±0.5	7.3

By studying the acetylation of cellulose and the reverse reaction of hydrolysis, Hiller[10] showed that the rate of reaction and activation energy in the acetylation of the primary hydroxyl groups in cellulose were of the same order as for the analogous reactions of butanol.

Salomon and coworkers[11,12] note that the activity of the chloride of natural rubber, which contains 20–30% allyl chloride, with respect to aniline is identical with that of low-molecular-weight allyl chlorides.

Losev and Trostyanskaya[13] state that in solutions, reaction between a polymer and a monomer proceeds at a rate similar to that for reaction of two low-molecular-weight substances.

Billmeyer[1] explains as follows the similarity between the kinetic parameters of the reactions of the functional groups in polymers and low-molecular-weight compounds in polycondensations.

Firstly, the mobility of the functional groups in a polymeric chain is considerably greater than the mobility of the chain itself. The functional groups move easily within a considerable region as a result of the change in configurations of the neighbouring parts of the chain. The frequency of the collision of these groups with their neighbours is comparable with the frequency of the collisions of low-molecular-weight compounds.

Secondly, in addition to the lower rate of diffusion, due to the high viscosity of the solutions of polymers and the increase in the time needed for the approach of the reacting groups, there is also an increase in the time for these groups being together and consequently in the effective collision number.

Thirdly, a screening effect can appear only in dilute solutions; at high concentrations the chains of the macromolecules are so greatly entangled that the chain proper, from the point of view of the screening of the functional groups forming part of it, has no advantage over the chains of other molecules.

Probably the same factors lead to the similarity between the kinetic parameters of the reactions of functional groups in polymers and in low-molecular-weight compounds as cited above.

III. INFLUENCE OF THE INTERACTION OF FUNCTIONAL GROUPS IN A POLYMERIC CHAIN ON THE REACTION KINETICS

The similarity of the kinetic parameters of the reactions of functional groups in high polymers and low-molecular-weight compounds can be upset if during the reaction the molecule of high polymer becomes charged and the charged groups are situated beside functional non-reacting groups.

Fuoss and coworkers[14] investigated the kinetics of the Menshutkin reaction for poly(vinylpyridine). The general kinetics of the reaction do not correspond with the kinetics of the reactions of low-molecular-weight pyridines. As the pyridine group forms part of the molecular chains, the successive reaction to form quaternary salts should take place at small distances from the groups that have already reacted. In solvents of high dielectric constant a considerable proportion of the bromide ions leaves the site of the pyridinium ions, creating a positive electric field of high intensity at the polymeric chain. As a result, after one-third of all the groups have reacted each remaining group will have an average of one charged neighbouring group, and when one-half of all the groups have reacted the remaining groups will have two charged neighbour groups. Thanks to the field of the positive charge of the nitrogen which reacted first, the rate constant falls to one-tenth of its initial value at the group of the neighbouring nitrogen.

Moens and Smets[7] showed the influence of the accumulation of charge on a macromolecule during the course of

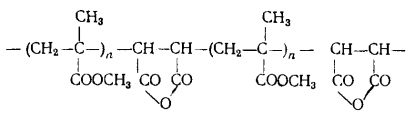
the reaction on the kinetic parameters of the alkaline hydrolysis of polyacrylamides. The hydrolysis can be divided into two clearly defined stages, the first being rapid, with a rate similar to that for the hydrolysis of the model low-molecular-weight compound, and the second being slow. During the initial stage the reaction is first order, but after reaching ~ 40% conversion the rate constant falls.

At low degrees of hydrolysis the molecule has a convolute configuration. At ~ 40% conversion the chain is uncoiled owing to electrostatic repulsion of the carboxyl groups present in a single molecule. The accumulation of charge on the macromolecule leads to an increase in the rigidity of the chain, a change in its configuration, and a diminution in the rate constant.

Kargin and coworkers [15] showed the influence of the electrostatic factor on the kinetic parameters of the hydrolysis of ethyl acetate, which is catalysed by poly(styrenesulphonic acid) (PSSA). Toluenesulphonic acid (TSA) served as a low-molecular analogue of PSSA. In the presence of PSSA the rate of hydrolysis was 1.3–1.8 times as great. The difference in the rates of reactions catalysed by PSSA and by TSA increases as the catalyst concentration is reduced.

The high activity of PSSA is explained by the increase in the concentration of protons (in the form of oxonium ions H_3O^+) close to the polymer chains. In the oxonium cloud around the macroanion the activity coefficients of the H_3O^+ ions are greater than in the TSA solution, where the H_3O^+ ions are distributed uniformly throughout the entire volume. During this, the increase in the rate of hydrolysis in the oxonium cloud is not compensated by the fall in the reaction rate in the regions of the solution denuded of H_3O^+ ions. Naturally, the more dilute the solution the more marked this effect.

Loucheux and Banderet [6] investigated the reaction of aniline with a copolymer of methyl methacrylate and maleic anhydride in which the anhydride groups were not adjacent:



The greater the number of anhydride groups in the macromolecule, the less the rate of reaction, all other conditions being equal. This occurs because, in a non-polar solvent (benzene), the macromolecule with a low concentration of anhydride groups mixes well with the solvent. An increase in the number of anhydride groups in the macromolecule increases its polarity, which leads to a complication of the polymeric chain into more intimate tangles. As a result, the anhydride groups become less accessible and the rate of reaction decreases.

The kinetic similarity of the reaction of polymers and low-molecular-weight compounds fails when an intramolecular reaction is possible for a polyfunctional polymer. Arcus [16] showed this by the example of the alkaline hydrolysis of poly(methyl methacrylate). At the start of the reaction the polymer contains only amido-groups which are mono-functional. During the reaction carboxyl groups appear as well as the amido-groups, and because both are fixed in a polymeric chain hydrogen bonds are formed between them, increasing the activation energy for hydrolysis of the amido-groups, as a result of which the reaction rate is sharply depressed. When each amido-group has two carboxyl groups as neighbours, the reaction ceases. Under those conditions the low-molecular-weight amides are hydrolysed to completion. Smets [8] considers that it is not hydrogen bonds but electrostatic repulsion and steric hindrance which lead to the progressive retardation of the alkaline hydrolysis of the alkaline hydrolysis of polyacrylamide.

Moens and Smets [7] observed the effect of intramolecular chemical reaction of functional groups on the kinetic parameters of their reactions by the example of the acid hydrolysis of poly(vinylamides). They thought that the hydrolysis was accompanied by imidisation, which lowers the reaction rate and raises the activation energy by 3.5 kcal.

Smets and Petit [38] observed an increase in the activation energy due to the association of functional groups in a monofunctional polymer. Thus in the acetylation of poly(vinyl alcohol) at a sulphuric acid concentration of 0.5 N and 0.05 N the activation energy was 9.5 and 15 kcal respectively. The increase in E_a by 5.5 kcal in the second case is due to the association of hydroxyl groups.

In polyfunctional polymers the kinetic parameters can be affected by catalytic action shown by one functional group to another.

Moens and Smets [7] compared the alkaline hydrolysis of polyacrylamide with the hydrolysis of low-molecular-weight amides (Table 4).

As Table 4 shows, the rate of reaction of the functional groups in the polymer is greater than that in the low-molecular-weight compounds. Morawetz explains this by the specific catalysis of the carboxyl groups in the first stage of the reaction.

TABLE 4. Hydrolysis of amides.

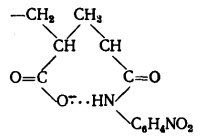
	$10^4 K_2$, OH, mole^{-1} s^{-1}					E_a	log PZ
	55°	65°	70°	75°	85°		
Polyacrylamide	6.66	—	18.6	—	38.8	13.7	5.99
Isobutyramide	1.16	2.36	—	3.95	—	14.2	5.56
Glutaramide	—	3.80	—	6.94	12.7	14.8	6.01
Acrylamide	1.47	3.70	—	6.66	13.8	16.6	7.24
Propionamide	5.24	9.98	—	17.7	—	14.6	6.10

The nature of the intramolecular catalysis of hydrolytic reactions was studied in detail by Bender and coworkers using the example of acid and alkaline hydrolysis of phthalamic acid [39,40] and the hydrolysis of methyl phthalate [41]. Kinetic comparison of several low- and high-molecular-weight compounds showed a great difference between the intramolecular and intermolecular hydrolysis [42].

Smets and Petit [38] observed the catalytic action of a hydroxyl group situated directly next to an acetyl group in the hydrolysis of poly(vinylacetal).

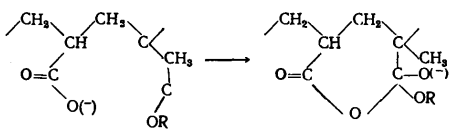
Schaefgen and Sarasohn [17] carried out the quantitative thermal decomposition of poly(butyl acrylate) into 2-methylprop-1-ene and poly(acrylic acid). Initially the reaction follows a statistical law. When 9.4 ± 2% has been converted, there is a rapid autocatalytic splitting-off of ester groups owing to the action of neighbouring carboxylic groups.

The investigations of Morawetz and coworkers [18,19] showed that the introduction of methacryl-*p*-nitroanilido--groups into a polyacid molecule makes these groups a thousand times more stable to sodium hydroxide, in comparison with the *p*-nitroanilides of trimethylacetic and glutaric acids. The stabilisation results from ring formation:



from an increase in the steric effect, and from an increase in the electrostatic repulsion. This explanation is confirmed by the accelerating effect of the addition of small quantities of Ba^{2+} ions, which, by bonding the carboxylate groups, free the anilide groups.

The hydrolysis of *p*-nitrophenylmethacrylic groups, introduced into the chain of poly(acrylic acid) to the extent of ~ 1%, goes a million times faster than the hydrolysis of *p*-nitrophenyl trimethylacetate [20,21]. Morawetz explains this by the selective catalytic action of a neighbouring carboxylate ion with the formation of an intermediate complex:

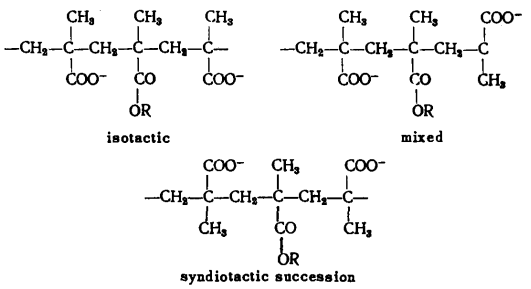


Smets and De Loecker [22] investigated the hydrolysis of copolymers of methacrylic acid and methyl methacrylate, at various ratios of the components. Under similar conditions the copolymer of methyl methacrylate and vinylpyrrolidone is hydrolysed 1000 times more slowly since with the latter the catalytic action of carboxyl groups is absent.

Smets and Hesbain [23] studied the hydrolysis of polyacrylamide and of copolymers of acrylamide and acrylic acid in an acetate buffer solution. The presence of the carboxyl group along with the amide in the copolymer increases the rate of hydrolysis three thousand times compared with the rate of hydrolysis of polyacrylamide.

The kinetic parameters of functional groups in a macromolecule are greatly affected by the stereoregularity of their distribution, when the polymer is polyfunctional — or when the reacting groups display a catalytic action on neighbouring functional groups, not taking part in the reaction. Thus, Glavis [24] showed, by the example of the alkaline hydrolysis of poly(methyl methacrylate)s of different tacticity, that the standard (atactic) and syndiotactic polymers are hydrolysed comparatively slowly but the isotactic polymers very rapidly and to a much greater degree. Smets [8] carried out the hydrolysis of atactic and isotactic copolymers of methacrylic acid with its ester (72% acid). The isotactic copolymer is hydrolysed 10–15 times more rapidly than the atactic and to a greater extent (40% instead of 20%).

The hydrolysis of a copolymer of methacrylic acid with 1–2% *p*-nitrophenyl methacrylate with isotactic succession of the carboxyl and ester groups is 12 times faster than that for a mixed succession [25]:



Smets and De Loecker [26,27] investigated the hydrolysis of copolymers of methacrylic acid with methyl methcrylate of the same chemical structure but different tacticity. The rate constants of the hydrolysis of a syndiotactic copolymer were four to five times those for the atactic. The syndiotactic copolymer is hydrolysed in a single stage, after which the reaction stops; the atactic copolymer in two stages with a ratio of the rates $K_1 : K_2 = 1 : 6$.

A comparison with the hydrolysis of a copolymer of methylmethacrylic acid and *N*-vinylpyrrolidone shows clearly that the ester and carboxyl groups interact with one another, which leads to a drop in the energy of activiation from 23 to 16 kcal.

Chapman [28] studied the acid hydrolysis of very crystalline isotactic and amorphous atactic poly-(*NN*-dimethylacrylamide)s. The isotactic polymer is hydrolysed more rapidly, since owing to the intramolecular nature of the hydrolysis the activation energy is reduced from 29 to 22.6 kcal. On the basis of his investigations Chapman proposes a method for determining the degree of tacticity by hydrolytic measurements.

Smets and Van Humbeeck [29] studied the hydrolysis of copolymers of acrylic acid and ethyl ethacrylate containing 50, 67, 77, and 85% of the acid. The hydrolysis rate is directly proportional to the concentration of the acid–ester–acid triad and the isotactic polymer is hydrolysed three to five times more rapidly than the atactic, and to a greater extent. The hydrolysis of copolymers of acrylic acid and t-butyl acrylate and of polymers of poly-(t-butyl acrylate) is independent of their stereoregularity, since the intramolecular interaction of the functional groups is ruled out by the strong steric effect.

Fujii and coworkers [30–32] showed the influence of stereoregularity on the kinetic parameters of the reactions of polymers by the example of hydrolysis of poly(vinyl acetate) and the acetalisation of poly(vinyl alcohol).

The kinetic similarity of the reaction of polymers and of low-molecular compounds breaks down when the functional groups or double bonds can bring about electronic interaction along the polymeric chain.

Cunneen [42–44] showed a diminution in the reactivity of double bonds relative to electrophilic agents on going from low-molecular monoalkenes to 1,5-polyenes, for example, of the reaction of polyisoprene and cyclohexene with ethanethiol, 3-methylbutane-1-thiol, thiophenol, thioglycollic acid [43], propane-1,3-dithiol and hexane-1,6-dithiol [44], and thioacetic and chlorothioacetic acids [45]. The reactivity is reduced in the order: cyclohexene > dihydromyrcene > > squalene > natural rubber.

We have found complete inertness of *cis*- and *trans*-polyisoprenes towards ethyl thioglycollate, whereas its addition to isopentene proceeds very readily [46].

Bateman and coworkers [47] note a fall in the reactivity of double bonds in polyisoprene compared with low-molecular-weight alkenes in hydrogenation.

We assume that the fall in reactivity of double bonds in 1,5-polyene systems in relation to electrophilic reagents is connected with the interaction of double bonds regularly alternating in the 1,5 positions. We have already considered the mechanism of this interaction [47]. Such an interaction of double bonds in diene polymers leads to the development of a series of reactions of these polymers by an intramolecular chain mechanism [46,48].

Alfrey and Lloyd [33] showed an intramolecular chain mechanism in the dehydrochlorination of poly(vinyl chloride). The act of reaction in one monomer unit converts a neighbouring unit into an allyl structure with an enhanced tendency to dehydrochlorination, which should lead to the chain development of the process and to the formation of a block of conjugated bonds.

There are several theoretical works on the kinetics of reactions of macromolecules in which the mean number of reacting functional groups is determined as a function of time under the condition that the reactivity of each group depends on how many of the neighbouring groups (one, two, or none) have already reacted [14,33-37].

The features noted do not, of course, exhaust all the specific characteristics of the kinetics of the reactions of polymers. The tasks of future investigations in this interesting and little studied field are the accumulation of information on the influence of the solvent on the course of the polymeric reactions, and also on the influence of secondary structures in solutions of polymers on the topochemical and kinetic features of the reactions.

VI. Experimental data on transport numbers in aqueous solutions of electrolytes 101

I. INTRODUCTION

Problems arising in the measurement of the transport numbers and mobilities of ions in electrolyte solutions have been the object of many experimental and theoretical investigations[1-4]. The development of experimental techniques was particularly vigorous at the beginning of the present century, when the moving boundary method and the e.m.f. method achieved a popularity as wide as that of the Hittorf method. Since the late 1940's, several new procedures have been developed intensively, and have helped to provide many experimental data whose effect has been to increase our understanding of the transport numbers and mobilities of ions in solutions of various chemical compounds.

The most important characteristic of the motion of ions in solutions is ionic mobility. The mobility is a function of all the parameters of the solution, and is defined as the velocity of the ions under the influence of a unit potential gradient (1 V cm^{-1}). The ability of an electrolyte to carry an electric current, *i.e.* the electrical conductivity of the electrolyte, is determined by the total charge and by the mobility of the ions. The total current passing through a unit cross-section of a solution containing a mixture of various ions is given by

$$j = F \sum_i c_i z_i u_i , \qquad (1)$$

where c_i, z_i, and u_i are the concentration, the charge, and the mobility of the ions of the i-th kind, respectively, and F is Faraday's constant.

The fraction of the current carried by ions of the i-th kind is called the transport number of those ions, and can be expressed in the form

$$T_i = \frac{u_i z_i c_i}{\sum_i u_i z_i c_i} . \qquad (2)$$

Obviously, the sum of the transport numbers of all kinds of ion present in solution is

$$\sum_i T_i = 1. \qquad (3)$$

In the simplest case of a binary electrolyte, dissociating into two ions ($MA \rightleftharpoons M^+ + A^-$), of mobility u_{M^+} and u_{A^-} respectively, the transport numbers are

$$T_{M+} = \frac{u_{M+}}{u_{M+} + u_{A-}}, \quad T_{A-} = \frac{u_{A-}}{u_{M+} + u_{A-}}, \tag{4}$$

since the equivalent concentrations of the ions are equal. Ionic mobilities can be determined experimentally by measuring the velocity of the ions and the electrical potential gradient. Lodge[5] and Whethem[6] were the first to attempt this measurement, but they experienced great difficulty in measuring the electric field (and therefore also the mobility) with adequate precision. Later workers determined mobility values by calculation, from measured transport numbers, and from the electrical conductivity of the solutions. Electrical conductivity data are now available for a large number of electrolytes, but data relating to transport numbers are far less plentiful. This is because transport number measurements present more serious experimental difficulties.

All existing methods for measuring transport numbers rely on the displacement of atoms of a given kind as a means of monitoring the motion of charges. In fully dissociated solutions, which includes most dilute solutions, the displacements of atoms and charges are identical, and existing methods of measurement give a correct assessment of the motion of ions in solutions. A more complicated situation exists when a given substance can contribute to the composition of both the anions and the cations. There is ample experimental evidence for the formation of ion pairs in solution, and also of groups of three ions (ion triplets)[7,8]. Complex formation very often takes place in electrolyte solutions[9-11]. All these effects cause the experimentally measured transport numbers to differ from the values given by Eqn. (4). If the M atoms in a solution of MA can enter into the composition of both the cations and the anions, the value of the transport numbers obtained experimentally can be expressed as

$$T_M = \frac{\sum_i^n z_i u_{ci} c_{ci} p_{cMi} - \sum_i^m z_i u_{ai} c_{ai} p_{aMi}}{\sum_i^n z_i u_{ci} c_{ci} + \sum_i^m z_i u_{ai} c_{ai}}, \tag{5}$$

where u_{ci} and c_{ci} are the mobility and the concentration of cations of the i-th kind, u_{ai} and c_{ai} the mobility and the concentration of anions of the i-th kind, p_{cMi} is the number of M atoms included in the composition of the i-th cationic component, and p_{aMi} the number of M atoms included in the composition of the i-th anionic component.

The summation is carried out over all kinds of cation (n) and of anion (m). It is evident that the case where $\sum_{i=1}^{m}$ is greater than $\sum_{i=1}^{n}$ corresponds to anomalous values of the transport number.

Thus, the experimentally measured transport numbers are a measure of the ratio of the resulting flux of atoms of the substance M to the total flux of charged species[12].

The interactions between ions and the solvent lead to the formation of solvation (hydration) shells around the ions, which move in the electric field together with the ions[13-15]. The difference in degree of solvation and in mobility between cations and anions results in a net transfer of solvent in one direction, which has given rise to the concept of apparent and true transport numbers. Existing methods of measuring transport numbers use the solvent as the system of coordinates, and do not take account of the motion of solvent with the ions. Transport numbers measured in this way are the apparent (or, as they are often called, Hittorf) transport numbers. To measure true transport numbers, the system of coordinates is based on the solution as a whole[16,17], so that the preferential motion of the solvent is automatically compensated.

Experimental methods for measuring apparent transport numbers can be divided into three groups: (a) Hittorf's method; (b) methods based on the measurement of the e.m.f. of galvanic cells; (c) methods based on the observation of ionic boundaries.

The present review deals with existing methods of measuring apparent transport numbers of ions in aqueous solutions of electrolytes, the main emphasis being on methods developed relatively recently. Generalised experimental data on transport numbers in aqueous solutions of electrolytes are presented. Problems arising in the determination of true transport numbers and in measurements in non-aqueous electrolytes are not considered.

II. HITTORF'S METHOD

The principle of the method was first proposed by Hittorf[18-25] in 1853. It is most conveniently discussed by considering a binary electrolyte which dissociates by the reaction $MA \rightleftharpoons M^+ + A^-$. Fig. 1 shows an electrolytic cell for transport number measurements. If no secondary chemical reactions occur at the electrodes during electrolysis, and ions disappear from the cathodic compartment V_c by being discharged, after time t the loss of M^+ cations from the volume V_c will be

$$P_{M+} = \frac{It}{F}, \tag{6}$$

where I is the current passing through the cell.

From the direction of the anode, a flow of M^+ cations enters V_c through the cross-section S:

$$I = \frac{T_{M+}}{F} \cdot \frac{\partial q}{\partial t} + DS\frac{\partial c}{\partial x}, \tag{7}$$

where T_{M^+} is the transport number of the M^+ ions, q the quantity of electricity carried by the cations, t the time,

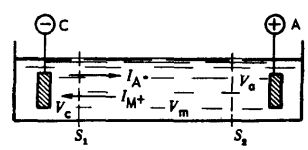

Fig. 1. Schematic diagram of an electrolytic cell for the measurement of transport numbers by the Hittorf method. C and A are the cathode and anode respectively; I_{M^+} and I_{A^-} are the cation and anion currents; S_1 and S_2 are arbitrary cross-sections defining the middle compartment of the cell; V_c and V_a are the cathodic and anodic compartments.

D the diffusion coefficient, and S the cross-sectional area of the cell.

The conditions are usually chosen so that the concentration of the solution in the middle compartment of the cell (V_m) does not change during the time (t) of the experiment. In this case the diffusional term $DS(\partial c/\partial x)$ vanishes, and

$$I_{M+} = \frac{IT_{M+}}{F}. \quad (8)$$

The overall cation balance in the compartment V_c is

$$\Delta P_{M+} = \frac{It}{F}(1 - T_{M+}) = \frac{It}{F} T_{A-}. \quad (9)$$

The quantity of anions moving out of V_c in time t is

$$\Delta P_{A-} = \frac{It}{F} T_{A-}. \quad (10)$$

The total change in the amount of the salt present in the cathodic compartment is

$$\Delta P_{MA} = \frac{It}{F} T_{A-} \quad \text{(equiv.)} \quad (11)$$

The same considerations can be applied to the anodic compartment. The values of ΔP_{MA} are obtained from the differences in concentration of the experimental solution before and after the experiment. The concentration differences produced by the passage of current are expressed in terms of the weight of solvent present in the solution at the end of the experiment. This allows for density changes, and therefore also volume changes, caused by changes in the amount of electrolyte.

The concentrations are usually found analytically by weighing the portion of the solution adjacent to the electrode. This method is therefore often referred to as the analytical or gravimetric method. Zhitomirskii and coworkers[286] have used a tracer method of analysis.

Many different types of measuring apparatus have been described. All of them have a cathodic, an anodic, and a central (intermediate) compartment[26-33]. In some designs porous diaphragms are used, including diaphragms made of ion-exchange resins[27,34-37]. However, different values of the transport numbers are usually obtained with diaphragms.

The application of Hittorf's method is limited by a number of factors:

(a) The need to choose reversible electrodes, or to make allowance for secondary electrode processes[27,38]. In the absence of an exact knowledge of the secondary products of the reaction, the results may be seriously in error[39].

(b) Analytical precision of a high order is needed[27,30,33].

(c) The thermal operating regime of the measuring apparatus must be optimised[38,40-44].

Most experimenters have confined their measurements to relatively small concentration changes: increasing the duration of electrolysis or the current enhances the effect of mixing (whether diffusional or convectional) on the results.

The accuracy of the results is also significantly influenced by the electrolyte concentration, since the relative concentration changes decrease, other things being equal, with increase in the concentration of the solutions. With dilute solutions different workers[38,45] have obtained results agreeing to 0.2% using Hittorf's method. However, the achievement of high precision presents real difficulties, and the moving boundary method is now used instead for accurate measurements of transport numbers.

III. METHODS BASED ON MEASUREMENTS OF THE E. M. F. OF GALVANIC CELLS

Measurements of the electromotive force (e.m.f.) of galvanic cells form the basis of two methods for measuring transport numbers. The first of these (the e.m.f. method) makes use of electromotive force measurements on concentration cells[46-49]. In the second method one measures the electromotive force of galvanic cells subjected to an external gravitational field[50-60].

The processes occurring in galvanic cells can be classified as thermodynamically reversible processes, and therefore thermodynamic methods are used to study them[61,62].

The electrical work done by a cell, excluding the mechanical work associated with any volume change, is equal to the change in the free energy G attending the process in the cell. At constant temperature and pressure dG can be expressed in terms of the change in the chemical potential μ_i of the individual components:

$$dG = Fde = \sum_i d\mu_i. \quad (12)$$

The quantity μ_i can itself be written in the form

$$\mu_i = \mu_i^0 + RT \ln a_i, \quad (13)$$

where μ_i^0 is the chemical potential in the standard state, R is the gas constant, T the temperature, and a_i the activity of the i-th component. These considerations are applied in calculating the e.m.f. of cells.

Concentration cells are a particular type of galvanic cell. Unlike the cells used as a source of e.m.f., whose electrical energy is derived from an overall chemical reaction, concentration cells derive their electrical energy from the tendency of the concentrations in different parts of the cell to reach a common level. According to the nature of the processes accompanying the equilibration of concentration, concentration cells can be divided into two types.

(a) Concentration cells without transport, of the type $\ominus$ reversible A electrode | $MA(c_1)$ | reversible M electrode $MA(c_2)$ | reversible A electrode $\oplus$. In such a cell there is no direct transport of electrolyte from one solution to the other. The solutions are separated by an additional reversible electrode. Transport takes place indirectly, as a result of chemical reactions. If the activities of the solutions differ by an amount da, the electromotive force of a cell without transport can be expressed, in general, by

$$de = \pm \frac{\nu}{\nu_\pm} \cdot \frac{RT}{z_\pm F} d \ln a, \quad (14)$$

where ν is the total number of ions formed when a solute molecule dissociates, and $\nu_\pm$ and $z_\pm$ are the number and the electrovalence, respectively, of ions of one sign. The $\pm$ signs refer to the ions with respect to which the external electrodes are reversible.

(b) Concentration cells with transport, of the type $\ominus$ reversible A electrode | $MA(c_1)$ | $MA(c_2)$ | reversible A

electrode ⊕ , have a liquid boundary between the solutions of different concentration. A diffusion potential, determined by the mobility difference between cations and anions, arises at the liquid junction. The value of the diffusion potential depends on the difference between the work needed to transfer anions from the more concentrated to the more dilute solution and the work needed to transfer cations from the more dilute to the more concentrated solution. The e.m.f. of a concentration cell with transport (ϵ_t) can be expressed as

$$d\epsilon_+ = \pm T_\pm \cdot \frac{\nu}{\nu_\pm} \cdot \frac{RT}{z_\pm F} d\ln a, \qquad (15)$$

where $T_\pm$ is the transport number of the ion with respect to which the electrodes are irreversible. Eqns. (14) and (15) are used in the e.m.f. method.

Two modifications of the e.m.f. method are used to measure transport numbers. In one of these electromotive forces are measured in cells with and without transport containing the same electrolyte. The concentration of one of the solutions is kept constant, whilst the concentration of the other is varied. Transport numbers are obtained from the slope of plots of $\epsilon = f(\ln a)$, according to the expression

$$\frac{d\epsilon_+/d\ln a}{d\epsilon/d\ln a} = T_\pm, \qquad (16)$$

where a is the activity of the solution whose concentration is varied.

The activities of the solutions of different concentrations should be determined independently. The activity is sometimes calculated from the concentration of the solution [$a = f(c)$] by means of the extended Debye–Hückel formula[63].

In the second modification of the e.m.f. method one measures the electromotive force of two concentration cells with transport, in one of which the diffusion potential is reduced to a minimum by introducing an intermediate electrolyte in which the cations and the anions have very similar mobilities[47,48,64]. Solutions of KCl or NH_4NO_3, which have been fully characterised, are commonly used as the intermediate electrolyte.

Many designs of cell have been used for the measurement of transport numbers[47,48,65–68]. A great deal of attention has been paid to the choice of electrodes[69–78] and to the formation of the liquid junction[79–84]. The use of this method is often limited by the difficulty of setting up satisfactory concentration cells. The need to establish the relation $a = f(c)$ complicates the procedure and introduces further errors.

The earliest report of the appearance of an electromotive force in a galvanic cell under the influence of external forces is due to Collie[50,51]. A thermodynamic discussion of the effect can be found in many monographs[2,3,8,52,57–61]. The essential features of the measurement are shown in Fig. 2. Vessel *1*, containing the reversible electrodes *2* and *3*, is filled with a solution of the experimental electrolyte MA and is subjected to the field of gravitational forces f. The cations and the anions, having different masses m_i and volumes V_i, move with different speeds in the gravitational field. The faster ions charge the electrode *3* to a potential ϵ. The charge on the electrode in equivalent to a definite internal electric field $E = \epsilon/h$, whose effect is to equalise the velocities of the ions. Allowing for the repulsive forces which act on the ions in

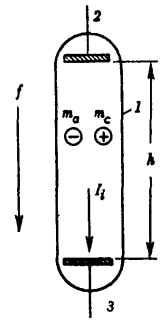

Fig. 2. Measurement of the electromotive force of a galvanic cell in a gravitational force field: 1) solution; 2) and 3) electrodes; h — interelectrode distance; f — external force; I_i — flux of the ith component; m_c and m_a — masses of the cation and anion.

the solution, the expression for the fluxes of cations and anions takes the form

$$I = c_i(u_i m_i g - u_i V_i \rho g \pm u_i \frac{\epsilon F}{h}), \qquad (17)$$

where c_i is the concentration of ions of the i-th kind, ρ the density of the solution, and g the acceleration due to the gravitational force.

The + sign corresponds to the slow ion, the - sign to the fast ion. In the gravitational field the movement of the ions causes transport of the solute as a whole, and the cell becomes a concentration cell. In time, the e.m.f. of the concentration cell opposes its gravitational electromotive force. Time changes of the e.m.f. have been observed experimentally[85,87]. The resulting e.m.f. can be calculated by imposing the condition of equal cation and anion fluxes:

$$\epsilon = -\frac{gh}{F}[T_c(m_c - V_c\rho) - T_a(m_a - V_a\rho)] + \epsilon_1,$$

where

$$\epsilon_1 = (T_a - T_c + 1)\frac{RT}{F}\ln\frac{\gamma_2\left[c_1 + \int_0^t AI_i(t)\,dt\right]}{\gamma_1 c_1},$$

c_1 is the initial concentration, $\gamma_{1,2}$ are the activity coefficients, and A is a parameter describing the distribution of the solution in the cell.

In the particular case of systems consiting of iodide solutions (such as KI with a small amount of free iodine) the transport number is calculated by the formula

$$T_{K^+} = \frac{\epsilon F\left|gh + \frac{1}{2}(M_{I_2} - V_{I_2}\rho)\right|}{M_{KI} - \overline{V}_{KI}\rho}, \qquad (19)$$

where M_{KI} and $\overline{V}_{KI}$ are the molecular weight and the partial volume of the salt and M_{I_2} and V_{I_2} the molecular weight and partial volume of the free iodine.

A considerable enhancement of the effect has been achieved by placing the galvanic cell in a centrifuge[55,56,85,86]. An e.m.f. generated by the centrifugal acceleration arises at the electrodes of the cell, located at distances r_1 and r_2

from the centre of rotation. To calculate the transport numbers, one uses formula (19) with the substitution

$$gh = 2\pi^2 n^2 (r_2^2 - r_1^2), \qquad (20)$$

where n is the number of revolutions per second.

As in the e.m.f. method, reversibility of the electrodes is an essential requirement in measurements of transport numbers by the gravitational method. Radial temperature gradients must also be carefully avoided[58].

Measurements of transport numbers by the e.m.f. method and by the method based on e.m.f. measurements on a galvanic cell in a gravitational force field are inferior in accuracy to measurements by the moving boundary method. In all these methods serious difficulties arise in the treatment of results for multicomponent systems: these require a knowledge of the relationship between the e.m.f.'s of the galvanic cells and the transport numbers of the individual components[68,88-90].

IV. METHODS BASED ON OBSERVATIONS OF IONIC BOUNDARIES

1. General Considerations and Stability Conditions of Ionic Boundaries

The existence of stable ionic boundaries between electrolytes[5,6,91] has been used as the basis for several methods of measuring transport numbers. The conditions under which such boundaries can exist, and their main features, arise from the following considerations. An ionic boundary can be formed between two electrolytes M_1A and M_2A whenever the mobilities of the non-common ions ($u_{M_1^+}$ and $u_{M_2^+}$) differ by a sufficient amount. To this end, the electrolytes are positioned so that $u_{M_1^+}$ and $u_{M_2^+}$ increase in the direction in which the ions move in the electric field (Fig. 3). The passage of an electric current through the electrolytes generates a stable boundary between the electrolytes, arising from the difference in mobility between the cations. When the electrolytes on either side of the boundary have reached a steady state, i.e. when their concentrations cease to change, the velocities v_1 and v_2 of the ions M_1^+ and M_2^+ become identical and equal to the velocity of the boundary (v_b):

$$v_1 = v_2 = v_b. \qquad (21)$$

If the solution as a whole does not move, we have

$$v_b = u_{M_1^+} \cdot E_1 = u_{M_2^+} \cdot E_2, \qquad (22)$$

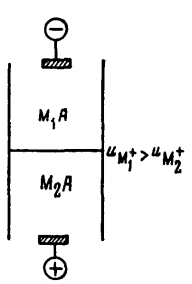

Fig. 3. Measurements by the moving boundary method.

where E_1 and E_2 are the electric field strengths in the electrolytes M_1A and M_2A respectively. Expressing E in terms of the current density j, we can write

$$v_b = jT_{M_1^+}/Fc_1 = jT_{M_2^+}/Fc_2, \qquad (23)$$

for the velocity of the boundary, where $T_{M_1^+}$ and $T_{M_2^+}$ are the transport numbers of the cations and c_1 and c_2 the concentrations of the solutions M_1A and M_2A.

The relation known as Kohlrausch's "regulating function"[92] follows from condition (23). Since in a steady state the fluxes of solvent on either side of the boundary must be equal[93], the regulating function can be written in the form

$$\frac{T_i}{c_i'} = \text{const.}, \qquad (24)$$

where c_i' is the electrolyte concentration expressed in equiv. per kg of solvent.

If the concentration of the indicator electrolyte (the solution containing the slower M^+ ions) does not satisfy relation (24), a concentration readjustment takes place as electrolysis proceeds[4,94]. The concentration change during this readjustment[95-97] is described by the following differential equation:

$$-\frac{\partial c}{\partial t} = \frac{j}{F} \cdot \frac{\partial T(c)}{\partial c} \cdot \frac{\partial c}{\partial x} - D\frac{\partial^2 c}{\partial x^2}. \qquad (25)$$

Ignoring the diffusional term, we can write an expression for the rate of readjustment[94], i.e. for the velocity of the Kohlrausch concentration front relative to that of the boundary:

$$v_{readj} = v_b - \frac{j}{F}\frac{\Delta T(c)}{\Delta c}. \qquad (26)$$

In most solutions the change in transport number with concentration, $\Delta T(c)/\Delta c$, is not large, and to a first approximation the Kohlrausch concentration front moves away from the boundary with the speed of the ions. The time needed to establish a steady state is

$$\tau = \frac{l}{v_{readj}}, \qquad (27)$$

where l is the length of the region over which the concentrations adopt the Kohlrausch value.

For univalent ions, the concentration ratio of the solutions in the region of the boundary can be obtained from the relation

$$\frac{c_2}{c_1} = b \cdot e^{-\frac{u_1 - u_2}{u_1} \cdot \frac{e}{kT} \cdot \frac{v_b x}{u_2}}, \qquad (28)$$

where b is a constant, u_1 and u_2 are the mobilities of the non-common ions, k is Boltzmann's constant, T the absolute temperature, e the electronic charge, and x the distance measured from the origin of the system of coordinates.

This expression can be used to calculate the width of ionic boundaries.

The stability of the boundary and the rate of readjustment depend essentially on a correct choice of the operating conditions of the measuring tube, in particular the range of currents and electric fields. The evolution of Joule heat causes various effects, which can seriously affect methods based on ionic boundaries. The following are the most significant effects associated with the temperature conditions:

(a) Change in temperature of the solution. Due to the evolution of Joule heat, the motion of the boundary occurs at a temperature which is not the same as that of the surroundings. The change of transport with temperature will cause a change in the Kohlrausch concentration.

(b) Ionic convection. Since the mobility of the ions is a function of temperature, ions at different distances from the centre of the tube will have different velocities:

$$v_i = [u_0 + \beta\Delta T(\rho)]E, \qquad (29)$$

where β is the temperature coefficient of mobility and u_0 the mobility of the ions at temperature T_0.

Since the boundary moves at an average velocity v_b, the speed of the ions in some central region will exceed that of the boundary, whilst the speed of the ions close to the walls wil be somewhat less than the speed of the boundary. Thus, ionic convection will occur along the tube with a velocity $\Delta v_i = v_i - \bar{v}_b$. This motion of the ions is equivalent to an additional contribution to diffusional mixing[99-101]. The increase in the effective diffusion coefficient causes the boundary between the electrolytes to become diffuse.

(c) Convective entrainment of indicator electrolyte. This phenomenon occurs because some of the indicator electrolyte is carried into the overlying electrolyte by convective flow. Usually, the boundary remains fairly sharp, but the velocity of the boundary becomes a non-linear function of the current[101]. Convective entrainment of the indicator electrolyte is associated with the difference in temperature between the top solution and the indicator solution, and can be minimised by suitable choice of the thermal regime under which the tube is operated. Alternatively, the measuring tube can be packed with a porous filler[102].

Several procedures for forming the boundaries and observing their position are known. A sharp separation between solutions can be obtained by the following methods.

(a) The sheared boundary method[103]. The simplest form of this method is illustrated in Fig. 4*a*. Two carefully lapped plates *1* and *2* are provided with openings in which are located the tips of tubes *3* and *4*, filled with different solutions. By sliding the plates, the tips of the tubes are brought into contact, and the drops of solution protruding from the tips are sheared together and generate a sharp boundary.

(b) The air bubble (air lock) method[104]. Fig. 4*b* shows part of the measuring tube. Vessels *5* and *6* are initially filled with a solution of the top electrolyte; an air bubble which separates the solution into two parts is introduced into the capillary *8* through the side tube *7*. Vesel *6* is then filled with a solution of the indicator electrolyte. A sharp boundary is obtained when the air bubble is forced out of capillary *8* into tube *7*.

(c) The self-generated boundary method[105]. The method (Fig. 4*c*) makes use of a soluble electrode *9*, above which is located the solution of M_1A. The solution of indicator electrolyte M_2A is formed by electrolysis, and is separated from the top electrolyte by a sharp boundary. Cady and Longsworth have pointed out[106] that the automatic adjustment of the concentration of the indicator electrolyte is confined to the immediate vicinity of the boundary.

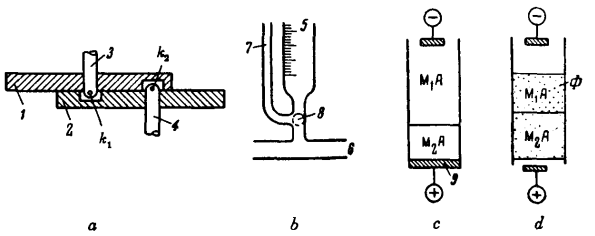

Fig. 4. Methods of forming ionic boundaries: *a*) sheared boundary method; *b*) air bubble method; *c*) self-generated boundary method; *d*) porous packing method; 1) and 2) lapped plates; 3), 4), 5), and 6) parts of the measuring tube; 7) and 8) capillaries; 9) a soluble electrode; k_1 and k_2 — drops of the solutions; Φ — the porous packing.

(d) The porous packing method[102,107]. The solutions of M_1A and M_2A are joined in the porous filter Φ (Fig. 4*d*). A boundary forms automatically when the current is switched on. The porous packing minimises mixing effects and eliminates convection of the solutions.

Various methods are used to observe the boundaries. The most important of these are as follows.

(a) Optical methods. Visual observation is used when one of the solutions contains coloured ions or when the refractive indices of the two solutions are very different. Occasionally, penumbra projections are photographed[44,95], or one observed the diffraction pattern produced on a screen behind the measuring tube by a narrow beam of light[98].

(b) Methods based on conductivity and temperature differences between the top and the indicator electrolyte. The position of the boundary is monitored either by auxiliary electrodes[35,108-112,287,288] or by miniature thermistors[113] located inside the tube.

(c) Methods involving radioactive tracers[107,114,115,289]. Small amounts of β- or γ-active isotopes of the same elements are added to one or both of the experimental solutions. The position of the boundary is detected by accurately collimated radiation counters.

The methods of measuring transport numbers which rely on ionic boundaries can be divided into two groups: the direct methods, including the moving boundary method and the method of simultaneous observation of the motion of the ions and of the solution, and the indirect methods, based on the use of Kohlrausch's regulating function.

2. The Moving Boundary Method

Expression (23), relating the transport number to the velocity of the boundary, forms the basis of the moving boundary method. The displacement of the boundary caused by the passage of a known quantity of electricity is measured experimentally[91,106,116,117]. A vertical cross-section through part of the measuring tube is shown in

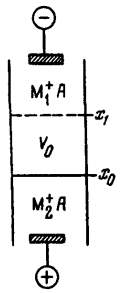

Fig. 5. Measurements by the moving boundary method: x_0 — initial position of the boundary; x_1 — final position of the boundary.

Fig. 5. The volume V_0, defined by the cross-sections with coordinates x_0 and x_1, is usually identified by fiducial marks and accurately measured before the experiment. By measuring the time t needed for the boundary to move between the marks, and knowing the current I and the concentration C_{M^+} of the electrolyte under study, the transport number can be calculated:

$$T_{M^+} = \frac{V_0 C_{M^+} F}{It}. \qquad (30)$$

Various corrections are usually applied to the formula. Miller[94] first drew attention to the fact that the volume change due to electrolysis and ion migration induces a drift of the solution relative to the measuring tube. An appropriate correction to the volume V_0 can either be determined experimentally[8,61,118-133] or calculated from data on the density of the solutions and of the electrode components[134]. At low concentrations of the experimental solutions another correction becomes necessary: it arises from the transport of current by the ions formed by dissociation of the solvent and of trace impurities[135]. Allowing for these effects, the expression for calculating the transport number takes the form

$$T_i = \frac{F}{It} c_i (V_0 - \Delta V) \frac{1}{1 - \frac{L_0}{L}}. \qquad (31)$$

where ΔV is Miller's correction, L the electrical conductivity of the solution, and L_0 the electrical conductivity arising from impurities.

Measurements by the moving boundary method are complicated by the need to choose the concentration of the indicator electrolyte, c_{ind}, in preliminary experiments. The velocities of the ions are equal to the velocity of the boundary if the state of the electrolytes is stationary ($\partial c/\partial t = \partial c_{ind}/\partial t = 0$), i.e. if Kohlrausch's regulating function is obeyed. It has been shown[106,109] that Kohlrausch conditions are established automatically and exactly only if the initial concentration of the indicator electrolyte, c_{ind}^{init}, is not very different from the Kohlrausch value c_{ind}^{K}. In practice, the difference between the two values should not be more than 5–10%. At larger deviations, the rearrangement process gives rise to an additional mode of transport of the solution as a whole. Since the value of c_{ind}^{K} is not known before the experiment, the normal procedure is to determine the relationship $T_i = f(c_{ind}^{init})$, whose form is shown in Fig. 6. The value of c_{ind}^{K} is taken

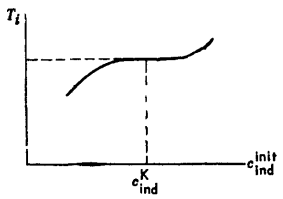

Fig. 6. Variation of the transport number with concentration of the indicator electrolyte during measurements by the moving boundary method.

to be the mid-point of the range over which the transport number remains constant.

The precision of transport number measurements decreases with increased concentration of the experimental electrolytes, because the correction for the transport of solution as a result of the motion of the boundary becomes larger.

The maximum concentration of the solutions which can be studied by the moving boundary method is no more than 0.1 N. The limitation arises from convective transport and convective entrainment effects. The use of a porous filler is not permissible, because the effect of electro-osmotic solution transport cannot be allowed for when using this method.

The analytical and the differential moving boundary methods are variants of this procedure.

The principle of the analytical method is as follows. The measuring tube, divided into two compartments by the porous diaphragm Φ (Fig. 7), is filled with the electrolytes M_1A and M_2A. When current is passed, the boundary emerges from the filter (position x_0) and reaches position x_1 after time t. The amount of M_2^+ ions above the filter is determined by a conventional analytical procedure, and hence the transport numbers in a solution of M_2A can be obtained. The calculation is based on a formula analogous to Eqn. (30):

$$T_{M_2^+} = \frac{V_0 C_{M_2^+} F}{It}. \qquad (32)$$

The shortcoming of this method is the uncertainty as to the concentration of the M_2A solution, which penetrates

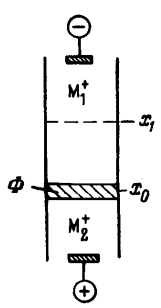

Fig. 7. Analytical form of the moving boundary method: Φ — porous diaphragm; x_0 and x_1 — initial and final positions of the ionic boundary.

into the volume above the filter if the initial concentrations of the leading solutions are not chosen in accordance with the Kohlrausch regulating function. In general, this should lead to a dependence of the results upon the concentration of the leading electrolyte.

The differential method[117] makes use of concentration boundaries[92,94,137,138], i.e. the boundaries formed by solutions of different concentrations c' and c'' of the same salt. The volume swept by the boundary is proportional to the difference in transport number of the ions at concentration c' and c''. Generally, the method is used to measure the concentration dependence of transport numbers, and is useful also when the direct method cannot be used[139]. The formula in this case is:

$$T'_{M+} - T''_{M+} = \frac{V_0 (c' - c'') F}{It}. \qquad (33)$$

The main limitation of this method is associated with the stability of concentration boundaries[96].

The precision of measurements by the moving boundary method depends essentially on the accuracy with which the ionic boundaries can be located. According to Spiro's review[2], the maximum attainable precision of the method is 0.03%.

3. Simultaneous Observation of the Motion of the Ions and of the Solution

Kaimakov and Fiks[102] have developed a method of measuring transport numbers which is free from the limitations and shortcomings inherent in the moving boundary method. Whereas in the moving boundary method the system of coordinates is based on the measuring tube, and allowance for the transport of solution has to be made by applying the Miller correction, in the method of simultaneous observation one measures the flow of solvent passing through the ionic boundary by observing the motion of the ions and of the solution at the same time. In general, transport of the solution can be caused by: (a) a difference in levels of the liquids in the cathodic and the anodic limb of the measuring tube (countercurrent); (b) a difference in density between the leading and the indicator solution; (c) electrode processes, and displacement of the boundaries; (d) electro-osmotic flow of the solution.

If the solution undergoes transport under the influence of external forces, the velocity of the boundary v_b is the sum of the velocities v_i of the ions and v_s of the solution:

$$v_b = v_i + v_s, \qquad (34)$$

or

$$v_i = v_b - v_s = \frac{fT_i}{Fc}.$$

This is the basic formula of the method of simultaneous observation of the motion of the ions and of the solution.

The essential features of the measurement of transport numbers are illustrated in Fig. 8. The measurements are made in a U-tube in which a porous plug *3* separates the cathodic limb *1* from the anodic limb *2*. The plug acts as a hydrodynamic resistance, and also as the region where the boundary is formed. The measurement of transport numbers consists, essentially, in measuring the velocity of the boundary and that of the solution over a range of current densities, and plotting $v_b = f(I)$ and $v_s = f(I)$. Clearly, the difference between the two curves

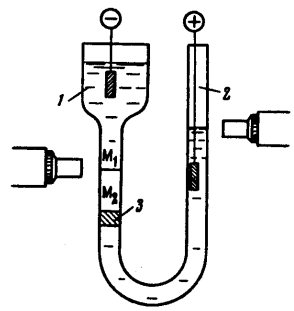

Fig. 8. Measurements by the method of simultaneous observation:
1) cathodic limb of the measuring tube;
2) anodic limb of the measuring tube;
3) porous diaphragm.

must be a straight line whose slope is related to the transport number by the expression

$$\tan\alpha = \frac{T_i}{Fc_i}, \qquad (35)$$

where c_i is the concentration of the ions in equiv. litre^{-1}.

The form of the experimental plots is shown in Fig. 9.

In the method of simultaneous observation there is no need to make a correct choice of the concentration of the indicator electrolyte. The perturbation of the hydrodynamic equilibrium associated with the establishment of the Kohlrausch concentration is automatically allowed for. The use of a countercurrent to control the motion of the boundary, in conjunction with a porous septum, makes a much wider range of temperatures and electrolyte concentrations experimentally accessible.

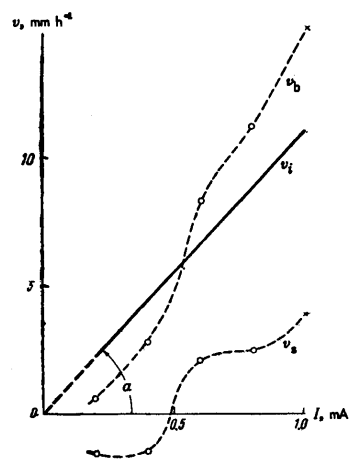

Fig. 9. Experimental curves obtained by the method of simultaneous observation[102] for 3 *N* solutions of NH_4Cl at 20°:
v_b — velocity of the ionic boundary; v_s — velocity of the solution; v_i — velocity of the ions.

The most important measurements, in practice, are made by keeping the boundary immobile with a suitable countercurrent, and measuring the accumulation of solvent in the anodic limb[101]. The transport number of the cations is calculated by means of the formula

$$T_{M+} = \frac{F}{I} v_s \cdot c_i' S_A, \qquad (36)$$

where v_s is the rate of accumulation of solvent in the anodic limb, c_i' the concentration of the ions in equiv. per kg of solvent, I the total current through the cell, and S_A the internal cross-sectional area of the anodic limb.

Thus, the cross-section of the tube which contains the boundary does not appear in the formula. When calculating transport numbers allowance should be made for possible changes in the volume of the solvent being accumulated[101,140].

The method of simultaneous observation has provided many data relating to concentrated solutions of electrolytes. In principle, this method should give results no less accurate than those of the moving boundary method.

4. Methods Based on Kohlrausch's Regulating Function

In the direct methods transport numbers can be deduced immediately from the results of a single experiment. The methods relying on the regulating function enable transport numbers to be calculated from a knowledge of the steady-state concentrations of the electrolytes moving in constant relative positions, and of the transport number of one of them. The problem of measuring transport numbers consists essentially in making the correct choice of electrolytes and experimentally determining their steady-state concentrations. Cady and Longsworth[106] were the first to measure steady-state concentrations. Hartley[93] proposed a method of measuring steady-state concentrations which he later used in a number of investigations[141-145]. Conductimetric analysis has also been used to measure concentrations[109,146]. Fig. 10 shows part of the measuring tube of Samis and Hartley's apparatus[147]. The leading electrolyte solution, in tube *1* and vessel *2*, was brought into contact with the indicator electrolyte in tube *4* by the air-lock method, using the side-arm *3*. When current was passed the boundary moved along tube *1*. By partial compensation of the motion of the boundary, using a countercurrent, some solution having the Kohlrausch concentration was forced into vessel *5*, provided with measuring electrodes.

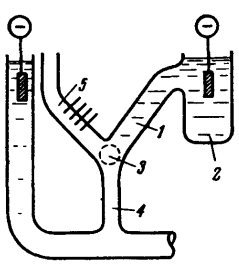

Fig. 10. Part of Samis and Hartley's apparatus[147] for measuring Kohlrausch concentrations:
1) leading electrolyte solution; 2) cathode vessel; 3) capillary connection; 4) indicator electrolyte; 5) auxiliary vessel with leads for measuring the electrical conductance of the electrolytes under study.

The upper limit of experimentally accessible concentrations, 0.1 N, was set by the fact that no precautions were taken to minimise the effect of convective transport.

Refractive analysis has also been used[44,95,148,149] to measure steady-state concentrations.

Some new procedures were developed when the problems associated with readjustment in concentrated solutions were overcome. Work with concentrated solutions is characterised by the need to avoid convective transport effects. This is achieved either by working with small-diameter tubes, or by using porous packing. Konstantinov and Oshurkova[98] made their measurements in capillaries of ~0.1 mm diameter, using large electric fields. Steady-state concentrations were determined by measuring the length of a thread of the experimental solution, "trapped" between the leading and the indicator solution.

Kaimakov and coworkers[150-152] used wide measuring tubes packed with ground quartz. Steady-state concentrations were measured either with platinum electrodes fitted to the tubes or with a miniature thermistor. By this procedure, steady-state concentrations could be measured in a single experiment for a number of electrolytes following each other.

V. MEASUREMENT OF TRANSPORT NUMBERS AND MOBILITIES IN MIXTURES OF ELECTROLYTES

Both the Hittorf method[151-161] and the moving boundary method[117,162-166] have been used to study mixtures of electrolyte solutions. To measure transport numbers by Hittorf's method, the concentration changes of all the components of the solution in the electrode compartments are measured simultaneously by chemical analysis. The lower limit of additive concentration is set only by the precision of the method of chemical analysis of the particular component. The upper limit of the total concentration of the mixture is set by convective mixing[167]. The early investigations of mixtures by Hittorf's method[154,155,292] relied on inadequate methods of analysis, and led the authors to erroneous conclusions as to the structure of mixtures of binary electrolytes. The most accurate results are obtained by the moving boundary method. A boundary is formed between the mixture and the indicator electrolyte, and an electric field is applied which causes the mixture to separate and form a second boundary between ions of different mobility. The velocity of this boundary is proportional to the transport number of the ion of the additive[117]. The use of the moving boundary method is confined to relatively low total concentrations of the mixture under study ($c_{tot} < 0.1$ N). A procedure for measuring the mobilities and transport numbers of ions added at low concentrations (a few per cent, or fractions of one per cent) to concentrated solutions of electrolytes has been described[168-170]. The method depends on separating the mixture in an electric field, the impurity ions accumulating between the mixture and the indicator electrolyte. The boundaries are located within the porous packing. The column of additive is held in a fixed position relative to the measuring tube by a counterflow. The transport number of the additive is found

by measuring the quantity of matter in the column. The accuracy of the results obtained by this method is 2–3%.

Data on transport numbers and mobilities in mixed solutions are few, and mostly of a tentative nature.

VI. EXPERIMENTAL DATA ON TRANSPORT NUMBERS IN AQUEOUS SOLUTIONS OF ELECTROLYTES

Many papers on the measurement of transport numbers, by different methods, have been published. Collected tables of transport numbers have appeared in many works of reference [171–174]. The fullest information, relating both to aqueous and to non-aqueous solutions of electrolytes, is to be found in Landolt and Börnstein's Tabellen [171]. However, these data are difficult to use, because the experimental results are reported uncritically. Furthermore, a significant volume of recent work, dealing mainly with concentrated aqueous solutions of electrolytes, has not yet found its way into standard tabulations. In the Russian literature tables of transport numbers can be found in "Spravochnik Khimika" (The Chemist's Handbook) [174] and in "Spravochnyi Tom Tekhnicheskoi Entsiklopedii" (Reference Volume of the Technical Encyclopaedia) [173]. However, the results given in those tabulations are based on early measurements of transport numbers in aqueous solutions of electrolytes, and do not provide a balanced account of recently developed new methods, or of the results obtained thereby.

Experimental values of the transport number for a given electrolyte are usually in marked disagreement. For dilute solutions, the discrepancies are relatively small: their causes have been discussed in the literature many times [2,3,36,117,172]. In the region of high solution concentrations the scatter of results is often very large [12,39,75]. For this reason, we adopted the following precedure to construct a general table of the transport numbers of cations in aqueous electrolyte solutions (Table 1) and a table of transport numbers for aqueous solutions of mixtures of electrolytes (Table 2):

(a) For each compound, the results covering the widest range of concentrations and temperatures were tabulated.

(b) When the results obtained by different methods in the same range of concentrations and temperatures showed serious disagreement, measurements by the moving boundary method were selected for the low-concentration region and measurements by the simultaneous observation method for the high-concentration region.

(c) In the few cases where the results obtained by different methods for a given compound were in good agreement, the values were combined.

The first column in Table 1 lists the chemical compounds. The second column gives the temperature at which the measurements were made. The concentration range from 0.005 N to 15 N is divided into 15 intervals; concentrations are expressed in equiv. litre^{-1} (N). Values of the transport number at intermediate concentrations, not given in the original paper, were found by graphical interpolation. Anion transport numbers were recalculated as cation transport numbers, assuming that $T_c + T_a = 1$. Figures in brackets denote the concentration corresponding to the transport numbers tabulated underneath. The column headed "method" indicates the method of measurement used, with the following abbreviations: Hitt. for Hittorf's method, e.m.f. for the e.m.f. method, m.b. for the

TABLE 2. Cation transport numbers in aqueous electrolyte solutions.

moving boundary method, s.o. for the method of simultaneous observation for the motion of the ions and of the solution, centr. for the method based on e.m.f. measurements in a gravity cell.

Column 1 of Table 2 lists the components of the mixture of aqueous electrolyte solutions, column 2 lists the temperatures. Columns 3 and 4 give the concentrations of the components (in equiv. litre^{-1}) in the order in which the components appear in column 1. Columns 5 and 6 give the transport numbers of the cations of the components, in the same order. The abbreviations used to indicate the method are the same as for Table 1. The abbreviation m.c. refers to the method of measuring transport numbers of minor constituents. The last column in both tables lists the literature references: the first number quoted is the paper from which the tabulated values were taken, other numbers refer to independent studies of the same compound.

I. INTRODUCTION

Aziridine and its derivatives have a number of very interesting physical, chemical, and biological properties, and they are attracting increasing attention of workers in different specialities. In addition to their theoretical and scientific interest, aziridine, some of its derivatives, and polyaziridine have found considerable practical uses. The object of the present review is to discuss briefly the main methods of synthesis, features of molecular structure and properties, and the chemical reactivity of aziridine together with its main uses in medicine and technology.

II. METHODS OF SYNTHESIS OF AZIRIDINE

The overwhelming majority of known methods of synthesis of aziridine and its derivatives may be divided according to reaction type into four groups of methods, leading to closure of a three-membered heterocycle: (1) intramolecular condensation reactions with elimination of the elements of an acid; (2) thermolysis of other nitrogen-containing heterocycles; (3) cyclisation reactions of nitrogen-substituted derivatives (oximes, hydrazones, dichloroamines); (4) addition reactions to C=C or C=N bonds.

Intramolecular condensation reactions. Aziridine was first synthesised by Gabriel in 1888 by the action of moist silver oxide on β-bromoethylamine hydrobromide[1]. Gabriel erroneously ascribed the structure of vinylamine to the compound obtained. This error was corrected by Marckwald, who showed that the product obtained by Gabriel was a secondary amine with a cyclic structure[2-4]; at the same time the true mechanism of

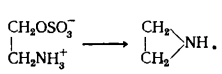
Gabriel's reaction for the cyclisation of β-halogenoethylamines, which is quite general, was discovered:

Thus, a whole series of free β-halogenoethylamines [5,6], *bis*-(β-chloroethyl)amine [7,8], and even *tris*-(β-chloroethyl)amine [9], are smoothly cyclised in aqueous, aqueous-alcoholic, or aqueous-acetone solutions with the formation of the corresponding aziridinium halides, which are then gradually hydrolysed with ring opening. In the absence of strong nucleophilic agents ($S_2O_3^{2-}$, HCO_3^-), aziridinium ions are comparatively stable and may accumulate in solutions in considerable quantities†. They may be detected titrimetrically (thiosulphate) and separated either as the poorly soluble picrates [12] and picrylsulphonates [6], or as free bases obtained by the addition of alkaline agents (Gabriel's reaction).

The rate of cyclisation of halogenoalkylamines depends on the nature of the halogen atom and the character of the substitution at both reactive centres of the molecule, the nitrogen atom and the carbon atom carrying the halogen. It increases in the order Cl < Br < I. [10] The negative inductive effect of the sulphonyl and acetyl groups in 2-chloro-3-sulphonamidobutane [13] and 1-bromo-1-acetyl-2-phenylamine [14] facilitates ring closure to such a degree that it occurs spontaneously with separation of the corresponding hydrogen halide. α-Methyl, αβ-cycloalkyl-, and even ββ-*gem*-dimethyl- substituents also have a favourable effect on the reaction centre [15-17]; this appears to be connected with corresponding changes in the conformations of the molecules of the initial halogenoalkylamines. The accumulation of bulky substituents, however, may cause steric hindrance at the reactive centre, preventing nucleophilic attack on the nitrogen atom, or even completely excluding cyclisation, as occurs with 1-chloro-2-(*N*-phenylamino)-1,1,2-triphenylethane [18] and 1-chloro-2-(*N*-acetyl)-1,1-diphenylethane [19].

Gabriel's reaction as a method of synthesising aziridines has been studied by various workers on numerous examples. It has been used for the preparation, apart from aziridine itself [20-27], of *N*- and *C*-alkyl- [28-35] and aryl-substituted [36-53] aziridines, bicyclic structures including the aziridine ring [33], and also *C*-acyl- [14], *C*-carboxy- [54], and *N*-sulphonyl-substituted [55-64] aziridine derivatives. It is inapplicable only in the case of *N*-acyl derivatives [65].

The second most widely used method of preparing aziridines after Gabriel's reaction is Wenker's synthesis, which is similar to it in principle [66-76]; this consists of cyclisation by the action of alkali of acid β-aminoalkylsulphates:



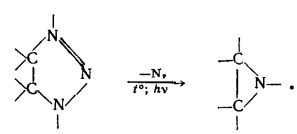
The most substantial differences between this method and Gabriel's reaction are the lower rates of cyclisation of β-aminoalkylsulphates compared with halogenoalkylamines [77]. However, since the aziridine formed remains in contact with hot alkaline solution for a longer period, the degree of hydrolytic cleavage increases and the yield correspondingly falls. A solution to the problem of the yield in Wenker's synthesis has been found by reducing the reaction time, either by increasing the reaction temperature [78], or by rapidly distilling off the aziridine formed by the slow addition of the aminoethyl sulphate to boiling aqueous alkali [79]. The yields thus obtained (up to 91%) correspond to the yields in Gabriel's reaction. The majority of industrial plants for the preparation of aziridine are based on Wenker's synthesis [80,81].

A study of the cyclisation of stereoisomeric β-halogenoalkylamines and β-aminoalkyl sulphates has shown that this is always accompanied by inversion of confirguration. Thus, the cyclisation of DL-*threo*- or L(+)-*threo*-3-aminobutan-2-ols leads to *meso*-2,3-dimethylaziridine (*cis*-isomer), but the L(+)-*erythro*-isomer gives L(-)-2,3-dimethylaziridine (*trans*-isomer) [82]. Similarly, *cis*-2,3-diphenylaziridine may be obtained by the cyclisation of *l*- or *dl*-iso-α-amino-β-chlorodibenzyls, and the *l*-*trans*- and *dl*-*trans*-isomers from *l*- and *dl*-α-amino-β-chlorodibenzyls respectively [37]. In systems in which *trans*-closure is impossible, the aziridine ring is not formed. Thus, when the stereoisomeric α-aminocyclohexyl sulphates are treated with alkali, only the *trans*-isomer gives an aziridine derivative (tetramethyleneaziridine) [83].

A large number of syntheses (mainly of various *C*-acyl substituted derivatives of aziridine) proceed in the same way as the Gabriel–Wenker reaction: vicinal dihalogeno-ketones [84-91], -ethers [92-94], -nitriles [95-97], or α-halogeno-substituted αβ-unsaturated ketones [98-100] and ethers [101-104] react with ammonia and amines, and there is also the analogous reaction of αβ-unsaturated ketones with iodine complexes of ammonia and amines [105,106]. The reaction with ammonia leads to aziridine derivatives unsubstituted at the nitrogen; the reaction with primary amines leads to substituted derivatives; and the reaction with secondary amines leads to the corresponding quaternary aziridinium compounds [99,100].

These reactions can be described in the most general way as cyclisation of bifunctional compounds of the type $(R_2CX)_2$ (R = H or a hydrocarbon group and X is a halogen atom, or a sulphate, nitrate, or other polar group) by ammonia or amines in the presence or absence of acid acceptors. One of these reactions — the condensation of dichloroethane with ammonia in the presence of calcium oxide — has proved such a successful method of synthesising aziridine that immediately after its discovery it was used on a production scale by the Dow Chemical Co. [107-109]. Experts of this firm consider that the successful development of the production of aziridine by this method will lead to a very considerable reduction in its cost in a short time [110].

Thermolysis of nitrogen-containing heterocycles. As in the synthesis of cyclopropanes by Kishner's method, thermal [111-116] or photolytic [117] decomposition of 1,2,3-triazolines leads to aziridine derivatives:

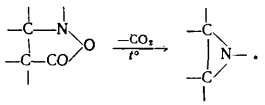


Evidently, the analogy in the structure of two strained rings may be extended to the thermolysis mechanism. In

† Since aziridine derivatives have an extremely high biological activity, the amount of aziridinium ions produced by decomposition is also reflected in the biological activity of the solutions [10,11].

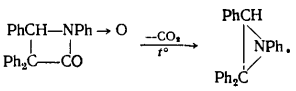
contrast to the pyrolysis of pyrazolines, which presupposes preliminary prototropic displacement of the double bond to the 1,2-position (catalysed by alkali), thermal decomposition of dihydrotriazoles, containing the ready-made azo-group in their ring, does not require the use of an alkaline catalyst.

A very similar thermolytic route is known for another five-membered heterocycle, oxazolid-2-one[118-120]:



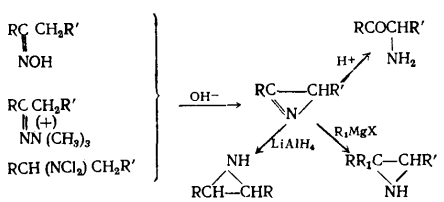
The two methods differ in that in the first contraction of the ring is accompanied by elimination of the azo-group as a nitrogen molecule, whereas in the second the $-C\overset{O}{\underset{O-}{<}}$ fragment of the lactam ring is removed as a molecule of carbon dioxide. Although simple heating is sufficient for decomposition of triazolines, pyrolysis of oxazolid-2-ones must be carried out in the presence of an alkaline solvent, since the carbon dioxide eliminated may react with the aziridine.

Mention should also be made of the formation of polyphenylated aziridine (1,2,3,3-tetraphenylaziridine) on heating the product of the addition of diphenylketene to benzaldehyde *N*-phenyloxime[18]:



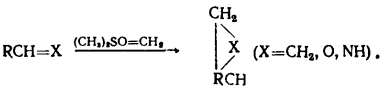
An attempt to prepare other aziridine derivatives in a similar way proved unsuccessful.

Cyclisation of oximes, hydrazones, and chloramines. The rearrangement of some derivatives of oximes (tosylates[121,122], magnesium halides[123-129]) and hydrazones (methyliodides of dimethylhydrazones[130]) of the structure $RC(=NX)CH_2R'$, where X = OH or $^+N(CH_3)_3$, and also *NN*-dichloro-s-alkylamines[131,132] of similar structure, to α-amino-ketones and -alcohols:

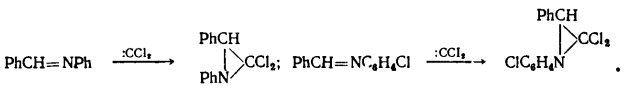


leads to common cyclic intermediate products, the corresponding azirines or alkoxyaziridines. Reduction of the latter with lithium aluminium hydride or Grignard reagents and the use of mild conditions for hydrolysis of the reaction products (ice + ammonium chloride) enabled the rearrangements mentioned to be used as a method of synthesis of the corresponding substituted aziridines.

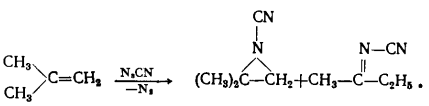
Addition to C=C and C=N bonds. Cyclisations by addition to C=C or C=N bonds include a number of recently discovered reactions in which the C=N bonds of imines, which are susceptible to nucleophilic attack, are methylenated, and reactions in which activated alkene C=C bonds are iminated with the aid of unstable and extremely active compounds of radical or ionic character. Thus, it has very recently been shown that sulphonium ylides, formed by the decomposition of the corresponding sulphonium salts by strong alkalis in anhydrous dimethylsulphoxide, react with polar C=C, C=O or C=N bonds to give good yields of derivatives of cyclopropane, ethylene oxide and aziridine respectively[133-136]:



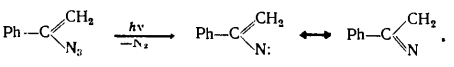
An analogous route is also known for radical reagents, carbenes and their nitrogen analogues — nitrenes or azocarbenes. The addition of hydrocarbon carbenes to C=N bonds of imines[137,138], or of azocarbenes to alkene C=C bonds[139,140] unambiguously leads to derivatives of aziridine, for example,



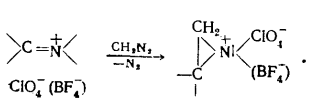
Since nitrenes are produced by the thermal or photolytic decomposition of azides, this mechanism is obviously also the basis of the synthesis of aziridine derivatives described in the literature in which alkenes react directly with certain azides (sulphonyl azides[141-143], cyanazide[144], and carbamoyl azide[145]), for example:



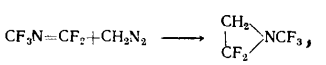
Apart from adding to multiple bonds, some nitrenes can undergo intramolecular cyclisation reactions[146-148]. For example, photolysis of t-butylazide and α-azidostyrene gives good yields of 2,2-dimethylaziridine[146] and 2-phenylazirine[147]:



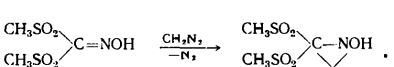
Diazomethane is another widely used methylenating agent; the addition of diazomethane to C=N bonds of imines gives triazolines, which are starting materials for the synthesis of aziridines by thermolysis (see above). In the case of tertiary iminium salts with weakly nucleophilic anions (perchlorates and fluoroborates) similar nucleophilic attack of diazomethane leads directly to the corresponding aziridine derivatives in high yield[149-152]:



Polyfluorinated imines react in a similar way, for example[153]:

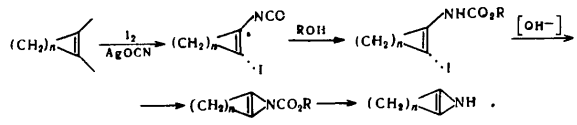


and also *bis*-methanesulphonylisonitrosomethane[154]:



Mention should also be made of the synthesis of condensed aziridines from cyclic alkenes (mainly in the

steroid series) by hydrolysis of the corresponding iodocarbamates, obtained by the reaction of alkenes with iodine in the presence of an excess of silver cyanate[155,156]:



III. STRUCTURE AND PROPERTIES

Physical properties. Closure of the three-membered C–C–N heterocycle is accompanied by a considerable increase in boiling point, specific gravity, and some other physical constants connected with intermolecular interactions (Table 1).

This effect is connected with the increased strength of H–N...H-hydrogen bonding (both in comparison with non-cyclic analogues and in comparison with isologues), which is characteristic of aziridine.

Thermochemical properties. The following are the main thermochemical values for aziridine:

		kcal mole^{-1}
Heat of combustion	C_2H_5N(liq.)	380.34 ± 0.15
Heat of formation	C_2H_5N(liq.)	21.96 ± 0.14
Heat of formation	C_2H_5N(gas)	26
Heat of evaporation	C_2H_5N	4

Comparison of the given experimental values[109,160] for the energy of formation of aziridine with those calculated from the summation of the bond energies (12 kcal mole^{-1}) gives a value of 14 kcal mole^{-1} for the strain energy of the three-membered heterocycle.

Solubility and properties of aqueous solutions. Examination of the three-component system aziridine–water–sodium hydroxide is of considerable practical interest. The relevant ternary diagram (Fig. 1) gives valuable information on the division into and composition of phases in this system[161]. Here each point inside the region bounded by the binodal curve and the upper tie-line corresponds to a system divided into two liquid phases. Their composition can be determined from the points of intersection of the corresponding tie-lines with the binodal curve and the base of the triangle.

Detailed study of the dependence on concentration of density, refraction, melting point, boiling point, surface tension, and viscosity of aqueous solutions of aziridine shows that all these undergo sharp changes at the point with an aziridine : water ratio of 1 : 2.[161] The nature of these changes (minima, breaks, and points of inflexion on the curves) indicates the formation of a characteristic chemical compound of aziridine and water of this composition. Infrared spectroscopic examination of the 1 : 2 compound of aziridine and water shows that the characteristic

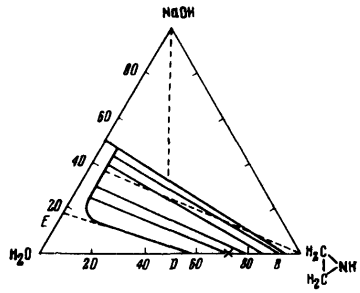


Fig. 1. Ternary diagram of the aziridine–water–sodium hydroxide system at 20°.

frequencies of aziridine are absent and suggests a cyclic chelate hydrate structure formed by intermolecular OH- and NH-bonding. It is interesting to note that the parachor and thermochemical properties of this compound also indicate that the three-membered heterocycle in it must be opened‡.

Molecular structure. As with cyclopropane, closure of the three-membered C–C–N ring is accompanied by considerable distortion of the valence angles, which in turn leads to the development of substantial ring strain. Clearly this strain is primarily reflected in the molecular structure of aziridine, that is, in bond energies, interatomic distances and angles, etc. Such methods as spectroscopy, microwave spectroscopy, mass spectroscopy, and electron diffraction give interesting information on this point. Thus, analysis of the microwave spectrum of aziridine shows that the imine hydrogen (NH bond) of aziridine does not lie in the plane of the ring[162–165]. Comparison of the experimental intensity of the bands with the calculated intensity confirms that the molecule is not coplanar. Structural parameters of the molecule and values of the components of the dipole moment (Table 2) have been determined from the microwave spectrum of aziridine[166,167].

The values in Table 2 agree with those calculated from electron-diffraction data[168].

Some conclusions on the structure of the aziridine molecule may also be drawn from an analysis of its infrared and

TABLE 2. Structural parameters of the aziridine molecule (from microwave spectroscopic data).

Bond	Bond length, Å	Angle	Value of angle	Component μ	Value of μ (D)
C–C	1.480	C_2NH	112°	μ_a	1.670
C–N	1.488	H_2CC	159°45′	μ_c	0.890
C–H	1.083	HCH	116°41′	μ_{total}	1.890

TABLE 1. Physical properties of aziridine and dimethylamine.

Compound	B.p., °C	M.p., °C	d_4^{20}	γ, dyn cm^{-1}	η, cP	Flash-point, °C	Refs.
Aziridine	55–56	−78.0	0.837	32.8	0.418	−11.1	157,158
Dimethylamine	7.4	−96.0	0.680	18	0.37	—	159

‡ Similar results obtained by workers by the Dow Company are given in the prospectus of this company published in 1965. This also gives some original physical constants of aziridine, and also recommendations for its transport and storage together with safety precautions for working with it, and the stability of various constructional materials in contact with aziridine.

Raman spectra[169-174]. The presence of increased (3012–3078 cm^{-1} compared with 2800–2980 cm^{-1} in aliphatic amines) CH stretching vibration frequencies indicates considerable strain in the three-membered heterocycle. The ring strain in aziridine leads to an increase in the polarity of the NH bond and to some reduction in its characteristic vibration frequencies compared with aliphatic amines[175]. This fact is in agreement with the low basicity constants of aziridine and its derivatives. A considerable shift in NH frequencies (from 3357 to 3280 cm^{-1}) in liquid compared with gaseous aziridine is explained by intensive NH...H-hydrogen bonding[176]. Deformation vibrations of the ring in the 1210 and 857–820 cm^{-1} regions, also noted in the spectra of cyclopropane and ethylene oxide, agree with calculations based on a triangular model consisting of three parts. Examination of the vibrational spectra of substituted aziridine derivatives shows that these frequencies sharply change in intensity and are even displaced when hydrogen atoms in the ring are replaced[177,178].

The dipole moment of aziridine, calculated from the results of measurements of the dielectric constant of a benzene solution, is 1.73 ± 0.1 *D*.[179] The component WKB constants for aziridine are x_{aa} = 0.69 mc/s; x_{bb} = = 2.17 mc/s; x_{cc} = -2.86 mc/s.[180]

The ionisation potential of aziridine, determined by mass spectroscopy, is 9.94 ± 0.15 eV.[181,182]

Stereoisomerism. As with cyclopropane, the planar structure of the aziridine ring leads to the existence of two (*cis*- and *trans*-) geometric isomers for 2,3-disubstituted derivatives. As in the case of cyclopropane, the internally compensated *cis*- form is optically inactive (*meso*-form), but the *trans*-isomer and also the *C*-monosubstituted derivatives may be separated into optical antipodes. The isomeric aziridines differ somewhat in physical constants. Differences between the geometric isomers in their ability to transfer strain between two unsaturated groups are also interesting. *Cis-trans*-isomerisation of 2,3-disubstituted aziridine is catalysed by irradiation or by dry hydrogen chloride[183].

Still another form of stereoisomerism of aziridine derivatives is connected with the presence of a nitrogen atom in the ring. The existence of optical isomers, due to the asymmetry of the tervalent pyramidal nitrogen, in *N*-substituted aziridine had long been suspected[184], but it has only recently been demonstrated definitely by nuclear magnetic resonance, which showed the presence of two triplet resonances of ring protons[185-189].

Electronic structure. Since two hybrid atomic *sp*-orbitals cannot form an angle of less than 90° with each other, the structure of the three-membered rings of cyclopropane, ethylene oxide, and aziridine cannot be explained by Pauling's hypothesis of directed valencies. In this case it must be assumed that the corresponding bonding orbitals are not aligned directly one towards the other, as this hypothesis requires, but are bent to form "banana" bonds (Fig. 2).

To form a ring, hydrocarbon atoms use their hybrid $(2s-2p)\sigma$-orbitals (at an angle of 92°).[190] This type of bonding is intermediate between lateral π-bonding and terminal σ-bonding modes of overlap[191-193]. Less overlap of the bent bonds is compensated by less distortion for the orbitals with less bending. Theoretical calculations show that these orbitals of the ring now become $sp^{4,12}$-orbitals instead of the usual tetrahedral sp^3-orbitals[194,195]. A study

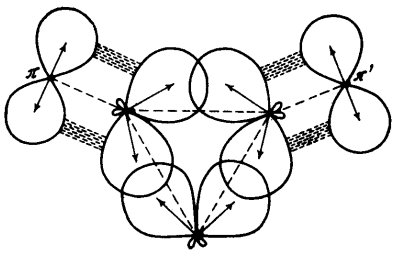

Fig. 2. Electronic structure of the aziridine molecule (plane projection: π and π' atoms, containing *p*-electrons, linked to both carbon atoms of the ring).

of the molecular structure of aziridine shows that the $sp^{4,12}$-bonds formed are shorter than normal single C–C or C–N bonds. The strong *p*-character of the *endo*-orbitals of the ring leads to a strong *s*-character of the external bonds ($sp^{2,28}$-*exo*-bonds). These bonds form an angle of 116° with one another, which exceeds the value of 109.5° for the tetrahedral angle. This strained structure is reflected in all the properties of compounds with a three-membered ring. The most important of these is overlapping (shown dotted on Fig. 2) of the deformed bonds of the ring with the *p*-orbitals of substituents (for example, a double bond or benzene ring) or free electron pairs of halogen atoms, known by the term conjugation.

A quantitative evaluation of conjugation with the aziridine ring is given by a comparison of Hammet's σ constants for ethylenimino-, dimethylamino-, and amino-groups, calculated from chemical shifts of the fluorine (^{19}F) signal in the NMR spectra of the corresponding *m*- and *p*-fluorophenylamines[196].

Ethylenimino-group	σ_{para} = + 0.066	σ_{meta} = −0.290
Dimethylamino-group	+ 0.098	−0.530
Amino-group	+ 0.115	−0.486

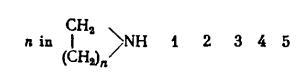
This comparison shows that, although the inductive effect of the three-membered heterocycle is close to the effects of non-cyclic groups, the capacity of its nitrogen atom for conjugation with the benzene ring is greatly reduced. This effect of the inclusion of the nitrogen atom in the three-membered ring is connected with a reduction of overlapping of rehybridised *endo*-orbitals of quadrivalent nitrogen with the π-orbitals of the benzene ring.

The position of aziridine in the cyclic imine series. In the series of cyclic imines the strained three-membered ring of aziridine occupies a special place. Thus, in the infrared spectra, a gradual shift of the upper limit of C–H bond frequencies (from 2919 cm^{-1} for hexamethyleneimine to 3078 cm^{-1} for aziridine) occurs on going from rings with a large number of atoms, in which there is no material strain, to strained three- and four-membered rings[197]. The N–H frequencies change in the reverse order (with increasing strain in the ring the N–H frequencies are reduced) and the basicity of the cyclic imines increases.

Comparison of the ultraviolet absorption intensities of *N*-phenylsubstituted cyclic imines and dimethylaniline in the 250 and 290 mμm§ regions shows that the conjugation energy of the nitrogen atom with the benzene ring increases

§ Linearly related to benzene ring–nitrogen delocalisation interaction.

in higher cyclic imines and dimethylaniline compared with aziridine[198]. In the same way, there is a regular reduction in ionisation potential as the ring increases in size:



and also in the stability of the corresponding complexes with trimethylboron[199].

These facts are most generally and basically reflected in the chemical shifts of the NMR spectra of cyclic imines. Results obtained show that the nitrogen atom of the three-membered ring has the minimum electron density[200]. It would be expected to have the minimum capacity for adding a proton and therefore the minimum basicity.

IV. REACTIONS OF AZIRIDINE AND ITS DERIVATIVES

All the diverse reactions of aziridine and its derivatives may be divided into two approximately equally large groups. The first of these comprises reactions in which only the free electron pair of the nitrogen atom participates and aziridine behaves simply as an amino-compound. The basic feature of reactions of this type is the relative ease with which they are transformed to reactions of the second group, because of the instability of the strained three-membered heterocycle. In this connection they require special precautions in that acids and strong nucleophilic reagents must be absent.

Reactions of the second group, which lead to opening of the three-membered heterocycle, constitute the most interesting feature of the chemistry of aziridine, a unique compound that combines the properties of saturated and unsaturated carbon and nitrogen atoms. Polymerisation¶ is a special ring-opening reaction; this proceeds by the step-wise stringing together of aziridine molecules by a polymer chain with an aziridinium ion at its growing end.

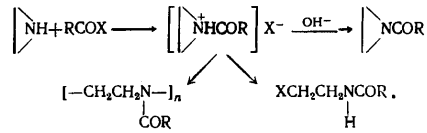
1. Reactions with Retention of the Aziridine Ring

Protonation. Potentiometric titration of aziridine with hydrochloric or perchloric acid in aqueous solutions of neutral salts has been used to determine the thermodynamic protonation constant[201-205]. The titration curves obtained in this way have the form characteristic of weak bases. Comparison of the calculated pK_a value (7.88) for aziridine with the corresponding constants for dimethylamine (10.72) and ammonia (9.25) shows a considerable reduction in the basicity of the nitrogen atom in the three-membered ring (see above)[202].

The temperature dependence of aziridine protonation has been studied and its heat of neutralisation has been determined as $\Delta H^\circ = 11.6$ kcal mole^{-1}.[206] This is lower than the corresponding value for ammonia, which also indicates the low basicity of aziridine.

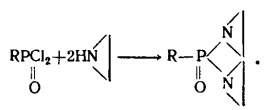
Complex formation. The ability of aziridine to act as a donor of the free electron pair of the nitrogen atom is also reflected in complex formation with transition metal ions[179,206-208]. The type of bond that aziridine forms as a ligand with metal ions and their coordination numbers in these compounds are similar to those of the corresponding ammine complexes. In agreement with the reduced basicity of aziridine, the stability of these compounds is lower than that of the analogous ammine complexes.

Acylation and alkylation. The reaction of aziridine with acid anhydrides or acid chlorides leads to the corresponding *N*-acylaziridines only when the acid formed is immediately removed from the site of reaction with some acid acceptor[209-214]. Otherwise the *N*-acylaziridinium compounds formed undergo further conversion with ring opening and the formation of substituted β-acylethylamides or their polymers:



The *N*-acylaziridines obtained in this way are very unstable compounds[210]. Some of them have interesting biological properties and are used industrially. Special mention should be made of tris-(1-aziridinyl)-*s*-triazine[215-217] (triethylenemelamine or TEM), the first aziridine preparation that was found to have a therapeutic effect in the treatment of cancer and sarcoma[218]. This discovery at once led to numerous syntheses of other aziridine derivatives of triazine and some heterocyclic systems, such as pyrimidine, purine, tetrazine, and others of similar structure.

The reaction between aziridine and phosphorus oxychloride formed the basis of the most numerous class of anti-cancer compounds of aziridine, the aziridinylphosphine oxide derivatives[219,220]. The possibility of varying their properties was discovered by first introducing a substituent (or two substituents) into phosphorus oxychloride and then treating it with aziridine[221]:



An analogous series of aziridinylphosphine sulphides based on the acid chlorides of thiophosphoric and thiophosphonic acids has been obtained[222,223].

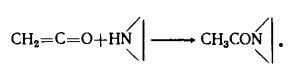
A recently proposed method of acylating aziridines differs in principle from the reactions considered[224]. It starts directly from aziridine and the corresponding free acid and does not require the use of alkaline agents. In this method *NN*-dicyclohexylcarbodiimide is used as a unique dehydrating agent. This method is particularly convenient in the preparation of amino-acyl aziridines; it is also applicable to carboxylic and sulphonic acids.

Since, as a rule, alkylation of amines requires more drastic conditions than acylation, its application to aziridine does not usually give individual monomeric *N*-alkylaziridines; the successful use of alkylation is limited to a few reactions with the most active alkyl halides[215,225]. It is interesting to note that the aziridine ring, stabilised by two alkyl substitutents at the ring carbon atoms[226] or by inclusion in the bicyclic structures of tetramethyleneaziridine[227] and spiro-cyclohexylaziridine[228], can be

¶ Polymerisation of aziridine and the properties of polyaziridine, see Uspekhi Khim., 34, 1249 (1965) [Russ.Chem.Rev., 515 (1965)].

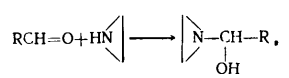
normally alkylated and even gives stable quaternary aziridinium compounds on reaction with an excess of alkyl halides.

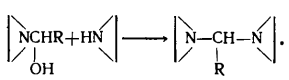
Addition to multiple bonds. While these reactions lead to products considered in the previous section, they proceed much more smoothly, because they are not accompanied by the elimination of any acid or nucleophilic compounds. Thus, the addition of aziridine to the C=C bonds of ketones gives the corresponding 1-acylaziridines in nearly quantitative yield[229,230], for example,



Similarly, aziridine readily adds to the activated double bonds of esters[231-234] and nitriles[235-237] of $\alpha\beta$-unsaturated acids; in the presence of catalytic quantities of metallic sodium, it also adds to the conjugated double bonds of dienes[238,239] and styrenes[238,240]. An analogous reaction of aziridine with quinone formed the basis of a new class of anti-tumour preparations, aziridinoquinones and hydroquinones[241,242].

The addition of aziridine to the carbonyl bonds of aldehydes and ketones at first leads to the corresponding aziridinyl carbinols, which are unstable compounds that tend to undergo polymerisation and cleavage to the starting components[215,243-248]. Aziridinyl carbinols can combine with a second molecule of aziridine, another amine or ammonia to form diaminomethanes[249-253]:





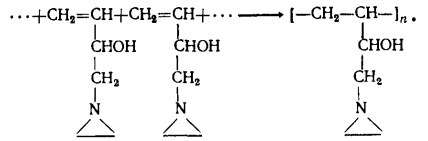
This mechanism is quite general. In the reaction of aziridine with $\alpha\beta$-unsaturated aldehydes and ketones the first stage is addition to the C=C bond[254,255]. A second molecule of aziridine combines with the C=O bond to form diaziridinyl carbinols, which have an appreciable anti-tumour effect[256].

Of the addition reactions of aziridine to C=N bonds, the most widely studied is the reaction with cyanuric acid and its esters[215,257-260], which leads to aziridinylureas. Aziridinylureas, and particularly bisaziridinylureas (based on diisocyanates), are used in the textile industry for the treatment of synthetic and natural fibres and fabrics.

Addition as a result of opening of strained rings. In common with other amines, aziridine opens vigorously the three-membered rings of epoxides, adding the β-hydroxyethyl group formed to its nitrogen atom[261-263]:

Tetramin is a compound of this kind; it is the product of the addition of aziridine to divinyl monoepoxide and is the most powerful cytostat of the aziridine derivatives[264-267].

An interesting anti-cancer preparation has also been synthesised by the radical polymerisation of tetramin[268]:



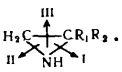
In this polymer, which is less toxic than tetramin, the aziridine rings with their anti-tumour activity are retained.

A similar reaction with thiiran has also been described[269]. Dimerisation of aziridine is an example of this reaction involving aziridine itself[270].

Of the other reactions of aziridine common to other amines, mention should be made of condensation with diborane[271], trimethylboron[199], alkali metals[272], and organometallic compounds[273], and also the formation of halogenoamines by the action of hypohalites[274-277].

2. Reactions with Opening of the Aziridine Ring

In the general case of asymmetrically substituted aziridines a variety of products is to be expected, corresponding to three possible ways of ring opening:



Clearly, these three ways of ring opening will not always occur. Examination of the nature of the attacking reagent enables definite conclusions to be drawn as to the structure of the products formed. In this respect homolytic reactions (non-polar reagents) are distinguished from heterolytic reactions (polar reagents). All homolytic reactions rigorously follow the route predicted by rupture of the least polar bond, but the reverse does not necessarily hold for heterolytic reactions. Here the nucleophilic properties of the attacking reagent must also be taken into account. Rearrangements of aziridine derivatives that usually proceed with participation of a polar substituent in the three-membered ring form an independent group of ring-opening reactions.

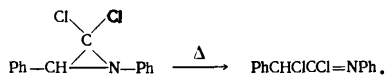
Homolytic opening of the aziridine ring. Hydrogenolysis of the three-membered ring of asymmetrically substituted aziridines proceeds exclusively homolytically at the least polar bond. Thus, the sole product of the hydrogenolysis of 2,2-dimethylaziridine (on a nickel catalyst at 130°) is t-butylamine[278-280].

Catalytic hydrogenolysis of the three-membered heterocycle is somewhat more difficult than that of a multiple bond; the C≡N bond in β-(2,2-dimethylaziridinyl)propionitrile, or the C=C bond in *N*-vinylaziridine, can be selectively hydrogenated in the presence of the aziridine ring[235,281].

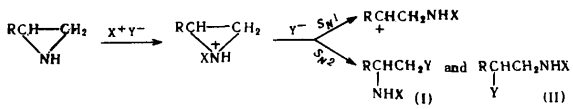
Another example of the homolytic opening of the three-membered heterocycle is thermal isomerisation of aziridine derivatives. Here the comparatively rare opening

of the ring at the C–C bond corresponds to the requirement of minimum polarity of the bond undergoing homolysis, for example[282,283]:

In 2,2-dichloro-1,3-diphenylaziridine the considerable polarisation of the bonds adjacent to the CCl_2 group results in the opposite group (C–N) in the ring undergoing pyrolytic rupture[284]:

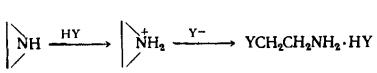


Heterolytic opening of the aziridine ring by various nucleophilic agents. When the three-membered ring in asymmetric aziridines is opened by polar reagent XY, two types of products (I) and (II) may be formed.



One of these may predominate or be formed exclusively, depending on the nature of the reagent and the substituents in the aziridine ring. Thus, in most cases hydrolysis of alkylated aziridines in acid solutions gives type (II) products, corresponding to preferential rupture of the bond at the tertiary carbon atom; ammonolysis with ammonia and amines is not so specific and leads to a mixture of products (I) and (II), and all remaining modes of nucleophilic ring opening mainly lead to products of type (I). In fact, heterolysis of the aziridine ring may proceed by two different mechanisms, depending on the nucleophilic character of the attacking reagent: (1) cationic addition, which includes protonation of the nitrogen atom, rupture of the ring with the formation of a carbonium cation, and addition of the nucleophilic agent (type S_N1 unimolecular mechanism), and (2) rupture as a result of nucleophilic attack by the anion Y^- on the protonated ring (type S_N2 bimolecular mechanism). Because of greater stability of the substituted carbonium cation, the first mechanism leads exclusively to type (II) products, but the second mechanism leads preferentially to the formation of type (I) products, because of the lower electron density of the methylene group and reduced steric hindrance to attack.

The action of acids on aziridine is accompanied by rapid opening of the protonated three-membered ring as a result of nucleophilic attack of the acid anion and addition of this anion to one of the carbon atoms of the ring with the formation of the corresponding β-substituted ethylamine:



With asymmetrically substituted aziridines the reaction leads to two isomeric products; however, in each individual case one or other of the two routes predominates. Thus, the main products of the reaction of 2-methylaziridine with hydrogen halides are β-halogenoisopropylamines[29,30]; with 2-phenylaziridine, α-isomers are preferentially formed[36,39–41].

A study of the kinetics of the opening of aziridine rings by a number of strong nucleophilic agents (see Table 3) has shown that in all the cases examined the reaction is of second order[285–288]; this means that heterolysis of the ring by strong nucleophilic agents proceeds preferentially by the bimolecular S_N2 mechanism. The most probable mechanism of these reactions is nucleophilic attack on the methylene link in the protonated aziridine ring according to the following mechanism:

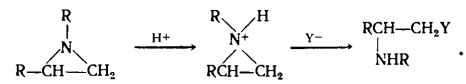


Table 3 also shows that the rate of these reactions is mainly determined by the nucleophilic character of the anion and depends to a lesser degree on substitution in the aziridine ring.

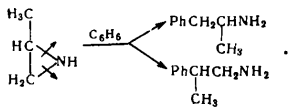
Study of the stereochemistry of the reaction of diastereoisomers of aziridines with acids shows that, as with ring closure, ring opening of three-membered aziridine derivatives is accompanied by inversion of configuration. Thus, as a result of *trans*-opening of the ring, reaction of *cis*- and L(-)-*trans*-2,3-dimethylaziridine with acetic acid gives DL-*threo*-2-acetoxy-3-aminobutane in the first case and L(-)-*erythro*-2-acetoxy-3-aminobutane in the second[289]. In the same way reaction of DL-*erythro*-3-methyl-2-phenylaziridine with hydrogen chloride gives DL-*threo*-2-amino-1-chloro-1-phenylpropane, which gives the starting aziridine when boiled with 50% potassium hydroxide[290].

Other reactions in which the aziridine ring is opened by acid agents include the unique reaction of aziridine with carbon dioxide which leads to derivatives of the unstable *N*-vinylamine[291]:

and also the aminoethylation of hydrocarbons by aziridine and its derivatives which is initiated by Lewis acids[292].



Here too asymmetrically substituted aziridines give two products corresponding to the two mechanisms of ring opening[293,294].

Such important reactions as ring opening by ammonolysis with ammonia and amines and by hydrolysis deserve special examination.

TABLE 3. Kinetics of the opening of aziridine rings by various nucleophilic agents.

Nucleophilic agent	10^6k, mole^{-1} s^{-1} at 25°

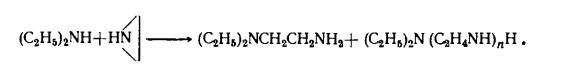
Ammonolysis. In the pure form, aziridine and most of its derivatives do not react with ammonia and amines even on prolonged heating[295,296]. In the presence of catalysts such as water, alcohols, and various acid agents (including ammonium chloride and Lewis acids) reaction occurs, leading to the formation of the corresponding ethylenediamine derivatives together with polymeric products of their further conversion[295-300]:



The ratio of ethylenediamine to polymer depends on the reaction conditions and the catalyst used. Considerable amounts of polyamines are formed in reactions catalysed by water[295-297] or ammonium chloride[298,299] at room temperature; lesser amounts are formed at increased temperature and pressure. An ideal catalyst for the preparation of ethylenediamines is aluminium chloride, which forms a stable complex with the reaction product[300].

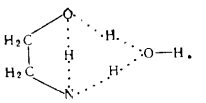
Ammonolysis of asymmetric aziridine is characterised by preferential rupture of the ring at the primary C atom, although in a number of cases considerable quantities of isomeric compounds are also formed. Thus, 2-ethylaziridine forms only one isomer with morpholine, *N*-β-aminobutylmorpholine, but with aniline a small quantity of the second isomer is formed; 2,2-dimethylaziridine forms equal quantities of both isomers with aniline[298].

The ammonolysis of "activated" aziridines without catalysts of any kind is of special interest. For most derivatives of aziridine preliminary protonation or coordination of their nitrogen atoms with a suitable Lewis acid is a condition for nucleophilic attack leading to opening of the aziridine ring, but "activated" aziridines undergo ring opening with great ease even in the absence of acid catalysts[301]. The ammonolysis of *O*-ethyl-*NN*-(1-aziridinyl)-urethane by aniline and a number of its substituted derivatives is an example of such a reaction[296]. Results of the kinetic investigation of this reaction suggest a bimolecular mechanism in which a carbon atom of the three-membered 1-aziridinylurethane ring is replaced by the amino-group of aniline.

Study of the steric course of ammonolysis shows that an overwhelming proportion of product is formed with inversion of configuration, and therefore results from *trans*-opening of the aziridine ring. Thus, DL-*threo*-2,3-aminobutane has been obtained by the ammonolysis of *meso*-2,3-dimethylaziridine with ammonia, and *meso*-2,3-diaminobutane by the reaction of L(-)-*trans*-2,3-dimethylaziridine with ammonia[302]. In the same way D(-)-*erythro*-2-amino-3-ethylaminobutane was obtained from L(-)-*trans*-2,3-dimethylaziridine by the action of ethylamine[303], and *meso*-2,2-bisethylaminobutane was obtained from L(+)-*trans*-*N*-ethyl-2,3-dimethylaziridine. In the latter case, in addition to the optically inactive *meso*-isomer, a small quantity of the optically active product, L(+)-2,3-bisethylaminobutane was observed; this corresponds to the contribution of the S_N1-reaction with frontal attack by the amine on the corresponding carbonium ion.

Hydrazinolysis of the aziridine ring, which is analogous to ammonolysis, has also been described[304].

Alcoholysis and hydrolysis. As has already been mentioned above, in aqueous solutions of aziridine a reaction occurs leading to the formation of a unique cyclic chelate hydrate, linked by hydrogen bonds and containing two molecules of water per molecule of aziridine[161], for example,



The addition of alkali suppresses this reaction, and heating of the solution converts the chelate hydrate in to a mixture of ethanolamine and water.

In acid solutions the mechanism of hydrolytic opening of aziridine rings is essentially different. Here the three-membered ring, previously protonated by acid, is opened as a result of nucleophilic attack of the hydroxide ion:

In the absence of catalysts, alcohols do not generally react with aziridine, but in the presence of strong acids or boron trifluoride, acid alcoholysis, similar to hydrolysis, occurs with the formation of the corresponding β-amino-ethers:

Numerous attempts to study the acid hydrolysis of aziridine derivatives under the action of aqueous hydrochloric acid have not given definite results, because of the competition between chloride ions and water molecules for opening of aziridine rings in aqueous hydrochloric acid solutions[306-309]. The ratio of the products obtained (four) largely depends on the reaction conditions.

Hydrolysis uncomplicated by other nucleophilic ring-opening reactions can only be studied for reactions catalysed by acids with very weakly nucleophilic anions (for example perchloric, picric, or fluoroboric acid) incapable of this kind of competition to an appreciable degree. The work of Clapp on the hydrolysis of aziridine, 2-ethylaziridine and 2,2-dimethylaziridine by a solution of perchloric acid is an example of this kind of reaction[286]. Study of the kinetics, activation energies, and entropies and also the composition of the products of these reactions shows (Table 4) that, although with 2,2-dimethylaziridine and 2-ethyl-2-phenylaziridine hydrolysis is mainly a unimolecular process, both uni- and bimolecular mechanisms operate with 2-ethylaziridine, and aziridine is probably hydrolysed exclusively by an S_N2 mechanism[310].

Table 4 shows that 2-ethyl-2-phenylaziridine is hydrolysed at the fastest rate. The rate of the S_N2 reaction at the primary carbon of aziridine is approximately equal to the overall rate of the S_N1 and S_N2 reactions at the secondary carbon of 2-ethylaziridine, but appreciably less

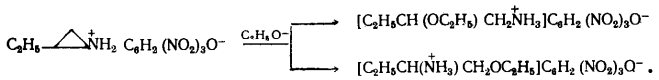
TABLE 4. Hydrolysis of aziridines by aqueous perchloric acid at 21°.

Compound	Composition of hydrolysate		10^7k	ΔH, kcal mole^{-1}	ΔS, e.u.
	S_N1, %	S_N2, %			
Aziridine	—	—	4.61	23.0±0.6	−9.4±1.0
2-Ethylaziridine	22	61	2.64	23.1±0.1	−10.0±0.5
2,2-Dimethylaziridine	80	—	21.0	24.3±0.4	−1.9±1.0
2-Ethyl-2-phenyl-aziridine	100	—	1400	23.6	1.1

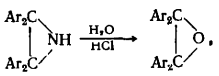
than the rates of the S_N1 reaction at the tertiary carbon of 2,2-dimethyl and 2-ethyl-2-phenylaziridine.

The results of the study of the steric course of hydrolysis of stereoisomeric aziridines are also ambiguous. With *cis*- and L(-)-*trans*-2,3-dimethylaziridine[302] *trans*--opening with inversion of configuration occurs, but hydration of 1,2-dimethyl-3-phenylaziridine (from *dl*-pseudoephedrine) leads to the formation of about equal quantities of *dl*-ephedrine and pseudoephedrine[311]. Finally, study of the hydrolysis of four stereoisomeric forms (*cis*, *d*, *l*, and *dl*) of 2,3-diphenylaziridine shows the predominance of *cis*-addition with retention of configuration at both asymmetric carbon atoms[312]. To a small extent *trans*-addition occurs in all the cases considered; this leads to Walden inversion at the carbon atom undergoing nucleophilic attack. The fact that racemisation does not occur in hydrolysis experiments on pure optical antipodes indicates that the configuration at the second carbon atom remains unchanged, and therefore only the C–N bond of the ring undergoes hydrolytic cleavage. Therefore, all the results mentioned indicate the presence in the hydrolysis reactions in some proportion of both (uni- and bimolecular) components of the ring-opening reaction.

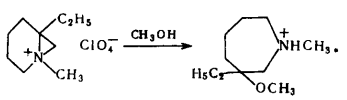
These principles are also valid for the acid alcoholysis of aziridines. Thus, alcoholysis (with methanol or ethanol) of 2,2-dimethylaziridine picrate is accompanied by preferential opening of the ring at the bond with the tertiary carbon atom, but 2-ethylaziridine picrate opens in ethanol to give a mixture of approximately equal quantities of both isomeric β-amino-ethers[235,305].



Mention should be made of an interesting hydrolytic reaction of tetra-arylaziridines, leading to derivatives of another strained three-membered heterocycle, ethylene oxide[313]:



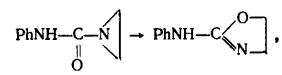
and also of the increased stability to hydrolytic cleavage of aziridine rings included in bicyclic structures of the type  , which increases further with the number *n*. Thus, trimethyleneaziridine[314], tetramethyleneaziridine[315], and pentamethyleneaziridine[316] are only hydrolysed by prolonged boiling with perchloric acid; hexamethyleneaziridine is hydrolysed by perchloric acid only at 150°;[317] and octamethyleneaziridine is not hydrolysed at all. Bicyclic aziridine derivatives with a common nitrogen atom are hydrolysed with rupture of the bridge bond and enlargement of the ring[74,318]:



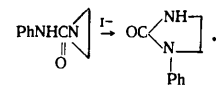
Rearrangement of aziridine derivatives occurs on heating or in the presence of catalysts. The best known catalysts are nucelophilic reagents, aluminium chloride, and acids. As a result of the reaction one C–N bond of the ring opens and a new bond is formed, usually with participation of a polar substituent in the ring.

Some rearrangements of aziridine derivatives are used for the preparation of other nitrogen heterocycles — oxazolines, imidazolines, thiazolines, etc., and also allyl amides and isocyanates.

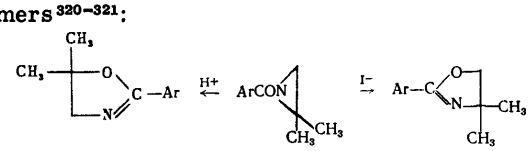
As with the aziridine ring-opening reactions by various reagents described above, the same two main ring-opening mechanisms operate in the rearrangements considered here: (1) intramolecular ionisation following rupture of the protonated ring, and (2) nucleophilic attack of the catalyst on one of the carbon atoms of the three-membered ring. The first type is most characteristic of rearrangements in the presence of acids; the second is catalysed by nucleophilic agents. Thus, in the presence of acids or simply on heating aziridinylureas rearrange by the first mechanism with the formation of corresponding derivatives of 2-oxazoline[319]



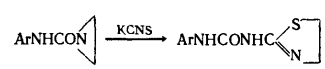
while in the presence of a large excess of a nucleophilic catalyst (for example sodium iodide) the rearrangement proceeds by the second mechanism, leading to 2-imidazoline derivatives[320]:



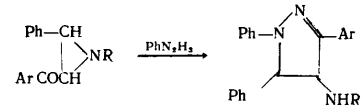
Rearrangement in the presence of a small quantity of a nucleophilic catalyst leads to a mixture of both isomerisation products[320]. Rearrangements of 1-acylaziridines, which lead to 2-oxazolines[320–324], proceed by one of the two mechanisms, depending on the catalyst, and in the case of asymmetric aziridines lead to one of the two 2-oxazoline isomers[320–321]:



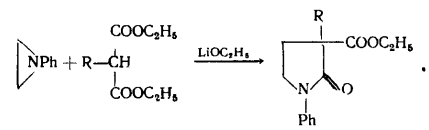
Another type of rearrangement of aziridine derivatives is that in which a molecule of the attacking reagent is included in the new ring. Examples of this mechanism include rearrangements of aziridinylureas in the presence of potassium thiocyanate, leading to 2-thiazolines[325]:



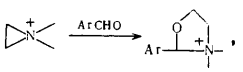
the formation of pyrazolines and pyrazoles by the reaction of β-arylaroylaziridines with phenylhydrazine[43,182,326–328]:



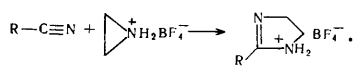
the condensation of 1-phenylaziridine with malonic ester[329]:



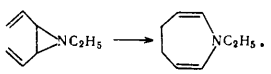
and the reaction of aziridinium salts with aromatic aldehydes[330]:



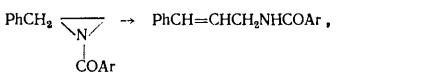
and nitriles[331]:



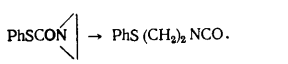
Mention should also be made of an interesting type of valence-tautomeric rearrangements of *cis*-2,3-divinyledaziridine derivatives to dihydroazepines[332]:



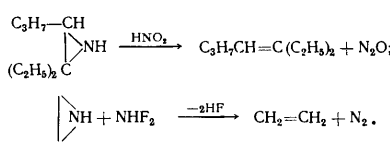
Examples of rearrangements of aziridine derivatives leading to non-cyclic compounds include the stereospecific thermal isomerisation of 1-acyl-2-alkylaziridines to the corresponding allyl amides[323,333-339]:



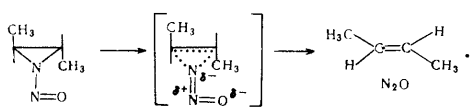
and the rearrangement of *NN*-(1-aziridinyl)-*S*-phenylthiourethane to isocyanate[340]:



Other reactions of aziridine. Deamination. Deamination of aziridine derivatives by the action of nitrosating agents[341-345] or difluoramine[346] is an interesting reaction in which both C–N bonds of the ring are simultaneously ruptured:



A study of this reaction based on the geometric isomers of 2,3-dimethylaziridine has shown that it is highly (> 90%) stereospecific[344]. The rate of deamination of aziridine derivatives is kinetically unimolecular. These facts suggest a mechanism for deamination in which simultaneous opening occurs of both C–N bonds of the ring in the *N*-nitrosoaziridine intermediate:



Reactions with natural compounds. The reaction of aziridine with cellulose, on which industrially important methods of modifying the properties of the latter are based, is of the greatest practical importance[347]. In this reaction the aziridine rings are opened by the free hydroxy-groups of the cellulose and β-aminoethylated cellulose is formed. The presence of basic amino-groups in the cellulose macromolecule does not change its mechanical properties but renders it capable of being dyed like wool with acid dyes and improves its adhesion to various fire-resisting, water-repellant and crease-resisting materials and additives. A somewhat different modification of the properties of cellulose is that produced by treatment with polyfunctional aziridine derivatives, for example, bisethyleneureas. This treatment leads to joining of the thread-like cellulose molecules by bis-(β-ureylene)alkoxy--bridges and is used industrially for the dry spinning of cellulose fibre.

The reaction of aziridine and its acyl derivatives with proteins, which is of biological interest, should also be mentioned[348]. The reactivity of proteins towards aziridine derivatives is due to the presence of acid groups in the protein molecules; the reaction probably proceeds by a mechanism in which various functional groups of the protein molecule are alkylated by protonated aziridine rings.

V. IDENTIFICATION AND QUANTITATIVE DETERMINATION OF AZIRIDINE DERIVATIVES

Numerous complex-formation[1,3,4,215] and salt-formation[6,12,21,349,350] reactions, leading to intensely coloured or poorly soluble compounds, have been proposed for the qualitative identification of aziridines. A basic disadvantage of these methods is that the reactions are common to the majority of amino-compounds, and in the presence of the latter they are of little use or entirely inapplicable. Methods based on opening of the three--membered ring, for example, the colour reaction with thiourea[351], and spectroscopy are more specific for aziridine.

The spectroscopic determination of aziridine derivatives is based on the presence in their vibrational spectra of high frequency (above 3000 cm^{-1}) C–H vibrations, due to bond strain in the three-membered rings[169-174,177,178]. The only limitation of this method is the requirement that multiple bonds and aromatic rings, which absorb in the same region, should be absent. This method is most convenient for detecting aziridine in mixtures with other aliphatic amines or in its polymerisation products.

Acidimetric titration and colorimetric methods have been described for the quantitative determination of aziridine. Recently a number of methods based on ring opening have been proposed. Obviously, these are the most specific methods.

Direct acidimetric titration is the least successful method for the quantitative determination of aziridine, because of the considerable number of side-reactions; these include polymerisation, hydrolysis, and nucleophilic ring opening by acids[20,199,202-204]. Colorimetric methods based on double decomposition with the potassium salt of 1,2-naphthoquinone-4-sulphonic acid are also not specific for aziridine[351,352]. Extraction with chloroform of the dye formed in aqueous solution has been proposed to increase the sensitivity of this method.

As with qualitative identification, the most specific and reliable quantitative methods are based on reactions in which the aziridine ring is opened by various nucleophilic agents. These methods include the extremely sensitive colorimetric determination of the product of the reaction of aziridine with γ(-4-nitrobenzyl)pyridine, proposed for the determination of very small quantities of aziridine in water and in air[353]. Reactions of this group suffer from one general disadvantage: they have a very low velocity,

which is characteristic of non-ionic reactions. Because of this the methods are generally used indirectly. Attempts to improve them involve a search for effective nucleophilic agents that would give the maximum reduction in the time of reaction with aziridine.

The most widely used method of this group, the thiosulphate method[354-357] and its latest modification in which thiocyanate is used[358], are based on the determination of alkali formed as a result of rupture of the aziridine ring by $S_2O_3^{2-}$ or CNS^- ions in an acidified solution. The second method of this group is a combination of the acidimetric method and ring opening by acid. The sample containing aziridine is boiled with an excess of acid, which is then determined by back titration[215]. The latest modification of this method comprises direct titration of aziridine derivatives with a solution of perchloric acid in acetic acid or dioxan in the presence of an excess of quaternary ammonium iodide[359]. The method is based on the rapid opening of the aziridine ring by hydriodic acid immediately it is formed (by displacement with perchloric acid from the quaternary ammonium salt). Verification of the results obtained by means of the thiocyanate method shows that direct titration is of sufficiently high accuracy.

VI. ACTION ON LIVING ORGANISMS

Aziridine and its derivatives surpass all known chemical compounds in their biological activity and in their many-sided action on living organisms (toxicity, mutagenesis, cytostatic properties). Since their action is very similar to that of penetrating radiation, they have been called radiomimetic compounds. The biological effect of aziridine derivatives is widely used in various fields of science and technology and therefore deserves special consideration.

Toxicity. Aziridine is extremely poisonous[360-366]. A single oral dose of 15 mg per kg of body weight is lethal. Death usually occurs in 1 to 24 hours as a result of respiratory paralysis[361]. It has been noted that in aziridine poisoning death can occur even 10 days after a symptomless period as a result of a combination of pulmonary and renal lesions with leukopenia[365-367].

The danger of poisoning by aziridine vapour is aggravated by the great similarity of its odour to that of ammonia, and also by the absence of symptoms during exposure[368]. The first signs of aziridine poisoning only appear after 2–8 h in the form of nausea and vomiting, and inflammation and oedema of the mucous membrane of the mouth, throat, and eyes[368,369]. A single exposure for 30–60 minutes to a concentration of 250 parts per million in air is dangerous to life[369]. Hydration, antihistamines, steroids, antibiotics, expectorants, and enzyme therapy are used in the treatment of aziridine poisoning[370]. It has been noted that, when suitable safety measures are taken, work with aziridine in the laboratory can be carried on for a long time without danger to health[368]. An ordinary gas mask provides individual protection against aziridine vapour.

Aziridine is readily absorbed by the skin and produces blisters and rashes that are difficult to heal[371]. Prolonged action of aziridine on the unprotected skin produces symptoms of systemic poisoning.

Mutagenic activity. Aziridine and its derivatives are the most powerful chemical mutagens. The mechanism of chemical mutagenesis by aziridine derivatives involves attack by the aziridine molecule on the pyrimidine precursors of deoxyribonucleic acid[372,373]. Compared with irradiation by ultraviolet light and X-rays, aziridine derivatives produce the maximum number of mutations per thousand surviving spores[374]. The combined effect of irradiation and the action of aziridine derivatives has a much greater mutagenic effect than each of these separately[375]. Aziridine and its derivatives are widely used in agricultural and industrial selection to increase the productivity of agricultural crops and for the selection and growth of strains of antibiotic producers.

Cytostatic activity. The discovery that triethylenemelamine, phosphoraziridates, and certain other aziridine derivatives can prevent the reproduction (mitosis) of plant and animal cells has prompted an extensive search for similar compounds amongst other aziridine derivatives. The exceptional interest in these compounds is due to the wide use of their cytostatic activity in the treatment of various forms of neoplastic disease, such as cancer, sarcoma, and malignant blood diseases.

VII. MAIN TECHNICAL USES

It has been noted above that the unique chemical, physicochemical, and biological properties of aziridine find considerable use in various branches of science and technology. We shall consider some of them briefly.

Judging from the number of publications, aziridine and its derivatives are most widely used in the textile and paper industries. Aziridines, which are fairly powerful alkylating agents (as a result of the opening of the three-membered ring), readily react with most compounds that form natural and synthetic fibres and paper; since amino-groups are introduced into the compounds, their properties are modified. Cellulose, acetylcellulose, viscose, and other cotton fibres acquire the capacity to take acid dyes in the same way as wool[376]. This also holds for most synthetic fibres; these include polyacrylic[377], vinylidene cyanide[378] and polyvinyl-alcohol[379] fibres. Polyalkene fibres, which have the best mechanical properties but contain no reactive groups in the molecule, must be partially oxidised[380] or subjected to γ-irradiation[381] before treatment with aziridine[381]. Treatment of synthetic and natural fibres with aziridine derivatives greatly increases their water-resistance[382,383]. Wool and other protein fibres acquire resistance to laundering[384], do not shrink, and do not break off after they have been treated with bisalkyleneureas, or other aziridine derivatives containing at least two aziridine rings in the molecule (because of the formation of cross-linking bonds in the keratin). Synthetic fibres and fabrics made from them do not accumulate electric charges when they have been treated with aqueous solutions of polyaziridine and some aziridine derivatives[365].

The addition of 0.3–0.6% of aziridine or polyaziridine in the process of paper making accelerates the coagulation of the paper mass and increases the productivity of the paper-making machines[386]; it also permits the use of raw material with low drainage properties, activates the cellulose fibres, increasing their adhesion to fillers[387], and increases (by about 60%) the mechanical strength of the paper under wet conditions and also its ability to fix dyes and pigments[368].

Some aziridine and polyaziridine derivatives are used in photography to strengthen the emulsion gelatin[389] and to fix a colour image on it[390], to sensitise photographic materials[391], and as developers of colour photographs[392].

Some cytostatically active aziridine derivatives find a very interesting use in the control of mosquitos, flies, and other blood-sucking insects[393,394]. The active compound (usually triaziridinylphosphine oxide or sulphide) is added in the proportion of 0.5% to the insect food (a corn bait); when the individuals that have eaten it are distributed amongst the natural populations, the latter are exterminated in about three generations[395].

The use of aziridine and a number of its derivatives in rocket engineering should also be mentioned. The high heat of formation, associated with the closure of the three-membered ring, the tendency to ignite spontaneously with most oxidising agents, and also the low melting point and relatively high density make aziridine[396,397] and 1-aminoaziridine[398] attractive combustible components of highly effective fuels for liquid rocket motors. Aziridine derivatives containing several aziridine groups in the molecule (for example, triaziridinylphosphine oxide and sulphide and triethylenemelamine) are used for hardening the composition of a mixed solid rocket fuel based on synthetic polymers containing terminal acid groups[399,400]. The fuels thus obtained have better physicomechanical characteristics compared with similar compositions hardened by epoxides[399].

ADVANCES IN THE CHEMISTRY OF IMIDAZOLE

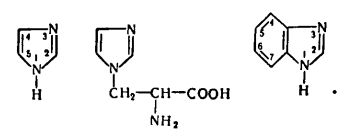
A. F. Pozharskii, A. D. Garnovskii, and A. M. Simonov

CONTENTS

I. Introduction 122
II. Synthesis of imidazoles 123
III. Physical properties and structure 130
IV. Chemical properties 132

I. INTRODUCTION

In recent times progress in the chemistry of certain classes of organic compounds has been closely related to advances in molecular biology. A striking example of this is the chemistry of imidazole (I) and its derivatives. Numerous natural compounds (enzymes, nucleic acids, alkaloids, etc.), which include in their composition the imidazole group, have been known for a long time. A new antibiotic, azomycin (2-nitroimidazole)[1-3] and a new amino-acid, isohistidine (II)[4], are further additions to this series of compounds.



(I) (II) (III)

At the beginning of the 1950's it was shown that purines are not the only condensed imidazole system which plays a role in vital processes. It was found that the structure of vitamin B_{12} incorporates a 5,6-dimethylbenzimidazole fragment[5]. This finding greatly stimulated the development of the chemistry of imidazoles condensed with aromatic rings, and in the first place of benzimidazole (III).

The advances in the elucidation of the role of the imidazole group of enzymes and nucleic acids in the chemistry of the most important living processes has been particularly remarkable[6,7]. All these discoveries naturally enough also required a considerable effort in research on the chemistry of imidazole. In terms of the volume and importance of the studies on imidazole and its derivatives the last decade may be compared to the entire preceding period. In this connection it is necessary to sum up all this work, particularly as the latest reviews on the chemistry of imidazole[8] and benzimidazole[9] cover the literature only up to 1951. In a number of monographs on the chemistry of heterocyclic compounds[10-15] the chemistry of imidazole is dealt with in a very brief and incomplete manner.

The present review covers the literature on the chemistry of imidazole and the most important imidazole derivatives condensed with aromatic rings from 1952 to 1963

(partly also 1964) inclusive. In view of their unusual properties, it is desirable to consider separately condensed imidazole systems consisting of two and more heterocyclic rings (imidazopyridines, purines, etc.)[16]. The extensive biochemical and pharmacological data on imidazoles, which themselves can be and already have been[6] the subject of a review, will be used only partially in dealing with the main problem — the exposition of the present state of the chemistry of imidazole.

II. SYNTHESIS OF IMIDAZOLES

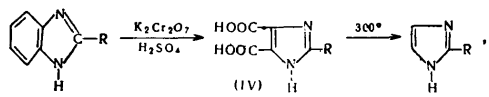
A. NON-CONDENSED IMIDAZOLES

The classical synthesis of imidazoles by the method of Debus and Radziszewski (reaction of α-diketones with ammonia and aldehyde) has a number of disadvantages[8]. In the 1930's two important modifications of this method were proposed: Weidenhagen's method, consisting in the reaction of α-hydroxy-ketones with ammonia and an aldehyde in the presence of copper acetate (sometimes copper citrate or sulphate is used) and Davidson's method, consisting in the reaction of α-diketones with an aldehyde and ammonium acetate in glacial acetic acid. Both these modifications have not lost their value even now. They are widely used for the preparation of a wide variety of mono-, di-, and tri-*C*-substituted (substituent — alkyl, cycloalkyl, aralkyl, aryl, or a heterocyclic residue) derivatives of imidazole[17-25] and 2-imidazolyl ketones[26].

One of the most important achievements in the chemistry of imidazole in recent years is the formamide synthesis of imidazoles proposed by Bredereck and Theilig[27]. It consists in the reaction between α-diketones or α-substituted ketones (substituents — halogeno-, hydroxy-, amino-, or isonitroso-groups) and formamide. As a rule high yields and simplicity are the main advantages of this method. However, it has limited applicability for the preparation of 2-substituted imidazoles, since it is then necessary to replace formamide by the amides of more complex acid and this reaction has so far been relatively little investigated[28,29]. Although a review of formamide syntheses was published in 1959[30], we shall consider this question briefly, since a number of new papers have been published since then.

1. Imidazole and Its Simplest 2-Alkyl(Aryl) Derivatives

A widely used synthesis of imidazole is from imidazole-4,5-dicarboxylic acid (IV) obtained by the oxidation of benzimidazole with chromic acid mixture[31]. 2-Methyl- and 2-ethyl-imidazoles are synthesised similarly[32-34]:



where R = H, CH_3, C_2H_5.

It is interesting that *N*-substituted benzimidazole derivatives cannot be converted in this way to the corresponding di-acid (IV).[31] Imidazole-4,5-dicarboxylic acid is also readily formed on hydrolysis[35] of its diethyl ester. In their synthesis of 2-cycloalkylimidazoles, Schubert and Ladish[37] also started from the corresponding di-acids obtained by Maquenne's method[8].

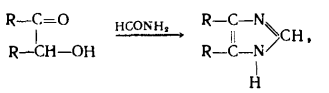
A new and probably the most economical synthesis of imidazole itself is the reaction between the glycol acetal of α-bromoacetaldehyde and formamide[38]:

The preparation of imidazole and its 2-alkyl(aryl) derivatives by the reaction of ethylenediamine with the corresponding alcohol, aldehyde, or acid at a high temperature in the presence of Pt/Al_2O_3 has been patented[39,40]. The yields of products are very high, but the method is experimentally very complex. 2-Benzyl- and 2-α-naphthylmethyl-imidazoles are comparatively readily obtained from ethylenediamine and phenyl- or α-naphthyl-acetic acids[41].

Reductive aminolysis of glyoxal, methylglyoxal, and acetoin with ammonia or hydroxylamine leads to the formation of imidazole only in the case of glyoxal[42].

2. *C*-Alkyl-, *C*-Aralkyl-, and *C*-Aryl-imidazoles

a. From α-hydroxy-ketones. 4,5-Disubstituted imidazoles can be obtained in excellent yield by boiling α-hydroxy-ketones with formamide for 2–4 h[24,27]:

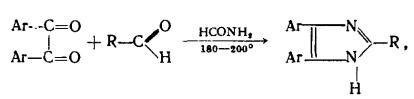


where R = alkyl, aryl, α-furyl, 4,5-octamethylene, etc. Highly branched α-hydroxy-ketones (hexamethylacetoin, tetrabenzylacetoin) do not form imidazole on heating with formamide.

A small amount of 4,5-disubstituted oxazole forms as a side-product. If conditions in which the imidazole ring is formed preferentially (large excess of formamide, t = = 180–200°) are not maintained, the formation of oxazole may begin to predominate. This situation is also favoured by the use of sulphuric acid as a condensing medium[43].

b. From carbohydrates. This pathway has been used in recent years mainly for the preparation of 4-hydroxymethylimidazole used in the synthesis of histamine[44,45]. An improved method of synthesis of 4-methylimidazole from glucose has been described[46].

c. From α-diketones. On reaction with aldehydes and formamide, α-diketones give 2,4,5-trisubstituted imidazoles in yields of 27–67%:[28]

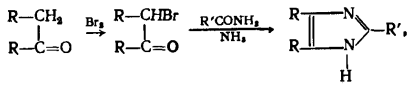


where Ar = C_6H_5, *p*-BrC_6H_4, *p*-$CH_3OC_6H_4$, *o*-ClC_6H_4; R = H, C_6H_5, 3,4-$Cl_2C_6H_3$.

On boiling with formamide (190°, 4 h) di-(2-furyl)-ethane-1,2-dione gives 2,4,5-trifurylimidazole; on the other hand, if a mixture of formamide and formic acid is used, 4,5-difurylimidazole is formed[47].

d. From α-halogeno-ketones. When α-halogeno-derivatives of aliphatic and aliphatic–aromatic ketones are boiled in formamide, 4,5-disubstituted imidazoles are formed[22,27]. 4-Phenylimidazole can be

obtained by this reaction from phenylacyl bromide in 90% yield. It is very convenient to brominate the ketone with an equimolar amount of bromine in formamide[48] or acetamide[29] and then, without isolating the α-bromo--derivatives, pass ammonia into the mixture heated to 180°:

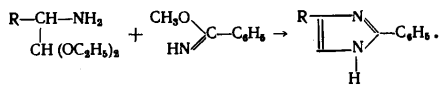


where R′ = H, CH_3.

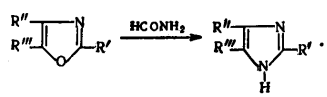
The preparation of 4,5-disubstituted imidazoles from 1-chloro-1,2-epoxides and formamide described by Durgaryan[49] may be regarded as a special case of this reaction. As before, imidazoles are also synthesised from α-halogeno-ketones by Kunckell's amidine method[20,50].

e. From α-amino-ketones and α-iso-nitroso-ketones. α-Amino-ketones and their α-acyl derivatives form the corresponding imidazoles in good yields on reaction with formamide[27,51] or ammonium acetate in acetic acid[51,52]. When benzil mono-oxime reacts with formamide in the presence of sodium hydrosulphite, 4,5-diphenylimidazole is formed in 71% yield[27]. The reaction of benzil mono-oxime with benzaldehyde is more unusual[53], resulting in an almost quantitative yield of 2,4,5-triphenylimidazole instead of the expected oxazole.

2-Phenylimidazole and its 4(5)-alkyl derivatives may be obtained[54] by the condensation of the acetals of α-amino--aldehydes with benzimidates in aqueous alcohol at pH 7:

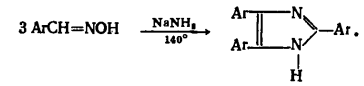


f. From oxazoles. It follows from what has been said above that formamide syntheses of imidazoles are frequently complicated by the formation of oxazoles. In order to find the optimum conditions for the formation of imidazoles from α-substituted ketones, Theilig studied the reaction of oxazoles with formamide[55]. After boiling for 3–6 h with formamide, most oxazoles were converted into the corresponding imidazoles in satisfactory yields:

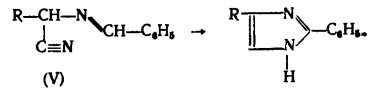


Oxazoles containing aliphatic radicals (C_3H_7, C_4H_9) in positions 2 and 5 were an exception. Some of these "difficult" oxazoles are converted into the imidazoles on reaction with formamide and ammonia in an autoclave at 200–210°.[56] Aromatic substituents, in particular in position 4 of the oxazole ring, facilitate the imidazole synthesis, probably by lowering the electron density at the oxygen atom[57,58]. Hence it follows that halogenoalkylated oxazoles should form imidazole even more readily; this is in fact found to be the case[57]. Benzimidazole cannot be obtained from benzoxazole in this way, although it would appear that a condensed benzene ring should also facilitate this reaction[57]. The mechanism of the formation of the imidazole ring from oxazoles and formamide has been discussed by Theilig[55]. A case is also known of the opposite conversion — of the imidazole ring into the oxazole ring[59].

g. Other methods. 2,4,5-Triarylimidazoles are formed in yields of 72–77% when aldoximes are heated with sodium amide in absolute xylene[60]:

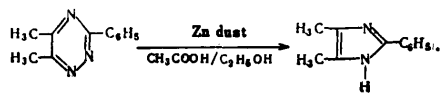


On prolonged storage or on distillation, benzylideneamino--derivatives (V) are converted into 2-phenyl- or 2,4(5)-diphenyl-imidazoles[61]:



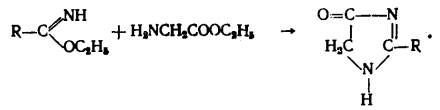
(V)

Metze and Scherowsky[62] observed an interesting case of contraction of the 1,2,4-triazine ring to the imidazole ring. They suggested the following mechanism for this reaction[62]:



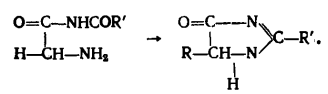
3. Hydroxyimidazoles

Relatively little work has been done on 4(5)-imidazolones. The principal method for their preparation is still the reaction of imidates with the ethyl ester of glycine:



Finger's classical work in this field[8] was checked[63,64] and a number of improvements have been made in the method of preparation of imidazolones. The synthesis of imidazolones from imidates is described in greater detail in the review of Roger and Neilson[65].

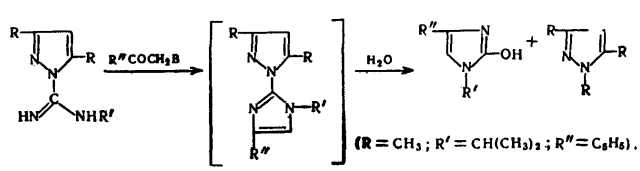
A new method for the synthesis of 4(5)-imidazolones consists in the spontaneous cyclisation of *N*-acylated amides of α-amino-acids[66,67]:



The substituent R in this reaction is usually an electrophilic group, such as CN, COOR, COR, etc.

2-Hydroxyimidazole and its 4(5)-substituted derivatives can be conveniently obtained by the action of potassium cyanate on solutions of amino-aldehydes made by the reduction of α-amino-acids with sodium amalgam[68].

Recently 2-hydroxy-1-isopropyl-4-phenylimidazole was synthesised in 51% yield by a fundamentally different procedure[69]:



(R = CH_3; R′ = $CH(CH_3)_2$; R″ = C_6H_5).

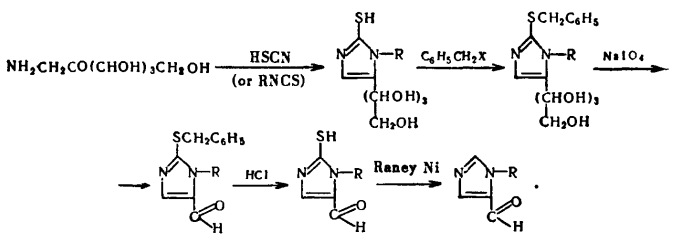
Some problems concerning the synthesis of imidazolones are also discussed by Roger et al. [70] and Wieland and Biener [71].

4. Mercaptoimidazoles

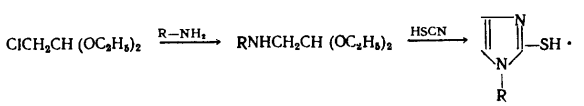
2-Mercaptoimidazoles are biochemically important as antithyroid agents, and Marckwald's synthesis of imidazoles [8] [reaction of α-amino-carbonyl compounds with thiocyanic acid or alkyl(aryl) isothiocyanates] is second in importance only to the method of Debus and Radziszewski, since sulphur can be readily removed from the resulting 2-mercaptoimidazoles with nitric acid, ferric chloride, hydrogen peroxide, or Raney nickel.

The principal problem in the preparation of 2-mercaptoimidazoles remains the synthesis of the initial α-amino--aldehydes and α-amino-ketones. The reduction of α-amino-acids with sodium amalgam [72-74] is in this case preferable to phthalimide methods [75,76] or the Dakin–West reaction [77-79], since it does not require the preliminary isolation of the α-amino-aldehyde from the reaction mixture and because the initial α-amino-acids are available.

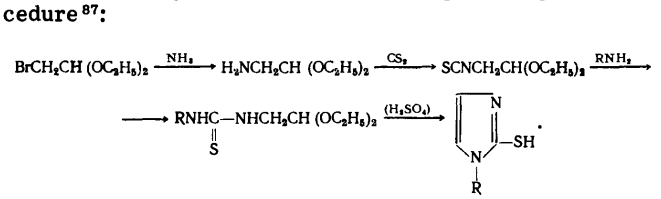
D-Glucosamine [80-83] or 1-alkylamino-1-deoxy-*D*--fructose [84] can serve as a source of 2-mercapto--4-(arabotetrahydroxybutyl)imidazoles which can be converted into 4-formylimidazoles:



N-Alkyl(aralkyl)-2-mercaptoimidazoles can be conveniently synthesised starting with *N*-substituted amino--acetals [85,86]:



A number of 2-mercaptoimidazoles containing alkyl, aralkyl, aryl, and 2-thiazolyl groups in position 1 have been obtained by a somewhat more complicated procedure [87]:

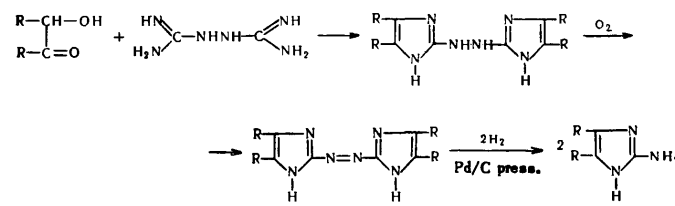


The condensation of the hydrochlorides of α-amino--ketones with potassium thiocyanate is best carried out in non-aqueous solvents (absolute alcohol, glacial acetate acid, etc.), since in aqueous media a certain amount of a pyrazine derivative is also formed as a result of the hydrolysis of the α-amino-ketones [88].

The methods of preparation of 4,5-dialkyl(diaryl)- and 1,4,5-triaryl(trialkyl)-imidazoles from α-hydroxy-ketones and thiourea or its *N*-substituted derivatives has been improved [89].

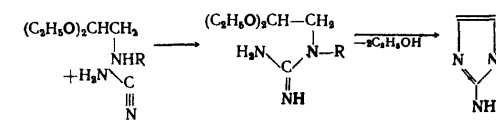
5. Aminoimidazoles

2-Aminoimidazoles have been little investigated so far because of the lack of convenient methods for their synthesis. The classical procedure for the synthesis of 2-aminoimidazoles consists in the reduction of azo-imidazoles obtained by coupling diazonium salts with imidazoles containing a free NH group [8]. However, not only are the yields low but the method is not always applicable [90]. A new promising modification of this method is via the synthesis and reduction of 2,2′-azo-imidazoles [91]:



where R = C_6H_5, $CH_3OC_6H_4$, β-$C_{10}H_7$, α-pyridyl. The yields of 2-amino imidazoles reach 89.5% in this case.

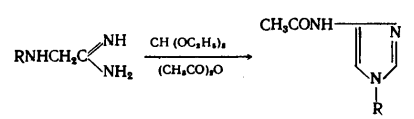
2-Amino-4,5-diarylimidazoles can also be obtained by the benzidine-like rearrangement of 2-phenylhydrazino-imidazoles [92] or by the reduction of the relatively readily available derivatives of 2-benzylidenehydrazinoimidazoles [93]. The most convenient method for the preparation of 2-aminoimidazole and its 1-alkyl derivatives is by the reaction of cyanamide with α-amino-acetals [94]:



The reaction of D-glucosamine with cyanamide gives 2-amino-4-(arabotetrahydroxybutyl)imidazole [95,96]. The preparation of 2-guanidino-4(5)-phenylimidazoles from phenylacylamines and cyanoguanidines is based on a similar reaction [97].

6. 4(5)-Aminoimidazoles and 4(5)-Aminoimidazole--5(4)-carboxamides

Two new methods for the preparation of 4(5)-amino-imidazoles have been proposed recently. In one of them the starting materials are the hydrochlorides of benzyl-oxycarbonyl or tosyl derivatives of aminoacetamidine and orthoformic ester [98]:

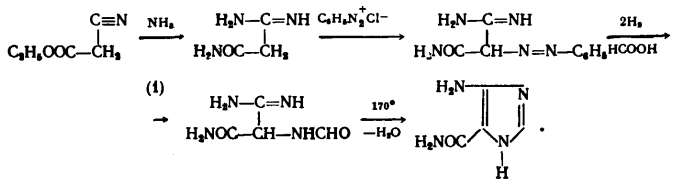


where R = *p*-$CH_3C_6H_4SO_2$ (a) and R = $C_6H_5CH_2OCO$ (b).

In the other method dinitriles RN(CN)CH(CN)R′ are cyclised into 4(5)-amino-2-bromoimidazoles by treatment with anhydrous hydrogen bromide [99].

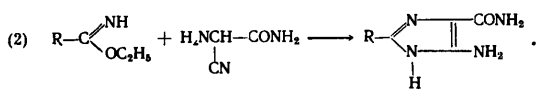
4(5)-Aminoimidazole-5(4)-carboxamides are of exceptional interest as the biosynthetic precursors of

purines [100]. At present several methods are known for the preparation of these compounds:

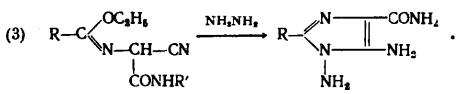


This method, proposed for the first time by Shaw and Woolley [101], is most convenient, after certain modifications [102-104], for the synthesis of large amounts of 4(5)-aminoimidazole-5(4)-carboxamides under laboratory conditions.

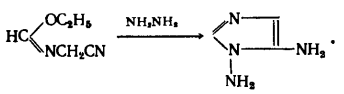
The reaction of amidines [105] or imino-esters [106] with aminocyanoacetamide proceeds as follows:



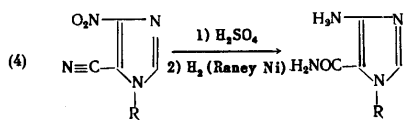
The reaction between *N*-(carbamoylcyanomethyl)imidates and hydrazine, phenylhydrazine, or 1,1-dimethylhydrazine yields the corresponding 1,5-diamino-4-carbamoylimidazoles [107,108]:



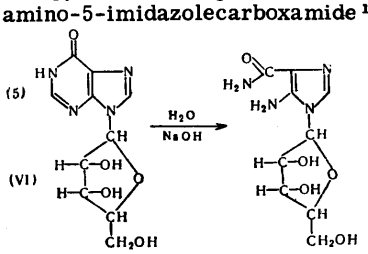
The parent compound of the series, 1,5-diaminoimidazole, is formed from ethyl *N*-cyanomethylformimidate and hydrazine [107]†:



Hydrazines not containing a free NH group, for example 1,2-dimethylhydrazine, do not give imidazoles in this reaction but 1,2,4-triazines. If a primary amine is used instead of hydrazine, it is possible to obtain 1-alkyl-(glucosyl)-5-amino-4-carboxamidoimidazoles [110-113]:



In the alkaline hydrolysis of certain purines, for example (VI), the pyrimidine ring opens forming the corresponding 4-amino-5-imidazolecarboxamide [104]:



In an acid medium the carbohydrate residue also hydrolyses.

† 1-Amino-2-mercaptoimidazoles have been described recently [109].

B. BENZIMIDAZOLES

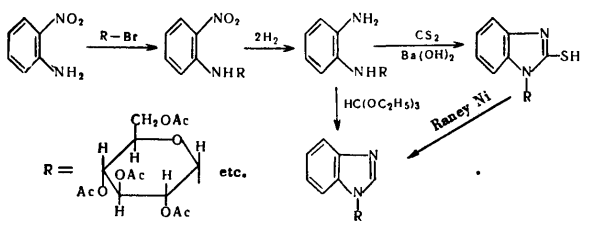
The principal method for the preparation of benzimidazoles is still condensation of *o*-arylenediamines with carboxylic acids and their derivatives. Attempts to find new ways of synthesising benzimidazoles, such as thermal decomposition of 1,5-diaryltetrazoles and 1,2,4-oxadiazol--5-ones [114-119] or the rearrangement of *N*-aryl-*N*-hydroxyamidines [120] are not of any preparative importance.

At the same time the classical synthesis of benzimidazoles from *o*-arylenediamines has been significantly modified. The method involving the ring closure of the imidazole ring of benzimidazole using directly the corresponding *o*-nitroanilines has been further developed, the reduction and cyclisation stages being combined into one [121-123]. Phillips' method for the synthesis of 2-arylbenzimidazoles has been improved [124-130], and many new modifications have been introduced into the reaction of *o*-arylenediamines with aldehydes [131-134].

1. Benzimidazoles without a Substituent in Position 2

The formation of benzimidazole from *o*-phenylenediamine and formic acid proceeds with exceptional ease: close to physiological conditions (18°, pH 0.5) the yield of benzimidazole after five days is 83%. [135] At 100–110° the time required for this yield is reduced to 2 h. Various benzimidazoles substituted in the benzene ring (substituents — alkyl, halogeno-, hydroxy-, alkoxy-, amino-, and nitro-groups, etc.) can be obtained just as readily by means of this reaction.

In connection with the interest attaching to vitamin B_{12}, much work has been done on the preparation of 5,6-dimethylbenzimidazole [121,136-141] and *N*-glycosidobenzimidazole [142-148]; particular attention has been devoted to 5,6-dichloro- and 5,6-dimethyl-1-glycosidobenzimidazoles [149], in view of their high physiological activity. 1-Glycosidobenzimidazoles are synthesised starting with the corresponding *o*-nitroaniline and acetylated glycosyl bromide:



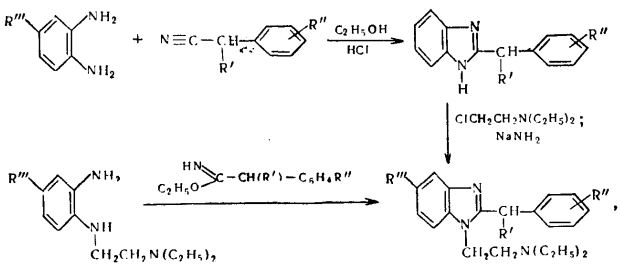
The condensation of *N*-substituted *o*-phenylenediamine is achieved with the aid of orthoformic ester, ethyl formate, or ethyl formimidate. Cyclisation under mild conditions can also be carried out by reaction with carbon disulphide in the presence of barium hydroxide [144,146]. The mercapto--group is subsequently eliminated with Raney nickel. A large number of *N*-arylbenzimidazoles have been obtained from *o*-aminodiphenylamine derivatives and formic acid.

2. 2-Alkyl(Aralkyl)benzimidazoles

The reaction of *o*-phenylenediamine and its 4-methyl-, chloro-, amino-, and alkoxy-derivatives with a number of aliphatic, aliphatic–aromatic, and aromatic acids in the presence of hydrochloric acid has been investigated [124-127].

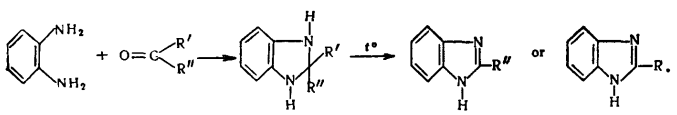
The yield of the 2-substituted benzimidazole depends on the nature of the diamine and carboxylic acid and on the concentration of hydrochloric acid. For example, it proved possible to obtain 2-benzyl- and 2-β-phenylethylbenzimidazoles in yields up to 88–99%.

Many 2-benzylbenzimidazoles have been synthesised according to the following scheme [151–154]:



where R′ = H, $CH_2CH_2N(C_2H_5)_2$, $CONH_2$; R″ = H, Cl, CH_3, AlkO; R‴ = H, NO_2. Many of these substances are muscle relaxants and are effective analgesics.

The reaction of *o*-phenylenediamine (VII) with aliphatic or aliphatic–aromatic ketones yields imidazolines which on thermal decomposition lose a hydrocarbon molecule (R′H or R″H) and are converted into 2-substituted benzimidazoles [155–157]:



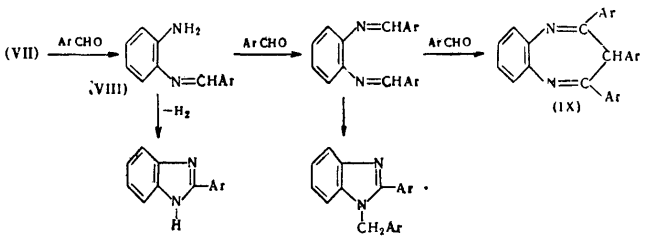
(VII)

The primary product of the reaction of *o*-phenylenediamine with benzophenone and its derivatives is not imidazoline but a Schiff's base [156] which on prolonged heating at 250–280° is converted into 2-arylbenzimidazole.

3. Benzimidazoles with Aryl or Heterocyclic Substituents in Position 2

Many new successful methods have been proposed for the synthesis of 2-acrylbenzimidazoles [124–133,158–162]. For example, 2-phenylbenzimidazole can be obtained in 76–95% yields from *o*-phenylenediamine and benzoic acid [124–127,129] or its derivatives: esters [129], nitrile [129,160], amide [129,161], and imidates [65,158,159]. The reaction is usually carried out by fusing together the components at 180–250° or by heating in a high-boiling solvent in the presence of condensing agents (hydrochloric acid, polyphosphoric acid, and others). We believe that the simplest and most convenient procedure is that of Porai-Koshits and coworkers in which equimolar amounts of *p*-phenylenediamine and benzoic acid are heated in a sealed tube at 180° in the presence of 25% hydrochloric acid. After heating for 40 min the yield of 2-phenylbenzimidazole is 95%. In the absence of hydrochloric acid the yield falls to 65% and when halogenobenzoic acids are used it is only 49% or less [162–163].

In the reaction of *o*-phenylenediamine with an equimolar amount of an aromatic or heterocyclic aldehyde a monoanil (VIII) is formed in the first stage and in the presence of oxidising agents can then yield a 2-substituted benzimidazole. The most successful oxidising agent, which at the same time serves as a solvent, proved to be nitrobenzene [131–133]. Sometimes (with 9-formylanthracene [164] and furfural [165]) the anil (VIII) is spontaneously oxidised by atmospheric oxygen to 2-substituted benzimidazole:



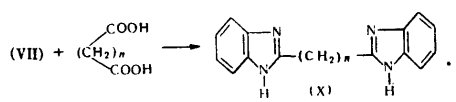
Depending on the conditions and on the nature of the reactants, in the reaction of *o*-arylenediamines with two and more moles of an aldehyde there is preferential formation of the corresponding 1-benzyl-2-arylbenzimidazole, 2-arylbenzimidazole, or, most often, their mixture with a small amount of 2,3,4-triaryldiazepine (IX). There is a review on the preparation of benzimidazoles from *o*-phenylenediamines and aromatic aldehydes [134].

None of these methods is universal but together they make it possible to synthesise any benzimidazole derivative. Thus in the synthesis of benzimidazoles with heterocyclic substituents in position 2 (pyridyl, quinolyl, furyl, thienyl, pyrrolyl, thiazolyl, etc.) best results are obtained by using aldehydes in the presence of oxidising agents, imidates [165], or acid amides [166].

Weidenhagen's classical method has been widely used in the synthesis of a large number of new 2-arylbenzimidazoles and their *N*-alkyl(aryl) derivatives [150,167]. The synthesis of 2-arylbenzimidazoles by the reaction of *o*-phenylenediamine with anil cyanides, ω-cyanoacetophenone, nitrones [168], and αβ-unsaturated compounds of the type ArCH=CHCOR [169] while not of preparative importance is of theoretical interest. 2-Phenylbenzimidazole forms in 40% yield in the pyrolysis of *N*-benzyl-*o*-nitroaniline in the presence of iron oxalate [123].

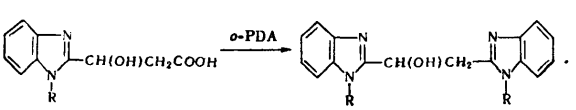
4. Bis(2-benzimidazolyl)alkanes and Related Compounds

In the reaction of *o*-phenylenediamine with dicarboxylic acids using Phillips' procedure [130,170–172] or at 190° [173] the corresponding bis(2-benzimidazolyl)alkanes (X) are formed:

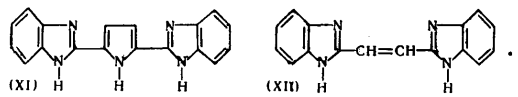


The synthesis of compound (X) with $n = 0$ and 1 can be achieved by using the diamide of oxalic or malonic acid [161,174]. For large values of n (8–10), the synthesis of compound (X) becomes difficult. Best results are then obtained when polyphosphoric or concentrated sulphuric acids are used as the catalysts [130].

Equimolar amounts of *o*-phenylenediamine (PDA) and malic acid give a β-hydroxy acid which on boiling with *o*-phenylenediamine gives a bis-derivative [171]:



The reaction between saccharic acid and *o*-phenylenediamine yields 1,4-bis(2-benzimidazolyl)-2,2,3,4-tetrahydroxybutane which can be converted to αα-bis(2-benzimidazolyl)pyrrole (XI) [175]:



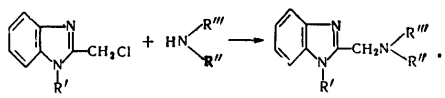
(XI) (XII)

The furan analogue of compound (XI) has also been described [176].

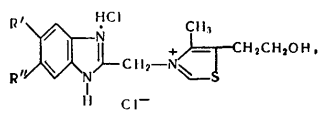
Various derivatives of 1,2-bis(2-benzimidazolyl)ethylene (XII) have been synthesised [177-179]. In the oxidation of bis(2-benzimidazolyl)methane or tetra(2-benzimidazolyl)-ethane Arnold obtained tetra(2-benzimidazolyl)ethylene, which is a powerful yellow chromophore [180].

5. 2-Aminoalkylbenzimidazoles and Amino-Acids of the Benzimidazole Series

2-Aminoalkylbenzimidazoles of various structures are readily obtained in the reaction between 2-chloromethylbenzimidazoles and a wide variety of primary and secondary amines [181-185]:



With tertiary amines quaternary ammonium salts are obtained. In particular, benzimidazolylmethyl analogues of thiamine have been prepared [186]:



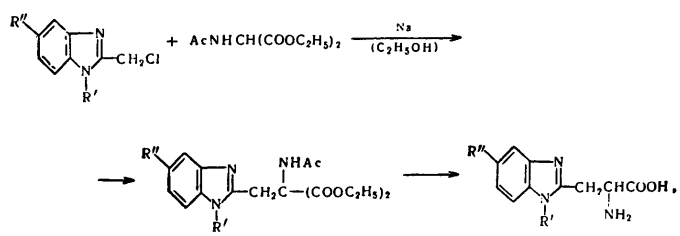
where R′ = H, CH_3; R″ = H, CH_3, Cl, CH_3O, $COOC_2H_5$.

Primary 2-aminoalkylbenzimidazoles can also be obtained by the reduction of nitriles [187], Hofmann degradation of amides, or by the Gabriel synthesis [188]. Until recently it was believed that the reaction between α-amino-acids and *o*-phenylenediamine does not give benzimidazole derivatives. However, it has been shown in a recent study [189] that, when the duration of heating is greatly prolonged, 2-aminoalkylbenzimidazoles can be obtained in satisfactory yield by this procedure. The reactivity of α-amino-acids in this reaction falls in the series glycine, alanine, α-aminoisobutyric acid. β-Amino-acids enter into this reaction much more readily.

Methods have been developed for the synthesis of 2-aminoalkylbenzimidazoles from *o*-phenylenediamines and peptides [190], benzyloxycarbonyl and *p*-tosyl derivatives of amino-acids, and their imino-ethers [191,192]. The reaction of *o*-phenylenediamine with peptides has been suggested for the identification of *C*-terminal amino-acid residues in peptides.

Attempts are being made to synthesise biologically active amino-acids containing a 2-benzimidazole residue.

Usually the synthesis is begun with 2-chloromethylbenzimidazoles and ethyl acetamidomalonate [187,193-196]:



where R′ = H, Alk, Ar; R″ = H, NO_2, CH_3, $N(CH_2CH_2Cl)_2$. In those cases where the method is inapplicable, a different procedure is followed, for example via the corresponding hydantoin [189]. The methods for the preparation of *N*-(2-benzimidazolylmethyl)amino-acids have been discussed [197].

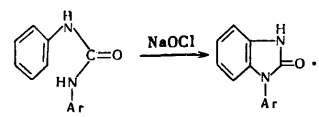
6. 2-Polyhydroxyalkylbenzimidazoles

The syntheses of 2-polyhydroxyalkylbenzimidazoles have been described in the monograph of Zhdanov and Dorofeenko [198].

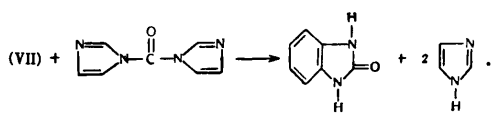
7. 2-Hydroxy- and 2-Mercapto-Benzimidazoles

2-Hydroxybenzimidazoles are readily formed from *o*-phenylenediamines and urea or phosgene [199-202]. In the first case the reaction components are fused together at 140–180° and in the second phosgene is bubbled through an acid aqueous solution of the diamine. Similarly 2-mercaptobenzimidazoles are formed from thiourea and phosgene [203-208].

A new method for the preparation of *N*-arylbenzimidazol-2-ones consists of the oxidation of *NN′*-diarylurea with sodium hypochlorite [209,210]:



Benzimidazolones are also formed in high yields in the reaction of *o*-phenylenediamines with *NN′*-carbonyldiimidazole [211]:



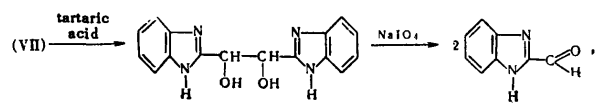
These compounds have been shown by means of electronic and vibrational absorption spectra to have the benzimidazolone and not the hydroxybenzimidazole structure [212,213].

8. 2-Formylbenzimidazoles

Aldehydes of the benzimidazole series have been investigated only in recent years. 2-Formylbenzimidazole [214-217] and its 6-chloro- [217], *N*-methyl-, and *N*-methyl-5-nitro-derivatives [218] are known. The oximes, arylhydrazones, products of condensation with compounds containing a reactive CH_3 group, and certain other derivatives have been obtained [214-219]. A study has been made

of the reaction of 2-formylbenzimidazoles with organomagnesium compounds [220] and their infrared spectra have been examined [221].

2-Formylbenzimidazole is formed in almost quantitative yield on oxidation of bis(2-benzimidazolyl)dihydroxyethylene with sodium periodate [214]:



or on hydrolysis of 2-dichloromethylbenzimidazole (yield 65%). [216] Oxidation of 2-hydroxymethylbenzimidazole [219,222] and 2-methylbenzimidazole with potassium persulphate or selenium dioxide gives less satisfactory results. Complications frequently arise in attempts to obtain *N*-substituted 2-formylbenzimidazoles by the above methods [219].

2-Formylnaphth[1,2-*b*]imidazole forms in 54% yield on oxidation of 2-methylnaphth[1,2-*b*]imidazole with selenium dioxide in acetic anhydride [223].

9. 2-Aminobenzimidazoles

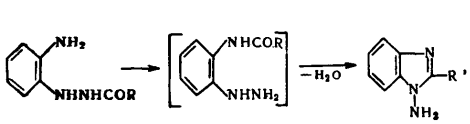
The best methods for the synthesis of 2-aminobenzimidazoles with an unsubstituted NH group is still the reaction of *o*-phenylenediamines with cyanogen bromide [224-227]. Cyanamide has also been suggested for this purpose [228]. 2-Amino-derivatives of 1-alkyl(aryl)benzimidazoles can be obtained by direct amination of *N*-substituted benzimidazoles using sodamide (see below). 2-Amino-1-*p*-nitrophenylbenzimidazole has been synthesised by fusing together guanidinium carbonate and 2-aminophenyl--4′-nitrophenylamine [229]. However, the attempts to use this method for the preparation of 2-aminobenzimidazole and 2-amino-1-phenylbenzimidazole were unsuccessful [202].

2-Guanidinobenzimidazoles form in the reaction between *o*-phenylenediamine and dicyanodiamide or its *N*-alkyl derivatives [230].

10. 1-Aminobenzimidazoles

Ried and Urlass [231] were the first to attempt the preparation of 1-aminobenzimidazoles, by the reduction of *N*-nitrosobenzimidazoles with zinc in acetic acid. However, this resulted only in the removal of the nitroso--group. Lithium aluminium hydride is also unsuitable in this case [232].

1-Aminobenzimidazoles can be obtained by heating acyl derivatives of *o*-aminophenylhydrazines with an aqueous solution of *m*-nitrobenzenesulphonic acid [233], which catalyses this reaction, or with a carboxylic acid [232]:

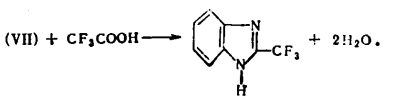


where R = H, CH_3, C_6H_5. When the Phillips procedure (4 *N* HCl) is used, this reaction yields benzo-1,2,4-triazine.

The amino-group in 1-aminobenzimidazoles is readily acylated and reacts with *p*-nitrobenzaldehyde with formation of an azomethine.

11. Fluorobenzimidazoles and Perfluoroalkylbenzimidazoles

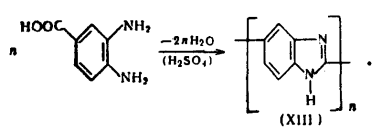
Trifluoroacetic acid and its homologues readily yield 2-perfluoroalkylbenzimidazoles on boiling with *o*-phenylenediamines [234-237]:



Benzimidazoles with a trifluoromethyl substituent in the benzene ring are usually obtained by an indirect procedure [236-241]. 2-Fluorobenzimidazole has not so far been obtained. The fluorine atom in the benzene ring of the benzimidazole molecule can be introduced by the Schiemann reaction [242] or indirectly, starting with fluorophenylenediamines [205,235-240].

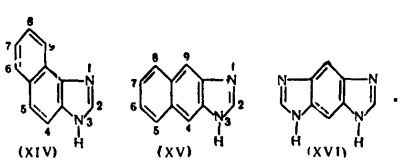
12. Polybenzimidazoles

The first polybenzimidazoles were obtained by Brinker and Robinson [243]. However, attempts, albeit unsuccessful, to obtain polybenzimidazoles of the type of compound (XIII) were made as early as 1953. [244] The synthesis of polybenzimidazole (XIII) in high yield was achieved in 1961 by Marvel and coworkers, who heated 3,4-diaminobenzoic acid in boiling concentrated sulphuric acid [245,246]. Methods for the synthesis of other polybenzimidazoles have also been developed in Marvel's laboratory [247]. All these compounds possess high thermal stability. The mechanism of the reactions resulting in the formation of polybenzimidazoles has been recently investigated by Korshak and coworkers [248]:



C. NAPHTHIMIDAZOLES

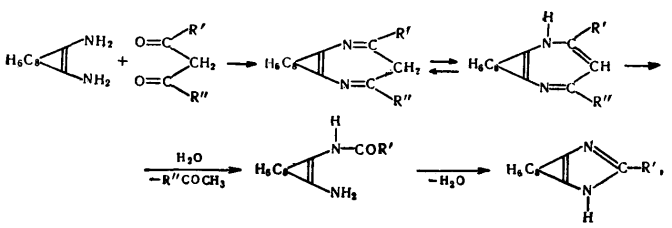
The yield of naphth[1,2-*b*]imidazole (XIV) in the condensation of formic acid with 1,2-naphthylenediamine is low [90]. However, when the sulphate of 1,2-naphthylenediamine is used, the yields of compound (XIV) reach 85% and more [90,249].



Relatively little work has been done on the chemistry of naphth[2,3-*b*]imidazole (XV) because the corresponding diamines are less readily available. The stage involving the cyclisation of the diamines with formic acid into compound (XV) and its 5,6,7,8-tetrahydro-derivative does not present any difficulties [250].

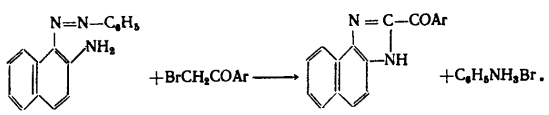
1,2- and 2,3-naphthylenediamines react with 1,3-diketones (acetylacetone, benzoylacetone, dibenzoylmethane) in acetic acid with formation of seven-membered products whose hydrochlorides are almost quantitatively converted

into the corresponding naphthimidazoles after heating with water for a short time [251,252]:



where R′ = CH_3, C_6H_5.

The reactions of acetoacetic and benzoylacetic acids with naphthylenediamines give satisfactory yields of 2-acetonyl(benzoyl)naphthimidazoles. Arylnaphthimidazolyl ketones can be obtained from phenylazo-β-naphthylamine and ω-bromo-ketones [253]:



Like *o*-phenylenediamine, *o*-naphthylenediamines readily react with phosgene, urea, and their sulphur analogues and also with cyanogen bromide, yielding 2-hydroxy(mercapto, amino)naphthimidazoles [226,254,255].

For the synthesis and properties of 1,2,4,5-diimidazobenzene (XVI), see Refs. 256 and 257.

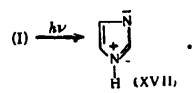
III. PHYSICAL PROPERTIES AND STRUCTURE

A. PHYSICAL PROPERTIES

Both experiment [258-264] and calculation [265-267] show that the dipole moment of imidazole and its derivatives (without polar substituents) is of the order of 3.8–4.0 D. The anomalously high dipole moments of imidazole (6.2 D) and 4-methylimidazole (6.3 D) found by Hückel and Jahneutz [268] are probably due to the fact that the measurements were made in too concentrated solutions where it was impossible to avoid the effect of association.

Substituents of low polarity have little effect on the dipole moments of imidazole derivatives [263]. The nitro-group increases the dipole moment by 2–2.5 D. [263] The replacement of the hydrogen in the NH group by an alkyl has almost no effect on the dipole moment [261,262]. However, *N*-arylation lowers appreciably the dipole moment, due to π-conjugation of the imidazole and aryl rings [264].

Imidazole almost does not absorb in the near ultraviolet, which indicates its high aromatic stability. The absorption in the region 207–208 mμm is due, according to Italian workers [167], to the conversion of symmetric species with a covalent structure into asymmetric and polar species [for example, (XVII)].



(XVII)

The introduction of alkyl groups into any position in the imidazole ring causes a small bathochromic shift of this absorption band [167,269-274] while in *N*- and *C*-arylimidazoles new very intense bands appear in the region 250–300 mμm, characterising the conjugation of the two aromatic rings (Table 1). Bands of this type are also present in the spectra of 2-arylbenzimidazoles [133,167,273-276].

The absorption spectrum of benzimidazole is much more complex. The short-wavelength absorption band (244–248 mμm) is attributed to electron transitions localised in the imidazole ring while the long-wavelength absorption is regarded as a displaced *B*-band of benzene (λ_{max} = 255 mμm). [167,270,277] In the spectrum of benzimidazole, as in those of other benzazoles, there is no absorption band corresponding to the interaction between the condensed benzene and heterocyclic rings. The reason for this phenomenon is still obscure.

The ultraviolet spectra of benzimidazoles have proved useful in the solution of problems associated with the elucidation of the structure of vitamin B_{12}. [278,279] The ultraviolet spectra of 2-imidazolones [212], benzimidazolones [213], 2-aminobenzimidazoles [202,280], and many other derivatives [208,281-284] have also been investigated.

The absorption spectra of naphthimidazoles are still more complex and have not been investigated in detail. There is a marked bathochromic shift in the series imidazole–benzimidazole–angular naphthimidazole–linear naphthimidazole.

The infrared spectra of imidazole [285,286] and its derivatives [283,284,287,288] are characterised by a series of intense absorption bands in the regions 760–880 cm^{-1} (imidazole ring), 1500–1620 cm^{-1} (aromatic C–C and C–N bonds), and 2200–3600 cm^{-1} (NH bond involved in association). The greatest interest attaches to the intense absorption in the region 2200–3600 cm^{-1}, which is attributed to the formation of intermolecular hydrogen bonds of the type $\gtrless N\ldots H-N$ [283,284,288-291] or the formation of the immonium structure $\gtrless N^+-H$. [285] A similar absorption is observed in the infrared spectra of benzimidazole and its 2-substituted derivatives [292], 4,5-diphenylimidazole [293], solutions of the *N*-anilides of imidazolecarboxylic acids [294,295], imidazolones [212], and imidazolethiones [212,296]. When the hydrogen atom of the NH group is replaced by a metal [285], deuterium [286], an acyl group [297], or an aryl group [293] the above absorption disappears, as would be expected.

TABLE 1. Ultraviolet absorption spectra of certain imidazoles.

Compound	λ_{max} and (log ε)	Refs.

* Inflection.

The Raman [260,285,286,298] and fluorescence [212,299] spectra of imidazole and benzimidazole derivatives have also been investigated.

The nuclear magnetic resonance spectrum of imidazole contains two lines associated with the proton in position 2 and the two protons in positions 4 and 5. [300-305] The proton of the NH group gives rise to a distinct signal only in concentrated benzene and acetone solutions of imidazole and 4(5)-methylimidazole [304].

Imidazoles are amphoteric compounds and therefore the knowledge of the basicity and acidity (for derivatives with an unsubstituted NH group) constitutes some of the most reliable evidence in the elucidation of various structural problems [283,284,290,306-314]. In the series imidazole (pK_a = 7.03)–benzimidazole (pK_a = 5.53)–angular and linear naphthimidazoles (pK_a = 5.28 and 5.24 respectively) there is a decrease in the basicity of the pyridine-type nitrogen hetero-atom. On the other hand, the acidity of the NH group increases in this series (pK_a = = 14.5, 13.2, 12.54, and 12.52 respectively) [255].

The thermodynamic properties of imidazole have been investigated only recently [315]. The enthalpy of formation of imidazole (in the crystalline state) is 14.6 ± 0.8 kcal × × mole^{-1}, its heat of sublimation is 16.0 ± 1 kcal mole^{-1}, and the heat of formation of gaseous imidazole is 30.6 ± ± 1.8 kcal mole^{-1}. These data made it possible to calculate the resonance energy of imidazole as 14.2 kcal × × mole^{-1}. [315,316]

Crystallographic [317], X-ray diffraction [318,319], and semiconductor [320] properties of imidazoles, and their ionophoresis [321] and paper chromatography [322] have been investigated; determinations have been made of the association energy [260,289], the dielectric relaxation time [323], and the ionisation potential [324]; calculations have been made of the dissociation constant in an aqueous medium [289] and of the formal charge on the C and N atoms, using Wheland's equation [308].

B. QUANTUM-MECHANICAL CALCULATIONS ON THE IMIDAZOLE MOLECULE

The values given for the π-electron density at various positions in the imidazole molecule (Table 2) are extremely contradictory, which reflects the gradual development of the computational technique by the MO LCAO method. Brown's early calculations [325,326], within the framework of the molecular orbital method, failed to take into account the difference between the two nitrogen atoms in imidazoles and show that in the neutral molecule the electron density in positions 4 and 5 is higher than in position 2, while in the imidazole anion the opposite situation obtains. Brown's latest data, based on the self-consistent field (VESCF) method, which do take into account the difference between the N_1 and N_3 atoms, show qualitatively the same picture [267]. It should be noted that the localisation energies in the imidazole molecule predict a different course of C-electrophilic substitution reactions, which is sometimes found to occur (see below).

TABLE 2. π-Electron density in imidazole.

Neutral molecule					Anion			Cation			Refs.
N_1	C_2	N_3	C_4	C_5	$N_{1(3)}$	C_2	$C_{4(5)}$	$N_{1(3)}$	C_2	$C_{4(5)}$

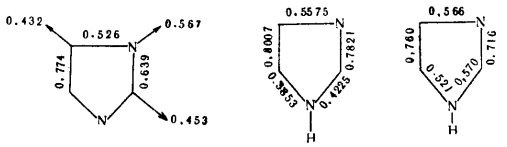
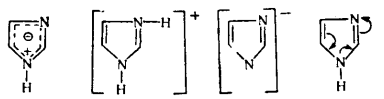
The molecular orbital method has also been used to calculate the reactivity of the benzimidazole molecule [327,328].

Bond orders and free valences in imidazole [266,326,327]:



C. STRUCTURE AND ASSOCIATION

The case of tautomeric transformations, bond equivalence, aromaticity, and the high dipole moment of imidazole are inconsistent with the classical structure (I). For this reason the structural formulae (XVIII)–(XX) have also been proposed for imidazole:



(XVIII) (XIX) (XX)

On the basis of their measurements of the dipole moments (4.8–6.2 D), Hückel and coworkers [268,329] attributed to the imidazole ring the structure of a dipolar ion (XVIII) in which the positive charge is centred on the immonium nitrogen and the negative charge in the centre of the five--membred ring. The calculated dipole moment for this structure (5.5 D) agrees satisfactorily with Hückel's data but is inconsistent with numerous subsequent determinations [258,260-267].

On the basis of data obtained from the potentiometric titration of benzimidazole derivatives, Efros and Porai-Koshits [313] suggested the possibility of the formation of ionic saltlike compounds (XIX) in aqueous solutions. Otting [285] arrived at a similar treatment of the imidazole structure in solid and non-polar media. However, Zimmerman obtained evidence from X-ray diffraction analysis [318], ultraviolet and infrared spectra [271,289,291], acid–base equilibria [289], measurements of the energy of association and mesomerism [289,316], and dipole moments [260] that the saltlike structure (XIX) cannot form.

Analysis of the dipole moments [261-263] shows that the imidazole ring is polarised in the direction of the C–N bond but this polarisation falls far short of that required for the formation of the dipolar structure let alone the ionic structure. The properties of the imidazole ring are most satisfactorily represented by the mesomeric structure (XX). [261,262]

The problem of the causes of the association of compounds containing the imidazole ring with an unsubstituted NH group, is immediately related to the considerations set out above. The investigators who have adopted structures (I), (XVIII), and (XX) for the imidazole ring explain association by the formation of intermolecular hydrogen bonds [259,263,288,290-293,304,305,318,320,325,330]. Nevertheless, Otting [285] attributes the association of imidazole to the formation of an ionic bond in the saltlike structures (XIX).

In Otting's opinion this view is confirmed by the unusual displacement of the NH band to the region 2500–3200 cm^{-1} in the infrared spectrum of imidazole. However, infrared spectroscopic data cannot be regarded as a convincing demonstration that the association of imidazole is of an ionic type, because similar bands (2500–3200 cm^{-1}) are also present in the infrared spectra of compounds which form hydrogen bonds of the type E... HE. [288,331] Furthermore, dilute benzene and acetone solutions of imidazole and 4(5)-methylimidazole do not give rise to a band in the region of 2500–3200 cm^{-1} despite the fact that in such solutions the compounds are present as dimers [292]. At high imidazole concentrations in non-aqueous media the coefficient of association reaches 5–20, [8,290,332] and not 2 as would be expected from Otting's postulate [285],

Finally, other evidence in favour of intermolecular hydrogen bonds as the principal cause of the association of imidazole is the association energy (5 kcal $mole^{-1}$), [289] the distance between the nitrogen atoms in neighbouring molecules (3 Å), [318] and the dependence of the dielectric constant on the concentration of the solutions [262] (the coefficient α varies in the same sense as the concentration [333]).

D. TAUTOMERISM

The isomers of imidazoles with an unsubstituted NH group (the difference between which consists in substituents being present in positions 4 or 5 [8,57,334,335]) cannot be isolated, although they enter into chemical reactions predominantly in one of the tautomeric forms [336–339]. This is due to continuous migration of the proton of the NH group between the two nitrogen atoms of the imidazole ring and also the equivalence of the cations and anions of both isomers. However, there does exist one claim that the above isomers have been separated in the case of sparingly soluble imidazole derivatives [335].

IV. CHEMICAL PROPERTIES

In this section there is no subsection headed "Radical substitution", since homolytic reactions in the imidazole series have been virtually uninvestigated (it is possible that free radicals participate in the formation of 2-mercaptoimidazoles when imidazoles are heated with sulphur [340]). Nor is the extensive class of imidazole metal complexes discussed, a separate review being desirable for these compounds.

In conformity with the guiding principle of this review, in examining the chemistry of arylimidazoles the authors have dealt only with the chemical properties of the imidazole part of the molecule.

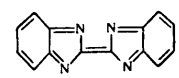
A. AROMATICITY OF THE IMIDAZOLE RING: REDUCTION, OXIDATION, DIENE SYNTHESIS

The imidazole ring is distinguished by high stability with respect to reduction. In the catalytic reduction [22,24,341] of a wide variety of arylimidazoles and furylimidazoles only the aryl or furyl rings reduced and not the imidazole rings, as was believed earlier [342]. The reduction of benzimidazole and its *N*-alkyl derivatives over platinum oxide leads to 4,5,6,7-tetrahydrobenzimidazoles [343]. Naphth[1,2-*b*]imidazole is hydrogenated on the same catalyst to 6,7,8,9-tetrahydronaphth[1,2-*b*]imidazole, while phenanthr[9,10-*b*]imidazole is reduced to an octahydro-derivative [343].

However, 2-methyl-4,5-diphenylimidazole may be reduced over a palladium catalyst to 2-methyl-4,5-diphenylimidazolidine [18]. In the reduction of benzimidazole with lithium aluminium hydride, Bohlmann obtained a substance to which he attributed on inadequate grounds the structure of 2,3-dihydrobenzimidazole [344]. Bayer showed that imidazole and benzimidazole are hydrogenated in acetic acid over platinum oxide *NN'*-diacetylimidazolidine and *NN'*-diacetylbenzimidazoline [345]. The corresponding derivatives of 2,3-dihydroimidazole are formed on addition of the dimethyl ester of acetylenedicarboxylic acid to 1,2-dialkylimidazoles in a reaction of the Diels–Alder type [346,347] (*cf.* Refs. 348 and 349).

The imidazole ring is more stable than benzene and naphthalene rings in oxidation reactions, as shown by the oxidation of benzimidazole with potassium permanganate, potassium dichromate [31–34], or hydrogen peroxide [350] to imidazole-4,5-dicarboxylic acid. In the oxidation of naphth[1,2-*b*]imidazole the product is 4-(*o*-carboxyphenyl)-5-carboxyimidazole and not imidazole-4,5-dicarboxylic acid [10]; napth[2,3-*b*]imidazole is oxidised to imidazo-4,9-naphthoquinone [249].

The oxidation of benzimidazole with lead peroxide [351] is quite unusual, leading to the formation of $\Delta^{2,2'}$-diisobenzimidazolidene (XXI). The same substance was also obtained in the oxidation of 2,2'-dibenzimidazolyl with PbO_2: [351]



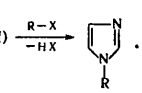
(XXI)

Selenium dioxide in dioxan oxidises 2-methylbenzimidazole to *o*-hydroxyacetanilide [352].

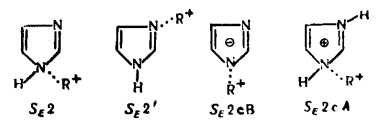
B. ELECTROPHILIC SUBSTITUTION

1. *N*-Substitution

In this section we shall consider the methods of direct introduction of substituents into position 1 of the imidazole ring (indirect methods have been examined above). Disregarding the mechanism of the process, the reaction may be represented in a general form as a simple substitution of the hydrogen atom of the NH group by a radical R:

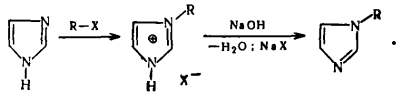


a. Alkylation of imidazoles. Reaction mechanisms. *N*-Substitution in the imidazole ring is by no means as simple as is suggested in a number of reviews [8–10]. It must be borne in mind that, depending on the conditions, imidazole can enter into alkylation reactions in several forms (sometimes several forms at the same time) — as a base (S_E2 and S_E2' mechamisms), anion (S_E2 cB mechanism), or as the conjugate acid (S_E2 cA mechanism):

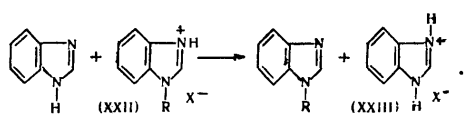


S_E2 S_E2' S_E2cB S_E2cA

The classical method for the preparation of *N*-alkylimidazoles consists in the reaction between the heterocyclic compound and an alkyl iodide (bromide, or, less frequently, chloride) in a sealed tube at 100–150° (Wallach, Wyss, Fischer, Pyman)[8–10]. Under these conditions the reaction involves preferentially the pyridine-type nitrogen atom (S_E2' mechanism)[337,353]:



If the process stopped at the stage in which the hydrochloride of the *N*-substituted derivative is formed, this method could yield the theoretical amount of 1-alkylimidazole (after treating the salt with alkali). However, in fact the yield of the *N*-substituted derivative when imidazole is alkylated in a neutral medium reaches 50% at most. Using benzimidazole as an example, it has been shown that the initial base which fails to enter into the main reaction then reacts with the hydrochloride of benzimidazole[353] and the resulting 1-alkylbenzimidazole is further alkylated with the alkyl halide to a 1,3-dialkylbenzimidazolium salt. Thus these side-reactions lead to an irreversible conversion [the conjugate acids (XXII) and (XXIII) cannot undergo further alkylation[337,353]] of about 50% of the starting compound into benzimidazolium (XXIII) and 1,3-dialkylbenzimidazolium salts. The use of two moles of imidazole (to bind the HX) per mole of the alkylating agent cannot be regarded as a successful solution of this problem:

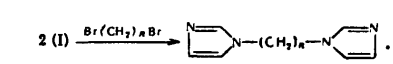


The most satisfactory results are obtained when imidazoles are alkylated in the presence of alkaline agents. Apart from alkali metal hydroxides, sodium alkoxides[354,357], sodium acetate[358], sodium carbonate[359], sodamide[360–363], sodium hydride[348], etc. have been used. The reaction is carried out in alcohol, less often in hydrocarbons[354,362], water[359], dioxan[360,363,364], acetone[366], and liquid ammonia[361,365].

The enhanced nucleophilic character of the nitrogen atoms in the imidazole anion makes it possible to achieve the alkylation at a lower temperature and thereby avoid the formation of a large amount of quaternary salts. In the case of benzimidazole it is permissible to vary the initial amounts of alkyl halide and alkali in order to improve the yield[366]. The maximum yield of 1-alkylbenzimidazole (76–83% for primary and 50–60% for secondary alkyl and aralkyl bromides) can be achieved by using two moles of alkyl bromide and 1.5 moles of alkali per mole of benzimidazole.

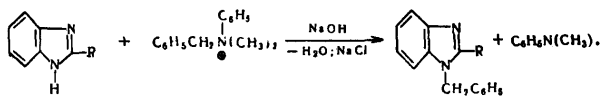
The ease of formation of quaternary salts constitutes a serious obstacle in the alkylation of imidazole itself, since the latter is much more basic than benzimidazole. Here it is almost impossible to use an appreciable excess of the alkylating agent and temperatures higher than 20–40°.[355,361,367] Best results are obtained when imidazole is alkylated in liquid ammonia in the presence of sodamide[361].

Bis(1-imidazolyl)alkanes are formed in the reaction of benzimidazole[368] and imidazole[369] with dibromoalkanes:



In the presence of alkaline agents the imidazole ring is readily alkylated with ethylene chlorohydrin[370,371], chloroacetic acid or its ethyl ester[132,372,373], and dialkylaminoalkyl chlorides[363,374–376].

It is extremely convenient to introduce primary aralkyl radicals (benzyl, α-naphthylmethyl, etc.) into the NH group of benzimidazole by allowing the latter to react with dimethylphenylaralkylammonium chlorides[219,353,377,378]. The reaction proceeds rapidly and almost with a quantitative yield in an aqueous solution of sodium hydroxide:



In the imidazole series this reaction has not been investigated.

The use of the silver salts of imidazoles or *N*-chloromercuri-imidazoles is the only method available for the introduction into position 1 of the imidazole ring of substituents such as triphenylmethyl[379,380] or glycosyl[381–389]. The alkylation of 2-arylbenzimidazoles in an alkaline medium proceeds with considerable difficulty because of steric hindrance[133,353]. In this case it is also desirable to use the corresponding silver salts.

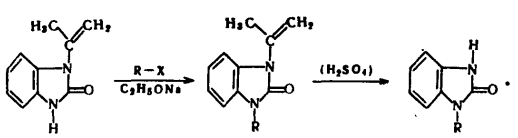
As a result of the formation of two isomers, the alkylation of asymmetric imidazole and benzimidazole derivatives proceeds in a very complex manner. This problem has been recently thoroughly reexamined on the basis of information derived from kinetics and spectroscopy[337,338]. The data obtained are however inconsistent not only with the old results but also with the results of many new studies[358,390–392] and therefore final conclusions would probably be premature. Also contradictory are the results obtained on the alkylation of the asymmetric napth[1,2-*b*]-imidazole[8,10,90,393]. There is a review of work done on the alkylation of asymmetric imidazoles[353].

Benzimidazoles[394,395], benzimidazolones[396], and benzimidazolethiones[397] react with formaldehyde and secondary amines (Mannich reaction), forming *N*-aminomethyl derivatives.

The reaction of benzimidazole derivatives with ethylene oxide, yielding *N*-β-hydroxyethylbenzimidazoles, has been investigated in detail[398–400].

Imidazole, benzimidazole, and their substituted derivatives are alkylated at the NH group by a wide variety of unsaturated compounds: acetylene[401,402], acrylonitrile[313,392,403] and other derivatives of acrylic acid[404,405], and vinyl acetate[406]. The methylation of imidazole with diazomethane proceeds smoothly[393,407,408].

The reaction of *o*-phenylenediamine with acetoacetic ester in a neutral medium gives 1-isopropenylbenzimidazol-2-one, from which *N*-monoalkyl derivatives of benzimidazolone can be obtained[356,357]:

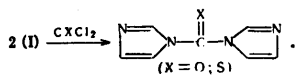


2-Mercapto-derivatives of imidazole [36,409-413] and benzimidazole [204,414,415] are alkylated with alkyl halides [36,409,410,204,414,415], α-halogeno-ketones [411,412], α-halogeno--aldehydes [412], and α-halogeno-acids [35,413]: the reaction involves initially the SH group, this being followed by *N*-alkylation.

In alkaline [225] and neutral [416,417] media 2-aminobenzimidazoles are alkylated at the ring nitrogen.

b. *N*-Arylation of imidazoles. Until recently the only example of direct *N*-arylation of the imidazole ring was the ready synthesis of *N*-dinitrophenyl- and picryl--imidazole derivatives, starting with 2,4-dinitrohalogenobenzenes and picryl chloride [293,418-420]. Not long ago a method was developed for the direct arylation of imidazole and benzimidazole with aryl halides, without substituents activating the halogen atom in the arylating agent [421,422]. The reaction is carried out in nitrobenzene in the presence of potassium carbonate and cuprous bromide (catalyst). The yield of *N*-aryl derivatives reaches 73%. The replacement of nitrobenzene by other solvents (tetralin, diethylaniline, excess of aryl bromide) gives worse results.

c. Acylation of imidazoles. Studies made in the 1950's established that *N*-acylimidazoles and their reactions are of fundamental importance in enzymic transacylation [6,7]. Staab synthesised unusually reactive acylimidazoles which served as models for the most important biochemical reactions (see Staab's review [423]):



Imidazolides of this type have found application in the synthesis of aldehydes, amidines, esters, acid anhydrides, and in peptide synthesis [424,427], the last application being particularly important.

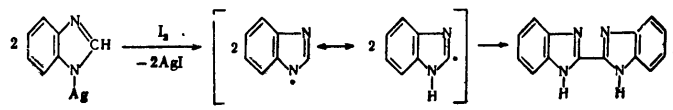
N-Formylimidazoles [428] and *N*-benzyloxycarbonylimidazoles [429] can be used as formylating and benzyloxycarbonylating agents.

The reaction of imidazole with potassium thiocyanate in a neutral medium yields *N*-carbamoylimidazole [430], while aryl cyanates react with imidazoles in a more complex manner, involving not only the N but also the C_2 atom [431].

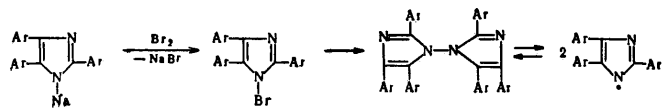
The chlorides of aromatic sulphonic acids readily acylate imidazole and benzimidazole at the NH group in the presence of weakly basic agents (potassium carbonate, sodium acetate) [432-434].

2-Mercapto- and 2-hydroxy-derivatives of imidazole and benzimidazole are acylated with acid anhydrides and chlorides at the N atoms [435-437]. 2-Aminobenzimidazoles are acylated at the exocyclic amino-group [416]. In the reaction of acetic anhydride with the *N*-oxide of benzimidazole the product is 1,3-diacetylbenzimidazolone [437] and not 1-acetyl-2-acetoxybenzimidazole [438].

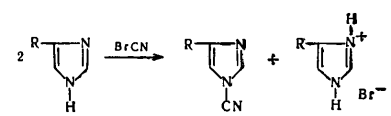
d. Halogenation and cyanation. It has been established that the product obtained [8,9] by the action of iodine on an alkaline solution of benzimidazole is *N*-iodobenzimidazole and not the 2-iodo-derivative [439,440]. It might have been supposed that on reaction with iodine the silver salt of benzimidazole would also yield *N*-iodobenzimidazole and then the hitherto unknown *NN'*-dibenzimidazolyl. Actually the reaction is more complicated, apparently involving the 2-benzimidazolyl radical, and leading to the formation of 2,2'-dibenzimidazolyl [351]:



Imidazole reacts with halogens, yielding *C*-substituted derivatives, but it has been demonstrated convincingly [441] that here too the intermediates are *N*-halogenoimidazoles (*trans*-halogenation). For example, the reaction between the sodium salts of 2,4,5-triarylimidazoles and bromine in absolute ether gives *NN'*-diimidazolyls, since the intermediate *N*-bromoimidazoles formed in this reaction cannot undergo a rearrangement to the *C*-bromo-derivatives [441]. The N–N bond in diimidazolyls readily undergoes homolytic splitting with formation of two *N*-imidazolyl radicals [441,442]:

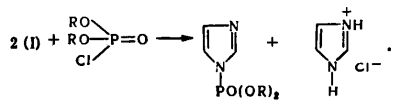


Cyanogen bromide is known [8] to react with *N*-substituted imidazoles with formation of 2-bromoimidazoles. Imidazoles with a free NH group undergo *N*-cyanation [443]:

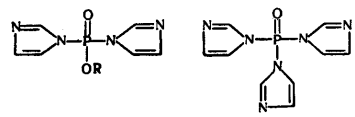


where R = H, CH_3. Cyanogen bromide introduces the CN group into 2-mercaptoimidazole at the SH group [444].

e. Phosphorylation. *N*-phosphorylimidazoles play an important role in enzymic transphosphorylation [6]. They form in the reaction of two moles of imidazole or benzimidazole with one mole of a dialkyl(diaryl)phosphoric acid chloride [445,446].



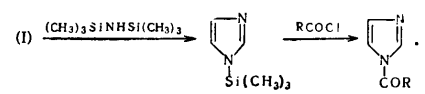
Di- and tri-imidazolides of phosphoric acid can be obtained similarly from phosphoric acid dichloride or from phosphorus oxychloride [447,448]:



The reaction between *NN'*-carbonyldiimidazole and phosphoric acid esters also yields *N*-phosphoroimidazoles [449]. *N*-phosphoroimidazole is extremely unstable and rapidly undergoes autocatalytic hydrolysis. Its derivatives, in which the phosphoryl residue is combined with an organic radical, are more stable. These compounds readily phosphorylate amines, alcohols, and the carboxy--group at room temperature [450].

f. Silylation. Imidazole, benzimidazole, and other heterocyclic compounds with a nitrogen atom of the pyrrole

type react with hexamethyldisilazane with formation of *N*-trimethylsilyl derivatives[451], which exhibit remarkably high reactivity. They are acylated with the chlorides of organic and mineral acids with almost quantitative yields even at 0°:



g. Nitrosation. When an acetic acid solution of benzimidazole and its 2-substituted derivatives is treated with aqueous sodium nitrite, *N*-nitrosobenzimidazoles, giving a positive response to the Lieberman test, are formed[173,231].

2. *C*-Substitution

Electrophilic substitution (azo-coupling, nitration, halogenation, etc.) of the carbon atoms in the imidazole ring is characteristic only of imidazole itself and those condensed systems in which the imidazole ring is linked to a non-aromatic ring: tetrahydrobenzimidazole, phenanthr[9,10-*b*]imidazole, etc.[90] For compounds such as benzimidazole or naphthimidazoles, nucleophilic substitution reactions at the 2-carbon atom of the imidazole ring (see below) are typical, as a result of the electrophilic effect of the aromatic ring condensed with the imidazole ring.

One of the classical problems of imidazole chemistry is associated with electrophilic substitution. Only in recent years has it become more or less clear why in some cases (nitration, sulphonation, etc.) electrophilic substitution takes place at positions 4 and 5 of the imidazole ring while in others (coupling with diazonium salts) position 2 is involved. As late as 1950 Schofield suggested that the imidazolium cation is involved in nitration and sulphonation while the neutral molecule is involved in the coupling reaction[452] (the latter hypothesis subsequently proved to be erroneous). Kinetic studies of iodination[453] and diazo-coupling[454] of imidazole and molecular-orbital calculations[325,326] made a decisive contribution towards the solution of this problem. It was found that the mechanisms of the halogenation and coupling reactions involve the formation of the conjugate base of imidazole (iodination proceeds via the imidazole anion B^- even at pH 7). This is confirmed by the fact that 1-methylimidazole does not undergo the coupling reaction. Furthermore, deuteration of imidazole in a neutral medium with D_2O leads to 4(5)-substitution, while in NaOD solution the C_2 atom is deuterated preferentially[300].

The data on the halogenation of imidazole are contradictory. Earlier it was found that bromination proceeds preferentially in position 4(5), while iodination leads to a 2-substituted derivative. However Ridd[454] reported that, even in the presence of a 20-fold excess of imidazole, the main iodination product is the di-iodo-derivative (see also Refs. 455 and 456). Study of the iodination of deuteroimidazoles (the kinetic isotope effect method) showed that the iodination proceeds, like bromination, in position 4(5).[457] This finding lent support to Brunings'[458] hypothesis of primary *N*-iodination of imidazole with subsequent rearrangement of the *N*-iodoimidazole to the *C*-iodo-derivative. The kinetic equation for the iodination of imidazole includes, in addition to the term corresponding to the reaction of the imidazole anion with the I^+ or H_2OI^+ cations, a second term which depends on the concentration of imidazole and indicates that the reaction may be catalysed by imidazole itself:

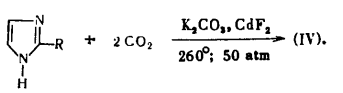
$$V = k[B^-][H_2OI^+] + k'[B^-][BHI^+].$$

This finding can be understood as a special case of a *trans*-reaction with participation of the imidazole ring. Recently yet another report of the conversion of *N*-bromoimidazoles into *C*-bromo-derivatives has appeared[441]. We may also recall that in an alkaline medium benzimidazole is iodinated at the N atom[439,440].

How then can we explain why two reactions, iodination and coupling, apparently equivalent as regards mechanism and involving the same intermediate (imidazole anion), result in attack at different positions? As stated above, molecular-orbital calculations on the conjugate base of imidazole lead to two different conclusions: the charge densities suggest that electrophilic substitution should occur in position 2, while according to the values of the localisation energies, electrophilic agents should attack the imidazole rings in positions 4 and 5. It is believed that in the above two reactions iodination follows the values of localisation energies, i.e. depends on the transition state of the reaction, in which the removal of the proton determines the rate of the process as a whole. The overall kinetics of imidazole iodination are very complex and the reason for the instantaneous iodination of the monoiodo-compound to give the di-iodo-derivative still remains obscure. Certain phenylimidazoles substituted in position 2 can couple with diazonium salts also in position 4(5).[464]

In the presence of sodium ethoxide, pentyl nitrite nitrosates phenylimidazoles with an unsubstituted NH group in position 4(5). If positions 4 and 5 are occupied, nitrosation in position 2 does not occur. The properties of the resulting 4(5)-nitrosoimidazoles have been investigated in detail[459-465].

The synthesis of imidazole-4,5-dicarboxylic acids by the reaction of carbon dioxide with imidazole and its 2-alkyl derivatives constitutes a new electrophilic substitution reaction in the imidazole series[466]:



Sulphur tetrafluoride converts both carboxy-groups of the acid into trifluoromethyl groups[467].

It has been known for a long time that formaldehyde or paraformaldehyde hydroxymethylate *N*-substituted imidazoles in position 2. Unexpectedly this reaction was achieved also with *N*-vinylbenzimidazole[468]. It would be desirable to verify this unique electrophilic *C*-substitution reaction in the imidazole ring of benzimidazole.

N-substituted imidazoles undergo thermal condensation with aliphatic (except for acetaldehyde) and aromatic aldehydes with formation of imidazol-2-yl carbinols[361], which can also be obtained by the action of the aldehydes on 2-lithioimidazoles[361,469].

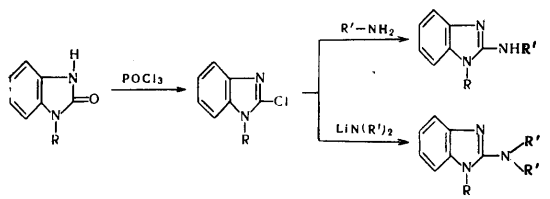
C. NUCLEOPHILIC SUBSTITUTION

In monographs and reviews on the chemistry of imidazole[8-15] little attention has been given to nucleophilic

substitution, because reactions of this type in the imidazole series began to be investigated systematically only in recent years.

1. Substitution of Groups in Position 2 of the Imidazole Ring

The first example of nucleophilic reactions in the imidazole series is the synthesis of 2-chlorobenzimidazole from benzimidazolone and phosphorus oxychloride[470]. Later this reaction was studied in detail[440] and extended to 4,5-diphenylimidazolone[471], benzimidazolone derivatives[201,202,393,471-478], naphthimidazolone[479], and tetrahydronaphthimidazolone[480]. The chlorine atom in position 2 of the imidazole ring can be relatively readily exchanged for amino-, alkylamino-, arylamino-, and hydrazino-groups[255,393,440,472,475,477,480,484]:

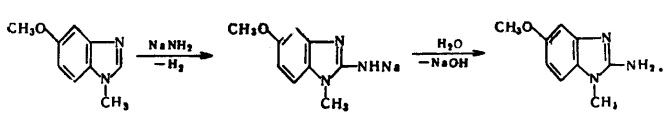


where R′ = alkyl, aryl, NH_2. Chlorine is exchanged even more readily in quaternary benzimidazolium salts[485].

It should be noted that all these reactions have been mainly investigated for condensed systems containing the imidazole ring, but not for imidazole itself. Other groups in position 2 of the imidazole ring also exhibit considerable mobility. Thus the methylthio-group can be exchanged for amino-, benzylamino-[255], and hydrazine-groups[481]. The sulpho-group is readily replaced by chloro-[485], hydroxy-, alkylamino-, and cyano-groups[9]. The ready hydrolysis of sulphones of the benzimidazole series probably belongs to the same class of reactions[486,487].

2. The Action of Sodamide on Imidazole Derivatives (Chichibabin Reaction)

By allowing sodamide to react with 5-methoxy-1-methylbenzimidazole in xylene, Simonov and Uglov obtained the corresponding 2-amino-derivative in good yield[488]:



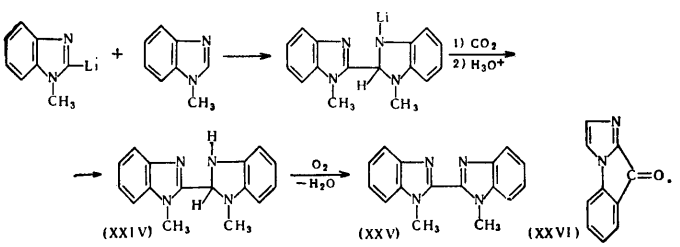
Later this reaction was extended to other *N*-alkyl, aralkyl, and aryl derivatives of benzimidazole[90,202,368,375,377,378,433], naphth[1,2-*b*]imidazole, and tetrahydronaphth[1,2-*b*]imidazole[489]. Heterocyclic compounds with an unsubstituted NH group are not aminated by sodamide, since the anion formed initially, clearly cannot be subject to nucleophilic attack[433,488].

Apart from the formation of the 2-amino-derivative, in the amination of *N*-arylbenzimidazoles the imidazole ring opens as a result of the p,π-conjugation of the *N*-aryl and imidazole rings with consequent loss of aromaticity by the latter[202,264].

Amination of *N*-alkylbenzimidazoles substituted in the benzene ring showed that this reaction is significantly influenced by the nature of the substituent in position 5 of the benzene ring. Whereas 5-alkyl- and 5-alkoxy-1-alkylbenzimidazoles form 2-amino-derivatives, 5-hydroxy-, 5-halogeno-, 5-nitro-, and 5-carboxy-derivatives do not enter into this reaction[490,491]. Attempts to extend the Chichibabin reaction to *N*-alkyl derivatives of 4,5-diphenylimidazole, 4,5,6,7-tetrahydrobenzimidazole, and phenanthr[9,10-*b*]imidazole were unsuccessful[492]. Thus amination of the imidazole ring at the 2-carbon atom occurs only when the former is condensed with an aromatic ring (in 4,5-diphenylimidazole the phenyl rings are not coplanar with the imidazole ring while in phenanthrimidazole the aromaticity of the middle benzene ring of phenanthrene cannot be compared with the aromaticity of the benzene ring in benzimidazole — a well known fact). From this point of view, the derivatives of imidazole itself should not enter into the Chichibabin reaction either.

3. Metalation Reactions

N-alkylimidazoles[361,469] and *N*-alkylbenzimidazoles[365] undergo metalation under the action of butyl-lithium at low temperatures with formation of 2-lithio-derivatives. In the metalation of 1-methylimidazole a small amount of the 5-substituted derivative also forms[469]. The reaction of butyl-lithium with 1-methylbenzimidazole at room temperature yields the corresponding 2,2′-dibenzimidazolyl (XXIV) and its dihydro-derivative (XXV), which can be explained by the following mechanism[365]:

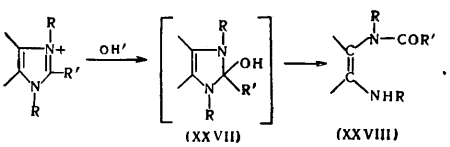


1-Alkylbenzimidazoles are also readily metalated in position 2 by phenyl-lithium[122] and phenylsodium[493].

The reaction of 1-phenylimidazole with an excess of butyl-lithium followed by reaction with carbon dioxide leads to the formation of 4-oxoimidazo[1,2-*a*]indoline (XXVI), which also constitutes evidence that the imidazole ring is metalated at the 2-carbon atom[469]. *N*-arylbenzimidazoles are not metalated by butyl-lithium at low temperature but at room temperature butyl-lithium adds to the C–N bond[122], a reaction which was observed earlier also for *N*-methyl-2-t-butylbenzimidazole[494].

4. Imidazolium Salts and Their Reactions

1,3-Dialkylimidazolium salts are known to be converted under the action of bases into the so-called "pseudo-bases". This reaction is a consequence of the nucleophilic attack by the hydroxide ion on the C_2 atom of the imidazole ring[418,419,495]:



Pseudo-bases have been regarded for a long time as cyclic carbinols (XXVII) and it was not until a study had been made of their infrared spectra and their acylation reaction that their non-cyclic structure (XXVIII) was established [293,418,419,496]. The existence of a ring–chain tautomerism between the cyclic and non-cyclic forms has been suggested [495].

The benz- and naphth-[1,2-*b*]imidazolium salts, containing the 2,4-dinitrophenyl substituent at the N atom are converted irreversibly into derivatives of 2-amino-2′,4′-dinitrodiarylamine even under the action of bases as weak as aniline and pyridine [418,419] (*cf.* Ref. 497). The conversion of 4,5-diphenylimidazolium and 4,5,6,7-tetrahydrobenzimidazolium salts occurs similarly although under somewhat more severe conditions (ammonia, sodium carbonate) [498,499].

ADDED IN PROOF

After this review had been sent for editing, the following papers were published:

On Physical Properties

Spectra: infrared [500,501], nuclear magnetic resonance [502], ultraviolet [503].
Phototropic transformations and chemiluminescence [504–507].

On 1-Substituted Imidazoles

Methylation of 2-perfluoroalkylimidazoles with diazomethane [508].
Preparation of 1-vinylimidazoles [509].
New synthesis of glucopyranosides of benzimidazole [510].
Acylation of benzimidazoles [511].
Acylation of the OH group of serine with *N*-acetyl derivatives of histidine [512].
New stereospecific synthesis of olefins from 1,2-diols and *NN*′-dithiocarbonylimidazole [513].
Imidazolide method for the preparation of diacetyl peroxides and per-acid esters [514].
N-Carbamoylimidazoles [515].
N-hydroxyimidazoles [516] and benzimidazoles [517–520].

On 2-Substituted Imidazoles

Syntheses of 2-nitroimidazole (azomycin) [521], 2-aminoimidazole [522], 2-arylaminoimidazole [523], 2-arylaminobenzimidazole [524], 2-piperidino-2-dimethylaminobenzimidazole [525].
Reaction of 2-aminobenzimidazoles with halogeno-esters [526].
Synthesis and reactions of 1-phenyl-2-hydrazinobenzimidazole [527].
Benzimidazol-2-ones [528] and dihydrobenzimidazoles [529,530].
Benzenesulphonyl- and methanesulphonyl-benzimidazolones [531].
Nucleophilic substitution of chlorine in 2-chlorobenzimidazoles: preparation of 2-hydroxy- and 2-mercapto-benzimidazoles [532,533].

1. INTRODUCTION

Nucleic acids play an important part in the processes of the biosynthesis of protein, growth, reproduction, and heredity of living organisms. However, even now very little is known about the actual mechanism of their participation in these processes; this explains the considerable interest of investigators in the various types of reaction of nucleic acids.

In recent years it has been found that nucleic acids react with ions of many metals, the result being a change in several properties of the acids. It is extremely probable that the reaction with metals is of great importance in the biological functions of nucleic acids but there have been very few investigations in this direction and there is still no direct proof that metals play an essential part in the biological functions of the nucleic acids.

The study of the reactions of complex formation between metals and nucleic acids is also of independent interest in connection with the search for so-called electronic stains for electron microscopy of nucleic acids (metal ions in compounds with the nucleic acids can act as electron dyestuffs) and for obtaining especially pure preparations of nucleic acids.

In order to understand the reactions which take place between metals ions and nucleic acids, we will briefly consider the structure and properties of the latter.

2. STRUCTURE AND PROPERTIES OF NUCLEIC ACIDS

The nucleic acids are linear polymers [1] the chains of which are composed of residues of phosphoric acid, pentoses [deoxyriboses in deoxyribonucleic acid (DNA) and riboses in ribonucleic acid (RNA)] and heterocyclic nitrogen bases (purines and pyrimidines).

Sections of the polymeric chains of DNA and RNA are shown in Fig. 1, which represents conventionally four links in each chain. The monomer links differ from one another in the structure of the purine or pyrimidine bases. The natural long molecules of nucleic acids consist of many thousand differently alternating monomeric links. It is evident from Fig. 1 that the DNA chain differs from the RNA chain not only in the composition of the sugars but also in the composition of the pyrimidine bases. The thymine present in DNA is replaced by uracil in RNA.

X-Ray diffraction study of films of nucleic acids showed that the DNA structure is much more ordered than the RNA structure, and that DNA is a two-chain spiral, diameter 20 Å and length of turn 34.6 Å. A turn of the spiral contains ten monomeric links. The lateral groups — purine and pyrimidine bases — are packed in the centre of the spirals.

According to the model of Crick and Watson[2], these bases in the two-chain DNA molecule are located in such a manner that the adenine in one chain is always opposite the thymine in the other, and the guanine is opposite the cytosine. The two chains are connected with one another by hydrogen bonds (see Fig. 2).

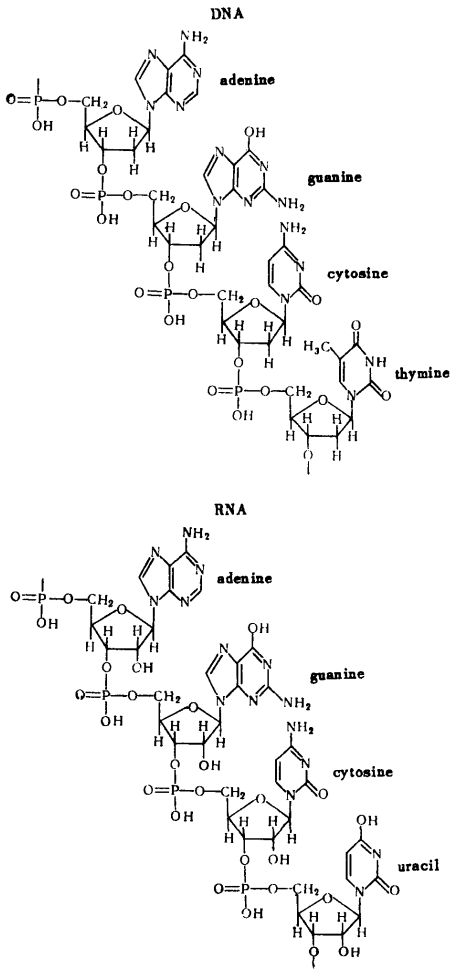

Fig. 1. Sections of the polymeric chains of DNA and RNA.

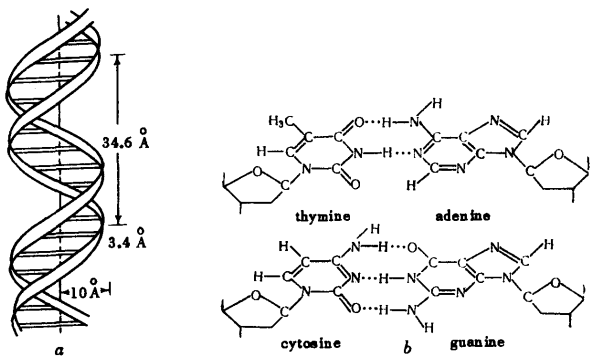

Fig. 2. Macromolecular structure of DNA: *a*) two spirals: phosphato-deoxyribose chains; horizontal lines: pairs of nitrogenous bases connecting the two chains by hydrogen bonds; *b*) hydrogen bonds in pairs of bases.

The RNA molecule consists of one flexible polynucleotide chain, the configuration of which is not stable and fixed, but is determined by the surrounding medium[3-6]. Thanks to the hydrogen bonds, in some places the RNA chain is turned into a double filament, formed by separate turns of the spiral. Between the turns, single-chain sections are situated randomly. This secondary structure of RNA in turn does not remain stable — depending on the conditions of distribution of the spiral portions it can become ordered: more complex compact tangles of tertiary structure are formed. Fig. 3 shows the macromolecular structure of RNA[5].

The hydrogen bonds create a definite structural rigidity in nucleic acids, which is evidently a general characteristic of the macromolecules of biopolymers and determines their biological function[7]. The destruction of the hydrogen bonds of isolated nucleic acids is observed over a narrow range of temperatures, in which "fusion" of the intramolecular regular structure occurs with change of the spirals into disordered tangles[8]. This process is termed denaturing. The change from the native stage into the denatured ("phase transformation") can occur not only on heating,

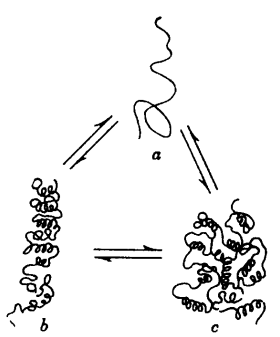

Fig. 3. Macromolecular structure of RNA: *a*) primary structure — loose, random tangle or straightening chain; *b*) secondary structure — compact rod with more or less ordered orientation of the double-spiral portions; *c*) tertiary structure — compact tangle with spiral portions.

but also as the result of other factors. This transformation can be followed by the change in light absorption of solutions of nucleic acids in the ultraviolet region.

In the spectrum of the nucleic acids there is an absorption band in the near ultraviolet region, which is due to light absorption by the chromophoric groups of the heterocyclic bases. The maximum of the band is approximately at 260 mμ. The optical density of native nucleic acids is ~ 40% less than the total optical density of their monomer constituents. This fall (hypochromic effect) is explained by the parallel arrangement of the chromophoric groups of the bases in the native preparations. The optical density rises during denaturing. This hyperchromic effect is explained by the destruction of the parallel arrangement of the chromophoric groups of the bases during the phase transformations from the spiral-shaped ordered forms to the less ordered. The decrease in optical density thus shows the increase in the structural rigidity of nucleic acids due to the increase in spirilisation, but an increase in optical density shows their degradation into disorientated chromophoric groups, in any breakdown of ordering [1,9-12].

Some information about the dimensions, form, and molecular weight of the nucleic acid macromolecules was obtained by sedimentation analysis and measurements of viscosity and diffusion rates [13].

3. EFFECT OF METAL IONS ON THE PROPERTIES OF NUCLEIC ACIDS

The nucleic acids isolated from different biological objects usually contain insignificant amounts of ions of one or more metals [14-28]. Thus Wacker and Vallee [29] reported the presence of chromium, nickel, iron, manganese, zinc, and other metals in preparations of DNA and RNA. The concentration of some metals in nucleic acids of different origins is constant, but the bond between the metals and nucleic acid is so strong that they are removed with difficulty even using such strong chelating reagents as ethylenediaminetetraacetic acid, quinolin-8-ol, dithizone, etc.[29] These facts are evidence that the metals form chemical bonds with the nucleic acid macromolecules.

It was stated above that there are still no direct proofs of the participation of metals in the biological function of the nucleic acids. However, it is suggested that the metal ions bring about a bond between the nucleic acids and proteins [30], play a fundamental part in the structure and function of nucleoproteins [31,32], and affect the synthesis of proteins and the transmission of heredity information [29]. Gol'dshtein and Gerasimova [33] think that Fe^{3+} ions have a special role in the function of DNA: they take part in the formation of bonds between separate chains of DNA and as a result are able to regulate the denaturing of DNA, and are also the cause of the enzymeless transverse cleavage of the DNA molecule. According to the hypothesis of Ivanov [34] the biosynthesis of DNA is linked with the redox changes of iron or copper ions during their chelation with DNA, in which the oxidation of the metal ions brings about a weakening of the bonds between the complementary pairs of DNA bases, and reduction the stabilisation of the double-track conformation of DNA. Ascorbic acid, which participates in the synthesis of DNA in the cell, is a possible electron carrier in the oxidation and reduction of iron in DNA [35]. The correctness of this type of hypothesis is confirmed by the change in the properties of isolated nucleic acids and nucleoproteins under the action of ions of various metals. We will list some of these factors.

The dimensions and form of nucleoproteins suspended in cytoplasm and the degree of their polymerisation depends on the concentration of magnesium ions in the medium [32,36-38]. Alkaline earth metal ions affect the structure and properties of chromosomes [39-44]. In the presence of metal ions RNA is stable in relation to the action of ribonuclease [45,46], the macromolecular configuration of RNA depends on the ionic strength of the solution [6,12]. Various metal ions change the infectivity of tobacco mosaic virus RNA [25,47]. For example, it is found that the infectivity of the RNA of this virus correlates with the iron concentration in the preparations [25]. Nickel ions affect the infectivity of RNA more strongly than any of the other metal ions [47]. True, some authors [48] suggest that metal ions affect only the physical properties of tobacco mosaic virus RNA and not alter its infectivity.

The physical properties of RNA depend considerably on the presence of metal ions. Thus the sedimentation rate of solutions of nucleic acids [49] and their viscosity [50] decrease in the presence of Mn^{2+}, Ni^{2+}, Ca^{2+}, and Mg^{2+} ions. Na^+ and K^+ ions have a much weaker action than these and to bring about the same effect the concentration of alkali metal ions must be 2–3 orders of magnitude greater than the concentration of bivalent ions.

The melting point of the nucleic acids depends on the ionic surroundings [3,51,52]. On adding sodium chloride to DNA there is a linear relation between the melting point and the logarithm of the ionic strength of the solution. The increase in melting point with ionic strength is explained [3,51] by the stabilisation of the DNA with respect to the denaturing. It is suggested that the addition of electrolyte leads to screening of the charges in the DNA chains and this decreases the electrostatic repulsion forces between the charged phosphate groups, facilitating an increase in the rigidity of the structure.

Manganese, cobalt, zinc, and nickel behave like sodium chloride in raising the melting point of DNA, but copper, cadmium, and lead ions depress it [53,54]. Under conditions which facilitate the destruction of hydrogen bonds (heating the solutions of nucleic acids to 80° or dissolving them in 6 M urea — a reagent capable of destroying hydrogen bonds) such metal ions as Ni^{2+}, Mn^{2+}, Zn^{2+}, and Cr^{3+} decrease the optical density of RNA (raise the melting point), but alkali and alkaline earth metal ions hardly affect it. The conclusion was [7] that ions of the transition metals of the first period stabilise the structure of nucleic acids due to the formation of additional bonds between the metal and the bases of the acid. The intramolecular bonds formed with the metal are strong enough to withstand the destructive influence of a rise in temperature or the action of a concentrated solution of urea. With RNA the stabilising influence of the metal ions appears only on heating, when the hydrogen bonds are destroyed.

The change in the properties of the nucleic acids during the action on them of various metal ions is reversible. Katz [21] first drew attention to this ability by the reaction of DNA with mercury. He found that during reaction with $HgCl_2$ the DNA molecules become much smaller, but are restored by the action of reagents which bind mercury. On adding mercury salts to DNA there was a decrease in the characteristic viscosity of the DNA solution and in the spectral shift [20,21,55]. In combining with mercury the chacteristic viscosity and the position of the maximum in the DNA absorption spectrum acquired their original values. Reversible changes were also observed in studying sedimentation rate, scattering of light, optical rotatory

dispersion[56], and also the transforming ability[57] of DNA preparations†.

Hence no doubts remain about the complete reversibility of the reaction of DNA with mercury. This was confirmed by studying this reaction by methods sensitive with respect to the form and dimensions of DNA (viscosity, sedimentation rate, scattering of light), the peculiarities of the stereochemical configuration (optical rotatory dispersion), the presence of chromophoric groups and their relative orientation (absorption spectra in the near ultraviolet region). This was also confirmed by biological methods (transforming ability).

Such reversibility is characteristic for the reaction between tobacco mosaic virus RNA and mercury(II) chloride[56]. Unlike DNA, however, here the biological changes are not completely reversible. Thus Hg^{2+} ions completely deactivate the infectivity of tobacco mosaic virus RNA, but removal of these ions does not lead to complete reduction of the infectivity of RNA in comparison with the control.

Evidently the reaction DNA with Fe^{3+} ions, which was investigated by Gol'dshtein and Gerasimova[33,58], belongs to this type of reversible reaction. On introducing sodium pyrophosphate, which can bind iron, into a solution containing DNA and Fe^{3+} ions the ability of DNA to hydrolyse decreases.

The study of such reversible reactions, which are accompanied by a profound change in the physical properties of the nucleic acids, can evidently be of great importance in explaining the biological functions of the nucleic acids.

4. COMPOUNDS OF NUCLEIC ACIDS WITH METALS

Only a few compounds of the nucleic acids with metals have been isolated in the individual state. These compounds have mainly been investigated with the aim of finding methods for purifying DNA preparations. We will examine the method of obtaining them in somewhat greater detail.

As long ago as 1924 Hammarsten[59] observed that salts of lanthanum and iron(III) precipitate DNA from solution. The precipitation is maximal at pH 2.5–4. It was shown that the lanthanum nucleate compound has a very low solubility. This observation was confirmed later[60,61]. Stern and Steinberg[62] isolated and analysed compounds of DNA with lanthanum, neodymium, praseodymium, samarium, and yttrium, by adding the metal chloride solution to DNA solution, filtering off the fibrous precipitate, and thoroughly washing it with water, then alcohol, and drying in air. The dry products resembled asbestos fibres and had the colour characteristic of the rare-earth element. Suspensions of these compounds in glycerol had a marked absorption of light in the visible region of the spectrum. For the neodymium nucleato-complex the maxima of the absorption bands were at 510–512, 520–525, 570–590 mμ, and those for the praseodymium nucleato-complex were at 440–450, 465–470, and 475–480 mμ. The bands were clearly displaced relative to the bands for solutions of the pure rare-earth chlorides. The nucleate bands were much broader and less sharp than those for the chlorides. The solubility of the compounds was very low; for example, in the filtrate after separation of the neodymium nucleate from an aqueous suspension neodymium could not be detected spectrophotometrically by its absorption at 790 mμ or nucleic acid at 260 mμ. Ultimate analysis of the products showed that they contained 10.5 % neodymium and 11.1% lanthanum respectively.

The reaction between the lanthanide chlorides and sodium nucleate follows the equation[62]:

$$Ln^{3+} + 3\,DNA^- \rightleftarrows Ln(DNA)_3$$

where Ln is the lanthanide and DNA^- is the anion of sodium desoxyribonucleate.

The phosphate groups of the polynucleotide chain are ~ 6 Å from one another. The combination of one atom of rare-earth element with three phosphate residues is explained[62] by the formation of a sharply convolute polynucleotide tangle from one two-chain DNA spiral with the lanthanide ion in its centre. It was also suggested[62] that lanthanum ions can connect phosphate groups of neighbouring nucleotide chains, forming a network of filaments of different DNA molecules cemented to one another. The concentration of the lanthanide in such a complex should be 14%, but, as mentioned above for lanthanum and neodymium, the lanthanide concentration found did not exceed 11%. This is still unexplained.

The stoichiometry of the complex formation of metals with DNA was determined conductimetrically[63,64]. On the conductimetric curves for the titration of DNA with magnesium, manganese, barium, and calcium ions there are breaks corresponding to the stoichiometric ratio of one equivalent of metal ion : one of nucleotide. The position of the breaks is independent of the degree of denaturing of DNA and of the initial concentrations of the solutions.

As, however, such a ratio is not always[65,66] attained, additional proofs of the simple stoichiometry of the complexes were made[67,68]. Conductimetric titrations were made of synthetic polynucleotides: polyadenylic (poly-A) and polyuridilic (poly-U) acids, which contain only one base. These acids are capable of reacting with one another (this ability depends greatly on the nature and concentration of the metal ions present in the solution[69-71]). As a result of the reaction, the two single-chain acids form the double-chain acid poly-AU, which has properties reminiscent of those of DNA[70,72,73]. It has been shown that the titration curves of the two polymers and poly-AU are similar and reminiscent of the titration curves of DNA with magnesium ions and with manganese ions. The break on the titration curves (when a large number of points was taken during the titration) corresponded to the addition of 1 equiv. cation per 1 mole polymer phosphate. This ratio was the same whether native or denaturated DNA was titrated[74].

The composition of complexes of uranyl with DNA was also determined graphically[75]. The equilibrium concentration of uranyl ions in the solution after precipitation of the uranyl–DNA complex was plotted on the graph against the total concentration of uranyl ion in the initial solution. The approximate composition of the complex was determined from the break on the curve and it was shown that the stoichiometry of the complexes formed changes with the pH and the uranyl ion concentration, as Table 1 shows[75].

† Transforming ability is the name given to the ability of DNA isolated from one strain of bacteria to transmit definite characteristics, distinctive to the given progeny, for example, resistance to a certain poison, to another strain of bacteria. Transforming activity is inherent only in the native form of DNA. This index can be used as an experimental quantitative characteristic of the depth of denaturing and renaturing of DNA (Ref. 1, p. 269).

TABLE 1. Stoichiometry of the complex formation of uranyl with DNA as a function of pH and uranyl ion concentration. The DNA concentration has been recalculated per nucleotide link or per phosphorus of the nucleotide.

Experiments made at constant DNA concentrations ($\sim 4-6\times10^{-6}$ M) and variable pH		Experiments at constant pH ($\sim$3.5) and variable uranyl ion concentrations	
pH	UO_2^{2+}/P molar ratio	UO_2^{2+} concentration, M	UO_2^{2+}/P molar ratio
2.3	0.34	$1\cdot10^{-2}$	0.7
3.6	0.49	$4.8\cdot10^{-3}$	1.3
3.7	0.53	$6\cdot10^{-3}$	1.5
4.8	1.72		
5.8	2.42		

Probably this behaviour can be explained by the ability of the metal to form a compound not with a definite functional group of the DNA but, depending on the conditions, with different groups: phosphate, amino-, and enol.

The change in the stoichiometry of the metal–nucleic acid complexes with the pH and metal concentration was also observed in studying complex formation of Co^{2+}, Zn^{2+}, Ca^{2+}, Mg^{2+}, and Mn^{2+} ions with RNA and DNA by the equilibrium dialysis and isotope dilution methods[76]. On increasing the metal ion concentration the bonding of metal increases. Table 2 gives the results of determining the value of the "degree of bonding" at different pH and constant metal ion concentration, expressed in the number of metal atoms per atom of DNA phosphorus.

The complex formation of different metals with DNA has also been studied by the NMR method[77]. The paramagnetic metal ions in aqueous solution shorten the time of spin-lattice relaxation of the water protons. The relaxation time for protons in aqueous solution containing paramagnetic metal ions depends not only on the metal concentration but also on its chemical environment. It is known that there is greater effectiveness in shortening the relaxation time when there are small ions or molecules in the environment than when the metal is inside a large molecule.

TABLE 2. Bonding of the doubly-charged ions of certain metals with DNA at various pH and constant metal ion concentrations. Concentrations: metal ion 10^{-2} g litre^{-1}; Ca^{2+} 2.1×10^{-2} g litre^{-1}; DNA 10^{-5} g.*

pH	No. of metal ions per RNA phosphorus atom					No. of metal ions per DNA phosphorus atom

8.8	—	—	0.071	—	—	—	—	—	—	—

* These concentrations do not agree with those given in Table II of Ref. 76 (Ed. of Translation).

TABLE 3. Determination of the number of DNA parts available for absorption.

Metal ion	No. of metal ions arriving per 1 mg DNA	No. of equivalents of metal arriving per nucleotide
Mn^{2+}	$7\cdot10^{17}$	0.7
Cr^{3+}	$7\cdot10^{17}$	1.1
Fe^{3+}	$8\cdot10^{17}$	1.2

A theoretical appraisal was made of the decrease in relaxation time during the bonding of a metal ion with one or another part of the DNA molecule (by the parts of the linking DNA we mean the phosphate, amino-, and enol groups of the molecule) and the calculated quantities were compared with the experimental results obtained. On this basis the probable parts of the bonding DNA with various metals were determined and the "capacity" of the DNA molecule in relation to these metals. Table 3 gives these quantities.

As Table 3 shows, the same ratio is retained for complex formation for ions of iron and chromium: 1 equivalent of metal to 1 of nucleotide. Manganese ions do not obey this rule.

In studying the reaction of metal ions with tobacco mosaic virus RNA using labelled atoms (the radioactivity of a solution of a salt of the metal before reaction with RNA was compared with the radioactivity of a mixture of solutions of the metal salt and RNA after removal of the metal–RNA complex from it by centrifuging), it was found that the RNA bonds 0.5 mole calcium salt per nucleotide and $\sim$ 1 mole mercury or silver salt per nucleotide[78].

Despite the fact that the composition of the complexes formed by metals with nucleic acids often corresponds to simple stoichiometric ratios, it must be remembered that simple stoichiometry cannot be fulfilled on account of the possibility of complex formation by the metal with different functional groups of the nucleic acids.

5. STRUCTURE OF COMPLEXES OF METALS WITH NUCLEIC ACIDS

In studying the structure of compounds of the type mentioned the region of the metal–nucleic acid bond is usually determined. To identify the region, the reaction of the metals with native and denatured forms of DNA are often compared. When these reactions do not depend on the form of DNA, the bond between the acid and the metal is effected directly with the phosphate groups. When the reaction depends on the form of DNA, this is evidence of the formation of a bond between the metal and the purine or pyrimidine bases of the acid. In native DNA these bases, as already mentioned, are linked by hydrogen bonds, and consequently their reaction with metal ions is hampered

By use of conductimetric titration[63,64,74] it was found that magnesium, manganese, barium, and calcium ions behave similarly in relation to native and denatured DNA. The position and character of the breaks on titration curves of the acid by these ions are independent of the degree of denaturing and over a wide range of concentrations correspond to a definite stoichiometric ratio of DNA and metal ions. Consequently it can be assumed that these metal ions are connected with the phosphate groups of the DNA. This conclusion is also confirmed by the following facts[74].

It is known[79] that the dye Acridine Orange reacts only with the phosphate groups of nucleic acids in 1 : 1 ratio and that the conductimetric titration curves for DNA by this dye are analogous to the curves for the titration of DNA by Mg^{2+} or Ba^{2+} ions and also the curves for the titration of poly-A, poly-U, and poly-AU by these ions. Hence the reaction of these metal ions with the different polynucleotides is independent of the composition of the bases and is determined by the phosphate groups.

In studying the reaction of the same metal ions with nucleic acids by the equilibrium dialysis method[76] differences were also noted in the degrees of bonding for the same ion with different forms of DNA. The effect of magnesium and calcium ions on the fluorescence of the ring of adenine, adenosine, adenosine monophosphate, adenosine diphosphate, and adenosine triphosphate was also studied[80]. The maximal intensity of the fluorescence of these substances, observable at 395 mμ, changed in the sequence: adenosine < adenosine monophosphate < adenosine diphosphate, adenine < adenosine triphosphate. Magnesium and calcium ions lowered to an almost equal extent the fluorescence of adenosine triphosphate and adenosine diphosphate to the intensity of adenosine monophosphate and adenosine respectively. These results serve as yet another confirmation that magnesium and calcium ions are connected mainly with the phosphate moiety of the nucleotide and are not attached to the ring of the base.

Study of the effect of metal ions on the melting point of nucleic acids can also be used to determine the region of bonding. It is known[53,54] that Mn^{2+}, Co^{2+}, Zn^{2+}, and Ni^{2+} ions raise the melting point but Cu^{2+}, Cd^{2+}, and Pb^{2+} ions depress it. This is explained[53,54] by the fact that the metals of the first group are connected with the phosphate residues at the DNA surface, which prevents electrostatic repulsion of the negatively charged phosphate residues and stabilises the DNA molecule. The metals of the second of these groups are bound to the purine or pyrimidine bases inside the spiral, in the sites of the hydrogen bonds, and destabilise the DNA molecule.

By use of the NMR method[77] it was also found that Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, and Cr^{3+} ions are most probably bound to the phosphate groups and not the nitrogenous bases of the DNA, but Fe^{3+} ions are linked with the nitrogenous bases. As for copper ions, they bring about the aggregation of the DNA molecules and, it is thought[77], are connected with the outer phosphate parts of the DNA. However, in the EPR spectra of DNA solutions treated with Cu^{2+} ions signals are observed which are explained[81] by the formation of a bond between the copper ions and the bases of the DNA.

The reaction of uranyl ion with DNA[75] apparently occurs at the phosphate groups. In investigating the complex-forming ability of several phosphates in relation to the uranyl ion it was found that the molar ratio of uranyl to phosphorus increases with the number of phosphate groups in linear phosphate polymers. Undoubtedly DNA can be included among these polymers. Direct proof of the connection of the uranyl ion and the phosphate groups is given by the infrared absorption spectra of DNA solutions in the presence and absence of uranyl salts[75].

Fig. 4 shows the infrared absorption spectrum of DNA. The 900–1300 cm^{-1} band belongs[82] to the vibrations inside the phosphate groups and sugars, the strong 1500–1600 cm^{-1} band to the vibrations of the >C=N–, >C=O, and >C=C groups of the nitrogenous bases, and the 3000–3500 cm^{-1} band to the vibrations of the amino- and hydroxyl groups in the sites of the hydrogen bonds[83].

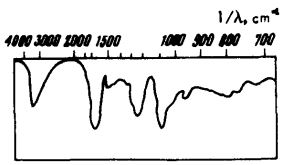

Fig. 4. Infrared spectrum of calf thymus DNA (sodium salt).

During complex formation with the uranyl ion some shifts in the position of the bands were observed only in the region from 900 to 1300 cm^{-1}. However, it must be noted that in comparing the infrared spectrum of DNA with that of the DNA–iron complex[84], only displacements of the bands of the stretching vibrations of the phosphate ester groups are observed and not a displacement in the region of the vibrations of the >C=N–, >C=O, and >C=C< groups of the bases. Moreover, it was found by differential spectrophotometry in the ultravoilet region (spectra of solutions of the metal–DNA complex recorded in relation to solutions of the free ligand and metal[85]) that iron ions also react with the DNA bases[84]. Similarly, in comparing the infrared spectra of adenosine triphosphate (ATP) and of copper–ATP complexes a displacement in the regions of the vibrations of the chromophoric groups of the bases was not observed. A displacement of the ATP absorption band into the ultraviolet region is observed in the differential spectrum and can be explained only by the reaction of copper ions with the bases[85]. The possibility of coordination between copper ions and purine components of the DNA has also been established in studying the effect of nucleic acids and their components on the oxidation of ascorbic acid, which is catalysed by copper ions[86].

Apparently infrared spectroscopy has still not unambiguously settled the problem of the locations of the bonds between the metals and nucleic acids.

Studying the absorption spectrum of DNA solutions in the near ultraviolet region in the presence of ions of various metals also allows conclusions to be drawn about the locations of the bonding of metals to DNA. It is known[87] that additions of Mg^{2+}, Ca^{2+}, and Mn^{2+} ions do not change the position of the bands in the DNA absorption spectrum, whereas Hg^{2+} or Ag^{+} ions displace the absorption band (Fig. 5)[55].

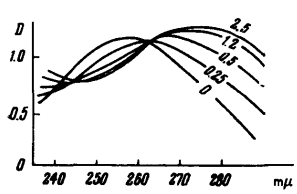

Fig. 5. Effect of $HgCl_2$ on the absorption spectrum of solutions of calf thymus DNA in 0.1 M $NaClO_4$, pH 5.6–5.7 at various ratios of moles $HgCl_2$ to moles DNA phosphorus (r). Values of r are shown on the curves.

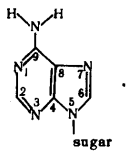
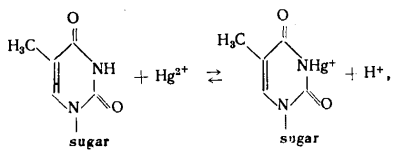
In this connection it is suggested[55,88] that mercury and silver ions bond with DNA through the nitrogenous bases. Depending on the value of r (the ratio $[Hg^{2+}]/[PO_4^-]$) this reaction proceeds either with or without release of hydrogen ions[55,88]. This is explained by the attachment of the metal ions to different DNA bases, during which the hydrogen bond between the chains can be destroyed or remain unchanged.

When complex formation is not accompanied by the liberation of hydrogen ions it is suggested[55] that the metal ion is attached to the electron pair of the 7-N or 3-N of the purines adenosine or guanosine. The hydrogen bonds are not destroyed during this.

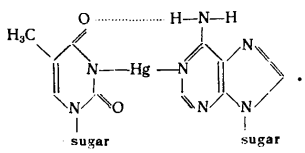


When hydrogen ions are released it can be assumed that there is a reaction of the type:



accompanied by the rupture of the hydrogen bonds.

Considering the reaction between mercuric ions and DNA, Katz[89,90] proposes that in the region $0 \leq r \leq 0.5$ compounds are formed in which the mercury play the part of an intermediate bridge between two coils of the DNA double spiral, the hydrogen bonds of which are not completely destroyed:



Such a complex is a two-filament polynucleotide in which almost all the bases of one filament are connected to the bases of the other by bridges of mercury atoms. The composition of such a complex corresponds to a mercury-nucleotide ratio of 1 : 2.

At $r \geq 0.5$ the filaments are separated, with formation of complexes of 1 : 1 composition by the reactions

$$\text{chain–base } a\text{–}Hg^{II}\text{–base } b\text{–chain} + Hg^{II} \rightleftharpoons$$
$$\rightleftharpoons \text{chain–base } aHg^{II} + \text{chain–base } bHg^{II}.$$

A conclusion about the bonds between metals and the nucleic acid bases can be drawn from a study of the ultravoilet spectra only when there is a marked displacement of the maxima of the absorption bands of the nucleic acids as a result of the action of the metal, as happens for silver and mercury ions; when this is not so, it is necessary to study differential spectra in the ultraviolet region[85].

There are grounds for assuming that all the above mentioned methods of determining the structure of the metal–DNA complex do not give unambiguous results. It would appear, undoubtedly, that alkaline earth metal ions are bonded with DNA through phosphate groups. However, in using the equilibrium dialysis method[65] it was shown that Mg^{2+} ions act differently in relation to denatured and native forms of DNA. In this connection there is the possibility[54,91-93] that Mg^{2+} is bonded with the bases, mainly the purines, which have a structure reminiscent of quinolin-8-ol, whose great affinity for magnesium is well known.

It has been shown[93] that the addition of Mg^{2+} or Ca^{2+} to unionised nucleoside triphosphates brings about the same spectral shift as their neutralisation with OH^-. Probably, protons are displaced from the ring in both instances.

It is suggested[93] that because of the spiral configuration of the nucleoside triphosphate, the formation of bonds between magnesium and two parts of the nucleotide — the phosphate group and base — is possible.

Conformational analysis made with Steward models of atoms for the iron–nucleotide system[94] also confirm the possibility of bonds being formed simultaneously between metal, phosphate group, and base.

It is quite probable that the metal ions form bonds not with individual atoms of the rings of the bases but with the entire molecule of the base as a whole; this involves the overlap of the molecular orbitals of the base and the orbitals of the metal. It can be assumed that sometimes compounds are formed of the type of complexes with charge transfer using both the orbitals of the metal and molecular orbitals of the base and the d orbitals of the phosphorus atoms.

6. STABILITY OF COMPLEXES OF METALS WITH DNA

Some idea of the stability of the compounds formed can be obtained by comparing their association constants. Table 4 gives the values of the known association constants of complexes of DNA with various metals and shows that there are no sharp differences in the constants for different metals.

The example of silver complexes (Table 5) shows that the origin of the DNA has little effect on the association constants.

In calculating the constants it was assumed that the formation of a bond in each portion is independent of the occupation or unoccupation of the other parts. In one study[95] it was assumed that the composition of the complex corresponds to a metal : nucleotide ratio of 1 : 1. In the other studies the number of combining parts of the nucleic acid and the association constants were determined by a graphical method, the general principles of which for polyelectrolytes have been described[96].

TABLE 4. Association constants of complexes of metals with DNA.

Complex of DNA with the metal ion	Method of determining the equilibrium concentration of the metal	pH	Ionic strength	Association constant	Reference
Mg^{2+}	equilibrium dialysis		0.2	$2.8 \cdot 10^2$	65
Mg^{2+}	metal-indicator (Eriochrome T)	10	0.002	$2 \cdot 10^5$	97
UO_2^{2+}	titration with cyanoferrate(II)	3 5	0	$8 \cdot 10^6$	75
Ag^+	potentiometric	5.6	0.1	k_1 $2.4 \cdot 10^6$	88
Ag^+	potentiometric	5.6	0.1	k_2 $3.4 \cdot 10^5$	88
Fe^{3+}	kinetic	3.1	~0	$1.3 \cdot 10^5$	95

TABLE 5. Association constants of complexes of silver with DNA from various sources [88].

Specimen of DNA	k_1 $0<r<0.2$	k_2 $0.2<r<0.5$
Calf thymus DNA 1 native	$2.1\cdot10^6$	$4.1\cdot10^4$
Calf thymus DNA 2 native	$2.2\cdot10^6$	$7.4\cdot10^4$
Calf thymus DNA 2 denatured	$4.2\cdot10^6$	$1.3\cdot10^5$
E. Coli	$2.2\cdot10^6$	$5.7\cdot10^4$
M. Lysodeikticus	$3.1\cdot10^6$	$2.4\cdot10^5$

It has been shown [95] for the iron–DNA complex that the equilibrium constant is almost independent of temperature and consequently the heat of the reaction is small. On this basis the entropy of complex formation has been calculated to be ~ 23 e.u. The positive change in entropy is due to the dehydration of the ions during complex formation.

As stated above, metal ions, especially those of the transition metals, can be coordinated simultaneously with many functional groups, and for each group the stability constant will be different. Therefore association constants quoted are often mean values.

---o0o---

For a long time it was thought that the occurrence of metals in nucleic acids was due to accidental contamination. From this review it is clear that metals can react with nucleic acids and the compounds formed often exhibit properties differing from those of the original acids.

One of the most interesting properties which characterise the complex formation between nucleic acids and metals is the reversibility of changes in the structure of the nucleic acids brought about by coordination with the metals. It is thought that the reversibility is a general feature of the behaviour of double-filament, polynucleotides consisting of two filaments bound by hydrogen bonds [98]. At high metal concentrations this reaction takes place up to complete separation of the filaments of the spiral of the DNA and the formation of 1 : 1 complexes. This form of separation of the chains is different from thermal separation in that chemical damage to the structural entity of the DNA (liberation of purines, breaking of phosphate ester bonds, etc.) is excluded completely.

Study of the absorption spectra of nucleic acids in the presence of $HgCl_2$ showed [56] that, in contrast to DNA, RNA forms a complex at $r > 1.0$. The same phenomenon was observed in experiments with DNA denatured by heating [55]. It is therefore proposed [56] that the reaction with $HgCl_2$ can also be used for finding differences between single-filament and two-filament polynucleotides.

Only a few metal ions (Hg^{2+}, Ag^+, and apparently Fe^{3+}) have yet been found which are capable of such reversible action towards nucleic acids. Probably a search for reversible reactions for other metal ions can give interesting results.

A necessary prerequisite for such investigations should be the determination of the regions of bonding of the metals with the nucleic acids. As the above review shows, there is no incontrovertible proof of a bond between the metal and any specified sections.

We see the importance of studying the complex formation of nucleic acids with metals also in the possibility of obtaining especially pure preparations of these substances. For this purpose quantitative characterisation of the complex formation is necessary — information about the association constants of the corresponding complexes. As we have seen, these data are extremely fragmentary. Moreover, we need further confirmation and reasons for the fact that the association constants for such different metals ions as Mg^{2+}, UO_2^{2+}, Ag^+, and Fe^{3+} are very similar.

SPECTROSCOPIC STUDIES ON REVERSIBLE REACTIONS IN COMPOUNDS OF THE PORPHIN SERIES

A.N. Sidorov

CONTENTS

Introduction 153

I. Nomenclature and molecular structure of compounds of the porphin series 153

II. Isomerism and tautomeric changes 154

III. Molecular compounds 155

IV. Hydrogen exchange in compounds of the porphin series 160

V. Hydrogenation and dehydrogenation of the pyrrole rings in compounds of the porphin series 161

VI. Reversible photochemical reduction of compounds of the porphin series 162

INTRODUCTION

One has merely to list only a few examples of compounds of the porphin series to show clearly, without further comment, the urgent need for a comprehensive study of the compounds of this series, from the simplest onwards. Compounds of this series include chlorophyll — the green pigment of the photosynthesising mechanism in plants, haem — the red pigment of blood, responsible in haemoglobin for the transport of oxygen and carbon dioxide in the circulatory system, the prosthetic groups of cytochromes — biological catalysts controlling the processes of tissue respiration, and phthalocyanines — synthetic compounds which have found extensive application as dyestuffs.

The structure and physicochemical properties of chlorophyll were first studied at the beginning of last century, but it was only in the nineteen-twenties and -thirties that the work of several generations of Russian and other scientists led to the first synthesis of the simplest porphin derivatives and the determination of the structural formulae of chlorophyll and haem†. In the post-war years the attention of many research workers was drawn to the specific ability of compounds of the porphin series to undergo reversible reactions. These reactions are undoubtedly of particular scientific interest, since they characterise or even determine the biological activity of the pigments. Considerable progress was made in this field as a result of the application of new physical methods, particularly spectroscopic methods: electronic and vibrational absorption spectra, luminescence spectra, electron spin resonance (ESR) spectra, and nuclear magnetic resonance (NMR) spectra. Valuable experimental material has now accumulated, but is is difficult to see one's way through the vast quantity of unrelated data. Thus at the present time, in addition to a continuation of experimental work, there is a need for systematisation and summary of published results, and this is the purpose of the present review. We shall examine the interactions of molecules of the porphin series with the medium and also some of their photochemical reactions. The reversible reactions involved in the reduction and oxidation of chlorophyll, and its photosensitising action, have been studied in detail in reviews by Krasnovskii[8], Evstigneev[9], and Livingston[10] and in a monograph by Rabinowitch[1], so that we shall not deal with these topics. In view of their specific character and direct relationship to the function of haemoglobin, the properties of the iron-containing complexes form a separate chapter of science and will be discussed only in the examination of the general properties of metal derivatives of the porphin series. The purely spectroscopic characteristics of compounds of the porphin series have been described in a review by Gurinovich et al.[11] and their physicochemical properties have been described in papers by Phillips[12,13] and Falk[14].

† The history of the discovery and study of chlorophyll, haem, and other porphin derivatives is described in more detail in a number of monographs[1-7].

I. NOMENCLATURE AND MOLECULAR STRUCTURE OF COMPOUNDS OF THE PORPHIN SERIES

The skeleton of the porphin molecule (I, II) is made up of four pyrrole rings joined to one another by methine bridges to form a closed cyclic system with conjugation throughout the entire ring. Depending on the arrangement of the two central H atoms, two isomers of porphin are possible in principle, with *trans*- or *cis*-arrangement of the imine NH bonds.

Porphin derivatives with substituents in positions 1–8 are called porphyrins. For example, etioporphyrin I is 2,4,6,8-tetraethyl-1,3,5,7-tetramethyl-porphin, and protoporphyrin IX is 1,3,5,8-tetramethyl-2,4-divinylporphin--6,7-dipropionic acid. It is possible to distinguish four isomers of etioporphyrin and 15 isomers of protoporphyrin, depending on the mutual arrangement of the substituents. The isomers are denoted by Roman numerals (etioporphyrin I, etioporphyrin **II**, etc.). The nomenclature of the porphyrins, methods for their preparation, and properties have been described in detail in a monograph by Fischer[6] and in a review by Phillips[13].

The H atoms of the methine bridges of the porphin molecule, like the H atoms of the pyrrole rings, can also be replaced. Thus for example $\alpha\beta\gamma\delta$-tetraphenylporphin and $\alpha\beta\gamma\delta$-tetramethylporphin (or simply tetraphenylporphin and tetramethylporphin) are known.

The porphin derivative in which a benzene ring is fused to each pyrrole ring is called **tetra**benzoporphin (III).

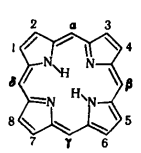
Hydrogenation of one or two of **the pyr**role rings of the porphin molecule gives dihydroporphin or chlorin (IV) and tetrahydroporphin or bacteriochlorin (V) respectively. Chlorin and bacteriochlorin also form derivatives corresponding to those of porphin. It is suggested that the hydrogenated pyrrole rings in the molecules of tetraphenylbacteriochlorin[15] and octaethylbacteriochlorin[16] may be situated in either the *trans*-position or the *cis*-position relative to one another (V, VI). It may be assumed that the same possibility exists for other bacteriochlorin derivatives‡.

A unique position among porphin derivatives is occupied by the azaporphins — compounds in which some or all of the methine bridges are replaced by nitrogen atoms. Derivatives of monoaza-, diaza, triaza, and tetra-azaporphin(VII) are known. Tetrabenzotetraazaporphin is usually called phthalocyanine (VIII).

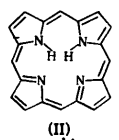
Porphin and all its derivatives can form complexes with various metals, by replacement of the H atoms of the imine groups in the centre of the molecule. The complex

‡ The term "bacteriochlorin" is obtained by analogy with the term "bacteriochlorophyll" (the tetrahydro-derivative of porphin with the *trans*-arrangement of the hydrogenated pyrrole rings). Up to the present, therefore, this term has been applied in the literature only to the *trans*-isomers of tetrahydroporphin and its derivatives. Since a terminology for the hydrogenated derivatives of porphin has not yet been established, however, it will be convenient to extend this term to the *cis*-isomers.

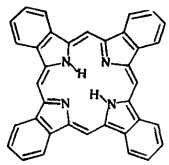
formed by porphin with a bivalent metal (M-porphin) is represented by formula (IX). When porphin derivatives form complexes with tervalent or quadrivalent metals, one or two anions respectively, usually OH^-, HSO_4^-, Br^-, or Cl^-, are attached to the metal atom at ring angles to the plane of the molecule.



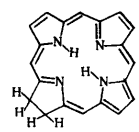
(I) porphin, *trans*-isomer



(II) porphin, *cis*-isomer



(III) tetrabenzoporphin



(IV) chlorin

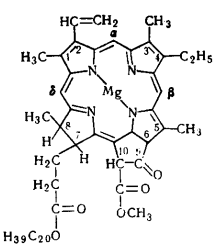
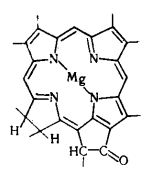
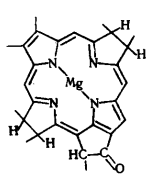
(IX) M-porphin



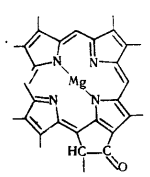
(X, *a*) chlorophyll *a*



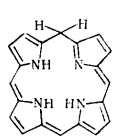
(X) chlorophyll



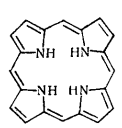
(XI) bacteriochlorophyll



(XII) protochlorophyll



(XIII) phlorin



(XIV) isophlorin

Most of the biologically important pigments among the porphin derivatives are complexes with metals. Thus haem is Fe^{II}-protoporphyrin IX; haemin (chlorohaemin) is $Fe^{III}Cl$-protoporphyrin IX; and haematin is $Fe^{III}OH$-protoporphyrin IX. Chlorophyll, bacteriochlorophyll, and protochlorophyll are magnesium-containing derivatives of chlorin, bacteriochlorin, and porphyrin respectively. The skeleton of the molecular structure of these pigments is given by formulae (X), (XI), and (XII); the substituents in all are the same [see formula (X,*a*)]. An important characteristic of the molecular structure of chlorophyll, bacteriochlorophyll, and protochlorophyll is the presence of the so-called cyclopentanone ring joined to the tetrapyrrole skeleton of the molecule via the C atoms in positions 6 and γ. There exist analogues of chlorophyll without a metal atom in the centre of the molecule (pheophytin) and analogues in which the Mg atom is replaced by an atom of another metal (Cu-pheophytin, Ni-pheophytin, etc.). Methylchlorophyllide is a chlorophyll analogue with a methyl group in place of the $C_{20}H_{39}$ group in position 7.

Woodward [17] recently suggested that porphyrins may be hydrogenated not only in the pyrrole rings but also at the methine bridges and central nitrogen atoms with the formation of the so-called phlorins (XIII) and isophlorins (XIV). Strictly speaking, phlorin cannot be included among the compounds of the porphin series, since these are characterised by the presence of a closed ring of conjugated bonds.

The presence of the cyclic system of conjugated bonds in the molecules of porphin and its derivatives is the factor which determines the characteristic features and properties of these molecules. Measurements of the limiting luminescence polarisation of symmetrically substituted M-porphin derivatives (where M is a bivalent metal) have led to the conclusion that the molecules of these compounds belong to a point group with symmetry D_{4h}. This means that, as a result of the delocalisation of the π electrons in the system of conjugated bonds, all four pyrrole rings and all four M–N bonds and other symmetrically arranged atoms and bonds become equivalent [11]. In particular, the concept of "semi-isolated" double bonds [1] in the porphyrin molecules becomes meaningless. In the case of non-symmetrical derivatives of porphin (chlorins, bacteriochlorins, and unsymmetrically-substituted porphyrins) the equivalence of the atoms and bonds breaks down to some extent, leading to a change in some of the properties of the compounds. In this case also, however, the degree of delocalisation of the π electrons in the conjugated system is fairly high and it is possible to speak of the relative equivalence of the M–N bonds and non-hydrogenated pyrrole rings.

II. ISOMERISM AND TAUTOMERIC CHANGES

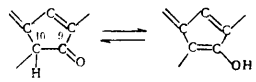
Let us examine first the problem of the isomerism of the imino-groups in the porphin molecule. As noted above, isomers of porphin with *cis*- and *trans*-arrangement of the imino-groups (I) and (II) are possible in principle. The point group symmetry of the molecule of the *trans*-isomer is D_{2h}, and that of the molecule of the *cis*-isomer is C_{2v}. According to the selection rules, for molecules with symmetry D_{2h} the range of the stretching vibrations of the NH bonds should contain only one absorption band, but for symmetry C_{2v} two bands are possible [18]. Spectroscopic measurements have shown that porphin [18] and all its derivatives, including chlorin, bacteriochlorin [19], and phthalocyanine [20], have only one band in this range, corresponding to *trans*-arrangement of the imino-groups. Measurements of the limiting luminescence polarisation of porphin and its symmetrically substituted derivatives [11] confirmed that the molecules of these compounds belong to the point group with symmetry D_{2h}.

It would, however, be premature to conclude that the possibility of *cis*-arrangement of the imino-groups in molecules of the porphin series is excluded. Spectroscopic measurements in the infrared range have up to the present been mainly qualitative; they do not exclude the possibility that the absorption bands are superimposed and hence that the interpretation of the results is ambiguous. This possibility is confirmed by the infrared spectrum of pheophytin *a*. In this spectrum the range of stretching vibrations of the NH bonds contains an absorption band with three maxima, which can be assigned to isomers of the pigment with different arrangements of the imino-groups [21].

The conclusion that tautomeric transformations of the *trans*- and *cis*-isomers of porphin compounds into one another are possible was reached by Dorough and Shen [22], who observed reversible changes in the fluorescence and

absorption spectra of solutions of tetraphenylporphin and tetraphenylchlorin with decrease in temperature from 20° to -196°. The spectra of metal derivatives of these pigments did not show similar changes. This phenomenon was attributed to displacement of the dynamic equilibrium between tautomers with change in temperature. This explanation requires verification, however, since it is held that the change in the spectroscopic characteristics of tetrapyrrole pigments with decrease in temperature is due not to tautomeric changes in the molecules but to resolution of the vibrational structure of electronic transitions [11]. Further progress towards a solution of the problem of isomerism and tautomeric changes in porphin compounds requires new studies, particularly in infrared and NMR spectroscopy.

According to data obtained by many workers [1], the Molisch phase-test reaction, which involves the production of a brown colour in an ethereal solution of chlorophyll when alcoholic alkali is added, begins by alkali-induced enolisation of the carbonyl group in position 9:



(XV).

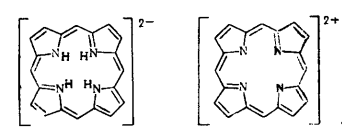
It is not excluded that keto–enol tautomeric changes also take place in chlorophyll molecules in the absence of alkali. In the determination of the proportion of enolised chlorophyll molecules under different conditions, considerable reliance is placed on infrared spectroscopy. It is suggested that the intensity of the absorption bands corresponding to the vibrations of the OH, C=C, and C=O bonds may provide a reliable measure of the quantity of keto and enol forms of chlorophyll molecules. The difficulties of interpretation of the infrared spectra, however, have led to contradictory views on the data obtained [23-28]. It is found that the presence of absorption bands in the spectrum of chlorophyll in the range corresponding to the stretching vibrations of the OH groups does not provide adequate proof of the existence of enolised molecules, since in this range radiation is also absorbed by molecules of water, which is associated with the chlorophyll and is difficult to remove [29]. The absorption bands of chlorophyll in the range of vibrations of the C=C and C=O bonds (1500–1750 cm^{-1}) can be interpreted in different ways [23-28,30] and therefore cannot provide a sufficient basis for concluding that keto–enol tautomerism occurs in chlorophyll. In this connection it must be admitted that conclusions regarding the presence of an appreciable quantity of enolised chlorophyll molecules in various solvents, reached merely on the basis of spectro-analytical measurements in the infrared range [23-25,30,31], have insufficient foundation. Recently, study of isotope exchange between chlorophyll and CD_3OD in chloroform has shown that the rate of replacement of the H atom in position 10 by deuterium is relatively low. Without excluding the possibility, in principle, of the existence of enolised chlorophyll molecules, this experiment shows that the proportion of such molecules under the conditions of the experiment is small and cannot determine to any significant extent the absorption spectrum of the pigment in the infrared range [26,32,33].

III. MOLECULAR COMPOUNDS

Let us examine the reaction of molecules of porphin compounds with one another or with the molecules of the medium, leading to the formation of association and molecular complexes with a significant change in the properties of the pigments, including their spectroscopic characteristics. The ability of molecules of the porphin series to form complexes with the molecules of the medium is by no means a distinctive feature of this series but is of exceptional biochemical importance. This property is decisive in enabling haemoglobin to perform its function as oxygen carrier. The reaction of chlorophyll molecules with the molecules of the medium ensures that the interacting components are prepared for the fundamental photochemical step.

1. Compounds with an ionic structure. In the extreme case of strong interactions ionisation of the pigment molecule takes place. Porphyrins are amphoteric compounds [12,13]. All four nitrogen atoms of the porphyrin molecule are basic centres and may act as proton acceptors. The imino-groups (NH) are capable of losing protons under certain conditions, that is, of acting as acidic centres. If the neutral porphin molecule is denoted by $H_2\Pi$, six ionic forms are possible in principle: reaction with strong bases may lead to the formation of $(H\Pi)^-$ and Π^{2-} ions and reaction with acids to the formation of the ions $(H_3\Pi)^+$, $(H_4\Pi)^{2+}$, $(H_5\Pi)^{3+}$, and $(H_6\Pi)^{4+}$. Divalent anionic and cationic forms of some porphyrins have been isolated in the form [12] of salts $Na_2^+\Pi^{2-}$ and $(H_4\Pi)^{2+}Cl_2^-$. In particular, tetraphenylporphin and tetraphenylchlorin dihydrochlorides are formed when the original pigments are kept in gaseous HCl [34,35]. This method can apparently also be used to prepare the hydrochlorides of other porphin derivatives.

Measurements of the luminescence polarisation show that the divalent porphyrin cation $(H_4\Pi)^{2+}$, like the metal–porphin molecule, has the point group symmetry D_{4h}. From this it follows that the excess of charge in the divalent ion is distributed uniformly throughout the cyclic system of conjugated bonds and that all four pyrrole rings are equivalent [11]. The position and width of the absorption bands in the region of the stretching vibrations of the NH bonds in the infrared spectra of tetraphenylporphin and tetraphenylchlorin dihydrochlorides [34,35] show [36] that these bonds have ionic character $(NH)^+$. This means that the excess of charge in the structure of the divalent porphyrin and chlorin cations, although included in the cyclic system of conjugated bonds, is chiefly concentrated close to the NH bonds and is distributed uniformly between them. On the basis of these ideas, the structure of the cation can be represented by formula (XVI). The analogous formula (XVII) can be used to describe the structure of the divalent anion:



(XVI) porphin divalent cation (XVII) porphin divalent anion

Singly-charged porphyrin ions have as yet been observed only in exceptional cases. Thus it is suggested that the absorption spectrum of the monovalent protoporphyrin cation can be observed in the presence of certain aqueous detergents [37]. The singly-charged porphyrin ions are evidently short-lived intermediate products which are rapidly converted into doubly-charged ions. This is apparently due to the instability of structures in which one of the central N atoms is not equivalent to the others (in the case of the monovalent anion it form an imino-group, unlike

the other three N atoms, and in the case of the monovalent cation it has no H atom whereas the other N atoms form imino-groups). In the reaction between acids and chlorins in which the equivalence of the pyrrole rings has been broken down by hydrogenation of one of the lateral double bonds both divalent and monovalent cations can be observed spectroscopically [11].

The ionic forms of metal derivatives of the porphin series have been less extensively studied. On contact with metallic sodium in absolute dry tetrahydrofuran in a vacuum, Mg-phthalocyanine is converted into the anionic form [38,39]. The number of electrons attached to the pigment molecule in the process is still unknown. On contact with oxygen, the Mg-phthalocyanine anions are reversibly converted into the original pigment. It was recently found that the reaction of Zn-tetraphenylporphin with certain organosodium compounds leads to the formation of salts of the monovalent and divalent anions of the pigment. The salts $Na^+(ZnTPP)^-$ and $Na_2^+(ZnTPP)^{2-}$ were isolated in pure form [40]. As in the case of porphyrins containing no metals, the excess of charge in the Mg-phthalocyanine and Zn--tetraphenylporphin ions is apparently distributed uniformly throughout the cyclic system of conjugated bonds.

The metal derivatives of compounds of the porphin series can be divided into two groups according to the nature of their reaction with acids. The first group consists of those derivatives in which this reaction leads to replacement of the central metal atom by two H atoms, that is to irreversible conversion of the metal-containing complex into pigment containing no metal. The second group consists of metal derivatives which are fairly stable towards acids but which react to form cations in which the central metal atom is preserved. The stability towards acids depends chiefly on the stability of the bond formed by the metal atom with the ligand. This stability decreases in the order [12]:

$$Pt^{II} > Pd^{II} > Ni^{II} > Co^{II} > Ag^{II} > Cu^{II} > Zn^{II} > Mg^{II} > Cd^{II} > Sn^{II} > Li > Na > K > Ag.$$

The stability towards acids also depends on the structure of the pigment molecule and on the conditions under which the reaction with acids takes place. Thus when sublimed layers of Zn-phthalocyanine and Zn-tetraphenylporphin are brought into contact with gaseous HCl, the former is stable [41] whereas the latter is converted into the hydrochloride of tetraphenylporphin containing no metal. In the same way, a sublimed film of Mg-phthalocyanine is stable both towards gaseous HCl and towards acetic acid, whereas in acetone solution Mg-phthalocyanine is gradually converted into metal-free pigment when HCl is added [42], and a film of chlorophyll deposited from solution is converted into pheophytin in the presence of acetic acid vapour [43].

Let us turn to the question of the structure of the reaction products formed by phthalocyanine and its stable M--derivatives with acids. Unlike other porphin derivatives, the phthalocyanine molecule has not four but eight nitrogen atoms (VIII), each of which is capable of acting as a proton acceptor. Evstigneev and Krasnovskii observed a marked displacement towards longer wavelengths of the red absorption band of metal-free phthalocyanine and Cu--phthalocyanine when these compounds were dissolved in concentrated H_2SO_4. Since this displacement was not observed in the case of chlorophyll, it was suggested that in acid medium the protons are attached not to the pyrrole nitrogens but to the peripheral N atoms of the phthalocyanine [44]. In a study of ionic equilibrium in solutions of phthalocyanines in H_2SO_4, Berezin [45,46] concluded that the solutions of both the metal-free phthalocyanine and the M-phthalocyanines contain only the cations H_2PcH^+ and $MPcH^+$, where Pc is the ligand in the M-phthalocyanine molecule; he also suggests that the proton is attached to the peripheral N atom. Comment on these conclusions is necessary.

Firstly, it is known that, when Cu-tetraphenylporphin, which is stable in this solution and has no peripheral N atoms, is dissolved in H_2SO_4, the displacement of the absorption towards longer wavelengths, characteristic of the reactions of compounds of the porphin series with acids, is observed [47]. In this case there is apparently no reason to doubt that the protons can be attached only to the pyrrole N atoms, although they are also joined to a metal atom, which creates steric hindrance for this attachment. The possibility of attachment of protons to the pyrrole N atoms in metal-free phthalocyanine is also confirmed by the possibility of H → D isotope exchange in the imino-groups in the presence of DBr.[41]

Secondly, in the reaction with gaseous HCl or HBr the M-phthalocyanine molecule may add one or more protons. Grounds for this statement are provided by the stepwise nature of the desorption of HCl from M-phthalocyanine, revealed in the associated sequence of changes in the infrared spectra of the specimens [41].

It must evidently be assumed that both the pyrrole nitrogen atoms and the peripheral nitrogen atoms of the phthalocyanine molecules may react with protic acids, depending on the conditions.

Important evidence confirming the ionic structure of the products of the reaction of phthalocyanines with gaseous HCl, HBr, and acetic acid is provided by the infrared spectra of these products [41]; absorption bands corresponding to the vibrations of the ionic NH^+ and CH_3COO^- groups can be readily identified. The ionic structure of tetraphenylporphin and tetraphenylchlorin hydrochlorides is confirmed by the presence of absorption bands [34,35] due to the NH^+ groups in their spectra.

The influence of the central metal atom in a phthalocyanine molecule on the ability of this molecule to form hydrochlorides and hydrobromides [41] is remarkable. Thus Mg-, Zn-, and Fe-phthalocyanines react with HCl to form the corresponding hydrochlorides, whereas Cu-phthalocyanine and the metal-free phthalocyanine do not react. All the above phthalocyanines react with the more active HBr molecules. We shall see later that this ability of the central metal atom to facilitate intermolecular interaction between the pigment and the medium is shown not only for HCl and HBr but also for a number of other compounds.

The salts formed by the cations of porphin derivatives are generally readily decomposed with formation of neutral molecules. Thus phthalocyanine hydrochlorides and hydrobromides are converted into neutral phthalocyanines when the specimens are heated in a vacuum to 280–300° or kept in pyridine vapour (an organic base). In concentrated sulphuric acid phthalocyanine cations are converted into neutral molecules when the solutions are diluted with water. Tetraphenylporphin and tetraphenylchlorin are also regenerated from their hydrochlorides with increase in temperature or by treatment with pyridine.

2. Complexes. Let us examine the complexes formed by compounds of the porphin series with the medium, where

the reaction of the components is not so clearly ionic as in the reaction of the pigments with strong acids and bases. Such complexes may be formed in the reaction with comparatively weak bases (aniline, pyridine, or hydrazine), NO, CO, water, and other compounds. The formation of complexes may take place in solutions or when the pigments in the solid state are brought into contact with various gaseous compounds. The process of complex formation is generally reversible.

The ability of metal derivatives of the porphin series to form complexes is much greater than that of the corresponding metal-free pigments. This is apparently due to the ability of certain metal atoms to form additional coordinate bonds as well as valence bonds and to the ability of these atoms to activate the tetrapyrrole ligand with respect to various reactions, including complex formation. The metal atoms in M-derivatives of the porphin series can be divided into three classes [12] according to their coordinating power:

1. Fe, Co, and Mn have a coordination number of 6. In the pigment molecule these atoms are combined with four nitrogen atoms and are able to combine with a further two molecules of a ligand by means of coordinate bonds. The resulting complex has the structure of an octahedron whose centre is occupied by the metal atom and whose apices are occupied by the four nitrogen atoms, joined to the metal atom, and two molecules of a ligand at right angles to the plane of the pigment molecule.

2. Mg, Zn, and Cd have a coordination number of 5 and combine with one additional molecule of a ligand. The complexes have the shape of a four-sided pyramid. The metal atom lies at the centre of the base of the pyramid, the N atoms lie at the corners of the base, and the ligand molecule occupies the fifth apex of the pyramid above the plane of the pigment molecule.

3. Cu and Ni are very weak complex-forming atoms and generally retain the coordination number 4. All free main and coordinate valencies are satisfied by the nitrogen atoms of the tetrapyrrole ring of the pigment molecule. This classification is not rigorous. It is suggested, for example, that in some cases Mg-, Zn-, and even Cu-porphyrins form complexes with an octahedral structure [26,27,48].

As expected, the stability of the complexes decreases with increase in temperature [48,51]. Moreover, it depends to a marked extent on the nature of the central metal atom. Thus direct measurements of the constants for the equilibrium between the monopyridine complexes and free molecules of M-tetraphenylporphin in benzene solution in the presence of small quantities of added pyridine showed that the stability of the monopyridine complexes decreases in the order: Zn, Cd, Hg, and Cu. It is suggested that Mg-tetraphenylporphin and Mg-tetraphenylchlorin, unlike the other metal derivatives studied, form bispyridine complexes under these conditions. On going from porphin to chlorin, there is a slight increase (compared with the change on going from one metal atom to another) in the stability of the pyridine complexes [49].

The formation of complexes by the pigment with a ligand generally leads to changes in the spectroscopic characteristics of both reacting components. These changes are observed not only in the electronic spectra but also in the vibrational spectra [52-55], in the fluorescence spectra [58], and in the photoelectric conductivity [57] of the pigments. The spectroscopic changes on complex formation are more marked, the more stable the resulting complex. They are very marked in the absorption spectra of the Fe-porphyrins, which give particularly stable complexes in their reactions with CO, pyridine, and water [12]. In these cases the appearance of the spectrum of the pigment changes completely. When less stable complexes are formed, the absorption bands are displaced with a more or less marked change in intensity [49,51,52]. Weak interaction between the components in the complex may not produce changes in the electronic spectra of the pigments capable of being recorded at the present stage of development of spectrometric technique. In this case evidence for complex formation is obtained indirectly. For example, in a study of the quenching of the fluorescence of chlorophyll and pheophytin by various oxidising agents and reducing agents it was found that in some cases quenching is observed at concentrations of the quenching agent equal to the concentration of the pigment. Further increase in the concentration of the quenching agent did not lead to an increase in quenching. This phenomenon can apparently be attributed to the formation of complexes between the molecules of the pigment and the quenching agent, although the existence of these complexes is not revealed by the electronic spectra [59].

The electronic absorption spectra of the ligands in complexes with tetrapyrrole pigments have unfortunately not yet been observed, since the pigments and solvents themselves absorb in this range. In the infrared spectra of solid films of M-phthalocyanines it has been possible to observe the absorption bands of indole, aniline, benzylamine, water [52-54], and nitric oxide [55], attached to the pigments from the gaseous phase.

There is apparently no reason to doubt that the central metal atom in molecules of the porphin type is the most probable centre at which a ligand molecule exhibiting electron-donating properties is attached in the formation of a complex. The bond formed between the central metal atom and the ligand molecule is a donor–acceptor bond. This structure for the complex is confirmed by the following evidence: (1) the complexes formed by metal-free pigments with electron-donating molecules are not so stable as those formed by metal derivatives; (2) the frequencies of the absorption bands of aniline, benzylamine, and indole in their complexes with M-phthalocyanines depend to a marked extent on the nature of the metal atom [52,53]; and (3) the magnetic susceptibility of Fe^{II}-phthalocyanine decreases on complex formation with NO, indicating pairing of the *d* electron of the Fe atom with the unshared electrons of the N atom of the nitric oxide [55].

The possibility that the ligand molecules are localised at other active centres in the structure of the pigment molecule cannot, however, be denied. These centres include particularly the pyrrole N atoms, which carry unshared electron pairs and which can therefore take part in the formation of donor–acceptor bonds, including the formation of hydrogen bonds of the type N...H–X. In the spectra of the complexes formed by indole with Mg- and Zn-phthalocyanines, in the range of the stretching vibrations of the NH bonds, it is possible to observe two absorption bands instead of the single band characteristic of free indole (solution or solid layer) [52,53]. These bands apparently correspond to complexes of different type: the comparitively narrow high-frequency band corresponds to indole molecules attached to the metal atom and the broad low-frequency band corresponds to indole molecules joined to

the pyrrole nitrogen atom by a hydrogen bond. An analogous explanation can also be given for the spectra of aniline and benzylamine, which in their complexes with certain M-phthalocyanines give more absorption bands in the range corresponding to the NH bonds than in the spectra for the liquid state[52,53]. The fact that the metal-free phthalocyanine is unable to form complexes with indole, aniline, and benzylamine does not mean that the molecules of these compounds in the complexes with M-phthalocyanine are necessarily attached to the metal atom. As already noted, the inclusion of a metal atom in the phthalocyanine molecule leads to a significant change in its properties, and groups which were previously inactive become active. Thus the metal atom activates the phthalocyanine molecule towards HCl molecules, which are undoubtedly attached not to the metal atom but to the nitrogen atom[42].

In organic solvents in the absence of moisture chlorophyll forms stable 1 : 1 complexes with the metal chlorides $FeCl_3$, $HgCl_2$, $BeCl_2$, $AlCl_3$, $BiCl_3$, $NbCl_5$, and $SnCl_2$, and also with $AgClO_4$. These complexes, whose formation leads to marked spectroscopic changes in the pigment, can be isolated from solutions in the solid form[60-62]. With the passage of time, the chlorophyll in complexes with metal chlorides is gradually converted into the corresponding M-pheophytin. This leads to the suggestion that, when the metal ion of the halide forms a complex with chlorophyll, it establishes a bond with the nitrogen atoms of the pyrrole rings, leading to the possibility of conversion of the chlorophyll into M-pheophytin[60].

Let us consider separately the reaction of phthalocyanines and chlorophyll with water. In air Mg-phthalocyanine forms a stable dihydrate[63]. A dihydrate, slightly less stable than the dihydrate of Mg-phthalocyanine, is also formed by Be-phthalocyanine[64]. The infrared spectrum of an Mg-phthalocyanine specimen kept in water vapour, in the range of the stretching vibrations of hydroxy-groups, shows an absorption band consisting of several components[54]. The characteristic isotopic displacement of this band when H_2O is replaced by D_2O and its disappearance on treatment in a vacuum at 50–100° show unambiguously that this band is due to molecules of water in a complex with Mg-phthalocyanine. Since on treatment of the specimen in a vacuum the components of this band do not disappear simultaneously from the spectrum[54], it may be assumed that the two water molecules in the Mg-phthalocyanine dihydrate are joined to the pigment in different ways. This difference is possibly due to a difference in the localisation of the water molecules in the complex. It is possible to picture a scheme in which one water molecule is coordinated to the magnesium atom via its oxygen atom. The resulting complex has a pyramidal structure in which the magnesium atom has a coordination number of 5. The second water molecule is joined to the nitrogen atoms of the Mg-phthalocyanine molecule by a hydrogen bond on the other side of the pigment molecule.

The stepwise character of the desorption of the water molecules from Mg-phthalocyanine may be given a different explanation, according to which the two water molecules are joined to the central magnesium atom to form a complex with an octahedral structure. As the water is desorbed, the Mg-phthalocyanine dihydrate is converted first into a monohydrate with a pyramidal structure and then into the anhydrous pigment. The states of the water molecules in the Mg-phthalocyanine dihydrate and monohydrate should naturally be different, leading to spectroscopic differences in the infrared range. In this interpretation, however, it is difficult to explain the extremely complex structure of the absorption band of the water joined to Mg-phthalocyanine, so that the first explanation (a difference in the localisation of the two water molecules in Mg-phthalocyanine dihydrate) is to be preferred.

Like Mg-phthalocyanine, chlorophyll adds on water molecules[1]. In this case, however, we cannot speak of the existence of hydrates with definite composition: the decisive feature is the conditions under which the reaction between chlorophyll and water takes place[29]. The infrared absorption spectrum of the water in the complex with chlorophyll depends to a marked extent on the state of the pigment. In the spectra of chloroform solutions and amorphous chlorophyll film the structureless band at 3400 cm^{-1} is similar to the absorption band for liquid water[24]. In the spectrum of a crystalline film of chlorophyll *a* the absorption band for the water, like the absorption band for water joined to Mg-phthalocyanine, consists of several components[31]. This suggests that the localisation of the water molecules is approximately the same in the complexes with chlorophyll and Mg-phthalocyanine. The absence of structure in the absorption band for water joined to chlorophyll in solutions and in the amorphous film can be attributed to the interaction with one another of the water molecules in neighbouring complex molecules. This interaction is reduced to a considerable extent when the complexes are arranged in ordered fashion in the crystalline specimens.

It is suggested that, on contact with chlorophyll, the water molecules may react with the carbonyl group of the cyclopentanone ring[65,66]. This possibility cannot be denied, but the reaction of a water molecule with the keto-group of the cyclopentanone ring is apparently insufficiently strong and does not determine the location of the molecule in the complex with chlorophyll. As in the complex with Mg-phthalocyanine, the water molecules are apparently localised at the N and Mg atoms of the chlorophyll molecule. This suggestion is confirmed by the following evidence: (1) complexes with water are formed not only by chlorophyll, but also by Mg-phthalocyanine, which has no cyclopentanone ring; and (2) although pheophytin and Cu-pheophytin, like chlorophyll, have a cyclopentanone ring, they form only comparatively weak complexes with water[24]. This cannot be attributed to the influence of the central magnesium atom on the cyclopentanone ring, since the similarity in the absorption bands of the keto-groups of chlorophyll, pheophytin, and Cu-pheophytin in the infrared range[24] shows that the influence of the metal atom on the keto-group of the cyclopentanone ring is slight. In the complexes with pheophytin and Cu-pheophytin water molecules are apparently localised at the pyrrole nitrogen atoms.

The structure of the absorption bands for water in complexes with Mg-phthalocyanine[54] and crystalline chlorophyll[31] in the range of its stretching vibrations indicates that strong distortion of the H_2O molecule takes place when it is attached to the pigment. In particular, the presence of broad components extensively displaced towards lower frequencies in the structure of these bands indicates a considerable decrease in the strength of the bonds between the H atoms and O atoms in the water molecules, that is, it indicates a partial positive charge on the H atoms in these molecules. In the green leaf this "dark" partial dissociation of the water molecule possibly precedes the fundamental photochemical step leading to complete splitting of the H_2O molecule followed by the formation of the primary products of photosynthesis.

3. Complexes with charge transfer. In some cases derivatives of the porphin series form complexes, illumination of which leads to transfer of an electron from one of the components of the complex to another. In the process the neutral complex acquires an ionic structure, whose existence, however, cannot be prolonged, since the structure is energetically unstable, and the electron is returned with the liberation of a quantum of energy in the form of heat[67]. A charge-transfer complex is detected spectroscopically by the appearance of a specific absorption band which corresponds to the transition between the energy levels characterising the complex in the neutral ground state and in the excited state with ionic structure.

The study of charge-transfer complexes of the porphin series is extremely important, since these complexes may be intermediates in various photochemical reactions of the pigments. Only preliminary work has as yet been carried out in this field, however. It has been found that etioporphyrin, tetraphenylporphin, and Zn-tetraphenylporphin in solution form 1 : 1 complexes with trinitrobenzene. The system absorbs in the region of 500 mμm, which has been attributed to charge transfer in the complex[68]. 1 : 1 charge-transfer complexes are also formed by Zn-phthalocyanine with trinitrobenzene, trinitrotoluene, and other compounds[69]. In all these cases the partners of the porphin derivatives in the complexes are typical electron acceptors, so that in the excited state the pigment molecule forms a positive ion. Since porphin derivatives are amphoteric, we may expect the existence of complexes in which electron transfer takes place from the ligand molecule to the pigment molecule. Electron-donor ligands include triethylamine and ammonia, in the presence of which the spectra of solutions of Mg-etioporphyrin II show a new absorption band, attributed to charge transfer in the complex[70]. The correctness of this interpretation is doubtful, however, since the position of this band in the spectrum (640 mμm) is the same for the complexes formed by the pigment with ammonia and triethylamine, which have quite different ionisation potentials.

4. Association. Association of the molecules of tetrapyrrole pigments with one another is observed in the solid state and in solutions. It is detected in the vibrational and electronic emission and absorption spectra.

In the solid phase phthalocyanines have a crystalline structure; two crystalline modifications, referred to as the α- and β-modifications, are known. The α-modification is less stable and on heating is converted into the β-form. The crystalline structure of phthalocyanine is clearly revealed in the vibrational[20,71,72] and electronic absorption spectra and in the photoconductivity and photoelectromotive force spectra for layers of the pigment[73]. Comparison shows that the infrared spectrum of the β-modification of phthalocyanines is richer than the spectrum of the α-modification with respect to the number of absorption bands and their relative intensity. This is apparently due to the closer packing of the phthalocyanine molecules in the β-form, leading to stronger intermolecular interaction than in the α-form. As a result of the intensification of these interactions, conversion of the α-modification into the β-modification leads to the appearance, in the spectrum of the specimen, of new absorption bands, forbidden for the α-modification. The frequency of the stretching vibrations of the NH groups in the metal-free phthalocyanine decreases in the $\alpha \rightarrow \beta$ conversion, again indicating an increase in the intensity of the intermolecular interactions, in which the imino-groups evidently take part[20]. It is suggested that in the Cu-phthalocyanine crystal (β-modification) the pigment molecule is arranged in such a way that the copper atom interacts with two peripheral nitrogen atoms of neighbouring molecules situated on either side of the plane of the given molecule[74].

Solid chlorophyll, chlorophyllide, and bacteriochlorophyll may exist in either the amorphous or the crystalline state. The spectroscopic characteristics of these states differ appreciably. Thus the red absorption band for chlorophyll *a* lies at 670–675 mμm in the spectrum of the amorphous film and at 692 mμm and 740 mμm in the spectra of the two different crystalline modifications of chlorophyll *a*[75]. Marked differences between amorphous and crystalline specimens of chlorophyll *a* are observed in the infrared absorption spectra[23,24,31]. Unfortunately, the fact that no reliable interpretation has been given for these spectra means that as yet they tell us nothing of the nature of the interaction between the chlorophyll molecules in the solid state.

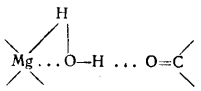
Association of chlorophyll molecules is observed not only in the solid state but also in solutions. Direct measurements of the molecular weights show that chlorophyll *a* in pure non-polar solvents (CCl_4, benzene, and chloroform) exists in the form of dimers, whereas chlorophyll *b* in benzene forms trimers. In polar solvents, or in non-polar solvents in the presence of small quantities of polar compounds, breakdown of the association complexes takes place and the pigments are present chiefly as monomers. Pheophytin does not form association complexes in either polar or non-polar solvents[26,27]. Association of the pigments leads to changes in their infrared absorption spectra. In particular, there is a decrease in the intensity of the 1700 cm^{-1} band corresponding to the vibrations of the C=O keto-group in position 9 in the cyclopentanone ring, and a new band appears at 1665 cm^{-1}§. This band has been interpreted in different ways. We can apparently reject the interpretation which relates this band to the vibrations of enolised chlorophyll molecules[23-25,30,31], since the proportion of such molecules is small under ordinary conditions (see section II). According to another viewpoint[26-28], the 1665 cm^{-1} band corresponds to the vibrations of the keto-group of the cyclopentanone ring, taking part in the formation of chlorophyll dimers according to a mechanism in which the keto-group is attached by a coordinate bond to the central Mg atom of a neighbouring pigment molecule:

(XVIII)

Vacuum drying of layers of amorphous chlorophyll, however, leads to a decrease in the intensity of the band at 1665 cm^{-1}.[65,66,76] Moreover, the intensity of this band in the spectrum of crystalline chlorophyll (in this case the band is displaced to 1650 cm^{-1}) decreases when the specimen is vacuum-treated and increases again when the specimen is brought into contact with water vapour[31]. These experimental facts are difficult to explain on the basis of the theory that chlorophyll is associated according to mechanism (XVIII). Since the increase in the intensity of the 1665 cm^{-1} band is always accompanied by a decrease in the intensity of the 1700 cm^{-1} band, the suggestion that the 1665 cm^{-1} band is due to keto-groups

§ Katz et al.[26] give for the position of this band in the spectrum the figure 1650 cm^{-1}.

perturbed as a result of intermolecular interactions is convincing. The structure of the chlorophyll association complexes in which this perturbation of the keto-groups takes place is not yet clear, however. In some cases a water molecule is apparently one of the components in the association complexes formed by the chlorophyll molecules. It may be suggested that in crystalline chlorophyll a water molecule attached to the central Mg atom of one of the pigment molecules interacts simultaneously, by means of its partially charged (positively) H atom (see section III, *2*), with the keto-group of a neighbouring pigment molecule according to the mechanism:



(XIX)

In the absence of combined water, association of chlorophyll possibly also takes place according to mechanism (XVIII). The absorption bands of keto-groups associated according to mechanisms (XVIII) and (XIX) have different positions in the spectrum: 1665 cm^{-1} and 1650 cm^{-1} respectively (when crystalline chlorophyll is vacuum-dried, the decrease in the intensity of the 1650 cm^{-1} band is accompanied[31] by its displacement to 1665 cm^{-1}).

The important part played by water molecules in the association of chlorophyll is confirmed by the fact that crystallisation of the pigment takes place only in the presence of water[1]. The ability to form association complexes with the participation of water molecules is characteristic not only of Mg-derivatives of porphin, but also of certain other M-derivatives of this class of compound. It is suggested, for example, that similar association complexes are formed in the presence of moisture in an alcoholic solution of Fe^{III}-pheophorbide[77].

In the presence of polar molecules in chlorophyll solution, the 1665 cm^{-1} absorption band disappears completely and the intensity of the 1700 cm^{-1} band increases. This is attributed to the fact that the polar molecules form coordinate bonds with the Mg atom and lead to disaggregation of the chlorophyll molecules[26]. In addition to changes in the infrared spectrum, the disaggregation of the chlorophyll in solution also leads to significant changes in the electronic spectra: there is an increase in the intensity of the luminescence, which is generally characteristic only of monomeric molecules, and an increase in the intensity of the bands in the absorption spectrum[78,79]. Similar phenomena are observed not only for chlorophyll, but also for a number of other M-derivatives of the porphin series: Mg-phthalocyanine[79], bacterioviridin[80], Ca-, Mg-, and Zn-derivatives of mesoporphyrin, and Zn- and Ca-pheophytins[81].

It was previously mentioned that pheophytin does not associate in either polar or non-polar solvents. Association of the molecules of the pigment can be brought about, however, by adding to its solution a liquid in which the pigment is insoluble. In this way it has been possible to carry out spectroscopic studies of the association of pheophytin, and also chlorophyll, chlorophyllide, and Mg-phthalocyanine in polar solvents[11,82,83]. Gradual increase in the water content of the solution leads to the formation of first dimers and then polymeric aggregates. The red absorption band at 665 mμm for pheophytin in alcoholic solution is displaced to 695 mμm when dimers are formed[82]. The formation of chlorophyll dimers under these conditions leads to a displacement of the red band by only 2 mμm (from 666 mμm to 668 mμm); the formation of chlorophyllide dimers[82] leads to a displacement of 22 mμm (from 630 mμm to 652 mμm). It is suggested[11,82] that, when pheophytin dimerises, the planes of its molecules come into contact. A result of this interaction is the marked bathochromic shift of the pheophytin absorption band on dimerisation. The association of chlorophyll takes place with the direct participation of water molecules, which, by forming coordinate bonds with the Mg atom, do not allow the pigment molecules to approach one another to distances sufficiently short for π-electron interaction. The absence of the phytyl radical from the chlorophyllide molecule makes this interaction possible, despite the presence of combined water.

As expected, increase in temperature leads to disaggregation of the pigments in solutions[82]. Conversely, decrease in the temperature of the solutions to -100° and below leads to dimerisation of chlorophyll molecules even in such polar solvents as alcohol[84,85]. The degree of aggregation of the molecules of tetrapyrrole pigments in solutions also depends on the concentration. This was shown for the trimethyl ester of coproporphyrin by NMR spectroscopy[86].

The type of interaction between molecules of the porphin type in their associates are not limited to the cases examined above. It is evident that in view of the large number of and variety of substituents in the porphin derivatives, they may form association complexes of different structures, depending on the conditions and the properties of the substituents[11].

Thus the problem of the structure of the molecular compounds formed by pigments of the porphin type, and the problem of their role in biochemical processes, are far from being solved. Further spectroscopic studies, including NMR and ESR studies, are necessary. The value of spectroscopic studies will be greatly increased if they are accompanied by kinetic measurements and by chemical analysis of the pigments and the products of their interaction with the environment.

IV. HYDROGEN EXCHANGE IN COMPOUNDS OF THE PORPHIN SERIES

Is it possible for the chlorophyll molecule to exchange its hydrogen atoms with the molecules of the medium, in particular with H_2O molecules? It first became possible to answer this question, which is of fundamental importance for an understanding of the chemical properties and sensitising action of chlorophyll in photosynthesis, when tracer methods were developed. In the molecule of chlorophyll *a* (formula **X**, *a*) all the hydrogen atoms are joined to carbon atoms, which, unlike O, N, and S atoms, do not carry a free pair of electrons in a neutral molecule. In this case hydrogen exchange with water requires a high activation energy. The latter may be decreased in the presence of a catalyst or when the molecule contains electronegative substituents which increase the lability of the hydrogen atoms[87,88] in adjoining CH bonds.

The results of the first work on isotopic exchange between chlorophyll and D_2O or T_2O did not lead to an unambiguous conclusion regarding the possibility of hydrogen exchange between chlorophyll and water[89-95]. Even when isotope exchange was detected, it was not clear whether this involved the H atoms belonging to chlorophyll itself or the H atoms of the water molecules firmly bound to the pigment[94]. The possibility of H → D isotope

exchange between chlorophyll or pheophytin molecules and D_2O molecules was established finally and unambiguously when the products of the interaction of the pigments with D_2O were analysed by infrared spectroscopy[21,43], instead of by measurement of the radioactivity or by the mass-spectrometric method previously employed[89-92]. When films of chlorophyll or pheophytin were brought into contact with D_2O vapour, their absorption spectra showed changes which could be attributed only to H → D exchange involving the hydrogen atoms belonging to the pigment molecules themselves. The nature of the spectroscopic changes taking place during exchange established that the location of the exchanging atoms is the same for the chlorophyll and pheophytin molecules. As expected, pheophytin shows deuterium exchange with the hydrogen atoms of the imino-groups[21]¶ in addition to exchange involving the labile atoms, which are also present in chlorophyll. It was found, moreover, that the nature of the spectroscopic changes in the H → D isotope exchange and hence the location of the exchanging atoms in the pigment molecules are the same for exchange[43] involving CH_3OD, D_2O, or CH_3COOD.

Unfortunately, difficulties in the interpretation of the infrared absorption spectra make it impossible to reach unambiguous conclusions regarding the location of the exchanging atoms in the molecules of chlorophyll and its analogues. The use of NMR spectroscopy has led to considerable progress towards a solution of this problem. Woodward and Škarić[17,96,97] found by NMR spectroscopy that chlorins, unlike porphyrins, are highly sensitive to electrophilic attack in the γ- and δ-positions, that is at the methine bridges adjoining the hydrogenated pyrrole ring of the pigment molecule. This property is revealed, in particular, by the fact that in the presence of CH_3COOD chlorins readily undergo deuterium exchange involving the H atoms in the γ- and δ-positions. Such exchange does not take place in porphyrin molecules. This phenomenon is evidently due to increased electron density in the γ- and δ-positions in the chlorin molecules. Theoretical calculations of the electronic structure in fact show that all the methine bridges of porphin have the same electron density deficit. In the chlorin molecule this deficit is increased in the α- and β-positions but an excess of electron density appears in the γ- and δ-positions[98].

When powerful reagents are used (CF_3COOD, D_2SO_4), isotope exchange in the methine bridges becomes possible even for porphyrin molecules[99], apparently as a result of redistribution of the electron densities in the pigment molecules in the presence of the strong acids.

Woodward's work naturally led to experiments on isotope exchange in chlorophyll and its analogues using NMR spectroscopy. These experiments not only gave independent proof of the possibility of hydrogen exchange in the chlorophyll molecule but also made it possible to solve the problem of the location of the exchanging H atoms. It was shown[32,33,100-102] that, as a result of exchange with deuteriated alcohols, the peaks in the NMR spectra of chlorophyll, pheophytin, and other analogues of chlorophyll, corresponding to the protons in the δ-position and in position 10, disappear, that is, it is in these positions that H → D isotope exchange takes place. The rates of the isotope exchange are different for positions δ and 10. The rate of exchange is also influenced to a marked extent by the presence of the central magnesium atom in the structure of the molecule[33,101]; this is evidently due to a difference in the densities of the electron clouds close to the exchanging H atoms in the molecules of the metal-free and metal-containing pigments.

According to NMR spectroscopy, in the presence of deuteriated alcohols, the H atoms of all three unsubstituted methine bridges in molecules of bacteriochlorophyll (XI) undergo exchange with deuterium[101]. In the presence of deuteriated trifluoroacetic acid, the H atoms of the three methine bridges adjoining the hydrogenated rings in the molecules of octaethylbacteriochlorin with the *cis*-arrangement of the hydrogenated pyrrole rings undergo exchange with deuterium. The rate of exchange of the H atom adjoining two hydrogenated rings is greater than the rate of exchange of the H atoms which adjoin only one hydrogenated pyrrole ring[99].

The rate of isotope exchange in the molecules of chlorophyll and its analogues depends to a marked extent on the acid or basic nature of the medium in which the exchange takes place[21,43,101,102]. More detailed studies of the dependence of the kinetics of exchange on the properties of the pigment and the medium will reveal the mechanism of the isotope exchange, which is not yet clear.

Experiments not directly related to the problems under consideration have been carried out on the biosynthesis of chlorophyll in media containing tracer atoms. It has been possible to prepare completely deuteriated chlorophyll from seaweed grown in almost pure D_2O (99.8%). The absorption spectra of this chlorophyll were recorded in the visible and infrared ranges[103]. Unfortunately, these spectra revealed nothing new for the interpretation of the infrared absorption bands of the pigment. The chlorophyll in chlorella grown in the presence of T_2O shows radioactivity which does not decrease when the chlorophyll is illuminated or treated with alcohols or alkali. The radioactivity decreases, however, when the pigment is oxidised with silver using Fischer's method, in which it is assumed that the hydrogenated pyrrole ring of the chlorophyll molecule is oxidised[104]. If this is the case, it may be concluded that the hydrogenated chlorophyll ring is unable to undergo hydrogen exchange with alcohol, alkali, or water.

V. HYDROGENATION AND DEHYDROGENATION OF THE PYRROLE RINGS IN COMPOUNDS OF THE PORPHIN SERIES

Despite the fact that chlorophyll has recently been synthesised[105-107], the route by which it is formed in the green leaf is not yet clear. It has been proved, for example, that, when etiolated leaves containing protochlorophyll are illuminated, the protochlorophyll is converted almost quantitatively into chlorophyll[1]. Attempts to reproduce this reaction under artificial conditions[108,109], and attempts to carry out the hydrogenation of chlorophyll to bacteriochlorophyll, however, have not yet been successful. In order to investigate the possibility and mechanism of hydrogenation of the pyrrole rings in the molecules of

¶ Isotope exchange in the imino-groups of molecules of the porphin series has been observed repeatedly in studies of the infrared spectra of these compounds[19,21,41]. Since, however, the ability to undergo rapid hydrogen exchange in N–H bonds is a general property of NH-containing molecules, and since there is no reason to distinguish in this connection the tetrapyrrole pigments from other NH-containing compounds, exchange in the imino-groups is not examined here.

chlorophyll and its analogues, it is natural to begin the study with the simplest compound of the porphin series.

1. Dark hydrogenation. The hydrogenation of some porphyrins has been carried out in alcoholic solutions in the presence of sodium [15,16,110-117], in a pyridine + + acetic acid mixture in the presence of zinc [117], in ether or dioxan in the presence of Raney nickel [15], and in pyridine containing hydrazine [118]. Theoretical calculations [119], chemical analysis, and comparison of the spectra of the porphyrin hydrogenation products with the spectra of compounds of known structure have established that these products are the corresponding chlorins, bacteriochlorins, and hexahydro- and octahydro-porphyrins. The reaction of chlorophyll with hydrazine in pyridine solution takes place in two stages. Spectroscopic data indicate that the cyclopentanone ring of the pigment molecule is broken in the first stage and that hydrogenation of the molecule takes place in the slower second stage, leading to the formation of the analogue of bacteriochlorophyll with neighbouring hydrogenated pyrrole rings and a closed cyclopentanone ring [118].

An important feature is that the hydrogenation of the tetrapyrrole pigments was carried out in solutions containing dissolved oxygen. The hydrogenation of tetraphenylporphin, Zn-tetraphenylporphin, and chlorophyll by hydrazine takes place readily in air but not in degassed solutions [118]. The rate of hydrogenation depends on the temperature of the solution and the structure of the pigment molecule. In particular, the reaction rates are different for the metal-free and metal-containing molecules and in the case of the latter they also depend on the nature of the central metal atom [115,117].

2. Photochemical hydrogenation. As in the case of dark hydrogenation, the photochemical hydrogenation of porphyrins in the presence of reducing agents leads to the formation of the corresponding chlorins, bacteriochlorins, and more extensively hydrogenated derivatives [120-123]. The difference lies in the mechanism of the reaction, which takes place readily in degassed solutions under illumination but which in the dark takes place only in the presence of dissolved oxygen (as shown by experiments with tetraphenylporphin, Zn-tetraphenylporphin, and chlorophyll [118]). It may be assumed that the dark hydrogenation is possible only in the presence of molecular complexes formed by the pigment or reducing agent with oxygen, whose formation decreases the activation energy for the introduction of additional H atoms into the pigment molecule. The photochemical hydrogenation evidently involves an optically excited state of the molecule [120], in which the molecule becomes active in the absence of oxygen.

It has already been pointed out that in experiments *in vitro* it has not yet been possible to carry out the hydrogenation of the pyrrole rings of protochlorophyll and chlorophyll without changing the structure of the remainder of the molecule. The assumed formation of the analogue of bacteriochlorophyll with the *cis*-arrangement of the hydrogenated pyrrole rings by the action of hydrazine on chlorophyll [118] is accompanied by irreversible rupture of the cyclopentanone ring of the pigment molecule. It was recently found that, when a concentrated degassed alcoholic solution of chlorophyll containing phenylhydrazine is illuminated, the main absorption bands of the pigment are displaced towards shorter wavelengths [124]; this is analogous to the displacement observed on going from chlorin to bacteriochlorin with the *cis*-arrangement of the hydrogenated pyrrole rings [15,119]. The spectrum of the original chlorophyll is regenerated when the solution is brought into contact with air [124]. It may be assumed that this reaction leads to the formation of the *cis*-isomer of bacteriochlorophyll with a closed cyclopentanone ring, which is insufficiently stable and is oxidised to the original chlorophyll on contact with atmospheric oxygen.

If the properties of the medium are close to those characteristic of green plants, it is possible to select conditions under which protochlorophyll undergoes photochemical reduction to chlorophyll [109]. It is believed that appropriate selection of the medium will make it possible to carry out the further hydrogenation of chlorophyll to bacteriochlorophyll with the *trans*-arrangement of the hydrogenated pyrrole rings, which is characteristic of this pigment. This hydrogenation apparently takes place when the water-soluble "667 protein chlorophyll" is illuminated, leading to a decrease in the intensity of the absorption bands of the original pigment and the production of new bands [125] at 362, 567, and 743 mμm, closely resembling the bands due to natural bacteriochlorophyll.

As in the case of dark hydrogenation, the ability to undergo photochemical hydrogenation depends to a marked extent on the structure of the pigment molecule. For example, illumination of Zn-tetraphenylporphin in the presence of reducing agents leads to its ready conversion into dihydro- and tetrahydro-derivatives [118,120], whereas photochemical hydrogenation of metal-free tetraphenylporphin and tetraphenylchlorin does not take place under the same conditions [34,35].

3. Dehydrogenation of chlorins and bacteriochlorins. The hydrogenation of the pyrrole rings of tetrapyrrole pigments is reversible: the action of oxidising agents under suitable conditions may lead to the conversion of bacteriochlorins into chlorins and of chlorins into porphins. This change can be carried out in the dark or photochemically. For example, unsubstituted chlorin is dehydrogenated to porphin when its solutions are heated in the presence of various quinones [126]. Metal derivatives of chlorin and bacteriochlorin are dehydrogenated much more rapidly than the metal-free pigments [16,126]. Dehydrogenation of bacteriochlorins takes place more readily than the dehydrogenation of chlorins. For example, the *cis*-isomer of octaethylbacteriochlorin is converted immediately into octaethylchlorin by treatment with mineral acids [16], and tetraphenylbacteriochlorin is oxidised to tetraphenylchlorin even by passage through a chromatographic column of talc.[15]

The photochemical dehydrogenation of chlorins by quinones apparently takes place when the pigment molecules are in an optically excited triplet state [119,121,127-129].

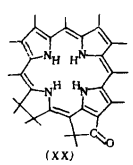
VI. REVERSIBLE PHOTOCHEMICAL REDUCTION OF COMPOUNDS OF THE PORPHIN SERIES

From the time of Krasnovskii's discovery (1948) of the reversible photochemical reduction of chlorophyll [8,130], this reaction has been extensively studied. In particular, it has been established that this reaction is characteristic not only of chlorophyll, but also of many other compounds of the porphin series, and that the final result of the photoreduction is the attachment to the pigment molecule of two or more H atoms which can be readily removed in the presence of an oxidising agent, or even without oxidising

agents, with the regeneration of the original pigment molecule. Up to the present, however, no agreement has been reached regarding the molecular structure of the products of the photoreduction of chlorophyll and other tetrapyrrole pigments. Without going into questions of the mechanism of photoreduction (the formation of primary and secondary photoreduced forms, the influence of the properties of the medium, the part played by complex formation in photoreduction, the influence of the structure, particularly of the central metal atom, on the ability of the pigment molecule to undergo photoreduction, and other topics), we shall concentrate attention in this section on the molecular structure of the photoreduced forms of compounds of the porphin series.

For the red photoreduced form of chlorophyll, Rackow and König proposed a structure in which, as a result of the photoreaction, one H atom is attached to one of the central N atoms and the second is attached to the cyclopentanone ring of the pigment molecule so that the C=O keto-group of the cyclopentanone ring is converted into a C–O–H carbinol group [131]. Serious objections to this structure can be put forward, however. Firstly, the ability to undergo photoreduction is shown not only by chlorophyll but also by a whole series of other tetrapyrrole pigments which do not contain a cyclopentanone ring. Secondly, the infrared absorption band corresponding to the stretching vibrations of the C=O group of the cyclopentanone ring in pheophytin does not disappear from the spectrum after photoreduction of the pigment [132], as would have been expected if the keto-group had been converted into a carbinol group.

Sidorov and Terenin [132] were able to isolate the photoreduced form of pheophytin from solution and to measure its infrared absorption spectrum. On the basis of the spectroscopic data obtained, they proposed the following structure (XX) for the photoreduced form of pheophytin:

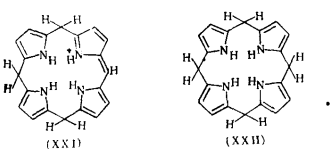


(XX)

Objections to this structure were also put foward, since it was shown that in the photoreduction of mesoporphyrin and tetraphenylporphin the degree of luminescence polarisation of the pigment increases, and this usually corresponds to a decrease in the symmetry of the structure of the luminescent molecules [133,134]. The molecule with structure (XX), however, has a higher symmetry than that of the original pheophytin molecule. Infrared spectroscopy cannot yet give us sufficient information to resolve unambiguously the problem of the structure of the photoreduced porphins. There is also insufficient foundation, however, for the objections to structure (XX) on the basis of polarisation measurements. The molecules of the reduced pigments show an increased tendency to form complexes with the molecules of the medium, leading to appreciable perturbation of the electronic structures of the interacting molecules [122]. These perturbations can undoubtedly lead to breakdown of the symmetry of the molecules and hence to an increase in the degree of luminescence polarisation. From this follows that a high degree of luminescence polarisation, indicating low symmetry of the electronic structures, does not provide sufficient grounds for excluding the possibility of high symmetry for the atomic configurations of the molecules of the photoreduced forms.

On the basis of recent data, it may be suggested that on photoreduction different compounds of the porphin series give products with different molecular structures or, in other words, that the location of the H atoms attached as a result of the photochemical reaction is different for different tetrapyrrole pigment molecules [35,123,135]. The following main classes of porphin molecule can be distinguished, depending on the structure of the photoreduced forms: porphyrins, chlorins, metal derivatives of the porphin series, and phthalocyanines. The number of these classes apparently does not limit the number of possible structures for the photoreduced forms.

Most workers at present ascribe to the molecules of the photoreduced forms of porphyrins a structure of the phlorin type (XIII) [34,97,123,136,137]. The photoreduction of porphyrins often does not stop at the attachment of only two H atoms but proceeds further, leading to the formation of tetrahydro- and hexahydro-porphyrins. According to Mauzerall [136], the latter have the structures of porphomethene (XXI) and porphyrinogen (XXII) respectively:



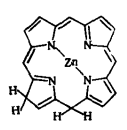
(XXI) (XXII)

In a study of the properties of various compounds of the porphin series, Gurinovich concluded that the introduction of substituents in the pyrrole rings (positions 1–8) in porphin makes the photoreduction of the pigments more difficult. Tetrabenzoporphin and phthalocyanine do not undergo photoreduction under conditions in which other porphin derivatives are fairly readily reduced [133,138]. This fact, the polarisation studies discussed above [133,134], and certain general chemical considerations led to the suggestion that in the photoreduction the H atoms are attached not to methine bridges, where substitution does not reduce the reactivity of the pigment with respect to photoreduction, but to the pyrrole rings. In the process the two H atoms are attached not to a single pyrrole ring, as in the case of the hydrogenation of porphin to chlorin, but to two rings, with a corresponding redistribution of the double bonds in the molecule [133,134,138,139]. Without denying that hydrogenation of the pyrrole rings is possible in principle in the photoreduction of compounds of the porphin series, one must point out some unsatisfactory features of the arguments put forward in support of this photoreduction mechanism. It is natural that pigments with different structures should have different reactivities with respect to photoreduction under identical conditions. The fact that tetrabenzoporphin and phthalocyanine do not undergo photoreduction under the usual conditions for this reaction does not mean that these pigments cannot be reduced under any conditions. For example, Mg-phthalocyanine gives a photoreduced form under certain conditions [8]. It is then difficult to imagine that the reduction takes place at the pyrrole rings, which in the phthalocyanines are fused with benzene rings.

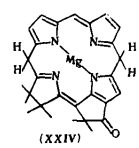
The infrared absorption spectra indicate that the structures of the photoreduced forms of tetraphenylporphin and tetraphenylchlorin differ significantly [34,35]. The photoreduction of tetraphenylporphin leads to the appearance of

an absorption band in its spectrum at about 2600 cm^{-1}, which can be assigned to the stretching vibrations of the newly-formed C–H bonds. This absorption band is not observed in the photoreduction of tetraphenylchlorin. The infrared spectrum of the photoreduced form of tetraphenylchlorin resembles in many respects the spectrum of its hydrochloride. This leads to the idea that, like the protons in the formation of the hydrochloride, in the photoreduction of the tetraphenylchlorin molecule the H atoms are attached to its two central N atoms. In other words, the molecule of the photoreduced form of tetraphenylchlorin has a structure analogous to that proposed for the photoreduced form of pheophytin (XX). The most probable structure of the photoreduced form of tetraphenylporphin is the phlorin structure. Whether this difference is general for all porphyrins and chlorins is an open question. It is believed that differences should exist in the structures of the photoreduced forms of metal-free pigments and their complexes with metals.

Seely and Talmadge [123] consider it improbable that in the photoreduction of M-derivatives of the porphin series the H atom is attached to a central nitrogen atom joined to the M atom. For the photoreduced form of Zn-porphin, they proposed the structure (XXIII), assuming this to be one of the intermediate forms in the conversion of Zn-porphin into Zn-chlorin. There are as yet no direct experimental facts confirming or refuting structure (XXIII) proposed for the photoreduced form of Zn-porphin. It may, however, be held that this form is not necessarily an intermediate in the conversion to Zn-chlorin. This is indicated by the absence of an intermediate photoreduced form in the photohydrogenation of Zn-tetraphenylporphin to Zn-tetraphenylchlorin in the presence of benzoin or hydrogen sulphide [120-122], although it is known that under illumination in the presence of hydrazine Zn-tetraphenylporphin gives a photoreduced form [122] similar to the photoreduced form of Zn-porphin. It must apparently be assumed that the photohydrogenation of porphins to chlorins may take place without the formation of an intermediate reduced form similar to the photoreduced form of Zn-porphin and Zn-tetraphenylporphin. The photoreduced forms of M-derivatives of porphin, which show an increased reactivity, may undergo various changes depending on the conditions. Chlorins are only one of the most stable final products of these changes.



(XXIII)



(XXIV)

After comparing the spectra of the photoreduced form of ethyl chlorophyllide *a* with the spectra of biliverdin and mesobiliviolin, Seely and Folkmanis [135] concluded that the molecule of photoreduced ethylchlorophyllide does not contain a ring of conjugated bonds covering more than two pyrrole rings. On this basis the photoreduced form of ethyl chlorophyllide was assigned the structure (XXIV) with two hydrogenated methine bridges in the β- and δ-positions. According to the suggestion of Seely and Folkmanis, the photoreduced form of pheophorbide (metal-free chlorophyllide) has two spectroscopically different tautomeric structures: the phlorin structure and a structure similar to structure (XXIV).

To summarise this section, it may be concluded that there are as yet insufficient experimental data for a final solution of the problem of the structure of the photoreduced forms and that all proposed molecular structure schemes are to some extent hypothetical. Further progress in the determination of these structures requires the continuation of systematic spectroscopic studies of the photoreduction of compounds of the porphin series, accompanied by kinetic measurements and chemical analyses.

I. INTRODUCTION

The organic chemistry of the transition metals is a new, rapidly developing branch of chemistry, which already forms the subject of hundreds of investigations, and a large number of complexes of different types have been prepared. Following the discovery of ferrocene and other metallocenes there was the discovery of the analogously constructed sandwich bisarene complexes, cyclopentadienylcarbonyl and arenecarbonyl complexes were obtained, and from about 1957 the area was considerably extended owing to the use of a wide range of alkenes, both cyclic and acyclic. The existences of complexes containing alkenes from ethylene to tropylene suggests that from two to seven carbon atoms from a single molecule can be bonded simultaneously with a metal atom. The best combinations of ligands in such complexes, which make them the most stable, are the combinations of alkenes with CO groups, phosphines, amines, sulphides, acetylacetone, or simple electronegative atoms, such as halogen. Recently, purely alkene complexes have also been obtained and shown to be considerably less stable than the mixed complexes. It was found that all transition metals — without exception — are able to form π-complexes with alkenes. Usually the Dewar–Chatt scheme [1,2] is employed to explain the structure of these compounds. Several reviews and monographs devoted to this field have appeared, among which can be recommended the reviews of Wilkinson and Cotton [3] and Dyatkina [4] on the cyclopentadienyl and arene complexes, Nesmeyanov and Perevalova [5] and Rausch [6] on ferrocene chemistry, Bennett [7], Guy and Shaw [8], the monograph of Fischer and Werner [9] on alkene and alkyne π complexes of the transition metals, the review of Treichel and Stone [10] on fluoroalkyl derivatives of metals. The review article of Fritz [12] is devoted to spectroscopic results, and the theoretical side of the problem has been stated in the books by Orgel [13] and Ballhausen [14], both of which have been published in Russian.

Simultaneously with the study of the conditions for the formation of π complexes many of the conditions for the formation and stabilisation of covalent σ-bonded derivatives of the transition metals were found and although the problem of the carbon–transition metal bond has not been solved completely, the empirical data which have been accumulated allow some conclusions to be drawn. Besides the preparation of many mixed complexes which include a σ-bound organic group, the conditions for the σ derivative →

→ π complex transition and the reverse are now known. A repeat study of some structures showed that in several instances where the π complex structure has been proposed earlier, actually there is the addition of metal to a system of double bonds of the Diels–Alder type and the bonding with the organic molecule is effected by one π and two σ bonds. A large group of fluorocarbon σ complexes of various types has been obtained. Besides comparatively old reviews, a book [15], and Cotton's review [16], the material on the σ-bonded derivatives of the transition metals has not been surveyed. The review we offer is an attempt at such a survey and embraces the literature up to December 1964. The tables do not exhaust the available information, but only illustrate it.

II. THEORETICAL PREMISES

The problem of the transition metal–carbon covalent bond remained an enigma for a long time. As is well known, the hydrocarbon σ derivatives of most transition metals are almost impossible to isolate in a pure state; they are unstable, exist only at low temperatures, are sensitive to oxygen and atmospheric moisture. The latter is inherent, however, in an alkyl derivative of certain non-transition metals, for example, the alkali metals, but is not characteristic of derivatives of Hg, Sn, Pb, etc. Furthermore, the alkyl derivatives of the main groups have a considerably better thermal stability than their transition metal analogues.

The strength of a covalent bond depends on the extent of the overlap of the valence orbitals of both atoms. The instability of the covalent derivatives of the transition metals is connected with insufficient overlap of the completed 3*d*, and also the 4*s* and 4*p* orbitals of the metal in the first transition series with the typical σ orbitals of the ligands, owing to the small dimensions of these orbitals of the metal. Confirmation of the correctness of this conclusion is provided by the fact of the formation of alkyl derivatives of metals with *d* orbitals of the largest dimensions. However, it was acknowledged that the difference in the size of the overlap integrals is not very great and possibly the difficulty of obtaining these compounds is explained, not by their thermodynamic instability, but by their high reactivity. If that is so, when the covalent bond is formed as a donor–acceptor bond, the great strength of the bond facilitates a greater polarisability of the donor molecule and the great affinity of the acceptor ion for an electron. With increase in the charge on the metal ion, its electronegativity, within the limits of a single period of the Periodic System, and also the polarisability of the ligand, the covalency of such ordinary bonds should increase [13].

The transition metal–carbon bond can be either a simple ordinary bond or a bond of multiple character. Carbonyls, cyanides, etc. are examples of comparatively stable and long-known carbon derivatives of the transition metals. The order of the metal–carbon bond in the compounds of these classes is greater than unity, thanks to additional overlap of symmetry-suitable filled orbitals of the metal and free orbitals of the ligand. Fig. 1 shows the different ways of representing the increase in the multiplicity of the metal–carbon bond in carbonyls.

The additional overlap is termed a π bond or dative component of the bond. Usually π bonding, and consequently the formation of bonds of significant multiplicity is an

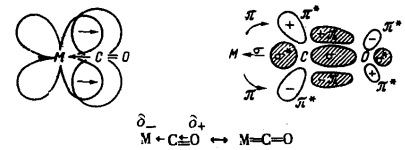

Fig. 1. Different methods of representing the increased multiplicity of the metal–carbon bond in metal carbonyls.

ability of an electronegative atom in the vicinity of carbon, such as oxygen in carbonyls, nitrogen in cyanides, etc. In explaining the properties of the derivatives of transition metals, the π component of the bond plays an important part. The excess of negative charge is removed from the metal with its aid to the ligand and double-bond character appears, which in total leads to the strengthening of the bond and increases the stability of the molecule as a whole. Actually, without such an assumption of reverse transfer of electrons from the metal to the ligand it would be difficult to understand why in the majority of their most stable derivatives transition metals have an electron configuration of a noble gas, that is, they receive from 8 to 15 electrons, which generally is not characteristic of metals. The reverse transfer does not occur with simple alkyl derivatives, since they do not have low-lying free orbitals. Furthermore, the establishment of a cyclic configuration due to σ groups alone is evidently impossible from even steric considerations.

All this does not explain, however, why the alkyl derivatives of transition metals should be less stable than the alkyl analogues with non-transition metals and why just carbon is so poorly bonded with the transition metal. As will be shown below with the help of experimental data, the transition metals can under certain conditions form stable σ bonds with carbon. In such molecules, in addition to the σ bound group stabilising ligands are present — carbonyl, phosphine, cyanide, or cyclopentadienyl groups. These mixed complexes are often very stable and represent a contrast to the extremely unstable simple organic derivatives of the MR_n type.

Chatt and Shaw [17,18] consider that the peculiarity of the transition metals is that the *d* orbitals of the penultimate layer are energetically close to their *s* and *p* valence orbitals. This creates the possibility of easy transition of non-bonding electrons from the higher occupied *d* orbital to the antibonding orbital of the metal–carbon bond. When the *d* orbital is vacant then the reverse transition from the orbital of the metal–carbon bond to this vacant orbital is possible. One or the other should weaken the M–C bond, the transfer of electrons is the first stage in the rupture of this bond. Fig. 2 shows the scheme of the energy levels of the vacant and occupied orbitals of the metal atom. To form a stable complex the energy difference of the highest occupied and the lowest vacant orbital ΔE should be greater than some critical value. Chatt and coworkers made several alkyl and aryl derivatives of the metals of Group VIII, stabilised by tertiary organic phosphines. The authors connect the stabilising role of the ligands with the fact that their addition to the metal allows ΔE to be increased. This is brought about by the formation of a strong dative bond with the metal as the result of the involvement of the non-bonding electrons of the highest occupied level in the formation of a bond with this ligand

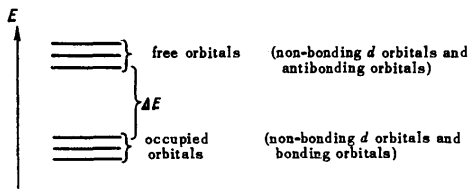

Fig. 2. Suggested condition of stability of covalent organic derivatives of the transition metals.

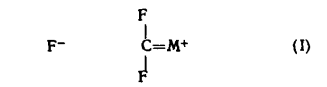
which leads to the lowering of the level, that is, to an increase in ΔE. In square-planar and octahedral complexes the stabilising influence of such ligands is greater than in tetrahedral. With the heaver transition metals the splitting of the orbitals is greater than in the lighter ones and there is a greater capability to form dative bonds. Therefore the heavy metals should give more stable organic σ derivatives, which is what occurs in reality. This is the reverse of what is observed for all the other elements of the Periodic System, where the heaviest element in each subgroup forms the least stable organic derivatives. The zinc group is an exception, where there is no true relationship: the mercury derivatives are thermally more stable, but the chemical reactivity is completely the reverse. Chatt considers that in the zinc group there is still a shade of transition metal character.

The cleavage of the metal–carbon bond is irreversible and it is evident, therefore, that as a result a very active particle is produced — a radical or carbanion. Unlike this, the metal–halogen bond, for example, can be broken reversibly since the halide anion is stable and can exist until it is possible for the broken bond to be reformed.

Behaviour towards oxygen and moisture, that is, towards chemical reaction, also enters into the concept of stability — which is generally not very definite. Apparently, complexes which have available free or only partly occupied orbitals will be sensitive to nucleophilic attacks.

Jaffé and Doak [19] calculated the bond energy in alkyl and aryl derivatives of transition metals and drew the following conclusions about the reasons for the instability of these compounds: (1) the bonds with transition metals have only one-third of the energy of ionic resonance which makes stable the alkyl derivatives of the alkali metals, (2) they have only one-half of the covalent energy which makes stable bonds with all the other elements. The aryl σ derivatives are somewhat more stable than the σ alkyl derivatives. This is due to the increase in the s character of the bonds formed by the sp^2 orbitals in comparison with the sp^3 orbitals, which is favourably reflected in the ionisation potential, the overlap integral, and the ionic resonance energy of the M–C bond, and also the large electronegativity of the sp^2 orbitals of carbon compared with the sp^3 orbitals. The same conclusions are drawn in respect of the vinyl and ethynyl derivatives and are also confirmed experimentally.

Starting from Jaffé and Doak's conclusions that the instability of the simple transition metal–carbon bond can be linked with the low ionic resonance energy, a group of investigators [20,21] concluded that σ-bound fluorocarbon derivatives of the transition metals should exist. The effective electronegativity of the CF_3 group is ~ 3.3 on the Pauling scale and is situated between those for fluorine (4.10) and chlorine (3.0) [22]. The effective electronegativity of the C_6F_5 group is approximately equal to that for bromine (2.8). Therefore the ionic character of the metal–carbon bond should increase on going from hydrocarbon to fluorohydrocarbon derivatives. And although fluoroalkyls — like alkyls — cannot participate in π bonding, the metal–fluoroalkyl bond should be considerably more stable. The bonding electrons of such bonds are drawn out towards the fluorocarbon group, decreasing the charge on the metal. The spectroscopic data for them confirm the essential importance of structure (I):



(I)

The preparation of a large number of fluorocarbon derivatives of different type, the ease with which they are obtained, and the stability (both thermal and chemical) of most of them confirms the general correctness of the premises.

Hence the stability of a complex depends on various factors, the influence of which is not always understood and cannot *a priori* be predicted and explained. We will turn therefore to the experimental data, classified according to the groups of the Periodic System. Fluorinated σ complexes will be considered in parallel.

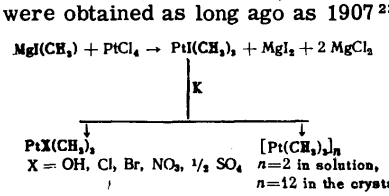
As a review on a similar theme by Razuvaev and Latyaeva was recently published [11], which described in detail the chemistry of organotitanium compounds†, we exclude Group IV from consideration. The copper subgroup is also not considered here, as there is already a sufficiently complete review [15].

III. EXPERIMENTAL DATA

1. Group VIII

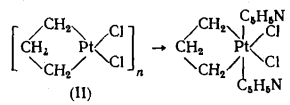
Platinum, palladium, nickel. In addition to the comparatively stable alkyl derivatives of platinum of composition $PtXR_3$, PtR_4, $[PtX_2R_2]_n$, the following types of mixed complexes have been obtained for this group of metals: $PtX_2R_2L_2$, $MXRL_2$, MR_2L_2, MXR_fL_2, and $MR_f{}_2L_2$, where M = Pt, Pd, Ni; L is a unidentate ligand of the organic phosphine type; X halogen; R alkyl or aryl; R_f a fluorocarbon radical; Ni-(π-C_5H_5)R(PR_3), Ni-(π-C_5H_5)R_f(CO), $K_2M(C{\equiv}CR)_4$, and $K_2M(C{\equiv}CR)_2$ for all three metals. A systematic comparison of the stability was made for the example of square-planar phosphine complexes MR_2L_2, and it was shown that their stability varies in the order: $NiR_2L_2 < PdR_2L_2 < PtR_2L_2$.

The platinum(IV) alkyl derivatives are the most stable of the known transition metal alkyl derivatives. The first of these, iodotri(methyl)platinum(IV), and some of its derivatives were obtained as long ago as 1907 [23,24].



† The review mentioned [11] covers the covalent organometallic compounds of the transition metals of Groups IV–VIII (Ed. of Translation).

Subsequently, in the repetition of this work[25-27], in addition to iodotri(methyl)platinum(IV) and tetramethylplatinum(IV), diiododi(methyl)platinum(IV), triiodo(methyl)-platinum, etc. were isolated. There are also other paths for obtaining iodotri(methyl)platinum(IV), for example, the alkylation of tetrachloro-dipyridino-*cis*-platinum(IV) with a Grignard reagent[28] or the reaction of methylmagnesium iodide with Zeise's salt‡ or with Na_2PtCl_4 in the presence of an excess of methyl iodide[2,29]. Gilman and coworkers found[25,26] that tetramethylplatinum(IV), isolated originally as a side-product, can be obtained satisfactorily from iodotri(methyl)platinum(IV) and methylsodium. It is crystalline and without a definite melting point or decomposition temperature. Tetramethylplatinum, etc. are of special interest because of their tetrametric structure[30], which is shown in Fig. 3. The bridge function of the methyl groups is unusual, although also not unprecedented. Halogen, sulphur, or phosphorus atoms, which have free electron pairs, are most often encountered in such a role. The formation of the tetramer, and also the solvation and association in solutions reflect the coordination unsaturation of the platinum atoms and the tendency to add on more than four groups. In these compounds, and also in alkylacetylacetonatomethylplatino and similar dimers[31-34] platinum tends to become 6-coordinate. Unlike these complexes, cyclopentadienyltri(methyl)platinum(IV) is monomeric[35]. Chatt and coworkers isolated the polymeric trimethyleneplatinum complex(II) from the reaction between H_2PtCl_6 and cyclopropane[36]. The polymerisation is effected by means of halogen bridges, as was confirmed by the breaking down of the polymer with amines. Phosphines replace the trimethylene ligand, both in the polymeric complex and in the pyridine-containing monomer.

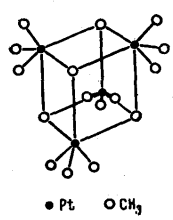


(II)

Platinum(IV) derivatives are also obtained by addition of alkyl halide to certain platinum(II) complexes or by oxidation of the latter with halogens[17]:

$$PtI(CH_3)(PR_3)_2 + CH_3I \rightarrow PtI_2(CH_3)_2(PR_3)_2,$$
$$Pt(CH_3)_2(PR_3)_2 + Cl_2 \rightarrow PtCl_2(CH_3)_2(PR_3)_2.$$

σ-arylphosphine complexes are obtained similarly. Derivatives of the $PtAr_4$ type have not been obtained pure, although there are indications that a mixture of phenyl derivatives is formed in the reaction of $PtCl_4$ with bromo(phenyl)magnesium[27].



• Pt ○ CH_3

Fig. 3. Structure of tetramethylplatinum, after Rundle[30].

‡ $K[PtCl_3(C_2H_4)]$ (Ed. of Translation).

The simplest platinum(II) derivatives PtR_2 are unknown, but platinum(II) complexes are easily alkylated, giving stable crystalline square-planar complexes, which exist as *cis*- and *trans*-isomers[17,37]:

$$PtX_2(PR_3)_2 + 2MgXR' \text{ or } 2LiR' \rightarrow PtXR'(PR_3)_2 \text{ or } PtR'_2(PR_3)_2.$$

The alkyl groups of such complexes are detached by the action of acids or salts like magnesium iodide[17]. Analogous aryl and ethynyl complexes are obtained which are usually more stable than the alkyl complexes.

Halogeno(alkyl)phosphine complexes of platinum and palladium are known to undergo the reaction termed carbonylation, in which CO from the gas phase is inserted at the R–M bond[38]. This interesting reaction, characteristic of many complexes, will be considered in detail below. In the present example, typical acyl derivatives capable of the reverse, decarbonylation, with recovering of the initial substance, are obtained.

As is well known, the reaction of platinum derivatives with alkynes leads to the formation of π complexes of the Zeise's salt type, where acetylene is present instead of ethylene. Such a structure is confirmed by the infrared spectra, in which there are frequencies of coordinated triple bonds, and also the regeneration of acetylene as a result of various effects. Perfluorobut-2-yne is an exception, and is reported[39] to add on by two σ bonds, giving (III):

(III)

Yet another type of alkyne derivative of platinum, palladium, and nickel is obtained — acetylido-complexes, for example, $K_2Pt(C{\equiv}CR)_4$, which are non-explosive, diamagnetic complexes, which on reduction give pyrophoric $K_2Pt(C{\equiv}CR)_2$, readily oxidised to tetraalkynylplatinates[40].

The simplest organic derivatives of palladium and nickel have not been described although attempts to obtain them have been made[16] and there is indirect confirmation of their existence. Just as for platinum, square-planar mixed complexes of composition MR_2L_2 or $MXRL_2$ are characteristic for palladium, where R can be alkyl, aryl, or ethynyl[41]. For nickel, only aryl and ethynyl derivatives have been obtained[42,43]. Only the *trans* forms of these Pd and Ni complexes have been isolated. Aryl derivatives of nickel exhibit moderate stability with the exception of those whose aryl groups have *ortho*-substituents. For example, $[NiBr\{2,4,6\text{-}(CH_3)_3C_6H_5\}\{P(C_2H_5)_3\}_2]$ sublimes in the atmosphere at ~ 160° at normal pressure.

The general theory of stability and the stabilising effect of some ligands were considered above. Fig. 4 shows the splitting of the levels of the *d* orbitals in planar complexes of type d^8 analogous to the organometallic derivatives being considered[44]. The stability of these complexes thus depends on the difference in the energy of the least stable $d_{x^2-y^2}$ orbital and d_{xy} orbital lying in the plane of the molecule. Evidently in alkyl phosphine derivatives of nickel, the splitting of the *d* levels is insufficient to stabilise them and the necessary value is reached only in aryl complexes. Unsubstituted phenyl groups are capable of free rotation around the metal–carbon bond; in this, their π orbitals overlap with the d_{xy}, d_{xz}, and d_{yz} orbitals, somewhat lowering all these levels and increasing ΔE the more so. In this way the metal–phenyl bond acquires some degree of multiplicity, making worse the mesomeric electron displacement from the metal to the phenyl group.

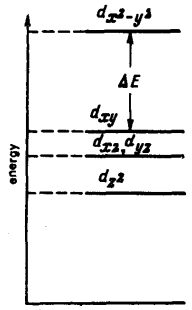


Fig. 4. Scheme of energy levels of the *d* orbitals for square planar configuration.

This makes them more stable in comparison with the alkyl derivatives. With *ortho*-substituted aryl derivatives, bulky substituents prevent free rotation, the aryl group is held in the plane perpendicular to the plane of the complex. In that position the π orbital of the aryl group should react preferentially with the d_{xy} orbital, hence ΔE will be greater than when there is free rotation. The increase ΔE prevents the thermal dissociation of the complex, leading to breaking away of the free radical and the screening of the metal atom by the ortho-substituents hinders the attack by chemical reagents. *Meta*- and *para*-substituted aryl complexes are analogous to the unsubstituted phenyl and — depending on the substituent — somewhat increase or decrease ΔE.

All these complexes are obtained from metal halogeno--complexes and Grignard reagents or alkyllithiums, some of which are shown in Table 1.

A recent paper by Yamazaki and Hagihara[45] describes the production of the first σ alkyl complexes of nickel which contain π-cyclopentadienyl and phosphine groups in the molecule:

$$NiCl(\pi\text{-}C_5H_5)P(C_6H_5)_3 + MgIR \rightarrow NiR(\pi\text{-}C_5H_5)P(C_6H_5)_3,$$

where R = CH_3, C_2H_5, C_6H_5, C≡CH, etc. The least stable of these are again those with alkyl groups. They are all comparatively difficult to decompose by heating, but the solutions are unstable, especially in air. It is interesting to note that attempts to obtain $NiR(C_5H_5)(CO)$ did not give a positive result, although the formation of a labile non--isolable methyl derivative was proved spectroscopically.

Hence the combination of π-cyclopentadienyl and phosphine is so effective that it allows stable alkyl derivatives of nickel to be obtained.

The high electronegativity of R_f groups is due to the pseudo-halogen nature of the perfluoroalkyl iodides. In

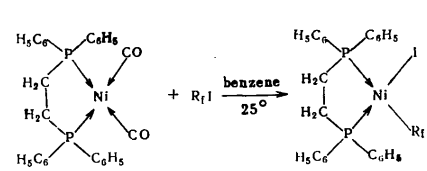
* Because of the number of complexes involved, no attempt has been made to rearrange the formulae in the tables into the IUPAC form (Ed. of Translation).

relation to the transition metals this is expressed in their ability to displace some of the carbonyl groups or carbonyl complexes from carbonyls or carbonyl complexes just as elemental iodine does. This reaction, which occurs under exceptionally mild conditions, is one of the methods of making perfluoroalkyl derivatives of transition metals (Method A). McBride and his coworkers[46] used it for nickel; they obtained iodo(perfluoroalkyl)nickel complexes containing the desired diphosphines, as diamagnetic crystals with a square-planar arrangement of the ligands — examples of complexes in which the effective atomic number rule is not obeyed. Nevertheless they are stable substances, with decomposition temperatures > > 200°, which is very remarkable considering that the analogous alkyl derivatives are incapable of existence:



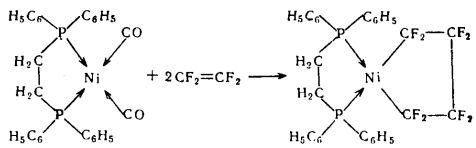
The perfluoroaryl complexes $NiAr_{f2}(PR_3)_2$ and $NiXAr_f.(PR_3)_2$ are stable even in solution[47]. Many of them

melt without decomposition and can be melted a second time.

Dimeric cyclopentadienylcarbonylnickel also decomposes readily under the action of perfluoroalkyl iodides, to form cyclopentadienylperfluoroalkylcarbonyl complexes[48]:

$$[Ni(C_5H_5)(CO)]_2 + R_fI \xrightarrow[25^\circ]{\text{benzene}} Ni(C_5H_5)R_f(CO) + NiI(C_5H_5)(CO).$$

Carbonyls and carbonyl complexes of some metals react with perfluoroethylene, some of the carbonyl groups being replaced. The expected π complexes are not formed, however, but σ heterocycles with the metal atom in the ring. This is one of the methods of obtaining stable perfluorinated σ derivatives of nickel, cobalt, and iron (Method B)[49]:



Single examples of perfluoroalkyl derivatives of platinum and palladium are known. Thus in the treatment of bipyridyldimethylpalladium with perfluoropropyl iodide replacement of one or both of the methyl groups occurs[50]:

$$Pd(C_{10}H_8N_2)(CH_3)_2 + CF_3CF_2CF_2I \xrightarrow[20^\circ]{\text{tetrahydrofuran}} Pd(C_{10}H_8N_2)(C_3F_7)_2.$$

There is a reference to the bis(perfluoroethyl)platinum complex $Pt(C_2F_5)_2\{P(C_2H_5)_3\}$ obtained by the addition of perfluoroethylene to a fluoro-complex in hydrogen fluoride medium[10].

The example of nickel is a clear, convincing illustration of the stabilising influence of fluorine on the transition metal–carbon σ bond.

Iron, ruthenium, osmium. Numerous attempts to bring about reaction between a Grignard reagent and iron(II) or iron(III) halides have ended in the reduction of the metal and the formation of the dimer of the radical of the arylating agent:

$$2MgBr(C_6H_5) + FeCl_2 \rightarrow C_6H_5C_6H_5 + Fe + MgBr_2 + MgCl_2.$$

The dimerisation was subsequently used as a method of preparation, and, as is well known, one of the two discoveries of ferrocene is connected with an attempt to obtain biscyclopentadienyl from bromo(cyclopentadienyl)-magnesium and iron(III) chloride. On the other hand this reaction was considered to be a measure of the stability of the σ derivative formed as an intermediate and all the metals of Group VIII have been studied from this viewpoint in terms of reaction with phenylmagnesium bromide[27,51]. When the yield of biphenyl is taken as a measure of the instability of the σ derivative, then it must be concluded that the phenyl derivatives of iron, cobalt, nickel, ruthenium, rhodium, and palladium are evidently completely unstable and exist only briefly. As shown above, platinum gives stable methyl derivatives. Probably its phenyl derivatives are also fairly stable, since under comparable conditions only traces of biphenyl are formed. The low yield of biphenyl is also found with osmium(III) and iridium(III) chlorides, and their phenyl derivatives evidently exhibit moderate stability. The catalytic reaction of dimerisation, which takes place in the presence of non-stoichiometric amounts of transition metal salt, was studied by Kharasch and coworkers[52-56], and it was shown that $CoCl_2$ exhibits the greatest activity of them all. The mechanisms advanced for different types of R took into account the strength of the metal–carbon bond in the hypothetical MR_n.

Subsequently the formation of unstable derivatives in the first stage was used in the original synthesis of π alkene complexes by Fischer and coworkers[57-60], for example:

$$FeCl_3 + 3MgBrPr^i \xrightarrow{\text{ether}} [FePr^i_3(\text{ether})_n] \xrightarrow[35^\circ,\ \text{ultraviolet}]{2C_6H_8} \pi\text{-}C_6H_8FeC_6H_8\text{-}\pi + C_3H_8 + C_3H_6 + H_2.$$

The labile ethereal complex of triisopropyliron decomposes when irradiated and the vacated coordination sites are occupied by the alkene. If the geometrical or electronic properties of the alkene structure do not match up to the metal then there is a simultaneous rearrangement of the alkene, in the present example dehydrogenation. In this way otherwise unobtainable pure alkenic π complexes of iron, ruthenium, osmium, and chromium of low stability were prepared.

The polymerisation of acetylene in the presence of derivatives of chromium, nickel, etc. is apparently brought about by an analogous mechanism. Hence because of their reactivity the unisolable, unstable σ derivatives of the transition metals play an important part in the intermediate stages of many processes.

In addition to these organic derivatives of iron, ruthenium, and osmium, which apparently exist in solutions but cannot be isolated pure, several completely stable mixed complexes have been obtained. For iron there are first of all derivatives of cyclopentadienyldicarbonyliron and corresponding dinuclear complexes, some tetracarbonyl-complexes and their fluorinated analogues and also complexes of the MR_2L_2 type, although the last are evidently the least characteristic. For ruthenium and osmium only the four-coordinated complexes of composition $MXRL_2$ are known.

Derivatives of cyclopentadienylcarbonyls are obtained by two main methods (C) and (D), developed by Piper and Wilkinson[61]:

$$\left.\begin{array}{l} C_5H_5M(CO)_nNa + RCl \\ MX(C_5H_5)(CO)_n + MgXR \end{array}\right] \rightarrow M(C_5H_5)R(CO)_n \qquad \begin{array}{l}\text{(Method C)}\\ \text{(Method D)}\end{array}$$

A method which has limited application for obtaining only methyl derivatives is the methylation of hydro(cyclopentadienyl)carbonyl complexes with diazomethane[61,62]:

$$C_5H_5M(CO)_nH + CH_2N_2 \rightarrow C_5H_5M(CO)_nCH_3 + CO. \qquad \text{(Method E)}$$

Method C forms the basis of the preparation of dinuclear complexes[63,64], dihalides being used. Acyl and fluorocarbon derivatives are also obtained by Method B. It has been shown that trimethylsulphonium iodide can be used as a methylating agent in Method B.[65] The yields in all three methods vary considerably. Table 2 gives the physical properties of some representatives of this class of complexes. Usually the isoalkyl derivatives are considerably less stable than the n-alkyl. Many of these are liquids which are readily oxidised even at low temperatures.

The following methods for obtaining σ alkyl and aryl derivatives involves the decarbonylation of the corresponding σ acyl derivatives:

$$M(RCO)(C_5H_5)(CO)_n \rightarrow MR(C_5H_5)(CO)_n + CO. \qquad \text{(Method F)}$$

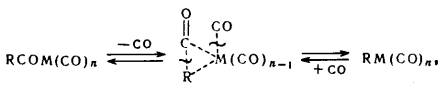
This method is widely used in the chemistry of the carbonyl complexes of manganese and cobalt, where the acyl derivatives are more accessible than the alkyl derivatives. The decarbonylation of manganese and cobalt acylcarbonyls proceeds very easily on heating. It is often so easy that even at room temperature and normal pressure an equilibrium mixture of the alkyl and acyl derivatives is formed. However, when there is only one phosphine or cyclopentadienyl group in the complexes then the decarbonylation is greatly hindered. Thus although a series of acyl derivatives of cyclopentadienyldicarbonyliron was obtained[64,66,67], they could not be decarbonylated just so long as the change from σ allyl to π allylcyclopentadienylcarbonyl complexes did not succeed[68].

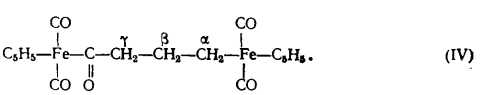
Radiochemical methods were used to show[66] that the reversible carbonylation–decarbonylation process takes place by the mechanism:



that is, it is not the acyl carbonyl that is detached, but one of the CO groups of the carbonylmetal moiety. The reverse reaction of carbonylation of the alkyl complex proceeds in such a way that the CO entering bonds only with the metal, and the acyl group is formed by an inner-sphere rearrangement. Therefore the success of the decarbonylation of acylcarbonyls probably depends on how strongly the carbonyl groups of such complexes are bound to the metal, which can be judged from the ease with which they are replaced by a phosphine. King and Bisnett found[69] that decarbonylation of acyls is facilitated by ultraviolet irradiation, just as the replacement of CO by phosphine is sometimes facilitated. A synthesis path was worked out for certain previously inaccessible alkyl complexes, for example, cyclopentadienylvinyldicarbonyliron. All this relates also to cyclopentadienylperfluoroacyl complexes. They are obtained by Method C; when the acyl halides are gaseous, the anhydrides of the perfluoro-acids are used. The yields of perfluoroacyls are usually about 10% low and in the reactions a large quantity of the dimer of cyclopentadienyldicarbonyliron is always obtained. Acyl derivatives of unsaturated acids also give low yields.

It has been repeatedly noted[64,69] that in the nuclear magnetic resonance spectra of the complexes $FeR(C_5H_5)(CO)_2$ the position of the signals of the ring protons depends on the nature of R. Thus when R = alkyl it is $\sim 5.27\ \tau$, with R = acyl $\sim 5.17\ \tau$, with R = perfluoroacyl $\sim 5.04\ \tau$, and with R = I 4.93 τ, that is, the displacement varies inversely with the electronegativity of R. The shifts for ring protons in fluoroalkyls and fluoroacyl complexes are very similar.

The displacements for the α and β protons of an alkyl chain are almost the same, that is, by the NMR method it is impossible to distinguish them



(IV)

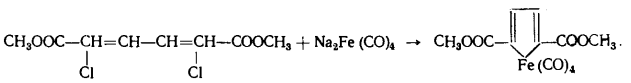
In the acyl groups two types of protons are evident, corresponding to the γ and β positions. Non-symmetrical doubly-charged complexes of type (IV) have two ring proton signals associated with the different electronegativity of the groups attached to the iron.

Quite recently a new reaction between the σ complexes of iron with liquid SO_2 was discovered. Analogously to carbon monoxide, SO_2 is inserted at the R–Fe bond. The reaction proceeds easily at -40° to -60° immediately the complex is dissolved in liquid SO_2:[70]

$$Fe(C_5H_5)R(CO)_2 + SO_2 \rightarrow Fe(C_5H_5)(SO_2R)(CO)_2,$$

where R = CH_3, C_2H_5, or C_6H_5.

A derivative of the so-called ferrole — a five-membered unsaturated heterocycle with iron in the ring — is obtained by the reaction of dihalogenoalkenes with $Na_2Fe(CO)_4$:[71]



It is crystalline, m.p. 57°, and capable of being chromatographed under the usual conditions.

The ferrole motiv is repeated in a series of complexes obtained from iron carbonyls and alkynes, which will be considered below.

Hydro-complexes are capable of addition to alkenes, and this reaction is one of the paths for the synthesis of σ derivatives (Method G). In the group of metals now being considered addition to the butadiene system takes place:[68]

$$FeH(C_5H_5)(CO)_2 + CH_2{=}CH{-}CH{=}CH_2 \rightarrow Fe(CH_2{-}CH{=}CH{-}CH_3)(C_5H_5)(CO)_2.$$

The sole example of a four-coordination iron complex — bis(pentachlorophenyl)bis(diethylphenylphosphine)-iron — is crystalline, with decomposition temperature $\sim 130°$.[72] The analogous complexes of ruthenium and osmium usually contain only one alkyl group and a halogen atom, which can be reduced and the corresponding hydro(alkyl) complexes obtained. Unlike all the others, the square complexes of ruthenium and osmium are obtained by the action of trialkylaluminium on dihalogeno--complexes[73]. Judging by the decomposition temperature, the least stable complexes of this group are those of iron.

It was shown above that perfluoroalkyl halides displace the carbonyl groups in carbonyl complexes of nickel. Pentacarbonyliron also reacts under mild conditions at 25–70° with perfluoroalkyl halides, giving a mixture of derivatives of composition $FeIR_f(CO)_4$ and $[FeIR_f(CO)_3]_2$.[21,74] The latter is dimerised by means of halogen bridges. On heating, the monomeric complexes lose CO, being converted into dimers.

Unlike the cyclopentadienylperfluoroacylcarbonyls, which are decarbonylated only under ultraviolet irradiation[64,69], perfluoroacylcarbonyls of iron are decarbonylated apparently quite readily, since when perfluoroacyl chlorides and $Na_2Fe(CO)_4$ react, only bisperfluoroacylcarbonyls can be isolated[74,75]. In this respect they are more similar to the acyl derivatives of cobalt and manganese. It should be noted, however, that the replacement of even one of the carbonyl groups by a phosphine makes the acyl derivatives stable to thermal decarbonylation. Decarbonylation of perfluoroacyl derivatives gave complexes of the type $Fe(C_5H_5)R_f(CO)_2$,[69] with different R_f, shown in Table 2. Some of these can also be obtained by Method C[74,76] (see p. 173). The perfluoroaryl complexes are obtained with yields of 2–7% by the action of pentafluorophenyllithium[77] or bromo(pentafluorophenyl)magnesium[78] on the corresponding halogen derivatives.

Nucleophilic replacement of fluorine by other groups is characteristic for highly fluorinated aromatic hydrocarbons. King and Bisnette[79] used this feature to obtain fluorinated aromatic σ derivatives of iron. On heating fluorobenzenes in tetrahydrofuran with $Na[Fe(C_5H_5)(CO)_2]$, fluorine is replaced by the cyclopentadienyl dicarbonyliron cation:

$$C_6F_5R + Na[Fe(C_5H_5)(CO)_2] \rightarrow [Fe(C_5H_5)(p\text{-}RC_6F_4)(CO)_2],$$

where R = H, or CF_3.

With octafluorotoluene in this reaction, fluorine is displaced from the benzene nucleus, not the side-chain, 1,2,3,4-tetrafluorobenzene gives $[Fe(C_5H_5)(2,3,6\text{-}C_6H_2F_3).(CO)_2]$ that is, the C–Fe bond is bound in such a way that both *ortho*-positions are occupied by fluorine. The yields in these reactions reach 30–50%, but the method is not applicable to $Na_2[Fe(CO)_4]$, $Na[Mo(C_5H_5)(CO)_3]$, and some other carbonylmetalates. The complexes obtained are stable on heating and against oxidation, melt without decomposition, and can be chromotographed on Al_2O_3.

Yet another type of iron complexes — heterocyclic complex (V), obtained by Method B[21,80] originally was thought to be a π perfluoroethylene complex — is the substance

(V)

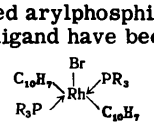
stable in all respects.

It is not decomposed by bromine, phosphines do not displace the perfluorohydrocarbon and only prolonged thermal treatment (120 h at 70°) leads to the detachment of perfluorocyclobutane.

As Table 2 shows, fluorocarbon complexes do not differ from the hydrocarbon analogues in ability to exchange ligands. One or two of their carbonyl groups can be replaced by phosphines or amines[82]. NMR data for the fluorocarbon complexes have been given by Pitcher and coworkers[81].

Cobalt, rhodium, iridium. It has been reported[83,84] that organometallic derivatives of the composition $CoX_3(C_{10}H_7)$ and $CoX_2(C_{10}H_7)_2$ are obtained by the action of halogeno(naphth-2-yl)magnesiums on ethereal solutions of cobalt salts. But since data about their composition, hydrolysis products, and thermal decomposition are insufficient, it is impossible to consider the existence of the simplest σ derivatives of cobalt as proved. Those classes of derivatives which contain carbonyls or phosphines, etc. instead of σ groups have been more thoroughly studied. Quite recently a new class of stable organic derivatives was discovered — the alkylpentacyanocobaltates. Perfluorinated analogues of some of these complexes have been obtained. Cobalt, like the other elements of Group VIII, is capable of forming four-coordinated complexes of *trans*-configuration $CoAr_2L_2$, where Ar is a bulky aromatic radical of the mesityl type[72]. They are all crystalline and melt with decomposition above 100°. They are somewhat less stable than the analogous derivatives of Pt, Pd, and Ni, which Chatt explains by a tetrahedral (instead of planar) arrangement of the ligands. The stabilising action of the phosphine groups is less in such a configuration.

Five-coordinated arylphosphine complexes (VI), having halogen as a fifth ligand have been obtained for rhodium[85]:

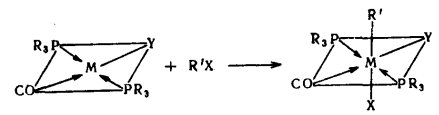


(VI)

In these compounds the rhodium(III) — usually six-coordinated — is coordinatively unsaturated and it could be expected that these substances would be unstable towards nucleophilic attack; however, they are completely stable. This is explained by the almost spherical structure formed by the bulky ligands which compactly surround the metal and shield it from the attacking agent.

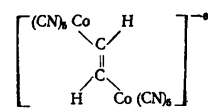
A preliminary communication that complexes of the type MR_2L_2 are obtained has been published[18].

Six-coordinated σ complexes of iridium(III) and rhodium(III) have been obtained[86]. They are formed as a result of the addition of active organic halides to some planar complexes of iridium(I) and rhodium(I):



During this, the metal is oxidised to the tervalent state. Table 3 lists some of the complexes obtained in this way. They are all crystalline, high-melting materials, stable in air.

Griffith and Wilkinson[87] observed, as long ago as 1959, that aqueous solutions of a pentacyanocobaltate absorb acetylene. They isolated a crystalline, diamagnetic salt of composition $K_6[Co_2(CN)_{10}(C_2H_2)].4H_2O$, which has been ascribed the structure (VII) on the basis of infrared and NMR analyses:



(VII)

The *trans*-configuration was chosen arbitrarily, as there are no analogues for these compounds and the available data are insufficient to settle the question of configuration conclusively. It was later shown[88] that aqueous solutions of $[CoH(CN)_5]^{-3}$ and $[Co(CN)_5]^{-3}$ absorb perfluoroethylene at atmospheric pressure. Salts of the composition $K_3[Co(CN)_5(CF_2CF_2H)]$ and $K_6[(CN)_5Co(CF_2CF_2)Co(CN)_5]$ were isolated. Unlike (VII), which is of comparatively low stability, decomposes slowly in air and rapidly in a vacuum at 70°, the fluorinated complex salts are stable to oxidation and thermally up to 300°. The reaction with perfluoroethylene goes so easily and unambiguously, that, in the authors' opinion, it can be used analytically for determining metal–hydrogen bonds when the latter cannot be observed by NMR analysis.

A variant of the synthesis of this class of complexes consists of the reactions of pentacyanocobaltates with alkyl halides[89]. It is possible to start from a mixture of $CoCl_2$ and NaCN:

$$2[Co(CN)_5]^{-3} + C_6H_5CH_2Br \rightarrow [Co(CN)_5(C_6H_5CH_2)]^{-3} + [CoBr(CN)_5]^{-3}.$$

Methyl, ethyl, and n-propyl derivatives are obtained analogously. The most stable of these are the benzyl complexes, which are slowly decomposed in air, split off bibenzyl when heated in a vacuum, and are decomposed by acids and mercury(II) chloride.

Many investigations have been devoted to acyl and alkyl derivatives of cobalt carbonyls. The interest in them is undoubtedly connected with explaining the mechanism of

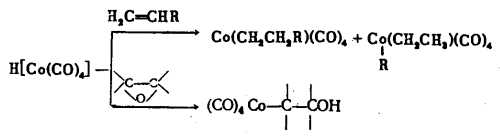
the oxo-synthesis. Alkylcarbonylcobalts can be obtained from alkyl halides and sodium carbonylcobaltates [90,91]:

$$Na[Co(CO)_4] + XR \rightarrow RCo(CO)_4, \qquad \text{(Method H)}$$

or by addition of hydrogen tetracarbonylcobaltate(-1) to alkenes [92] or epoxy-compounds [93,94]:



Alkylcobaltcarbonyls evidently exist in equilibrium with an acyl form. This is suggested

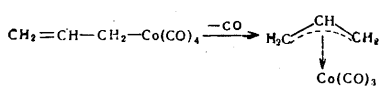
$$RCo(CO)_4 \rightleftarrows RCOCo(CO)_3 \overset{CO}{\rightleftarrows} RCOCo(CO)_4$$

by the existence of a 5.8 μ band in the spectra of alkylcarbonyls in the gas phase and in solutions. The ease of the reciprocal changes and the instability of one or the other often does not allow them to be isolated in a pure state. This applies especially to the alkylcarbonyls. Irrespective of the nature of R they can be characterised only in the form of acylcarbonylphosphine complexes. This is because during the treatment of the alkylcarbonyl with phosphine the CO being displaced does not depart to the outer sphere, but is inserted at the R–Co bond, with formation of an acyl complex:

$$RCo(CO)_4 + PR'_3 \rightarrow RCOCo(CO)_3PR'_3.$$

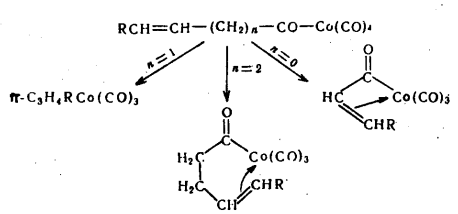
Hence the acyl complex is obtained directly by Method H in the presence of phosphines.

When R is an unsaturated radical the molecule is stabilised by rearrangement into a π complex. For example, the stage of the σ allyl derivative could not be isolated since on heating it is converted into the π allylcarbonyl [90,95]:



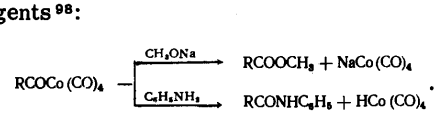
The special nature of the bond in a π allyl complex makes it incomparably more stable compared with the σ complex, although in either the metal has a closed electron configuration of krypton and the same stabilising ligands. When phosphines act on it, one of the carbonyl groups is replaced, but acyl complexes are not thus obtained.

Acylcarbonyls of cobalt are obtained by the carbonylation of alkylcarbonyls or by Method H. When the acyl radical has an unsaturated chain, reaction H takes place with liberation of CO, but the products obtained contain an acyl group. It is thought that one of the CO groups of the carbonyl residue is displaced by the carbon–carbon double bond and a $\sigma\pi$ complex is obtained:



The intermediate acyltetracarbonyl complexes are not usually isolated, but sometimes their crystalline phosphine derivatives can be obtained [90,96,97].

The acylcarbonyls readily react with various nucleophilic reagents [98]:

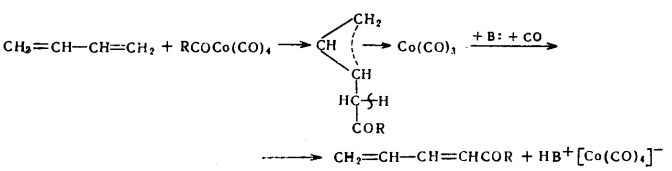


Like the alkyl compounds they are extremely unstable thermally. Thus methyltetracarbonylcobalt exists as yellow crystals at -80° and decomposes at higher temperatures, but the acyltetracarbonylcobalt is a crystalline substance with m.p. -33° and decomposition temperature -20°. The combination of the properties described for the acyl and alkyl derivatives of cobalt carbonyl determines their role in catalytic processes, and in turn in hydroformylation.

Analogous syntheses and transformations are also possible for manganese carbonyl. Here also the reversible reaction of carbonylation–decarbonylation is characteristic, but both the alkyl and the acyl derivatives of manganese carbonyl are considerably more stable and can be isolated.

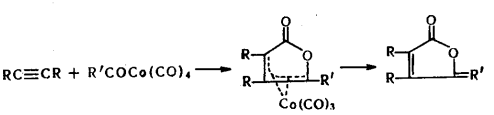
Phosphines replace one of the carbonyl groups of acyl complexes [98-100]. Some sterically strained tertiary phosphites are capable of displacing one, two, and even three carbonyl groups, but the phosphito(acyl) complexes thus obtained are unstable to oxidation [101].

Heck [102-104] observed an interesting ability of acylcarbonyls to add to a diene system or acetylene. With the former, substituted π allylcarbonyls are obtained, which under the action of nitrogenous bases decompose with the liberation of acyldienes:



Since the acyl complex is always found in equilibrium with the alkyl, the same result is obtained on starting from the alkylcarbonyls, or what is even simpler, on taking a mixture of the sodium salt of a carbonyl, an alkyl halide, diene, and amine.

The addition of acylcarbonyls to the acetylenes leads to a complex type of π-enyl, the formation of which is confirmed spectroscopically, and also the liberation of phosphine derivatives. An intermediate complex, by breaking down in the presence of amine, gives an unsaturated lactone:



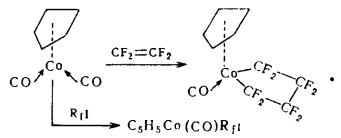
Some examples are known of perfluoroalkylcarbonyl-cobalt complexes, obtained by Method H [106-108] (see above). In attempts to use this method to obtain perfluoroacylcarbonyls, decarbonylation took place simultaneously. However, when the reaction is carried out below room temperature perfluoroacylcarbonyls can be isolated [106,108]. If then one of their carbonyl groups is replaced by a phosphine, then acyl derivatives completely stable to decarbonylation are obtained [106,108]. Both types of σ complex are considerably more stable than their hydrocarbon

analogues. It should be noted that the back reaction of carbonylation of the perfluoroalkylcarbonyls evidently occurs with greater difficulty than for the alkylcarbonyls, since during reaction with phosphines, arsines, or stibines CO is liberated and an acyl complex is not obtained.

Cobalt carbonyl in tetrahydrofuran under very mild conditions at room temperature reacts with perfluoroethylene, which is inserted between the two metal atoms, giving a dinuclear σ complex[80]:

$$Co_2(CO)_8 + CF_2{=}CF_2 \rightarrow (CO)_4CoCF_2CF_2Co(CO)_4.$$

Under somewhat more severe conditions, in an autoclave at 160° perfluoroethylene reacts with cyclopentadienyldicarbonylcobalt, one of the carbonyl groups being replaced by a perfluorinated ring[109]:

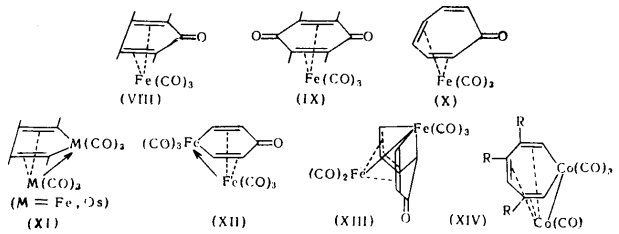


Finally, one of the carbonyl groups can be displaced by a perfluoroalkyl iodide[110]. Cyclopentadienyldicarbonylrhodium behaves analogously[111].

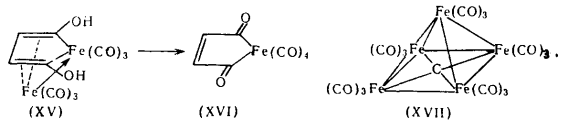
Table 3 contains some examples of σ complexes of cobalt. rhodium, and iridium.

Products of the reaction of alkynes with carbonyls and carbonyl complexes of Group VIII metals. Diels–Alder type of metal addition. The variety of complexes obtained from acetylenes and carbonyls or carbonyl complexes may be recalled again. Although the structure of many of these is not indisputable, continuing study of them led to an interesting hypothesis and paths for future investigation were noted.

Acetylene, as such, hardly ever participitates in the formation of π complexes, although acetylenic π complexes are evidently the first stage in the reaction and can be isolated when platinum is involved. Among the products of the reaction of iron and cobalt carbonyls with acetylene, two classes of derivatives (in addition to others) have been isolated: (1) carbonyl complexes of unsaturated ketones, obtained as the result of the cyclic polymerisation of several acetylene molecules, with the participation of carbon monoxide, (VIII), (IX), (X), etc.; (2) five-, six-, and seven-membered heterocycles with metal atoms in the ring (XI), (XII), (XIII), (XIV)[113-119]. For the structure of (XIV), however, see Mills and Robinson[120].

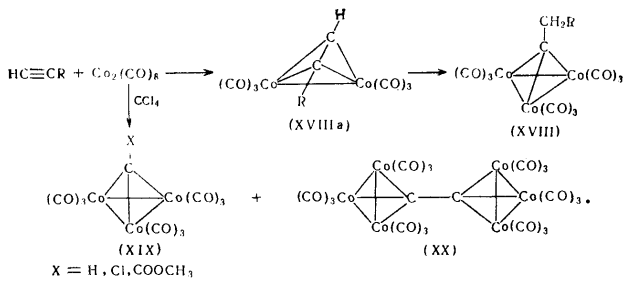


The formation of heterocycles is thus brought about by σ bonding with the metal. The molecules are stabilised by the attachment of a second carbonylmetal grouping of the π complex formation type. Their structure was confirmed by chemical destruction and also by X-ray analysis. Most of them are sufficiently stable thermally to be isolated in a pure state. The chemical stability is confirmed by such facts as, for example, the possibility of replacing the CO groups by other ligands, in particular, SO_2 [121], or by the oxidation (XV) → (XVI) with retention of the ring structure[122]:



The reaction of $Fe_3(CO)_{12}$ with some substituted acetylenes leads to the formation of (XVII) together with other complexes. The substance is diamagnetic, does not have bridging CO groups, and X-ray structural analysis has shown it to be a tetragonal pyramid at the apices of which tricarbonyliron groups are situated, and a single carbon atom lies in the base of the pyramid[123].

The analogous carbide-like compounds (XVIII), (XIX), and (XX) (if the carbon of the CO groups is not considered) are also obtained from octacarbonyldicobalt and monosubstituted acetylenes[114,124,125] carbon tetrachloride, or bromoform[126]:

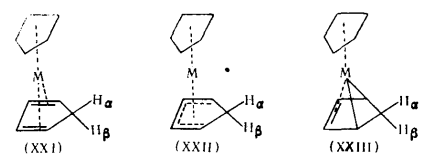


Structures of type (XVIIIa) have been proposed for the products of the reaction of $Hg[Co(CO)_4]_2$ and disubstituted acetylenes[127,128] and also for some derivatives of cyclopentadienylcarbonylnickel[129]. All are crystalline, often deeply coloured substances, sometimes with high melting points (~ 200°) and stable in air.

Hence the transition metal–carbon σ bond is widely used in complex molecules.

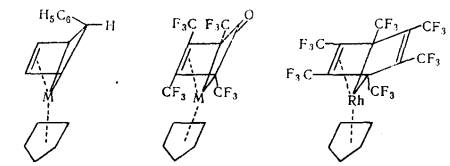
Within the last two years a series of crystallographic investigations made in England by Churchill and coworkers have been published, and these have changed some former concepts about the structure of several complexes and the nature of the bonds.

As long ago as 1959, Wilkinson[130] proposed three possible structures, (XXI), (XXII), and (XXIII), for compounds of the general formula $C_5H_5MC_5H_6$:



The NMR spectra, which are consistent with structure (XXIII), do not, however, agree with the infrared results, and it was impossible to settle the question in favour of one of these structures. A structure analogous to (XXIII) was

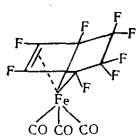
also proposed for the tetrakis(trifluoromethyl)(cyclopentadienone)tricarbonyliron [131]. The proximity of H_α to the central atom and the interaction with non-bonding electrons of the metal explained its mobility and spectroscopic characteristics. The absence of the characteristic H_α bands from complexes substituted in the methylene group is considered a sign that the H_α and not the H_β is substituted and that the substituent is therefore in the *endo*-position [132,133]. However, as an X-ray study of cyclopentadienyl(phenylcyclopentadiene)cobalt has shown [134-136], in fact addition occurs to the cyclopentadiene ring of type (XXIII), but the CHC_6H_5 group departs from the plane of the remaining part of the ring to the side opposite from the metal and the phenyl occupies the *exo*-position (XXIV):



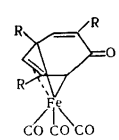
(XXIV) M = Co
(XXVII) M = Rh

(XXV) M = Co
(XXVI) M = Rh

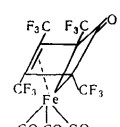
(XXVIII)



(XXIX)



(XXX)
R = H, C_6H_5

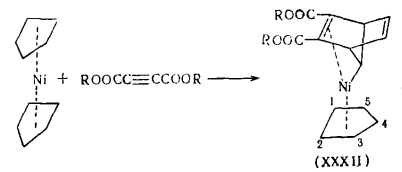


(XXXI)

A quasi-Diels–Alder addition of metal to a diene system, and consequently the rehybridisation of the carbon atoms of the ring which take part in the σ bonding, is shown by X-ray diffraction also for (XXV) [135,137], (XXVI) [138,139], (XXVII) [140], (XXVIII) [138,139,141], (XXIX) [142], (XXX) [143], (XXXI) [144]. The bond lengths, ring conformations, and bond angles show that the bond of the metal with the diene moiety in these molecules consists of one μ and two σ bonds. (XXVIII) is the first example of a localised addition of a transition metal to the benzene ring, as a result of which the planarity and the aromaticity of the ring are completely destroyed. It is thought [142] that the structure of butadienetricarbonyliron, which according to the most recent information [145] contains a delocalised system, should be studied more thoroughly.

Both the metal ion and the other ligands bonded with it play a part in determining the degree of σ bonding. The formation of a localised bond also depends on the fall in the delocalisation energy under the influence of electronegative substituents, such as the CF_3 group. Bailly and coworkers [144] think that the departure from planarity should be taken as a measure of the σ bonding rather than the bond lengths, the difference in which is generally not significant. The greater departure of the ketone group in cyclopentadiene complexes shows the greater $sp^2 \rightarrow sp^3$ rehybridisation of neighbouring carbon atoms. According to Dahl and Smith's results [146] cyclopentadienyl(tetramethylcyclopentadienone)cobalt has, unlike (XXV), a levelled system [sic]§ and as it were a sandwich type of bond. However, the insignificant departure of the carbonyl group which is observed can also be considered as an indication of some localisation of the bond. The localisation energies at appropriate carbon atoms have been calculated [144].

The examples mentioned above showed the possibility of the localised addition of metal to a diene system. The possibility of a greater or less distortion of the delocalisation in a cyclopentadienyl ligand is also not excluded. Dahl and Chin Hsuan Wei [147] first drew attention to this, by studying the structure of the product of the addition of an ester of acetylenedicarboxylic acid to nickelocene (XXXII) [148]:



(XXXII)

The Ni–C and C–C distances in the cyclopentadienyl ring show partial delocalisation in the adduct with a μ bond from $C_{(1)}$–$C_{(2)}$ and a σ bond from $C_{(4)}$. It is thought that this type of bond with cyclopentadienyl is possible in rhodium(I) and nickel(I) complexes. An approximate calculation [149] shows that the structure (XXXIII) is possible for the cyclopentadienyl ring, where the bond order in the $C_{(1)}C_{(2)}C_{(3)}$ group of atoms is relatively lower than in the $C_{(4)}C_{(5)}$ group which is confirmed crystallographically for several complexes which do not possess cylindrical symmetry. The $C_{(1)}C_{(2)}C_{(3)}$ group is always in the *trans*-position to the ligand with the stronger field.

(XXXIII)

Despite the distortion of the delocalisation in the cyclopentadienyl ligand its aromatic nature is evidently unchanged, as in the NMR spectra there is, as before, a single signal for the ring protons [147,148]. This is explained by the dynamic effect of internal rotation.

2. Group VII. Manganese, Rhenium

See Cotton [16] for the early attempts to obtain organic derivatives of manganese and rhenium. Subsequently, iodo(methyl)manganese, dimethylmanganese, and diphenylmanganese, which are unstable to oxidation and insoluble in ether, were obtained [150,151]. With an excess of organolithium reagent they form colourless amorphous insoluble salts of composition $LiMnR_3$. The salts also decompose in air but more slowly than the initial dialkyl derivatives [150]. Dicyclopentadienylmanganese [152] and bis(methylcyclopentadienyl)manganese [153] have been obtained, and their properties show the ionic nature of the bonds in the molecules. These compounds have low oxidation resistance, the first of them burning in air with an explosion. Water and acids immediately destroy it with liberation of cyclopentadiene.

Complexes of the type $MR(CO)_5$, where R represents alkyl, aryl, the corresponding acyl, or fluorinated analogues, are more characteristic derivatives for manganese and rhenium. They are obtained by Method H [20,64,95,154-158] (p. 178), and dinuclear complexes $(CO)_5Mn(CH_2)_nMn(CO)_5$ are obtained by the same method. Features of the structure of some of them are discussed by King [64]. The methyl

§ There is delocalisation of the four π electrons of the tetramethylcyclopentadienone and the CO is tipped out of the plane of the other atoms by 9° away from cobalt (Ed. of Translation).

derivative is also obtained by Method E [159] (p. 173). Some derivatives with an unsaturated σ ligand are obtained by Method F [95] (p. 173), in which, just like the hydrocarbonyls, already prepared $MnR(CO)_5$ can be attached to the diene, to form new derivatives [160]. As for cobalt, here transitions of the σ allyl → π allyl type are characteristic [20,95], and others, but the σ derivatives of manganese are much more stable thermally, and can be isolated and characterised.

The acylcarbonyls of manganese and rhenium are, from their ability to reversible decarbonylation, analogues of the acyl derivatives of carbonylcobalt, although here also great stability is noted. See elsewhere [90,161-163] for the mechanism and kinetics of these changes.

As was recently reported [164], the cations of the carbonyl complexes of manganese and rhenium in alcoholic alkali undergo an interesting transformation into neutral σ carboalkoxycarbonyl complexes:

$$[Mn(CO)_4L_2]^+ + RO^- \underset{HCl}{\rightleftharpoons} ROOC{-}Mn(CO)_3L_2,$$

where L = phosphine, etc.

In this the carbonyl group of the complex is converted into σ bound carbonyl. The reaction is reversible: acid splits off the ester group and the original cation returns.

The preparation of some σ derivatives of dicyclopentadienylrhenium, formed as a result of the addition of dicyclopentadienyl hydride to substituted alkynes, has been described [165].

Perfluoro-alkyl or -aryl and perfluoroacyl derivatives of the carbonyls of manganese and rhenium have been obtained by Methods H [20,64,76,77,107,154] and D [78] (pp. 178 and 173). Perfluoroalkyl derivatives can also be obtained by decarbonylation of perfluoroacyls above 80° for manganese and above 120° for rhenium [20,64,107,154], or by the addition of $MnR(CO)_5$ to fluoroethylenes [75,166-168]. The addition to non-symmetrical fluoroethylenes of the type $CF_2{=}CFCl$ and $CF_2{=}CCl_2$ depends on the reaction conditions. Usually the more fluorinated end of the molecule adds on to the metal, but with ultraviolet irradiation a mixture of products in which the $-CFCl-Mn$ derivative predominates is obtained [167,168]. The irradiation facilitates the addition of methyl- and phenyl-carbonylmanganese to fluoroethylenes.

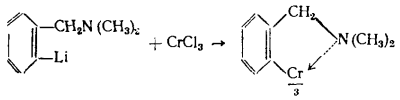
Table 4 contains examples of all classes of the σ derivatives of manganese and rhenium.

3. Group VI. Chromium, Molybdenum, Tungsten

We will not dwell on the well-known history of the phenyl derivatives of chromium, but note only that certain covalent derivatives, stabilised by the addition of solvent molecules — Lewis bases, or carbanions — were isolated in a pure state. First of all, there is $Cr(C_6H_5)_3.3THF$, a red crystalline substance which decomposes at 85° and the product of the addition to it of magnesium salts $Cr(C_6H_5)_3.3THF.3(MgBrCl.THF)$ [169]. In solutions they exist briefly, regrouping into π complexes, and are instantly decomposed by water and mercury(II) chloride. The stabilising action of the tetrahydrofuran molecule is clearly demonstrated by the decomposition of the complex on drying.

The phenylation of chromium(III) chloride with an excess of phenyllithium in ether leads to the formation of $Li_3[Cr(C_6H_5)_6].2\frac{1}{2}$(ether) [170], which later results [171] suggest should be $Li_3[Cr(C_6H_5)_6].4$(ether). It consists of orange-yellow crystals, sensitive to oxygen and atmospheric moisture, capable of being reduced to the monohydride. Corresponding salts of substituted phenylchromium [172] and phenyltungsten [173] have been obtained.

There is proof of the formation of benzyl derivatives of chromium: $[Cr(C_6H_5CH_2)(H_2O)_5]^{2+}$, [174] $[Cr(C_6H_5CH_2)_3]$, and $CrCl(C_6H_5CH_2)_2$, [171] which contain solvent molecules, etc. (XXXIV) has been briefly described — an amino-σ-aryl chelate complex, obtained [175] thus:



(XXXIV)

— as have the alkynyl derivatives $K_3[Cr(C{\equiv}CR)_3(CO)_3]$ [176]. We will not dwell on the role of this kind of chromium derivative in catalytic processes.

By the reaction of molybdenum(V) chloride with an excess of cyclopentadienylsodium, Fischer and Hristidu [177] obtained tetrakiscyclopentadienylmolybdenum. This diamagnetic substance, which is extremely sensitive to oxygen, has one π and three σ cyclopentadienyl groups, according to the authors' results.

General methods for obtaining cyclopentadienylcarbonyl σ complexes (Methods C, D, and E, p. 173) [61] are applicable to various extents to the Group VI metals. Table 5 shows derivatives obtained in this way and some of their fluorinated analogues [69,178]. Among them, the instability of molybdenum compounds of type $Mo(RCO)(C_5H_5)(CO)_3$ has been repeatedly noted. Attempts to obtain them often end in the formation of a dimer cyclopentadienyltricarbonylmolybdenum. Even their perfluorinated analogues are 50–80% decarbonylated during isolation. Unlike them, the analogous acyl complexes of tungsten are completely stable and are not decarbonylated even on irradiation.

The σ allyl derivatives of molybdenum and tungsten, like the iron analogues, are only converted into π allyl complexes on irradiation [179,180].

The interesting thermal decomposition of ethylcyclopentadienyltricarbonylmolybdenum has been described, in which such products as $[Mo(C_2H_5C_5H_4)(CO)_3]_2$ and $(C_5H_5)Mo(CO)_3Mo(CO)_3(C_5H_4C_2H_5)$ are obtained, that is, the ethyl group is transferred from the metal to the ring [181]. This is explained by the general nature of the ethyl–molybdenum bond.

4. Group V. Vanadium, Niobium, Tantalum

According to the results of Meijer and coworkers [182], dicyclopentadienylvanadium is capable of adding alkyl halides according to the equation:

$$2V(C_5H_5)_2 + RX \rightarrow VR(C_5H_5)_2 + VX(C_5H_5)_2.$$

Dicyclopentadienylvanadium dichloride and LiR also give alkyldicyclopentadienvylvanadium. In this way derivatives stable when solid were obtained, with $R = C_6H_5CH_2$ (m.p. 109°), CH_3 (decomp. 80–100°), and C_2H_5, still less stable.

Quite recently, Juvinall [183] reported the production of the first alkyl derivatives of niobium and tantalum by the alkylation of the halides with diethylzinc:

$$2NbCl_5 + 3Zn(CH_3)_2 \rightarrow 2NbCl_2(CH_3)_3 + 3ZnCl_2.$$

The reaction proceeds in pentane at -78°. The yellow, crystalline, trialkyl derivatives are monomers (from mass spectroscopic studies), volatile, decompose in a few hours at room temperature, but are fairly stable at -78° in the absence of water and oxygen. The tantalum analogue is less thermally stable. Their compositions were determined from the ratio of the products of alkaline hydrolysis.

Somewhat earlier, Fischer and coworkers [184] obtained complexes of composition $M(C_5H_5)_4$ by reaction of tantalum and niobium pentachlorides with cyclopentadienylsodium. These are extremely sensitive to oxygen, monomeric, and paramagnetic. From the infrared analysis, X-ray powder diagrams, and behaviour on hydrogenation, structures with two π and two σ-C_5H_5 groups are proposed.

5. σ-Derivative → π-Complex Transitions and the Reverse

In conclusion we think it necessary to mention the interesting reaction, σ-derivative → π-complex and the reverse, which became known from the work of Green and Nagy. They showed that σ allyldicarbonyliron-

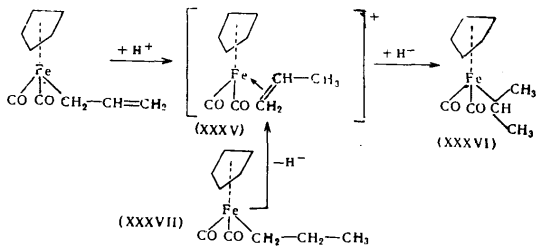
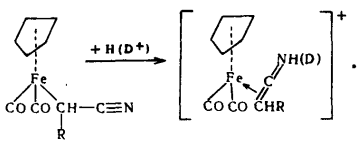
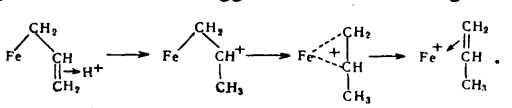
cyclopentadienyl is very easily protonated by gaseous HCl, giving the π propene complex cation (XXXV)[68,185,186]:



The protonation of σ-cyclopentadiene[187], σ-propargyl[188], and σ-cyanoalkyl[189,190] complexes of iron and the σ-allylcyclopentadienyltricarbonyl complexes of molybdenum[180] and tungsten[179] was then studied and it was shown that the reaction is general and always leads to a π-alkene complex cation. Although its products with the propargyl and cyanoalkyl complexes are more complicated there are results which confirm the allene and ketimine structure in the cations obtained:



Results with deuterium chloride show that the third carbon (or hetero-) atom of the ligand its protonated. The following mechanism was suggested for this change:



The reduction of the cations by the hydride reductants leads to neutral σ-alkyl complexes of iso-structure[191]. It was shown that the change (XXXV) → (XXXVI) does not exclude a hydro-complex stage with participation of the Fe–H bond.

The same authors[186,191,192] established the possibility of the change (XXXVII) → (XXXV) as a result of the detachment of the hydride ion from the σ-complex with salts of the triphenylmethyl cation. The change from n-propyl to isopropyl was brought about in this way. The mechanism of the hydride detachment is analogous to that of protonation. The structure of the cation obtained as a result of the hydride ion removal from $Fe(C_5H_5)CD(CH_3)_2(CO)_2$ shows that this occurs at the β carbon atom. In agreement with this is the fact that reaction does not occur with the methyl complex where there is no β carbon, or with the 2-cyanoethyl and 1,1,2,2-tetrafluoroethyl complexes, where such removal is hindered by the neighbouring electronegative groups. The detachment of the hydride ion from the σ ligand is evidently also general, like protonation. For example, it was observed[186] with ethylpentacarbonylmanganese, that is, it is present not only in cyclopentadienyl complexes. These reactions are considered to be models for understanding the mechanism of isomerisation of alkenes in chemisorption.

The following fundamental conclusions can be drawn on the basis of the experimental material considered: (1) comparatively stable carbon–transition metal covalent bonds are formed only in mixed complexes; (2) the observation of Sidgwick's rule in this is not obligatory. There are many examples of stable MR_2L_2 in Group VIII in which the metal is short of two to four electrons for the completed electronic configuration and on the other hand the extremely labile $CoR(CO)_4$ or $NiR(C_5H_5)(CO)$, etc., where this condition is observed, confirm this. These examples of planar complexes show what an important role the steric factors and the nature of the stabilising ligands play; (3) although fluorinated analogues have not yet been obtained for every σ-alkyl (aryl) derivative and the comparison of their stability is purely qualitative it

can be stated, however, that such thermal stability is less probable for σ carbon derivatives, than for σ fluorocarbons. Thus, $Co(CH_3)(CO)_4$ exists only at temperatures below 0° and $CF_3Co(CO)_4$ distils without decomposition at 91°; $Fe(C_2F_5)_2(CO)_4$ decomposes at ~ 100°; whereas $FeR_2(CO)_4$ could not be isolated; $Ti(C_5H_5)_2(C_6H_5)_2$ is stable in a vacuum up to 110° and decomposes at 150°, but $Ti(C_5H_5)_2 \cdot (C_6H_5)_2$ slowly decomposes at room temperature and rapidly at 100°. It must be mentioned, however, that in comparing the thermal stability it is thought that the decomposition mechanisms for the two classes of complexes are the same, although as far as we know there has not been any systematic investigation of the thermal dissociation of either class. Furthermore, in several instances there is no such sharp difference between the fluorinated and unfluorinated analogues.

Hence the factors which determine the stability of a σ derivative can be summarised as follows: (1) the valency state of the metal; (2) the nature of the ligands; (3) the electronegativity of the metal–ligand system (4) the electronegativity of the σ-bound group; (5) steric factors. Their role has been demonstrated, as far as is possible, by experimental data. The extent of the influence of the various factors cannot always be explained sufficiently satisfactorily and apparently it can be different in each particular instance. It is quite evident, however, that it is always necessary to take into account not any of the factors but all of them together.

CONTENTS

1. Introduction 186
2. Lower chalcogenides of molybdenum 187
3. Molybdenum dichalcogenides 189
4. Higher chalcogenides of molybdenum 198

1. INTRODUCTION

The investigation of the chemistry of molybdenum can be said to have begun in the first half of the XIXth century, when Berzelius obtained and described some of the principal compounds of molybdenum. Both the metal itself and various of its compounds find wide and diverse applications in industry and in chemical technology. However, several molybdenum compounds of theoretical and practical importance have been studied far too inadequately. These include the molybdenum chalcogenides, that is, the compounds of molybdenum with sulphur, selenium, and tellurium.

It is well known that the most widely distributed molybdenum-bearing mineral — molybdenite — exhibits specific electrical and photoelectric properties and is a semiconducting material.

The field of use of semiconducting materials requires from them the most diverse properties. Therefore an intensive search for new semiconducting substances with various electrical characteristics is now being carried out. In particular, there is now interest in semiconductors which exhibit high thermoelectric characteristics and are suitable for efficient thermoelectric generation.

Because the higher the junction temperature the higher the efficiency of the thermoelement, there is special interest in those materials which exhibit the thermoelectric effect and retain its positive properties at high temperatures. These are, above all, high-melting-point compounds. It is also known that the best thermoelectric materials were obtained from chalcogenides, or combinations of them, which have as constituents metals of high atomic weight. What has just been said explains the special

interest which has recently developed in the chalcogenides in general and in molybdenum chalcogenides in particular.

The practical importance of these compounds necessitates broadly based theoretical investigations, since to obtain semiconducting substances with reproducible properties it is necessary to know the mechanism of their formation, and also all their physicochemical characteristics. The character of the chemical bond, structure, valency state, distribution of electron density in the bonds, magnetic properties, thermodynamic and kinetic characteristics — these are the main directions for the theoretical investigation of thermoelectric materials, including the molybdenum chalcogenides.

A marked intensification of the work on the physicochemical investigation of molybdenum chalcogenides in recent years has led to the production of a series of new facts, which cardinally correct and supplement the old work, the results of which were inadequate, and frequently also erroneous.

In the well-known monographs and reviews[1-4] devoted to the chemistry and technology of molybdenum and its compounds, the information about the molybdenum chalcogenides is usually limited only to their mention and to some of the most general information, mostly out of date.

The authors hope that this review devoted to the chemistry of the molybdenum chalcogenides will make good these deficiencies and allow the reader to obtain exhaustive information, based on the most recent data, about this extremely interesting and promising class of compounds.

On the basis of an analysis of the known experimental data the authors have considered the methods of investigating the molybdenum chalcogenides and of determining the most promising and important regions (in theory and practice) of study of these compounds.

Table 1 gives the chalcogenides of the chromium subgroup elements that are known at present.

Berzelius[21,22] was the first to describe the method of production and some of the properties of the molybdenum sulphides.

The most stable of all the molybdenum chalcogenides is the disulphide MoS_2. It is also the most important sulphide of molybdenum from the practical standpoint. It is the main industrial source for the preparation of molybdenum metal and its compounds.

Molybdenum disulphide, whether natural or artificial, is used as a dry lubricant, forms part of anti-friction lacquer coatings, and allows the production of highly efficient lubricant systems capable of operating at high velocities and at elevated temperatures (up to 400°C), which is especially important in contemporary technology[23-30].

TABLE 1. Chalcogenides of the elements of the chromium subgroup[1-20].

Chalcogen	Metal			
	Cr	Mo	W	U
S	CrS, Cr_7C_8, Cr_5S_6, Cr_3S_4, Cr_2S_3	Mo_2S_3, MoS_2, Mo_2S_5, MoS_3, (MoS_4)	WS_2, WS_3	U_4S_9, US, U_2S_5, U_3S_5, US_2, US_3
Se	$CrSe$, Cr_7Se_8, Cr_5Se_6, Cr_3Se_4, Cr_2Se_3	Mo_2Se_3, $MoSe_2$, Mo_2Se_5, $MoSe_3$	WSe_2, WSe_3	USe, U_3Se_4, U_2Se_5, U_2Se_3, USe_2, USe_3,
Te	$CrTe$, Cr_7Te_8, Cr_5Te_6, Cr_3Te_4, Cr_2Te_3	Mo_2Te_3, $MoTe_2$	WTe_2	UTe, U_2Te_4, U_2Te_5, UTe_2

After molybdenum disulphide, the compound which is second in practical importance and the extent to which it has been studied must be the trisulphide MoS_3, which is widely employed in analytical chemistry[31].

The molybdenum atom has incomplete inner electron shells, which can bring about catalytic activity. The ease of transfer from one valency state to another allows molybdenum to function either as a donor or as an acceptor of electrons. Therefore many molybdenum compounds are used as catalysts for various chemical processes. An important point is that molybdenum compounds exhibit high catalytic activity and selectivity, and are also stable against such a common catalyst poison as sulphur. For example, molybdenum sulphides are used as catalysts in condensations, dehydrations, etc.[32-36].

Of the selenides and tellurides of molybdenum, $MoSe_2$ and $MoTe_2$ have been studied most. The interest in them is due above all to their semiconducting properties.

The following oxide chalcogenides and chalcogenide halides of molybdenum are known: MoO_2S [37], $MoO_2S.3H_2O$, $MoOS_2.3H_2O$ [33], $2MoS_3.MoO_3.9H_2O$, $MoS_3.5MoO_3.6.5H_2O$ [39], $MoCl_2S$ [40], $Mo_5Cl_9S_8$ [41].

2. LOWER CHALCOGENIDES OF MOLYBDENUM

Of the lower molybdenum chalcogenides, the compounds corresponding to the sesqui-composition, Mo_2X_3, are known for all chalcogens.

The first information about the preparation and some properties of molybdenum sesquisulphide was published around 1900, when Guichard[42-44] isolated long steel-grey needles of Mo_2S_3 by brief heating of MoS_2 out of contact with air, at a high temperature. The reaction products were treated with a cold dilute mixture of nitric and hydrochloric acids.

Later Muthmann and Mai[45] obtained well-formed blue-black crystals of Mo_2S_3 on heating MoS_2 (previously boiled in hydrochloric acid) with a mixture of calcium oxide and calcium fluoride. The Mo_2S_3 crystals were separated from the sinter by treating it with concentrated hydrochloric acid followed by elutriation of the unreacted material.

Of the early works it is also worth remembering a low-temperature method of obtaining Mo_2S_3, based on the prolonged action of hydrogen sulphide on a sulphuric acid solution of Mo^{III}, leading to the formation of a black precipitate, which is evidently a hydrated form of molybdenum(III) sulphide[46].

The most contradictory opinions were held for a long time about the formation of molybdenum sesquisulphide from MoS_2 during its thermal decomposition. Thus Guichard[43,44], and later Parravano and Malquori[47], considered that the reduction of molybdenum disulphide in hydrogen proceeds to the metal without formation of intermediate compounds:

$$MoS_2 + 2H_2 = Mo + 2H_2S.$$

It has been reported[48-50] that the thermal dissociation of MoS_2 in a vacuum is also not accompanied by the formation of Mo_2S_3.

In view of the contradictory opinions and the absence of sufficient experimental data, the problem of the existence of Mo_2S_3 and the temperature range of its stability remained unsolved for a long time. A definitive solution of the problem became possible only recently after new precise data about the thermal decomposition of MoS_2 had been obtained, tensimetric investigations had been made, and some physicochemical properties of Mo_2S_3 had been studied.

It is now established that the thermal decomposition of MoS_2, whether in an inert atmosphere, in hydrogen, or in a vacuum, is accompanied by the formation of Mo_2S_3 as an intermediate; its existence has been shown chemically and by X-ray diffraction.

Zelikman and Belyaevskaya [51] showed that in argon MoS_2 rapidly decomposes at 1650–1700°C with formation of a lower sulphide.

The vapour pressure of sulphur over Mo_2S_3 in equilibrium with molybdenum has been measured [52] by the Knudsen method between 1025° and 1150°C and it has been found that not MoS_2 but Mo_2S_3 is in equilibrium with metallic molybdenum and sulphur vapour at these temperatures.

Stubbles and Richardson [53] have shown the error in earlier data [47] on the reduction of MoS_2 in hydrogen at high temperatures. They studied [53] the equilibrium in the Mo–S–H system between gaseous (H_2–H_2S) and solid (Mo–Mo_2S_3 and Mo_2S_3–MoS_2) mixtures at temperatures from 850° to 1200°C by the circulation method. The equilibria are described by the following equations:

$$^2/_3\,Mo + H_2S \rightleftarrows {}^1/_3\,Mo_2S_3 + H_2,$$
$$Mo_2S_3 + H_2S \rightleftarrows 2\,MoS_2 + H_2,$$

which show that the reaction of MoS_2 with hydrogen at high temperatures is accompanied by the formation of Mo_2S_3 as an intermediate. The method of studying the equilibria involves establishing equilibrium between the gases and heated solids on circulating hydrogen over the ground materials [54,55]. The constancy of the hydrogen sulphide pressure was determined by radiochemical determination of its concentration in the gas phase (radioactive sulphur was introduced during the preparation of the sulphides).

The following free energy equations were proposed [53] for the above equilibria:

$$^2/_3Mo(solid) + H_2S(gas) \rightleftarrows {}^1/_3Mo_2S_3(solid) + H_2(gas),\ t = 850\text{–}1200^\circ,$$
$$\Delta G^\circ = -21\,270 + 6.4T \text{ cal } (\pm 100 \text{ cal}),$$
$$Mo_2S_3(solid) + H_2S(gas) \rightleftarrows 2MoS_2(solid) + H_2(gas),\ t = 1000\text{–}1200^\circ,$$
$$\Delta G^\circ = -21\,610 + 8.23T \text{ cal } (\pm 100 \text{ cal}).$$

The free energy equations for the formation of each sulphide from diatomic sulphur and molybdenum are:

$$^4/_3Mo(solid) + S_2(gas) = {}^2/_3Mo_2S_3(solid),$$
$$\Delta G^\circ = -85\,700 + 36.41T \text{ cal}.$$

$$Mo(solid) + S_2(gas) = MoS_2(solid),$$
$$\Delta G^\circ = -85\,870 + 37.33T \text{ cal}.$$

It has been shown [56] that the vacuum thermal dissociation of molybdenum disulphide at 1280°C leads to the formation of the sesquisulphide.

The thermal dissociation of MoS_2 was brought about [56] by putting a few grammes of it in a thoroughly cleaned and previously outgassed quartz ampoule, which was evacuated to a residual pressure of 1×10^{-5} mmHg, sealed and put in a tube furnace in such a way that the end with the substance was in the furnace while the other end projected outside it and could be cooled. The material was heated to a known temperature and held there for a few hours. A sublimate of sulphur condensed in the cold end.

Heating MoS_2 at 1280–1300°C leads to the formation of steel-grey products with a marked metallic lustre, the composition of which corresponds to the formula $Mo_{1+x}S_2$, where x varies according to the time held at a given temperature. The crystal lattice of the phases of variable composition is based on hexagonal MoS_2 with slight distortion in the c direction.

Mo_2S_3 is formed when MoS_2 is heated for a long time under these conditions.

Gorokh and coworkers [57] synthesised Mo_2S_3 from the elements by direct heating of stoichiometric quantities of molybdenum and sulphur in an evacuated quartz ampoule to 500°C and holding at this temperature for 6 h, after which the temperature was raised to 900°C, held there for 14 h, heated again at 1400°C, and held at that temperature for 15 h.

Mo_2S_3 dissociates into the elements at 1600°C, that is, in an inert atmosphere at normal pressure it undergoes thermal dissociation before fusion [57]. Heating Mo_2S_3 with sulphur again leads to the formation of MoS_2. [43,44]

There is evidence that molybdenum sesquisulphide forms a non-stoichiometric compound of composition $Mo_{2.08}S_3$. [52,58,59]

The lower selenides and tellurides of molybdenum have been studied less than the sulphide.

The selenide Mo_2Se_3 is obtained by fusing a finely ground mixture of MoO_2, K_2CO_3, and Se†. The closed crucible with the mixture is put into a furnace at 800°C, the furnace temperature raised to 1200°C, and the mixture held at that temperature for ~1 h until fusion is complete. The cooled melt is treated with water in an atmosphere of nitrogen, to dissolve the potassium selenide. The residue — a steel-grey powder — is Mo_2Se_3. [60]

The telluride Mo_2Te_3 is obtained during the vacuum distillation of the alloy prepared by heating a mixture of molybdenum and an excess of tellurium in an evacuated sealed quartz ampoule. After the reaction the excess of tellurium is sublimed into the cooled upper end of the ampoule, by heating its lower end with the material for a few days at 815–890°C. [61]

Recent work [62,63] on the investigation of molybdenum chalcogenides showed that the lower selenides and tellurides of molybdenum are compounds of variable composition with narrow homogeneity regions. The authors [62,63] note that in composition the molybdenum lower selenides and tellurides do not correspond precisely with the sesqui--compounds, but correspond better with the formula Mo_3X_4 (where X is Se or Te).

As a result of the thermographic investigations and also the data on the vacuum-thermal decomposition of the dichalcogenides, the following general methods for preparing Mo_3Se_4 and Mo_3Te_4 were proposed: (a) thermal dissociation of the molybdenum dichalcogenides — $MoSe_2$ and $MoTe_2$ — in a vacuum at definite temperature ranges; (b) reaction of stoichiometric amounts of the elements in evacuated quartz ampoules; (c) reaction of metallic

† The mixture is covered with a layer of potassium carbonate.

molybdenum with the corresponding dichalcogenide in evacuated quartz ampoules according to the reaction:

$$Mo + 2\,MoX_2 = Mo_3X_4,$$

where X is selenium or tellurium.

All these reaction lead to temperature intervals which ensure the decomposition of the corresponding dichalcogenides to the lower compounds, that is, for selenides at 1180–1240°C, for tellurides at 770–920°C.

The lower molybdenum chalcogenides show great similarities in physical and chemical properties. They are grey crystalline substances, comparatively resistant to attack by acids. At ordinary temperature Mo_2S_3 does not react with hydrochloric and sulphuric acid, or with a mixture of dilute hydrochloric and nitric acids, but it dissolves readily on heating in nitric acid, with the formation of molybdic and sulphuric acids[42-44,57]. The dissolution is apparently due to the reaction:

$$Mo_2S_3 + 10\,HNO_3 = 2\,H_2MoO_4 + 3\,H_2SO_4 + 10\,NO.$$

The molybdenum lower selenide shows similar behaviour[60].

The molybdenum lower telluride is oxidised by nitric acid to MoO_3 and TeO_2, but boiling sulphuric acid is decomposed with the liberation of SO_2 and formation of a cherry-red product of unknown composition[61].

The behaviour of the lower chalcogenides of molybdenum on heating has been insufficiently studied. Such information as has been published[47-53,57] about the thermal stability of Mo_2S_3 has been given in detail above. The molybdenum lower selenides and tellurides are stable in a vacuum up to 1250° and 950°C respectively, above which they dissociate to the elements[61-63].

According to Wendehorst's results[60] the lower molybdenum selenide does not change composition on heating in a stream of H_2Se. However, this is doubtful in the light of subsequent results from studies of the equilibrium in the Mo–S–H system[53] and the great similarity between the properties of these compounds.

The hardness of Mo_2S_3 is somewhat greater than that of MoS_2, and is five on Mohs' scale; the density, determined pyknometrically, is 5.75 g cm^{-3}.[57] The density of the lower telluride is 7.35 ± 0.01 g cm^{-3} at 15°C.

The magnetic properties are known only for the lower telluride of molybdenum. It is paramagnetic, the magnetic susceptibility being $+(0.185 \pm 0.002) \times 10^{-6}$.[61]

A determination of the crystal structure of Mo_2S_3 by the powder method[53] showed that it is tetragonal with unit cell parameters c = 10.9 Å and c/a = 1.27. However, it was shown later[64] that Mo_2S_3 is monoclinic with parameters a = 8.6335 Å, b = 3.208 Å, c = 6.092 Å, β = 102°43′, Z = 2, space group $P2_1/m$, density calculated from the X-ray measurements 5.806 g cm^{-3}.

In the Mo_2S_3 structure each molybdenum atom is situated at a distance of 2.36 Å from three neighbouring sulphur atoms and at a distance of 2.57 Å from three other sulphur atoms (Fig. 1). The molybdenum atoms in direction b are displaced 0.32 Å relative to one another and form a zig-zag chain with Mo–Mo distance of 2.85 Å.

According to Gorokh and coworkers[57], Mo_2S_3 is orthorhombic with the rhombobipyramidal class of symmetry ($3L^23PC$). The Mo_2S_3 crystals are elongated prisms with a rhomb cross-section and angles of 40° and 140° between the adjacent faces. The Mo_2S_3 crystal lattice is similar to the Sb_2S_3 lattice.

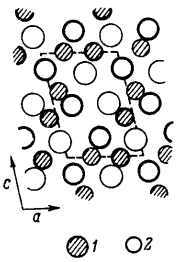

Fig. 1. Structure of Mo_2S_3 projected along axis b. The broken line marks out a unit cell. The atoms at $y = \frac{1}{4}$ are drawn with a light line, those at $y = \frac{3}{4}$ with a heavy line: 1) molybdenum atom; 2) sulphur atom.

TABLE 2. Structural data for Mo_3Se_4 and Mo_3Te_4.

Compound	Symmetry	Lattice parameters, Å			β	Z	Density, g cm^{-3}	
		a	b	c			X-ray	pykno-metric
Mo_3Se_4	monoclinic	4.61	4.77	6.62	93°09′	1	6.88	6.75
Mo_3Te_4	monoclinic	4.87	5.09	7.04	93°46′	1	7.61	7.45

The crystal structure of the molybdenum lower selenides and tellurides has been investigated by the powder method. Mo_3Se_4 and Mo_3Te_4 are isostructural, their crystals are monoclinic. Table 2 gives the results of X-ray investigations[65].

The lower chalcogenides have been studied insufficiently, especially the selenides and tellurides. Probably one of the reasons is that until recently the methods for preparing them were not simple and reliable enough. The methods developed recently for the preparation of molybdenum lower chalcogenides will undoubtedly facilitate their more intensive study[57,62,63].

Structural information about the lower molybdenum chalcogenides is limited to studying them by the powder method. There is a future possibility of obtaining single crystals of these compounds to carry out thorough structural investigations.

Information on the chemical properties of the molybdenum lower chalcogenides is limited to the qualitative characteristics of the behaviour of these compounds in certain acids. It is evident that a study of their reaction with certain elements, with various acids and bases, and also with solid salts and salt solutions, allows interesting data to be obtained on the properties of these compounds, and this in turn opens a path for the preparation of new molybdenum compounds.

3. MOLYBDENUM DICHALCOGENIDES

The molybdenum dichalcogenides are the most stable, most fully studied, and most industrially important compounds of those considered in this review.

The properties of MoS_2 have been described more fully than those of $MoSe_2$ and $MoTe_2$ but the latter are now of special interest in connection with the rapidly developing investigations of semiconductors.

Molybdenum disulphide, molybdenite, is encountered in nature but can be made artificially by various methods. $MoSe_2$ and $MoTe_2$ are only made artificially.

Of the many methods for obtaining molybdenum dichalcogenides we will consider those which are the most general and important in practice (Fig. 2). Several different methods for making MoS_2 have been proposed, but $MoSe_2$ and $MoTe_2$ are made commercially only by the direct reaction of the elements. The exceptional position of MoS_2 is explained above all by the extent to which methods of preparing MoS_2, $MoSe_2$, and $MoTe_2$ have been studied. There is no doubt that further investigation of $MoSe_2$ and $MoTe_2$ will lead to the development of new methods for preparing them, both by methods similar to those for making MoS_2 and by original methods, specific for each of the compounds under consideration.

The method most frequently used for obtaining $MoSe_2$ and $MoTe_2$ — direct synthesis from the elements — apparently still attracts investigators because it allows the purest materials to be obtained, suitable for the investigation of their semiconducting properties without additional purification. However, the use of transport reactions[73,77,82], which not only allow the substances to be purified but also to be obtained in the form of single crystals, make the old preparative methods of interest today.

In addition to the methods for obtaining molybdenum chalcogenides shown in Fig. 2, mention must be made of a method of synthesising crystalline MoS_2, proposed by Spengler[83]. MoS_2 is obtained by the reaction of molybdenum metal or its compounds (molybdenum oxides, salts of molybdic acids, etc.) with sulphur or sulphur(II) compounds (for example, H_2S, alkali metal polysulphides, etc.), in an alkaline medium at 300–500° and at increased pressure in an atmosphere free from oxidising agents.

Methods for obtaining the molybdenum dichalcogenides from the gas phase are also known. Thus MoS_2 can be obtained by the direct reaction of H_2S and CS_2 with molybdenum[84] or by reaction of S and H_2S with volatile molybdenum compounds on heating[85]. The last method can also be used to make $MoSe_2$ and $MoTe_2$.

Of the methods for obtaining molybdenum dichalcogenides which are considered the following are used most often: to prepare MoS_2, the reaction of molybdenum trioxide with sulphur in molten potassium carbonate[70]; to prepare $MoSe_2$ and $MoTe_2$, direct synthesis from the elements[59,73–77].

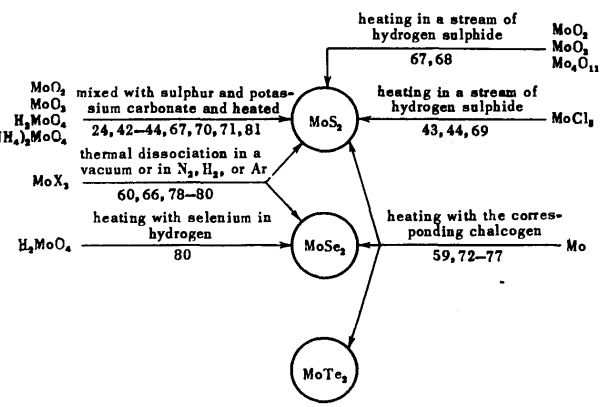

Fig. 2. Methods of preparing the molybdenum chalcogenides (the numbers underneath the arrows are literature references).

In the method of making MoS_2, the potassium carbonate plays a dual role: it serves as a solvent for the sulphur and is a flux, protecting the product formed from oxidation. To obtain MoS_2, four parts by weight of K_2CO_3 are fused with six of sulphur in a closed porcelain retort at 700°. The reaction continues until SO_2 is no longer lost, after which the retort containing the melt is removed from the furnace and cooled. One part by weight of pure MoO_3 (obtained as a sublimate) is added, the retort is heated to 900° and held at that temperature for 30 min. The operation is repeated until six parts by weight of MoO_3 have been added. On cooling, the whole mass solidifies.

The excess of the reagents and the impurities are removed by prolonged boiling in dilute ammonia solution, followed by washing with distilled water, boiling for 30 min in dilute hydrochloric acid, and thoroughly washing with water, alcohol, and ether successively. The product is dired in a vacuum at 75°C.

Bell and Herfert[86] think that the formation of MoS_2 takes place in two stages:

$$2\,MoO_3 + S \rightarrow 2\,MoO_2 + SO_2,$$

$$MoO_2 + 3\,S \rightarrow MoS_2 + SO_2$$

The disulphide obtained always contains MoO_2. These authors were unable to carry out the second reaction to completion by various methods, therefore they removed unreacted MoO_2 present as impurity by treating the material with dilute KCNS (similar to the method developed by Milbauer[87]) with subsequent treatment with dilute solutions of ammonia and hydrochloric acid. This operation almost completely frees the disulphide preparation from MoO_2 and a fairly pure product is obtained ($< 0.01\%$ MoO_2).

It is interesting to note that in the reaction of various molybdenum oxides (for example, MoO_3, MoO_2, Mo_4O_{11}) with hydrogen sulphide at 400–550°C, the final product always contains some MoO_2 as well as MoS_2.[68] The process takes place differently, depending on the initial substance. With molybdenum trioxide the following reactions are possible:

(a) exchange of oxygen with sulphur:

$$MoO_3 + 3\,H_2S \rightarrow MoS_3 + 3\,H_2O;$$

(b) reduction of the higher oxide to MoO_2:

$$MoO_3 + H_2S \rightarrow MoO_2 + H_2O + S;$$

(c) reaction of MoO_2 with hydrogen sulphide:

$$MoO_2 + 2\,H_2S \rightarrow MoS_2 + 2\,H_2O;$$

(d) decomposition of the sulphide obtained earlier (a) at 400–500°C:

$$MoS_3 \rightarrow MoS_2 + S.$$

The reaction of Mo_4O_{11} with hydrogen sulphide proceeds as follows:

$$Mo_4O_{11} + 3\,H_2S \rightarrow 4\,MoO_2 + 3\,H_2O + 3\,S,$$

and subsequently by scheme (c). When the initial substance is MoO_2 the reaction with hydrogen sulphide apparently leads only to reaction (c).

The reaction products always contain MoS_2 and MoO_2, the sum of the stoichiometric coefficients $(x + y)$ in the empirical formula MoO_yS_x are often greater than two, which shows that either elemental sulphur or MoS_3 is present in the products.

As molybdenum disulphide has recently been widely used in technology as a lubricant, the problem arises as to the methods for obtaining pure MoS_2 containing $\gtrsim$ 0.2% impurities. Quartz, 5–7% of which is present in molybdenite concentrates, is an especially harmful impurity. Therefore to obtain pure MoS_2 suitable for use as a lubricant the natural concentrates are subjected to many treatments, which greatly increases the cost of the product[24]. The use of flotation-leaching chemical purification in association with the grinding of molybdenite in ball mills enables a sufficiently pure (99.8%) MoS_2 to be obtained from natural molybdenite concentrates[88].

However, it is more economical to obtain pure MoS_2 by artificial means. A proposed[81] method of preparing MoS_2, by the reaction of MoO_3 or $CaMoO_4$ with sulphur in molten sodium carbonate at 700°C, allows a product with the theoretical ratio of the elements to be obtained.

The direct synthesis of the molybdenum dichalcogenides from the elements is carried out as follows. Stoichiometric amounts of the pure powdered elements are mixed well and put into a quartz ampoule which has previously been cleaned and thoroughly outgassed in a vacuum. The ampoule is outgassed to a residual pressure of 10^{-5} mmHg, sealed, and heat treated, to ensure completion of the reaction and to give a homogeneous product. The ampoule with the reaction mixture is heated slowly in a furnace having smooth temperature regulation. As Table 3 shows, the temperature and holding time in the thermal treatment are different for different authors.

Obviously a higher temperature in the preparation ensures a more rapid completion of the reaction and the best homogenisation of the product. However, in high-temperature preparations explosion of the ampoule is possible. Therefore it is more convenient to carry out direct preparation from the elements at low temperatures, when this is possible, as was suggested for the explosion-free preparation of compounds of the $A^{II}B^{VI}$ type[89].

TABLE 3. Conditions for the preparation of molybdenum dichalcogenides from the elements in evacuated quartz ampoules.

Compound prepared	Heat treatment conditions		Reference
	temp., °C	time, h	
$MoSe_2$	700 anneal I	100	74
$MoSe_2$ / $MoTe_2$	600—700 anneal II	10—15	73
	1000—1200	10—15	76
$MoTe_2$	1100	5—10	75
$MoTe_2$*	460	16	61
$MoTe_2$**	580	20	
	640	24	
	780	48	
	640	40	
	775	24	
$MoTe_2$	600	2 d	77

* After the reaction the product was crushed, passed through a 125 mesh sieve and heated at 600°C for 48 h in a vacuum.

** In preparing $MoTe_2$, an excess of tellurium was taken; after the reaction it was removed by sublimation at 580–815°C in a vacuum.

Finally, in this instance the time of heat treatment to obtain a homogeneous product should be greatly increased.

All the molybdenum dichalcogenides are crystalline. As is known, the ions S^{2-}, Se^{2-}, and Te^{2-} have large radii (1.82, 1.93, and 2.11 Å respectively[90]), and consequently can readily be polarised. On the other hand, the Mo^{4+} ion, which has an ionic radius of 0.65 Å,[90] is a strongly polarising anion. Under such conditions, when the anion is readily polarised and the cation exhibits strong polarising properties, compounds of the type AX_2 show layer structures[91], which have a layer of the cation atoms situated between two layers of anion atoms, as a result of which a packet of three layers is formed. The bonds inside the three layers are considerably stronger than those between two three-layer packets. The molybdenum dichalcogenides are representatives of just this type of layer structure.

Natural molybdenite forms normally flat, thin, very flexible, soft, blue-grey flakes or scales, greasy to the touch and similar to graphite. Its crystals are hexagonal[92,93], space group $P6_3/mmc$–D^4_{6h}. The unit cell contains two MoS_2 molecules and has the following parameters[94]: a_0 = = 3.16 Å, c_0 = 12.32 Å, a_0/c_0 = 1 : 3.899.

Molybdenite has the typical layer structure. The layers of molybdenum ions are situated between two layers of sulphide ions parallel to the $(000\bar{1})$ plane. The ions in the layers are joined by strong bonds and the slip forces between such triple packets are very weak and apparently are of the van-der-Waals type.

This also explains the properties of molybdenite, such as the exceptional ease of slip in the direction perpendicular to the c axis — cleavage is completely by $(000\bar{1})$, the predominant flaky form.

Molybdenum has a coordination number of six in MoS_2 but because of the peculiar electronic structure of molybdenum it corresponds to a trigonal prism and not an octahedron. A molybdenum atom is surrounded by six sulphur atoms at the apices of a regular isosceles trigonal prism (Fig. 3).

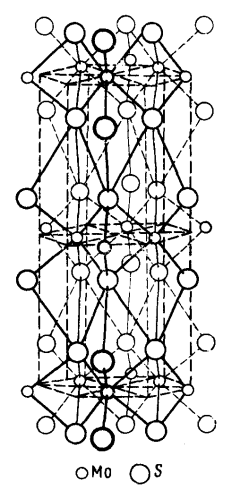

Fig. 3. Structure of hexagonal molybdenum disulphide, MoS_2.

The layer nature of the MoS_2 structure can be represented more graphically[95] as alternating layers of trigonal prisms with Mo^{4+} ions in their centres alternating with empty layers of octahedra (Fig. 4). The hexagonal axis c is perpendicular to the triangular surface of the prism. In MoS_2 the Mo–S distance is 2.35 Å, the S–S distance between two neighbouring layers is 3.66 Å, and the S–S distance in a trigonal prism is much less (2.98 Å)[96].

Synthetic MoS_2, $MoSe_2$, and $MoTe_2$ crystallise as blue-grey tablets or leaflets, and even in thin needles a few millimetres long[70,73,75].

For a long time the crystal structure of MoS_2 remained uncertain, since the preparation of the disulphide was confirmed mainly by chemical analyses, or sometimes microscopically. Although X-ray examination showed the preparation obtained from the elements in an iron tube[72] to have the structure of natural molybdenite, the identity of natural crystals with artificial ones obtained by other methods[67,69,70] was not established. It was suggested that there was a trigonal morphology of artificial MoS_2 crystals[92,97].

The polymorphism of MoS_2 which had been suggested earlier was demonstrated in 1957, when Bell and Herfert[86] obtained the X-ray diagram of synthetic molybdenum disulphide differing in structure from natural molybdenite.

It is now known that MoS_2 can exist in at least two, and possibly in three, polymorphic states[75,86,98–100].

Bell and Herfert[86], who first described a new crystalline form of synthetic MoS_2, obtained by the de Schulten method[70], concluded on the basis of X-ray investigations that the artificial MoS_2, unlike the hexagonal natural molybdenite, is tetragonal with a rhombohedral unit cell, parameters $a = 3.16$ Å, $c = 12.32 \times 1.5$ Å, that is, with the same a parameter, but with the c parameter 1.5 times that for the hexagonal form of the natural disulphide.

The authors[86] explained this difference as follows. Since the interatomic distances in the two modifications are equal, the structures differ in the disposition of the sulphur atoms in the packets, namely: in the hexagonal form a molybdenum atom is situated at the centre of a triangular prism with the three upper sulphur atoms directly above the three lower atoms (Fig. 5a), in the rhombohedral form one layer of sulphur atoms in the packet (for example, the upper) is turned 60° relative to the other (the lower) (Fig. 5b), which on a more thorough examination of the structure leads to octahedral coordination of the molybdenum atom[99].

Hence for the new modification of MoS_2 they proposed a structure with a centre of symmetry, which is described by

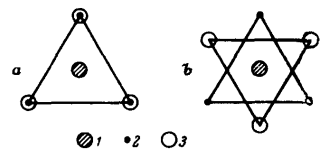

Fig. 5. Coordination of molybdenum atoms in molybdenum disulphide[86]:
a) natural hexagonal MoS_2; b) synthetic rhombohedral MoS_2;
1) molybdenum atom; 2) lower sulphur atoms; 3) upper sulphur atoms.

the space group $R\bar{3}m$–D^5_{3d}, that is, a $CdCl_2$-type structure, where the mutual orientation of the three layers is effected so that only the fourth layer of anions repeats the first, the fifth repeats the second, and so on.

However, this structure did not correspond sufficiently accurately with reality, because of the great discrepancies between the theoretical and experimental intensities of the reflections.

Subsequently a new rhombohedral MoS_2 structure was considered and worked out more precisely. A scheme was proposed[98] with triangular-prismatic coordination of the molybdenum (Fig. 6). The structure shown can be described by space group $R3m$–C^5_{3v} with the following distribution of atoms:

3 molybdenum atoms in 3 (a): 00z with z = 0.000
3 sulphur atoms I in 3 (a): with z = 1/4.001/4
3 sulphur atoms II in 3 (a): with z = 5/12.005/12.

This scheme for the rhombohedral modification of molybdenum disulphide agrees well with the experimental results.

Semiletov[99] confirmed this theoretically. He showed that a structure of the $CdCl_2$ type proposed by Bell and Herfert[86] for rhombohedral MoS_2 was wrong and the constructed a model of a structure with the molybdenum atoms distributed in a trigonal prism (and not in an octahedron, as they should be according to Bell and Herfert).

According to Semiletov[99] the rhombohedral modification is obtained from the hexagonal by rotating through 60° entire three-layer packets and not one of the layers of a single packet, which leads to a structure without a centre of symmetry and with space group $R3m$–C^5_{3v}.

Knop and MacDonald arrived at the same conclusion[75]. They considered both layer structures consisting of hexagonal layers of atoms of molybdenum and sulphur situated

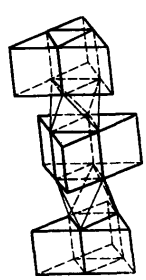

Fig. 4. Structure of MoS_2.[95]

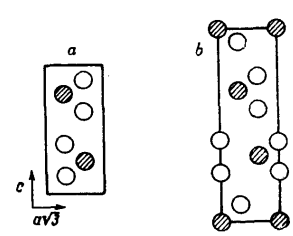

Fig. 6. Polymorphic structure of MoS_2:[98]
a) hexagonal form; b) rhombohedral form.

parallel to the basal plane as differing from one another in the sequence of periods of combination of packets with respect to one another, namely:

. . . AMA BHB/AMA BHB/AMA . . . for the hexagonal form,
. . . APA CMC BHB/APA CMC BHB/APA . . . for the rhombohedral form,

where *A*, *B*, *C* refer to sulphur layers and *M*, *H*, *P* to molybdenum layers. However, in both instances they give trigonal-prismatic coordination of the molybdenum atoms with the nearest atoms of sulphur.

Hence in hexagonal MoS_2 with parameter c = 12.32 Å there are two three-layer packets and in the rhombohedral, the lattice parameter of which is 1.5 times as much (a ratio of 3 : 2), there are three packets.

Apparently the rhombohedral form of MoS_2 is unstable and on prolonged heating it is converted into the stable hexagonal form[79].

Study of the chemical bonds in molybdenite, where the Mo^{IV} atom has a coordination number of six, leads to the conclusion that the six sulphur atoms do not form an octahedron around the molybdenum, but — by virtue of the special structure of the electronic cloud of the molybdenum atom — a triangular prism with a ratio of the axes equal to unity, and S–Mo–S angles of 82° and 136°.[92,101-103]. dsp orbitals participate in the bondformed. Most investigators think that d^4sp hybridisation occurs here, that is, 4*d*, 5*s*, and 5*p* electrons of the central atom participate in the formation of the bond and the only 4*d* orbital (fifth shell) not participating in the bond of the molybdenum atom is occupied by two electrons (one unshared pair)[104-106].

Barinskii and Vainshtein[104] confirmed the d^4sp hybridisation by investigation of the fine structure of X-ray absorption and emission *L* spectra of molybdenum in MoS_2. Knop and MacDonald[75] consider that the magnetic properties of MoS_2 confirm that bond; they think that this results in the diamagnetism and the considerable anisotropy of the diamagnetism of MoS_2 crystals, in which the negative susceptibility in a direction parallel to the hexagonal axis is almost twice that in the direction perpendicular to the axis. The marked temperature dependence of the magnetic properties of molybdenite crystals[107-109] and also the considerable electrical conductivity in the direction perpendicular to the hexagonal axis (that is, along the base of the plane)[110], is explained by the existence of strongly delocalised mobile π-electrons inside the layers, which can be understood, starting from d^4sp orbital configuration of the molybdenum atom.

Investigation of the structure of $MoSe_2$ and $MoTe_2$ began only recently. A hexagonal modification of MoS_2 type is known for these compounds, with space group $P63/mmc$–D^4_{6h}. Table 4 shows some structural characteristics of $MoSe_2$ and $MoTe_2$.

Fig. 7 shows the structure of the ditelluride schematically. The Te–Mo–Te angles[75,76] are respectively α 80.74° ± ± 0.50° and 80.4°; β 83.10° ± 0.60° and 83.5°; γ 134.95° ± ± 0.60° and 133.9°, which corresponds to d^4sp hybridisation[101].

Molybdenum diselenide and ditelluride are thought to be structurally isomorphous with molybdenum disulphide. As MoS_2 exhibits polymorphism, the structural data for $MoSe_2$ and $MoTe_2$ obtained by different methods should be considered incomplete.

TABLE 4. Structural characteristics of molybdenum diselenide and ditelluride.

It is interesting that in the thermal dissociation of molybdenum trisulphide or ammonium thiomolybdate products of composition MoX_{2+x}, or sometimes $Mo_{1-x}S_2$, are obtained under definite conditions[78,79,112]. x decreases as the decomposition temperature is raised. Such products are considered as subtractional solid solutions based on hexagonal MoS_2 with disorder in the crystal lattice: the higher the value of x, the more distorted the structure in the direction of axis c. Above 800° ordering of the structure occurs and stoichiometric molybdenum disulphide is obtained.

The molybdenum dichalcogenides exhibit semiconducting properties. The quality of different thermoelectric materials is compared by use of the figure of merit, which is calculated by the formula[113]:

$$Z=\frac{\alpha^2\sigma}{\kappa},$$

where α is the Seebeck coefficient, σ the electrical conductivity, and κ the thermal conductivity.

At the same time the efficiency of the thermoelectric element increases with the temperature of the hot junction[114].

TABLE 5. Electrical and thermoelectric properties of the molybdenum chalcogenides.

* t is presumably g cal s^{-1} (Ed. of Translation).

Consequently, to obtain large thermoelectric effects, materials with a high Seebeck coefficient and low thermal conductivity, capable of retaining these properties at high temperatures, are required.

Table 5 gives the electrical and thermoelectric characteristics of the molybdenum chalcogenides.

Interesting structural and thermoelectric investigations were made with compositions of the systems $W_{x/2}Mo_{x/2}Ta_{1-x}Se_2$ and $W_{x/2}Mo_{x/2}Ta_{1-x}Se_yTe_{2-y}$.[116] It was shown that compositions of the first system at $x \leq 0.65$ have a space group of type $CdCl_2$ (D^5_{3d}); after this there is a narrow two-phase region with approximately the same intensity for both types, and with $x > 0.8$ all the compositions crystallise in the space group of MoS_2 type (D^4_{6h}). The pyknometric and X-ray densities of compositions in the system were compared.

A structural study of the $W_xMo_{1-x}Se_2$ system showed a linear dependence of lattice parameters (a, c, c/a, ρ_{X-ray}) on x: with successive replacement of molybdenum by tungsten a decreases c increases (Table 6). All the compositions in this system crystallise with MoS_2-type structures.

The thermoelectric characteristics for the composition of these systems have been given. Since the conductivity mechanism in $MoSe_2$ is electronic (n type), but that in WSe_2 is hole (p type), the solid solutions of these compounds of different conductivity types show high electrical resistivity, due to compensation of two opposing conductivity mechanisms. $TaSe_2$ has a comparatively high electrical conductivity and is a metal-like conductor[73,117]. Brixner and Teufer[116] showed that by varying the concentration of the individual components in the compositions of the $W_{x/2}Mo_{x/2}Ta_{1-x}Se_2$ system, the optimal values of the parameters in which an investigator is interested can be found.

TABLE 6. Lattice parameters of compositions of the $W_xMo_{1-x}Se_2$ system.

Composition	a, Å	c, Å	c/a	ρ_{X-ray}, g cm^{-3}	Unit-cell volume, Å^3
$MoSe_2$	3.289	12.930	3.931	6.959	121.128
$Mo_{0.85}W_{0.15}Se_2$	3.289	12.935	3.933	7.318	121.175

$Mo_{0.25}W_{0.75}Se_2$	3.287	12.965	3.944	8.754	121.308
WSe_2	3.286	12.976	3.949	9.353	121.337

Guennoc[77] stated that solid solutions corresponding to the general formula (Mo, W)(Se, Te)$_2$ with additions of niobium or tantalum can operate as thermoelectric materials at 200–400°.

There is great interest in investigating thermoelectric materials in the problem of obtaining substances with thermal conductivities as low as possible. As Ioffe and coworkers showed[121], this can be achieved by fusing the thermoelectric material with an isomorphous element or alloy. Then in the solid solution of two isomorphous crystals the short-range periodicity of the lattice is destroyed, which leads to considerable scattering of phonons. Such destruction of the short-range order of the crystal lattice of the material (while retaining the long-range periodicity) gives a marked decrease in thermal conductivity at very small change in mobility of the charge carriers, which leads to a considerable increase in the figure of merit.

Brixner and Teufer[116] attempted to obtain such alloys based on the $W_xMo_{1-x}Se_2$ system. The results of measuring the thermal conductivity of these compositions show that the thermal conductivity of an alloy of the two isomorphous substances WSe_2 and $MoSe_2$ is less than the thermal conductivity of either of its components and is least when half the tungsten atoms have been replaced by molybdenum.

Study of various alloys of the molybdenum dichalcogenides MoS_2, $MoSe_2$, and $MoTe_2$ with the structurally isomorphous tungsten chalcogenides and also with additions of metals of the neighbouring groups of the Periodic System (for example, niobium, tantalum, rhenium, etc.) for thermoelectric purposes is a future problem of the chemistry of the molybdenum chalcogenides.

The coefficient of thermal conductivity of molybdenite MoS_2 at 80°C is $\kappa = 4.75 \times 10^{-4}$ cal cm^{-1} deg^{-1} s^{-1}.[119] Since the thermal conductivity of semiconductors is of great importance for determining the usefulness and quality of a material, such data are of great interest.

In semiconductors the thermal conductivity is made up of the transfer of heat by waves of thermal motion of the

molecules of the lattice (or phonons) κ_{ph} and from the transfer of the energy of the free charges (or electrons) κ_{el}. However, phononic thermal conductivity plays the principal part, since for semiconducting materials the part of the thermal conductivity which is determined by the diffusion of electrons is negligible.

In semiconductors with carrier current of a single sign the electronic constituent of the thermal conductivity κ_{el} is determined by the Wiedemann–Franz law:

$$\kappa_{el} = \frac{k^2}{e^2} A\sigma T,$$

where k is the Boltzmann constant, e the charge of an electron, A a coefficient (= 2 when undegenerate), σ the electrical conductivity, and T the absolute temperature.

The value $\sigma = 4.3\ \Omega^{-1}\ cm^{-1}$ was found for molybdenite at $T = 353°K$, and the electronic thermal conductivity was calculated to be $\kappa_{el} = 0.0557 \times 10^{-4}$ cal cm^{-1} deg^{-1} s^{-1}.[119] Consequently the phononic thermal conductivity is $\kappa_{ph} = \kappa - \kappa_{el} = 4.75 \times 10^{-4} - 0.0577 \times 10^{-4} = 4.69 \times 10^{-4}$ cal $cm^{-1} \times deg^{-1}\ s^{-1}$, which is ~ 84 times the electronic thermal conductivity. However, it is clearly evident that lattice vibrations make the main contribution to the mechanism of the thermal conductivity of MoS_2.

The Debye temperature for MoS_2 is $\Theta = 209°K$.[119] The dielectric constant of MoS_2 at -196°C is $\epsilon = 7.6$.[122]

The electrical conductivity of molybdenite has been measured over a wide range of temperatures: from 100° to 500°K.[110] It was shown that the electrical conductivity along the basal plane, that is, in the direction perpendicular to the c axis ($\sigma_\perp$), is approximately 10^3 times greater than that in the direction parallel to the hexagonal axis ($\sigma_\parallel$). Ohm's law is obeyed on passing current in the two directions at ~ 420°K, but at room temperature Ohm's law is not obeyed in either direction (Fig. 8).

Measurements of the electrical conductivity in molybdenite crystals at high temperatures show the electronic nature of the conductivity[110]. The mechanism of electronic conductivity in MoS_2 is confirmed by the measurements of the surface conductivity of thin plates of molybdenite cleaved off natural crystals. The surface conductivity rises in an atmosphere of ammonia vapour and falls in an atmosphere of nitric acid vapour. Apparently the adsorption of the vapours of these substances changes the mobility and concentration of the charge carriers[123–125].

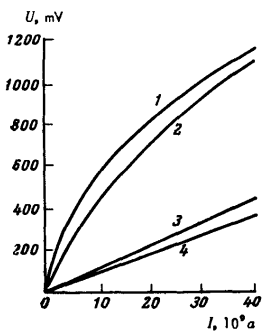

Fig. 8. Dependence of the electrical conductivity of crystals of molybdenite on the stress[110]:
1) $\sigma_\parallel$ at room temperature; 2) $\sigma_\perp$ at room temperature; 3) $\sigma_\perp$ at ~ 420°K; 4) $\sigma_\parallel$ at ~ 420°K.

An investigation of the magnetic properties of MoS_2 confirms the presence of free electrons in the planes of the crystal. Considerable anisotropy (~ 72%) of the diamagnetism of molybdenite crystals was found: the susceptibility in the direction parallel to the hexagonal axis is $\chi_\parallel = -87.1 \times 10^{-6}$, and that in the direction perpendicular to this axis is $\chi_\perp = -44.3 \times 10^{-6}$.[107] Such an increase in diamagnetism in the direction perpendicular to the basal plane is due to the presence of free electrons, which are completely free in the plane of the base but have restricted mobility in the perpendicular direction. A similar diamagnetism of free electrons was found earlier for graphite[126,127].

Still more conclusive facts in support of this were obtained on measuring the magnetic properties of MoS_2 at various temperatures[108,109]. It is known that the susceptibility of free electrons is very sensitive to a change in temperature. With weak magnetic fields and not very low temperatures the diamagnetic susceptibility of the electron gas is[128]:

$$(\chi_e)_{dia} = -\frac{nN\mu_B^2}{3kT},$$

where n is the number of free electrons per unit volume, N Avogadro's number, μ_B the Bohr magneton, k the Boltzmann constant, and T the absolute temperature.

The results of measurements of the temperature dependence of the susceptibility of molybdenite shows that the observed electron susceptibility of MoS_2 equals the diamagnetic susceptibility of free electron gas having an electron density of 0.3 electron per atom[108]. The temperature dependence of the diamagnetic anisotropy resembles the behaviour of graphite single crystals on heating[129].

The above suggests that in MoS_2, where the bond between the molybdenum and sulphur atoms is covalent, bonds of partly metallic character are formed along the basal plane, which agrees well with the results of electric and magnetic measurements of molybdenite crystals. For $MoTe_2$ the specific magnetic susceptibility is -0.345×10^{-6}.[61]

The effect of pressure on the electrical resistivity of MoS_2 has been investigated[130]. At $P = 20$ kbar and 296°K the resistivity of MoS_2 is 300–600 Ω cm. The resistivity decreases considerably with increase in pressure. Phase transformations were not observed up to 500 kbar.[130]

The optical properties of single crystals of MoS_2[131–134] and $MoTe_2$[135] have been studied, using very thin crystals (thickness: MoS_2 100 Å, $MoTe_2$ 200–1000 Å), obtained by splitting at cleavage planes. The optical spectra give valuable information about the bond energies and the excited state in the crystal. Conclusions about the covalent nature of the bonds in crystals of MoS_2 and $MoTe_2$ can be drawn from the spectra.

The molybdenum dichalcogenides are rather stable. For a long time the melting point of molybdenite was thought to be 1185°.[97] Zelikman and Belyaevskaya[51] found, by subjecting MoS_2 to rapid and short-time (2–3 min) heating, that specimens of MoS_2 start to melt at 1650–1700°C; this is accompanied by intensive decomposition with formation of a lower sulphide. However, Cannon[136] considers that this temperature is depressed owing to the reaction of the material with the graphite vessel used in the work[51]. On

heating specimens of MoS_2 in molybdenum crucibles in a vacuum, he[136] observed fusion on heating for 10 min at 1800° ± 20°C. He concluded that if MoS_2 obeys Tammann's rule, that is, the temperature for the start of appreciable sintering is approximately one-half *Tf*, then the melting point of MoS_2 must be ~2375°C.

In view of the contradictory data[51,136], the problem of the melting point of MoS_2 requires further investigation. However, it is clear that the above experimental results[51,136] are erroneous. As shown recently[56], when heated in a vacuum MoS_2 decomposes before melting, and when heated for a sufficient time even at 1280°C the dissociation of MoS_2 is accompanied by the formation of the sesquisulphide. At 1400°C the thermal decomposition of MoS_2 goes to metallic molybdenum[137]. On heating MoS_2 to a temperature above 1000°C, sintering of the material occurs and the surface of the MoS_2 is covered with a dense, difficultly permeable scale, which retards the dissociation[56,138]. This may be the reason for the erroneous results[136].

Careful examination of Zelikman and Belyaevskaya's results[51] suggests that the dissociation of MoS_2 in an inert medium also starts before 1350°C, as is shown by the chemical analysis of the products. Although their X-ray diagrams do not differ from that of the original disulphide it is evident from the chemical analysis that the products of the heating are appreciably enriched in molybdenum. Probably there is formation of a phase of type $Mo_{1+x}S_2$, based on the hexagonal MoS_2 type which has been described[56]. The authors[51] concluded that MoS_2 had no phase transformations up to 1350°C according to the results of the heating curves recorded with a pyrometer; this is evidently due to a very small rate of dissociation of molybdenum disulphide and consequently an insignificant thermal effect.

It must be emphasised that both the formation and the dissociation of the chalcogenides take place rather slowly, especially at low temperatures. This must be remembered in considering various equilibria in chalcogenide systems. This is why the published results[51,136] obtained in short-time heating should be regarded critically.

$MoSe_2$ and $MoTe_2$ dissociate with formation of lower chalcogenides when heated in a vacuum to 1170° and 750°C respectively[61,62].

The thermodynamic characteristics of MoS_2 are known[139-141]. Smith and coworkers[140] carried out calorimetric measurements and calculated some thermodynamic quantities for solid MoS_2 at low temperatures (Table 7).

The free energy and heat of formation of MoS_2 from the elements have been calculated[53]:

$$\Delta G^\circ_{298} = -78\,420 \text{ cal}, \qquad \Delta H^\circ_{298} = -91\,340 \text{ cal}.$$

The molybdenum dichalcogenides are quite stable in air at room temperature but the finely-divided ditelluride is reported[76] to oxidise slowly.

On heating in air all the compounds burn to form MoO_3 and the corresponding chalcogenide oxide.

Since the oxidation of MoS_2 is widely used industrially for the treatment of molybdenite concentrates the kinetics of the oxidation of molybdenite at 400°, 500°, and 600°C has been studied[142,143]. It is thought[142] that within the range 400–600°C molybdenum disulphide is oxidised by oxygen to MoO_3, without the stage of formation of MoO_2. The mechanism of the oxidation of MoS_2 is probably:

$$MoS_2 + O_{2ads} \rightarrow MoS_2O + O,$$
$$MoS_2 + O_{2ads} \rightarrow MoSO_2 + S,$$
$$MoS_2O + O_{2ads} \rightarrow MoO_3 + 2S,$$
$$MoSO_2 + O_{2ads} \rightarrow MoO_3 + SO.$$

The initial act of reaction of MoS_2 with oxygen consists in the adsorption of oxygen molecules on the surface of the molybdenite. The formation of intermediate compounds of the oxide sulphide type is facilitated by the presence on the surface of the MoS_2, which is a semiconductor, of active centres with free valencies[144]. Above 600°C the secondary reaction of MoS_2 with the MoO_3 occurs, with formation of MoO_2.[142]

Heating in the absence of air gives different results, depending on the conditions of the experiment, which has already been discussed in detail above. As the results of different authors show, the question of the thermal dissociation of molybdenum dichalcogenides under different conditions is still not completely clear. Taking into account that most of these investigations are comparatively old, the problem of the behaviour of the molybdenum chalcogenides on heating remains unsolved and requires repetition of the experiments on a contemporary level.

According to Wendehorst's results[60], when heated in hydrogen, molybdenum diselenide does not give a lower selenide but is slowly reduced to the metal if the temperature is high enough.

Not one of the chalcogenides of the MoX_2 type is converted into a compound richer in chalcogen by heating with the chalcogen concerned[42-44,60,61]. Apparently compounds of the MoX_3 type are always thermodynamically unstable, as Biltz and Köcher[145] found for MoS_3, and the reaction $MoX_3 \rightarrow MoX_2 + X$ must be considered irreversible. However, there have been reports of the possibility of obtaining molybdenum trisulphide by the reaction of the disulphide with elemental sulphur[53].

MoS_2 is rather inert chemically. It is insoluble in boiling water. It reacts with the halogens as follows. On gentle heating, fluorine reacts with crystalline MoS_2 with ignition[42-44]. Below 400°C, chlorine reacts very slowly, forming $MoCl_5$ and the intermediate compounds $MoSCl_2$ and $MoOCl_4$. The chlorination of the disulphide with $Cl_2 + 3O_2$ mixture is thermodynamically more favourable, MoO_2Cl_2 being formed. In the presence of nitrogen oxides or nitric acid fumes the reaction is appreciable even at 170°C.[40] Bromine vapour reacts very slowly; the composition of the reaction products has not been established[146].

When SF_4 is used as a fluorinating agent, molybdenum can be oxidised to the quinquevalent state. Thus the reaction of SF_4 with MoS_2 at 350°C gives MoF_4[147] and with the mixture $2NaF + MoS_2$ at 400° the compound $NaMoF_6$ is formed[148].

$SOCl_2$ does not react with MoS_2 even on heating for a few days[149]. Gaseous hydrogen chloride does not react with MoS_2 at temperatures up to red heat[42-44]. Liquid anhydrous hydrogen fluoride also does not react with the disulphide in the temperature range -18° to -7°C.[150]

However, MoS_2 is completely soluble in *aqua regia*, is decomposed in boiling concentrated sulphuric acid, and is oxidised to MoO_3 in nitric acid.

Aqueous solutions of acids, alkalis, and salts react differently with molybdenum disulphide. Alkali solutions with pH 10 oxidise and dissolve MoS_2 most actively[151]. In acid, neutral, and weakly alkaline solutions the oxidation of MoS_2 is weaker[151]. This is confirmed by an investigation[152] of the anodic dissolution of molybdenite in 0.5–5% solutions of H_2SO_4 and NaOH. The results show that MoS_2 is almost insoluble in these solutions in the absence of current, but is electrochemically soluble. The rate of dissolution increases with increase in current density, increase in NaOH concentration, and decrease in H_2SO_4 concentration. Probably oxidation takes place by the following reactions:

$$MoS_2 + 9O + 3H_2O \rightarrow 2H_2SO_4 + H_2MoO_4,$$

$$MoS_2 + 9O + 6NaOH \rightarrow 6Na^+ + 2SO_4^{2-} + MoO_4^{2-} + 3H_2O.$$

In aqueous solutions of 3 *N* Na_2CO_3 and 8 *N* HCl, MoS_2 is almost insoluble up to 90°C.[153]

The reaction of finely dispersed MoS_2 with water vapour at 200–500°C showed that at 200–300°C a little hydrogen and traces of sulphur dioxide are formed, but at 400–500°C traces of hydrogen and measurable amounts of sulphur dioxide. The gaseous products of the reaction were identified mass-spectroscopically[154].

The reaction of MoS_2 with MoO_3 was studied at 400–700° in an inert atmosphere, in a vacuum, and in SO_2 at atmospheric pressure[155-159]. MoS_2 reacts with MoO_3 to form molybdenum dioxide:

$$MoS_2 + 6MoO_3 \rightarrow 7MoO_2 + 2SO_2.$$

Reaction starts even at 400°C and the reaction rate rises rapidly with the temperature. Below 550°C the reaction products contain (in addition to MoO_2) the intermediate oxide Mo_4O_{11}, which is formed by the reaction:

$$MoS_2 + 12MoO_3 \rightarrow 2Mo_4O_{11} + 5MoO_2 + 2SO_2.$$

This oxide reacts further with the disulphide to form MoO_2:

$$2Mo_4O_{11} + MoS_2 \rightarrow 9MoO_2 + 2SO_2.$$

The results were confirmed by chemical and X-ray analyses.

Solid molybdenum disulphide readily reacts with the alkali and alkaline earth metals dissolved in liquid ammonia[160]. From solutions which contain the alkali metals in excess, black homogeneous compounds of the composition:

$$Cs_{0.5}MoS_2;\ K_{0.6}MoS_2;\ Na_{0.8}(NH_3)_{0.2}MoS_2;\ Li_{1.1}(NH_3)_{0.6}MoS_2,$$

can be separated after filtration, washing with liquid ammonia, and removing the remaining ammonia in a vacuum at room temperature.

The last two compounds do not lose ammonia when held for a long time in a vacuum at room temperature.

All the compounds are extremely sensitive to heat and air. The potassium and caesium compounds glow in air, and react readily with water to form the sulphide and hydrogen, which contains a very slight amount of hydrogen sulphide. On heating in a vacuum a slight amount of alkali metal is detached. At 100°C the preparations decompose appreciably and give new compounds, which correspond to the polarised form of $K^+(MoS_2)^-$ type.

Such compounds are considered as interstitial compounds, in which a layer of alkali or alkaline earth metal is introduced between the molybdenum disulphide layers. The distance between the layers increases considerably with an insignificant increase in the Mo–Mo interatomic distances.

The reaction of liquid ammonia with MoS_2 has been described[161]. Under the influence of the NH_4^+ and NH_2^- ions present in liquid ammonia, at low temperatures there is a disturbance of the layers in molybdenum disulphide, as was shown by recording infrared spectra of thin layers of MoS_2. Adsorption of ammonia leads to far-reaching changes in the mechanical properties of the solid.

The adsorption of argon, krypton, and organic substances on MoS_2 has been studied[162-164].

Carbon dioxide and sulphur dioxide gases do not react with molybdenum disulphide at low temperatures; the reaction only takes place above 500°C and at ~ 800°C there is a sudden increase in the reaction rates. The final product of these reactions is MoO_2.[165]

The main reaction of MoS_2 with carbon dioxide is expressed by the following equation:

$$MoS_2 + 6CO_2 = MoO_2 + 2SO_2 + 6CO.$$

Apart from these products, a little COS, S, and MoO_3 are obtained, due to side reactions taking place.

The reaction of the disulphide with sulphur dioxide follows the equation:

$$MoS_2 + SO_2 = MoO_2 + 3S,$$

which is almost complete at 1100°C.

The molybdenum chalcogenides, like those of other transition metals, are capable of forming ternary phases. Heating MoS_2 with the sulphides of iron group metals at 500–1300°C in an inert atmosphere (argon or nitrogen) or in hydrogen sulphide leads to the formation of a new class of stable crystalline compounds of type $AMoS_y$, where A is the iron-group metal (Fe, Co, Ni) and y = 2.5–3. The $FeMoS_{2.5}$ crystals have strongly expressed ferromagnetic properties[166].

A thermoelectric material of composition Ag_2MoX_3 (where X is selenium or tellurium) is obtained by reaction of the components at 700–1100°C.[167] However, a study of the solubility of copper and silver in molybdenum disulphide by heating the components at 800°C in evacuated ampoules did not give positive results. Compounds similar to Cu_xNbS_2 ($\sim 0.6 \leq x \leq 0.8$) could not be prepared for molybdenum disulphide[168].

In the coprecipitation of thallium with molybdenum trisulphide, the formation of the compound $TlMoS_2$, which is amorphous to X-rays, was established[169,170].

A series of mixed chalcogenides is known for molybdenum[171].

There is only limited information about the chemical behaviour of $MoSe_2$. It is insoluble in hot concentrated hydrochloric acid, but is readily soluble in hot concentrated sulphuric acid with liberation of sulphur dioxide. The

diselenide is completely insoluble in ammonia, and in alkali metal sulphides and selenides, and dissolves very slightly on prolonged boiling in concentrated alkalis[60].

The chemical properties of $MoTe_2$ have been studied even less. Water and hydrochloric and sulphuric acids do not react with $MoTe_2$ on boiling, whereas dilute nitric acid breaks down the ditelluride even in the cold[61].

Finely ground $MoTe_2$ powder is gradually oxidised by atmospheric oxygen at room temperature[76].

4. HIGHER CHALCOGENIDES OF MOLYBDENUM

A. Molybdenum(V) Chalcogenides

Only the sulphide and selenide of molybdenum(V) are known. Mawrow and Nikolow[172] obtained Mo_2S_5 and described its properties. Their method of preparation will now be described.

A solution of 5 g $(NH_4)_2MoO_4$ in 150 ml water was mixed with sufficient concentrated sulphuric acid to give a concentration of 20% H_2SO_4. The acid solution was reduced with metallic zinc to give a dark red coloration, then diluted with an equal quantity of water, filtered, and saturated with hydrogen sulphide. The precipitate which separated was filtered off, washed with hot water until an acid reaction was no longer obtained, and then washed with alcohol. The precipitate was washed to remove free sulphur by repeatedly shaking with carbon disulphide, and was washed on the filter with ether. The moist brown-black precipitate was dried at 68–75°C, whereupon it became dark brown. The compound corresponded to the formula $Mo_2S_5.3H_2O$. Sufficiently pure preparations are obtained when the product is well washed with hot water (to give a negative reaction with H_2SO_4) and carbon disulphide and dried for a long time on a water-bath at 68–75°C in the finely dispersed state.

$Mo_2S_5.3H_2O$ is completely insoluble in water. On boiling with alkalis or ammonia it dissolves with a brown-yellow coloration and liberation of hydrogen sulphide. $Mo_2S_5.3H_2O$ dissolves well in alkali metal sulphides, especially on heating. On cooling, an orange-yellow precipitate separates from the solutions. When heated with concentrated hydrochloric acid the compound dissolves, with a green coloration, but with concentrated sulphuric acid a red-yellow liquid is formed, which gradually turns green with separation of free sulphur and sulphur dioxide.

When heated in air up to 135–140° $Mo_2S_5.3H_2O$ loses one molecule of water and gives the compound $Mo_2S_5.2H_2O$. However, on further heating to 195–200° in air, this compound is partly oxidised.

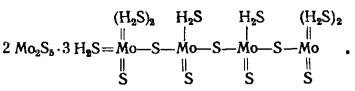
Very careful heating of $Mo_2S_5.3H_2O$ in a stream of carbon dioxide gives brown-black Mo_2S_5. The heating takes place so that the tip of the flame of a burner did not touch the tube which contained the compound.

The sulphide obtained in this way sometimes contains a slight amount of water of hydration, which is very difficult to remove, since at a higher temperature the compound is oxidised and then burns, but heating in a current of hydrogen, even at a very low temperature, leads to partial reduction to MoS_2.

In an attempt to dehydrate $Mo_2S_5.3H_2O$ by heating in a current of hydrogen sulphide the authors[172] obtained a brown-black compound corresponding to the formula $2Mo_2S_5.3H_2S$, which is evidently formed as a result of the replacement of water by hydrogen sulphide by the equation:

$$2(Mo_2S_5 \cdot 3H_2O) + 3H_2S \rightarrow 2Mo_2S_5 \cdot 3H_2S + 6H_2O.$$

The following structural model was proposed for this substance:



The compound is insoluble in water and hydrochloric acid, very difficultly soluble with a green coloration on boiling in sulphuric acid, and on boiling with alkalis and alkali metal sulphides it dissolves to give a yellow solution and separation of a dark green mass, which turns blue in air.

Wendehorst[60] obtained the molybdenum(V) selenide similarly. The precipitate of selenide is decomposed during drying, even in a stream of nitrogen, therefore it is analysed moist. The atomic ratio Mo : Se = 2 : 5 shows that the material obtained is molybdenum(V) selenide.

In its chemical properties the selenide is reminiscent of the corresponding sulphide, but even more unstable. On dissolution in alkalis, sulphides, and acids there is an intense coloration of the solutions.

B. Molybdenum(VI) Chalcogenides

The oldest method for obtaining MoS_3 and $MoSe_3$ consists in the decomposition of solutions of thio- and seleno-molybdates respectively with acids.

Thus Berzelius[21] first obtained a dark brown precipitate of MoS_3 by saturating with hydrogen sulphide a concentrated solution of alkali metal molybdate and then decomposing the thiomolybdic acid which was formed. $MoSe_3$ was obtained similarly[173].

Wendehorst[60] obtained $MoSe_3$ by saturating with hydrogen selenide a solution containing 5 g $(NH_4)_2MoO_4$ in 10 ml conc. sulphuric acid and 50 ml water. The excess of H_2Se was removed with a stream of nitrogen. The black fine-grained precipitate of $MoSe_3$ was washed successively with ice water, alcohol, and ether, and dried in a stream of nitrogen with slow heating.

The MoS_3 and $MoSe_3$ thus obtained always contain an excess of the chalcogen[60,174,175]. To obtain the sulphide in a purer form, an aqueous solution of pure thiomolybdate — for example, ammonium tetrathiomolybdate, $(NH_4)_2MoS_4$ — is first obtained, which is then decomposed by the action of acid (for example, sulphuric acid). A method for obtaining pure solutions of H_2MoS_4 by passing dilute solutions of $(NH_4)_2MoS_4$ through a column with an anion-exchange resin in the H^+ form[176] is interesting.

The so-called "crystalline"‡ molybdenum trisulphide is obtained as fine gleaming black leaflets, resembling graphite, from salts of thiomolybdenic acid with some organic compounds — for example, that with piperazine, $C_4H_{10}N_2.H_2MoS_4$ — by decomposing them with hydrochloric or acetic acid[177].

Molybdenum trisulphide is obtained in the high-temperature reaction of KCNS with MoO_3.[178–181]

‡ Reported[78] to be amorphous to X-rays.

Another method of obtaining MoS_3 by dry means is the thermal decomposition of ammonium tetrathiomolybdate in the temperature range 190–200°C in a vacuum or inert medium[78,79,182].

It has been noted[79,112] that during the decomposition of $(NH_4)_2MoS_4$, stoichiometric MoS_2 is obtained at ~1000°C, but below 800°C the homogeneous phases MoS_{2+x} (x = 0–0.5), which have a distorted MoS_2 structure, are produced. The distortion grows with increase in x in the direction c but the lattice parameter a remains constant. Measurement of the density of such products shows that they must be considered as MoS_2 with insufficient metal, that is, they are best given the formula $Mo_{1-x}S_2$.[79]

In any of the above methods the molybdenum trisulphide obtained always contains some excess of sulphur and corresponds to the formula MoS_{3+x}, where $0 < x < 1$ and depends on the method of preparation: the value of x in the wet method reaches 0.7; in the dry method it is less[78].

Such compounds are considered either as polysulphides, whose composition is expressed, for example, by the formulae $MoS_3.S_2$ or $MoS_3.S_3$,[183] or as phases of variable composition based on MoS_3 with the addition of a certain amount of chemically unbound sulphur[78].

However, it is maintained[184–188] that molybdenum trisulphide with composition corresponding accurately to the formula $MoS_3.2H_2O$ can be obtained. For this, first 15 N ammonium sulphide or 2 N sodium sulphide is prepared by saturating the corresponding hydroxide with hydrogen sulphide below room temperature and then using the reagent obtained to treat ammonium molybdate solution. The solution of thiosalt $(NH_4)_2MoS_4$ formed is decomposed by an excess of dilute (6 N or 2 N) hydrochloric acid until completely decolorised and molybdenum sulphide is precipitated. The mixture is heated to boiling, gives a precipitate, and is filtered, the precipitate being washed successively with water, alcohol, ether, and then air is sucked through for 15 min. The precipitate, dried for 30 min in a vacuum dessicator, is reported to accurately correspond to the formula $MoS_3.2H_2O$, which enables us to use this method to determine molybdenum quantitatively. It is possible to obtain $MoSe_3$ by a similar procedure[189,190].

The thermal dissociation of air-dry preparations of $MoS_3.2H_2O$ proceeds as follows (Fig. 9). At 80–120°C the loss in weight is 1–2%. At 170–290°C the loss in weight corresponds with two molecules of water. At 290–390°C anhydrous MoS_3 is stable and at higher temperatures it is oxidised to MoO_3, which sublimes at 800°C.[187]

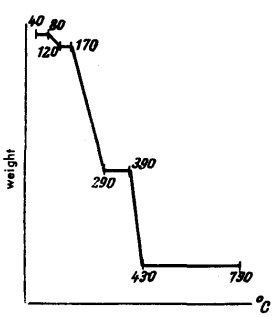


Fig. 9. Thermal dissociation curve of $MoS_3.2H_2O$.[187]

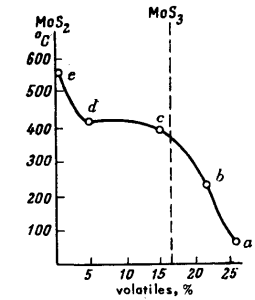

Fig. 10. Decomposition polytherm of a specimen of molybdenum trisulphide[78].

On heating in a non-oxidising atmosphere (for example, in nitrogen), molybdenum(VI) chalcogenides disproportionate into the dichalcogenide and the free chalcogen. The thermal decomposition of MoS_3 in nitrogen has the following result[78]: on heating a preparation of composition $MoS_{3+x}.yH_2O$ to 250°C there is a loss of hygroscopic and loosely bound water together with part of the sulphur in excess (Fig. 10, section a–b). Subsequently between 250° and 400°C sulphur in excess of the composition MoS_3 is removed, then the main mass of MoS_3 decomposes with simultaneous evaporation of sulphur formed during this decomposition (Fig. 10, section b–c–d). As a result, a new phase of variable composition is formed (with an excess of sulphur) based on MoS_2, which on further heating to 900–1000°C gradually loses sulphur and approaches molybdenum disulphide in composition (Fig. 10, section d–e).

Crystallisation of molybdenum disulphide has already started at 350°C, and when molybdenum trisulphide decomposes the disulphide produced crystallises as the hexagonal form. The suggestion[78] that the rhombohedral modification crystallises initially and changes into the more stable hexagonal modification as the temperature rises has not been confirmed[79].

The vapour pressure of sulphur on heating molybdenum trisulphide has been measured[80,191] between 350° and 500°C:

Temperature, °C:	355	390	418	475	480	500
Pressure, mmHg:	4.0	28.8	178.6	250	313	980

There is a difference of opinion about the reversibility of the process:[192]

$$MoS_3 \rightleftarrows MoS_2 + S.$$

For long it was thought that the decomposition of molybdenum trisulphide is reversible and that in the range 350–400°C there is an equilibrium with the disulphide[80]. However, Biltz and Köcher[145] showed the thermodynamic instability of molybdenum trisulphide. Despite this, some investigators tend to assume that it is possible to obtain the trisulphide by heating the disulphide with sulphur, if the reaction is carried out over several days at 400°.[53] Probably, such a reaction can be brought about by selecting suitable conditions.

In this connection, work[193] on the preparation of tantalum triselenide by direct synthesis from the elements is of interest. The authors[193] consider that with very slow cooling (~250 h) of the reaction products, heated to 820°C,

tantalum triselenide (which dissociates at 780°C) can be formed according to the equation:

$$TaSe_3 + Se \rightleftarrows TaSe_4.$$

They also obtained[193] tantalum trisulphide by heating the disulphide with sulphur for a week at 450–500°C.

It is interesting that tungsten trisulphide was obtained by heating the disulphide in sulphur vapour[194]. In view of the great similarity between the chalcogenides of molybdenum and tungsten, it seems quite probable that there would be similar results with the molybdenum chalcogenides.

On heating in hydrogen, the molybdenum(VI) chalcogenides are reduced to the dichalcogenides. In hydrogen selenide $MoSe_3$ does not change composition[60]. On heating in air, dry molybdenum triselenide is stable up to 410°C but at higher temperatures it is oxidised to MoO_3.[190]

The molybdenum(VI) chalcogenides are amorphous to X-rays. Evidently the chemical bond in molybdenum trisulphide is formed by d^2sp^3 hybridisation[104].

Molybdenum trisulphide readily dissolves in *aqua regia*, ammonium sulphide, and in alkali metal sulphides; it also dissolves in alkalis on heating[21]. On fusing the trisulphide with sodium carbonate the reaction is[37]:

$$MoS_3 + 2\,Na_2CO_3 \rightarrow Na_2MoO_2S_2 + Na_2S + 2\,CO_2.$$

Even in the cold molybdenum trisulphide dissolves in alkali metal sulphides and selenides, in concentrated alkali solutions, and even in concentrated ammonia. Molybdenum triselenide dissolves in concentrated sulphuric acid on heating[60].

It is interesting to note that dissolution of molybdenum triselenide, like the molybdenum(V) chalcogenides, is almost always accompanied by coloration of the solutions with a rich hue.

Molybdenum triselenide is a rather unstable compound. It reacts readily with many oxidants, but not with organic acids[60].

Molybdenum tritelluride has not yet been obtained. Apparently this compound is still more unstable than molybdenum triselenide.

The magnetic susceptibility of molybdenum trisulphide powder at 15°C is 0.361×10^{-6}.[195]

Oxide sulphides of molybdenum(VI) are known. MoO_2S is obtained by the reaction of MoO_2Cl_2 with Na_2S in alcoholic medium by the reaction[37]:

$$MoO_2Cl_2 + Na_2S \rightarrow MoO_2S + 2\,NaCl.$$

The MoO_2Cl_2 is obtained by passing dry gaseous hydrogen chloride over MoO_3 at 180°C; the alcoholic solution of the oxide chloride is kept in an atmosphere of carbon dioxide. The brown-black precipitate of MoO_2S, which resembles MoS_3, is filtered off, washed well with water (until there is no alkaline reaction), and dried in a vacuum.

There has been a report[196] of the preparation of $MoOS_2$ by the thermal dissociation of $(NH_4)_2MoO_2S_2$ in nitrogen at 300–400°C. As was found later, the decomposition of ammonium oxothiomolybdate under these conditions does not give an oxide sulphide[68]. The final product of the reaction is molybdenum disulphide with MoO_2 as impurity. Romanowski[68] has confirmed this not only by chemical analysis (which was used in the earlier work[196]) but also by X-ray and thermographic studies.

The oxide sulphides $MoO_3.2MoS_3.9H_2O$ and $MoS_3.5MoO_3.6.5H_2O$ are also known[39]. The method of obtaining these compounds consists in the reaction of solutions of Na_2MoO_4 and Na_2S followed by neutralisation with hydrochloric acid to pH 4.5. Then the mixture is heated to 90°C and held there for an hour with constant stirring, after which the solution and precipitate are kept another 12 h in a thermostat at 25° ± 0.1°C. The compounds are washed with alcohol and ether and dried at 140°C.

Particular note should be made that in these preparations the atomic ratio Mo : S plays an important part. Thus a pale brown oxide sulphide of composition $MoO_3.2MoS_3.9H_2O$ is obtained at Mo : S = 1 : 2 and 1 : 1 and the green $MoS_3.5MoO_3.6.5H_2O$ ratio at Mo : S = 2 : 1, 1.75 : 1, and 1.5 : 1. At Mo : S = 1 : 3 or over, MoS_3 is formed.

The oxide sulphides $MoO_2S.3H_2O$ and $MoOS_2.3H_2O$ are obtained by saturating a molybdate solution at pH 8.6 with hydrogen sulphide for 30 min and 12 h respectively, washing the precipitate with alcohol, and drying. On heating them to 200°C almost all the crystallisation water is lost and at higher temperatures they start to decompose[38].

Oxide compounds have not been obtained for molybdenum triselenide.

Only two molybdenum chalcogenide halides have been obtained: $Mo_5S_5Cl_9$ and $MoSCl_2$. The first of these is obtained on passing S_2Cl_2 vapour in a gentle stream of carbon dioxide over incandescent molybdenum powder. $Mo_5S_8Cl_9$ is formed as a red-brown amorphous sublimate, stable in air. It is insoluble in water and alkalis but dissolves completely in concentrated nitric acid[41].

$MoSCl_2$ was observed in the products of the chlorination of molybdenum disulphide at ~ 400°.[40]

Sulphides richer in sulphur than molybdenum trisulphide have been described[21,197,198]. Thus sulphides of the approximate composition MoS_4 and MoS_6 are obtained during the decomposition of alkali metal thiomolybdates with acids (hydrochloric or sulphuric). The compounds are insoluble at ordinary temperatures in water and acids but dissolve in alkalis and alkali metal sulphides. The authors[198] also regard such higher sulphides as anhydrides of perthio-acids of molybdenum. However, in view of insufficient experimental facts, the physicochemical properties of these products have hardly been studied at all and the homogeneity of the phases has not been established.

---o0o---

Transition metal chemistry is now developing very rapidly. A series of new facts have now been obtained which are interesting not only from the practical aspect but are also of great importance theoretically. Therefore the chalcogenides of such a typical transition metal as molybdenum are undoubtedly of theoretical interest and their detailed study allows us to hope for new results of practical importance.

Study of the electrical, thermoelectric, magnetic, thermodynamic, and other properties of the transition metal chalcogenides has shown that "transition metal–chalcogen" systems are extremely complex. The tendency of chalcogenides to form compounds of non-stoichiometric composition has set the task of finding the reason for this departure, since even insignificant changes in composition lead to essential changes in some of the physical properties. Since the non-stoichiometry of the compounds is

the result of defects in the crystal lattice, the investigation of the chalcogenides is directed first to the determination of the crystal structure, to revealing the fine character of the interconnection between chemical impurities and lattice defects, and between the structure of the molecule and the physical properties of the substance.

The crystal structure of the molybdenum chalcogenides has been studied most fully only for the molybdenum(IV) compounds. However, the polymorphism of MoS_2 and the various interpretations of this phenomenon again emphasise the insufficiency of our knowledge in this region.

The information about the structure of Mo_2S_3 is little and contradictory. The structural study of the lower molybdenum selenide and telluride is restricted to the powder method. Therefore detailed structural investigation of the lower chalcogenides of molybdenum is one of the first tasks.

Data about the non-stoichiometric nature of the phases in the molybdenum–chalcogen systems confirms the necessity for a thorough study of the non-stoichiometric molybdenum chalcogenides.

The detailed determination of the structure of the compounds and the lattice defects, and of the regions and conditions of existence of the phases, requires modern physicochemical methods for the study of equilibrium diagrams. The volatility of the components and the decomposition of the compounds before melting create additional difficulties in the study of molybdenum–chalcogen systems. However, without knowledge of the physicochemical data it is impossible to correctly select methods of preparation especially in making materials suitable for semiconductor purposes. Therefore future investigation of the molybdenum chalcogenides should be directed above all to the detailed study of the physicochemical properties of systems which include these compounds.

Since the molybdenum dichalcogenides are widely used as thermoelectric materials their study in this direction is extremely promising. Good thermoelectric properties can be expected from various combinations of MoS_2, $MoSe_2$, and $MoTe_2$ with other transition metal chalcogenides.

We consider that the known molybdenum chalcogenides, oxide chalcogenides, and chalcogenide halides are only the first representatives of this class of materials. Molybdenum is known to be a rather reactive element. The variety of its chemical properties, expressed above all in its ability to vary its valency, suggest that the systematic investigation of the molybdenum chalcogenides will lead to a whole series of new compounds, not only of theoretical interest but also important for practical use.

Compounds in which the molybdenum has a lower valency should be especially reactive. The oxidation of molybdenum to higher valencies uncovers wide prospects for the preparation of new mixed compounds.

The different molybdenum compounds show greatest stability at different oxidation states. Thus in the compounds with oxygen or fluorine the most stable valency of molybdenum is six (MoO_3 and MoF_6); with chlorine, five ($MoCl_5$); with sulphur, four (MoS_2); with bromine and iodine, the most stable valency is apparently even lower. Such a selectivity of the valency of molybdenum in its compounds with different non-metals can be used to obtain new stable mixed compounds with a different degree of oxidation.

The chemical properties of the molybdenum chalcogenides have been quite inadequately investigated. The behaviour of the compounds in alkalis and acids has been described only qualitatively. Such an interesting problem as the solubility in salts has hardly received any attention. And yet here it is possible to obtain interesting results, to find possible paths for making new compounds, to find mechanisms for some reactions of molybdenum which are important to chemists.

There is great interest in carrying out the reactions in non-aqueous solvents. Such solvents as liquid ammonia, sulphur dioxide, dinitrogen tetroxide, nitrosyl chloride, hydrogen fluoride, bromine, interhalogen compounds, etc. unconditionally give rich material for theoretical investigations and allow a preparative route to be found for compounds with specially intended specific properties.

The study of the behaviour of the molybdenum chalcogenides on heating acquires special value in connection with the possibility of using them in thermoelectric assemblies. Therefore extensive thermographic analysis of the molybdenum chalcogenides in various media is urgently required.

What has been stated undoubtedly does not exhaust all the tasks which are presented by the chemistry of the molybdenum chalcogenides. However, the problems listed are the most pressing and their solution can be expected to give promising theoretical and practical information.

KINETICS OF RECOMBINATION AND DISPROPORTIONATION REACTIONS OF ALKYL RADICALS

A. D. Stepukhovich and V. A. Ulitskii

The present review is an attempt to collect and systematise information from numerous Russian and non-Russian papers on the kinetic study of recombination and disproportionation reactions of free radicals.

Recombination and disproportionation of alkyl radicals

$$R_1+R_2 \begin{cases} \longrightarrow R_1R_2 & (1) \\ \longrightarrow P+O, & (2) \end{cases}$$

(R_1 and R_2 are alkyl radicals, P is a paraffin molecule, and O is an olefin molecule) are the main types of reactions in which chains are broken, or free valencies disappear, in numerous organic reactions that proceed by a radical chain mechanism in the gas or liquid phase. On the other hand, these reactions are thermodynamically linked with the dissociation of alkanes and the molecular dismutation of alkanes and alkenes, which are possible routes to radical initiation in conversions of hydrocarbons at high temperatures. Actually, the radical chain mechanism results from the competition between these reactions and chain-propagation reactions.

In the experimental study of substitution reactions

$$R + M \rightarrow RH + R_1, \quad (3)$$

the difficulty of setting up an experimental model of reaction (3) is encountered, since under experimental conditions with sufficiently complicated radicals (beginning with C_2H_5), reactions (1) and (2) occur to a great extent, and these require virtually no activation energy. This makes difficult the determination of the absolute rate constant of reaction (3) from experimental results. However, the relative value of the rate constant of reaction (3) may be determined experimentally, when it is expressed in the form of the rate constants of the recombination k_1 and disproportionation k_2 of radicals. The rate of disappearance of radicals by recombination and disproportionation in reactions (1) and (2) is

$$W = (k_1 + k_2)(R)^2. \quad (4)$$

Eliminating the concentration of radicals (R) from Eqn. (4) and Eqn. (5) for the rate of reaction (3):

$$W_3 = k_3(R)(M), \quad (5)$$

we obtain the relation

$$\frac{k_3}{(k_1+k_2)^{\frac{1}{2}}} = \frac{W_3}{W^{\frac{1}{2}}(M)}. \quad (6)$$

Since the right-hand side of Eqn. (6) contains values that can be calculated from the experimental kinetic curves for the accumulation of products (RH, R_1R_2, P, O) and for the disappearance of M, the relative value of the rate constant of reaction (3) can be calculated from experimental results.

As will be seen, by comparing reactions of the same radical R with different molecules it is possible to determine the relative values of the rate constants of radical reactions (3) without finding the concentrations of free radicals (R), which up to now has presented considerable difficulties. The essential feature of this determination forms the basis of the now well developed method of competitive reactions[1,2]. In the simplest type in the method of competitive reactions we are concerned with competing reactions of the same order, for example

$$R + M_1 = RM_1, \quad (7)$$

$$R + M_2 = RM_2. \quad (8)$$

The ratio of the rate constants of reactions (7) and (8)

$$\frac{k_7}{k_8} = \frac{W_7(M_2)}{W_8(M_1)}, \quad (9)$$

is determined from experimental measurements of the reaction rates W_7 and W_8 and the concentrations of the molecules taking part in the reactions. If the value of one of the rate constants (k_7 or k_8) can be determined (or calculated) by some independent method, the absolute value of the other constant can be determined from Eqn. (9).

However, it is not always possible successfully to choose a suitable competing reaction, and then Eqn. (6) must be used to determine the absolute rate constant of reaction (3). The solution of this problem requires independent experiments to measure absolute rate constants of the radical recombination (1) and disproportionation (2) reactions; at present these experiments present serious difficulties and must be supplemented by theoretical calculations.

Experimental difficulties are one of the reasons for the view long held that radical recombination reactions occur with every collision[3]. It should be mentioned that even

now in many experimental papers dealing with radical recombination reactions it is assumed that $k = 10^{14}$ mole^{-1} × × cm^3 s^{-1} (i.e. the steric factor $s = 1$ and $E = 0$)[4]†.

However, although the absence of a true activation energy E has been confirmed by numerous experimental results, the assumption that every collision is effective can be shown to be doubtful. This is confirmed by the fact that the steric factors for the addition of H atoms to alkenes, and also the factors for addition and replacement reactions of H and CH_3 radicals with various molecules (alkanes and alkenes), calculated by the transition-state method as applied to radical reactions[5,6,7], have low values. It may therefore be assumed that recombination reactions of CH_3, or more complex radicals, must also have low steric factors; otherwise, it would have to be accepted that reactions in which two free valencies disappear have special steric features compared with radical replacement reactions, in which the free valency is retained, but there are no grounds for this[8]. Moreover, if the preexponential factors A of the rate constants of recombination reactions are taken as equal to 10^{14} mole^{-1} cm^3 × × s^{-1}, examination of the frequency factors of decomposition reactions on the basis of entropy changes leads to values that are too high for the preexponential factors (from 10^{17} s^{-1} for n-alkyl radicals to 10^{20} s^{-1} for t-butyl radicals[4,9]). Interpretation of the negative temperature coefficient found for the rate of recombination of CH_3 radicals[3] also unambiguously indicates that the steric factor s is less than unity and its value decreases with increase of temperature[10].

Approximate evaluation of steric factors for recombination reactions of the simplest radicals shows that their values are less than unity even for the recombination of H atoms and CH_3 radicals (900°K)[8]. If it is assumed that ternary collisions are necessary for the successful recombination of these particles, as in the combination of hydrogen atoms, then the steric factor will be still lower. When one of the recombining H atoms is replaced by a CH_3 radical, the steric factor of the recombination reaction decreases at first sharply, but then more gradually as the radicals become more complex (C_2H_5, C_3H_7). In the recombination of CH_3 radicals, the steric factor decreases still further, by one order of magnitude in comparison with its value in the H + CH_3 reaction. However, calculation gives a lower value (10^{-5}) than that found experimentally ($\sim 10^{-3}$) by Brodskii[11].

The calculation of the absolute rate constants of reactions (1) and (2), and especially the preexponents of these reactions, is therefore of interest, since unfounded assumptions connected with a difference of several orders between the preexponents of reactions (1), (2), and (3) lead to the competing relations between different radical reactions appearing in a distorted light. However, we shall first examine somewhat more widely the question of the calculation of the kinetic parameters of bimolecular reactions, since recombination and disproportionation reactions belong to this class.

The calculation of the rate constants of bimolecular reactions must be based on a detailed analysis of the collision process between the particles and the accompanying redistribution of energy, and it is complicated by the fact that the interaction forces between the particles have been little studied. This calculation of intermolecular forces can only be made for a small number of the simplest atoms and molecules. It is virtually impossible with complex particles, since their electronic molecular wave functions and potential energy surfaces are not known with sufficient accuracy. Therefore, only the approximate calculation of the reaction rate constant on the basis of a simplified collision model can be considered; quantum-mechanical methods of calculating the cross section may be used for these. One of these approximate calculations was made by Bauer and Wu for the exchange reaction $H_2 + X = HX + H$, where X is a Cl or Br atom[12]; an approximate value of 10^{-2} (300°K) was found for the steric factors of these reactions, which is in good agreement with calculations by the activated-complex method[8] and also with experimental results[13].

In recent years electronic computers are being increasingly used for quantum-mechanical calculations. However, the calculations could only be carried out in the simplest of cases and with approximate methods and models. A number of papers deal with the computer calculation of the probabilities of exchange reactions AB + C = = A + BC, which has permitted a more detailed study of the effect of vibrational excitation of the initial molecule on the effective activation energy (minimal initial translational energy necessary for the reaction to occur)[14,15].

The question of the calculation of the rate constants of bimolecular reactions on the basis of quantum-mechanical collision theory has been considered by Eliason and Hirschfelder[16]; by making a number of assumptions, they related the rate constant of a bimolecular reaction to the reaction cross section by means of a Laplace transformation, and they obtained an expression in terms of transition-state theory.

Attempts have also been made to calculate the rate constant of an elementary bimolecular reaction without making the assumption of equilibrium between the activated complex and the starting molecules[17,18]; the results are approximately equal to those obtained by transition-state theory.

Recently, phenomenological and statistical thermodynamics of irreversible processes are becoming more widely used in kinetic investigations. An important step in the construction of a logical theory of irreversible microscopic processes is the deduction of general expressions for kinetic coefficients from correlation functions[19]. However, their application to chemically reacting systems meets with great mathematical difficulties. Thus, a more nearly correct calculation of the rate constant of bimolecular reactions encounters serious mathematical difficulties, and a number of assumptions leads to a result similar to that obtained by transition-state theory[20,21]. The activated-complex theory makes it possible to determine the steric factor in the expression for the preexponential factor of the rate constant ($A = sZ$), which for bimolecular reactions has the form[5]:

$$s = \gamma \frac{kT}{h} \frac{1}{Z} \frac{Q^*}{Q_A Q_B} \exp\left[-\frac{1}{2} + T \frac{d}{dT} \ln\left(T \frac{Q^*}{Q_A Q_B}\right)\right] \quad (10$$

(the generally accepted symbols have been used in this equation[7]; in what follows it is assumed that $\gamma = 1$).

† For this reason, in the method of competing reactions for studying the kinetics of reactions in which radicals are replaced by various organic molecules, the radical recombination reaction was used as a convenient standard of comparison, since then the relative values of the steric factors and activation energies agree with their absolute values.

Approximation expressions for the temperature coefficient of s for reactions in which complex particles participate may be obtained[7,22] by logarithmic differentiation of Eqn. (10):

$$s_T/s_{T_1} = (T_1/T)^{3.5} \quad (11)$$

and for reactions in which H atoms participate:

$$s_T/s_{T_1} = (T_1/T)^2. \quad (12)$$

In the transition from higher to lower temperatures (900–300°K) the steric factors of the corresponding reactions increase within the limits of two orders (for CH_3 and more complex particles) or one order (for H atoms). Experimental results obtained by the study of recombination of CH_3 radicals confirm this conclusion[3,10].

Because of the absence of spectroscopic data, the calculation of the rotational and vibrational partition functions of radicals and activated complex required by formula (10) meets with considerable difficulties. The necessary assumptions that enable satisfactory results to be obtained have previously been discussed in detail[7]. The results of calculation of steric factors of addition and replacement reactions of H atoms and CH_3 radicals with saturated and unsaturated hydrocarbons on the basis of Eqn. (10) leads to good agreement with experiment[7,23]. In later papers by non-Russian authors, preexponential factors in reactions between the simplest molecules and radicals have been evaluated in the same way.

The preexponential factors for twelve bimolecular reactions between simple inorganic molecules and radicals (including the atoms N, O, F, Cl) have been calculated by the transition-state method by Herschbach and coworkers[24]. In these reactions, the number of atoms in the activated complex did not exceed 5 or 6, and its structural and mechanical properties were calculated from the properties of the initial and final molecules. For the reaction $NO + O_3 = NO_2 + O_2$ the normal vibrational frequencies for the complex $NO{-}O_3$ were calculated from the assumed geometry and the force constants of NO_2 and O_3 molecules. The values of the steric factors found for these reactions were low (10^{-1}–10^{-3}) and are in satisfactory agreement with experimental results‡; however, usually the calculated preexponents were less than those obtained experimentally, which confirms the necessity of regarding the activated complex as a molecule in which a somewhat elongated bond is being formed[21].

In a number of reactions in which a hydrogen atom is detached ($R + M \rightarrow RH + R_1$; R = H, CH_3, CD_3, Br) the bonds formed in the activated state were assumed to be longer than those in the corresponding hydrocarbons; in finding the length of the bonds formed the authors[25,26] followed Pauling's empirical rule[27] for the relation between the covalent radii of bonds and their order:

$$R(1) - R(n) = 0.3 \log n, \quad (13)$$

where $R(1)$ is the radius of the corresponding single bond, $R(n)$ is the radius of the bond formed, which by hypothesis is always considered to be a bond of half order ($n = \frac{1}{2}$)[25,26].

‡ The preexponential factors are also calculated by making an analogy between the entropies of the activated complexes of the reactions considered and the corresponding hydrocarbon molecules similar to them in structure, but the results are not always confirmed by experiment[24].

Formula (13) shows that the length of the C–C bond in the activated complex increases by about 0.18 Å.§

The application of Pauling's empirical rule (13) enabled the structure of the activated complexes to be determined and Q_{rot} to be approximately calculated (in the calculation it was assumed that the H atoms are localised in the nuclei of the C atom with which they are linked).

The vibrational partition function has been approximately evaluated[24]. On the basis of these and a number of other assumptions, the preexponential factors for reactions in which H atoms are abstracted have been found within a factor of ten. Values of the steric factor (10^{-1}–10^{-3}) in a number of available instances are in good agreement with those found by calculation from formula (10) and by experiment[23].

The preexponential factor of a reaction of the type $RH + Cl = R + HCl$ (where R = CH_3 (has been obtained from partition functions calculated by the classical method[29] and is in agreement with the experimental value¶. This method of calculation has the advantage that it requires less detailed information on reagents and activated complexes; in particular, and this is very important, data on the normal vibrational frequencies of the reagents and the activated complex are not required. Calculation of the classical partition function, of course, requires a knowledge of the potential energy surface. The authors assume that it corresponds approximately with the potential energy surface for the reaction $H_2 + Cl = HCl + H$. The bonds in the activated complex (C–H and H–Cl) were assumed to be longer than in the corresponding compounds, in accordance with Pauling's empirical rule (see above). The preexponential factor of this reaction was evaluated on the basis of these assumptions.

The method of calculating preexponential factors considered has been generalised for reactions of the type $CF_3 + RH \rightarrow CF_3H + R$, (where RH = C_2H_6, n-C_3H_8, n-C_4H_{10}) and the case has been considered in which the activated complex may be represented as an aggregate of three rigidly linked groups, each with its own reaction centre (three-centre problem X–Y–Z)[31]. Information on the potential energy surface may be obtained from the force constants of the particles. The preexponential factor A may then be expressed in terms of the force constants and other characteristics of the reacting particles and the activated complex (bond length, symmetry number, etc.). The unknown valence force constants for the selected geometric structure of the activated complex were roughly evaluated[31] by Badger's empirical rule[32], and the deformation force constants were obtained from a comparison with simpler known examples. The calculated preexponents of these reactions agree with the experimental values; it has been shown that the quantum correction in this classical evaluation of the partition function is not great, being less than 1.4 when $\omega < 1000$ cm^{-1} at 400°K.[31]

In radical polymerisation reactions a number of questions may be interpreted in the light of the calculations of steric factors[33]. It has been found that the steric factor of the

§ This rule has also been used for other types of bonds[26,28,29].

¶ Some divergencies from experimental results which have been found by Knox and Trotman-Dickenson in the evaluation of the preexponents of the rate constants of analogous reactions on the basis of transition-state theory are due to a somewhat simplified approach to the calculation of the partition functions of the initial particles and activated complexes[20].

propagating reaction in the molecular and radical polymerisation of ethylene greatly diminishes only in the early stages of polymerisation, but then the formation of trimer, tetramer, etc. occurs at a constant value of s (10^{-5}–10^{-6}). Similar relationships are observed in radical polymerisation reactions of propene, in which the steric factor of initial chain growth is particularly low (10^{-7}–10^{-9}). This explains why polymerisation of unsaturated molecules is frequently interrupted at the dimerisation stage[34], and also indicates that polymers of different chain length are equally reactive[35]. A comparison of the steric factors in radical and molecular polymerisations† shows that under the same conditions radical polymerisation must proceed more rapidly than molecular, because of the low activation energy in the propagating reaction (4–7 kcal instead of 38 kcal for molecular polymerisation).

Thus, numerous calculations of preexponential factors of addition and substitution reactions between simple molecules and radicals based on transition-state theory show that these reactions have low steric factors ($s \simeq \simeq 10^{-1}$–10^{-5}), in agreement with experimental results.

We shall now consider the kinetic characteristics of radical recombination and disproportionation reactions[23,37-43].

A current model for radical recombination reactions enables activation energies to be calculated and also permits a more nearly correct calculation of steric factors of these reactions, and rate constants can be evaluated from these.

Let us consider the recombination reaction A + B = AB. If A and B are atoms, the potential energy surface is two--dimensional, i.e. it is a curve similar to a Morse curve. Since the approaching atoms have a relative angular momentum, it is still necessary to calculate their centrifugal energy of rotation for each quantum state and for each distance between them. From this the position of the activated state on the potential energy surface can be determined; the energy maximum equal to the sum of the rotational and potential energies will correspond to this position. From this and the most probable value of the rotational quantum number j^* for the activated complex, the most probable interatomic distance (effective collision diameter) in the transition state can be calculated. As calculations show[21], the value of the effective collision diameter r^* is several times greater than the equilibrium interatomic distance in the molecule AB (for H–H, $r^* = = 4$–5 Å), and therefore the energy of dispersion interaction may be used as an approximate evaluation of the energy barrier. The rate constants of recombination reactions of some simple radicals have been calculated from the theory of absolute reaction rates by the use of this method with some assumptions[44-47].

The steric factors of radical recombination reactions can be calculated from more detailed information on the activated state, and the activation energies can also be calculated by the solution of two transcendental simultaneous equations which may be obtained from the accepted model of the recombination reaction. Actually, the energy barrier E is the difference between the centrifugal energy ϵ_j and the polarisation energy ϵ_p of the approaching radicals; when account is taken of the dissociation energy of the molecule D and its vibrational energy ϵ_v the energy barrier is given by:

$$E(r, j) = \varepsilon_j - (D - \varepsilon_v) - \varepsilon_p. \quad (14)$$

In the activated state Eqn. (14) has a maximum, that is, the following condition holds:

$$\frac{\partial E(r, j)}{\partial r} = 0,$$

from which the equation for r follows:

$$r = r(j). \quad (15)$$

The probability of the activated state $\omega(r, j)$ is calculated in the usual manner

$$\omega(r, j) = (2j+1)\exp\left(-\frac{E}{kT}\right).$$

The most probable values of j^* for the activated complex may be calculated from the condition

$$\frac{\partial \omega(r, j)}{\partial j} = 0 \quad (16)$$

and then the interatomic distances r^* of the separating particles in the transition state may be evaluated. The height of the barrier (Eqn. 14) that must be overcome by radicals to form a stable molecule may be evaluated from the values of r^* and j^* found. The parameters in Eqn. (15) and Eqn. (16) characterise the physicochemical properties of the radicals (their polarisabilities and ionisation potentials) and the bond of the activated complex formed (its dissociation energy, vibrational constant, and equilibrium distance).

It is well known that free radicals have ionisation potentials that differ little from the ionisation potentials of the molecules from which they are obtained. Concordant values of the ionisation potentials of many alkyl radicals have been obtained by electron-impact, photoionisation, and other methods[48]. Since the occupied electronic radical orbitals are not lower than the orbitals of the related molecules, it may be assumed that they are geometrically similar to one another[49]. This suggests that the polarisability of the radical is intermediate between the polarisabilities of the alkane and alkene molecules (the values for the latter are close[50]).

$$\alpha(R) \simeq \frac{\alpha(C_nH_{2n+2}) + \alpha(C_nH_{2n})}{2}.$$

Values of the dissociation energy of the corresponding bonds may be found in the literature[48,51]. The numerical value of the vibrational force constant differs little from the stretching vibration of the corresponding C–C (or C–H) bond. Data required for calculating the parameters in the equations above, and also the parameters themselves, have been published[23,37].

Table 1 is concerned with recombination reactions, mainly of alkyl radicals.

The transcendental Eqns. (15) and (16) have been solved on a Ural-1 electronic computer. The following conclusions may be drawn from the results obtained.

1. With regard to the energy barrier, radicals entering into the reactions are practically equivalent, since the activation energy of the recombination reaction E is 200–300 cal.

† Low steric factors in polymer chain-lengthening reactions mean low preexponents, and therefore reaction rates are not so high, although the reactions have low activation energies. Recently it has been found[36] that in methyl methacrylate polymerisation reactions the steric factor is 10^{-4}.

TABLE 1. Steric factors and rate constants for the recombination and disproportionation of alkyl radicals.

Reaction No.	Reaction	900°K				300°K			
		recombination		disproportionation		recombination		disproportionation	
		s_1	k_1	s_2	k_2	s_1	k_1	s_2	k_2
1	$H+CH_3$	$2.3\ 10^{-2}$	$2.0\ 10^{-11}$	—	—	$3.6\ 10^{-1}$	$1.8\ 10^{-10}$	—	—

2. The distance r^* between the radicals in the activated complex is several times greater than the distance separating the radicals in the corresponding hydrocarbon and is equal to 4–5 Å for all reactions (900°K).

3. At normal temperatures ($\sim$300°K) the value of r^* increases by about 1 Å, which increases the temperature dependence of the steric factors.

4. A change of 10–20% in the values of the parameters in Eqn. (15) and Eqn. (16) leads to virtually the same solutions, which indicates the lack of sensitivity of the equations and the possibility of using them in the calculation of kinetic characteristics.

Therefore, in the study of radical recombination reactions the preexponents of the rate constants of these reactions are particularly significant, since the exponential factor is always of the order of unity — $\exp(-E/RT) \simeq 0.7$. Here it is easy to follow the effect of the structure of the reacting particles on the change in their reactivity, since the difference between the activity of the radicals in combining is due only to a change in steric factors.

The steric factors of recombination reactions of alkyl radicals were calculated from Eqn. (10). In contrast to previous calculations[8] (the length of the bond formed in the activated complex of recombination reactions was taken to be 15–20% greater than the bond in the corresponding hydrocarbon) values of r^* obtained by solving the equations above were used. This led to a tenfold to fifteenfold increase in the steric factors compared with values previously calculated.

The results of the calculation (Table 1) show that the steric factor is of the order of unity only for the recombination of such simple radicals as H and CH_3 (300°K). At higher temperatures the value of s decreases by two orders ($s \simeq 1\times10^{-2}$). For more complex radicals in reactions of the type (H + R = HR), the value of s decreases at first by an order and then more gradually.

The value of the steric factor for the recombination of two CH_3 radicals is 9×10^{-2} (300°K), or 10^{-3} (900°K). As one of the combining radicals becomes more complex, the value of s decreases, and for the recombination of CH_3 and C_5H_{11} radicals it reaches a limiting value ($s_{300} \simeq 10^{-3}$; $s_{900} \simeq 10^{-5}$).

A similar picture is observed for the recombination of C_2H_5 radicals; the steric factors for their recombination are 8×10^{-4} (300°K) and 10^{-5} (900°K), which are lower by two orders than the factors for the recombination of two methyl radicals. For this group of reactions the value of s decreases gradually as the radicals become more complex, and the limiting value is lower than in reactions in which CH_3 radicals take part ($s_{900} \simeq 10^{-6}$, $s_{300} \simeq 10^{-4}$).

In the recombination of C_3H_7 radicals there is a slight reduction in the steric factor ($s_{300} \simeq 10^{-4}$, $s_{900} \simeq 10^{-6}$), which scarcely changes as the combining radicals become more complex.

Recombination reactions of more complex radicals have about the same values of s ($s_{300} \simeq 4\times10^{-5}$, $s_{900} \simeq 10^{-7}$).

Recombination reactions of the isomeric radicals iso-C_3H_7, s-C_4H_9, and t-C_4H_9 have lower steric factors. Evidently, this is because the branched structure of the radical inhibits the formation of the dimer.

Thus, as the reacting radicals become more complex the steric factors of their recombination reactions decrease. Therefore, more complex radicals are less reactive; the value of the steric factor may be taken as a measure of the activity of the radicals. The results of the calculation of steric factors show that the activity of free alkyl radicals decreases with increasing chain length up to a certain limit (C_3–C_4), after which there is almost no further change; secondary and tertiary radicals also show a decrease compared with primary radicals. According to Semenov[51], this is connected with the interaction of an electron of the free valency with electrons of the adjacent C–C and C–H σ-bonds. This leads to a change in the shape of the radicals and to comparatively small changes in electron density due to overlap and interaction of the electron clouds of the free electron and the electrons of the σ-bonds. It is this type of interaction that reduces the activity of alkyl radicals in the transition from CH_3 to C_4H_9, and also when hydrocarbon branching increases up to a certain limit.

The recombination rate constants were evaluated from the values found for the steric factors, numbers of binary collisions z of reacting radicals, and activation energies of these reactions; the values of these constants together

with the calculated steric factors are given in Table 1. It is of interest to compare the theoretical and experimental values of the kinetic parameters considered.

Avramenko and Postnikova [53] made a kinetic study of the recombination of the simplest CH_3 radicals at low temperatures, when the steric factor of this reaction has the low value of ~ 0.1 (the calculated value of s_{300} is 9.1×10^{-2}). As the temperature is raised, the value of the rate constant falls, because of the temperature dependence of the preexponential factor. The calculated steric factor for the recombination reaction of CH_3 radicals falls to 10^{-3} at high temperatures; this agrees with the experimental value obtained by determining the temperature dependence of the rate constant by means of tracer atoms [11].

A negative temperature dependence was also found for the recombination of CH_3 and C_2H_5 radicals in a study of the mechanism of high-temperature cracking of ethane; this indicates a low steric factor for this reaction [54]. The experimental value of the steric factor ($\sim 10^{-3}$) is close to the calculated value (2.3×10^{-4}) (Table 1).

In a number of instances the concentrations of reacting radicals have been obtained from experimental results [44,45,55]; this enables the rate of accumulation of dimer, $W = k_1(R)^2$, to be evaluated from the calculated rate constant of the radical recombination reaction. Comparison shows that the calculated rates of recombination and disproportionation of C_2H_5, C_3H_7, and C_5H_{11} radicals are in good agreement with the experimental values (Table 2).

It is interesting to study the change in the reactivity of radicals with the introduction of substituents and also with the introduction of a new partner in the recombination reaction. Theoretical examination of the recombination of CF_3 radicals, and also of the combination of CF_3 and CH_3 radicals [37], shows that these reactions are energetically similar to the reactions described above ($E \simeq 200$–300 cal, $r^* \simeq 5$ Å). The calculated steric factor for the recombination of CF_3 radicals is considerably lower (4.6×10^{-6}, 900°K) than the factor for the analogous reaction with CH_3 radicals. For the recombination of CF_3 and CH_3 radicals s has an intermediate value (5.2×10^{-4}). It follows from these results that replacement of H atoms in CH_3 radicals by F atoms (with a greater atomic volume and the more polar C–F bond) leads to a sharp reduction in the steric factor, but differences between the recombination reactions of CH_3 and CF_3 radicals have not been observed experimentally [56]. The experimental activation energy for CF_3 radicals ($E \simeq 2.1$ kcal [57]) does not agree with the value calculated from the accepted model. If it is assumed that the activation energy is low, as in other cases, a value of 10^{-2} is obtained for the steric factor, which is greater than the value found, $s \simeq 4 \times 10^{-4}$ (300°K)‡.

Experimental results show that CF_3 radicals remove hydrogen from methane and ethane molecules more easily than CH_3 radicals [59,60]. Only relative steric factors of these reactions can be determined experimentally, and since the calculated value of s for the recombination of CF_3 radicals is considerably less than that for the recombination of CH_3 radicals, this may be a simple explanation of the experimentally observed increased activity of CF_3 radicals in reactions with saturated molecules (the activation energies of both substitution reactions are close).

TABLE 2. Calculated and experimental rates of recombination and disproportionation of alkyl radicals.

When radicals collide, in addition to recombination, the competing process in which they are disproportionated with the formation of two molecules is observed. In disproportionation reactions, as in exchange reactions, a hydrogen atom migrates from one particle to another. However, ordinary exchange reactions are exothermic by not more than 25 kcal, but the heat given out in disproportionation reactions is considerably greater (50–60 kcal). Disproportionation reactions would therefore be expected to have a low activation energy, and as a result are encountered no less frequently than radical recombination reactions. This may be demonstrated by an experimental study of the products of these reactions, which include saturated and unsaturated molecules as well as dimer.

Free radicals are mainly obtained by photolysis or pyrolysis of suitable compounds, by mercury photosensitisation of saturated molecules, or by the addition of a hydrogen atom to an alkene. Sources of the radicals include molecules of metal alkyls, ketones, aldehydes, and also other compounds. The following reaction scheme may be used to study the mechanism and kinetics of recombination and disproportionation reactions [52,61]:

$$M + h\nu \rightarrow 2R\,(\text{or } R_1 + R_2) \qquad (17)$$

$$2R \rightarrow R_2\,(k_1)$$
$$2R \rightarrow P + O\,(k_2).$$

Clearly,

$$k_2 = \frac{W_O}{(R)^2} \text{ or } \frac{W_P}{(R)^2} \text{ and } k_1 = \frac{W_{R_2}}{(R)^2} \qquad (18)$$

$$\Delta = \frac{k_2}{k_1} = \frac{W_O}{W_{R_2}} \text{ or } \frac{W_P}{W_{R_2}}.$$

The ratio Δ may be found by analysis of the reaction products, the dimer R_2, P, or O, with subsequent determination of the rates of formation W of the corresponding compounds. However, the reaction scheme may be more complex than that considered above. Frequently alkene and alkane molecules are formed by the following reactions

$$R + M = r + RH\,(k_3) \qquad (19)$$

$$r = O + R' + X, \qquad (20)$$

where r is the radical formed by removal of a hydrogen atom from the molecule M. If at the temperatures under

‡ On the basis of experimental results on the rates of the radical recombination reactions $2CH_3 = C_2H_6$ (a), $CH_3 + CF_3 = CH_3CF_3$ (b), and $2CF_3 = C_2F_6$ (c), the relative change in activation entropy of reaction (b) in relation to reactions (a) and (c) $\Delta S_b^* - \frac{1}{2}(\Delta S_a^* - \Delta S_c^*)$ has been calculated. Calculation of this by the theory of absolute reaction rates with the use of known values of the internal rotation barriers for ethane and substituted ethanes gives a value close to the experimental ratio of the preexponents [58].

study it is still necessary to take reaction (19) into account, then

$$W_P = k_2(R)^2 + k_3(R)(M)$$
$$W_{R_2} = k_1(R)^2.$$

Therefore

$$\frac{W_P}{W_{R_2}} = \frac{k_2}{k_1} + \frac{k_3(M)}{\sqrt{k_1 W_{R_2}}}.$$

Since W_P, W_{R_2}, and (M) may be measured experimentally, the ratio Δ is found graphically using plots of W_P/W_{R_2} against (M). Extrapolation of the straight line obtained to (M) = 0 will give an intercept on the ordinate equal to k_2/k_1. Sometimes additional difficulties are encountered, because alkane and alkene molecules are formed in the initial photolytic step [52].

When radicals are formed in the presence of an excess of hydrogen atoms by addition of the latter to alkenes, the value of Δ may be found by determining the relative amounts of P and R_2 in the products, provided that the reaction $R + H_2 = RH + H$ plays an insignificant part at the experimental temperatures [62]. This method of investigation has two disadvantages [63]. The first is that a careful mass-spectrometric analysis of the dimer (which is not an easy task) must be carried out to determine which radicals are present in the reacting system. Moreover, radicals formed by the addition of H-atoms to alkenes have a considerable excess of internal energy (~ 40 kcal), which makes them unstable with regard to decomposition into simpler particles. For these reasons, results obtained by this method should be viewed critically.

Numerous experimental results that have been quoted very frequently in recent years for the ratio of the rate constants of disproportionation and recombination reactions have been obtained by a study of the systems mentioned. The main reason for the divergence of experimental values of Δ appears to be the use of different methods of initiation, leading to the production of radicals with different internal energies. The reasons for the divergence of experimental results obtained by different workers is discussed by Thynne [64].

The parameters s and E for radical disproportionation reactions have been obtained from Eqn. (18) with the use of experimental values of Δ and on the assumption [4] that each collision leading to the combination of two radicals is effective ($s = 1$, $E = 0$). Since the experimental ratios of the rate constants are of the order $1-10^{-1}$, it is concluded that the steric factors of radical disproportionation reactions are within the same limits; it is assumed that the activation energies of these reactions are approximately equal to the activation energies of recombination reactions [65]. However, it has been shown in a number of experimental and theoretical papers that s is less than unity in radical recombination reactions (Table 1). Such an approach to the numerical evaluation of the preexponential factors of disproportionation reactions on the basis of experimental values of Δ and the assumption that $k_1 = 10^{14}$ mole^{-1} cm^3 s^{-1} for all alkyl radicals is therefore unsound. In this connection, the calculation of absolute rate constants of radical disproportionation reactions and, in the first instance, more detailed evaluation of preexponential factors are of interest.

Available experimental results on radical disproportionation reactions (the systematic study of which began in the last decade) do not allow the setting up of any definitive reaction model. Combination and disproportionation reactions of deuterated ethyl radicals have been observed in the photolysis of 2,2,4,4-tetradeuterodiethyl ketone [66]; two possible mechanisms for the disproportionation of ethyl radicals were considered: the "head-to-tail" mechanism

$$CH_3-CH_2- + H-CH_2-CH_2- = C_2H_6 + C_2H_4, \quad (21)$$

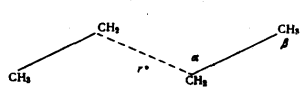
and the "head-to-head" mechanism

$$CH_3-CH_2- + H-CH-CH_3 = C_2H_6 + C_2H_4. \quad (22)$$

On the basis of a study of the isotopic composition of the products (the ethylene consisted of 90% $C_2H_2D_2$), it was concluded that the radicals preferentially disproportionate by the "head-to-tail" mechanism ($CH_3-CD_2\ldots H-CH_2-CD_2$). Similar results were obtained in the pyrolysis of the same ketone [67]. Mass-spectrophotometric analysis of the products showed that CH_3CD_2H and $CH_2=CD_2$ are mainly obtained in the disproportionation of ethyl radicals.

The possible mechanism of the disproportionation of alkyl radicals has again been discussed in a number of recent papers. Bradley draws attention to the similarity of the values of the rate constants of radical recombination and disproportionation reactions [40]. It has previously been noted that the activated complex in recombination reactions consists of two freely rotating radicals [46]. Since the rate constants of recombination and disproportionation reactions are close, it is reasonable to assume that the radicals also rotate freely in the activated complex in disproportionation reactions. From this it can be concluded that the transition states are identical. However, the "head-to-tail" mechanism cannot allow such freedom to the radicals in the activated state undergoing disproportionation, and since the energy surfaces corresponding to radical recombination reactions scarcely change with the radicals considered (this is demonstrated quantitatively by calculations of the activation energies of these reactions), it must be assumed that rearrangement of the activated molecule for disproportionation occurs after passage through the transition state. Because disproportionation is a highly exothermic process, the energy barriers to rearrangement cannot exceed the initial activation energy of the radicals, and therefore cannot be expressed experimentally as temperature coefficients of the reaction.

For the reaction between ethyl radicals Bradley considers the rearrangement of an activated molecule formed by the "head-to-head" mechanism, which has the following form in the case of radical recombination reactions:



The central C–C bond is ruptured in the reaction and a hydrogen atom is transferred from one half of the activated butane molecule to the other. The author concludes from an examination of the activated butane molecule that a β-hydrogen atom migrates to the methylene group of the other radical, and this converts the system into the reaction products, ethane and ethylene; as a result of intramolecular movements, the hydrogen in the β-position of one radical comes closer to the methylene group of the other radical than do the other hydrogen atoms. Bradley presents a number of proofs of the proposed mechanism [40].

Kerr and Trotman-Dickenson have proposed a similar explanation of the mechanism of disproportionation of alkyl

radicals[4,41]. Because of the closeness of the rate constants of reactions (1) and (2), they assume that radicals in the activated complex of disproportionation reactions are no less free than in the complex of recombination reactions. The structure of the activated complex in a "head-to-tail" disproportionation reaction does not allow such freedom to the radicals. It is considered that a dimer is formed initially and this then decomposes by a four-centre reaction. Since such dimerisation is a highly exothermic process, the activation energy required for decomposition is available.

This view of the mechanism of disproportionation of alkyl radicals has been confirmed by the work of Matsuoka and coworkers[42]. They investigated recombination and disproportionation reactions of ethyl radicals obtained by photolysis. The dependence of $\log\Delta$ of $1/T$ is linear in the temperature range -78° to + 85°C (some side reactions were excluded by the use of low temperatures). The observed negative temperature coefficient of this reaction may be explained by assuming that the radical disproportionation results from deformation vibrations of the active butane molecule which is formed by the union of two ethyl radicals. This leads to the migration of a hydrogen atom in the β-position from one radical to the methyl group of the other. This process competes with the intermolecular dispersion of energy of an incipient C–C bond which leads to butane as the product of the radical recombination reaction.

Quite recently Bradley and Rabinovitch have critically reexamined the mechanism of radical disproportionation[43]. They point out that, because of the rigidity of the activated complex, the previously accepted "head-to-tail" mechanism cannot correspond to the transition state of the disproportionation reaction, for which a looser structure is assumed. It may be assumed from the similarity between the activated complexes of radical disproportionation and recombination reactions that the corresponding saddle points are energetically and configurationally similar, and some reaction complexes may pass through both configurations. However, the experimental divergence between the values of k_1 and k_2, which differ by almost a factor of ten for most reactions of alkyl radicals, indicates that caution must be used in drawing an analogy between the mechanisms of these reactions. Moreover, possible amendments to the mechanism of radical reactions§ obviously change the existing point of view on the mechanisms of these reactions.

The well-known experimental fact that $E_{rec} - E_{dis} \simeq 0$ may be used to evaluate the rate constants of disproportionation reactions of alkyl radicals[65]. It is also assumed that the transition state in a disproportionation reaction is formed by a "head-to-head" mechanism; the reaction products then result from the transfer of a hydrogen atom in the β-position from one radical to the other[40]. Moreover, by analogy with exchange reactions (the distance between the particles in the activated complex has been found theoretically and experimentally for the simplest of these reactions[20,21]), it has been assumed that for migration of a hydrogen atom the disproportionating radicals must approach one another to a distance r^*, which is of the same order as the length of the interatomic bond in the corresponding hydrocarbon.

§ Rice recently pointed out another possible mechanism for radical recombination reactions, which consists in the coupling of combining radicals by means of three-centre H-atom bonds[68].

The rate constants for the disproportionation of alkyl radicals have been calculated from Eqn. (10) with the use of these assumptions. The data necessary for the calculation of the preexponents of these reactions have been published[23,37,39].

The results obtained show that disproportionation reactions have lower steric factors and rate constants than recombination reactions (Table 1). The reaction between a hydrogen atom and an ethyl radical, which is one of the simplest disproportionation reactions, has a steric factor much less than unity (2.4×10^{-2}) at room temperature. Disproportionation reactions in which hydrogen and more complex radicals participate have lower steric factors. At higher temperatures ($\sim$ 900°K) these values of s become still lower (Table 1), in accordance with Eqn. (11).

Replacement of a hydrogen atom by a CH_3 radical in the reaction between methyl and ethyl radicals leads to a reduction of the steric factor by about one order (1.7×10^{-3}, Table 1). As the reacting radicals become more complex (reactions 6–9, Table 1), the steric factor decreases more gradually, reaching a limiting value in these reactions of $\sim 10^{-4}$ (300°K) or $\sim 4\times10^{-6}$ (900°K).

A similar situation is observed with ethyl radicals (see reactions 10–13 in Table 1); the steric factor for the disproportionation of ethyl radicals is 10^{-4}.

We have made supplementary calculations in connection with the discussion above on the possible mechanism of disproportionation of ethyl radicals. Different directions of approach of two ethyl radicals which may disproportionate by the "head-to-tail" mechanism, and local changes of up to 20% in bond lengths and angles change the final result by less than a factor of 1.5. Similar calculations on the basis of the "head-to-head" mechanism, which is also accepted for other radical disproportionation reactions, lead to virtually the same values of the rotational partition coefficient of the activated complex. Thus, the difference between these two mechanisms cannot materially affect the value of the preexponential factors[37].

For reactions in which more complex radicals participate (reactions 14–19 in Table 1), the values of the steric factors scarcely change from one disproportionation reaction to another ($s_{300} = 10^{-5}$ and $s_{900} = 10^{-7}$). These may be considered as limiting values of the steric factors, which no longer depend on the complexity of the disproportionating radicals. The reduction in the reactivity of isomeric radicals (Table 1) appears to be due to the partial screening of the free valency caused by the branched structure of the radicals.

The rate constants of disproportionation reactions have been evaluated (Table 1) from calculated values of the steric factors and the numbers of binary collisions with the use of the assumption mentioned above on the values of the activation energies of these reactions.

When more extensive experimental results have been obtained, it should be possible to put forward a more precise mechanism for radical disproportionation reactions and to examine the energy barrier in these reactions both qualitatively and quantitatively. At present, because of the lack of precision of initial and experimental data which has been pointed out, a more precise calculation of the rate constants of disproportionation reactions would be premature.

The ratio of the rate constants for the disproportionation and recombination of alkyl radicals can be calculated

from the results that have been obtained. Most of the experimental results (which have been discussed in detail by Stepukhovich[23] and Ulitskii[37]) are given in terms of Δ; experimental and calculated values can therefore be compared. As Table 2 shows, the theoretical ratios of the rate constants of radical disproportionation and recombination reactions are close to the corresponding experimental values.

A number of attempts have been made to correlate values of Δ with some characteristics of the processes under consideration. If such a correlation were established, known values of Δ for some reactions could be used approximately to evaluate the ratios of the rate constants for other reactions.

If, as Ausloos and Steacie assume[69], the rate constants for the recombination of different butyl radicals are equal, values of the ratio Δ will be proportional to the rate constants of the disproportionation reactions (k_2). Let $\Delta = ak_2$, the value of a being selected to make ak_2 equal to 5 for s-C_4H_9 radicals. The number of hydrogen atoms which could be eliminated from the radical to form an alkene product is indicated for comparison in the fourth column of Table 3. Clearly there is a similarity between the numbers in the third and fourth columns. This indicates (under conditions such that the rate constants of the recombination reactions are equal) that the main factor determining the rate of disproportionation of butyl radicals is the number of hydrogen atoms that could be eliminated from the radical to form a stable alkene.

Kerr and Trotman-Dickenson have shown[70] from experimental results that values of Δ(CH$_3$, Alk) are simply related to the analogous Δ(Alk, Alk) for the corresponding reaction of two identical alkyl radicals. They examined recombination and disproportionation reactions between the same and different radicals (CH_3, C_2H_5, iso-C_3H_7, and t-C_4H_9). The corresponding values of Δ(CH_3, Alk) and Δ(Alk, Alk) are shown in Table 4. The second column of this table shows the number of hydrogen atoms which can migrate in a disproportionation reaction in which CH_3 and Alk radicals participate; thus in a ethyl radical the number is 3, in an isopropyl radical 6, and in t-C_4H_9 it is 9 (the number is denoted by the symbol | H |). The fourth and sixth columns of Table 4 show what are termed reduced values of the ratios of the rate constants of radical disproportionation and recombination reactions (Δ/| H |). A linear relationship of the following type may be established for these values:

$$\log \frac{\Delta(CH_3, Alk)}{|H|} = 0.55 \log \frac{\Delta(Alk, Alk)}{|H|} - 0.95.$$

By means of this equation, known reduced ratios of the rate constants of reactions between the same radicals may be used to find analogous values for disproportionation and

TABLE 3. Ratio of the rate constants of disproportionation (k_2) and recombination (k_1) of butyl radicals near 100°C (it it assumed that k_1 is the same for all these reactions[69]).

recombination reactions between CH_3 radicals and other alkyl radicals. This relationship may be expressed in the more general form:

$$\log \frac{\Delta(Alk', Alk'')}{|H|} = 0.55 \log \frac{\Delta(Alk', Alk')}{|H|} + C,$$

which links the reduced rate constants of these reactions between like and unlike radicals (C is a constant which is equal to 0.95 when Alk = CH_3). Too much significance should not be attached to these linear relationships, since they are constructed from three experimental points¶. Moreover, the experimental results of Boddy and Robb[62] do not show such a correlation.

Obviously, correlations between values of Δ(Alk', Alk") and Δ(Alk', Alk') must link not only the number of hydrogen atoms that can migrate in radical disproportionation, but they must also include other characteristics of radical recombination and disproportionation. In particular, it has been found in a number of examples examined that changes in Δ(Alk', Alk") or Δ(Alk', Alk') and $S_{dis} - S_{rec}$ are symbathic and a relationship can be established between them[40]. Moreover, as Table 1 shows, there are no grounds for assuming that the reactivity of recombining radicals does not change with a change in their structure (this conclusion is true only for sufficiently complex radicals). Therefore, the assumption that the rate constants for the recombination of different radicals are equal is not always justified, and the assumption that the correlations depend only on radical disproportionation processes cannot always be considered valid.

The ratios of the rate constants for the disproportionation and recombination of alkyl radicals found in different experiments are close. The calculated values of analogous ratios of the rate constants agree with the experimental values (Table 5). Since the calculated and experimental values of steric factors of radical recombination reactions are low, and the ratios of the rate constants of reactions (1) and (2) are close to unity, the steric factors for the disproportionation of alkyl radicals are also low, and these determine the kinetics of the reactions.

Since it is concluded that the steric factors for the recombination and disproportionation of alkyl radicals are low, these reactions may be classified as fairly slow bimolecular reactions, and not as rapid bimolecular reactions (as has been done in the literature). At high temperatures (in the cracking of hydrocarbons and other thermal conversions) the steric factors are particularly low and the kinetics of the processes are determined entirely by these factors. Therefore, the not too high reaction

¶ With these relationships Δ(Alk', Alk") can be calculated from a knowledge of Δ(Alk', Alk') with an uncertainty covered by a factor of 3–4.[71]

$C_2H_5+C_3H_7$	0.16	—	2s-C_4H_9	2.1	2.27^{80}
$C_2H_5+C_4H_9$	0.16	—	2t-C_4H_9	4.5	$4.59^{80}4.38^{84}3.2^{71}$
$C_2H_5+C_5H_{11}$	0.16	—			

rates of radical recombination and disproportionation reactions under these conditions are determined not only by the low radical concentrations in the reaction zone but also by low values of the preexponents.

1. INTRODUCTION

One of the fundamental tasks in modern science is to study the structure and properties of polyatomic molecules. In the past two decades, in addition to traditional chemical methods, an ever-increasing and in many instances decisive part has begun to be played by various physical methods, particularly methods based on the study of the energy levels of polyatomic molecules. These methods include electronic, vibrational, and rotational spectroscopy and radiospectroscopic methods. The great importance of these methods lies primarily in the fact that they make possible the study of the structure and properties of molecules and molecular associates in any state of aggregation without breakdown of the molecules, as usually takes place when chemical methods are used. At present the methods most widely used are electronic and particularly vibrational spectroscopy. This is due both to the fact that historically they appeared before the radiospectroscopic methods and also to the high degree of development and ubiquity of electronic and vibrational spectroscopy and the wide range of varied problems which can be solved by these methods. The rapid development of experimental techniques and the appearance of automatic spectrophotometers have also been of considerable importance.

Unlike electronic absorption spectra and luminescence spectra, the overwhelming majority of vibrational spectra consist of a large number of discrete lines and bands, whose appearance is related to the presence and interaction of various atomic groups in the molecule, so that the very nature of the vibrational spectra gives considerable information on the detailed structure of a complex system.

Vibrational spectroscopy, however, is an indirect method. Experimental measurement of the parameters of the spectrum alone (the number of bands, their position on the frequency scale, intensities, etc.) is useless if a relationship has not been established between the observed quantities and the structure of the polyatomic molecule, that is, if the appropriate theory has not been developed. The need to develop a special theory of vibrational spectra arose in the nineteen-thirties and -forties as a result of the accumulation of experimental material on the infrared absorption spectra (IRS) and Raman spectra (RS) of complex molecules and the resulting desire to interpret these spectra. At that time a solution to the problem of the vibrational energy levels (normal vibrations) of polyatomic molecules had been roughly outlined; the problem involved primarily the development of a theory to explain the general features characteristic of the vibrational spectra of homologous series, to relate the vibrational spectra to the internal structure of molecules, and to carry out the necessary numerical calculations. This theory could be only semi-empirical, since direct quantum-mechanical methods were here quite inadequate.

A decisive step in this direction was taken by El'yashevich[1-6], who proposed a general method for formulating equations for the vibrations of polyatomic molecules in a special system of coordinates, which he called the natural system. An analogous method was developed independently by Wilson[7-10]. The introduction of natural coordinates made it possible to apply to the theory of vibra-

tional spectra the system of ideas developed in the structural chemistry of polyatomic molecules and this in turn made it possible to make the most important classification of all normal vibrations on the basis of the vibrations of the valency bonds (stretching vibrations), the vibrations of the valency angles (bending vibrations), and the vibrations of structural groups. This made it possible to explain the characteristic vibrations in the spectra of homologous theories. The theory of characteristic vibrations was later developed by Mayants [11] on the basis of a classification of the vibrations according to the characteristic nature of the frequency and mode, and also the frequency and mode themselves.

When natural coordinates were used, the coefficients in the expression for the potential energy (force constants) in a large number of molecules were found to be closely related to the properties of the corresponding structural elements, and specific calculations showed that the force-constant structural elements, within certain limits, retain their numerical value in a series of molecules containing the given structural elements. This property of the force constants, which is closely related to the comparatively unchanged nature of the individual "building bricks" of the molecule, predetermined the collection of a set of force constants necessary for numerical calculation of the vibration frequencies of a large number of molecules.

The creation of this set began after the development of effective methods for calculating the eigenvalues and eigenvectors of the equations for molecular vibrations, taking account of the specific features of these equations (the diagonalisation method of El'yashevich and Stepanov [12], the improved iteration method of Mayants [13]), and the determination of the force constants for a number of basic compounds by Stepanov and El'yashevich [14]. On the basis of the theory developed by these authors, Kovner's and Sverdlov's groups, together with Kovalev, Bogomolov, Peregudov, Popov, and a number of others, calculated the frequencies and modes of the vibrations and interpreted a large number of molecular spectra (chiefly organic molecules) and determined the force constants of the most important bonds and groups. This provided the necessary starting material for the extensive use of calculations and the solution of a variety of applied problems.

The development of the theory of molecular vibration frequencies was accompanied by the development of a theory of intensities in IRS and RS. By using an additive scheme for representing the dipole moment and polarizability tensor of a molecule in the form of the vector and tensor sums of the dipole moments and polarizability tensors of the individual bonds, Vol'kenshtein [15,16] formulated a semi-empirical theory of intensities in IRS and RS, later improved with El'yashevich [17,18]. Because of the lack of experimental material on the measurement of intensities in spectra at that time and the tedious nature of the calculation, however, the theory of intensities remained at this stage of development for a prolonged period.

Thus at the start of the nineteen-sixties considerable progress had been made in the theory of vibrational spectra (particularly in the theory of the frequencies and modes of the vibrations), as a result of which the extensive application of calculation methods to practical spectrochemical studies became possible. It was also shown for many examples that in the overwhelming majority of instances sufficiently well-founded and reliable conclusions regarding the structure and properties of a molecule could be obtained from spectroscopic data only by a theoretical study.

This possibility, however, could not be completely realised until all the calculation part had actually been reduced to programmes for electronic computers (EC). This important task in turn required the transformation of the entire mathematical technique of the theory into a form convenient for use with EC, and the development of a system of algorithms. EC were first used to calculate the eigenvalues and eigenvectors of the equations for the vibrations, and also for a number of other operations (normalisation, calculation of the displacements of atoms, etc.) [19]. This is related to the fact that the methods for solving the equations are already formulated in the form of algorithms and the problem involves merely encoding.

The choice of algorithm for formulating the equations, which is the specific task of the theory of molecular vibrations, was found to be much more complex. It is significant that programmes of this type have appeared only recently [20]. The solution of this problem required not only a change in the mathematical techniques but also the abandonment of most of the procedures used in manual calculation. For example, the use of standard formulae for calculating the kinematic coefficients was found to be unsuitable.

The reduction of the mathematical apparatus of the theory to a single form and its simplification inevitably concerned one of the most important sections of the theory — the consideration of the symmetry of the molecule and the calculation of the symmetry coefficients in the symmetry coordinates. All the other sections of the theory of molecular vibrations can be readily formulated in the language of vector and matrix algebra and require for their understanding a fairly limited knowledge of these branches of mathematics, but the calculation of the symmetry coefficients was based on the use of group theory, unfamiliar to the great majority of spectroscopist chemists. Despite the existence of tables of symmetry coefficients, this feature created serious difficulties in carrying out the calculations for specific molecules. The attempt by Mayants [21] to solve this problem without using group theory was thus understandable, but the method which he proposed was also tedious and was not widely accepted. A simple solution to this problem and clear selection rules depending on symmetry in the IRS were obtained only recently by introducing the concept of directed symmetry vectors and the study of their properties [22].

A most important problem, unfortunately still unsolved, is that of decreasing the arbitrary nature of the choice of force constants for polyatomic molecules. The existing modifications of the force functions have not led to a cardinal solution and cannot be regarded as satisfactory. Since direct application of the methods of quantum mechanics to the solution of this problem is still impossible, the development of the theory of molecular vibrations must apparently involve the construction of a theory which will also require the use of empirical parameters whose introduction, however, will be based on the results of quantum chemistry. The ordinary force constants should then be functions of these parameters.

In recent years the theory of intensities in the IRS has been further developed. As noted above, the work of Vol'kenshtein and El'yashevich, who laid the foundations of the theory, was followed by stagnation for several years. In this period the non-Soviet literature included a large number of papers (see the bibliography in the review by Gribov and Smirnov [23]) on the measurement of the absolute intensities of absorption bands in the IRS using methods

developed by Kemble and Bourgin[24,25], Wilson and Wells[26], and others[27]. On this basis attempts were made to calculate the dipole moments of the bonds in many molecules. The failure of these calculations (the lack of agreement between the dipole moments of the molecules determined by other methods and the values calculated from the IRS) produced a sceptical attitude towards the theory itself. Sverdlov's calculations[28-32] of the electro-optical parameters of a number of simple molecules, carried out from 1959 onwards according to the scheme of Vol'kenshtein and El'yashevich, did not greatly improve the situation, since the parameters which he found were obtained in the form of combinations which were so cumbersome that their physical significance was completely lost and their further use impossible.

Thus the theory of intensities was faced with the following tasks: the extension of the theory to any molecules (additive and non-additive), the creation of a convenient calculation scheme, the development of some of the most important general questions (the theory of characteristic intensities and the dependence of the intensities on the number of identical groups in the molecule) formulated in Vol'kenshtein's papers, determination of the numerical values of the electro-optical parameters for a number of the simplest groups, and proof that the values for these parameters are preserved in a series of molecules containing the given groups. This last problem determined the possibility of creating a set of electro-optical parameters for bonds and groups, similar to the set of force constants, and hence the possibility of using the theory to carry out numerical calculations of the absorption band intensities in the IRS. A number of papers by the authors of the present review were devoted to the solution of all these problems[33-43]. As a result it was possible for the first time to calculate the intensities of the absorption bands in the spectra of complex molecules[42,43]. In recent papers[44-46], the methods of the theory of intensities in the IRS are used to study the structure and properties of a number of compounds. It can thus now be stated that the theory which has been developed can serve as a basis for corresponding spectrochemical studies.

More work has also been carried out on the theoretical study of the electro-optical parameters for Raman spectra using a modernised form of Vol'kenshtein's calculation scheme[47-51], but the existing situation (the number of empirical parameters introduced is three times that for IRS) does not lead us to expect marked advances in this direction.

Methods for analysing molecules according to their vibrational spectra can be provisionally divided into two groups according to the nature of the problems to be solved. The first group includes methods which use only directly measurable quantities (the number of absorption bands or lines in the RS, their position on the frequency scale, and their intensities). These data make it possible to determine the symmetry of molecules and free radicals, to calculate thermodynamic functions, and to carry out qualitative and quantitative molecular analysis and the analysis of mixtures.

The second group includes methods of structural group analysis, the isolation of atomic groups with closed structure in the molecule, the study of the influence of the environment of the group, substituents, intramolecular interaction, and intermolecular interaction, and the study of rotational isomers. In these studies, in addition to the measured parameters of the spectrum, it is necessary to have additional information on the relative amplitudes of the vibrations of the parts of the molecule in a given normal vibration (the mode of the vibration), and also on those factors (the geometry of the molecule, the characteristics of the interatomic forces and interactions between the groups, the dipole moments of the bonds, etc.) which determine the position of the bands or lines in the spectrum, and their intensity and polarisation (or depolarisation). The accumulation of information of this type is generally described as the interpretation of the band (or line). A sufficiently reliable and complete interpretation of a band can be obtained only on the basis of appropriate theoretical study and model calculations.

In studies of the first type, a close combination of theoretical and experimental methods is often necessary. For example, in the calculation of the thermodynamic functions of polyatomic molecules (free energy, entropy, heat capacity), calculation makes it possible to find all the vibration frequencies, which cannot always be done by purely experimental methods, and also to distinguish, among the observed bands or lines, those due to the fundamental frequencies.

At the present time, when it is constantly necessary in chemistry to use the results of spectroscopic studies, it is absolutely essential for chemists not only to be aware of the fundamental possibilities and characteristic features of the method, in general outline at the very least, but also to be familiar with the "pitfalls" characteristic of this method. Otherwise, it is impossible to adopt a critical attitude towards published material, and this may have very serious consequences. Unfortunately, it must be said that although the method of vibrational spectroscopy has for long been fruitfully used in chemical studies, a very large number of chemists, even sometimes those who make fairly extensive use of the infrared spectra and Raman spectra of polyatomic molecules, have insufficiently clear ideas regarding the most important aspects and concepts of the method. This situation has apparently arisen as a result of the fact that existing publications on the problems of vibrational spectroscopy can be fairly sharply divided into theoretical publications intended for specialists in this field and, if we can use the expression, experimental publications based chiefly on various types of empirical studies of individual classes of compound. The latter often contain very valuable material but their perusal gives an oversimplified and often incorrect picture of the methodology of vibrational spectroscopy.

It is of course impossible in a single paper to outline even briefly the essential features of the many important and interesting problems of vibrational spectroscopy. We shall therefore restrict ourselves to two of the most important: the influence of kinematics on the position of the frequencies in the spectrum, and its consequences, and also the problem of determining force constants. It is these two problems which arise most frequently in spectrochemical practice, and without a clear understanding of these problems any serious spectroscopic study of the structure and properties of polyatomic molecules is impossible. Most errors in spectrochemical work, moreover, are due to neglect of kinematic factors.

2. ELEMENTS OF THE THEORY OF VIBRATIONS OF POLYATOMIC MOLECULES

The appearance of the discrete vibrational spectrum of a polyatomic molecule results from the existence of definite

energy levels in the molecule. Of fundamental importance in the discussion of the problems of energy levels in polyatomic molecules is the possibility of examining separately, with a reasonable degree of approximation, the various forms of motion for the particles in the molecule: the motion of electrons, vibration of nuclei, rotational motion of the molecule as a whole, and finally the translational motion of the molecule.

We shall be interested in the purely vibrational motion, that is, the movement of the atoms in a force field which is determined by the given electronic state of the molecule. The equations of motion are usually formulated in the system of natural vibrational coordinates q_i (the changes in the equilibrium bond lengths, valency angles, etc.), the number of which is equal to the number of vibrational degrees of freedom for a system of N particles, that is, $3N$ - 6 (or $3N$ - 5 for linear molecules)†.

The coordinates q_i, which characterise the departure of the configuration of the molecule from the equilibrium configuration and become equal to zero for the equilibrium state, describe the state of the separate parts of the molecule. For small vibrations (of the order of hundredths of an ångström unit) they are linearly related to the Cartesian coordinates of the displacement of the atoms from their equilibrium positions, so that the kinetic energy of the vibrating atoms is described in the generalised momenta p_i corresponding to the coordinates q_i in the quadratic form

$$T_{\text{kin}} = \frac{1}{2}\sum_{i,j} \tau_{ij}\, p_i p_j,$$

with coefficients τ_{ij}, which can be calculated if the equilibrium geometry configuration of the system is known. The potential energy, which has the significance of the difference between the energies of the displaced and equilibrium configurations, depends only on the relative coordinates of the nuclei to a reasonable degree of approximation and is described by the function $V(q)$. By expanding $V(q)$ into a series with respect to powers of q_i close to the equilibrium position, it is possible to represent the potential energy of any displaced state by means of a set of derivatives of $V(q)$ with respect to q_i of different order and a set of values of q_i. These derivatives are constant for any small deformations of the molecule and are determined by the properties of the given electronic state. It is assumed (in the so-called harmonic approximation which is satisfactory for small vibrations) that the displacements of the atoms from the equilibrium positions during the vibrations are symmetrical and that the resulting restoring forces are linearly dependent on the magnitude of the displacement. We then have (with allowance for the conditions of stable equilibrium)

$$V = \frac{1}{2}\sum_{i,j} K_{ij} q_i q_j$$

The coefficients $K_{ij} = \left(\dfrac{\partial^2 V}{\partial q_i\, \partial q_j}\right)_0$ (the force constants) are at present found only from measurements of the vibrational frequencies of the molecule. This feature, which makes the theory of vibrations semi-empirical, is its chief weakness, since it restricts the possible applications of the theory in calculations chiefly to organic molecules. In order to solve the equation for the vibrations it is necessary to change to new coordinates, which have been called normal coordinates. When normal coordinates are used the expressions for the kinetic and potential energies acquire the form $T_{\text{kin}} = \frac{1}{2}\sum_i P_i^2$ and $V = \frac{1}{2}\sum_i \lambda_i Q_i^2$, that is, they do not contain the terms P_iP_j and Q_iQ_j $(i \neq j)$. This can be achieved by the following change of variables (coordinates)

$$q_1 = l_{11}Q_1 + l_{12}Q_2 + \ldots + l_{1n}Q_n,$$
$$\ldots\ldots\ldots\ldots\ldots\ldots$$
$$q_n = l_{n1}Q_1 + l_{n2}Q_2 + \ldots + l_{nn}Q_n \quad (n = 3N - 6).$$

The coefficients λ_i and elements l_{ij} are found from the solution for the system of $3N$ - 6 algebraic equations:

$$\begin{cases} (d_{11} - \lambda)q_1 + d_{12}q_2 + \ldots + d_{1n}q_n = 0 \\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ d_{n1}q_1 + d_{n2}q_2 + \ldots + (d_{nn} - \lambda)q_n = 0 \end{cases} \quad (1)$$

where $d_{ij} = \sum_m \tau_{im}K_{mj}$.

This system of equations assumes a non-trivial solution for q_i only for certain values of the factor λ, which are calculated from the condition for solvability of the system; this makes it possible to formulate an equation of degree $3N$ - 6 in λ (the secular equation). For each root λ_i with subscript i for this equation we find from system (1) a set of unknowns $q_1 \ldots q_n$, whose value is given by the elements l_{ki} $(k = 1, \ldots, n)$ in the formulae for the transformation of the coordinates.

After the change to normal coordinates, the equation for the vibrations is broken down into $3N$ - 6 first-order equations, each of which describes a linear harmonic oscillator and can be readily solved. The frequencies of the vibrations of these oscillators (normal vibrations) will be equal to $\nu_i = \sqrt{\lambda_i}$. To characterise the vibrations of the individual parts of the molecule, it is necessary to change again from coordinates Q_i to natural coordinates. In each normal vibration, only one coordinate Q_i will be different from zero. We then have, for example, for the first coordinate according to the formulae for transformation of the coordinates,

$$q_1 = l_{11}Q_1,\ q_2 = l_{21}Q_1,\ \ldots,\ q_n = l_{n1}Q_1. \quad (2)$$

Thus the relative amplitudes of the changes in all the natural coordinates in the vibrations will be given by the numbers l_{k_1}, and the relative phases will be determined by the signs of l_{k_1}. The set of elements l_{k_1} is therefore called the mode of the given normal vibration. It can also be seen that the changes in all q_i in a normal vibration will take place with frequency ν_i and that all q_i pass through zero simultaneously.

Despite its limitations (the harmonic approximation), the concept of normal vibrations is important in the theory of the vibrations of polyatomic molecules and provides a basis for solving the most varied problems.

3. CHARACTERISTIC VIBRATIONS OF POLYATOMIC MOLECULES

Study of the properties of normal vibrations makes it possible to reach general conclusions regarding the behaviour of the vibrational frequencies in the spectra on

† Strictly speaking, the coordinates used are the projections of these changes on the equilibrium unit vectors of the molecule (the directing vectors of the bonds, valency angles, etc.), which undergo translational movement and rotate with the molecule.

going from a given atomic group in one molecule to the same group in another molecule. This problem is important in applied spectroscopy, since the great majority of present-day spectrochemical investigations are aimed at studying the influence exerted on a given group of atoms by its immediate environment and in some instances by its more distant environment. Measurements are usually made of the displacements of the vibration frequencies for the given group with change in its environment. The magnitude of these displacements and the observed regular features in a series of compounds contain information on the structure and properties of the group itself and on the changes in the structure of the molecule. This obviously raises a most important question — does the displacement or change in the intensity of the absorption bands characteristic of a given group provide a sufficient indication of breakdown of its structure? It is known, for example, that this is in fact the case for the electronic absorption spectra of polyatomic molecules. This feature, and also the fact that some experimental workers are insufficiently familiar with the general theory of the vibrations of polyatomic molecules, leads to a situation where the authors of whole series of papers tend to interpret any change in the position or intensities of the vibrational absorption bands in the IRS or lines in the RS due to a given group as a sign of breakdown in the structure of the group; they forget long-familiar simple experimental facts which show directly that appreciable displacements of the frequencies may have no connection with breakdown of the electronic structure of the molecule. For example, the frequency of the vibrations of the C≡C bond is extremely stable in various compounds but changes from 1974 cm^{-1} in the acetylene molecule to 1851 cm^{-1} in monodeuterioacetylene and to 1765 cm^{-1} in dideuterioacetylene, that is, by a total of more than 200 cm^{-1}, although it may be assumed with a reasonable degree of approximation that no changes in the properties of the electronic ground state of the molecule take place when H is replaced by D.

It is quite obvious that without a clear understanding and detailed study of all the factors leading to change in the bands studied in the spectrum, no reliable conclusions can be reached regarding changes in the molecule.

Here we come up against the most important concept of characteristic vibrations. The existence of characteristic vibrations has to a large extent been responsible for the extensive application of vibrational spectroscopy in spectrochemical practice. At the same time no topic has been associated with so many errors as the interpretation of characteristic vibrations‡. To examine the essential features, let us take a simple example.

Let us imagine a given group of atoms. Let us assume that this group is present in a molecule. Since each vibration of the molecule is characterised by its frequency and mode, it is natural to classify vibrations according to their frequencies and modes [52]. When the frequencies of vibrations are measured, their mode is not recorded directly, but it is of decisive importance in the study of the intensities of vibrations. There may be vibrations which are stable with respect to frequency but not with respect to mode, so that the absorption bands in the IRS and lines in the RS retain their position in the spectrum, but with a change in intensity.

‡ It is paradoxical that in this an undesirable part has been played by various tables of characteristic vibrations, which in many cases are accepted too literally.

We shall describe a vibration as characteristic with respect to frequency for a given group if one of the normal vibrations of the molecule coincides in frequency with one of thenormal vibrations of the given group as a free molecule. If one of the normal vibrations of the molecule coincides with a normal vibration of the given group with respect to mode, that is, if the vibration is such that only the configuration of the isolated group changes, this vibration will be described as characteristic with respect to mode for the given group. If both conditions are satisfied, the vibration will be described as characteristic with respect to frequency and mode or completely characteristic. This distinction is meaningful (although strictly speaking there cannot be vibrations characteristic with respect to frequency but not characteristic with respect to mode, and vice versa), because the degree of non-characteristic nature of different types is different in a very large number of instances. This classification is to some extent arbitrary and approximate, but it has nevertheless been found to be extremely convenient in practice.

There may be instances where the above properties of normal vibrations are preserved in a series of molecules containing a given group. It is then usual to speak of the stable characteristic nature with respect to frequency, mode, and frequency and mode for a given group. The property of stability in characteristic nature with respect to frequency and with respect to frequency and mode is manifested by the appearance of absorption bands or lines in the same region of the IRS for a series of molecules containing the given group. This in turn makes it possible to carry out the qualitative analysis of unknown substances and mixtures from their IRS and RS and their structural group analysis.

Let us consider the basic hypotheses of the theory of characteristic vibrations. For this purpose let us examine a given group of atoms (radical) and let us introduce it in turn into different molecules of a given series, that is, let us examine a set of molecules consisting of two groups (first and second), where the first group remains unchanged. It is obvious that in these molecules we can expect the appearance of characteristically normal vibrations only if the contribution made by the group being studied is additive. It is also clear that the distortions of the normal vibrations of the selected group as a free group when it is attached to a molecule will be smallest when the group is attached to the molecule through a single atom. We shall therefore restrict ourselves to the case where the group has only one atom attached to the molecule.

Let us divide the natural coordinates characterising the vibrations of molecules into three sets: coordinates describing the movement of the first and second groups as free molecules (natural vibrations of the groups), and coordinates describing the movements of the first and second group relative to one another. If the first and second groups are assumed to be additive, with a reasonable degree of approximation, the expression for the potential energy need take account only of the coefficients K_{ij} (force constants), relating to the internal coordinates of the first and second groups and intermediate coordinates. Here the force constants of the groups will depend only on the properties of these groups taken separately. In the formulation and solution of the equations for the vibrations of the first and second groups as free molecules and the equation for the vibration of these groups relative to one another, we can change from natural coordinates to normal coordinates for each of the groups. This form of representation is convenient in the investigation of the nature of

the characteristic vibrations, since it makes it possible to describe the normal vibration of a molecule as the superposition of the normal vibrations of the individual groups. It should be remembered that the change to normal coordinates can be regarded as the construction of a molecular model in which the real system is replaced by a set of one-dimensional oscillators — bonds — selected in definite fashion. When two groups are combined to form a single molecule the various normal oscillators of the first and second groups will interact with one another and the resulting vibration will be complex. In order to analyse the qualitative picture we can restrict ourselves to the instance where only pairs of normal oscillators of the first and second groups interact, that is, to the interaction of pairs of hypothetical "bonds".

The equation for the vibrations of this pair of "bonds" will have the form

$$\begin{cases}(\lambda_1^{(0)}-\lambda)Q_1+\tau\lambda_2^{(0)}Q_2=0,\\ \tau\lambda_1^{(0)}Q_1+(\lambda_2^{(0)}-\lambda)Q_2=0,\end{cases} \quad (3)$$

where $\lambda_1^{(0)}$ and $\lambda_2^{(0)}$ are the squares of the frequencies of the selected pair of normal vibrations of the first and second groups (these frequencies are usually called partial frequencies), and Q_1 and Q_2 the corresponding normal coordinates, which have the physical significance of the "elongation" of the hypothetical "bonds". The quantity τ (the coefficient of kinematic interaction of the pair of oscillators) is inversely proportional to the mass of the atom which is common to both groups and to the cosine of the angle α between the "directions" of the normal oscillators.

When the common atom has a high mobility and the angle α approaches 180°, the value of τ may become appreciable. It then follows from Eqn. (3) that the normal vibrations of the pair of "bonds" will not have frequencies equal to $\lambda_1^{(0)}$ and $\lambda_2^{(0)}$ and modes $Q_1 = 1$, $Q_2 = 0$ and $Q_1 = 0$, $Q_2 = 1$ respectively, that is, they will not be characteristic either with respect to frequency or with respect to mode for each of the "bonds". We thus reach an extremely important conclusion: the vibrations of a group of atoms may change both with respect to frequency and with respect to mode in a series of molecules containing the given group merely as a result of its kinematic associations with the rest of the molecule, even if the structure of the group itself remains quite unchanged. Thus the displacement of absorption bands assigned to a given group of atoms, or a change in their intensity (the latter depends very strongly on the mode of the vibrations) for different types of substitution outside the given group cannot provide a sufficient indication for breakdown of the structure of the group. On the other hand, absence of change in the frequency, and more particularly, the intensity of a band in the IRS or of a line in the RS indicates with a very high degree of probability that the group itself remains unchanged.

Despite its obvious nature, this feature has somehow been overlooked in many papers. It is sufficient to point out that errors of this type are not infrequent in Bellamy's well-known monograph[53], a handbook of the majority of spectrochemists. Displacements of frequencies as a result of kinematic associations are particularly large for groups situated inside a molecule but they may reach 100 cm^{-1} or more even for terminal groups. A classical example of this type is the marked displacement of the bands and changes in their intensities on deuteration, which often leads to a change in frequencies corresponding to the vibrations of groups in which no replacement of H by D has taken place.

The possibility of appreciable displacements of absorption bands or lines in the IRS as a result of kinematic interaction is responsible for fundamental difficulties in the study of molecules by the methods of vibrational spectroscopy. In order to make allowance for kinematic factors it is almost always necessary to calculate the frequencies and modes of vibrations for the selected molecular models. It is most convenient to begin with calculations for simplified models and then to proceed to more complicated structures as required.

Let us assumed that the atom by means of which the group is attached to the molecule is much heavier than the other atoms. It will then undergo almost no displacement when the group vibrates. It is obvious that then we shall be dealing with vibrations which are characteristic with respect to frequency and mode for the given group. In actual fact this corresponds to the case where $\tau = 0$. This property is shown, for example, by the vibrations of CH, OH, NH, CH_2, CH_3, NH_2, and other groups containing a light terminal atom.

For most groups $\tau \neq 0$. Of practical interest in this connection are the two extreme cases: $\lambda_1^{(0)} = \lambda_2^{(0)} = \lambda$ and $\lambda_1^{(0)} \gg \lambda_2^{(0)}$ $(\lambda_1^{(0)} \ll \lambda_2^{(0)})$.

Let us assume that $\lambda_1^{(0)} = \lambda_2^{(0)} = \lambda^{(0)}$; by solving Eqn. (3) we find that the kinematic interaction of the corresponding pair of normal vibrations of the first and second groups leads to the production of two vibrations, for which the squares of the vibrations are $\lambda_{1,2} = \lambda^{(0)} \pm \tau\lambda^{(0)}$ and the relative amplitudes (modes) are $Q_1^{(1)} = 1$, $Q_2^{(1)} = 1$, $Q_1^{(2)} = 1$, and $Q_2^{(2)} = -1$.

Thus the interaction of two normal vibrations of groups with identical frequencies leads to splitting of the frequencies and "mixing" of the amplitudes. This is one example of mechanical resonance. For its production, the natural vibrations of the first and second groups must contain vibrations with identical frequencies, and the displacement of the common atom in these vibrations of the first group should differ from zero and should not take place in a direction perpendicular to the displacements in the resonating vibration of the same atom of the second group. When resonance takes place the vibration of the first group extends throughout the entire molecule and will not be characteristic for this group either with respect to frequency or with respect to mode. The phenomenon of mechanical resonance is observed particularly frequently in the vibrations of molecular skeletons, so that they are almost never characteristic for individual bonds. This can readily be seen, for example, from Table 1, which gives the calculated modes of vibrations of the polyene chain in the $C_2H_5OOC[CH=CH]_4COOC_2H_5$ molecule.

If $\lambda_1^{(0)} \gg \lambda_2^{(0)}$, we obtain vibrations for which the squares of the frequencies are equal to

$$\lambda_1 \simeq \lambda_1^{(0)} + \frac{\tau^2\lambda_1^{(0)}\lambda_2^{(0)}}{\lambda_1^{(0)}-\lambda_2^{(0)}};\quad \lambda_2 \simeq \lambda_2^{(0)} - \frac{\tau^2\lambda_1^{(0)}\lambda_2^{(0)}}{\lambda_1^{(0)}-\lambda_2^{(0)}}$$

and the relative amplitudes are

$$Q_1^{(1)} = 1;\ Q_2^{(1)} = \frac{\tau\lambda_1^{(0)}}{\lambda_1^{(0)}-\lambda_2^{(0)}} \to \tau \neq 0,$$

$$Q_1^{(2)} = \frac{-\tau\lambda_2^{(0)}}{\lambda_1^{(0)}-\lambda_2^{(0)}} \to 0;\ Q_2^{(2)} = 1.$$

TABLE 1*. Mode of the vibrations of the polyene chain in $C_2H_5OOC(CH=CH)_4COOC_2H_5$.

Symmetry	ν, cm^{-1}	Mode of the vibration			
		Q	q	Q_1	q_1
A_g	1623	—0.28	0.05	0.27	—0.24
	1597	0.25	—0.31	0.26	—0.18
A_u	1626	0.15	—0.30	0.35	—
	1573	—0.36	0.10	0.19	—

* Q and q are the normalised modes of the vibrations in symmetry coordinates, characterising the changes in the lengths of the double and single bonds respectively (from the start of the chain to the centre).

Thus both frequencies will differ from the natural frequencies of the vibrations of the first and second groups, and if the natural frequency of the first group is greater than the natural frequency of the second group, its vibration will extend throughout the whole molecule with coefficient τ. If $\lambda_1^{(0)} \gg \lambda_2^{(0)}$, the relative displacement of the λ_1 relative to $\lambda_1^{(0)}$ will be small and we can speak of the production of vibrations characteristic for the first group with respect to frequency but not with respect to mode. This property is shown, in particular, by the stretching vibrations of non-conjugated C=C, C≡C, N=N, and certain other bonds. For example, in the ethylene molecule for the 1620 cm^{-1} vibration the extension of the C=C bond is accompanied by a marked change (of up to 50% in arbitrary units) in the HCC angles. In the stretching vibration with frequency 2270 cm^{-1} in the acetonitrile molecule, usually assigned to the vibration of the C≡N bond, a significant part is played by the neighbouring C–C bond (up to 50%). Neglect of this feature has led, in particular, to an incorrect explanation[54] for the almost eightfold change in the intensity of this absorption band when hydrogen atoms are replaced by chlorine[45].

The second normal vibration of the set of coupled oscillators when kinematic interaction takes place will have a frequency less than $\lambda_2^{(0)}$ (for $\tau > 0$), but it does not extend throughout the whole molecule. There appear vibrations which are not characteristic with respect to frequency for the first group but are characteristic with respect to mode.

Let us take one simple example (the HCN molecule) which effectively illustrates the case of the interaction of the vibrations of two groups described above. Since the C atom is much heavier than the H atom, the H–C vibration will be characteristic with respect to frequency and mode. Accurate calculation[39] gives $\nu_1 = 3312$ cm^{-1} and $q_1 = 1$ (stretching of the C–H bond) and $q_2 = -0.136$ (stretching of the C≡N bond). The frequency of the vibrations of the C≡N bond is lower than the frequency of the vibrations of the C–H bond, so that in the C≡N vibrations the change in the length of the C–H bond should be less than the change in the C≡N bond. We have $\nu_2 = 2089$ cm^{-1}, $q_1 = 0.37$, and $q_2 = 1$. When H is replaced by D for C≡N vibrations the decrease in the D–C frequency relative to the H–C frequency makes possible resonance of the D–C and C≡N vibrations. We have in fact: $\nu_1 = 1921$ cm^{-1}, $q_1 = 1.13$, and $q_2 = 1$. "Mixing" of the vibrations takes place. This case of resonance and in general change in the mode of the vibrations is found very frequently in deuteration, so that, as already noted, deuteration is often accompanied not only by displacement of many absorption bands in the spectrum but also by an extremely sharp change in their intensities. This may even introduce difficulties in the interpretation of the bands. A good example of this is provided by the acetonitrile molecule[44]. Its spectrum shows vibrations with frequencies of 919 cm^{-1} and 1059 cm^{-1}, which may be interpreted as the stretching vibration of the C–C bond and external bending vibrations of the HCC angles. It might seem that this interpretation can be readily verified by deuteration. When this is done we obtain two frequencies at 850 cm^{-1} and 833 cm^{-1}, that is, both of the controversial bands are displaced by a considerable amount. This is again due to resonance of the vibrations.

To summarise, we can reach a number of conclusions regarding the possibility of existence of vibrations characteristic of a given group. These conclusions are qualitative in character, but they may help, in a large number of instances, to achieve rapid orientation in a spectrum and evaluation of various phenomena, and also to select the analytical absorption bands necessary for solving appropriate specific problems. They can of course be used only to explain sufficiently marked effects.

1. If the atoms of the first group, shared with another part of the molecule, are much heavier than all the other atoms of this group, we should observe vibrations which are characteristic with respect to frequency and with respect to mode for the given group. The position of the band in the spectrum and its intensity (if the group is additive and if certain other conditions are satisfied)[33] will be determined only by the parameters of this group. When these conditions are satisfied in a series of molecules we shall observe absorption bands whose frequency and intensity are preserved. With substitution of any groups in the molecule, the displacements of the bands of the group being studied and the changes in their intensity will be associated with breakdown of its structure.

2. A vibration will also be characteristic with respect to frequency and with respect to mode when in a given normal vibration the set of atoms shared with the remainder of the molecule does not undergo displacement or when this displacement takes place perpendicular to the displacements of these atoms for all normal vibrations of the remainder of the molecule. The frequency and mode of this vibration is again determined chiefly by the properties of the given group, but they will now be more sensitive to the environment, since replacement of atoms outside the group may lead to breakdown of the above condition that the movements of the common atoms in the normal vibrations of the first and second groups be at right angles to one another.

3. If any of the normal frequencies of the selected group and one of the normal vibrations of the remainder of the molecule coincide and the common atoms in these vibrations do not move in mutually perpendicular directions, resonance between the vibrations of these two groups is possible. We then obtain two normal vibrations of the entire molecule, whose frequencies and modes will not coincide with the frequencies and modes of the component vibrations, that is, the vibration will not be characteristic with respect to frequency and mode, in particular for the first group. The position and intensity of the corresponding band in the spectrum will be determined by the properties of the entire molecule and will change with substitution outside the group being studied. As already noted, the various skeletal vibrations of organic molecules are extremely common examples of such vibrations.

4. If the frequencies of the normal vibrations of a given group are greater than the frequencies of the normal vibrations of the adjoining part of molecule and if the common atoms are mobile in the vibrations, we may observe vibrations which are characteristic with respect to frequency for the group being examined but which are not characteristic with respect to mode. The position of the corresponding bands in the IRS or of lines in the RS will be determined by the properties of this group, and their intensities will depend on the properties of the environment (they will sometimes even be determined entirely by the properties of the environment[33]). With substitution outside the group being examined, the frequencies of its vibrations may remain unchanged, but the intensities must alter. An example of such vibrations is provided by the previously mentioned stretching vibrations of the C≡N bond in the molecules of acetonitrile and trichloroacetonitrile. The frequencies of the C≡N vibrations in these molecules are extremely close (2267 cm^{-1} and 2256 cm^{-1} respectively), but the intensities of the absorption bands differ appreciably.

5. If the frequencies of the normal vibrations of the group being considered are lower than the frequencies of the normal vibrations of the surrounding groups, vibrations may be produced which are characteristic with respect to mode for the given group but which are not characteristic with respect to frequency. As an example we can take the bending vibrations of the C–C≡N group in the CH_3CN and CCl_3CN molecules. These vibrations show an appreciable difference in frequency (380 cm^{-1} and 160 cm^{-1} respectively) but have almost identical modes[44,45].

All our discussion has concerned the instance where the groups are additive, that is, where there is no mutual electronic influence. We have seen that, even with this condition, it is only as a result of purely mechanical factors that the absorption bands or lines observed in the IRS can undergo appreciable displacement and change in intensity. For real molecules this treatment is often too approximate, and the displacements of the absorption bands observed in practice for various types of substitution result from a large number of factors.

In recent years a large number of papers have given correlations, for many functional groups, between the vibration frequencies (and in a number of instances, the intensities) and the electronegativities of the substituents, the Hammett constant σ, the Taft constant, etc. The search for various types of correlation can only be welcomed, but it must be remembered that, as shown by the above discussion, the reduction of the large number of factors determining the value of the vibration frequencies, even of the characteristic vibrations for an individual group, to a single factor cannot in general be justified. In particular, such correlations are meaningful only when the influence of kinematics is taken into account or is known to be small. Unfortunately, this last feature is not always recognised, so that in a number of instances the relationships obtained have no physical significance.

The chief requirement for the correct utilisation of spectroscopic data is an estimate (as far as possible quantitative) of the influence of various parameters on the position and intensity of the frequencies. This is tedious but it is the only way. A basis for such studies may be provided by the existing theory of the vibrations of polyatomic molecules; despite a number of inadequacies, this theory is quite capable of solving a large number of very important general and specialised problems.

The simplest is the determination, on the basis of the assumed symmetry of the molecule, of the number of fundamental vibrations which will be shown in the infrared and Raman spectra. Comparison of the calculated total number of vibrational frequencies active in a given spectrum, or of only that fraction of the vibrations which should be observed in a narrow range of the spectrum, with the experimentally-observed number of frequencies often makes it possible to establish unambiguously the symmetry of the molecule being studied. This method has for long been widely applied in the study of the structure of molecules, particularly in the gaseous phase. For example, the absence from the infrared spectrum of frequencies observed in the Raman spectrum, and vice versa (mutual exclusion) indicates unambiguously the presence of a centre of symmetry. In particular, the use of the mutual exclusion rule often makes it possible to identify reliably the structure of *cis*- and *trans*-derivatives of ethylene and diene compounds with identical substituents.

By solving the equation for the vibrations for the example where a set of force constants is known even provisionally, it is possible to calculate all the vibration frequencies of the molecule. The importance of this even approximate calculation is that it makes it possible to find the frequencies of vibrations which are not revealed either in the absorption spectrum or in the Raman spectrum. Moreover, not all the frequencies of the vibrations can be determined experimentally because of the low intensity of the corresponding lines and bands or because of the absence of suitable instruments (for example, for measurement of frequencies in the infrared spectrum in the range below 400 cm^{-1}). A molecule often has a number of identical frequencies (degeneracy with respect to symmetry or accidental degeneracy). It is impossible to detect this effect experimentally. A knowledge of the complete vibrational spectrum is absolutely necessary, for example, for calculating the thermodynamic functions of a molecule.

We can also find the amplitudes of the displacements of atoms from their equilibrium positions during vibrations or the amplitudes of the changes in the equilibrium geometric parameters of the molecule, that is, the mode of the vibration. The fundamental importance of calculations of this type is obvious, since they provide a basis for the interpretation of spectra. Calculation methods make it possible to determine sufficiently accurately which groups are producing the vibrations responsible for the appearance of various frequencies in the spectra. It must be stated directly that all present-day interpretation of spectroscopic data is based to a certain extent on the appropriate calculations.

There are many papers devoted to the calculation of the frequencies and modes and to determination of the force constants. Work by Soviet authors has some advantages over other work. In the first place, all the work has been carried out in a single system of coordinates by a single procedure for complete classes of compounds, and this has made it possible to obtain data which are comparable for different molecules and also to create a single set of force constants, and in the second place the authors have tried to select a potential function in general form with allowance for all possible interactions. A list of molecules for which theoretical studies have been carried out in the USSR is given in the Appendix (p. 227).

The proportion of the total number of spectroscopic studies devoted to calculation is quite insufficient. This is particularly true of the spectra of inorganic compounds, where it is difficult to make extensive use of existing

methods of calculation, for purely objective reasons (the impossibility of using for the calculations the spectra of isotopically-substituted molecules and the absence of homologous series).

Another noteworthy feature is that the methods of calculating the frequencies and modes of vibrations are as yet used only very rarely to solve various problems of molecular structure. The great majority of calculations which have been carried out, aimed at interpreting the observed spectra, are based on a molecular structure which is already known. This approach was unavoidable until a basic set of force constants for polyatomic molecules had been developed. It is now desirable, however, that these methods should be widely introduced into spectroscopic laboratory practice, particularly since the use of fast computers makes it possible to test many models without great effort.

In particular, computer methods are indispensible in spectroscopic studies aimed at investigating the influence of various types of substitution, breakdown in the geometric structure, etc. As shown above, here the observed changes in the frequencies in the spectra may be related to a change in the force field of the molecule or to a change in the masses or geometric parameters.

A characteristic example in this connection is that of the stretching vibrations of the C≡N bond in the HCN, CH_3CN, CCl_3CN, and $(CN)_2$ molecules. The frequencies and intensities of the absorption bands due to the C≡N vibrations in these molecules differ appreciably (for example, the frequencies have the values 2089, 2267, 2256, and 2329 and 2149 cm^{-1} respectively). At first sight the experimental data indicate a significant difference in the properties of the C≡N bonds in these compounds. This explanation has in fact been put forward [54], but theoretical analysis [39,44,45] has shown that the force and electro-optical parameters of the C≡N bond remain almost unchanged in the above series of molecules and that the appreciable changes in the corresponding frequencies and intensities of the absorption bands are due chiefly to the influence of kinematic factors. Another example is provided by the molecules of *gem*-dinitroethane and trinitromethane, whose spectra show a marked displacement of the frequencies of the so-called symmetrical stretching vibrations of NO_2[1402 cm^{-1} and 1343 cm^{-1} for $C_2H_4(NO_2)_2$ and 1371 cm^{-1} and 1305 cm^{-1} for $HC(NO_2)_3$]. Appropriate calculation [55] showed that this displacement can also be attributed entirely to kinematic factors. Allowance can readily be made for these effects using calculation methods. This, of course, is not the only value of calculation methods. Often it is possible to obtain extremely valuable information on molecular structure. For example, theoretical analysis of the frequencies of the normal vibrations and the intensities of the absorption bands in the IRS of the molecules of butadiene, hexatriene, and other linear polyenes with longer chains [56] has made it possible to study the important problem of double-bond conjugation. In particular, it was shown that in the ground electronic state of the molecules with alternating double and single bonds there is appreciable bond interaction due to partial displacement of the π-electron density from the double bonds to the single bonds. No tendency towards further levelling of the bond orders takes place with increase in the length of the polyene chain. It was also shown that in conjugated molecules in the stationary state the intramolecular mutual influence of substituents is rapidly extinguished with increase in the length of the conjugated chain, despite the π-electron delocalisation.

In the study of characteristic vibrations, calculation methods help to establish the maximal group of atoms whose vibrations will exhibit the property of characteristic nature of a given type. In particular, theoretical study of the characteristic nature of the vibrations has shown that the reproducebility of various frequencies in a spectrum does not always indicate that the vibration is localised. This must be taken into account in experimental practice. A rigorous solution to the problem of the characteristic nature of vibrations of given functional groups can be obtained only on the basis of appropriate theoretical analysis. In this, in order to determine the smallest group of atoms responsible for a given characteristic frequency, it is sufficient to know merely the orders of magnitude of the force constants. By then calculating the sensitivity of this frequency to changes in various quantities characterising the molecule as a mechanical system, it is possible to investigate the influence of the quantities used in the calculation and sometimes the nature of the changes in this frequency on going to other molecules.

The calculation of the sensitivity of the characteristic frequencies to change in various quantities for three-dimensional molecular configurations can be used successfully to identify rotational isomers of certain molecules from the vibrational spectra.

Calculation methods should undoubtedly play an important part in the study of intermolecular interactions and molecular association, where the interpretation of the observed changes in the spectra often presents an extremely complex problem.

The importance of theoretical methods in vibrational spectroscopy will undoubtedly increase greatly in the near future.

4. FORCE CONSTANTS OF POLYATOMIC MOLECULES AND THEIR DETERMINATION

The most important problem in vibrational spectroscopy is to determine the coefficients K_{ij} in the expression for the potential energy. A knowledge of these quantities is necessary for carrying out numerical calculations on the vibrational spectra of polyatomic molecules. For the determination of the coefficients τ_{ij} in the expression for the kinetic energy it is sufficient to have information on the geometric structure of the molecule and the distribution of the masses, obtained independtly using other methods for studying molecules, but in the present state of the theory the force constants can in practice be determined only on the basis of experimentally measured frequencies of vibrations. This type of problem is described as the inverse spectroscopic problem and is specific for the theory of molecular vibrations.

In the study of polyatomic molecules a characteristic closed logical circle has developed: numerical calculations on molecular spectra require the introduction of quantities which are themselves found from these spectra. A way out of this situation is possible only because it has been found that some force constants can be put equal to zero and, moreover, that the force constants corresponding to individual additive groups remain unchanged within certain limits in a series of molecules containing these groups. This makes it possible to use the numerical values of the force constants, found from some molecules, for calculations on the spectra of related compounds. A consequence of this is the restriction of the possible

application of the theory chiefly to calculations on organic compounds.

When force constants are used for numerical calculations of spectra and for reaching conclusions regarding the structure of a molecule and the nature of chemical bonds it is necessary to understand clearly the physical significance of the quantities and their complex nature. Force constants depend not only on the properties of interatomic forced but also on the method adopted for describing the vibrations (the system of coordinates).[52] The same model of interatomic forces will be expressed in different ways in different systems of coordinates. In the general case when interactions take place between all the atoms, the force constants will not be characterised merely by the individual structural elements but will depend on the properties of the whole molecule.

It may be said that the force constants are representations of the elastic properties of the interatomic forces in the system of coordinates selected. Thus the choice of a working system of coordinates should correspond to the model of interatomic forces adopted. A criterion of the correspondence between the model and the system of coordinates is the smallness of the elements K_{ij} $(i \neq j)$ compared with K_{ii} $(K_{ii} \gg K_{ij})$. This requirement in turn arises because here the vibrations of the molecules can be described by the minimum number of empirical parameters (force constants); this is fundamental, since, as already noted, they are determined on the basis of experimental data on the frequencies of vibrations.

Let us examine briefly various models of interatomic forces.

Central-forces model. The central-forces model involves the assumption that the forces of interaction between all pairs of atoms depend only on the distance between the atoms and act along the straight line joining them. This model has not justified itself and is now almost never used. The inadequate nature of the model is particularly clearly seen for the bending vibrations of linear molecules. The frequencies of these vibrations should then be equal to zero, but this contradicts experimental results.

Valency-forces model. The valency-forces model is free from the above difficulties associated with the central-forces approximation for linear molecules and is closer to chemical ideas regarding interatomic forces. It is thus not accidental that the valency-forces model gives much better results in the great majority of cases. This model has formed the basis for all fundamental calculations on the spectra of polyatomic molecules in the Soviet Union and for the creation of a set of force constants suitable for the theoretical analysis of a very large number of compounds. In this model we consider the forces related to the change in the bond lengths, valency angles, and other elements forming the natural vibrational coordinates. In the expression for the potential energy it is usual to introduce, in addition to the elements K_{ii}, a series of small elements K_{ij}, that is, to use the valency-forces model not in the pure form but with slight corrections. The chief advantage of this approximation is the possibility of examining the individual structural elements of the molecule, which may be expected to be sufficiently closed units, and thus to reduce the problem of the force field of the molecule to the problem of studying the properties of its individual elements. The following rules have been empirically established for selecting the force constants in this model in the system of coordinates formed by the changes in the bond lengths, valency angles, etc.

1. The largest force constants are encountered for the bond stretching coordinates; the force constants for the other coordinates are smaller by approximately one order of magnitude.

2. The constants K_{ij} $(i \neq j)$ usually must be taken into account only for coordinates having common atoms (for angular coordinates, a common bond). This rule applies usually, but there may be exceptions. It is difficult to verify it accurately, since the attempt to find the values of force constants from experimental data is usually made (see below) on the assumption that this rule applies.

Unfortunately, these rules do not eliminate the arbitrariness in the choice of force constants, although they limit it to some extent. This intermediate character is still appreciable, and this is the weakest aspect of the present-day theory of the vibrational spectra of polyatomic molecules. Thus the actual calculations on the spectra in many instances are model calculations and this must be taken into account when theoretical methods are used to solve a given spectrochemical problem.

Analysis of the experimentally-obtained expressions for the potential energy shows that the appearance of the elements K_{ij} $(i \neq j)$ often leads to a change in the corresponding elements K_{ii}, that is, a definite functional relationship exists between K_{ij} and K_{ii}. This relationship is not examined in the valency-forces approximation. An attempt to take account of this functional relationship is made in the approximation of Urey and Bradley, which is based on an approximation of the valency-forces type but which includes several additional terms corresponding to central forces between atoms which are not joined by valency bonds. With the inclusion of the extra coordinates thus produced in the force-constants matrix, there appear coefficients for the interaction of the bonds with one another and the angle, with a simultaneous change in their force constants. Thus the introduction of the force constant for the interaction of the pair of terminal atoms in addition to the angular elasticity in the same valency angle to some extent makes it possible to take account of the above relationship between the different force constants by means of a single parameter. In the method of Urey and Bradley, however, linear terms appear in the expression for the potential energy of the vibrations. In addition to a number of contradictions which then arise, this feature leads to complication of the mathematical formalism. The Urey–Bradley approximation has not found extensive application in the Soviet Union. In practice it has no advantages over the valency forces approximation (with the addition of certain non-diagonal elements) and for many molecules it is not satisfactory and requires refinement.

In practical calculations of the frequencies and modes of molecular vibrations, use is made of the values of the force constants of bonds and groups of atoms, on which a large volume of material has accumulated. In the USSR all calculations are carried out according to a single scheme, and this has made it possible to obtain a single set of force constants. The actual force constants are found from experimental data on frequencies of vibrations. Their number, even if we neglect many non-diagonal elements, is generally found to be greater than the number of experimentally observed frequencies for a single mole-

cule. Thus the determination of the force constants of a molecule entirely from its spectrum, that is, a rigorous solution of the inverse spectroscopic problem, its impossible. It becomes possible, however, if we impose a number of additional conditions, and also make use of the spectra of isotopically substituted molecules (for which it may be assumed with sufficient accuracy that K_{ij} do not change) and the spectra of molecules of a homologous series. Considerable work has been done in this direction and an extensive set of force constants has been developed, making it possible to carry out model calculations of the frequencies and modes of vibrations, and to solve a variety of problems associated with the estimation of the characteristic nature of vibrations, the influence of substitution, etc., for almost any class of organic compound.

The material at present available on force constants is scattered in a large number of original papers. The appendix to the present review (p. 227) gives the values of the force constants characterising the elastic properties of the bonds and valency angles in some of the most important groups of organic molecules. Table 3 gives the most reliable data obtained by sufficiently correct solution of the vibrational problem. Nevertheless it should be noted that the numerical values of some of the force constants given in Table 3 must be regarded as provisional, particularly in the study of the vibrations of other molecules§.

In view of its unique importance, let us consider the problem of the determination of the force constants on the basis of experimentally-measured frequencies. Let us make use of the property of the quasidiagonality of the force-constants matrix, that is, the property $K_{ii} \gg K_{ij}$, which can be taken as proved, since there are no exceptions in all the molecules which have been studied up to the present. We shall restrict ourselves initially to the simplest case in which the values of the squares of the frequencies are close to the values of the diagonal elements. This is often encountered in practice. We shall moreover assume that the assignment of the frequencies is already known. Let us assume that the force-constants matrix is diagonal, that is that all $K_{ij} = 0$ $(i \neq j)$. The approximate values of the diagonal force constants are then found from the formulae

$$K_{ii}^{(0)} = \frac{\lambda_{i\,\mathrm{exp}}}{\tau_{ii}},$$

where $\lambda_{i\,\mathrm{exp}}$ represents the experimental values of the squares of the frequencies of the vibrations. The set of values of $K_{ii}^{(0)}$ for all ith vibrational coordinates forms the zeroth approximation of the force-constants matrix¶. The values of $\lambda_i^{(1)}$ for variation of the force constants by the quantity ΔK_{ij} can obviously be written in the form

$$\lambda_i^{(1)} = \lambda_i^{(0)} + \sum_{i,j} \left(\frac{\partial \lambda_i}{K_{ij}}\right)_0 \Delta K_{ij}, \qquad (4)$$

where $\lambda_i^{(0)}$ represents the eigenvalues of the secular equation with the force matrix in the zeroth approximation. Here it is necessary to impose certain restrictions on the values of ΔK_{ij}; the values of $\lambda_i^{(1)}$ calculated from the approximate formulae of type (4) should agree within the limits of permissible error with the values calculated by exact solution of the secular equation. The derivatives $\left(\frac{\partial \lambda_i}{\partial K_{ij}}\right)_0$ of λ_i with respect to the force constants for a given force-constants matrix are readily calculated[52]. The summation is carried out with respect to all varying force constants, which are regarded as independent. In order to simplify the subsequent notation we shall replace the double subscript for the force constants by a single subscript, arranging all the force constants in a definite order.

By varying ΔK_j within the above range, we can obtain different values of $\lambda_i^{(1)}$. We shall write $\lambda_i^{(1)} = \lambda_{i\,\mathrm{exp}} + \alpha_i$, where α_i represents certain fractions. We then have

$$\alpha_i = \lambda_i^{(0)} - \lambda_{i\,\mathrm{exp}} + \sum_j \left(\frac{\partial \lambda_i}{\partial K_j}\right)_0 \Delta K_j.$$

The problem of constructing a force-constants matrix from the given set of squares of the normal vibration frequencies will be solved (where solution is possible with the restrictions noted above) if we can select values of ΔK_j such that all $\alpha_i = 0$. This is equivalent to finding a solution for a system, of nth order, of non-homogeneous linear equations with respect to the unknowns ΔK_j:

$$\lambda_i^{(0)} - \lambda_{i\,\mathrm{exp}} + \sum_j \left(\frac{\partial \lambda_i}{\partial K_j}\right)_0 \Delta K_j = 0. \qquad (5)$$

This system will have a single solution if the number of variable force constants is equal to the number of experimentally observed frequencies, and an infinite number of solutions if the number of variable force constants is greater than the number of observed frequencies. The maximal number of unknown force constants for a non-symmetrical molecule is equal to $\frac{(3N-6)(3N-5)}{2}$, where N is the number of atoms in the molecule, and is hence much greater than the number of normal vibrations of the molecule $(3N - 6)$, that is, the number of $\lambda_{i\,\mathrm{exp}}$ measurable in principle for a single molecule. Thus the inverse spectroscopic problem in the general case has no single solution. It becomes soluble only when some of the force constants are assumed to be equal to zero (an approximate model for the force field of the molecule is selected) or are obtained by analogy with related compounds. In order to increase the number of observable frequencies it is possible to use isotopically-substituted molecules in addition to the main molecule. The system of equations including various isotopically-substituted molecules will be consistent since it may be assumed with a reasonable degree of approximation that the coefficients K_j remain unchanged in a series of isotopically-substituted molecules. It should be noted, however, that not all the equations related to various isotopically-substituted molecules will be linearly independent. This is due to the existence of definite correlations between λ_i for different isotopically-substituted compounds.

Despite the fact that this problem has already been discussed[145], the problem of the a priori choice of independent equations for isotopically-substituted molecules in specific instances cannot be regarded as solved. It is not clear, moreover, which force constants can be determined with greatest reliability from the available system of equations. However, the use of a set of vibration frequencies for isotopic molecules is always necessary for averaging the calculated force constants. Essentially different equations are obtained with a marked change in the masses of the atoms. Thus in practice use is made chiefly of the replacement of H atoms by D atoms and of vibrations in which these atoms play the main part.

§ The data are taken only from Soviet literature.

¶ In many instances it is convenient to use as the zeroth approximation of the force-constants matrix the product of the matrix which is the reciprocal of the kinematic-coefficients matrix from the right and the diagonal matrix of the squares of the experimental vibration frequencies.

If, however, the number of observed frequencies of the main molecule plus its isotopically-substituted derivatives is still less than the number of variable elements in the force-constants matrix, it is obviously always possible to select a set of elements ΔK_j, which will completely satisfy experiment but which will not be the only set. It is, of course, possible to impose on the variation of ΔK_j the condition that they lie within a given section, but then the set of values of ΔK_j and hence the final force-constants matrix will not be single ones, and at present there is no criterion for selecting the most reliable from the various sets, unless certain assumptions are made regarding the magnitudes of some of the force constants.

Let us next assume that the number of $\lambda_{i\,\mathrm{exp}}$ with the use of isotopic molecules becomes greater than the number of unknown elements K_j. The number of equations of type (5) for $\alpha_i = 0$ will then be greater than the number of unknowns and from these it is possible to separate various groups of equations which, generally speaking, will give various sets of ΔK_j, that is, the problem again to some extent loses its definite character. In such instances use is made of the method of least squares proposed by Gauss, and the problem is formulated as follows: we have to select values of ΔK_j which will satisfy the extra system of equations (5) with the highest degree of probability. It is possible to satisfy all the equations only with a certain error $\Delta\alpha_i$, that is, for the values of ΔK_j being sought we have:

$$\Delta\alpha_i = \lambda_i^{(0)} - \lambda_{i\ \mathrm{exp}} + \sum_j \left(\frac{\partial\lambda_i}{\partial K_j}\right)_0 \Delta K_j \text{ (for all values of } i).$$

These values will be the most probable values if $\sum_i (\Delta\alpha_i)^2$ has its smallest value, which is possible for values of ΔK_j satisfying the conditions $\frac{\partial}{\partial K_j}\left[\sum_i (\Delta\alpha_i)^2\right] = 0$, which lead to a system of non-homogeneous linear equations whose order is equal to the number of unknowns ΔK_j. By solving this system of equations we find a single set of ΔK_j and hence the force-constants matrix.

The method of least squares can also be extended to where the initial approximation for the force-constants matrix is not sufficiently close to the true one for linear extrapolation to be satisfactory [146].

In the solution of the problem by the method of least squares according to the scheme described it is necessary to make allowance for the following important features. Firstly, considerable arbitrariness may be introduced in the formulation of the differences $\lambda_i^{(0)} - \lambda_{i\,\mathrm{exp}}$ (particularly if $\lambda_i^{(0)}$ differ greatly from $\lambda_{i\,\mathrm{exp}}$). As a result, different solutions of the inverse problem will be obtained for different combinations of $\lambda_i^{(0)}$ and $\lambda_{i\,\mathrm{exp}}$. It can be shown, for example, that the number of solutions of the inverse problem for a single molecule with $3N - 6$ force constants to be determined, for a given set of $3N - 6$ squares of experimental frequencies, is equal to $(3N - 6)!$ [147]. It can also be shown that not all of these solutions satisfy isotopically substituted molecules; when the frequencies of the vibrations of certain isotopically substituted derivatives are used in addition to the frequencies of the single molecule, this makes it possible to decrease the arbitrariness in the choice of the single solution. At present, however, we do not have at our disposal methods which in the solution of the problem according to the scheme described would make it possible, for all isotopically substituted molecules, to select in advance combinations of $\lambda_i^{(0)}$ and $\lambda_{i\,\mathrm{exp}}$ in the differences between the calculated and experimental squares of the frequencies such that the above arbitrariness would be decreased to the maximal extent or eliminated. This becomes possible only when the selection of the zeroth approximation of the force-constants matrix is so successful that the frequencies of the vibrations calculated on this basis are close to the experimental values for all isotopic molecules and the interpretation of the frequencies is known.

It should also be noted that when the method of least squares is used to solve the inverse spectroscopic problem it is strictly speaking necessary to take account of the statistical weights of the squares of the experimental frequencies and this introduces difficulties associated with the fact that it is not always clear which physical principles should form the basis of the selection of the values of these weights.

It is also important to understand that the use of the simple method of least squares is in general justified only when the quantities obey the Gaussian distribution and the number of equations used is much greater than the number of force constants to be determined. These two conditions are comparatively rarely satisfied in practice, however.

An undoubted advantage of the method is the simplicity of the mathematical formalism, and this is the main reason why this method has recently found extensive application.

There is another possible method for solving the inverse problem of determining the values of the force constants of a molecule from the given frequencies of its vibrations; this method is convenient chiefly in that it does not require the formulation of differences between experimental and calculated squares of the frequencies, where, as already noted, a certain arbitrariness may be introduced. Here it is most natural to use as experimental points not the numbers $\lambda_{i\,\mathrm{exp}}$, but their combinations. In particular, we can obtain a non-linear system of equations for the values of K_j being sought; these are used since the equation for determining λ_i, with the usual form:

$$\mathrm{Det}\begin{pmatrix} (d_{11} - \lambda); d_{12}; \ldots; d_{1n} \\ \ldots\ldots\ldots\ldots \\ d_{n1}; d_{n2}; \ldots; (d_{nn} - \lambda) \end{pmatrix} = 0,$$

is equivalent to the equation

$$\lambda^n + p_1\lambda^{n-1} + p_2\lambda^{n-2} + \ldots + p_n = 0,$$

where p_1 is a function of the first powers of K_{ij}, p_2 a function of the squares and paired products of K_{ij}, etc. The coefficients p_i are in turn related to λ_i by the relationships:

$$p_i = (-1)^i \sum_{1 \leqslant n_1 < n_2 \ldots < n_i < n} \lambda_{n1}\lambda_{n2}\lambda_{n3} \ldots \lambda_{ni}.$$

Thus the problem of determining K_{ij} can be reduced to the solution of the non-linear system of equations:

$$p_i = (-1)^i \Sigma\lambda_{n_1} \ldots \lambda_{ni}.$$

In practice it is more convenient to use not this system of equations but the system converted into the form $p_i' = \sum_n \frac{1}{i}\lambda_n^i$. This can be done by taking account of the fact that the quantities $\sum_n \lambda_n^i$ and p_i are related to one another by simple relationships. This last system of equations can be solved if even only the orders of magnitude of the force constants are known and it is possible to construct

in approximate force-constants matrix; it is significant that it may differ from the true one to a much greater extent than is possible when the method of least squares is used. Approximate matrices of this type can almost always be constructed if account is taken of the fact that usually the interpretation of the spectra of polyatomic molecules begins with the simplest molecules of the selected homologous series, which generally exhibit fairly high symmetry, so that when symmetry coordinates are used and the stretching and bending vibrations are separated approximately, we obtain secular equations and equations of extremely low degrees for determining force constants. As a result of work by a number of authors there has now been created such an extensive set of force constants for individual atomic groups and molecules that a rough approximation of the force-constants matrix can be constructed for almost any organic molecule. We can thus start from a certain approximation for the force-constants matrix. It is then possible, for the solution of the system of equations

$$p_i' = \sum_n \frac{1}{l} \lambda_n^i \text{ exp (for all values of } i), \qquad (6)$$

to use the so-called method of steepest descents[148]. The method of solution can be demonstrated by the following illustrative geometric method. Let us assume that we have a certain surface Φ (1), inside which we have a point corresponding to the solution of the system. The initial approximation is given by a certain point on the surface. We draw a perpendicular to the surface and move along it. The function Φ, which has the significance of the "distance" of the moving point from the solution of the system (the point *O*), will then decrease until it reaches point 2, the closest point on the perpendicular to point *O*, after which it will begin to increase. We then take point 2 for the start of a new process and construct a new perpendicular to the surface, passing through this new point [Φ (2)]. By moving along this perpendicular, we find a point 3 which will now lie much closer to the solution being sought, etc.

A disadvantage of the method described is that the system of equations being considered, in the range of force constants in which we are interested, may have more than one solution. In order then to find all the solutions or to satisfy ourselves that the solution obtained is the single solution, we must select different initial points on the surface $\Phi(k)$, separated as far as possible from one another. A choice of solution corresponding to the true set of force constants (the set having physical significance) can then be made only be studying isotopically substituted molecules and homologous series.

The methods described are extremely tedious and their use requires the extensive application of electronic computers. In practice, in the great majority of investigations, the force constants are found by selecting (varying) them within a definite range until satisfactory agreement is obtained between λ_i and the experimental values $\lambda_{i\,\text{exp}}$ (method of trial and error). To facilitate the variations, a set of partial derivatives of λ_i with respect to the force constants is usually also calculated. Unfortunately, this type of approach involves a considerable contribution from factors which are difficult to take into account, such as the experience and intuition of the author.

Thus the solution of the inverse spectroscopic problem involves appreciable difficulties. In the great majority of instances it is, in general, impossible to determine the force-constants matrix without making assumptions regarding the magnitude of some of its elements. Such approximations, as already noted, include the assumptions that the non-diagonal elements are small compared with the diagonal elements, that the force constants of the interaction of coordinates at a distance from one another are equal to zero, and that the force constants of the individual atomic groups in a series of similar compounds remain unchanged. These assumptions are based on a definite view of the nature of chemical forces in a molecule and the existence of characteristic vibrations.

With certain assumptions, these methods can also be extended to the study of homologous series. In doing so, some of the force constants are always put equal to zero, and some are assumed to be unchanged at least within a range of two to three adjacent molecules in a series. It is on this basis that an appreciable set of force constants has been created for molecules and functional groups, shown to be completely satisfactory for many calculations on specific compounds. It should be remembered, however, that because of the limitations noted above, the force constants are obtained with a certain error, which may be particularly large in the non-diagonal elements. A major shortcoming is the impossibility at present of making an objective estimate of this error. At the present stage, however, this feature presents almost no restriction to the study of the frequencies and modes of vibrations of polyatomic molecules, but it must be taken into account in all attempts to compare the values of force constants and other molecular parameters. It is for this reason that in a number of instances little trust can be put in the comparison of force constants and interatomic distances, bond energies, etc., frequently encountered in the literature.

The most reliable set of force constants is that which describes sufficiently accurately the frequencies of vibrations of a given molecule and its available isotopically substituted derivatives, and is preserved in the closest members of a homologous series.

---o0o---

The development of studies of polyatomic molecules by the methods of vibrational spectroscopy are characterised primarily by the ever-increasing use of theoretical analysis to solve applied problems. The reason for this is to be found in the constant increase in the complexity of the materials and problems being studied and also in the gradual recognition by experimental workers of the fact that in principle it is only on the basis of theoretical analysis that it is possible to distinguish more or less confidently the various factors leading to the phenomena observed in spectra and to reach sufficiently well-founded conclusions regarding intramolecular interactions. The choice of appropriate spectroscopic characteristics for the solution of applied problems should also be based on theoretical analysis. Thus modern spectrochemical study must consist of a close combination of experiment and calculation of the spectrum for a model of the molecule being studied.

The need arises, however, for extensive calculations, so that theoretical methods cannot be introduced into practical spectrochemical studies until the entire calculation side has passed completely to electronic computers and is in fact reduced to the form of the input to be supplied

to the computer. Considerable progress has been made in this direction in recent years. Programmes have appeared which not only solve the equations for the vibrations but also formulate them[20] and also carry out a number of other operations. The situation is much less satisfactory in the development of programmes for solving the inverse spectroscopic problem and for the automatic interpretation of the spectra for homologous series. The existing programmes are far from perfect and their possibilities are extremely limited.

The extensive use of electronic computers in spectrochemical practice makes it possible, with very little expenditure of effort (for example, the preparation of material for the calculation for a molecule containing 9–10 atoms according to a programme developed by one of the present authors[20] occupies a total of 2–2½ h) and in a short time to carry out a large number of calculations for the selected molecules in order to establish the characteristic nature of the vibrations, the reasons for the displacements of the frequencies as a result of given substitutions, etc. It has also become possible to use theoretical methods for the analysis of a variety of regular features and to assign frequencies in those compounds for which the system of force constants is as yet insufficiently developed.

At the same time another extremely important problem is being solved; it is becoming possible for proper numerical calculations for the spectra of molecules to be carried out by persons who are not completely equipped with the mathematical apparatus of the theory. The latter is not necessary using the system of programmes developed, paradoxical as it may seem at first glance. Thus it is possible to confound the great principle: "No one can comprehend the infinite!" and to bring modern theoretical methods to a wide range of spectroscopists without imposing upon them the great additional task of studying a number of new disciplines.

The calculation methods of the theory, based on electronic computers, give to research workers a powerful tool for the study of spectra, but it is necessary to understand the use of this tool. The chief difficulty in the practical application of modern theoretical methods, after the transfer of all the calculation side to electronic computers, lies in the choice of problem in which these methods can be applied with the greatest efficiency.

The study of vibrational spectra has become one of the fundamental means of investigating the structure and properties of polyatomic molecules. It is difficult even to list approximately the vast range of problems which are solved by the methods of vibrational spectroscopy. These methods are far from having exhausted their possibilities. There is no doubt that in the near future we shall witness considerable progress in this branch of science. This requires primarily the extensive introduction of theoretical methods which have already been developed and which until recently were the acquisition of a narrow group of specialists, into everyday practice in spectroscopic laboratories. This will undoubtedly result in a sharp raising of the level of spectrochemical studies. This process is already taking place, as indicated, in particular, by the continuously increasing proportion of papers dealing with calculations.

At the same time the next urgent problem concerns the further improvement of the theory itself and the development of new aspects of the theory. Unfortunately, it must be stated that this work is not proceeding rapidly enough at present.

5. APPENDIX

Table 2 lists the compounds whose vibrational spectra have been calculated as a result of work published in Soviet literature up to the middle of 1964. The formulae for isotopically substituted molecules whose spectra have been used to determine the set of force constants are given in parentheses after the name of the compound.

TABLE 2.

Methane (CH_4, CH_3D, CH_2D_2, CHD_3, CD_4)[14]; ethane (C_2H_6, C_2D_6)[14]; propane[14,57,58]; butane[57-59]; isobutane ($HC(CH_3)_3$, $DC(CH_3)_3$)[14,61]; 2,3-dimethylbutane[62]; pentane[60]; isopentane[14]; neopentane[14]; cyclopropane (C_3H_6, C_3D_6)[63]; methylcyclopropane[64]; 1,1-dimethylcyclopropane[64]; cyclobutane[65]; cyclopentane (C_5H_{10}, C_5D_{10})[66-69]; cyclohexane (C_6H_{12}, $C_6H_{11}D$, C_6D_{12})[70,71]; methylcyclohexane[72]; ethylcyclohexane[73]; *trans*-1,4-dimethylcyclohexane[71]; *cis*-1,3,5-trimethylcyclohexane[71]; halogeno-derivatives of methane[14,41]; chloro-derivatives of ethane[14]; methanol (CH_3OH, CH_3OD, CD_3OH, CD_3OD)[14]; methanethiol[14]; ethylene (C_2H_4, C_2H_3D, C_2HD_3, *asym*-$C_2H_2D_2$, *trans*-$C_2H_2D_2$, *cis*-$C_2H_2D_2$)[14,73,74]; propene (C_3H_6, C_3D_6)[75]; but-1-ene[75]; *cis*-but-2-ene[76]; *trans*-but-2-ene[76]; isobutene[77]; *cis*- and *trans*-isomers of ethylene[79,80]; 2,3-dimethylbut-2-ene[76]; penta-1,4-diene[78]; halogeno-derivatives of ethylene[81,82]; allene (C_3H_4, HDC_3H_2, $D_2C_3H_2$, C_3D_4)[83,85]; methylallene[85]; 3-methylbuta-1,2-diene[78]; cyclobutene (C_4H_6, C_4D_6)[84]; butadiene (C_4H_6, C_4D_6)[86,86]; acetylene (H_2C_2, HDC_2, D_2C_2)[39]; methyl vinyl ether[87]; methyl vinyl sulphide[88]; hydrogen cyanide (HCN, DCN)[89]; acetonitrile (CH_3CN, CD_3CN)[44]; mono-, di-, and tri-chloroacetonitriles[48]; cyanamide (H_2NCN, D_2NCN)[89]; nitromethane (CH_3NO_2, CD_3NO_2, $CH_3N^{18}O_2$)[90]; nitroethane[90]; *gem*-dinitroethane[88]; trinitromethane ($HC(NO_2)_3$, $DC(NO_2)_3$)[88]; silane (SiH_4, SiH_2D_2, $SiHD_3$, SiD_4)[91]; methylsilane (CH_3SiH_3, CH_3SiD_3)[92,93]; dimethylsilane[93]; trimethylsilane[92]; tetramethylsilane ($Si(CH_3)_4$, $Si(CD_3)_4$)[94]; halogenomethylsilanes[96-99]; disilane (Si_2H_6, Si_2D_6)[100]; chloromethylgermanes[101]; germanium tetraiodide[102]; benzene (C_6H_6, C_6H_5D, $C_6H_4D_2$, $C_6H_3D_3$, $C_6H_2D_4$, C_6D_6)[103-108]; toluene ($C_6H_5CH_3$, $C_6H_5CD_3$)[106-108]; ethylbenzene[109]; isopropylbenzene[110]; *o*-xylene[111,112]; *m*-xylene[113]; *p*-xylene[114]; 1,3-diethylbenzene[115]; mesitylene[116,117]; durene[116,117]; 1,2,3-trimethylbenzene[118]; biphenyl ($C_{12}H_{10}$, $C_{12}H_9D_4$, $C_{12}H_4D_6$, $C_{12}D_{10}$)[119-121]; naphthalene ($C_{10}H_8$, α-$C_{10}H_4D_4$, β-$C_{10}H_4D_4$, $C_{10}D_8$)[122-124]; pyridine (C_5H_5N, 4-C_5H_4DN, 2-C_5H_4DN, 3-C_5H_4DN, 2,6-$C_5H_3D_2N$, 3,5-$C_5H_3D_2N$, C_5D_5N)[125,126]; pyrazine[127]; *sym*-triazine ($C_3H_3N_3$, $C_3D_3N_3$)[127]; *sym*-tetrazine ($C_2H_2N_4$, C_2HDN_4, $C_2D_2N_4$)[127]; the cyclopentadienyl ring of ferrocene (C_5H_5, C_5D_5)[128]; the hydroperoxide group (C—O—OH)[129]; trimethyl phosphate[130]; trimethyl thiophosphate[130]; phosphorus oxide trichloride[131]; phosphorus ovide tribromide[131]; phosphorus sulphide trichloride[131]; phosphorus sulphide tribromide[131]; ammonia (NH_3, ND_3)[14]; methylamine (CH_3NH_2, CD_3NH_2, CH_3ND_2, CD_3ND_2)[132]; boron trifluoride–ammonia ($F_3B.NH_3$, $F_3B.NH_2D$, $F_3B.NHD_2$, $F_3B.ND_3$)[133]; the tetrahalides of C, Si, Ge, Ti, Sn, and Pb[134]; boric oxide ($^{10}B_2O_3$, $^{11}B_2O_3$, $^{10}B^{11}BO_3$)[135]; boron sulphide ($^{10}B_2S_3$, $^{11}B_2S_3$)[135]; SF_4[136]; SF_3Cl[137]; titanium tetrachloride[138]; silicates[139-141]; the UO_2^{2+} ion[142]; water (H_2O, D_2O, HTO, DTO, T_2O)[143]; hydrogen sulphide (H_2S, D_2S, HDS, DTS, HTS, T_2S)[143,144]; hydrogen selenide (H_2Se, HDSe, D_2Se, HTSe, DTSe, T_2Se)[143].

INTRODUCTION

Many compounds are known in which the number of chemical bonds exceeds the number of electron pairs: boron hydrides [1]; the dimers of the alkyl compounds of aluminium [2], beryllium [3], organolithium complexes [4], etc.[5,6]. Compounds of this type have become known as electron-deficient.

By use of the nuclear magnetic resonance (NMR) method information has been obtained about the structure of these compounds and also about the electron distribution and about its symmetry for certain nuclei. The most important results of the study of electron-deficient compounds by the NMR method are considered below.

Before discussing the NMR results some questions of the qualitative theory of electron-deficient bonds [1,5-7] are considered.

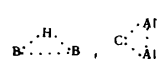
I. QUALITATIVE QUANTUM-MECHANICAL IDEAS ABOUT THE FORMATION OF ELECTRON-DEFICIENT BONDS

The presence of a metal atom with vacant orbitals on which the bond-establishing electrons can be promoted without a large expenditure of energy, and of an atom or group of atoms which do not possess unshared electron pairs are general for most electron-deficient compounds. The conditions for the formation of donor–acceptor bonds do not exist.

Compounds with electron-deficient bonds have been insufficiently studied, but it can be maintained that the principal features of the structures of these compounds are clear. Thus, the data on diamagnetic susceptibilities [2] suggest that the bonds cannot be "one-electron". Each of the bridge bonds has less energy than if it were "normal" and its length also differs from the "normal". Some examples from the compounds that have been most studied are given in Table 1.

The bridge bonds B...H, Be...C, and Al...C are longer than the corresponding terminal bonds. The latter have the same length as the "usual" bonds.

The experimental values for the metal–metal distances in these compounds are close to those for the M_2 molecules. Attempts were therefore made to explain the bonding in such complexes by the formation of "protonated double bonds" [2]. Next considerations were advanced in support of the formation of polycentric orbitals [13] of the type:



Apparently a short M–M distance is necessary for the formation of localised three-centre orbitals.

TABLE 1.

Structure of the compounds		Heats of formation of the complexes (Ref. 5), kcal	r_{M-M}, sum of covalent radii (Refs. 11 and 12), Å	r_{C-C}, sum of intermolecular radii, Å
	$r_{BB}=1.78$ Å[a] $r_{BH_K}=1.19$ Å $r_{BH_M}=1.34$ Å $\angle H_K BH_K=121.5°$ $\angle H_M BH_M=100°$	32	1.82	3.8
	$r_{Al-Al}=2.55$ Å[a] $r_{Al-C_K}=1.99$ Å $r_{Al-C_M}=2.24$ Å $\angle C_M AlC_M=70°$	20	2.86	3.8
	$r_{Be-C}=1.93$ Å $\angle Be-C-Be=66°$ $r_{Be-Be}=2.10$ Å	—	2.26	3.8

The C–C distance in complexes is usually close to the van der Waals distance and the C atoms can be considered as non-bonded from the point of view of valency.

A characteristic feature is that the M–C–M angle is less than 90°, which suggests that the orbitals of the metal atoms form a bond with one orbital of the carbon atom and also that the metal atoms interact with one another. Apparently the formation of such bonds becomes hindered as the size of the metal atom is increased.

Electron-deficient bonds can differ in degree of polarity. In diborane, for example, the B...H bonds are close to covalent and in the dimer of phenyllithium they are apparently strongly polar. This can suggest starting from the characteristics of the atoms which form the bond. Table 2 gives some facts about the atoms, the bonds between which are discussed below.

Although electronegativity is a very crude characteristic of ionic character of the bonds, nevertheless it allows us to state, for example, that the C–Li bond should be more polar than B–H, etc.; therefore for organolithium complexes the contribution of the ionic state must also be considered.

Spectrographic data about the atomic levels also somewhat elucidate the problem of the use of free orbitals. Actually it is most favourable to use those orbitals for which the energy of promotion is less, and also the energy of the orbital itself is less. When the atoms are of similar size, the strength of the bond in the complex will be greater for that atom whose vacant levels are close to the occupied level with lower energy. For example, the aluminium and lithium atoms are similar in size and therefore it could be expected that the C–Li bond would be stronger than the C–Al bond. The available information about the energy of the C...Li bond confirms this hypothesis [16,17].

TABLE 2.

Property	Atoms				
	Li	Be	B	Al	C
Position of the atomic levels (occupied and lower free)[14]	—3.6...— —5.4...— E, eV				
Electronegativity[15]	0.95	1.5	2.0	1.5	2.5
Covalent radii [11,12]	1.34	0.96	0.84	1.26	0.77

Theoretically the formation of electron-deficient compounds with predominantly covalent bonds can be considered as the usual problem for quantum chemistry involving a few electrons in the field of a few centres, in which the number of atomic orbitals from which the molecular orbitals are constructed is greater than the number of electrons which participate in the bonds [1,5-7].

As the simplest example, let us consider the molecular ion $[A-B-C]^+$, the bonding in which is provided by a pair of electrons. We will consider that the atoms A, B, and C are disposed along a straight line, there is no exchange between A and C, and the overlap can always be neglected.

Then within the framework of the simplest method of LCAO MO, [18] by expressing the molecular orbital in the form

$$\psi = a_1\psi_A + a_2\psi_B + a_3\psi_C,$$

we obtain the secular equation for determining the energy:

$$\begin{vmatrix} \alpha_A - E & \beta_1 & 0 \\ \beta_1 & \alpha_B - E & \beta_2 \\ 0 & \beta_2 & \alpha_C - E \end{vmatrix} = 0.$$

When the atoms A and C are greatly different and the interaction of atom B with one of them (for example, with A) is considerably greater than that with the other, that is, $\beta_1 \gg \beta_2$, then this is equivalent to dealing with the system $[A-B]^-$ ion C^+.

The energy of an electron in the molecular orbital (we assume that $\alpha_A - \alpha_B \ll \beta$) will then be:

$$E = \frac{\alpha_A + \alpha_B}{2} + \beta.$$

When atoms A and C are the same and the ion C^+ has approached to the closest distance, then since A–B is equal in length to A–C, the secular equations will have the form:

$$\begin{vmatrix} \alpha_A - E & \beta & 0 \\ \beta & \alpha_B - E & \beta \\ 0 & \beta & \alpha_A - E \end{vmatrix} = 0$$

and the energies of the molecular orbitals will be:

$$E_1 = \frac{\alpha_A + \alpha_B}{2} + \sqrt{2}\beta,$$

$$E_2 = \alpha_A,$$

$$E_3 = \frac{\alpha_A + \alpha_B}{2} - \sqrt{2}\beta.$$

The gain in energy which is obtained in the formation of the electron-deficient compound $(A-B-A')^+$, is calculated as the difference in energy of the ion $(A-B-A')^+$ when a free orbital is used and the energy of the system consisting of the isolated molecule AB and the ion A^+ when the A orbital is not used:

$$\Delta E = 2\left(\frac{\alpha_A + \alpha_B}{2} + \sqrt{2}\beta\right) - 2\left(\frac{\alpha_A + \alpha_B}{2} + \beta\right) = 0.82\beta,$$

where ΔE is the delocalisation energy of the electron.

We note that this result is obtained with the following assumptions: (1) the atoms A and A′ are similar in properties or the same, (2) the overlaps A–B and B–A′ are the same (that is, the A–B and B–A′ bond lengths are the same), (3) the energy of promotion of the electrons in the valence state equals zero. As noted, this requirement is satisfied by some of the compounds considered above.

It can be assumed that the orbitals used by atom B should be the same in the A and A′ directions, that is, there should be known local symmetry in the structure of the complex. When atom B gives one orbital then its overlap with the atoms A and A′ should be the same.

Polycentric orbitals should be formed when there is conjugation and in electron-deficient molecules. In reality, when n orbitals are used for the formation of the "usual" two-centre bonds then $n/2$ bonding and $n/2$ anti-bonding orbitals are obtained from them. n electrons are distributed in the bonding orbitals, but the anti-bonding orbitals remain vacant. If there were more than n electrons then they would occupy some of the anti-bonding orbitals. When n orbitals are used for the formation of three-centre bonds they give $n/3$ bonding orbitals. The others will be non-bonding or anti-bonding. $2n/3$ of the electrons will be distributed in the bonding orbitals, and the remaining electrons would occupy the anti-bonding orbitals. Evidently electron-deficient compounds will be short of just those electrons which should have occupied the anti-bonding orbitals.

Besides the bonding in the complex where there is formation of polycentric orbitals with bonds close to covalent, as considered above there is a possibility of the formation of complexes due to polar bonds.

For any two-atom molecule A–B the molecular orbital can be presented in the form $\psi = a_1\psi_a + a_2\psi_b$ and the energy of the occupied orbital is

$$E = \frac{\alpha_1 + \alpha_2}{2} + \beta,$$

where

$$\alpha_i = \int \psi_i^* \mathbf{H} \psi_i \, d\tau; \quad \beta = \int \psi_1^* \mathbf{H} \psi_2 \, d\tau.$$

When the A–B bond is strongly polar, then the complex $(A-B)_2$ is formed. For simplicity we will consider it to be symmetrical, with the lengths of the bonds close to those for the monomeric molecule AB.

To describe the complex $(A-B)_2$ for the initial atomic orbitals we can select symmetrical orbitals, the form and symbolic representation of which are shown in Table 3.

The molecular orbitals are selected in the form: $\psi = \sum_i c_i\sigma_i$, in which the lowest energy is determined from the equation:

$$\begin{vmatrix} H_{11} - E & H_{12} \\ H_{21} & H_{22} - E \end{vmatrix} = 0,$$

where

$$H_{11} = \int \sigma_1 \mathbf{H} \sigma_1 d\tau = \int \frac{1}{\sqrt{2}}(\psi_{A_1} + \psi_{A_2}) \mathbf{H} \frac{1}{\sqrt{2}}(\psi_{A_1} + \psi_{A_2}) d\tau =$$

$$= \frac{1}{2}\left[\int \psi_{A_1} \mathbf{H} \psi_{A_1} d\tau + 2\int \psi_{A_1} \mathbf{H} \psi_{A_2} d\tau + \int \psi_{A_2} \mathbf{H} \psi_{A_2} d\tau\right] =$$

$$= \int \psi_{A_1} \mathbf{H} \psi_{A_1} d\tau + \int \psi_{A_1} \mathbf{H} \psi_{A_2} d\tau = \alpha_1 + \beta' = (1 + k_1)\alpha_1, \qquad k_1 > 0$$

$$H_{22} = \int \sigma_2 \mathbf{H} \sigma_2 d\tau = (1 + k_2)\alpha_2, \quad k > 0$$

$$H_{12} = \int \sigma_1 \mathbf{H} \sigma_2 d\tau = 2\beta$$

Since all the bond lengths in the diameter are the same, the solution will be:

$$E_1 = \frac{(1 + k_1)\alpha_1 + (1 + k_2)\alpha_2}{2} + 2\beta,$$

$$E_2 = \frac{(1 + k_1)\alpha_1 + (1 + k_2)\alpha_2}{2} - 2\beta.$$

TABLE 3.

Orbital	Atoms	
$\frac{1}{\sqrt{2}}(\psi_{A_1}+\psi_{A_2})=\sigma_1$		a_{1g}
$\frac{1}{\sqrt{2}}(\psi_{B_1}+\psi_{B_2})=\sigma_2$		a_{1g}
$\frac{1}{\sqrt{2}}(\psi_{A_1}-\psi_{A_2})=\sigma_3$		b_{1u}
$\frac{1}{\sqrt{2}}(\psi_{B_1}-\psi_{B_2})=\sigma_4$		b_{1u}

We find other solutions from the equations:

$$\mathbf{H}\psi_3 = E_3\psi_3 \quad \psi_3 = \sigma_3$$
$$\mathbf{H}\psi_4 = E_4\psi_4 \quad \psi_4 = \sigma_4$$
$$E_3 = \int \sigma_3 \mathbf{H} \sigma_3 d\tau = (1-k_1)\alpha_1, \quad k_1 > 0,$$
$$E_4 = \int \sigma_4 \mathbf{H} \sigma_4 d\tau = (1-k_2)\alpha_2, \quad k_2 > 0.$$

We assume that

$$|(1-k_1)\alpha_1| > |(1-k_2)\alpha_2|.$$

The occupied orbitals have the energies:

$$E_1 = \frac{(1+k_1)\alpha_1 + (1+k_2)\alpha_2}{2} + 2\beta,$$
$$E_3 = (1-k_1)\alpha_1.$$

The difference in energy between the dimer and the two monomeric A–B molecules is:

$$\Delta E = (1-k_1)\alpha_1 - (1-k_2)\alpha_2.$$

Hence, when $k_1 = k_2 = 0$,

$$\Delta E = \alpha_1 - \alpha_2.$$

Thus the above analysis shows the possibility of complexes being formed without use of free orbitals due to polar interaction. We note that in this a complex from polar molecules acquires the properties of a covalent compound: the dipole moment of the complex equals zero, there is a molecular orbital envoloping all the nuclei, etc.

In this instance the part played by overlap is small, not because there is little overlap of the atomic bonding orbitals, but on account of the low electron density in these orbitals and because the increase in overlap due to the utilisation of more directed vacant orbitals changes nothing (the overlap of "empty" orbitals does not give bonds). A similar situation occurs in some organometallic compounds and also in the formation of intramolecular hydrogen bonds [2,19]. Accurate calculations [20,21] made for H_3^+ and B_2H_6 confirm the correctness of what has been stated for the formation of non-polar bridge bonds.

On the basis of the above, it can be stated that the bonding in electron-deficient compounds is due to: (1) the delocalisation of electrons in the formation of polycentric orbitals with the utilisation of the free orbitals of the metal atom, or (2) strong polar interaction in the formation of structures with alternating charges of different polarity; polycentric orbitals can be formed here without utilisation of the free orbitals of the metal atom.

II. WHAT IS UNDERSTOOD BY THE EXPRESSIONS "ENERGETICALLY FAVOURABLE ORBITAL" AND "UTILISATION OF VACANT ORBITALS"

In speaking about "energetically favourable free orbital" we mean that the energy for the promotion of an electron in a valence state is moderate and can be restored in the formation of chemical bonds of the given atom with others. The use of this definite orbital ("free orbital") signifies that in it there is some electron density, that is, the most favourable polycentric molecular orbitals are obtained when this particular free orbital takes part in their formation. In the MO LCAO language this signifies that when a molecular orbital can be written in the form $\psi_M = \sum_k a_k \psi_k$, then the coefficient in the "favourable" orbital is not zero.

Often no mention is made in the literature of what is understood by these expressions [6,7,22]. For example, Hoffmann [23] considers that when the free $3p$ orbital of aluminium is used in compounds of the $[Al(C_2H_5)_3]_2$ type, the CH_2 bridging group should be in weaker fields than the terminal, since then the electrons of atom C will be distributed in two aluminium orbitals. This statement signifies that some charge is transferred from the CH_2 bridging group to the "favourable" orbitals of the aluminium atoms. However, this would be correct were it to be shown that in using the free orbitals of the aluminium atom there is a "flowing in" of charge into its free orbitals from other atoms or atomic groups, but the use of these free orbitals by the electrons of the aluminium atom for the purpose of creating more directed orbitals is unfavourable. Such an analysis has not been made. The reverse effect occurs in boron hydrides. With diborane [24] the bridging protons are in stronger fields than the terminal protons, that is, charge is transferred from the boron to the bridging protons, however, it is thought that in the formation of polycentric molecular orbitals the free p orbitals of a boron atom are used. That being so the free orbitals of the atom are used by "its own" electrons.

One of the fundamental problems in the study of bonds in electron-deficient compounds is that of the participation of the free orbitals of the metal atom in the formation of the polycentric molecular orbitals.

In the subsequent discussion of NMR results attention will be drawn to the experiments which confirm the use of free p orbitals of boron, aluminium, and lithium atoms.

III. NMR SPECTRA OF BORON HYDRIDES

There have been many detailed articles [1,25] about the investigation of the structure and properties of the boron hydrides, therefore we will limit the discussion to only the NMR results obtained for these compounds.

The study of the boron hydrides by the NMR method began as soon as their most important peculiarities had been revealed. However, the use of the NMR method gave more than confirmation of the results obtained earlier.

1. Proton Magnetic Resonance (PMR) Spectra

The PMR spectra of the boron hydrides are very complex owing to splitting, which is connected with the interaction of the protons with the ^{11}B and ^{10}B nuclei. As an

example, Fig. 1 gives the PMR spectra of diborane, pentaborane, and decaborane. The asymmetric form of the PMR spectrum for diborane rules out the possibility of an "ethane-like" structure existing.

When the method of double nuclear resonance is used a simplified spectrum is obtained [26]. Esentially, in addition to the high-frequency field bringing about the transition of the ^1H nucleus, a strong field, corresponding to the frequency of the transitions of the ^{11}B nucleus is imposed. This leads to saturation of the ^{11}B signals. At saturation the ^{11}B nucleus appears to cease to interact with protons and the splitting due to the $^{11}B-^1H$ interaction ceases. Fig. 2 shows the PMR spectra of the same compounds as in Fig. 1 obtained by the double resonance method.

The diborane spectrum shows the presence of two types of protons. The ratio of the intensities of the signals suggests that one group consists of two hydrogen atoms, and the other of four. This confirms the "bridge" structure of diborane.

The molecule of pentaborane, B_5H_9, has a tetragonal pyramidal structure [27]. The boron atom situated at the apex of the pyramid is combined with one proton and each boron atom lying at the base of the pyramid is linked with one terminal hydrogen atom and two bridging hydrogen atoms. The NMR spectrum should in principle give three groups of lines with 1:4:4 ratio of intensities. The PMR spectrum observed experimentally (Fig. 1*b*) consists of four

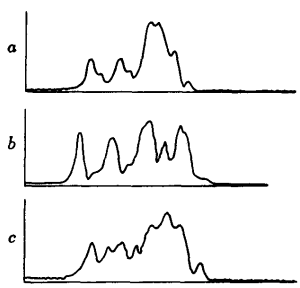


Fig. 1. PMR spectra of boron hydrides [24] (f_{res} = 30 MHz): *a*) diborane; *b*) pentaborane-9; *c*) decaborane.

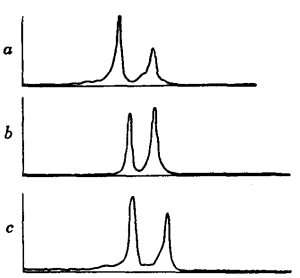

Fig. 2. PMR spectra of boron hydrides (f_{res} = 30 MHz) obtained on saturation of ^{11}B at the frequency 9.65257 MHz: *a*) diborane; *b*) pentaborane; *c*) decaborane.

intense lines (the signal of the terminal protons, bound to the boron atoms at the base of the pyramid, split owing to interaction with ^{11}B), four weak lines, somewhat displaced into the region of stronger fields (the line from the proton at the apex of the pyramid is split because of interaction with ^{11}B) and finally a group of lines from bridging protons, which is superimposed on the spectrum of the terminal protons. By using the double resonance method, on saturating the ^{11}B nuclei lying in the base a spectrum consisting of two lines of different intensities is observed. This indicates that the number of terminal and bridging protons connected with the boron atoms in the base of the pyramid are the same. In saturation of the ^{11}B "vertex" nucleus a signal from the proton bound to it is observed; the signal is positioned between the signals from the terminal and bridging protons lying in the base of the pyramid.

The PMR spectra of pentaborane-11, decaborane, etc. have been described in detail [28-33]. The analysis of the spectra confirmed the earlier findings concerning the peculiarities of the structure of these compounds.

The PMR spectra were obtained for the pure compounds and not solutions, external standards were not used, and in the overwhelming majority of the instances the spectra were not calibrated. The internal chemical shift was measured for diborane: the NMR bridging protons are shifted into the strong field region by 4.3×10^{-6} relative to the terminal protons. This suggests that the negative charge on the bridging protons is greater than that on the terminal, and when terminal B–H bonds are considered close to covalent bonds then the bridging bonds have a significant percentage of ionicity. Actually by using the wave functions of diborane obtained by Jamadjaki [21] it is easy to show that the excess of negative charge on the bridging proton compared with the terminal is $\sim 0.25\ e$. On each of the boron atoms there is a positive charge of $\sim +0.24\ e$. It is evident that such a charge distribution corresponds to the model of Pitzer and Gutowsky [2] which explains the bond by the formation of a B–B "protonated double bond", since the appearance of a signal from the bridging protons in weak fields would then be expected.

Kern and Lipscomb [34] made an approximate calculation of the magnetic screening for bridging and terminal protons in diborane and obtained qualitative agreement with the experimental results. They showed that the bridging protons are situated in strong fields and the internal chemical shift was found to be 3.2×10^{-6}.

2. ^{11}B NMR Spectra

The NMR spectra of the boron hydrides showed the presence of non-equivalent nuclei of ^{11}B and protons and gave additional confirmation of the correctness of the structures found by other methods.

The ^{11}B NMR spectrum of diborane consists of nine lines [24] (Fig. 3). Due to the strong interaction with the terminal protons the ^{11}B lines give a triplet $J_{^{11}B-^1H_K}$ = = 137 Hz), but the interaction with the bridging protons gives an additional triplet splitting of each of the three lines ($J_{^{11}B-H_M}$ = 48 Hz). Analysis of the spectrum confirms the non-equivalency of the two groups of protons and shows the equivalency of the boron nuclei.

The pentaborane-9 spectrum consists of two lines with intensity ratio $\simeq$ 4:1 (Fig. 4). The interaction of the boron atoms lying at the base of the pyramid with the

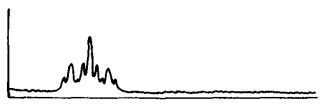

Fig. 3. ^{11}B NMR spectrum of diborane[24] (f_{res} = 12.3 MHz).

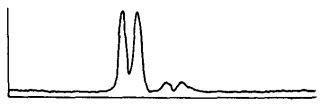

Fig. 4. ^{11}B NMR spectrum of pentaborane[24] (f_{res} = 12.3 MHz).

bridging protons is not shown clearly but the lines are appreciably broader than in diborane. Possibly one of the reasons for the broadening of the ^{11}B NMR lines is the interaction of the ^{11}B nucleus with the bridging proton.

The ^{11}B NMR spectrum of other boron hydrides has been described in detail[30-33,35,36] and since the interpretation of the spectra is usually given for confirmation of their structure, we will restrict the discussion to diborane and pentaborane-9.

The study of ^{11}B NMR has been carried out more thoroughly than the NMR of the protons. We now have much information about the chemical shifts of ^{11}B and about the $^{11}B-^{1}H$ spin–spin interaction. Table 4 gives data on the chemical shifts and spin–spin interactions for some boron-containing compounds[36].

As Table 4 shows, the ^{11}B shift in diborane relative to $B(OCH_3)_3$ is very small. It can evidently be assumed that the boron atom in compounds such as $B(OCH_3)_3$, is "stripped".

However, such a hypothesis would not be correct for other boron compounds (for example, for diborane), since it has been noted that with change in the hybridisation of

TABLE 4.

	+ 0.7		162	

the boron atom (on transition from sp^2 to sp^3) the paramagnetic contribution to the screening constant decreases[35,36].

Without evaluating the changes in the paramagnetic contribution it is impossible to draw any conclusions about the electron density at the ^{11}B nucleus.

The spin–spin constants of the $^{11}B-^{1}H$ interaction for the boron hydrides can be explained qualitatively on the basis of the hypothesis of Gutowsky and coworkers[37] that the spin–spin interaction between ^{1}H and other nuclei will depend on the fraction of s character in the hybrid orbital bound to the hydrogen atom. Hence the interaction constant between ^{1}H and the sp^2 hybridisation of the boron atom should be greater than that between ^{1}H and the sp^3 hybridised atom. The results in Table 4 confirm this hypothesis. Thus, for compound (3), in which the hybrid boron orbitals are close to sp^2, the quantity $J_{^{11}B-^{1}H}$ is 134 Hz, but for $NaBH_4$ where the hybridisation of the boron atom is close to sp^4, $J_{^{11}B-^{1}H}$ = 81 Hz.

When the spin–spin interaction constant $J_{^{11}B-^{1}H}$ reflects the influence of the s character of the hybrid orbitals of the boron atom, then the hybrid orbitals of the boron atom in hydrides are intermediate between sp^2 and sp^3. With diborane a difference in the hybridisation of the orbitals of the boron bound with the terminal and the bridging protons appears quite distinctly (137 and 48 Hz). In the last the contribution of p character is greater.

The information on spin–spin interaction shows that the B–H bonds (even bridging) are predominantly covalent. Were they strongly polar, then it is evident that the $J_{^{11}B-^{1}H}$ spin–spin interaction would be close to zero, as it is for $B(OCH_3)_3$.

3. Saturation of the ^{11}B NMR Signals

The ^{11}B nucleus is known to have a nuclear quadrupole moment, and the interaction of nuclear quadrupole with the "lattice" and with other nuclei diminishes[26] with the spin–lattice relaxation time T_1, and with the spin–spin relaxation time T_2. The optimal conditions for recording the spectra are short T_1 (since the signal intensity $\propto \sqrt{T_2/T_1}$) and long T_2 (since the signal decay $\propto 1/T_2$). The difference in the line breadths or their intensities can give some information about the electron environment of the ^{11}B nucleus.

Actually in many ^{11}B NMR spectra of boron hydrides the peak area of the NMR signals of the ^{11}B nuclei in non-equivalent positions give only approximately the number of nuclei found in the corresponding positions. The explanation is that the ^{11}B nuclei are in electronic surrounding with unusual symmetry and the interaction of the quadrupole moment ^{11}B with the electric field alters the spin–lattice relaxation time differently for nuclei situated in different positions. For example, the ^{11}B NMR signal of the BH_4^- ion is easily saturated (T_1 is large) and this is the result of the symmetry of the electronic environment of the ^{11}B nucleus, which decreases the interaction of the ^{11}B quadrupole moment with the lattice. The position for exchange is similar.

The study of "relative ease of saturation" for the boron hydrides gave the following results: the BH_2 groups in tetraborane-10 are saturated more readily than the BH groups[38]; the apex boron atom in pentaborane-9 is saturated more readily than the boron atoms lying at the base

of the pyramid, etc.[33,39]. In both instances the saturation at these nuclei is easier because of the high symmetry of the electron environment.

It was found for hexaborane-10 that the ^{11}B nuclei lying in the base are saturated much more easily than those at the vertices and this is difficult to explain by the presence of a symmetrical electron environment, due to the structure of the compound itself. Evidently this is brought about by the exchange of "bridging" hydrogen atoms, as the symmetry of the electron environment increases in similar intramolecular rearrangements. Exchange leads to the absence of $J_{^{11}B-H_M}$ spin–spin interaction noted earlier for pentaborane-9 and for other compounds[39].

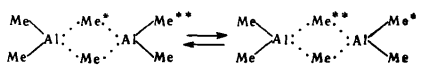
IV. NMR OF ORGANOALUMINIUM COMPOUNDS

Some organoaluminium compounds are electron-deficient. For example, there are the dimers of trimethylaluminium and triethylaluminium, the polymers of $Al(OPr^i)_3$, etc.[2,40].

The difference between the organoaluminium compounds and the boron compounds is that the polarity of the bonds can play a greater part in the formation of bridge bonds in them. Actually, in accordance with the electronegativity rules[15] the polarity of the C–Al bonds is ~ 30%. Furthermore, in the formation of polycentric orbitals with participation of the free 3*p* orbitals, the energy of the Al...C bridging bonds should be appreciably less than for B–H, since the energy for promoting in the valence state for the aluminium atom is greater than that for boron (see Table 2). And finally, in the formation of dimers by the alkylaluminiums steric hindrance to complex formation may arise[2].

1. PMR Spectra

It was established earlier that trimethylaluminium exists as a dimer in the solid state (its structure is shown in Table 1). In benzene solutions[2] and in the gaseous state[41] trimethylaluminium also exists as a dimer, but in early work on PMR, the spectrum of $[Al(CH_3)_3]_2$ appeared as a single line[26,42]. This can be explained either by the equivalence of all groups in the dimer, or by rapid exchange:



(I)

Miller and Pritchard[43] showed that at ordinary temperatures there is an exchange between bridging and terminal CH_3 groups. On cooling a solution of trimethylaluminium in cyclopentane to -75° a spectrum is obtained which consists of two lines with an intensity ratio of 2 : 1. The form of the spectrum is shown in Fig. 5. The shifts of the bridging and terminal methyl groups relative to the signal of cyclopentane are respectively 1.04×10^{-6} and 2.17×10^{-6}. At elevated temperatures the signal from the bridging groups broadened and merged with the signal from the terminal groups.

The activation energy for the transition mentioned, calculated from the temperature dependence of the form of the spectrum lay within the limits 6–14 kcal mole^{-1}. The heat of dissociation of the dimer[5] is 20.2 kcal mole^{-1}, and apparently trimethylaluminium does not dissociate into the monomer during change (I). It is thought[43] that the formation of a transitional state can rule out rupture of one

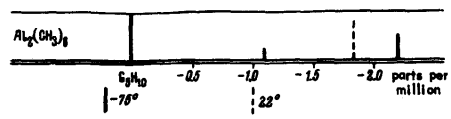


Fig. 5. PMR spectrum of the dimer of trimethylaluminium[44].

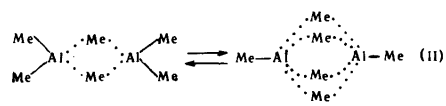
Al–C bond or the formation of new Al...C bonds for the transitional structure, that is,



(II)

Hyperfine splitting due to the $^{27}Al-^1H$ interaction was not observed.. The PMR lines are very broad (~ 6 Hz).

For dichlorotetramethyldialuminium $Al_2Cl_2(CH_3)_4$ the PMR lines have a breadth of ~ 1 Hz (f_{res} = 40 MHz), but here in the temperature interval -85–0° the $^{27}Al-^1H$ spin–spin interaction was not observed[44].

The absence of hyperfine splitting is easily explained by the great polarity of the C–Al bonds or by the fact that in the hybrid Al orbital the 3*s* state "impurity" is small.

The PMR spectrum of $[Al(C_2H_5)_3]_2$ shows that all the CH_2 groups are equivalent[23,45]. If the "usual" association were assumed, the non-equivalency of the CH_2 groups would be expected:

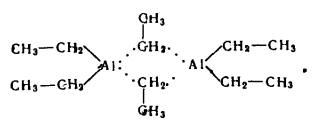


Fig. 6 shows the PMR spectrum. The methylene group signal appears at the "mean" value of the field: between the positions expected at a stronger field for

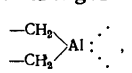
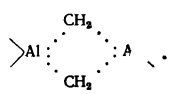


and the position for the bridging CH_2 gr' ups in the configuration:



Hoffmann considers[23] that the NMR signal of the bridging groups should be expected in a weaker field, since then the electrons of the C–Al bond will be distributed on two orbitals of the aluminium.

The hypothetical positions of the signals of the outer ethyl groups (or the bridging groups) can be judged from the spectra of compounds with –Al–CH_2– groups which

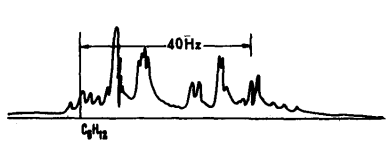


Fig. 6. PMR spectrum of the dimer of triethylaluminium[44] (f_{res} = 40 MHz).

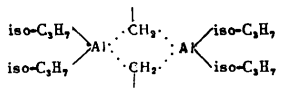
either are not associated, for example[46], $AlPr^i_3$, or contain an ethyl group only in the bridge bond, for example,



For the CH_2 groups in these instances[23] a frequency difference of 17.6 Hz is obtained (at f_{res} = 40 MHz), in which the bridging methylene group gives a signal in weaker fields than the terminal groups. But because a single line is observed for triethylaluminium, it is thought[23] that here there is an alkyl exchange. Assuming that the shift between the terminal and bridging $-CH_2-$ groups should be ~ 17 Hz it can be concluded that the Al...C bridging bond is unstable and has a life of $\tau \ll 10^{-2}$ s.

However, the instability of the Al...C bonds cannot be considered to be finally established, since the NMR spectra at low temperatures have not been investigated (as they have for trimethylaluminium[43]), and there have also been no studies of the applicability of the "static" model, proposed earlier by Pitzer and Gutowsky[2] (bonding in the complex by the formation of Al...H bonds is suggested, as shown in Fig. 7). This model is reasonable from the standpoint of "geometry" and to explain the same position of the signals for the methylene groups there is no need to invoke the existence of exchange.

The data about the PMR spectra of other compounds (diethylaluminium hydride, etc.[23,44,45]) are fragmentary and will not be discussed here.

2. ^{27}Al NMR

The ^{27}Al nucleus has a comparatively large quadrupole moment ($Q = 0.149 \times 10^{-24}$ e cm^{-2}) and if its electronic environment does not have sufficient symmetry then owing to the interaction of the quadrupole moment with the electric field T_2 decreases and the aluminium line broadens. The ^{27}Al NMR usually is very broad but since the range of shifts for ^{27}Al is great not only the line breadth but also the chemical shifts can be measured with an accuracy of $\pm 10 \times 10^{-6}$. Some data[47] for the NMR of aluminium compounds are given in Table 5.

The spectra of the compounds mentioned in Table 5 were taken at a frequency of f_{res} = 7.2 MHz.

The narrow lines of the ^{27}Al NMR show compounds having electric field symmetry around the ^{27}Al nucleus close to the tetradhedral $Al(CH_3)_3$, $AlCl_3$, and solutions of the polymer $Al(OPr^i)_3$.

Pure trimethylaluminium gives a wider ^{27}Al NMR line than $AlCl_3$, and this can be explained by the dimer

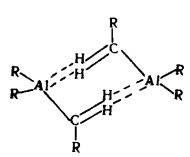


Fig. 7. Structure of the dimer of triethylaluminium according to Pitzer and Gutowsky[2].

TABLE 5.

Compound	$\delta = \frac{H_{specimen} - H_{std}}{H_{std}} \times 10^6$	Line breadth, G
$Al(N_2O)^{+3}_6$	0	0.05
$[Al(CH_3)_3]_2$	—156	0.4
$[Al(C_2H_5)_3]_2$	—171	1.5
$Al(iso\text{-}C_4H_9)_3$	—220	5.4
$Al(O—iso\text{-}C_4H_9)_3$ (Solution in heptane)	—7	0.09
$[AlCl_3]_2$	—91	0.3
$H—Al(iso\text{-}C_4H_9)_2$	—162	8.9

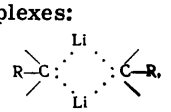
$[Al(CH_3)_3]_2$ being formed by the setting up of Al...H bonds[47], that is, a hydrogen atom of the methyl group, and not the carbon, takes part in the intermolecular bond. This is not in agreement with the X-ray data, but accords well with the Raman and infrared spectra[2] where it is found that the symmetry of $[AlCl_3]_2$ is higher than that of $[Al(CH_3)_3]_2$.

The dimer of triethylaluminium gives a relatively "narrow" line, evidently because the gradient of the electric field at the ^{27}Al nucleus diminishes on formation of the A...H bonds. Were exchange to exist, an NMR line almost coinciding in breadth with the trimethylaluminium line would be expected. For the molecule-monomers, for example, $AlPr^i_3$, the symmetry of the electronic environment of the ^{27}Al nucleus is lower and the line becomes significantly wider.

The chemical shifts of the compounds discussed have not been interpreted.

V. NMR OF ORGANOLITHIUM COMPOUNDS

It has been found[4] that organolithium compounds are strongly associated, and with ethyllithium even in the vapour the molecules exist predominantly in the form of tetramers and hexamers[48]. The considerably branched molecule of $(CH_3)_3CLi$ gives tetramer complexes in benzene solution[49]. The simplest dimer associate was found in an ethereal solution of phenyllithium[50]. However, not one of the papers we have read reports the observation of monomeric molecules of organolithium compounds. It is suggested[2,50] that the intermolecular bonds in the complexes arise because of the strong polarity of the C–Li bonds. From the infrared spectra[51] and the chemical properties of the substances (solubility in non-polar solvents, electrical conductivity, etc.) its was proposed that multicentric molecular orbitals and C...Li bridge bonds are formed in the organolithium complexes:



and the 2p orbitals of the lithium atom participate in the formation of the multicentric orbitals. The proposed C...Li bonds are essentially covalent.

The difference between the lithium atom and the atoms of boron and aluminium is that the 2p orbitals of the lithium atom are not used in the normal state (and therefore information about the participation of any of the 2p orbitals in bonds is needed for the solution of problems). In addition allowance must be made for polarity of the bonds playing an important part in the formation of complexes.

1. PMR Spectra

Table 6 gives some information about the PMR spectra of some organolithium compounds.

Figs. 8–10 show PMR spectra of methyl-, ethyl-, and phenyl-lithium.

The results for the chemical shifts of PMR for the CH_2 group cannot be explained in terms of electronegativity by the rules found earlier for alkylmetals [54]. The large shift of the CH_2 line in the region of strong fields can be explained if it is assumed that the C–Li bond is strongly polar. In reality the shift of the CH_2 group in $(R-Li)_n$ complexes relative to the CH_2 group in normal hydrocarbons is [26] $\sim 2.6 \times 10^{-6}$. To obtain such a shift the charge on the 1s cloud of the hydrogen atom must be increased by 0.2 *e*. When it is assumed that the charge is transferred from the lithium atom to the CH_2 group and there distributed in accordance with the electronegativity of the atoms, then there should be a charge of $\sim 0.7\ e$ on the CH_2 group.

The NMR results for alkyl compounds of normal structure show that outside the dependence on the complexity of the complex, the CH_2 group directly bound with the lithium atom is always found in the same electronic environment, although for different complexes some differences could be expected. For example, for the tetramer and hexamer of ethyllithium structures in the form of "bookcases" [layers (Ed. of Translation)] of dimers joined by C...Li bonds have been suggested [55] and also the structures [4] shown in Fig. 11. However, with the "bookcases" for the hexamer there should be a difference in the shifts of the CH_2 groups for different "layers" of the bookcase. Probably, for the structure proposed by Brown and coworkers [4] in the tetramer and hexamer there should be different electronic environments for the CH_2 groups.

When alkyl exchange is not taken into account the structures proposed above do not explain the PMR results, besides which these structures are highly stressed due to the mutual repulsion of the non-valence bonded atoms [52], which was noted earlier for the example of the triethylaluminium complexes [2]. Evidently as for $[Al(C_2H_5)_3]_2$ complexes [2], C_2H_5Li can exist in solution thanks to the formation of Li...H bonds [52] (Fig. 12). Such a structure also exists for the hexamer.

The size of the chemical shift of the CH_2 group, as for other structures is readily explained by the high polarity of the C...Li bond. The equivalence of the methylene groups is also evident, since the Li...H bonds are identical. The

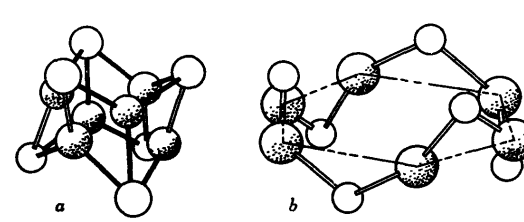

Fig. 11. Structure of the ethyllithium hexamer [4] (lithium atoms omitted). The alkyl exchange between the structures (*a*), postulated to explain the breadth of the ^7Li lines, is suggested as possible because of the formation of intermediate structures (*b*).

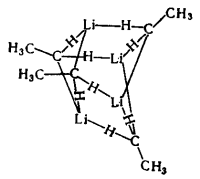

Fig. 12. Hypothetical structure of the tetramer of ethyllithium [52].

Li...H bonds are preferentially polarised bonds in which there is apparently some overlap of the 1*s* orbitals of the hydrogen atom with the 2*s* orbitals of the lithium atom. A feature of these bonds is that the free 2*s* orbital of the hydrogen atom agrees in energy [14] with the free 2*p* orbital of the lithium atom and on transfer of the 2*s* electron of the lithium atom to the 2*p* level, the electron can use the 2*s* orbitals of neighbouring hydrogen atoms without expenditure of energy [52].

The chemical shifts of the PMR lines for $(CH_3)_3CLi$ and C_6H_5Li were not interpreted.

All authors note the absence of $^7Li-^1H$ spin–spin interaction. This is associated either with alkyl exchange or with the great polarity of the C–Li bond (the latter is the more probable).

X-Ray analysis [55] of crystalline C_2H_5Li showed that the ethyllithium molecules form tetramers in the crystals. Apparently the dissolution of ethyllithium in non-polar solvents is due to the comparatively slight interaction of the tetramers with one another. The retention of the form of the tetramer in solution should give different shifts for the NMR lines of the methylene group protons. It can therefore be assumed that the complex changes its configuration to some extent during dissolution.

2. ^7Li NMR Spectra

The ^7Li nucleus has a quadrupole moment ($Q = 4.2 \times \times 10^{-26}$ *e* cm^{-2}) and therefore the breadth of the ^7Li line can be considerable owing to the interaction of the quadrupole moment with the "lattice". However, the ^7Li NMR lines of solutions of a series of compounds give narrow lines. Some of the NMR results are given in Table 7.

Brown and coworkers [4] explain the narrow ^7Li NMR lines by the exchange of radicals as for trimethylaluminium [43]. However, the line breadth is unaltered on cooling to -75° (and ether solutions to -100°) therefore it can be assumed that the narrow ^7Li line is due to the symmetry of the electron environment and not to exchange. Actually if it is assumed that the structure shown in Fig. 12 is stable, then the absence of electric field gradients at the ^7Li nucleus is the result of the compensating action of the neighbouring H, C, and Li atoms.

TABLE 7.

Substance	Solvent	ΔH_{Li}, Hz (t = 27°)	ΔH_{Li}, Hz (t = −75°)
C_3N_3Li [4]	C_6H_6	$\sim 10^{-3}$	
C_2H_5Li [5]	C_6H_6	$<6\cdot10^{-3}$	
	C_6H_{12}	$<6\cdot10^{-3}$	
	$(C_2H_5)_2O$	$<6\cdot10^{-3}$	$<6\cdot10^{-3}$
$n\text{-}C_4H_9Li$ [52]	C_6H_{14}	$<6\cdot10^{-3}$	$<6\cdot10^{-3}$
$C_{12}H_{25}Li$ [52]	C_6H_6	$<6\cdot10^{-3}$	
	C_6H_{12}	$<6\cdot10^{-3}$	
$C_6H_5.CH_2Li$ [53]	$(C_2H_5)_2O$	$<6\cdot10^{-3}$	$<6\cdot10^{-3}$

We note that the strongly polar C–Li and Li...H bonds will give a narrow ^7Li NMR line for almost any configuration of the complex. The alkyl exchange postulated for the explanation of the small line breadths [4] of ^7Li lines apparently does not occur, since even at low temperatures a narrow line is observed. It is especially difficult to admit the possibility of exchange for such compounds as dodecyllithium.

Apparently in these compounds the ^7Li nucleus is almost in an environment of 1*s* electrons, that is, the C–Li and Li...H bonds are strongly polar.

This hypothesis is supported by comparison with the NMR results [47] for ^{27}Al. When it is assumed that for compounds of the $(Li-R)_n$ type in solutions the correlation time, viscosity, etc. are just the same as for $[Al(CH_3)_3]_2$ (which is probably not true, as there are changes in the direction of the broadening of the ^7Li line) then the ratio of the line breadths should determine the ratios of the squares of the quadrupole moments [56] and the ^7Li NMR lines should have a breadth of more than 2×10^{-1} Hz. Comparison with the experimentally observed line breadths allows the conclusion to be drawn that the ^7Li nucleus has an electronic environment of high symmetry. Evidently there is very little utilisation of free orbitals and the lithium in these compounds is in a form close to Li^+. This suggestion explains the PMR results, the line breadths, and the absence of spin–spin interaction.

The chemical shifts in ^7Li were observed in only one work [4], but definite conclusions were not drawn, since the standard was a solution of lithium bromide in water. The shift of $\sim 1 \times 10^{-6}$ of the lithium lines (ethyllithium) towards weaker fields relative to lithium bromide does not seem significant since the transfer of electrons from the water molecule to the free orbitals of Li^+ is possible (in the formation of a hydrated ion).

---o0o---

The examples considered show that the bonds in organo--lithium, -aluminium, and -boron complexes differ considerably: from close to covalent to strongly polar bonds. Therefore to formulate the principles of electron-deficient bonding it is necessary to consider both polar interaction and also the possibility of using free orbitals. The principle formulated by Rundle [6,7] does not take polar interactions into account.

It is interesting to note that at first glance allowance for polar interactions can explain many experimental facts. For example, Pitzer and Gutowsky [2] suggested that when the bonds in the alkylaluminium dimers are predominantly polar then all the alkylmetals in which the metal atoms have less electronegativity are associated and those with greater electronegativity are monomers. This suggestion is equivalent to saying that M–C bonds for metals of low electronegativity are strongly polar. Such a compound will give complexes with formation of polar bonds, spin–spin interaction in these complexes will be absent, and the chemical shift of M relative to the M^+ ion will be small. In metals with high electronegativity the C–M bond will be predominantly covalent, there will be spin–spin interaction, etc. Cryoscopic and NMR data confirm this hypothesis.

Table 8 gives some cryoscopic and NMR results for various groups of organometallic compounds.

Pitzer and Gutowsky's views are also confirmed for alkylmetal complexes.

As for boron hydrides, it is almost impossible to confirm the use of all the 2*p* orbitals in the formation of bonds, but quantum mechanical calculations show the correctness of this hypothesis.

RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

April 1966

NIKOLAI NIKOLAEVICH SEMENOV

Dear Nikolai Nikolaevich,

The whole Soviet scientific community, all chemists in our great Motherland warmly greet and congratulate you on the day of your glorious anniversary.

Your fundamental discoveries in the fields of chain reactions, of combustion, and of explosive processes have deservedly brought you world-wide recognition.

You won the deep gratitude of the Soviet peoples as an untiring propagandist for and organiser of science. Throughout your brilliant life you have been a convinced and staunch champion of the unity of theory and practice.

It is gratifying to realise that you come to your jubilee in the prime of your creative powers and your untiring talent for scientific organisation.

Together with all Soviet scientists the Editorial Board of the journal "Uspekhi Khimii" sends you its greetings and most sincere wishes for health and ever new successes in your many-sided activities.

U. D. C. 541.124.7

STUDY OF THE KINETICS AND MECHANISM OF BRANCHED CHAIN REACTIONS IN THE GAS PHASE

A. B. Nalbandyan

I. INTRODUCTION

The present Review gives a brief account of the principal results obtained in investigations, conducted mainly at the Institute of Chemical Physics of the USSR Academy of Sciences during the past five to six years, in the field of branched chain reactions, the theory of which has been developed by Semenov. Thanks to the powerful research tools which have appeared comparatively recently — electron spin resonance (e.s.r.), electronic computers, etc. — it has become possible to undertake a broad testing of the mechanisms which have been suggested for complex chemical processes and to study new systems in which, with rare exceptions, it had not been possible to establish the nature of the active species responsible for the development of the chain processes.

Forty years ago Semenov and his students at the Leningrad Physicotechnical Institute, in a study of the quenching of the luminescence of the combustion products from a mixture of phosphorus vapour and oxygen, observed the remarkable phenomenon of lower and upper limits of spontaneous combustion. During 1926–1930 the phenomenon of ignition limits was discovered also in sulphur vapour–oxygen, carbon monoxide–oxygen, and hydrogen–oxygen mixtures[1-8]. Investigations showed that practically no reaction took place below the lower or above the upper limit. It was sufficient, however, to raise slightly the pressure of the mixture near the lower limit, or lower it when above the upper limit, for the mixture to ignite instantly. The investigators noticed that the lower and upper limits possessed unusual properties. For example, the lower pressure limit is lowered by increasing the diameter of the vessel. Under identical conditions, dilution of the reactant mixture with an inert gas results in a fall in the limiting pressure of the combustible mixture. In other words, a mixture which does not inflame at a given pressure immediately ignites if an inert gas is added to it. On the other hand, the partial pressure of the reactant mixture at the upper limit falls sharply if it is diluted with an inert gas. All these and many other phenomena discovered at the same time and later do not fit into the framework of classical chemical kinetics.

In order to explain these astonishing phenomena, Semenov[2-9] put forward a theory of chain branching in chemical reactions, according to which the combustion of a gaseous mixture involves the direct participation of atoms and free radicals, the so-called active centres or chain carriers. Atoms and radicals react with the starting materials to form the final product and a new active particle. The latter again reacts, to give the reaction product and an atom or a free radical as new active particle. In this way an unbranched chain reaction arises and is propagated in the gas mixture, a phenomenon known since the discovery of the photochemical chlorination of hydrogen by Bodenstein[10]. The ignition of fuel mixtures is due to the branching of chains, i.e. to the appearance from time to time, at some link or links in the developing chains, of more than one active particle. These additional active centres also become centres of new chains. As a result, an avalanche-like increase in the number of active centres occurs in the system after a brief interval, and hence also in the reaction velocity, which we perceive as ignition. Mathematical analysis of the growth in the number of active particles in the reactant mixture shows that in this case the increase obeys the law $N = N_0 e^{\varphi t}$, where φ is a positive quantity.

The lower and upper limits of spontaneous ignition observed experimentally by Semenov were explained by the destruction of active centres or chain carriers. According to Semenov's theory, the lower limit is associated with heterogeneous destruction of chains, and the upper limit with their homogeneous destruction. This theory provided a quantitative description of the experimentally observed ignition limits and their properties.

According to the theory of the limits, absence of ignition is explained by the rate of destruction of active centres on the walls or in space exceeding the rate of branching. Ignition occurs only when the rate of branching of chains is greater than the rate of destruction of active centres. The lower ignition limit is determined by equality of rates of branching and of heterogeneous destruction of active centres, and the upper limit by equality of the rates of branching and of homogeneous destruction of chain carriers. The experimentally observed decrease in the lower pressure limit with increase in diameter of the reaction vessel and with dilution of the mixture by an inert gas are brilliantly explained by Semenov's theory of the limits. With a reaction vessel of larger diameters, the average time taken by an active particle to diffuse to the walls of the vessel is longer, and consequently the probability is higher of its entering into new branching reactions before destruction on the walls. Additions of an inert gas should act similarly to an increase in pressure. With dilution of the reactant mixture, the mean residence time of an active centre in free volume increases, since diffusion is slower. The decrease in the partial pressure of the reactant mixture at the second limit and the second limit itself are well and quantitatively explained by the theory of branched chain processes on the assumption that in space an active centre is destroyed in a three-body collision[9,11], while the branching reaction is bimolecular. The rate of branching will then increase in proportion to the pressure of the reactant gas, while the rate of termination will increase according to the square of the pressure. With rise in pressure, these rates can obviously become equal when the pressure reaches a certain value, and above this pressure the mixture will cease to ignite. When part of the reactant gas is replaced by an inert gas, the number of three-body collisions remains constant, while the rate of branching falls. For this reason ignition ceases at a lower partial pressure of the reactant gases as the pressure is raised.

Semenov's theory of branched chain processes very soon obtained world-wide acceptance. An immense number of papers appeared, in which numerous examples were given of reactions occurring by a branched chain mechanism. It became evident that chain reactions are not rare exceptions. An urgent need therefore arose for a detailed study of the kinetics and mechanism of chain processes. It was obvious that the conscious control of a chemical process was indissolubly linked with a knowledge of the detailed mechanisms of actual chain reactions. Thus in 1930 a second important period began of further development and testing of the theory of chain reactions. In the study of the mechanism of complex chemical processes, each comprising the aggregate of a series of elementary reactions of atoms and free radicals with the starting materials and intermediate products, the question first arises of the nature and reactivity of the active particles responsible for development of the process.

At the outset of the development of the theory of branched chain reactions, the combustion of hydrogen provided the

example on which a quantitative check of the theory came to be made. This reaction, while being less complicated than others, nevertheless possessed many features in common with other complex reactions.

As a result of the great efforts made by investigators in various countries, the following most probable mechanism became generally accepted for the combustion of hydrogen at pressures not exceeding atmospheric

$$H_2+O_2 \rightarrow 2OH, \quad (0)$$

$$OH+H_2 \rightarrow H_2O+H, \quad (1)$$

$$H+O_2 \rightarrow OH+O, \quad (2)$$

$$O+H_2 \rightarrow OH+H, \quad (3)$$

$$H \xrightarrow{walls} {}^1/_2 H_2, \quad (4)$$

$$O \xrightarrow{walls} {}^1/_2 O_2, \quad (5)$$

$$H+O_2+M \rightarrow HO_2+M, \quad (6)$$

$$OH \xrightarrow{walls} {}^1/_2 H_2O_2. \quad (7)$$

It is assumed in this scheme that hydrogen and oxygen atoms and the hydroxyl radical are the active centres responsible for chain propagation and branching in mixtures of hydrogen and oxygen, i.e. for reactions (1)–(3).

Much was done by workers to prove that these active species were involved in the combustion of hydrogen. Indirect evidence of their important role is provided by experiments on the action of hydrogen and oxygen atoms on the range of ignition of hydrogen–oxygen mixtures and on the length of the induction periods preceding ignition.

It was shown in the Institute of Chemical Physics of the USSR Academy of Sciences that the effect of hydrogen atoms is to raise the upper limit of spontaneous ignition, while the range of ignition is displaced to lower temperatures [12]. The action of oxygen atoms is far stronger. In the presence of high concentrations of oxygen atoms, produced in an electric discharge, an upper limit cannot be detected. The ignition temperature of the reactant mixture falls from 400°C to room temperature [13]. It was also established [14] that the induction period preceding ignition is markedly shortened under the influence of hydrogen and oxygen atoms.

A great success of the theory of branched chain reactions was provided by the direct experimental proof of the formation of high concentrations of hydroxy-radicals in low-pressure flames of hydrogen with oxygen. Using the method of line absorption spectroscopy [15], Kondrat'ev and his collaborators [16–18] showed that, in a low-pressure hydrogen–oxygen flame at pressures somewhat exceeding that at the lower limit, the concentration of hydroxy-radicals is several thousand times as great as the equilibrium value under the conditions of the flame. Avramenko's investigations [18] showed that the reaction velocity, determined from the quantity of water formed, varies linearly with the total concentration of hydroxy-radicals.

Experimental results obtained in this work were used to determine the rate constant of reaction (1), which was

$$k_1 = 7\times10^{-12}\sqrt{T}\,e^{-\frac{10\,000}{RT}} \text{ cm}^3\,\text{s}^{-1}\,\text{mol.}^{-1},$$

Semenov [19] estimated the rate constant k_2 of the branching reaction (2) from Koval'skii's data [20]. Its activation energy was close to 18 kcal. The activation energy of reaction (3) was estimated as 6 kcal from experimental data obtained by Harteck and Kopsch [21] for two temperatures in a study of the interaction of atomic oxygen with hydrogen. The latest, more accurate data of Azatyan et al. [22] give values for the rate constants of the elementary reactions (2) and (3) of respectively

$$k_2 = 1.3\times10^{-10}e^{-\frac{16\,900}{RT}} \text{ cm}^3\,\text{s}^{-1}\,\text{mol.}^{-1}$$

$$k_3 = 1.1\times10^{-10}e^{-\frac{11\,700}{RT}} \text{ cm}^3\cdot\text{s}^{-1}\,\text{mol.}^{-1}.$$

According to the scheme given above for the combustion of hydrogen, the rates of reactions (1)–(3) are respectively

$$w_1 = k_1[OH][H_2];\ w_2 = k_2[H][O_2];\ w_3 = k_3[O][H_2].$$

For one intermediate temperature near which investigations are usually made, e.g. for $T = 600°$, the ratios of the rate constants can be written in the form

$$k_1[H_2]:k_2[O_2]:k_3[H_2] = \frac{k_1[H_2]}{k_2[O_2]}:1:\frac{k_3[H_2]}{k_2[O_2]} = 46\frac{(H_2)}{(O_2)}:1:7.6\frac{(H_2)}{(O_2)}.$$

For hydrogen-rich mixtures, e.g.

$$[H_2]:[O_2] = 9:1\quad k_1[H_2]:k_2[O_2]:k_3[H_2] = 415:1:68.$$

This means that the inequality

$$k_2[O_2] \ll k_3[H_2] \ll k_1[H_2]$$

should hold in very hydrogen-rich mixtures with oxygen.

The reciprocals of the rate constants

$$\frac{1}{k_1[H_2]};\quad \frac{1}{k_2[O_2]}, \text{ and } \frac{1}{k_3(H_2)},$$

measure the life of the corresponding active centres from the moment at which they appear until they undergo fresh reactions. Hence $t_H \gg t_O \gg t_{OH}$, where t is the life of the corresponding active species. From this inequality it follows that, in very hydrogen-rich mixtures, the concentration of hydrogen atoms should considerably exceed those of oxygen atoms and hydroxy-radicals. In an equimolecular mixture [H] > [O] > [OH]. In an $[H_2]:[O_2] = 1:9$ mixture, [O] > [H] > [OH].

Assuming the above mechanism as a basis, Semenov [23,24] studied in 1943 the kinetics of the burning of hydrogen-rich mixtures with oxygen at pressures somewhat exceeding that at the lower limit of spontaneous ignition. The investigations showed that under these conditions only the variation in the concentration of hydrogen atoms and their destruction on the walls of the reaction vessel need be taken into account. Changes with time in the concentrations of oxygen atoms and hydroxy-radicals can be neglected, since their concentrations are far lower than that of the hydrogen atoms. Simultaneous solution of the equations for time variation in the concentrations of atomic hydrogen and of one of the starting materials — oxygen — led Semenov to the important conclusion that large quantities of hydrogen atoms are formed in a low-pressure flame, the relative concentration of which may in some cases reach more than 20% of the initial hydrogen.

This cardinal conclusion of the theory was confirmed by experiments made by Kondrat'eva and Kondrat'ev [25], who used a thermoelectric probe method to detect hydrogen atoms and measure their concentration. Two fine thermocouples in very narrow thin-walled quartz sheaths were placed in a stationary low-pressure flame obtained under flow conditions. On the tip of the sheath of the first thermocouple was deposited a layer of $ZnOCr_2O_3$, a substance on which hydrogen atoms recombine at every collision. The tip of the second thermocouple was washed

with nitric acid, in order to minimise the recombination of atoms striking the surface. This thermocouple served to measure the flame temperature. These workers recorded temperature differences in the flame reaching under certain conditions 300 deg. This difference was obviously associated with the heat of reaction of atoms and radicals vigorously recombining on the surface of the thermocouple coated with $ZnOCr_2O_3$. From the equation which they deduced to link ΔT with the relative concentration ξ of hydrogen atoms, Kondrat'eva and Kondrat'ev obtained ξ = = 0.45. This value agrees very well with ξ = 0.51 calculated by means of Semenov's formula. It followed from the excellent agreement between the theoretical conclusions and experiment that, in very hydrogen-rich mixtures with oxygen, the lower ignition limit should be determined mainly by the two reactions of atomic hydrogen — the branching reaction $H + O_2 \rightarrow OH + O$ (2) and the loss of hydrogen atoms on the walls of the reaction vessel (4) — for the loss of oxygen atoms and hydroxy-radicals on the walls can be neglected under these conditions.

After 1930 it was increasingly remarked that the lower limit of spontaneous ignition depends not only on the diameter of the reaction vessel and on inert additions but also on the surface state and nature of the material of the reaction vessel[26-30]. This was allowed for in the theory of the lower limit by introducing a new parameter ϵ, the coefficient of recombination of active particles on the surface[31-33]. Variation in ϵ with surface state and material could be explained by the experimentally observed hundredfold variation in the pressure at the lower limit. At the same time several communications appeared in the literature[34,35] on the very strong action on the lower limit of thin metallic rods placed coaxially in the reaction space. The theory of this phenomenon was given by Semenov[33], who, on the hypothesis of an intense destruction of active centres on the surface of the thin rods, obtained an equation enabling the coefficient of recombination of the active centres to be linked with the lower limit and the diameters of reaction vessel and rod. The action of the thin rods on the lower limit of a stoichiometric mixture of hydrogen and oxygen was used[36] to determine the recombination coefficients of the active species. For this purpose thin rods ($d \simeq 0.1$ cm) of various substances were introduced by means of a movable electromagnet into a reaction vessel which had first been treated with $K_2B_4O_7$ (a substance on which recombination of hydrogen atoms is very poor), and the lower limits were determined in the absence and in the presence of the rods. The apparatus used is shown diagrammatically in Fig. 1. The ignition limit in these experiments was determined by rapidly admitting the mixture from the subsidiary volume B into the reaction vessel A. The rods were introduced and withdrawn by means of the movable electromagnet.

The results in Table 1 for a vessel having d = 1.83 cm show that the lower limit is raised to the greatest extent in the presence of rods coated with $ZnOCr_2O_3$ and made of graphite. The experimental data in Table 1 and the corresponding equations deduced on the basis of Semenov's theory were used to calculate the recombination coefficients ϵ of active particles on the surfaces investigated. The calculated results in Table 2 show that, depending on the material and state of the surface, the recombination coefficient may vary by factors of 10^4. The substances investigated can be arranged in a sequence according to their activity towards the recombination of active particles. The first place in this sequence is occupied by $ZnOCr_2O_3$ and graphite, which are followed by gold, platinum, tungsten, stainless steel, quartz which has been washed with HF solution, and finally Pyrex which has been treated with HF solution. In 1924 Bonhoeffer[37] studied the recombination of atomic hydrogen on various metals, and arranged the latter in the sequence — platinum, palladium, tungsten, iron, etc. — according to their activity. A comparison of this sequence with that obtained from experiments on the effect of the rods on the lower limit of ignition of hydrogen-rich mixtures with oxygen provides information on the identity of the recombining species.

TABLE 1.

Material of rod	Diameter of rod, cm	Temp., °C	Lower limit, mmHg, in vessel	
			without rod	with rod
Stainless steel	0.1	440	0.94	7.0
Gold	0.05	440	0.94	8.2
Tungsten	0.145	540	0.32	4.0
	0.1	440	0.53	10.3
Graphite	0.1	490	0.53	10.3
	0.1	530	0.42	7.8

An interesting phenomenon which clearly demonstrates the branched chain character of the combustion of hydrogen is that, if a hydrogen–oxygen mixture is transferred to a reaction vessel in which a graphite or other rod has previously been placed, ignition may be observed provided that the pressure of the mixture is higher than that of the lower limit p_1 in the presence of the rod. At pressures $p < p_1$ ignition does not occur: the mixture ignites only when the rod is withdrawn from the vessel. A rod placed in a reaction vessel may be likened to a powerful pump, which extracts all the hydrogen atoms from the reaction zone. On removal of the rod, the concentration of atomic hydrogen increases very rapidly, and the mixture ignites. By placing in the reaction vessel a series of rods of varying efficiency in bringing about the recombination of hydrogen atoms, it was possible to ignite the same mixture several

times by successively withdrawing rods from the reaction zone. The method described here of controlling the ignition of gaseous mixtures by means of rods strongly recalls the control of the radioactive disintegration of uranium nuclei by means of cadmium rods or boron steel rods, which strongly absorb fission neutrons. This analogy does not appear fortuitous when it is remembered that the above reaction of the combustion of hydrogen and the nuclear disintegration of uranium are both branched chain processes.

II. STUDY OF THE KINETICS AND MECHANISM OF THE COMBUSTION OF HYDROGEN AND CARBON MONOXIDE BY THE e.s.r. METHOD

1. Kinetics and Mechanism of the Combustion of Hydrogen at Low Pressures

The possibility of identifying directly all types of active centres involved in chain propagation in the oxidation of hydrogen, and of measuring their absolute concentrations, has appeared comparatively recently, after the discovery of the phenomenon of electron spin resonance (e.s.r.)[38] and construction of the appropriate instruments[39]. A great advantage of the e.s.r. method is that it permits the detection, without disturbance to the course of the reaction, not only of atoms but also of many radicals. The method was first used in the study of gas-phase chemical reactions, by Panfilov et al.[40] in the Institute of Chemical Physics of the USSR Academy of Sciences in 1960. They examined a low-pressure flame in hydrogen–oxygen mixtures with the aim of detecting atomic hydrogen and measuring its concentration. For this purpose they used the flow technique illustrated diagrammatically in Fig. 2. The low-pressure flame was established in a quartz tube *1* heated by the electric furnace *3*, placed directly above the EPR-12 cavity *2*. At pressures slightly exceeding that of the lower limit these workers found, in full agreement with Semenov's conclusions, immense concentrations of atomic hydrogen, which under certain conditions reached 10–15% of the initial hydrogen. Subsequently Panfilov[41] made a detailed study of the kinetics of the combustion of hydrogen as a function of the composition of the mixture. By measuring directly the concentration of hydrogen atoms and the variation in the concentration of molecular oxygen during the reaction, he showed that the rules deduced by Semenov, neglecting the wall destruction of oxygen atoms and hydroxy-radicals on the surface of the reaction vessel in hydrogen-rich mixtures, were completely satisfied.

The technique of using e.s.r. to study gas reactions has recently been considerably improved. It has become possible[42,43] to investigate low-pressure flames directly inside the e.s.r. cavity. Platinum wires (d = 0.2 mm) arranged along the walls of the reaction vessel and enclosed in a quartz sheath have been used to heat the reaction mixture. Such a reaction vessel, when placed inside an e.s.r. cavity, has hardly any effect on the Q factor of the latter, although the sensitivity of the instrument is slightly diminished. Tubes of larger diameter have come to be used[44], which enables flames to be obtained at lower pressures.

Using a reaction vessel heated with platinum filaments[43] and placed in an e.s.r. cavity, Balakhnin et al.[45] were in 1964 the first to observe the e.s.r. spectrum of oxygen atoms in a low-pressure hydrogen–oxygen flame (at 580° and 6 mmHg). The concentration of atomic oxygen proved to be very high. It depended greatly on the composition of the mixture. In a mixture containing ~ 15% of hydrogen and 85% of oxygen, atomic oxygen represents about 5% of the total pressure or 0.3 mmHg. The investigations showed that the concentration of oxygen atoms, while being greatest in oxygen-rich mixtures, fell as hydrogen was added. In an equimolecular mixture the concentrations of oxygen and hydrogen atoms are comparable, and in hydrogen-rich mixtures the concentration of hydrogen atoms far exceeds that of oxygen atoms. The first qualitative result obtained is fully consistent with conclusions drawn from an examination of the ratio of the kinetic constants described in the Introduction to the present Review.

In the same year 1964 Balakhnin et al.[46], employing a quartz reaction vessel with an absorbing cell completely filling the cavity, observed higher concentrations of hydroxy-radicals in low-pressure hydrogen–oxygen flames. Work with a new design of absorbing cell has shown[47-50] that the microwave absorption spectrum of hydroxy-radicals is due to electric dipole transitions, the intensity of which exceeds by several orders of magnitude that of the usual e.s.r. lines caused by magnetic dipole transitions. The concentration [configuration (?) (Ed. of Translation)] of the absorbing cell used enabled not only hydroxy-radicals but also hydrogen and oxygen atoms to be detected, since it covers antinodes both of magnetic and of electric components of the ultrahigh-frequency (UHF) field.

Fig. 3 gives the e.s.r. spectra of H and O atoms and OH and OD radicals recorded in low-pressure hydrogen–oxygen and deuterium–oxygen flames.

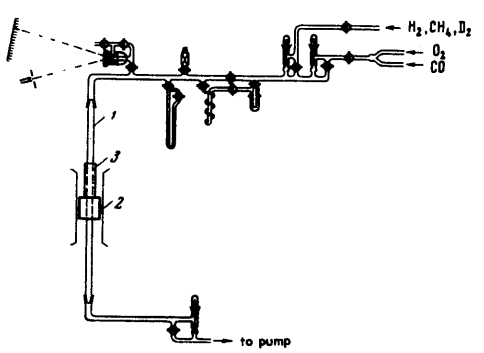

Fig. 2. Diagram of flow apparatus for the e.s.r. study of low-pressure flames.

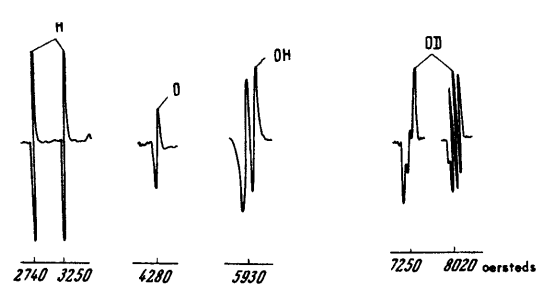

Fig. 3. Electron spin resonance spectra of H and O atoms and of OH and OD radicals obtained in low-pressure H_2–O_2 and D_2–O_2 flames.

The first stage has recently been completed[51] of investigations on the measurement of the absolute concentrations of hydrogen and oxygen atoms and hydroxy-radicals in low-pressure hydrogen–oxygen flames as functions of the composition of the mixture. In Fig. 4 the concentrations of hydrogen and oxygen atoms are plotted on the same scale, while for hydroxy-radicals the scale has been increased hundredfold. Fig. 4 also shows the variation in the quantity of water formed. The first striking feature is the parallelism between the curves for the variation in the concentration of hydroxyl and water, which pass through a maximum in the vicinity of the equimolecular composition. As noted in the Introduction, proportionality between the total concentration of hydroxyl and the quantity of water formed was at one time established by Avramenko. Such a relation arises directly from the mechanism of the oxidation of hydrogen, according to which the reaction velocity is given by the formula $w = k_1[OH][H_2]$. As was to be expected, the contribution of reaction (7), the destruction of hydroxyl on the walls, is negligible.

Fig. 4 shows that the concentration of atomic oxygen is a maximum for a mixture containing about 20% of hydrogen and 80% of oxygen. As the reactant gas is enriched with hydrogen, the concentration of oxygen atoms drops sharply. In a mixture containing 80% of hydrogen and 20% of oxygen, the concentration of oxygen atoms is $\sim 10^{14}$ cm^{-3}, while that of atomic hydrogen in this mixture is a maximum, amounting to approximately 1.3×10^{16} cm^{-3}, which exceeds the concentration of oxygen atoms by a factor of > 100. On replacement of part of the hydrogen by oxygen, the concentration of hydrogen atoms falls linearly. At the point corresponding to 20% H_2 + 80% O_2 the concentration of oxygen atoms exceeds that of hydrogen atoms by more than 50%. In an equimolecular mixture the concentration of hydrogen atoms exceeds that of oxygen atoms by a factor of about 10. However, in view of the fact that the rate constant for the destruction of oxygen atoms exceeds the corresponding constant for hydrogen atoms by a factor of about 5,[52] the heterogeneous recombination of oxygen atoms cannot be neglected. The greater rate of loss of oxygen atoms in comparison with hydrogen atoms is confirmed by curves *2* and *1* for the variation in their concentrations

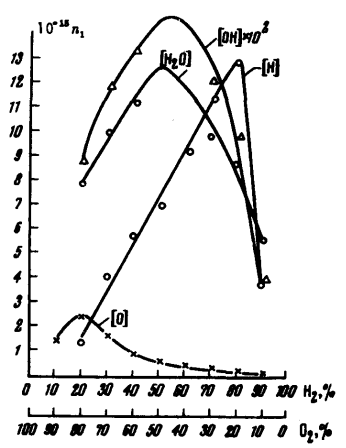

Fig. 4. Dependence of concentrations of H and O atoms and of OH radicals, and of the quantity of water formed, on the composition of the H_2–O_2 mixture.

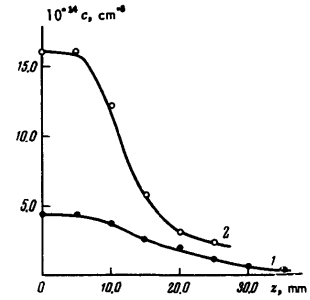

Fig. 5. Fall in concentration of atoms with distance between furnace and resonator: 1) H; 2) O.

with distance (Fig. 5), obtained by e.s.r. measurements[53] on the combustion products extractable from the reaction zone at a high linear velocity.

If the absolute concentrations of all the active centres in the combustion zone can be calculated[54–56], with simultaneous measurement of the quantity of water formed and of oxygen consumed, it will be possible to attempt to estimate the rate constants for the elementary reactions (1)–(3).

According to the above scheme for the burning of hydrogen, the reaction velocity is

$$\frac{d[H_2O]}{dt} = k_1[OH][H_2].$$

It is assumed that the contribution of reaction (7), loss of hydroxy-radicals on the walls, which also results ultimately in the formation of water, is small. By means of this equation, with the dependence of $[H_2O]$, $[OH]$, and $[H_2]$ on time of contact known, it is not difficult to calculate k_1. Such determinations have been made for an equimolecular mixture at p = 2.86 mmHg and four temperatures (900°, 943°, 993°, and 1052°K). The following expression was obtained for k_1

$$k_1 = (2 \pm 0.8) \times 10^{-10} e^{-\left(\frac{86\,100 \pm 1200}{RT}\right)} \text{ cm}^3 \text{ s}^{-1} \text{ mol.}^{-1},$$

which can be regarded as showing good agreement, within the limits of experimental error, with the value measured by Avramenko and Lorentso[57].

The rate constant k_2 of reaction (2) was calculated by means of the equation

$$\frac{d(O_2)}{dt} = -k_2[H][O_2].$$

Measurements were made, under the conditions described above, of the quantity of oxygen consumed and of the absolute concentrations of hydrogen atoms as functions of the time of contact. The value obtained for k_2 was

$$k_2 = (1.7 \pm 0.7) \times 10^{-10} e^{-\left(\frac{16\,600 \pm 1200}{RT}\right)} \text{ cm}^3 \text{ s}^{-1} \text{ mol.}^{-1},$$

which agrees well with many earlier determinations[22,58–63].

We have seen above that in hydrogen-rich mixtures with oxygen, $[H] \gg [O] \gg [OH]$. In this case the loss of oxygen atoms and hydroxy-radicals on the walls can be neglected, and hence it can be assumed that

$$\frac{d[O]}{dt} = \frac{d[OH]}{dt} = 0.$$

From the scheme for the combustion of hydrogen we have

$$\frac{d[O]}{dt} = k_2[H][O_2] - k_3[O][H_2] = 0, \quad (1)$$

$$\frac{d[OH]}{dt} = -k_1[OH][H_2] + k_2[H][O_2] + k_3[O][H_2] = 0. \quad (2)$$

Subtracting Eqn.(2) from (1), we obtain

$$\frac{[O]}{[OH]} = \frac{k_1}{2k_3}. \quad (3)$$

Measurements of this concentration ratio for hydrogen-rich mixtures showed that at 993°K and 2.55 mmHg its value was [O]/[OH] = 3. At this temperature $k_1 = 2.4 \times 10^{-12}$ cm^3 s^{-1}.

Eqn. (3) yielded for k_3 the value

$$k_3 = (0.3 \pm 0.1) \times 10^{-12} \text{ cm}^3 \text{ s}^{-1},$$

which is also close to that found previously by other workers [22,64].

2. Kinetics and Mechanism of the Combustion of Carbon Monoxide in the Presence of Small Additions of Hydrogen

Another system which obeys the laws of branched chain reactions is the combustion of carbon monoxide in the presence of small additions of hydrogen, water vapour, or any other substance which can act as hydrogen-donor. It is assumed [22,66,67] that the combustion of carbon monoxide in the presence of hydrogen at low pressures takes place in conformity with the above scheme for the combustion of hydrogen, except that reaction (1) is replaced by the reaction

$$OH + CO \rightarrow CO_2 + H, \quad (8)$$

in which the same chain carriers — hydrogen and oxygen atoms and hydroxy-radicals — are assumed as before. The rate constants of almost all the elementary reactions are known.

It is readily seen that, when the added hydrogen constitutes a few or a fraction of one per cent of the whole mixture, reaction (3), together with the chain-branching reaction (2), becomes rate-determining. Under these conditions the rates of reactions (2) and (3) are comparable. Similar considerations [22] show that, with low H_2 contents in the mixture, reaction (5) — the loss of oxygen atoms on the surface of the reaction vessel — begins to compete with reaction (3). Hence follows the necessity for taking into account reaction (5) together with the loss of hydrogen atoms. The contribution of reaction (7) is very small in comparison with that of reaction (8), which occurs at a very high rate (high rate constant [57]

$$k_8 = 4.8 \times 10^{-13} \sqrt{T}\, e^{-\frac{5700}{RT}} \text{ cm}^3 \text{ s}^{-1},$$

and high concentration of carbon monoxide).

It is to be expected from the above that the concentration of hydrogen and oxygen atoms would be comparable, and that of hydroxy-radicals considerably lower. With the appearance of the e.s.r. method it became possible to test quantitatively the scheme for the combustion of carbon monoxide. Investigations were first made of low-pressure carbon monoxide–oxygen flames containing various quantities of hydrogen. A flow-type apparatus was used with a quartz reaction vessel heated by an electric furnace. Active particles were sought among the reaction products about 10 mm below the end of the electric furnace. A stoichiometric mixture of carbon monoxide and oxygen was studied, with variation in the amount of hydrogen added, in the temperature of the vessel from 580° to 700°, and in the pressure of the reacting gases from 2 to 10 mm. Hydrogen atoms were first detected in a $2CO + O_2 + xH_2$ mixture by Azatyan et al. [68] in 1961. Measurements made by these workers showed that, when the partial pressure of hydrogen is varied from 0.06 to 0.39 mmHg, with a total pressure of the reactant gas of 4.3 mmHg, the partial pressure of hydrogen atoms varies from 0.04 to 0.1 mmHg, which constitutes some 10% of the initial hydrogen concentration.

In the same year 1961 Azatyan et al. [69] observed high concentrations of atomic oxygen with the reaction vessel at 607–650° and 5.5 mmHg, and measured the concentration of atomic hydrogen under the same conditions. At low hydrogen contents the concentration of atomic oxygen exceeded that of atomic hydrogen. With increase in the hydrogen content, the concentration of oxygen atoms rapidly reached a maximum and then fell sharply, while the concentration of atomic hydrogen steadily increased, becoming several times greater than that of oxygen atoms. In some cases the sum of the partial pressures of hydrogen and oxygen atoms reached 2% of the total pressure.

Quite recently, in 1965, Gershenzon et al. [70], using a reaction tube with an expanded portion which completely fills the e.s.r. cavity, have observed large concentrations of hydroxy-radicals among the products of the combustion of carbon monoxide in the presence of hydrogen.

The distribution curves for all active species measured in this work are reproduced in Fig. 6, from which it is seen that the concentration of hydroxy-radicals is much lower than those of hydrogen and oxygen atoms, which are comparable. At low contents of molecular hydrogen the concentration of oxygen atoms exceeds that of hydrogen atoms. Thus all types of active centres responsible for the development of a branched chain reaction have been detected in the carbon monoxide–oxygen system containing small additions of molecular hydrogen, and their absolute quantities have been measured. The concentrations of these species were in qualitative agreement with estimated values obtained on the basis of the known rate constants for the elementary reactions (8), (2), and (3).

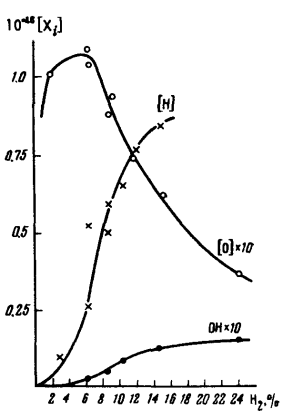

Fig. 6. Variation in concentration of H and O atoms and of OH radicals in $2CO + O_2$ mixture with percentage content of hydrogen.

On the basis of the values obtained for almost all the rate constants of the elementary reactions constituting the mechanism of the combustion of hydrogen at pressures close to the lower ignition limit, the first attempt was made to describe the kinetics of the combustion of these mixtures in the spontaneous ignition peninsula. For this purpose the following system of kinetic equations was set up to describe the time variation in all the starting materials and intermediate products

$$\frac{\partial [H]}{\partial t} = k_1[OH][CO] - k_2[H][O_2] + k_3[O][H_2] + D_H\Delta^2[H];$$

$$\frac{\partial [O]}{\partial t} = k_2[H][O_2] - k_3[O][H_2] + D_O\Delta^2[O];$$

$$\frac{\partial [OH]}{\partial t} = 2k_2[H_2][O_2] - k_1[OH][CO] + k_2[H][O_2] + k_3[O][H_2] + D_{OH}\Delta^2[OH];$$

$$\frac{\partial [CO]}{\partial t} = -k[OH][CO];$$

$$\frac{\partial [O_2]}{\partial t} = -k_0[H_2][O_2] - k_2[H][O_2];$$

$$\frac{\partial [H_2]}{\partial t} = -k_0[H_2][O_2] - k_3[O][H_2],$$

at $t = 0$, we have $[H] = [O] = [OH] = 0$. The boundary conditions are[33] $n_w \pm S(du/dx)_w = 0$, where n_w is the concentration of active centres near the wall and $S = 4\lambda/3\epsilon$, λ being the mean free path and ϵ the coefficient of destruction of active particles.

This set of differential equations cannot be solved analytically. It has been studied on an EVM-20 electronic computer.

The mixture $2CO + O_2$ was examined[70] with a content of molecular hydrogen varying from 1.5% to 10% at a total pressure of 1–8 mmHg and at the three temperatures 853°, 893°, and 923°K. The diameter of the reaction tube was 10 mm.

The first three equations of the above set contain diffusion terms representing the loss of active centres on the walls. In solving the system, the question arose of the possibility of replacing it by the simpler term $k(x)$, where k is the rate constant of heterogeneous chain termination and (x) the concentration of active centres. In the diffusion-controlled range of the loss of active centres, we have[24,71] $k = 23.2D/d^2$, where D is the diffusion coefficient of the active centres and d the diameter of the reaction vessel. In the kinetically controlled region of heterogeneous chain termination, $k = \epsilon u/d$ where ϵ is the recombination coefficient of active particles on the surface of the reaction vessel and u their thermal velocity. As long ago as 1931 Bursian and Sorokin showed[72] that, when the extent of combustion of the starting materials was small, i.e. in the initial stages of the process, such substitution is permissible, provided that the reaction velocity is limited by the reaction of one type of active centre, which is destroyed at each collision with the wall.

In 1943 Semenov[33] showed that such substitution was also possible when the rate-controlling active centre recombines on the wall in the kinetically controlled range, i.e. when $k = \epsilon u/d$. In order to establish the possibility of such substitution with more than one rate-controlling active centre (in this case three) and when the burning-up of the starting materials is not neglected, the solution was undertaken of the two sets of differential equations, with diffusion terms and with $k(x)$ terms. Values for the rate constants of the elementary reactions employed in the combustion of hydrogen (Table 3) were used in the solution.

TABLE 3.

Reaction	Value of constant	Ref.
$H_2 + O_2 \rightarrow 2OH$	$10^{-12} e^{-\frac{45\,000}{RT}}$ cm³ s⁻¹	24
$OH + CO \rightarrow CO_2 + H$	$4.8\times10^{-13}\sqrt{T}\,e^{-\frac{5700}{RT}}$ cm³ s⁻¹	57
$OH + H_2 \rightarrow H_2O + H$	$7\times10^{-12}\sqrt{T}\,e^{-\frac{10\,000}{RT}}$ cm³ s⁻¹	57
$H + O_2 \rightarrow OH + O$	$1.3\times10^{-10} e^{-\frac{15\,900}{RT}}$ cm³ s⁻¹	22
$O + H_2 \rightarrow OH + H$	$1.1\times10^{-10} e^{-\frac{11\,700}{RT}}$ cm³ s⁻¹	22
walls $H \rightarrow {}^1/_2 H_2$	$13.1\sqrt{T}\,e^{-\frac{5400}{RT}}$ s⁻¹	52
walls $O \rightarrow {}^1/_2 O_2$	$60\sqrt{T}\,e^{-\frac{6100}{RT}}$ s⁻¹	52
walls $OH \rightarrow {}^1/_2 H_2O_2$	$k_7 = k_5$	

The value of k_7 at high temperat res being unknown, it was taken to be equal to k_5.

Fig. 7 illustrates the solutions as the variation of the concentrations of active species with time. The points represent the solution of the simplified system. Agreement is seen to be good throughout the curves. Consequently replacement of the diffusion terms by $-k(x)$ is permissible in this case, too. In conformity with the branched chain character of the reaction, the curves representing the growth in active particles with time show an induction period, which becomes shorter with rise in temperature and in pressure. The concentration of active centres rapidly reaches a maximum, and then falls slowly. At points corresponding to maximum populations of the active centres, the concentrations of hydrogen and oxygen atoms are comparable, while the concentration of hydroxy--radicals is considerably lower. At small hydrogen concentrations the concentration of oxygen atoms exceeds that of hydrogen atoms. All these results agree well with experimental data, which is evidence of the correctness of the rate constants used for the individual elementary reactions in solving the set of equations.

An attempt was made to vary the rate constants — k_4, k_5, and k_7 — for the loss of active centres. When operating in the kinetically controlled range of heterogeneous chain termination, the surface of the reaction vessel was

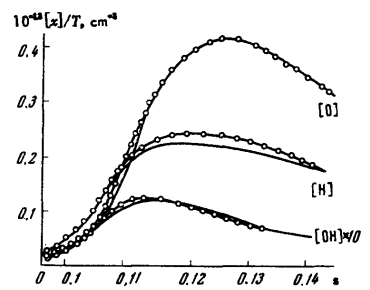

Fig. 7. Kinetics of the formation of active species in the $2CO + O_2 + 1.5\% H_2$ flame (theoretical curves).

quite often changed from one experiment to another, which directly affected the recombination constants. Analysis showed that the magnitude of the constant k_5, for the loss of oxygen atoms on the walls, had the greatest effect, with small additions of hydrogen, on the concentration of all types of active centres. The probable reason is that under these conditions the rate of reaction (3) considerably exceeds the rate of branching (2).

III. METHOD OF DETERMINING RATE CONSTANTS OF THE PRIMARY REACTIONS OF HYDROGEN AND OXYGEN ATOMS WITH VARIOUS COMPOUNDS

A good knowledge of detailed mechanisms of the combustion of hydrogen and carbon monoxide in the vicinity of their limits of spontaneous ignition enabled Azatyan et al.[22] to propose a new, improved method for determining the rate constants of the elementary reactions of hydrogen and oxygen atoms with various substances. The method is based on a remarkable property of chain processes, their high sensitivity to chemically active impurities. It is well known that minute additions of such substances are able to change sharply the reaction velocity, increasing or decreasing it several hundredfold or thousandfold. Thus, for example, small additions of iodine vapour to a mixture of hydrogen and oxygen can markedly diminish the rate of burning of hydrogen and considerably narrow the range of spontaneous ignition[73]. Fig. 8 gives the upper limit of ignition for a hydrogen–oxygen mixture (curve *1*) as a function of temperature. Curves *2* and *3* have been obtained for the same mixture but containing 0.004% and 0.006% of iodine. The lowering of the limit is obviously associated with the bulk removal of hydrogen atoms: $H + I_2 \rightarrow HI + I$. The iodine atom is known to be considerably less active than the hydrogen atom, and is unable to continue the hydrogen-oxidation chain.

Small additions of hydrocarbons, aldehydes, alcohols, acids, and many other substances have similar effects to iodine on the rate of burning of hydrogen. The action of various quantities of ethane on the lower limit of spontaneous ignition of the mixture $4H_2 + O_2$ can be cited as an example of the inhibiting action of small additions of a hydrocarbon[74]. It is seen from Fig. 9 that the lower limit gradually rises with increasing content of ethane in the mixture.

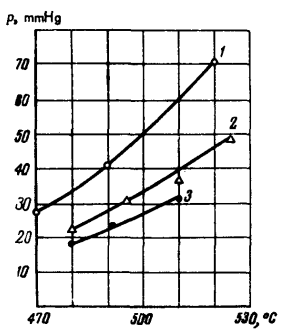

Fig. 8. Effect, on the upper ignition limit of $2H_2 + O_2$, of small additions (%) of iodine vapour:
1) 0; 2) 0.004; 3) 0.006.

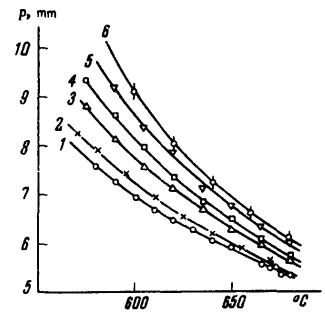

Fig. 9. Temperature dependence of lower ignition limit of $4H_2 + O_2 + xC_2H_6$ mixture for different values of x (%):
1) 0; 2) 0.0995; 3) 0.2006; 4) 0.3004; 5) 0.4070; 6) 0.4982.

Very clear cases exist of the promotion of burning by the presence of small additions of active substances. Such an example is provided by the combustion of carbon monoxide in oxygen containing small amounts of hydrogen, which we have examined previously[22,75]. As is known, an absolutely dry mixture of carbon monoxide and oxygen does not ignite, or does so, if at all, under different pressure and temperature conditions. However, it is sufficient to add a few per cent of hydrogen or water vapour to make the mixture readily ignitable. Fig. 10 illustrates how a carbon monoxide–oxygen mixture can be more readily ignited as the concentration of hydrogen added to it increases[22,75]. It was found that not only hydrogen and water vapour but also all compounds whose molecules contain hydrogen — all hydrocarbons and many other substances — possess these properties. As example of the promoting action of small additions we may cite the dependence of the lower carbon monoxide–oxygen limit on the presence of ethane[76]. It is seen from Figs. 9 and 11 that additions of ethane inhibit burning in one system and promote it in another. This dual effect of the same substance on rate of burning was found not only for different systems but also in the

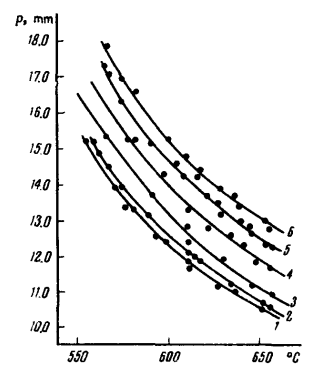

Fig. 10. Temperature dependence of lower limit of $2CO + O_2 + xH_2$ mixture for different values of x (%):
1) 3.79; 2) 3.28; 3) 2.14; 4) 1.48; 5) 1.06; 6) 0.78.

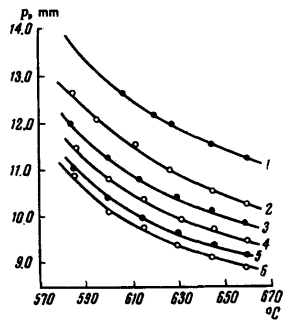

Fig. 11. Temperature dependence of lower ignition limit of $2CO + O_2 + xC_2H_6$ mixture for different values of x (%): 1) 0.0225; 2) 0.0389; 3) 0.0555; 4) 0.074; 5) 0.097; 6) 0.141.

same system[75,76]. If, for example, the concentration of ethane in the carbon monoxide–oxygen reactant mixture is further increased, a point is reached at which the limit begins to rise[76], as is well seen from Fig. 12. The dual effect of the simplest hydrocarbon, methane, on the lower carbon monoxide–oxygen limit was first reported in Ref. 77.

Let us consider in sequence the causes of the inhibiting action of small additions of active impurities on the combustion rate of hydrogen and its limits, and the dual effect of these substances on the combustion of carbon monoxide and oxygen and its lower limit of spontaneous ignition. The work of Voevodskii and Tikhomirova[78] simultaneously with that of Baldwin[59] showed that the inhibiting action of ethane and other hydrocarbons on the hydrogen–oxygen ignition limits is due to the additional homogeneous loss of hydrogen atoms by the reaction

$$H + C_2H_6 \rightarrow H_2 + C_2H_5. \quad (9)$$

followed by the reaction

$$C_2H_5 + O_2 \rightarrow C_2H_4 + HO_2. \quad (10)$$

The result of reactions (9) and (10) is to replace an active hydrogen atom by a relatively inactive HO_2 radical.

Investigations of low-pressure hydrogen–oxygen flames by the e.s.r. method show that the concentration of all

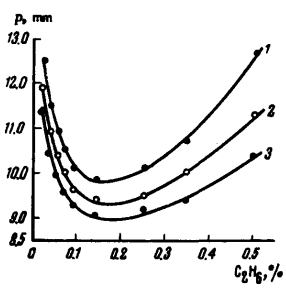

Fig. 12. Dependence of lower limit of spontaneous ignition of $2CO + O_2$ on percentage of C_2H_6 in mixtures at (°C): 1) 610; 2) 630; 3) 650.

active species — carriers of the chain oxidation of hydrogen — drops sharply on addition of the inhibitor. In this connection, the condition for the lower ignition limit in hydrogen-rich mixtures with oxygen must be written

$$2k_2[O_2][H] = k_4[H] + k_9[RH][H].$$

The left-hand side determines the rate of branching, and the right-hand side is the sum of terms determining the rates of loss of hydrogen atoms on the walls and in bulk. Hence the concentration of oxygen at the lower limit $[O_2]$ is determined by the equation

$$[O_2] = \frac{k_4}{2k_2} + \frac{k_9}{2k_2}[RH], \quad (A)$$

from which it is seen that, in full agreement with experiment, additions of an active impurity tend to raise the lower limit. When $[RH] = 0$, we have $[O_2] = k_4/2k_2$, the ratio of the rate constants for loss [of atomic hydrogen] (4) and branching (2).

The accelerating effect of small additions of various compounds RH, which act as hydrogen-donors in the combustion of carbon monoxide, can be explained by the following reactions of chain propagation and branching

$$OH + CO \rightarrow CO_2 + H, \quad (8)$$
$$H + O_2 \rightarrow OH + O, \quad (2)$$
$$O + RH \rightarrow OH + R. \quad (11)$$

Thus it is suggested that atomic oxygen, on interaction with the active additive, abstracts a hydrogen atom from the latter to form a hydroxy-radical. The flame of a carefully purified and dried mixture of carbon monoxide and oxygen has been studied by the e.s.r. method in the presence of over a score of different hydrogen-donors. The additives comprised methane, ethane, propane, butane, ethylene, propene, methanol, ammonia and several of its derivatives, and many other compounds[75,79,82]. In all cases large concentrations of hydroxy-radicals and hydrogen and oxygen atoms were detected, which increased as the impurity content increased to a certain value [RH] depending on the temperature and the nature of the additive. The inhibiting action of high concentrations [RH] is obviously due to reaction (9), which results in the bulk loss of hydrogen atoms. The e.s.r. measurements show that the concentration [RH] at which the limit begins to increase is followed by a sharp drop in the concentration of hydrogen and oxygen atoms and hydroxy-radicals[80].

The combustion of carbon monoxide in the presence of an active impurity RH can be represented by the sequence of elementary reactions (1)–(9). Mathematical analysis of the scheme by means of Semenov's method of steady-state concentrations[83] yields the following final expression for the ignition condition[76]

$$[O_2]_l^{CO} = \frac{k_4}{k_2}\left(1 + \frac{k_9[RH]}{k_4}\right)\left(1 + \frac{k_5}{k_{11}[RH]}\right), \quad (B)$$

from which it follows, in complete agreement with experiment, that the lower limit should have a high value in a mixture of carbon monoxide and oxygen ($[RH] \rightarrow 0$). With addition to it of an active impurity RH, the pressure at the lower ignition limit will fall with [RH] until reaction (9) begins to compete with reaction (2). With further increase in the impurity content beyond this concentration [RH], which can be termed a critical concentration, the lower limit begins to rise. When hydrogen is the added substance, this condition is written[22]

$$[O_2]_l^{CO} = \frac{k_4}{2k_2}\left(1 + \frac{k_5}{k_3[H_2]}\right), \quad (C)$$

where $[O_2]_1^{CO}$ is the oxygen concentration at the lower limit of the carbon monoxide–oxygen mixture containing various additions of hydrogen, and the k are the rate constants of the corresponding elementary reactions.

Unlike the method based on determination of lower limits in the kinetically controlled region of heterogeneous chain termination[84], the reaction is conducted in the diffusion-controlled region of heterogeneous destruction of active centres in the proposed method[75]. An advantage of this is the excellent reproducibility and the associated far greater accuracy of the constants obtained. Azatyan's detailed investigations[76] have shown that chain termination in the diffusion-controlled region is completely ensured by coating the walls of the reaction vessel with magnesium oxide. Let us examine the principle underlying the determination of the rate constants of reactions (9) and (3), with the combustion of hydrogen-rich mixtures with oxygen and of carbon monoxide–oxygen mixtures containing small additions of hydrogen as examples, for which purpose we consider in succession the equations to the lower limit (A) and (B), in which the heterogeneous chain-termination constants k_4 and k_5 can be calculated[75]. With cylindrical vessels

$$k = \frac{23.2\,D}{d^2} = \frac{23.2}{d^2} D_{stp} \frac{760}{(273)^{1.5}} \frac{T^{1.5}}{p} \quad \text{or} \quad k = k^0 \frac{T^{1.5}}{p}$$

where

$$k^0 = \frac{23.2}{d^2} D_{stp} \frac{760}{(273)^{1.5}}, \qquad (D)$$

D_{stp} being the diffusion coefficient of the corresponding active centre at standard temperature and pressure. Substituting for k_4 and k_5 in Eqn. (A) and replacing concentrations by pressure, we can rewrite the equation for the lower limit in a hydrogen-rich mixture with oxygen in the form

$$pp_{O_2} = \frac{k_4^0 T^{2.5}}{2k_2 \times 10^{19}} \left[1 + \frac{k_9 \times 10^{19}}{k_4^0 \times T^{2.5}} pp_{RH} \right]$$

where p is the pressure of the reactant mixture at the limit, and p_{O_2} and p_{RH} are the pressures of oxygen and the added impurity at this limit. When plotted as pp_{O_2} against pp_{RH} this is the equation to a straight line.

Fig. 13 shows the series of straight lines obtained by recalculating the lower limits as a function of temperature for the various additions of ethane shown in Fig. 9. The experimental points are seen to fit well on straight lines for the different temperatures. These straight lines make intercepts $a = k_4^0 T^{2.5}/2 \times 10^{19} k_2$ on the ordinate axis, and have a slope of $\tan\alpha = k_9/2k_2$. Dividing the latter by the former and taking logarithms, we obtain

$$\log \frac{\tan\alpha \cdot T^{2.5}}{a} = \log \frac{k_9^0 \cdot 10^{19}}{k_4^0} - \frac{E_9}{4.57} \times \frac{1}{T}$$

which represents a linear variation of $\log [T^{2.5}(\tan\alpha)/a]$ with $1/T$. Results calculated from the data in Fig. 13 are plotted in Fig. 14. In this case, too, the points lie on a straight line. From the slope of the straight line we can readily determine E_9, the activation energy of reaction (9), and from the intercept we can find k_9^0.

In this way rate constants have been determined for many elementary reactions of atomic hydrogen with molecules of various active impurities added to a hydrogen–oxygen mixture. A test of the method is provided by the boundary condition (A): at [RH] = 0 the intercepts a (Table 4) made by the straight lines on the ordinate axis at

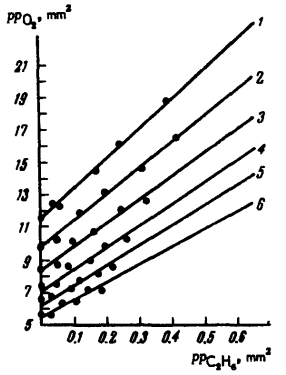

Fig. 13. Dependence of pp_{O_2} on $pp_{C_2H_6}$ at (°C):
1) 580; 2) 600; 3) 620; 4) 640; 5) 660; 6) 680.

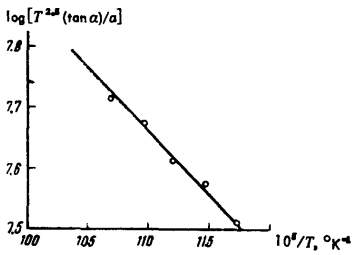

Fig. 14.

TABLE 4.

T, °C	a, mm³	$p^{H_2}p^{H_2}_{O_2}$, mm³
580	11.6	11.6
600	9.8	9.70
620	8.3	8.4
640	7.10	7.40
660	6.20	6.5
680	5.50	5.60

different temperatures should be identical with the product $p^{H_2}p^{H_2}_{O_2}$. The scatter of the values given as example in Table 4 is seen to be small.

The method can also be tested by the value of the branching rate constant k_2, which can be determined from the relationship $a = k_4^0 T^{2.5}/2 \times 10^{19} k_2$ and compared with the published value. This relationship can be rewritten in the form

$$\log \frac{a}{T^{2.5}} = \log \frac{k_4^0}{2k_2^0 \cdot 10^{19}} + \frac{E_2}{4.57} \times \frac{1}{T}.$$

The variation required by the equation is shown in Fig. 15, values of a having been taken from Table 4. The slope of the resulting straight line was used to calculate E_2, and the intercept on the ordinate axis gave k_2^0. The overall formula obtained for the constant was

$$k_2 = 2.1 \times 10^{-10} e^{-\frac{16\,600}{RT}} \text{ cm}^3\,\text{s}^{-1}\,\text{mol.}^{-1},$$

in good agreement with the corresponding published value.

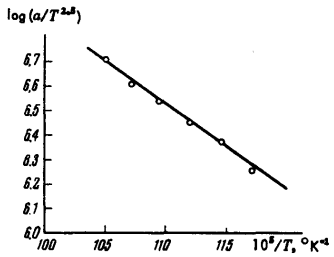

Fig. 15.

Let us now consider the method of determining the rate constant of reaction (3), for which purpose we use Eqn. (C) for the lower limit of ignition of a carbon monoxide–oxygen mixture in the presence of hydrogen. Substituting for k_4 and k_5, and replacing the concentrations $[O_2]^{CO}$ and $[H_2]$ by pressures, we can write the equation in the form

$$pp_{O_2} = \frac{(k_4^0)^{CO} \cdot T^{2.5}}{2k_2 \cdot 10^{19}} \left[1 + \frac{(k_5^0)^{CO} \cdot T^{2.5}}{k_3 \cdot 10^{19} \cdot pp_{H_2}} \right],$$

where p is the pressure at the lower limit of $2CO + O_2 + xH_2$, and p_{O_2} and p_{H_2} are the partial pressures of oxygen and hydrogen at this limit. The superscript CO attached to k_4^0 and k_5^0 indicates that these parameters relate to the above mixture. When plotted as pp_{O_2} against $1/pp_{H_2}$, this equation represents a straight line.

Fig. 16 shows the results of analysing the experimental data plotted in Fig. 10, and gives the temperature dependence of the lower ignition limit with various contents of hydrogen in the $2CO + O_2$ reactant mixture. The experimental data are seen to fit the corresponding curves well in Fig. 16. These curves make intercepts $b = k_4^0 T^{2.5}/2 \times 10^{19} k_2$ on the ordinate axis, and the slope of the straight lines is

$$\tan\alpha = \frac{(k_4^0)^{CO} \cdot T^{2.5}}{2k_2 \cdot 10^{19}} \times \frac{(k_5)^{CO} \cdot T^{2.5}}{k_3 \cdot 10^{19}}.$$

The logarithm of their ratio is

$$\log \frac{\tan\alpha}{b \cdot T^{2.5}} = \log \frac{(k_5^0)^{CO}}{10^{19} \cdot k_3^0} + \frac{E_3}{4.57} \cdot \frac{1}{T},$$

where E_3 is the activation energy of reaction (3), and k_3^0 is the preexponential factor.

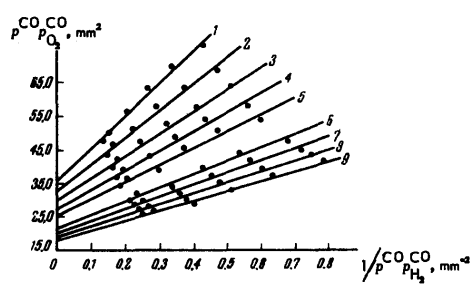

Fig. 16. Dependence of pp_{O_2} on $1/pp_{H_2}$ at (°C): 1) 570; 2) 580; 3) 590; 4) 600; 5) 610; 6) 630; 7) 640; 8) 650; 9) 660.

Fig. 17 shows that the dependence of $\log[(\tan\alpha)/bT^{2.5}]$ on $1/T$ calculated from the data plotted in Fig. 16 fit well on a straight line in this case, too. The slope of the line gave E_3, and the intercept on the vertical axis k_3^0. The expression obtained for the rate constant of the reaction was

$$k_3 = 1.1 \times 10^{-10} e^{-\frac{11\,700}{RT}} \text{ cm}^3 \text{ s}^{-1} \text{ mol.}^{-1}.$$

The value obtained[22] of E_3 = 11.7 kcal mole^{-1} considerably exceeds that calculated from the experiments of Harteck and Kopsch, and is somewhat higher than that given in Ref. 64. As has been shown above, the best agreement with experiment is obtained in fact with this value of E_3.

Let us consider the significance of the intercepts b made by the straight lines on the ordinate axis (Fig. 16) in the case of carbon monoxide–oxygen mixtures containing small additions of hydrogen. Writing Eqn. (D) for carbon monoxide–oxygen mixtures containing small additions of hydrogen and also for hydrogen–oxygen mixtures, and dividing the former by the latter, we obtain

$$(k_4^0)^{CO} = (k_4^0)^{H_2} \frac{(D_{stp})^{CO}}{(D_{stp})^{H_2}},$$

where $(D_{stp})^{CO}$ and $(D_{stp})^{H_2}$ are the respective diffusion coefficients of hydrogen atoms in the two mixtures under normal conditions. Substituting $(k_4^0)^{CO}$ in the formula for b, we have

$$b = \frac{(k_4^0)^{H_2} \cdot T^{2.5}}{2k_2 \cdot 10^{19}} \cdot \frac{(D_{stp})^{CO}}{(D_{stp})^{H_2}},$$

or, since

$$\frac{(k_4^0)^{H_2} \cdot T^{2.5}}{2k_2 \cdot 10^{19}} = p^{H_2} \cdot p_{O_2}^{H_2},$$

$$b = p^{H_2} \cdot p_{O_2}^{H_2} \cdot \frac{(D_{stp})^{CO}}{(D_{stp})^{H_2}}.$$

This means that the straight lines should make intercepts on the vertical axis[75] which are numerically equal to the product $p^{H_2} p_{O_2}^{H_2}$ at the lower limit of the hydrogen–oxygen mixture multiplied by the ratio of the diffusion coefficients of hydrogen atoms in the $CO + O_2 + xH_2$ and $H_2 + O_2$ mixtures. (When considering the lower limits of hydrogen–oxygen mixtures in the presence of RH, it was obviously necessary to take into account the appropriate correction D^{RH}/D^{H_2}. Since, however, the diffusion coefficients of hydrogen atoms in a hydrogen–oxygen mixture are very little changed by the addition of up to 1% of RH, this ratio can be taken as unity.) Azatyan's calculations showed[75] that $D^{CO}/D^{H_2} \simeq 0.72$. Comparison of the lengths of the intercepts b with the corresponding product obtained from

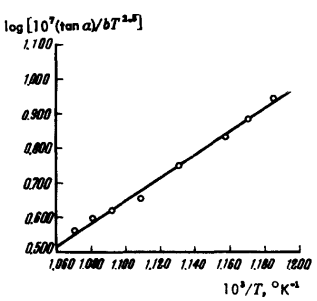

Fig. 17.

direct measurements of the lower limit of spontaneous ignition of hydrogen–oxygen mixtures, with the correction D^{CO}/D^{H_2} taken into account, showed good agreement between experiment and calculation. The temperature dependence of b was used to calculate the rate constant of reaction (2) as

$$k_2 = 1.3 \times 10^{-10} e^{-\frac{15\,900}{RT}} \text{ cm}^3 \text{ s}^{-1} \text{ mol.}^{-1}.$$

Eqn. (B) must be used[85] to determine the rate constants of elementary reactions of the type (11). This equation contains, besides the unknown constant k_{11}, the rate constant k_9 of the reaction $H + RH \rightarrow H_2 + R$, which is found from experimental results on the dependence of the lower limit of hydrogen-rich mixtures with oxygen containing RH as impurity. In several cases the radical R, formed in reactions (9) and (11), may interact with oxygen to form a new active centre in the main oxidation chain:

$$R + O_2 \rightarrow R'CHO + OH. \qquad (12)$$

As a result, the condition for the lower limit will contain, together with the required constant k_{11}, the additional unknown factor $k_9/(k_9 + k_{10})$.

A method which has been suggested[75] for eliminating this factor is to consider simultaneously the conditions of the lower ignition limits for the mixtures $H_2 + O_2 + xRH$ and $CO + O_2 + xRH$ deduced with reaction (12) taken into account. Table 5 gives values for the rate constants of elementary reactions of hydrogen and oxygen atoms with the molecules of several compounds, determined from the displacement of the lower limits of hydrogen–oxygen and carbon monoxide–oxygen mixtures in the presence of small additions of these compounds.

IV. USE OF e.s.r. METHOD TO ESTABLISH THE SITE AT WHICH ATOMIC OXYGEN ATTACKS A COMPLEX MOLECULE

The e.s.r. method, applied to low-pressure flames, enables us to establish the point at which a complex molecule is attacked by atomic oxygen, as has been shown in the case of the methanol molecule[81]. A low-pressure carbon monoxide–oxygen flame has been studied in the presence of small additions of methanol. It was first shown that small additions of the latter, as of other hydrogen-donors, depress the lower ignition limit. Fig. 18 illustrates the dependence of the lower limit on the methanol content for two temperatures. The low-pressure flames in $2CO + O_2 + xCH_3OH$ mixtures were investigated in an apparatus of the type illustrated in Fig. 2. Previously dried and

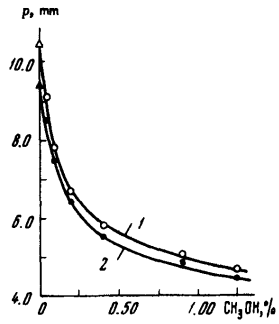

Fig. 18. Dependence of lower limit of spontaneous ignition of $2CO + O_2$ mixture on percentage content of methanol at (°C): 1) 670; 2) 690.

purified carbon monoxide was bubbled through methanol at 6°C, after which it was passed through a coil immersed in a thermostat at 0°C. The carbon monoxide saturated with the methanol vapour at 0°C was mixed through a regulating valve with a stream of carbon monoxide and oxygen, which had also first been purified and dried. The percentage of the alcohol in the stream was varied by changing the flow of carbon monoxide bubbled through it. Experiments were made over the temperature range 685–755°C at pressures of 3–7.4 mmHg with an initial alcohol content in the mixture of 0.86–1.7%. In all cases large quantities of hydroxy-radicals and hydrogen and oxygen atoms were observed in the flame. The presence of active species in the flame, as well as the depression of the lower limit with increasing concentration of methanol in the mixture, indicates that, as with the above promoters of the burning of carbon monoxide, the effective rate of chain branching is limited by the reaction of atomic oxygen with methanol, so that the mechanism of the combustion of carbon monoxide in the presence of methanol can be represented by the sequence of reactions

$$OH + CO \rightarrow CO_2 + H,$$
$$H + O_2 \rightarrow OH + O,$$
$$O + CH_3OH \rightarrow OH + CH_2OH \quad \text{or} \quad O + CH_3OH \rightarrow OH + CH_3O,$$
$$H \xrightarrow{\text{walls}} {}^1/_2 H_2,$$
$$O \xrightarrow{\text{walls}} {}^1/_2 O_2,$$
$$H + CH_3OH \rightarrow H_2 + CH_2OH.$$

It was stated above that hydroxy-radicals enter very rapidly into reaction (8). Hence by adding small quantities of CH_3OD or CD_3OH to the reacting mixture and determining the ratio of OH to OD, it might be possible to assess the point of attack. Since the maximum magnetic field strength in the EPR-2 apparatus does not exceed 6000 oersteds, whereas OD radicals are observed in stronger fields, the ratio [H]/[D] was measured on the assumption that they obeyed the same proportionality. Such substitution cannot influence the conclusion drawn by these authors, since two series of independent experiments were made with CH_3OD and CD_3OH. When CH_3OD was added as impurity, no lines at all due to D atoms were detected in the e.s.r. spectrum of the low-pressure flame. Yet the intensity of the lines due to hydrogen atoms exceeded the noise level by factors of 30–35. From the number of components in the spectrum of hydrogen and deuterium

atoms and the width of the lines, the ratio was found to be $[H]/[D] \geq 15$. This means that oxygen atoms attack preferentially the methyl group of the CH_3OD molecule. When CD_3OH was added, the low-pressure flame was found to contain large quantities of deuterium atoms and relatively few hydrogen atoms. The ratio was $[D]/[H] \simeq 6$. This means that oxygen atoms preferentially attack the CD_3 group on reaction with CD_3OH.

The change in the proportion of atoms which can be abstracted from the methyl group on passing from CH_3OD to CD_3OH is obviously associated with a difference in strength between the C–H and C–D bonds, and also between O–H and O–D, in methanol. If the difference in activation energy for abstraction by oxygen atoms of deuterium and hydrogen atoms from the methyl group is taken to be 1.2 kcal $mole^{-1}$,[91] the ratio of the rate of abstraction of a hydrogen atom from the methyl group to the rate of abstraction of a hydrogen atom from the hydroxy-group is 11. On a similar hypothesis concerning the abstraction of deuterium and hydrogen atoms from the hydroxy-group of the alcohol molecule CH_3OD, these workers showed that this ratio should exceed 8. It was thus established that at temperatures up to 755°C oxygen atoms attack preferentially the methyl group of the CH_3OH molecule.

V. INVESTIGATION OF SOME LOW-PRESSURE FLAMES BY THE e.s.r. METHOD

The above two systems unfortunately exhaust our fundamental knowledge of the detailed mechanisms of complicated chemical processes. During the forty years since the chain nature of the combustion of phosphorus was established, many new reactions which also obey the laws of branched chain reactions have been discovered: they give ignition limits which are sensitive to chemically active additions, to the diameter of the reaction vessel, to its surface properties, etc. Until recently, however, the active species – the carriers of chain oxidation – have not been identified in many systems. Great difficulties have arisen in this connection in constructing mechanisms for these reactions. We have seen above that optical spectroscopy has played a large part in developing the theory of chain reactions, in identifying hydroxy-radicals as one of the main chain-carriers, and in measuring their absolute concentrations. By this technique, incidentally, Emanuel'[92] discovered surprisingly large quantities of SO radicals in a slow chain reaction.

In view of the above discussion, it appears that electron spin resonance may play a still larger part in the study of the mechanisms of complex reactions. This method enables many radicals to be detected, as well as atoms. A combination of electron spin resonance, optical spectroscopy, and kinetic methods for studying chemical processes will undoubtedly permit a more rapid penetration into the detailed mechanisms of chemical reactions.

In the light of the above, the authors whose work is discussed below have decided to undertake a detailed examination of several systems which had formed subjects of earlier investigations.

1. Reaction of Sulphur Vapour with Oxygen

The reaction of sulphur vapour with oxygen was one of the first in which Semenov and Ryabinin[3] discovered lower and upper limits of spontaneous ignition. However, there is no indication in the literature of the detection of any active centres in this system. On the basis of indirect evidence, associated with the behaviour of the system on combustion, Semenov[24] suggested that oxygen atoms were formed.

Sarkisyan et al.[93] report the first results of an e.s.r. investigation of a low-pressure flame of sulphur vapour in oxygen. A novel feature of the experimental technique, compared with that discussed above, is the evaporator reaction vessel used for work both with solids and with liquids whose vapours undergo combustion. The diagram (Fig. 19) shows that the vessel consists of two coaxial tubes *1* and *2*. The outer tube has a widened portion *3* in an e.s.r. cavity resonator, which enables magnetic and electric components of the UHF field to be used. Use of the vessel illustrated in Fig. 19 became possible as a result of the improvement described in another paper[44]. The sulphur was placed in the cup *4* of the inner tube. A gentle stream of an inert gas was supplied through this tube, and entrained the sulphur vapour by flowing over the sulphur heated by means of a special furnace *5*. The gases emerged through the nozzle *6* into the combustion zone, where they mixed with oxygen supplied through the outer tube. The temperature of the combustion zone was maintained by means of the furnace *7*. The inner tube could be moved vertically by means of the ground glass joint *8*, which made it possible to move the combustion zone. The part of the reaction vessel located in the resonator was heated by a stream of hot air. By lowering the combustion zone, the flame could thus be drawn into the resonator. Experiments were made at 300–400°C, and the pressure of the mixture was varied over the range 1.5–3 mmHg.

Under these conditions large quantities of SO radicals and O atoms were observed in the flame. Three single lines were observed for the SO radical, which coincided with published e.s.r. spectral lines for SO radicals obtained by means of an electric discharge in sulphur dioxide[94,95]

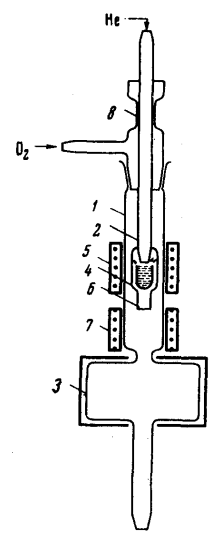

Fig. 19. Diagram of evaporator reaction vessel.

or by the reaction O + COS = CO + SO.[96] The concentration of oxygen atoms reached 25–30% of the initial oxygen, and that of SO was an order of magnitude lower. Experiments showed that small additions of methane resulted in a diminution in the concentration of oxygen atoms. At the same time lines were observed in the spectrum characteristic of the hydroxy-radical, their appearance obviously being due to the reaction $O + CH_4 \rightarrow OH + CH_3$.

In 1954 Semenov[98] considered the possible role of diradicals in chain reactions, and suggested the following mechanism for the diradical oxidation of sulphur vapour

$$S_8 = \dot{S}_7 + \dot{S},$$
$$\dot{S} + O_2 = \dot{S}O + \dot{O},$$
$$\dot{O} + S_8 = \dot{S}O + \dot{S} + S_6,$$
$$\dot{S}O + O_2 = SO_2 + \dot{O},$$
$$O + O_2 + M = O_3 + M,$$
$$SO_2 + O = SO_3,$$
$$O \xrightarrow{\text{walls}} {}^1/_2 O_2.$$

As we see, the main carriers of the diradical chain combustion of sulphur — oxygen atoms and SO radicals — have been detected. It will be shown further that sulphur atoms cannot be observed, either in this system or in other systems containing sulphur. The failure to detect sulphur atoms is obviously associated with their great reactivity, as a result of which their equilibrium concentration is considerably lower than the sensitivity of the e.s.r. instrument. Further investigation of the kinetics and the mechanism of the combustion of sulphur vapour will in the very near future enable the mechanism of this process to be finally established.

2. Investigation of Low-Pressure Carbon Disulphide–Oxygen Flames

The burning of carbon disulphide in oxygen was studied in detail by Kondrat'ev,[99] and was also investigated by Voronkov and Semenov[100]. The reaction was shown to develop by a branched chain mechanism. Using a flow technique, Kondrat'ev observed the interesting phenomenon of a sharp change in colour of the flame on passing from mixtures rich in oxygen to those poor in oxygen near the stoichiometric mixture. Analysis established the formation of COS and sulphur as intermediate products. The radical CS was detected in mixtures rich in carbon disulphide. The principal final reaction products were sulphur dioxide and carbon monoxide. Fig. 20 illustrates the yields of intermediate and final reaction products as functions of $\alpha = [O_2]/[CS_2]$. Spectroscopic investigations have shown that the concentration of CS radicals, which is very low near $\alpha \simeq 2.5$, increases rapidly as α decreases, i.e. with enrichment of the mixture with carbon disulphide.

As in previous work, the e.s.r. investigation of low-pressure carbon disulphide flames was conducted under flow conditions. The flame was produced in the part of the tube located in the e.s.r. resonator. Experiments were made over the temperature range 200–500°C and at 6 mmHg. The ratio α varied over the range 0.8–14. Azatyan et al.[101] observed large quantities of oxygen atoms in oxygen-rich mixtures, their spectrum being identified from the g factor of 1.5 and from the fine structure. The

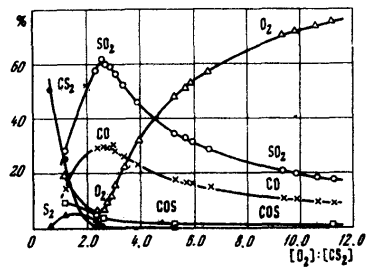

Fig. 20. Composition of combustion products of $CS_2 + O_2$ mixtures as function of $\alpha = [O_2]/[CS_2]$.

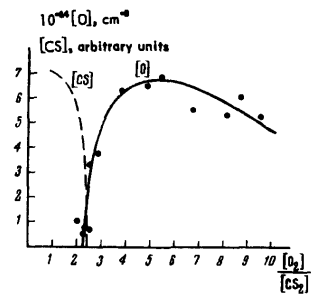

Fig. 21. Dependence of concentration of oxygen atoms on α.

assignment of the spectrum to atomic oxygen was also proved chemically: on addition of small amounts of molecular hydrogen to the reactant mixture, the concentration of oxygen atoms falls, while lines characteristic of the hydroxy-radical and hydrogen atoms appear, obviously as a result of the reaction $O + H_2 = OH + H$.

The dependence of the concentration of oxygen atoms on α is shown in Fig. 21, from which it is seen that at $\alpha \simeq 2.5$ the concentration is lower than the sensitivity of the e.s.r. instrument. Slight enrichment of the mixture with oxygen results in a sharp increase in the concentration of atomic oxygen. With further increase the concentration reaches a maximum and then slowly falls. Thus the atomic oxygen curve is, as it were, the mirror image of the curve for the variation in CS found by Kondrat'ev and included in the diagram on an arbitrary scale. This at first glance peculiar shape of the atomic oxygen curve seems to us to be due to reaction of the oxygen atoms with intermediate compounds, primarily with COS and S_2, which are the main intermediates in the region $\alpha < 2.5$. Quite recently a still further active species — the SO radical — has been detected in this system in the Institute of Chemical Physics of the USSR Academy of Sciences. Investigations will be continued on low-pressure carbon disulphide flames with the aim of elucidating the reaction mechanism.

3. Study of Low-Pressure Hydrogen Sulphide Flames

Great interest attaches to e.s.r. investigations of low-pressure hydrogen sulphide flames. It has been noted above that large quantities of SO radicals have been observed, and several of their properties studied, in the slow oxidation of hydrogen sulphide at pressures above the

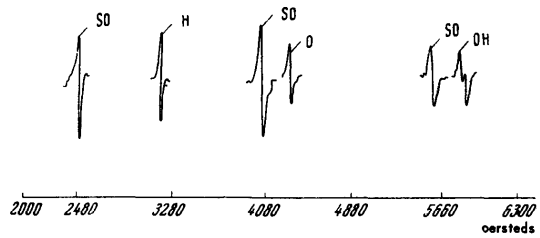

Fig. 22. Electron spin resonance spectrum of H and O atoms and OH and SO radicals detected in low-pressure hydrogen sulphide flames.

second limit of spontaneous ignition (100–200 mmHg). Emanuel'[92], and later Semenov[24], suggested mechanisms for the chain oxidation of hydrogen sulphide. The optical absorption spectra of SO, OH, and S_2 radicals had been observed[102] in the hydrogen sulphide flame before the e.s.r. method was applied. The absorption spectrum of sulphur monoxide — though in the form of the dimer S_2O_2 — has been observed[103] in the flash photolysis of hydrogen sulphide–oxygen mixtures under isothermal conditions. Mass-spectroscopic examination of the flame near the third limit indicates the existence of the S_2O radical[104]. The HS radical has not yet been detected in the flame.

Sachyan and Nalbandyan[105] have been able to observe large concentrations of hydrogen atoms and oxygen atoms in an e.s.r. study of low-pressure hydrogen sulphide flames using a heated reaction vessel placed in the e.s.r. resonator. Experiments were made at pressures up to 10 mmHg over the temperature range 350–450°C. In these experiments a signal due to atomic oxygen was detected at low hydrogen sulphide contents, but disappeared when the latter reached 25% of the whole mixture. The signal of atomic hydrogen was found at a hydrogen sulphide content of ~ 15% of the initial mixture, and became more intense as the latter increased to 45–50%.

In order to detect spectra possessing electric dipole transitions, a quartz cell completely filling the resonator was used. An electric furnace was placed above the resonator, which was heated up with hot air both to eliminate the formation of a deposit in the quartz tube and also in order to ignite the combustible mixture directly in the resonator space in the wide part of the quartz tube. Under these conditions Gershenzon et al. [106] observed the signals of hydroxy-radicals in the form of an unresolved doublet, and also three single signals in different parts of the magnetic field, due to the SO radical. Fig. 22 shows the spectra of the hydrogen and oxygen atoms and the OH and SO radicals obtained. It was expected that HS radicals would also be present in the flame, but all searches, in different systems and under different conditions, were fruitless. This is, perhaps, due to rapid reaction of HS radicals with oxygen.

We see that, among the systems discussed above, the mechanism of the combustion of hydrogen sulphide is the most complicated.

CRITICAL PHENOMENA IN CHAIN REACTIONS WITH DEGENERATE BRANCHING

N. M. Emanuel' and A. B. Gagarina

CONTENTS

I. Introduction 260

II. Kinetic equations of a chain reaction with degenerate branching, linear chain termination, and non-chain consumption of an intermediate product 261

III. Critical phenomena in the gas-phase oxidation of hydrocarbons 264

IV. Phenomenon of a critical inhibitor concentration in the liquid-phase oxidation of hydrocarbons in batches 266

V. Phenomenon of a critical inhibitor concentration in the continuous oxidation of hydrocarbons in reaction vessels with ideal mixing (open systems) 273

I. INTRODUCTION

Limiting (critical) phenomena constitute the clearest and most characteristic feature of branched chain reactions. These phenomena are shown quantitatively in a sharp change in reaction velocity at certain (limiting or critical) values of the external parameters (pressure, temperature, diameter of vessel, etc.). The essential nature of critical phenomena was explained by Semenov's theory of branched chains, supported by a large amount of experimental work by Soviet and foreign scientists. The limits of an autocatalytic chain reaction are certain boundary conditions under which an increase in the concentration of active centres carrying reaction chains becomes possible or impossible. In chain ignitions these conditions are represented by equality of the rates at which the elementary processes of chain branching and termination are occurring. Study of the chain ignition of hydrogen, phosphorus, etc. revealed numerous limiting phenomena (critical pressure, temperature, vessel diameter), and the effect on them of various factors, such as treatment of the walls of the vessel, the action of inert gases and active additions, was investigated.

Besides branched chain reactions, whose development at pressures exceeding the critical value involves ignition of the reactant mixture, slow autocatalytic reactions are known, among them the oxidation of hydrocarbons and other organic substances in both gas and liquid phases. These slow autocatalytic processes were termed by Semenov chain reactions with degenerate branching (or reactions of degenerate chain explosion) [1,2].

According to the theory of degenerate branching, the explanation of the peculiarities of slow oxidation is that, in the course of such reactions, radicals are involved only in the elementary processes of chain propagation and termination, i.e. that the main chain "develops at the normal rate (very rapidly) and is not accompanied by branching in the usually accepted sense" [2]. However, a relatively stable intermediate product is formed in the unbranched primary chain, which, on undergoing some independent reaction (decomposition, oxidation), is responsible for the formation of radicals, i.e. the appearance of secondary chains. "We can regard these secondary chains formally as branches of the primary chain, although a chain of 'degenerate branching' may appear a very considerable time after destruction of the primary chain".

If the number of chains increases by such a mechanism, development of the process is non-stationary:

$$w = \frac{\nu n_0 (k_1 + k_2)}{\varphi} (e^{\varphi t} - 1),$$

where w is the reaction velocity, ν the length of the unbranched chain, n_0 the rate of generation of chains, $\varphi = k_2(\nu - 1) - k_1 = (\nu\delta - 1)/\theta$ is the autocatalytic factor of the reaction, and k_2 and k_1 are the rate constants for decomposition of the intermediate product into radicals and into stable compounds respectively. The parameter $\delta = k_2/(k_2 + k_1)$ is the probability of chain formation involving the stable intermediate, and $\theta = 1/(k_2 + k_1)$ is the mean life of this compound in the reaction. The magnitude of the autocatalytic factor is determined by the low rate of breakdown of the intermediate product into radicals, so that conversion of the starting materials slowly accelerates with time.

The decisive part played by stable intermediate products in the occurrence of slow autocatalytic chain reactions is now supported by a large mass of experimental results. Analysis of kinetic equations [3-6] and also experimental data show that the peculiarities of reactions of this class are determined both by the mechanism of conversion of the intermediate product (radical, molecular, chain) and by the type of chain termination (linear or quadratic).

With variation in the external conditions (diameter of vessel, pressure of mixture, concentration of inhibitor) the autocatalytic factor $\varphi = (\nu\delta - 1)/\theta$ of the degenerate branched chain reaction may be either positive (when $\nu\delta > 1$) or negative (when $\nu\delta < 1$). Hence limiting phenomena should be observed in slow, non-stationary chain reactions, as in chain ignition, if the condition $\nu\delta = 1$ is satisfied [1,2,7-9].

In gas-phase reactions, destruction of chains occurs by the collision of active centres with the surface of the reaction vessel, and the rate of chain termination is proportional to the concentration of radicals (linear termination). In this case the length of the chain ν depends on the diameter and surface state of the reaction vessel and on the pressure of the reactant mixture. The existence of a critical vessel diameter and a critical pressure in the gas-phase oxidation of hydrocarbons has been shown experimentally [10-13].

In the liquid phase the high density of the substance makes the diffusion of active centres to the walls of the reaction vessel difficult, and chain termination occurs by the recombination of radicals (quadratic chain termination). In the quadratic recombination of radicals the length of the chain is independent of any external parameter. Linear chain termination occurs in the liquid phase in the presence of compounds such as phenols, naphthols, amines, etc., which contain a weakly bound hydrogen atom in the hydroxyl or amino-group. The active radicals which effect the chain conversion of the starting materials react with these compounds and are replaced by the corresponding phenoxyl or imino-radicals, which are incapable of chain propagation, so that the chain terminates.

If the rate of chain termination on an inhibitor exceeds the rate of quadratic recombination of radicals, the length of the chain decreases, and induction periods appear in the oxidation. With different inhibitor concentrations, the process of oxidation during the induction period may be stationary ($\varphi < 0$) or may develop autocatalytically ($\varphi > 0$) depending on the length of the chain. The existence of critical inhibitor concentrations, at which a sharp change occurs in the induction period in the liquid-phase oxidation of hydrocarbons, has now been shown experimentally [14,15].

The present Review examines the problem of limiting (critical) phenomena occurring in reactions with degenerate branching of the chains, non-chain consumption of an intermediate product, and linear chain termination.

II. KINETIC EQUATIONS OF A CHAIN REACTION WITH DEGENERATE BRANCHING, LINEAR CHAIN TERMINATION, AND NON-CHAIN CONSUMPTION OF AN INTERMEDIATE PRODUCT

The fundamental mechanism of a chain reaction with degenerate branching comprises the following elementary reactions of radicals r and stable intermediate products x

0) $A+B \xrightarrow{k_0} r$ — chain initiation,

1) $r' + B \xrightarrow{k_1} r + C$
2) $r + A \xrightarrow{k_2} r' + x$ — chain propagation,

3) $x \xrightarrow{k_3} r$ — degenerate branching,
$x \xrightarrow{k_3', k_3''[M]}$ — stable products,

4) $r +$ (wall, inhibitor) $\xrightarrow{g}$ chain termination.

On the basis of this scheme, the variation in concentration of radicals r and the intermediate product x during the reaction is represented by the equations

$$\frac{dr}{dt} = w_0 + k_3 x - gr, \quad (1)$$

$$\frac{dx}{dt} = ar - kx. \quad (2)$$

Chain initiation occurs very slowly in reactions of saturated molecules of the starting materials, its rate being $w_0 = k_0[A][B]$.

The radicals r and r', which are formed in the system, carry reaction chains in which the intermediate product x is formed. The length of the chain is $\nu = a/g$, where $a = k_2[A]$ and g are respectively the kinetic coefficients of chain propagation and termination. The intermediate product x may undergo various reactions during the process. Breakdown of x into radicals (or other reaction) results in an increase in the rate of formation of active centres, i.e. in autocatalysis of the process; the parameter k_3 is the effective rate constant of decomposition of the intermediate product in this way.

The intermediate product can decompose or react with some other molecule M to form stable, valency-saturated compounds, k_3' and $k_3''[M]$ being the effective rate constants of these processes. The parameter $k = k_3 + k_3' + k_3''[M]$ is the overall rate constant for consumption of the intermediate product in the various ways.

In oxidation reactions the intermediate product can be consumed also by a chain mechanism

$$x + r \xrightarrow{k_4} r' + \text{products}.$$

The rate of this process will depend on the concentration of intermediate product and radicals. In the initial stages of conversion, when the concentrations x and r are small, the rate of the chain consumption of the intermediate product $w_{ch} = k_5 xr$ is small, and is ignored in the above scheme.

Eqns. (1) and (2) have the solutions

$$r = \frac{w_0}{(ak_3 - gk)}\left[\frac{(k\lambda_2 + gk - ak_3)}{(\lambda_2 - \lambda_1)}e^{\lambda_1 t} - \frac{(k\lambda_1 + gk - ak_3)}{(\lambda_2 - \lambda_1)}e^{\lambda_2 t} - k\right], \quad (3)$$

$$x = \frac{aw_0}{(ak_3 - gk)}\left[\frac{\lambda_2}{(\lambda_2 - \lambda_1)}e^{\lambda_1 t} - \frac{\lambda_1}{(\lambda_2 - \lambda_1)}e^{\lambda_2 t} - 1\right], \quad (4)$$

where λ_1 and λ_2 are the roots of the characteristic equation $\lambda^2 + (g + k)\lambda - (ak_3 - gk) = 0$ of this system:

$$\lambda_{1,2} = \frac{(g+k)}{2}\left(\pm\sqrt{1 + \frac{4(k_3\nu - k)}{(g+k)(1+k/g)}} - 1\right).$$

If the inequality

$$(k_3\nu - k) \ll (g + k)(1 + k/g), \quad (5)$$

is satisfied, the exponents are

$$\lambda_1 = \frac{(k_3\nu - k)}{(1 + k/g)}, \quad \lambda_2 = -(g + k).$$

The inequality (5) is satisfied if $g \gg k$ or $g \ll k$.

The parameter $1/g = \tau_r$ represents the average life of the radical r, while $1/k = \theta$ is the average life of the intermediate product x. With degenerate branching of the chains, the life of the stable intermediate product should obviously be far longer than that of the radical: $\theta \gg \tau_r$, so that $g \gg k$. If we write $\varphi = k_3\nu - k$, we find that, when $g \gg k$, the exponents are $\lambda_1 = \varphi$ and $\lambda_2 = -g$, and the solutions of Eqns. (1) and (2) become

$$r = \frac{w_0 k_3 \nu}{g\varphi}\left(e^{\varphi t} - \frac{k}{k_3\nu}\right) - \frac{w_0}{g}e^{-gt} = \frac{w_0 k_3 \nu}{g\varphi}\left(e^{\varphi t} - \frac{k}{k_3\nu}\right)_{t \approx 1/g}, \quad (6)$$

$$x = \frac{\nu w_0}{\varphi}(e^{\varphi t} - 1) + \frac{\nu w_0}{g}e^{-gt} = \frac{\nu w_0}{\varphi}(e^{\varphi t} - 1)_{t \approx 1/g}. \quad (7)$$

The solutions (6) and (7) are evidently valid when $dr/dt = 0$, i.e. if the concentration of radicals can be regarded as quasistationary.

Inequality (5) is a condition of quasistationary character either in relation to the concentration of radicals ($dr/dt = 0$), when $g \gg k$, or for the concentration of the intermediate product, when its life θ in the reaction is far shorter than the life of the radicals τ_r, i.e. when $g \ll k$.

The latter case can obviously occur in branched chain reactions†. The inequality (5) can be satisfied whatever

† Fresh results have recently been obtained on the mechanism of branching in chain ignitions [16]. These indicate that the increase in the number of active centres in branched chain reactions is a consequence of the transformation of excited saturated molecules x^*, which are formed in the strongly exothermic stage of chain propagation, and concentrate the heat of reaction in the excitation of vibrational and rotational degrees of freedom.

In the oxidation of hydrogen, for example, chain branching occurs in the reactions

$$H + O_2 \rightarrow HO_2^*,$$
$$HO_2^* \rightarrow HO + O.$$

When $k \gg g$ and condition (5) applies, the concentration of x^* can be regarded as quasistationary, and Eqns. (1) and (2) as equivalent to the equation

$$\frac{dr}{dt} = w_0 + (a\delta^* - g)r = w_0 + (f - g)r,$$

where δ^* is the probability of radical formation from an excited molecule x^*, and $f = a\delta^*$ is the kinetic coefficient of chain branching.

the relationship among the kinetic constants a, k_3, g, and k, if the system is close to a limit, when $k_3\nu \to k$, i.e. $\lambda_1 \to 0$. However, it can be satisfied also if the system is remote from a limit, when $k_3\nu > k$. This case has already been discussed[3] for the degenerate branching of chains.

In degenerate chain branching ($g \gg k$) the condition of quasistationarity with respect to the concentration of radiclas is given by the inequality

$$k_3\nu - k \ll g \quad \text{or} \quad k_3\nu \ll g,$$

if the reaction system is remote from the limit, when $k_3\nu > k$. This inequality can be written[3]

$$\nu \ll \frac{\theta}{\tau_r} \quad \text{or} \quad \nu \ll \sqrt{\frac{\theta}{\tau_m}}, \qquad (5')$$

where $\tau_m = 1/a$ is the life of a radical in the reaction of chain propagation. If $\tau_r \leq 1$ s, while $\theta \simeq 10^3$–10^6 s, which corresponds to the average life of stable intermediate products — aldehydes, hydroperoxides — in the autoxidation of hydrocarbons, condition (5′) is valid with a chain length of $\nu = 10^3$–10^6 steps. In the autoxidation of hydrocarbons the chain length ν is far smaller than this value.

In the analysis of the kinetic equations of chain reactions with degenerate branching it will henceforward be assumed that the condition of quasistationarity is satisfied for the concentration of radicals.

1. Limiting Condition of a Chain Reaction with Degenerate Branching

It is evident from Eqns. (3) and (4) and Eqns. (6) and (7) that the concentrations of radicals r and of the reaction product x will increase with time, i.e. that the process will be autocatalytic, provided that $k_3\nu > k$ ($\lambda_1 > 0$, $\varphi > 0$).

When $k_3\nu < k$ ($\varphi < 0$, $\lambda_1 < 0$) the concentrations of x and r, and hence the reaction velocity $-dA/dt = ar$, will, after a certain time $t \simeq 1/|\varphi|$, become constant:

$$r \to \frac{w_0 k}{g|\varphi|}, \qquad (8)$$

$$x \to \frac{\nu w_0}{|\varphi|}. \qquad (9)$$

The possibility of a chain reaction with degenerate branching passing into a "degenerate unbranched stage" when limiting conditions are reached has been demonstrated previously[3].

The equality $k_3\nu = k$ is the condition for a process to pass from autocatalysis to a steady state. The parameter $\delta = k_3/k$ is none other than the "probability of formation... of a chain when one molecule of intermediate product is involved, i.e. a parameter (formally identical with the previous δ) defining the probability that a chain will branch at a given step" [2].

Thus if a stable intermediate product leads to the formation of active centres in a chain reaction, the limiting condition at which this reaction will be autocatalytic is $\nu\delta = 1$, when ν intermediate product molecules formed in the primary chain yield one secondary chain on further reaction.

Since $\nu = 1/\beta$, the limiting condition is that the probabilities of termination β and of degenerate branching of the chain should be equal: $\beta = \delta$.

2. Autocatalytic Factor in a Chain Reaction with Degenerate Branching and Transition through Limiting Values of the Parameters

The autocatalytic factor in a chain reaction with degenerate branching is the difference between the kinetic coefficients $k_3\nu$ and k, which represent respectively the rate of formation of intermediate product in those chains which have arisen from its breakdown into radicals $k_3 x\nu$ and the total rate of consumption of the intermediate product in the reaction kx:

$$\varphi = k_3\nu - k = k_3\nu(1 - 1/\nu\delta).$$

The expression for φ can be written

$$\varphi = k_3\nu(1 - \nu_{cr}/\nu) = k_3\nu\psi, \qquad (10)$$

where $\psi = 1 - \nu_{cr}/\nu$ and $\nu_{cr} = 1/\delta$ is the chain length at which the autocatalytic factor is zero.

In the liquid-phase oxidation of hydrocarbons the chain length can be varied by additions of inhibitors InH:

$$\nu = k_2[RH]/k_i[InH],$$

where k_2 and k_i are the rate constants for reaction of $RO_2^{\cdot}$ radicals with the hydrocarbon RH and with the inhibitor respectively. We then have $\psi = 1 - [InH]_{cr}/[InH]$.

In the gas-phase oxidation of hydrocarbons, chain termination takes place on the wall of the reaction vessel. The termination rate constant g depends on the diameter of the vessel (kinetic region) and on the pressure of the mixture and the diameter (diffusion region of chain termination).

In gas-phase reactions the rate of chain propagation will depend on the pressure of the mixture, since $a = k_2[RH] = k_2 N\gamma p$, where N is the number of molecules at pressure $p = 1$ mmHg and the temperature of the reaction vessel, γ is the mole fraction of the reactant in the gaseous mixture, and p is the total pressure of the reaction mixture.

If chain termination is determined by the probability of the capture of radicals by the surface of the reaction vessel ($\epsilon_r < 1$, kinetic region of chain termination), we have $g = \epsilon_r u_r/d$, where u_r is the mean thermal velocity of a molecule and d the diameter of the vessel. The chain length in gas-phase oxidation will depend on the pressure of the mixture and the diameter of the vessel:

$$\nu = a/g = \frac{k_2 N\gamma}{u_r \epsilon_r} pd.$$

In this case $\psi = 1 - p_{cr}/p$ for variation of the pressure of the mixture in a vessel of given diameter, and $\psi = 1 - d_{cr}/d$ for variation of the diameter of the vessel at constant pressure.

It follows from Eqn. (10) that, with degenerate chain branching, the autocatalytic factor is determined by the rate constant for decomposition of the intermediate product into radicals k_3 and by the length of the chain ν, and depends on ψ, which measures how far the reaction system is from the limit under given experimental conditions (e.g. how much less is the inhibitor concentration [InH], or how much higher, when $\psi > 0$, is the pressure of the mixture p, than the corresponding limiting values).

In a branched chain reaction the autocatalytic factor is given by the difference between the kinetic coefficents of chain branching f and chain termination g:

$$\varphi_{br} = f - g = f(1 - f/g) = f\psi.$$

In the oxidation of hydrogen above the lower limit in the kinetic region of chain termination ($\epsilon < 1$), the autocatalytic factor is

$$\varphi_{br} = 2a_2(1 - p_{cr}/p) = 2a_2\psi, \quad (11)$$

where $\psi = 1 - p_{cr}/p$, $f = 2k_2[O_2] = 2a_2$, and k_2 is the rate constant of the chain-branching reaction $H + O_2 \xrightarrow{k_2} HO^{\cdot} + {}^{\cdot}O^{\cdot}$. It is seen from Eqns. (10) and (11) that the autocatalytic factors of a branched reaction and of a reaction with degenerate branching are proportional to the rate constant (a_2, k_3) of the process in which the number of active centres increases.

In branched chain reactions the increase in the number of active centres is determined by rapid reactions of radicals with saturated molecules. In such processes the transition from a slow steady-state reaction, involving a negligible rate of initiation of chains (when $\varphi < 0$), to a rapid autocatalytic process (when $\varphi > 0$) is very sharp, with little departure of the external parameters from the critical values, i.e. with a very low value of ψ.

The consumption of the starting materials in the chain ignition of hydrogen is described by the formulae

$$\Delta[O_2] = \frac{n_0}{4a_2\psi} e^{\varphi t} \text{ when } \varphi > 0 \text{ and } t > \frac{1}{\varphi},$$

$$\Delta[O_2] = n_0 t\left(1 + \frac{1}{2|\psi|}\right) \text{ when } \varphi < 0,$$

where $\Delta[O_2] = [O_2]_0 - [O_2]_t$. When $\varphi > 0$, the time t_1 during which the amount $\Delta[O_2]$ of oxygen is used up is

$$t_1 = \frac{2.3 \log A}{\varphi} = \frac{2.3 \log A}{f\psi}, \quad (12)$$

where

$$\varphi = 2a_2\psi = f\psi, \; A = \frac{4a_2\psi^2\Delta[O_2]}{n_0}.$$

When $\varphi < 0$, the time t_2 during which the oxygen concentration falls by $\Delta[O_2]$ is

$$t_2 = \frac{\Delta[O_2] \cdot 2|\psi|}{n_0 \cdot (1 + 2|\psi|)} \quad (13)$$

The ratio t_2/t_1 gives the factor by which the time for a definite consumption of the starting materials $\Delta[O_2]$ increases on passing from $\varphi > 0$ to $\varphi < 0$:

$$t_2/t_1 = C\frac{f}{n_0}, \quad (14)$$

in which

$$C = \frac{\Delta[O_2]\psi^2}{1.15(1 + 2|\psi|)\log A}.$$

In a stoichiometric mixture of hydrogen and oxygen[9] at 800°K and p_{cr} = 7.6 mmHg, we have $a_2 = 310\ s^{-1}$. At the pressure $p_1 = 1.1p_{cr}$, i.e. with $\psi = 0.1$, the autocatalytic factor is $\varphi_{br} = 62\ s^{-1}$, and the time required for 10% of the oxygen to be consumed is $t_1 = 0.2$ s from Eqn. (12). At the pressure $p_1 = 0.9p_{cr}$ ($\psi = -0.1$) the time $t_2 = 3000$ s‡. Thus for a change in pressure of 20%, from $1.1p_{cr}$ to $0.9p_{cr}$, the reaction time increases by a factor of $t_2/t_1 = 1.5 \times 10^4$.

‡ The rate constant of chain initiation in the oxidation of hydrogen[9] is $k_0 \simeq 10^{-22}$ at 800°K. For a stoichiometric mixture of oxygen and hydrogen at 7.6 mmHg the rate of initiation is $n_0 = 10^{-22}[H_2][O_2] = 3.0 \times 10^{-10}$ M s^{-1}.

With degenerate branching of the chains, autocatalysis of a reaction is determined by the rate of formation of primary radicals from molecular intermediate products.

In the oxidation of hydrocarbons the rate constant for decomposition of the hydroperoxide into radicals is $k_3 = 10^{-3}$–$10^{-6}\ s^{-1}$; the autocatalytic factor in these reactions, many orders of magnitude smaller than φ_{br}, is therefore quite remote from the limit ($\psi \to 1$) and thus close to the limit ($\psi \to 0$). This is the reason for the slow increase in rate of a chain reaction with degenerate branching and the less sharp transition through the limiting values of the external parameters.

"Long before critical conditions are approached, the increase in rate is so slow that we find it difficult to fix the sharpness of the transition from complete absence of reaction when $\delta - \beta < 0$ to autocatalysis when $\delta - \beta > 0$". [1]

The variation in reaction time on passing through limiting values of the parameters in the case of degenerate chain branching can be analysed in a similar manner to that used for the branched chain oxidation of hydrogen. The starting materials are consumed in the chain process at the rate $-d[RH]/dt = ar$, where $a = k_2[RH]$, in which k_2 is the rate constant of chain propagation. If the reaction is autocatalytic ($\varphi > 0$), it follows from Eqn. (6) that, after a certain time $t \simeq 1/\varphi$, the variation in radical concentration is described by the equation

$$r = \frac{w_0}{g\psi} e^{\varphi t}.$$

In this case, integration of the equation for the consumption of hydrocarbon with the initial conditions [RH] = $= [RH]_0$ at $t = 0$ leads to the expression

$$\Delta[RH] = \frac{w_0}{k_3\psi^2}(e^{\varphi t} - 1),$$

which is valid when the extent of conversion of the starting materials is small.

Hence the time required for an amount $\Delta[RH]$ of the starting materials to be consumed in an autocatalytic process is

$$t_1 = \frac{2.3 \log A}{\varphi} = \frac{2.3\,\delta(1 - \psi)\log A}{k_3\psi}, \quad (12')$$

where

$$A = \frac{\Delta[RH] \cdot k_3\psi^2}{w_0} + 1$$

and from Eqn. (10)

$$\nu_{\varphi > 0} = \frac{1}{\delta(1 - \psi)}.$$

The variation in radical concentration during the steady state of the process ($\varphi < 0$) is described by Eqn. (8). In this case $\Delta[RH]$ increases with time according to the equation

$$\Delta[RH] = \frac{w_0(1 + |\psi|)\nu_{\varphi<0}}{|\psi|} t_2$$

and the time t_2 for consumption of an amount $\Delta[RH]$ of the starting materials under steady-state conditions of the process is

$$t_2 = \frac{\Delta[RH] \cdot \delta|\psi|}{w_0}, \quad (13')$$

where $\nu_{\varphi<0} = 1/\delta(1 + |\psi|)$ from Eqn. (10).

The change in reaction time on passing through $\varphi = 0$ is given by the ratio

$$t_2/t_1 = C\frac{k_3}{w_0}, \qquad (14')$$

where

$$C = \frac{\psi^3\Delta\,[RH]}{(1-|\psi|)2.3\log A}.$$

Eqns. (12) and (12'), (13) and (13'), and (14) and (14') for the dependence of reaction time on kinetic constants with branching and with degenerate chain branching are analogous to one another.

It follows from Eqns. (14) and (14') that the abruptness of the change in reaction time on passing from autocatalytic to steady-state conditions depends on the relationship between the rate constant for chain branching f (or degenerate branching k_3) and the rate of initiation of chains n_0 (w_0).

Table 1 gives for comparison values of t_1, t_2, and t_2/t_1 found for the oxidation of hydrogen and calculated from Eqns. (12')–(14') for a reaction with degenerate chain branching and different values of the rate constant for dissociation of the intermediate product into radicals. In Table 1 the times t_1 and t_2 relate to the consumption of 10 mole % of the starting materials respectively at $\psi = 0.1$ and $\psi = -0.1$, the rate of initiation of chains is $w_0 = 3\times 10^{-10}$ M s^{-1}, $\delta = 1$, and the concentration of the starting materials is $[RH]_0 = 0.002$ M (in the gas phase this concentration corresponds to 100 mmHg at 423°C).

The calculations show that, in slow non-stationary reactions, a quite abrupt transition through $\varphi = 0$ will be observed provided that the ratio $k_3/w_0 \geq 10^7$ litres mole^{-1}. With $k_3/w_0 \leq 10^6$ no significant change should occur in the reaction time on passing through $\varphi = 0$, and limiting phenomena are not observed. It is obvious that critical phenomena in periodic processes can be observed in sufficently rapid reactions, when $k_3 \simeq 10^{-2} - 10^{-3}$ s^{-1}.

With small values of $k_3 \simeq 10^{-5} - 10^{-6}$ s^{-1} for the rate constant of breakdown of the intermediate product into radicals, even if the rate of initiation is very small (e.g. $w_0 = 10^{-12}$–10^{-13} M s^{-1}) and the ratio t_2/t_1 is large, the absolute values of t_2 and t_1 are so large that it is not possible to study such a process in the vicinity of the limit.

III. CRITICAL PHENOMENA IN THE GAS-PHASE OXIDATION OF HYDROCARBONS

Autoxidation of hydrocarbons in the gas phase occurs at temperatures above 200°C and pressures from a few millimetres of mercury to atmospheric. At such high temperatures and low densities of the hydrocarbon, the main reaction of the peroxy-radical is isomerisation and decomposition with formation of a molecule of a valency-saturated compound and another radical:

$$RO_2^{\cdot} \rightarrow R'CHO + R''O^{\cdot},$$
$$R''O^{\cdot} + RH \rightarrow R''OH + R^{\cdot},$$
$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}.$$

Chain propagation with formation of a hydroperoxide is characteristic of liquid-phase oxidation, whereas in the gas phase it occurs at low temperatures (below 300°C).

Only traces of peroxy-compounds (mainly in the form of hydrogen peroxide, a secondary product) are detected in the products of the autoxidation of hydrocarbons in the gas phase above 300°C, and the only intermediate products are aldehydes [17–24]. The concentration of aldehydes reaches a high value during the reaction. In the oxidation of methane (p_{CH_4} = 110 mmHg at 491.5°C), for example, the maximum concentration of formaldehyde reaches 0.45 mole % of the initial hydrocarbon [21] ($[CH_2O] = 6\times 10^{15}$ cm^{-3}). In the oxidation of propane ($p_{C_3H_8}$ = 116 mmHg at 350°C) the formaldehyde concentration is p_{CH_2O} = 11.5 mmHg ($[CH_2O] = 1.5\times 10^{17}$ cm^{-3}) and that of acetaldehyde p_{CH_3CHO} = 4.5 mmHg ($[CH_3CHO] = 5.8\times 10^{16}$ cm^{-3}). [19] The concentration of radicals in the gas-phase oxidation of hydrocarbons is lower than the limit of sensitivity of modern methods of measurement: $r < 10^{13}$ cm^{-3}. Thus in slow, non-stationary oxidations of hydrocarbons, the concentration of stable intermediate products x is many orders of magnitude greater than the concentration of radicals r:

$$\frac{[RCHO]}{[RO_2]} = \frac{x}{r} > 10^3.$$

It follows from Eqns. (6) and (7) that the concentration ratio of radicals to intermediate product x, with quasi-stationary conditions for the concentration of radicals (when $t > 1/\varphi$), is

$$\frac{x}{r} = \frac{g}{k_3} \gg 1.$$

This is the relationship between the concentrations of stable intermediate products and radicals which is observed in actual processes.

It has now been shown by various methods [22–25] that, in the gas-phase oxidation of hydrocarbons, aldehydes are the only intermediate products involved in the degenerate branching of chains.

The most probable mechanism of degenerate branching is oxidation of the aldehydes according to the equation

$$(3)\ R'CHO + O_2 \rightarrow R'CO^{\cdot} + HO_2^{\cdot} - Q.$$

In a stoichiometric mixture of methane and oxygen at a total pressure of 235 mmHg and at 423°C, the rate of formation of radicals due to oxidation of the intermediate product (formaldehyde) is [22]

$$w_{\text{deg br}} \simeq f\times 10^{-10}\exp(-32\,000/RT)[O_2][CH_2O] \simeq 2\times 10^{-4}[CH_2O],$$

where $f = 10^{-2}$ is the steric factor.

Under these experimental conditions the rate of chain initiation is

$$w_0 \simeq 10^{-10}\exp(-55\,000/RT)[O_2][CH_4] \simeq 10^{-11}\ \text{M s}^{-1}.$$

Consequently the reaction is characterised by the ratio $k_3/w_0 \simeq 10^7$ litres mole^{-1}, where $k_3 = 2\times 10^{-4}$ s^{-1} is the effective rate constant of radical formation by oxidation of

TABLE 1. Abruptness of transition through limiting values of parameters in branched chain and degenerate branched reactions.

	Rate constant f or k_3, s^{-1}	f/n_0 and k_3/w_0	t_1	t_2	t_2/t_1
Oxidation of hydrogen	6.2×10^2	2×10^{13}	0.2 s	3×10^3 s	1.5×10^4
Degenerate branched reaction	$3\cdot 10^{-2}$	10^8	1.32 h	55 h	40
	$3\cdot 10^{-3}$	10^7	7.5 »	55 »	7
	$3\cdot 10^{-4}$	10^6	26 »	55 »	2
	$3\cdot 10^{-5}$	10^5	46 »	55 »	1.2
	$3\cdot 10^{-6}$	10^4	50 »	55 »	1.1

the intermediate product. According to the above calculations, with this ratio the transition through the limiting conditions should be far less abrupt than in the oxidation of hydrogen, as is confirmed by experimental results [13]. In the oxidation of methane at 423°C with p_{O_2} = 157 mmHg and p_{CH_4} = 78 mmHg, the life of the radicals $CH_3^{\cdot}$ and $^{\cdot}OH$ in the reactions of chain propagation is [9] $\tau_m = 5 \times 10^{-6}$ s. If the length of the chain is $\nu \simeq 100$ steps [26], the life of the chain is $\tau_\gamma = \tau_m \nu \simeq 5 \times 10^{-4}$ s. However, the average appearance time of a radical (i.e. of a secondary chain) by the breakdown of ν = 100 aldehyde molecules formed in the primary chain is $1/k_3\nu \simeq 50$ s. Hence it follows that, in processes of slow oxidation, propagation of chain — from the moment it is formed until it is destroyed — occupies a far shorter time than does formation of a fresh chain by breakdown of the intermediate product into radicals [2].

Apart from being used up in degenerate chain branching, the aldehydes are involved in several other reactions, which do not result in the formation of radicals. In the oxidation of methane, for example, it is supposed that formaldehyde may decompose on the walls of the reaction vessel [21]:

$$CH_2O \xrightarrow{\text{wall}} \text{products}.$$

Thus the probability of degenerate branching of the chains is less than unity ($\delta < 1$). In later stages of the reaction the aldehydes are consumed by a chain mechanism, e.g.

$$CH_2O + {}^{\cdot}OH \rightarrow H_2O + HCO^{\cdot}.$$

It has been shown [3] that, with consumption of the intermediate product by a chain mechanism and linear termination of chains, a steady-state concentration of the intermediate product is established, and the rate of oxidation becomes constant. After the induction period is over, however, the chain consumption of aldehydes in the gas-phase oxidation of hydrocarbons, and of hydroperoxides in the liquid-phase process, proceeds at an appreciable rate with a high radical concentration. In the early stages of conversion, therefore, the chain consumption of intermediate products can be disregarded. In the oxidation of methane it has been shown [25] that $\varphi\tau$ is approximately constant during the initial stages of the reaction (up to 10% conversion), which is consistent with a mechanism of the process which ignores the chain consumption of formaldehyde.

The gas-phase oxidation of hydrocarbons is greatly dependent on the state and treatment of the walls of the reaction vessel. The reaction velocity increases with increase in the diameter of the vessel and in the pressure of an inert gas [5,10,13]. This indicates that the destruction of active centres occurs on the surface of the reaction vessel. It has been established [5] that, in the oxidation of methane, chain termination takes place in the region of diffusion-controlled kinetics.

With chain termination on the surface of the vessel, a critical diameter d_{cr} and a critical pressure p_{cr} should be observed, their values being determined from the condition $\varphi = 0$. The existence of these critical parameters has been found in the gas-phase oxidation of various compounds. A study [10] of the oxidation of acetylene under flow conditions at 320°C and 400 mmHg in tubes of different diameters showed that the reaction occurred slowly at 2 and 4 mm, and quite rapidly at 6, 10, and 20 mm diameter. A change in diameter of the vessel from 4 to 6 mm produced a thirtyfold increase in reaction velocity. Thus the experimental results indicate the presence of a critical diameter $d_{cr} \simeq 4$ mm.

The existence of critical conditions d_{cr}, p_{cr}, and t_{cr} was found in the oxidation of ethane [11]. The increase in pressure during the process (Fig. 1), in a vessel of diameter 5 mm at 708°C and pressures of 134, 98, and 94.5 mmHg, was represented by the exponential law

$$\Delta p = N(e^{\varphi t} - 1).$$

The kinetic curves changed from concave to convex at pressures of 92–60 mmHg, and the variation in pressure was described by the equation to a steady-state process $\Delta p = A(1 - e^{-kt})$. A change in shape of the kinetic curves representing the autocatalytic and the steady-state process was observed with change in the experimental temperature and in the diameter of the vessel. In all cases the $\Delta p_{max} - p_0$ relationship changed abruptly at the critical values of the diameter, the pressure, and the temperature (Fig. 2). It was assumed [11] that, in the oxidation of ethane, the homogeneous reaction was accompanied by oxidation on the walls of the vessel, which prevented a sharper development of critical reaction conditions.

Critical phenomena are clearly evident in the oxidation of arsine [12]. A stoichiometric mixture of arsine and oxygen could remain in a spherical vessel of diameter d = = 10 cm at 50°C without change for an indefinite time if the pressure was lower than p_{cr} = 143 mmHg. At higher pressures the mixture slowly reacted, the pressure falling and As_2O_3 being deposited on the walls of the vessel. Reaction ceased when the pressure had fallen to a certain value p_{cr}. At constant temperature and pressure a critical diameter d_{cr} was shown to exist, which was linked with p_{cr} by the constancy of their product $p_{cr}d_{cr}$, a relationship known from the kinetics of chain ignitions. At a pressure of 94 mmHg, for example, the critical diameter is d_{cr} = = 15 cm, and at 143 mmHg it is 10 cm. The temperature dependence of the critical diameter is given by the relation $\log d_{cr} = A/T + B$. Thus the temperature dependence of d_{cr} exhibits the same regularities as does that of branched chain reactions.

An investigation has been made [13] of the effect of the diameter of the vessel on the rate of oxidation of a number of saturated and unsaturated hydrocarbons (methane, ethane, propane, ethylene, propene, and acetylene). Fig. 3 shown the dependence on vessel diameter of the time

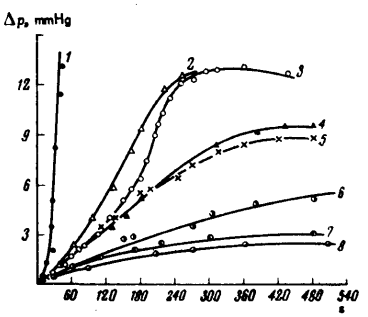

Fig. 1. Kinetic curves of increase in pressure in the oxidation of ethane (in a $C_2H_6 + 3.5O_2$ mixture at 708°C in a quartz vessel with d = 5 mm) at various initial pressures (mmHg) of the reactant mixture:
1) 134; 2) 98; 3) 94.5; 4) 91.5; 5) 92; 6) 90.5; 7) 80; 8) 60.

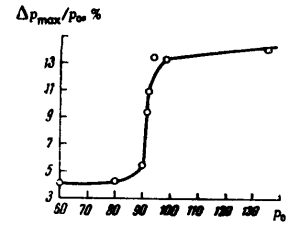

Fig. 2. Dependence of maximum increase in pressure in the oxidation of ethane on the initial pressure of the reactant mixture ($C_2H_6 + 3.5O_2$) at 700°C with d = 5 mm.

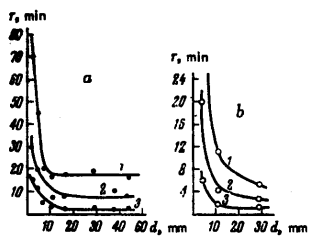

Fig. 3. Dependence of induction period on diameter of vessel in oxidation of: *a*) propene in $C_3H_6 + 3O_2$ mixture at 360°C; *b*) methane in equimolecular mixture with oxygen at 530°C; at various initial pressures (mmHg): 1) 150; 2) 200; 3) 300.

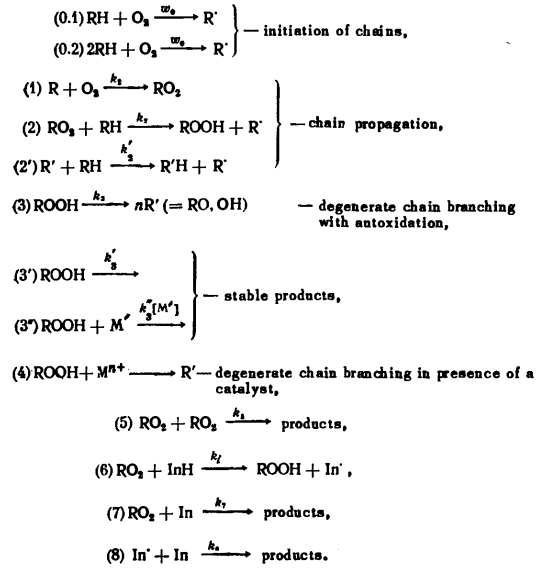
required for the reaction velocity to reach its maximum value (the induction period) in the oxidation of methane and propene. It is seen that a more or less sharp break occurs at a certain diameter, below which the reaction velocity falls sharply.

IV. PHENOMENON OF A CRITICAL INHIBITOR CONCENTRATION IN THE LIQUID-PHASE OXIDATION OF HYDROCARBONS IN BATCHES

1. Kinetics of the Inhibited Oxidation of Hydrocarbons from the Viewpoint of Limiting Phenomena

From a consideration of the fundamental mechanism of the oxidation of hydrocarbons with chain termination on an inhibitor, Semenov showed that a critical inhibitor concentration $[InH]_{cr}$ should exist, above which the process will be stationary, i.e. very slow, and below which it should be autocatalytic [9].

According to present-day ideas, the oxidation of a hydrocarbon in the presence of an inhibitor comprises the following set of elementary stages



In this scheme R′ denotes a primary radical RO or OH, formed by the breakdown of a hydroperoxide, and M′ is a sulphide, phosphite, etc., which decomposes hydroperoxides with the formation of valency-saturated compounds. Many quantitative data are now available on the rates of the elementary reactions in liquid-phase oxidation. The most probable mechanism of chain initiation is the bimolecular reaction (0.1) for a hydrocarbon of bond energy $Q_{RH} > > 90$ kcal mole^{-1} and the termolecular reaction (0.2) for a hydrocarbon of bond energy $Q_{R-H} < 90$ kcal mole^{-1}. [27] The value of w_0 is 10^{-11}–10^{-8} M s^{-1} depending on the temperature and the nature of the hydrocarbon [27,28].

The autocatalytic character of the liquid-phase oxidation of hydrocarbons is associated with the formation of radicals by the breakdown of hydroperoxides, the stable intermediate products formed in the reaction of chain propagation. Comparison, by a kinetic tracer method, of the rates of consumption of hydroperoxides and of accumulation of the final products (ketones, alcohols, acids) in the oxidation of n-decane [29] (at 140°C), and also in the oxidation of cyclohexane [30] (155°C) has demonstrated rigorously that hydroperoxides are the primary and practically the only intermediate products in the liquid-phase autoxidation of hydrocarbons.

A great amount of work has been done on the mechanism of the dissociation of hydroperoxides into radicals and the part played by this process in accelerating oxidation processes (degenerate chain branching). Radicals are formed by the unimolecular breakdown of hydroperoxides at the weak O–O bond and as a result of a bimolecular reaction with the hydrocarbon [31–33]:

The experimental data in Table 2 show that at 100–140°C, when the liquid-phase autoxidation of hydrocarbons takes place at a measurable rate, the radical decomposition constant of the hydroperoxides is $k_3 \simeq 10^{-6}$–10^{-4} s^{-1}.

TABLE 2. Rate constants for the dissociation of hydroperoxides into radicals.

Hydroperoxide	k_3, s^{-1}	k_3, s^{-1}, at 100–140°C	Ref.
n-Decyl	$6\cdot10^{8}\exp(-24\,800/RT)$	$1.5\cdot10^{-6}$—$5.0\cdot10^{-5}$	34
Cyclohexyl	$1.2\cdot10^{13}\exp(-34\,000/RT)$	$1.2\cdot10^{-7}$—$4\cdot10^{-6}$	35
Decahydronaphthyl	$8.5\cdot10^{13}\exp(-32\,100/RT)$	$1.2\cdot10^{-5}$—$7.9\cdot10^{-5}$	36

The dissociation of a hydroperoxide into radicals can be initiated by a metal of variable valency (by a cobalt, copper, manganese, nickel, or iron salt). Radical formation in the presence of such a metal in glacial acetic acid[37] results from the reactions

$$ROOH + M^{n+} \underset{k_b}{\overset{k_a}{\rightleftharpoons}} [ROOH \cdot M^{n+}],$$

$$[ROOH \cdot M^{n+}] + M^{n+} \xrightarrow{k_c} RO^{\cdot} + M^{n+} + M^{3+}(OH),$$

$$[ROOH \cdot M^{n+}] + M^{3+}(OH) \xrightarrow{k_d} RO_2^{\cdot} + 2M^{n+} + H_2O.$$

It follows from the stoichiometric equation for this process

$$2ROOH \rightarrow RO^{\cdot} + RO_2^{\cdot} + H_2O,$$

that one radical is formed per hydroperoxide molecule decomposed. The rate of breakdown of the hydroperoxide in the presence of a metal of variable valency is proportional to the hydroperoxide concentration:

$$-d[ROOH]/dt = k_4[ROOH],$$

where $k_4 = 2k_c k_a[M^{n+}]^2/k_b$ at low catalyst concentrations $[M^{n+}]$, and $k_4 = k_a[M^{n+}]$ at high concentrations thereof. Under the actual conditions of the catalysed oxidation of hydrocarbons (tetrahydronaphthalene[38], ethylbenzene[39], n-decane[40], cyclohexane[41]) in the presence of salts of metals of variable valency, $k_4 = 0.001$–$0.1\ s^{-1}$.

In the mechanism of the breakdown of hydroperoxides, reactions in which stable molecules are formed directly — reactions (3′) and (3″) — must be taken into account as well as those leading to the production of radicals. The formation of valency-saturated compounds by the unimolecular decomposition of substances in the liquid phase is associated with a "cage effect", consisting in recombination of a proportion of the radicals without their escaping from the "cage" of the solvent[42]. For example, the hydroperoxide of n-decane in this hydrocarbon as medium at 130°C breaks down into radicals at a rate, measured from the consumption of inhibitor, which is 0.6 of the total rate of decomposition: i.e. 1.2 radicals are formed per hydroperoxide molecule decomposed. The remaining 0.4 of the total rate of decomposition represents reactions in which molecular products are formed[43].

A hydroperoxide breaks down without radical formation on reaction with alkyl and aryl sulphides[44,45], selenium compounds[46], and phosphoric esters[47–49]:

$$(3'')\ ROOH + R'SR \longrightarrow ROH + R'S(O)R.$$

The role of a hydroperoxide in the autocatalysis of oxidation is governed by competition between reactions (3) or (4) and reactions (3′) and (3″), i.e. by the value of $\delta = k_3/k$.

In the liquid phase the diffusion of radicals to the walls of the vessel is made very difficult by the high density of the substance, and liquid-phase oxidation in the absence of inhibitors is characterised by quadratic chain termination with recombination of the radicals. At oxygen pressures of $p_{O_2} \simeq 200$–300 mmHg the concentration of alkyl radicals R$^{\cdot}$ is far lower than that of $RO_2^{\cdot}$ radicals, and therefore chain termination occurs by reaction (5).

The rate constant for the recombination of $RO_2^{\cdot}$ radicals has been measured for various hydrocarbons[50–56], and its value of $k_5 = 10^5$–10^7 litres mole^{-1} s^{-1} is almost independent of temperature ($E_5 \leq 2$ kcal mole^{-1}). In the absence of inhibitor, the variation in radical concentration is given by the equation

$$d[RO_2]/dt = w_0 + nk_3[ROOH] - k_5[RO_2]^2 = 0,$$

from which it follows that the radical concentration is $[RO_2^{\cdot}] = \sqrt{w_i/k_5}$, where $w_i = w_0 + nk_3[ROOH]$ is the rate of initiation of radicals. The length of the chain ν and the rate of oxidation of the hydrocarbon w are

$$\nu = a/g = k_2[RH]/\sqrt{w_i k_5},$$

$$w = k_2[RH]\sqrt{w_i/k_5}.$$

The parameter $g_{qu} = \sqrt{w_i k_5}$ is the effective rate constant for the destruction of $RO_2^{\cdot}$ radicals by quadratic chain termination.

The rate of oxidation of a hydrocarbon is diminished by the presence of an amine, a phenol, or a naphthol, containing an OH, NH_2, or > NH group. Much work has been done on the mechanism of the action of inhibitors and on the kinetics of inhibited oxidation in connection with the practical problems of the stabilisation of various substances (fats, oils, petroleum products, and polymeric materials) against oxidative degradation. Progress in the practical application of antioxidants and in studying the mechanism of their action has been summarised in several reviews and monographs[57–59].

The retardation of oxidation processes in the presence of compounds containing the above groups results from the abstraction of the weakly bound hydrogen by $RO_2^{\cdot}$ radicals with the formation of relatively inactive In$^{\cdot}$ radicals, reaction (i). The parameter $g_{In} = k_i[InH]$ is the kinetic coefficient of the loss of $RO_2^{\cdot}$ radicals in reactions with the inhibitor. The mechanism of the action of inhibitors represented by reaction (i) is supported by kinetic data on the rates of oxidation of hydrocarbons in the presence of inhibitors[61–65], by isotopic[63], spectroscopic[66], and chemiluminescent methods[67], and by several other data[68].

Various methods have been proposed[64,69,70] for measuring the rate constant k_i, which depends on the nature of the inhibitor, the medium (hydrocarbon), and the temperature. Values of $k_i \simeq 10^3$–10^5 litres mole^{-1} s^{-1} have been obtained for inhibitors of varying efficiency. The activation energy for abstraction of a hydrogen atom from an inhibitor molecule by $RO_2^{\cdot}$ radicals is $E_i \simeq 3$–8 kcal mole^{-1}.

The structure and the reactivity of In$^{\cdot}$ radicals have been studied by chemical[71] and physical methods. Most of the recent information on their structure and reactions has been obtained by the electron spin resonance method[72], by means of which In$^{\cdot}$ radicals have been detected in the oxidation of polypropylene in the presence of 1- and 2-naphthols, 4-methyl-2,6-di-t-butylphenol, diphenylamine, and other inhibitors[72,73]. The reaction products from inhibitors under oxidising conditions have been found to include compounds In–RO_2 and In–In, in which the In$^{\cdot}$ radical has either a phenoxy or a quinonoid structure. These compounds could be formed in reactions (7) and (8).[57] If the In$^{\cdot}$ radical is involved in chain termination by reaction (7),

the number of chains m destroyed on one inhibitor molecule exceeds unity ($m \geq 1$).

It has been found that many inhibitors containing one OH or NH_2 group terminate two oxidation chains ($m = 2$), and that bifunctional compounds terminate four oxidation chains ($m = 4$):[67,74,75] i.e. under these conditions the In$^\cdot$ radicals disappear only in reaction (7). The rate constant of this reaction has been determined[76] as $k_7 \simeq 10^9$ litres mole^{-1} s^{-1} for the tetrahydronaphthylperoxy-radical and the phenoxy--radical. Thus this constant is larger than k_i by factors of 10^2–10^4.

The stability of the In$^\cdot$ radical and its ability to react with saturated hydrocarbon molecules

$$(9)\ \mathrm{In}^\cdot + \mathrm{RH} \rightarrow \mathrm{R}^\cdot + \mathrm{InH},$$

vary according to the nature, positions, and number of substituents in the molecule of the initial inhibitor. The rate constant for the abstraction of a hydrogen atom by 2,4,6-tri-t-butylphenoxy-radicals from various hydrocarbons (n-decane, 2,4,6-trimethylheptane, ethylbenzene, cumene) is small ($E_9 \simeq 20$–27 kcal mole^{-1}).[77] In the case of other In$^\cdot$ radicals (in particular from phenol), however, it is supposed that both reaction (9) and

$$(10)\ \mathrm{In}^\cdot + \mathrm{ROOH} \rightarrow \mathrm{InH} + \mathrm{RO}_2^\cdot,$$

are very rapid[63,78,79]. In reactions (9) and (10) the In$^\cdot$ radicals are involved in chain transfer, which substantially lowers the efficiency of the inhibitors. Phenols whose radicals are involved in the chain-transfer processes (9) and (10) are relatively ineffective. The peculiarities of the retardation of oxidation processes by inefficient inhibitors have been analysed[57,63,78,79]. The possibility of various reactions of phenols and amines and their radicals, and hence the overall efficiency of the retardation of an oxidation process by inhibitors, depend on the conditions of oxidation, in particular on the temperature. Above 150°C phenols and amines are consumed mainly by direct oxidation. It is assumed that this process can result in the initiation of chains[45,80]. Little work has been done on the products of the direct oxidation of inhibitors or on their effect on the oxidation of a hydrocarbon.

Here we shall consider the kinetic laws of inhibited oxidation and experimental results on critical concentrations of efficient inhibitors, not involved in any reaction other than those of chain termination. The features of this phenomenon with amines and phenols as inhibitors at high temperatures of 180–220°C, when these compounds undergo reactions other than chain termination, have been discussed in other papers[60,80–84].

According to the above mechanism, the variation in radical concentration is governed by the equations

$$\frac{d[\mathrm{R}]}{dt} = w_0 + k_2[\mathrm{RO}_2][\mathrm{RH}] + k_2'[\mathrm{R}'][\mathrm{RH}] - k_1[\mathrm{R}][\mathrm{O}_2] = 0,$$

$$\frac{d[\mathrm{R}']}{dt} = nk_3[\mathrm{ROOH}] - k_2'[\mathrm{R}'][\mathrm{RH}] = 0,$$

$$\frac{d[\mathrm{RO}_2]}{dt} = k_1[\mathrm{R}][\mathrm{O}_2] - k_2[\mathrm{RO}_2][\mathrm{RH}] - k_i[\mathrm{RO}_2][\mathrm{InH}] - k_7[\mathrm{RO}_2][\mathrm{In}] - k_5[\mathrm{RO}_2]^2 = 0,$$

$$\frac{d[\mathrm{In}^\cdot]}{dt} = k_i[\mathrm{RO}_2][\mathrm{InH}] - k_7[\mathrm{RO}_2][\mathrm{In}] - k_8[\mathrm{In}]^2 = 0.$$

From the last equation it follows that the concentration of In$^\cdot$ radicals can be written

$$[\mathrm{In}] = \frac{k_i[\mathrm{RO}_2][\mathrm{InH}]}{k_7[\mathrm{RO}_2] + k_8[\mathrm{In}]} = \frac{\alpha k_i[\mathrm{InH}]}{k_7},$$

where $\alpha = k_7[\mathrm{RO}_2]/(k_7[\mathrm{RO}_2] + k_8[\mathrm{In}])$ is the probability of chain termination by In$^\cdot$ radicals. Adding up the first three equations, we obtain for the variation in concentration of $RO_2^\cdot$ radicals the equation

$$w_0 + nk_3[\mathrm{ROOH}] = k_i[\mathrm{RO}_2][\mathrm{InH}] + k_7[\mathrm{RO}_2][\mathrm{In}] + k_5[\mathrm{RO}_2]^2 = mk_i[\mathrm{RO}_2][\mathrm{InH}] + k_5[\mathrm{RO}_2]^2, \quad (15)$$

where $m = 1 + \alpha$ is the number of chains destroyed on one inhibitor molecule. With $\alpha = 0$, when the constant k_7 is zero, we have $m = 1$; and with $\alpha = 1$ and $k_8 = 0$, we find that $m = 2$. Thus the parameter m can have values of $2 \geq m \geq 1$.

From Eqn. (15) the concentration of $RO_2^\cdot$ radicals can be expressed

$$[\mathrm{RO}_2^\cdot] = \frac{mk_i[\mathrm{InH}]}{2k_5}\left(\sqrt{1 + \frac{4k_5w_i}{m^2k_i^2[\mathrm{InH}]^2}} - 1\right).$$

When $mk_i[\mathrm{InH}] \ll \sqrt{w_ik_5}$, i.e. when $g_{\mathrm{lin}} \ll g_{\mathrm{qu}}$, the quadratic termination of chains predominates over linear termination, and the inhibitor does not retard the reaction.

If

$$mk_i[\mathrm{InH}] \gg \sqrt{w_ik_5}, \text{ i.e. } g_{\mathrm{lin}} \gg g_{\mathrm{qu}}, \quad (16)$$

the radical concentration is

$$[\mathrm{RO}_2] = \frac{w_i}{mk_i[\mathrm{InH}]} = \frac{w_0 + nk_3[\mathrm{ROOH}]}{mk_i[\mathrm{InH}]}. \quad (17)$$

In this case the chain length $\nu_{\mathrm{inh}} = k_2[\mathrm{RH}]/mk_i[\mathrm{InH}]$ becomes less than the length ν_{qu} in the absence of inhibitor:

$$\frac{k_2[\mathrm{RH}]}{mk_i[\mathrm{InH}]} < \frac{k_2[\mathrm{RH}]}{\sqrt{w_ik_5}}.$$

In the presence of efficient inhibitors, therefore, induction periods appear in the oxidation process right up until the inhibitor is practically completely exhausted, when the relationship (16) ceases to be satisfied. The inequality (16) determines the inhibitor concentration [InH] at which linear termination predominates over quadratic termination[85,86].

This inequality is responsible for the fact that an inhibitor may retard oxidation when introduced at the start of the reaction ($w_i \simeq w_0$), but prove ineffective when introduced at later stages, when the rate of initiation w_i far exceeds the rate of generation of chains w_0. With linear termination of chains on the inhibitor, the variation in hydroperoxide concentration during the reaction is given by the equation

$$\frac{d[\mathrm{ROOH}]}{dt} = (k_2[\mathrm{RH}] + k_i[\mathrm{InH}])\frac{(w_0 + nk_3[\mathrm{ROOH}])}{mk_i[\mathrm{InH}]} - k[\mathrm{ROOH}],$$

which can be written

$$\frac{d[\mathrm{ROOH}]}{dt} = \nu' w_0 + \varphi[\mathrm{ROOH}], \quad (18)$$

where

$$\nu' = \frac{k_2[\mathrm{RH}]}{mk_i[\mathrm{InH}]} + \frac{1}{m} = \nu + \frac{1}{m},$$

is the chain length taking into account the hydroperoxide formed in the chain-termination reaction (i), and $\varphi = k_3n\nu' - k$ is the autocatalytic factor of the process. If ν and φ do not vary with time, integration of Eqn. (18) with the initial conditions $[\mathrm{ROOH}]_0 = 0$ at $t = 0$ leads to the equations

$$[\mathrm{ROOH}] = \frac{\nu' w_0}{\varphi}(e^{\varphi t} - 1) \quad (19)$$

and

$$[RO_2^{\cdot}] = \frac{w_0 k_3 \nu'}{m k_i [InH]\,\varphi}\left(e^{\varphi t} - \frac{k}{n k_3 \nu'}\right). \quad (20)$$

These equations are identical with Eqns. (6) and (7) for the variation in concentration of radicals and of intermediate product obtained on analysing the general scheme of a chain reaction with degenerate branching when $n = 1$ and $g = mk_i[InH]$. Therefore the consumption of hydrocarbon

$$-d[RH]/dt = k_2[RO_2^{\cdot}][RH]. \quad (21)$$

during the induction period of inhibited oxidation should be governed by the relations (12′) and (13′), as well as by Eqn. (14′), which defines the abruptness of the change in induction period on passing through the critical inhibitor concentration.

Fig. 4 (curves *1–3*) illustrates the dependence, calculated from Eqns. (12′) and (13′) of induction period on inhibitor concentration. The time required for 0.01 mole% of the hydrocarbon to be consumed was taken as the end of the induction period; formation of hydroperoxide in the termination reaction was ignored. Calculations were made with experimental values of the elementary rate constants obtained in a study of the liquid-phase oxidation of hydrocarbons: $k_2 = 2.0$ litres mole^{-1} s^{-1}, $k_i = 2 \times 10^5$ litres × × mole^{-1} s^{-1}, $k_3 = 10^{-2}$ (1), 10^{-3} (2), and 10^{-5} (3) s^{-1}, $w_0 = 10^{-10}$ M s^{-1}, [RH] = 5.0 M, $k = k_3$, $m = 1$, and $n = 1$.

Fig. 4 shows that, with the ratio $k_3/w_0 = 10^8$ and 10^7 litres mole^{-1} (curves *1* and *2*), the induction period

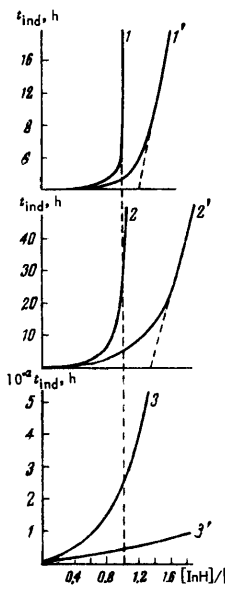


Fig. 4. Dependence of induction period (time required for 0.01% conversion of the hydrocarbon) on inhibitor concentration for different values of the rate constant k_3 (s^{-1}) for dissociation of the hydroperoxide into radicals: 1) and 1′) 10^{-2}; 2) and 2′) 10^{-3}; 3) and 3′) 10^{-5}; 1)–3) inhibitor concentration maintained constant; 1′)–3′) inhibitor used up (calculated values).

increases quite sharply at the critical inhibitor concentration. When the ratio is $k_3/w_0 = 10^5$ litres mole^{-1} (curve *3*), the induction period varies smoothly throughout the concentration range of the inhibitor; limiting phenomena are not found with such ratios of k_3 to w_0.

2. Value of Critical Inhibitor Concentration

The critical concentration of the inhibitor is evaluated from the condition that the autocatalytic factor of the process φ should vanish, i.e. that

$$\nu_{cr} + 1/m = 1/n\delta \quad (22)$$

and is given by

$$[InH]_{cr} = \frac{k_2[RH]\,n\delta}{k_i(m - n\delta)}. \quad (23)$$

According to Eqns. (22) and (23), at values of $n\delta \geqslant m$, oxidation should develop with autocatalysis at any inhibitor concentration — even with very short chains — owing to the hydroperoxide formed in the chain-terminating reaction (*i*). When, however, $\nu \leqslant 1$, reaction of $RO_2^{\cdot}$ radicals with the inhibitor should be accompanied by that of the primary radicals RO and OH (= R′) formed by dissociation of the hydroperoxide. In this case the mechanism of the process should be supplemented by the reactions

$$(i')\ R' + InH \xrightarrow{k_i'} R'H + In^{\cdot},$$

$$(7')\ R' + In \xrightarrow{k_7'} \text{products}.$$

These reactions should yield an alcohol or water, products which do not result in autocatalysis of the process. The occurrence of reactions between the R′ radicals and the inhibitor under oxidation conditions has been demonstrated experimentally [28].

If these reactions take place, and provided that $k_i/k_i' = k_2/k_2' = k_7/k_7'$, the concentrations of the radicals can be written

$$[R'] = \frac{nk_3[ROOH]}{k_2'[RH] + mk_i'[InH]}, \quad [RO_2^{\cdot}] = \frac{w_0 + \gamma n k_3[ROOH]}{mk_i[InH]},$$

where

$$\gamma = \frac{k_2'[RH]}{k_2'[RH] + mk_i'[InH]} = \frac{\nu}{\nu + 1},$$

is the probability of the formation of peroxy-radicals $RO_2^{\cdot}$ from the primary radicals R′, i.e. the probability of propagation of the chain by R′ radicals. In this case we have for m

$$m = 1 + \frac{\alpha(1 + a)}{1 + a\alpha}, \text{ where } a = \frac{k_i'[R']}{k_i[RO_2^{\cdot}]}.$$

Just as in the preceding case $m = 1$ when $\alpha = 0$, and $m = 2$ when $\alpha = 1$.

The autocatalytic factor of the process in Eqns. (19) and (20) becomes $\varphi = k_3 n\gamma(\nu + 1/m) - k$, while the limiting condition is given by

$$(\nu_{cr} + 1/m)\,\gamma_{cr} = \frac{(\nu_{cr} + 1/m)\,\nu_{cr}}{(\nu_{cr} + 1)} = \frac{1}{n\delta}, \quad (22')$$

from which it follows that in general, with various chain lengths taken into account, the critical inhibitor concentration is given by the formula

$$[InH]_{cr} = \frac{k_2[RH]\,n\delta\gamma_{cr}}{k_i(m - \gamma_{cr}n\delta)}. \quad (23')$$

It is seen from Eqn. (22′) that the critical concentration should be finite for any relationship between the parameters $2 \geqslant m \geqslant 1$ and $n\delta \leqslant 2$. We have

$$\nu_{cr} = \frac{1}{2}\left(\frac{1}{n\delta} - \frac{1}{m}\right) + \sqrt{\frac{1}{4}\left(\frac{1}{n\delta} - \frac{1}{m}\right)^2 + \frac{1}{n\delta}},$$

when $n\delta \ll m$, the chain length $\nu_{cr} \gg 1$, $\gamma_{cr} \simeq 1$, and the critical inhibitor concentration is

$$[InH]_{cr} = \frac{k_2[RH]n\delta}{k_i m}.$$

When $n\delta = m$ the critical inhibitor concentration is

$$[InH]_{cr} = \frac{k_2[RH]}{k_i\sqrt{m}}.$$

3. Effect of Inhibitor Consumption on Abruptness of Change in Induction Period on Passing through the Critical Inhibitor Concentration

Eqns. (19) and (20) for the variation in concentration of radicals and hydroperoxide have been obtained on the assumption that the chain length ν and the autocatalytic factor φ remain unchanged during the reaction. This might have been the case if the inhibitor concentration had been maintained constant. However, the chief feature of inhibited oxidation is the consumption of inhibitor, which occurs at the rate

$$-d[InH]/dt = k_i[RO_2][InH] = \frac{w_0 + nk_3[ROOH]}{m}. \qquad (24)$$

If inhibitor is consumed, the effective rate constant of chain termination $g_{1in} = mk_i[InH]$ continuously diminishes, while the chain length and the autocatalytic factor increase, during the reaction.

An analysis has been made[87] of the effect of inhibitor consumption on the sharpness of the transition through $[InH]_{cr}$. The set of equations (15), (18), (21), and (24) for the concentration variation of radicals, intermediate product, inhibitor, and hydrocarbon was solved by numerical integration on an electronic computer. The values chosen for the elementary rate constants were $k_2 = 2.0$ litres × × mole^{-1} s^{-1}, $k_i = 2 \times 10^5$ litres mole^{-1} s^{-1}, $k_5 = 2 \times \times 10^7$ litres mole^{-1} s^{-1}, $w_0 = 10^{-10}$ M s^{-1}, [RH] = 5.0 M, $k_3 = 10^{-2}$–10^{-5} s^{-1}, $m = 1$, $n = 1$, and $k = k_3$. The formation of hydroperoxide by chain termination on the inhibitor was ignored in Eqn. (15).

The data given above showed that the values chosen for the rate constants simulate very closely actual processes of the autoxidation (with $k_3 = 10^{-4}$–10^{-5} s^{-1}) and the catalysed oxidation (with $k_3 = 10^{-2}$–10^{-3} s^{-1}) of hydrocarbons.

Figs. 5 and 6 illustrate kinetic curves for inhibitor consumption at k_3/w_0 ratios of 10^8 and 10^5 litres mole^{-1} (Figs. 5*a* and 6*a*) and the variation in the autocatalytic factor (Figs. 5*b* and 6*b*) during the process. Fig. 4 (curves *1′*–*3′*) gives the dependence of the induction period on the initial inhibitor concentration in this process. The end of the induction period is taken to be the time at which 0.01 mole % of the hydrocarbon has disappeared, when the inhibitor has already been completely exhausted. Figs. 5*b* and 6*b* show that the autocatalytic factor increases steadily during the process from negative values at $[InH] > [InH]_{cr}$ to positive values at $[InH] < [InH]_{cr}$.

At the ratio $k_3/w_0 = 10^8$ the inhibitor is consumed autocatalytically during the induction period (Fig. 5*a*) when

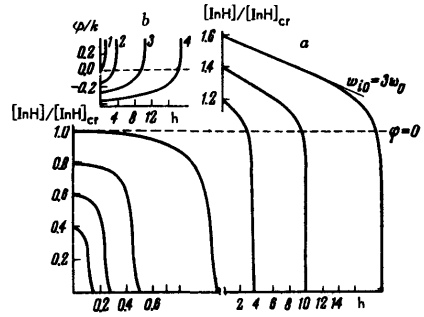

Fig. 5. *a*) Calculated kinetic curves for the consumption of inhibitor in the oxidation of a hydrocarbon with a ratio of the rate constant k_3 for dissociation of the hydroperoxide into radicals to the rate of generation of chains w_0 of $k_3/w_0 = 10^8$ litres mole^{-1}; *b*) variation in autocatalytic factor during reaction resulting from consumption of the inhibitor.

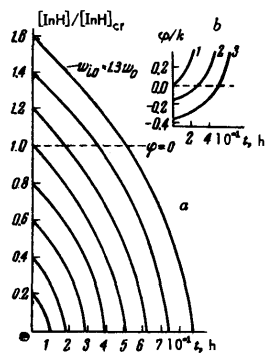

Fig. 6. *a*) Calculated kinetic curves for the consumption of inhibitor during the induction period in the oxidation of a hydrocarbon with a ratio of $k_3/w_0 = 10^5$ litres × × mole^{-1}; *b*) variation in autocatalytic factor during induction period resulting from consumption of inhibitor.

$[InH] < [InH]_{cr}$, but when $[InH] > [InH]_{cr}$ linear sections are present in which the inhibitor is consumed at a rate close to w_0. In this case the dependence of the induction period on the initial inhibitor concentration exhibits quite clear limiting phenomena (Fig. 4, curve *1′*). Autocatalytic consumption of the inhibitors 1- and 2-naphthols, 1- and 2-naphthylamines, and diphenylamine has been observed during the induction period in the oxidation of tetrahydronaphthalene (at 140°C),[27] cyclohexanone (at 120°C),[88] and hexadecane[89]. If the rate constant for dissociation of the intermediate product into radicals is small ($k_3 = 10^{-5}$ s^{-1}), the rate of initiation of chains due to degenerate branching may be close to the rate of generation of radicals. Fig. 6*a* shows that in this case the rate of consumption of inhibitor only slightly increases with time in comparison with the rate of generation of chains, and the induction period is proportional to the initial inhibitor concentration (Fig. 4, curve *3′*). A very frequent case is consumption of inhibitor at a constant rate, when the induction period is a

linear function of the inhibitor concentration. It follows from Figs. 6*a* and 4 that these regularities may be present at ratios of $k_3/w_0 \leq 10^5$ litres mole^{-1}. A constant rate of inhibitor consumption and a linear dependence of induction period on inhibitor concentration have been observed with the inhibitors *N*-phenyl-2-naphthylamine, 1-naphthol, and various alkylphenols in the oxidation of rubber[90], n-decane[87], ethyl methyl ketone, ethanol[91], and petrol[92].

Comparison of curves *1* and *1'*, *2* and *2'*, and *3* and *3'* in Fig. 4 shows that consumption of inhibitor diminishes the sharpness of the increase in induction period at the critical inhibitor concentration. It is seen from curves *1'* and *2'* that it is extremely difficult to determine $[InH]_{cr}$ when the transition through $\varphi = 0$ is unclear; extrapolation of the linear sections of the t_{ind}–$[InH]_0$ relationships yields values of $[InH]_{cr}$ which are too high.

However, the transition through $\varphi = 0$ should be sharp if $k_3/w_0 > 10^8$, and the experimental value of $[InH]_{cr}$ is close to the true value. The slope of the linear portions of curves *1'*–*3'* (Fig. 4) when $[InH] > [InH]_{cr}$ is close to the rate of generation of chains.

4. Results of Experimental Study of Critical Inhibitor Concentrations

Critical phenomena have been observed in the oxidation of n-decane in the presence of copper stearate as catalyst[93]. In this reaction the copper ions have a dual function, in that they catalyse the oxidation and act as inhibitor. The catalytic effect of copper stearate is already apparent at the very low concentrations of 10^{-5} mole % and right up to 0.060 mole %. At these concentrations the copper salt accelerates the formation of oxidation products — alcohols, ketones, and acids — in comparison with the uncatalysed reaction. At the same time the hydroperoxide concentration is diminished as compared with the uncatalysed reaction, more strongly the higher the copper stearate concentration. This fact indicates that the initiating effect of the copper salt is associated with an acceleration of the dissociation of hydroperoxide into radicals, as occurs with other metals of variable valency: $ROOH + Cu^{2+} \rightarrow RO_2\cdot$. Acceleration of the oxidation process, however, begins after a certain induction period has elapsed.

The plot of the variation in induction period with $CuSt_2$ concentration (Fig. 7) shows that the induction period gradually increases from 2 to 30 min up to $[CuSt_2] =$ = 0.06 mole %. Further slight increase in the copper stearate concentration by 0.005 mole % produces a sharp increase in the induction period of more than 15 h. Thus abrupt cessation of the reaction is observed at the critical copper stearate concentration of 0.065 mole %. This phenomenon may be associated with a transition at this concentration from autocatalytic ($\varphi > 0$) to steady-state ($\varphi < 0$) oxidation. The critical phenomenon in the presence of the copper salt is associated with the inhibiting action of copper ions.

The presence of a second, initiating action may explain the abrupt character of the transition to a steady state. The great rate of the catalysed dissociation of hydroperoxide into radicals ensures a rapid development of the reaction when $\varphi > 0$, and therefore the transition through the critical concentration $[CuSt_2]_{cr}$ occurs very sharply.

Critical phenomena are observed also in the oxidation of hydrocarbons in the presence of such typical inhibitors as phenols, naphthols, and amines. Figs. 8 and 9 show the dependence on inhibitor concentration of the induction period in the oxidation of ethylbenzene and n-decane in glacial acetic acid with cobalt acetate $CoAc_2$ as catalyst[40,87,94]. It is evident from these diagrams that a critical inhibitor concentration exists above which oxidation is sharply retarded, whereas induction periods are short at concentrations below $[InH]_{cr}$.

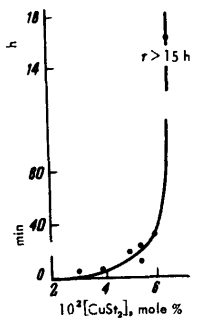

Fig. 7. Dependence of induction period in oxidation of n-decane on concentration of copper stearate at 140°C.

It has been shown[94] that the critical concentration of 1-naphthol varies little with temperature $E_{obs} = E_i - E_2 \simeq$ $\simeq$ 1 kcal mole^{-1}, is independent of the catalyst concentration (at $[CoAc_2] = 0.0056$–0.0565 M), and increases in proportion to the hydrocarbon concentration. These experimental results indicate that the effective activation energy and the dependence of the critical inhibitor concentration on the hydrocarbon concentration are consistent with Eqn. (23).

Table 3 lists experimental critical inhibitor concentrations together with values calculated from Eqn. (23) with

	tris-4-hydroxy-3,5-di-t-butylbenzylamine	0.12	1.34	11
	Ionol	1.0	15	15

* From Ref. 94: [RH] = 3.24 M, $[CoAc_2]$ = 0.0113 M, [RH] : $[CH_3COOH]$ = 2 : 3, at 60°.

** From Ref. 40: [RH] = 2.6 M, $[CoAc_2]$ = 0.034 M, [RH] : $[CH_3COOH]$ = 1 : 1, at 90°C.

$n = 1$, $\delta = 1$, $m = 2$, and $\gamma = 1$. The ratio k_i/k_2 was determined by special methods in each case. The last column shows that the experimental values are lower than the calculated values. The discrepancy indicates that, at some stage in the oxidation or the breakdown of the hydroperoxide, new reactions, hitherto disregarded, appear in the system comprising the metal of variable valency and the inhibitor. Two hypotheses can be put forward to explain the increased effectiveness of antioxidants in the presence of cobalt ions.

In the calculation of the critical inhibitor concentration it was assumed that $\delta = 1$. However, the probability of degenerate branching may be less than unity, if the complex $[ROOH.CoAc_2]$ can react directly with the inhibitor to form valency-saturated compounds:

$$[ROOH \cdot Co(Ac)_2] + InH \rightarrow ROIn + Co(Ac)_2 + H_2O.$$

The second hypothesis is that the inhibitor may interact with the metal ion of higher valency to form an In radical:

$$(11)\quad Co^{3+}(Ac)_2(OH) + InH \rightarrow Co^{2+}(Ac)_2 + H_2O + In^{\cdot}.$$

The occurrence of this reaction in the mechanism of inhibited oxidation in the presence of metals of variable valency is highly probable. Phenoxy, naphthyloxy, and other radicals are formed in the reactions of phenols and naphthols with hydroperoxides in the presence of cobalt salts and of such compounds as PbO_2, $(CH_3COO)_4Pb$, and $K_3[Fe(CN)_6]$, which contain the metal in the higher valency state [58,73,95-97]. If the In· radicals react with the $RO_2^{\cdot}$ radicals, the occurrence of reaction (11) will increase the rate of chain termination.

It has been shown[40] that, when reaction (11) is taken into account, the critical inhibitor concentration is (with $\gamma = 1$)

$$[InH]_{cr} = \frac{k_2[RH]n\delta}{k_i}\sigma.$$

The parameter σ is defined by the formula

$$\frac{\sigma}{1-\sigma} = \frac{k_d[Co^{3+}][ROOH]}{k_{11}[Co^{2+}][InH]},$$

where k_d is the rate constant for the reaction of Co^{3+} with ROOH (see p. 267). If Co^{3+} reacts more rapidly with the hydroperoxide than with the inhibitor, $\sigma \rightarrow 1$. When $\sigma = 1$, the formula (23) is obtained for the critical inhibitor concentration. If, however, Co^{3+} reacts predominantly with the inhibitor, $\sigma < 1$, and the critical inhibitor concentration decreases.

Thus the formation of phenoxy-radicals in the reaction of Co^{3+} with an inhibitor should result in a lower critical inhibitor concentration, as is observed experimentally. The very abrupt cessation of oxidation at this critical concentration found in these experiments completely confirms the kinetic analysis of the transition through limiting conditions with degenerate chain branching. The rate constant for dissociation of the hydroperoxides of n-decane and ethylbenzene in the presence of cobalt acetate under these experimental conditions is of the order of $k_3 \simeq 10^{-2}\ s^{-1}$, while the rate of generation of chains is $w_0 \simeq 10^{-10}-10^{-11}\ M\,s^{-1}$. Thus the ratio $k_3/w_0 \geqslant 10^8-10^9$ litres $mole^{-1}$, which corresponds to the relationships *1* and *1'* in Fig. 4.

In all cases considered above, limiting phenomena were associated with change in the autocatalytic factor from positive to negative values in the initial stages of the reaction: i.e. the induction period depended on an external parameter, the inhibitor concentration. Cessation of an autocatalytic reaction which has already begun has been observed[98] when limiting conditions are reached during the process. The oxidation of n-decane was studied in the presence of potassium permanganate, which, just like copper stearate[93], has a dual role in the oxidation. Addition of 0.076–0.576 mole % of potassium permanganate halves the induction period in the oxidation of n-decane compared with autoxidation at the same temperature (140° C). The maximum concentration of peroxides in the presence of the permanganate is one-third of that in the uncatalysed reaction, owing to participation of the catalyst in its radical dissociation.

Potassium permanganate was found to have an inhibiting as well as an initiating and controlling function. Fig. 10 shows kinetic curves for the accumulation of acids at various permanganate concentrations. It is seen that a reaction which has developed is abruptly stopped at different degrees of conversion depending on the permanganate concentration. The limiting yield of acids decreases with increase in this concentration.

Separate experiments in which potassium permanganate was withdrawn showed that the cessation of the reaction is due to chain termination involving a manganese salt. It

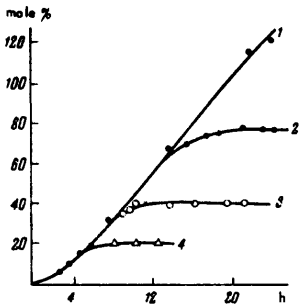

Fig. 10. Kinetic curves for the accumulation of acids in the presence of potassium permanganate (mole %):
1) 0.768; 2) 0.192; 3) 0.384; 4) 0.576.

follows from Eqn. (23) that the limiting condition can be reached if the hydrocarbon is exhausted to a definite concentration $[RH]_{cr}$. Fig. 11 shows that the hydrocarbon concentration at which reaction ceases is a linear function of the potassium permanganate concentration. This supports the conclusion that the cessation of oxidation in the presence of potassium permanganate is associated with the achievement of a limiting condition.

A critical solvent (benzene) concentration has been observed[99] in the oxidation of liquefied butane dissolved in it at temperatures and pressures close to the critical values (170°C and 50 atm). A certain relationship was observed to exist between the concentrations of butane and benzene

$$\gamma_{cr} = \frac{[RH]}{[C_6H_6] + [RH]},$$

below which butane is not oxidised at all, and above which the usual autocatalytic reaction develops.

Fig. 12*a* shows that the yield of acetic acid falls as the proportion of benzene in the initial mixture is increased, until a value corresponding to $\gamma = 0.28$ is reached, at which reaction ceases completely. This phenomenon can be seen in Fig. 12*b*, which illustrates the dependence on γ of the quantity of acetic acid formed during 2 h of the reaction. When mixtures having $\gamma > 0.28$ are taken for an experiment, reaction continues until the value $\gamma_{cr} = 0.28$ is reached (Fig. 12*c*).

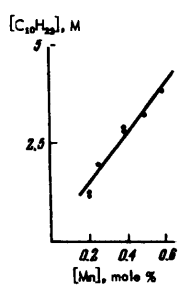

Fig. 11. Dependence of limiting hydrocarbon concentration on initial concentration of potassium permanganate.

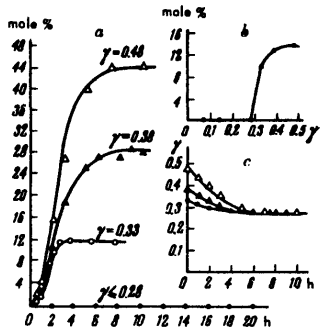

Fig. 12. *a*) Kinetic curves for the accumulation of acetic acid in the oxidation of liquefied butane in benzene at 170°C and 50 atm with various initial ratios γ of butane to benzene; *b*) dependence on γ of quantity of acetic acid formed in 2 h of reaction at 170°C and 50 atm; *c*) variation in γ during reaction.

It is assumed that in this reaction $RO_2^{\cdot}$ radicals add on to the benzene molecule, with the formation of relatively inactive radicals, which are incapable of chain propagation.

V. PHENOMENON OF A CRITICAL INHIBITOR CONCENTRATION IN THE CONTINUOUS OXIDATION OF HYDROCARBONS IN REACTION VESSELS WITH IDEAL MIXING (OPEN SYSTEMS)

All the experimental results discussed above on critical phenomena in the inhibited oxidation of hydrocarbons, and the kinetic analysis of this phenomenon, have related to batch processes occurring in a closed system. In such processes the starting materials are introduced into the reaction vessel in a single step at the start of the reaction, and remain together with the reaction products inside the reaction vessel until the end of the process. However, experimental results[14,100,101] show that the existence of limiting conditions in the inhibited oxidation of hydrocarbons is exhibited most clearly when the process is conducted continuously in reaction vessels with ideal mixing. In this method of conducting a process the starting materials enter continuously, at a rate u (in ml h^{-1}), a reaction vessel of volume V (ml), while a proportion of the reaction products are removed from the vessel at the same rate. Vigorous stirring should ensure a uniform concentration of the reaction components throughout the vessel. Such unclosed systems, which represent a flow system with perfect mixing, have been termed open systems, since every volume element is "open" for the entry of new substances[102].

The variation in concentration of the reactants in a continuous process can in general be represented by the equation

$$\frac{d[A_i]}{dt} = w_f - w_r + v[A_i]_0 - v[A_i].$$

where w_f and w_r are the rates of formation and removal of a component A_i by chemical reactions. The product $v[A_i]_0$ represents the rate of increase in concentration of this component resulting from its entry into the reaction vessel as a solution of concentration $[A_i]_0$; and the term

$-v[A_i]$ allows for the decrease in concentration of the component A_i due to the withdrawl of reaction products. The parameter v is the ratio $v = u/V$. When a process is conducted in this way, the concentration of each component A_i ceases to vary ($d[A_i]/dt = 0$) after a certain time, because the sum of the rates at which the concentration of the substance increases ($w_f + v[A_i]_0$) becomes equal to the sum of the rates at which the concentration decreases ($w_r + v[A_i]$).

In the steady state ($d[A_i]/dt = 0$) the rates w_f and w_r are constant, and the concentrations of the reactants remain unchanged indefinitely. The establishment of a steady-state chemical reaction in an open system is its most important feature [103-107].

In several cases of complex chemical reactions, the possibility has been shown both theoretically and experimentally of harmonic oscillations about the steady state [108-111].

In several cases the study of simple and complicated reactions under steady-state conditions, with the reaction conducted as a continuous process, permits the solution of many problems associated with the mechanism of the reaction. In particular, it is possible in open systems to study unstable intermediate products [103]. A new method has been proposed [112,113] for investigating, in complicated chain oxidations of hydrocarbons, the reactivities of various substances towards $RO_2^{\cdot}$ radicals, and for measuring the rates of formation and of consumption of the reaction products, etc.

The oxidation of a hydrocarbon has been studied [100,101] in the presence of an inhibitor in an open system. Fig. 13 illustrates the accumulation of hydroperoxide in the oxidation of n-decane in the presence of 1-naphthol as inhibitor. A reaction vessel of volume $V = 5$ ml was filled with n-decane containing 1-naphthol in concentrations which varied from experiment to experiment, and from the start of oxidation a similar solution was automatically and continuously fed into the vessel at a rate of $u = 2.6$ ml h^{-1}. Oxygen was bubbled through the oxidising hydrocarbon at 1.6 litres h^{-1}, and at the same time stirred the mixture. Fig. 13 shows that, with a continuous supply of pure n-decane in the absence of inhibitor (curve *1*) the concentration of the reaction product (hydroperoxide) increases to a certain value (0.8 mole %), after which the reaction proceeds at a constant rate.

If n-decane containing 1-naphthol enters the reaction vessel, increase in the inhibitor concentration over the range $(3-9) \times 10^{-6}$ M is accompanied by a lengthening of the induction period, but the previous steady state is established after the end of the induction period.

With further slight increase in the inhibitor concentration from 9×10^{-6} to 9.05×10^{-6} M a sudden change in the rate of the process occurs: the reaction does not emerge from the induction period, and oxidation does not take place. The critical character of the dependence of the induction period of the reaction and the hydroperoxide concentration in the steady state on the initial inhibitor concentration is evident from Fig. 13*b*.

Similar critical phenomena in the oxidation of n-decane in an open system have been observed with tris-4-hydroxy-3,5-di-t-butylbenzylamine as inhibitor (Fig. 14).

The relation between the phenomenon of a critical inhibitor concentration in a continuous process and the mechanism of oxidation has been analysed [94]. The variation in concentration of radicals r (= $RO_2^{\cdot}$), hydroperoxide x (ROOH), inhibitor i (InH), and hydrocarbon [RH] in an open system is described by the equations

$$dr/dt = w_0 + nk_3x - mk_i ir - k_6 r^2 = 0, \quad (25)$$

$$dx/dt = k_2[RH]r - (k_3 + k_3' + v)x, \quad (26)$$

$$di/dt = -k_i ir - vi + vi_0, \quad (27)$$

$$d[RH]/dt = -k_2 r[RH] - v[RH] + v[RH]_0. \quad (28)$$

In the experiments illustrated in Figs. 13 and 14, hydrocarbon and inhibitor enter the reaction vessel continuously at rates of $v[RH]_0$ and vi_0 respectively, and hydrocarbon, inhibitor, and hydroperoxide and other reaction products leave the reaction vessel continuously at rates of $-v[RH]$, $-vi$, and $-vx$ respectively, where [RH], i, and x are the concentrations of the corresponding substances in the reaction vessel. The change in concentration of radicals due to withdrawal of oxidation product ($-vr$) is insignificant, and can be neglected. In the equation for dx/dt the formation of hydroperoxide in chain termination on the inhibitor is disregarded, which is valid with sufficiently long chains ($\nu > 1$). With long chains the parameter γ, which determines the participation of RO and OH radicals in chain

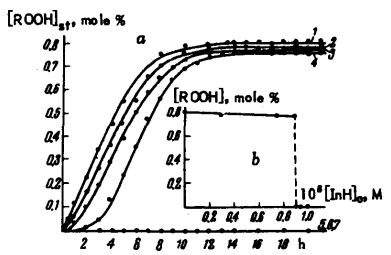

Fig. 13. *a*) Kinetic curves for the accumulation of hydroperoxide in the continuous oxidation of n-decane in the presence of 1-naphthol (M): 1) 0; 2) 3×10^{-6}; 3) 7.5×10^{-6}; 4) 9.00×10^{-6}; 5) 9.05×10^{-6}; 6) 1.2×10^{-5}; 7) 1.4×10^{-5}. *b*) Dependence of steady-state concentration of hydroperoxide on initial concentration of 1-naphthol.

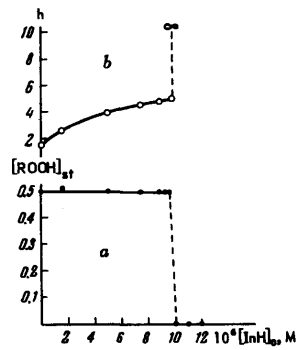

Fig. 14. Dependence, on concentration of tris-4-hydroxy-3,5-di-t-butylbenzylamine with inhibitor solution entering reaction vessel at a rate of $v = 1.83 \times 10^{-4}$ s^{-1} at 130°C, of: *a*) steady-state concentration of n-decane hydroperoxide; *b*) induction period.

propagation, is close to unity, and reactions of these radicals with the inhibitor can be disregarded. It is assumed that the In radicals are involved only in chain termination.

Provided that $k_5 r^2 \ll m k_i r i$, the equations for dr/dt and dx/dt can be combined to give

$$dx/dt = \nu w_0 + \varphi x,$$

where $\nu = k_2[RH]/mk_i i$ is the chain length, $\varphi = k_3(\nu - 1/\delta)$ the autocatalytic factor, and $\delta = k_3/(k_3 + k_3' + v)$ the probability of degenerate chain branching in the continuous process.

A feature of continuous reactions with perfect mixing of the components of the reaction mixture is the establishment of steady-state concentrations of the starting materials $[RH]_{st}$ and i_{st} and of the reaction products x_{st}, when the process occurs at a constant rate, so that $dx/dt = 0$, $di/dt = 0$, and $d[RH]/dt = 0$:

$$\nu w_0 + \varphi x_{st} = 0, \quad (26')$$

$$-k_i i_{st} r_{st} - v i_{st} + v i_0 = 0, \quad (27')$$

$$-k_2 r_{st}[RH]_{st} - v[RH]_{st} + v[RH]_0 = 0.$$

It follows from Eqn. (26') that, under steady-state conditions of continuous oxidation with chain termination on an inhibitor, the autocatalytic factor should always be negative ($\varphi < 0$), since both νw_0 and x are positive. The inhibitor concentration in the steady-state i_{st} should therefore exceed the value $i_{\varphi=0}$ at which the autocatalytic factor is zero:

$$i_{st} > i_{\varphi=0} = \frac{k_2[RH]n\delta}{mk_i}. \quad (29)$$

Let us denote the steady state established during oxidation in the presence of an inhibitor as state (I). In this state the rate of reaction of the hydrocarbon is very small. It follows from Eqn. (26') that the hydroperoxide concentration x_{st} at $\varphi < 0$ is given by

$$x_{st} = \frac{\nu w_0}{|\varphi|} = \frac{w_0}{nk_3(i_{st}/i_{\varphi=0} - 1)}.$$

When $i_{st}/i_{\varphi=0} = 1.4$, for example, the concentration of the intermediate product is $x_{st} = 1.1 w_0/k_3$ (with $n = 2$), and right up to the value $w_0/k_3 = 5 \times 10^{-4}$ M it is impossible to detect hydroperoxide in the steady state (I) by the usual iodometric method.

If the concentration of inhibitor falls to $i_{\varphi=0}$ during the oxidation, the autocatalytic factor of the process becomes zero.

Eqn. (26') shows that, when $\varphi \geq 0$, the reaction cannot arrive at the steady state (I). When $\varphi > 0$, the reaction is autocatalytic, the concentration of radicals r increases, and inhibitor is consumed. A new steady state (II) is then established, associated with high rates of autocatalytic oxidation.

The oxidation of a hydrocarbon in the presence of an inhibitor in an open system has been simulated by the numerical integration of Eqns. (25)–(28) on an electronic computer. The parameters and elementary rate constants, obtained experimentally under conditions of the liquid-phase autoxidation of the hydrocarbons, chosen for the simulation were $w_0 = 10^{-10}$ M s^{-1}, $[RH] = 5.0$ M, $k_2 = 2.0$ litres mole^{-1} s^{-1}, $k_i = 2 \times 10^5$ litres mole^{-1} s^{-1}, $k_5 = 2 \times 10^7$ litres mole^{-1} s^{-1}, $k_3 = 10^{-4}$ s^{-1}, $k_3' = 0$, $v = 1.7 \times 10^4$ s^{-1}, $m = 1$, and $n = 1$.

Fig. 15 gives the calculated kinetic curves for the accumulation of intermediate product, and also the change in its concentration in the steady state and the induction period with different inhibitor concentrations. It is seen from Figs. 13–15 that the calculated relationships completely reproduce the rules observed experimentally.

Fig. 16 shows the variation in the autocatalytic factor of the process at inhibitor concentrations $[i_0]$ of $0.96[i_0]_{cr}$ (curve *2*) and $1.04[i_0]_{cr}$ (curve *1*). At an inhibitor concentration slightly exceeding the critical value, the autocatalytic factor remains negative until the steady state is established. At this innibitor concentration the rate of oxidation of the hydrocarbon is insignificant (Fig. 15*a*). At an inhibitor concentration below the critical value the autocatalytic factor is at first negative, passes through zero, and then assumes positive values. In this case the reaction is autocatalytic (Fig. 15, curve *3*).

Thus the critical phenomena in an open system represent a transition from a steady-state process ($\varphi < 0$) to an autocatalytic process ($\varphi > 0$), as occurs in a closed system.

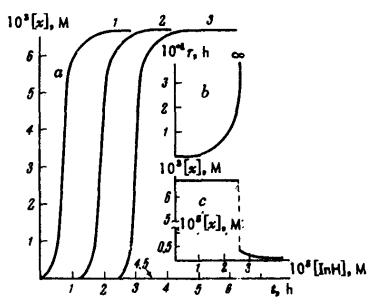

Fig. 15. *a*) Calculated kinetic curves for the accumulation of hydroperoxide in the continuous oxidation of a hydrocarbon in the presence of an inhibitor at an initial concentration $[i_0]/[i_0]_{cr}$ of: 1) 0; 2) 0.8; 3) 0.96; 4) 1.04; 5) 1.2.
b) Variation in induction period in presence of inhibitor with continuous oxidation.
c) Dependence of steady-state concentration of hydroperoxide on concentration of inhibitor.

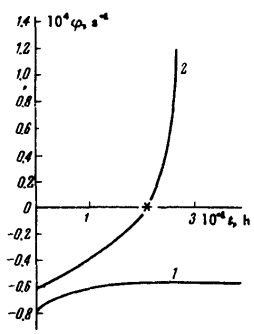

Fig. 16. Variation in autocatalytic factor during continuous oxidation of a hydrocarbon at inhibitor concentrations $[i_0]/[i_0]_{cr}$ of: 1) 1.04; 2) 0.96.

However, limiting conditions of oxidation are very sharply developed in an open system, and well-defined critical phenomena are observed even under conditions under which, in closed systems, the transition through $\varphi = 0$ is not accompanied by an abrupt change in the rate of the process (Fig. 4, curve *3*). The reason for this will become clear from a comparison of Fig. 16 with Figs. 5*b* and 6*b*, which illustrate the variation in the autocatalytic factor in continuous and batch processes.

In a batch process the inhibitor is introduced into the oxidising hydrocarbon in a single step, at the start of the reaction, and is continuously consumed during the reaction. The time of the steady-state development of the reaction (when $\varphi < 0$) in a closed system is limited by the time for the inhibitor to be exhausted to the critical concentration, and at any initial inhibitor concentration exceeding the critical value a transition will occur from the steady-state to the autocatalytic process ($\varphi > 0$) when the inhibitor has been consumed to the critical concentration.

In an open system the reaction cannot emerge from the steady state ($\varphi < 0$) for an infinite time. The advantage of an open system in revealing the limiting conditions of a process was emphasised[114] in connection with an analysis of the conditions of ignition in an exothermic reaction occurring in an adiabatic flow system with perfect mixing: "The boundary between spontaneous ignition and a steady state is absolutely sharp; physically this is connected with the fact that, in a flow system with a continuous supply of material, we can leave the system for an indefinite... time to reveal whether or not a steady state has been reached".

It has been shown theoretically[115] that several steady states may exist in an open system in which a composite process is occurring, consisting of a set of unimolecular and bimolecular reactions among N components. In particular, two stable steady states should occur in oxidation with a continuous supply of inhibitor together with the initial hydrocarbon to the reaction vessel.

The critical inhibitor concentration in an open system can be evaluated from Eqns. (26′) and (27′). These equations can be combined to give

$$x_{st}^2 - x_{st}\left[\frac{(mvi_0 - w_0)}{nk_3} - \frac{vk_2[RH]_{st}}{kk_i}\right] + \frac{vw_0k_2[RH]_{st}}{nk_3kk_i} = 0.$$

When $[i_0] > [i_0]_{cr}$, this equation has two positive roots, the smaller of which corresponds to the steady state (I), while the larger root defines an unstable state. When $[i_0] = [i_0]_{cr}$, the two roots are equal; and when $[i_0] < [i_0]_{cr}$, the equation has no positive root. Thus the value of $[i_0]_{cr}$ is determined from the condition that the above equation should have equal roots:

$$[i_0]_{cr} = (\sqrt{i_{\varphi=0}} + \sqrt{w_0/mv})^2. \qquad (30)$$

From the critical inhibitor concentration $[i_0]_{cr}$ we can determine by means of Eqns. (29) and (30) the relative activities k_i/k_2 of inhibitors towards chain radicals. For the inhibitors 1-naphthol and tris-4-hydroxy-3,5-di-t-butylbenzylamine the values of this ratio determined from experimental data (Figs. 13 and 14) were 3.8×10^5 and 6.5×10^4 respectively, which are very close to the values of 5.8×10^5 and 8.5×10^4 obtained by an independent method from experiments on the initiated oxidation of n-decane and by a chemiluminescent method[70].

Thus the striking property of branched chain processes — the existence of critical (limiting) phenomena — is clearly revealed in a variety of ways even with slow non-stationary processes with degenerate chain branching. Clear critical effects occur in the oxidation of organic compounds, especially in the condensed state (liquid phase). The presence of these effects, which confirms so vividly the branched chain character of the corresponding processes, should undoubtedly be taken into account in developing a general theory of the action of inhibitors (antioxidants), and will play its part in working out optimum conditions for the practical use of inhibitors, e.g. for the suppression of undesirable oxidative changes.

V. Mechanism of thermal explosion in condensed media 289

I. INTRODUCTION

Studies of scientific and practical problems associated with thermal explosions have attracted considerable interest in recent years. These investigations are highly relevant not only to the development of the physics of combustion and of explosions, which includes the theory of thermal explosions as one of its subdivisions, but also to fundamental branches of knowledge such as chemical kinetics and the theory of heat transfer. The phenomenon of thermal explosion is used in the laboratory as a method of physicochemical research. Thermal explosion is the simplest among the forms of transformation of matter considered in the physics of combustion and of explosion. Therefore the formalism of the theory of thermal explosions finds application in the study of more complicated phenomena, such as the initiation of explosion by external (non-thermal) effects (impact, friction, etc.), multistage combustion, and detonation. The practical interest in thermal explosion processes arises mainly from problems of industrial safety in some types of operation with explosive systems (processing, manufacture of articles, explosive operations in high-temperature boreholes, etc.). In many cases, safe conditions excluding the possibility of spontaneous explosion can in principle be predicted, on the basis of the theory of thermal explosions.

The first quantitative formulation of the theory of thermal explosions was published in 1928 by Semenov [1], who used the simplest ideas on the evolution and extraction of heat to calculate critical conditions leading to thermal explosion, and the heating effect preceding explosion. This paper by Semenov laid the foundations for the development of the theory of thermal explosions, and stimulated numerous investigations in the 1930's, notably those of Todes, Rice, Frank-Kamenetskii and others [2-10]. A generalised treatment of these researches, which we shall call the classical theory of thermal explosions, was given in a review by Semenov [11] and in monographs by Frank-Kamenetskii [12] and by Semenov [13].

Since gas-phase reactions were studied intensively in the investigation of chemical kinetics in the 1930's, the classical theory of thermal explosion deals mainly with gases. In later years, in connection with the great interest taken in condensed matter, systematic studies of thermal explosions in condensed media were begun. These studies contributed to the development of the general principles of the theory as well as to some specific aspects characteristic of condensed phases.

No reviews dealing with the work done since the formulation of the classical theory of thermal explosions have appeared in the literature. A few papers have been discussed [14] from the standpoint of the thermophysical aspects of the theory of thermal explosions. Thus the present review is of definite interest, since it gives an account of the present state of the theory of thermal explosions and suggests probable lines along which further development can be expected.

II. GENERALISATION AND DEVELOPMENT OF THE CLASSICAL THEORY OF THERMAL EXPLOSIONS

In the classical theory, the problem of thermal explosion is formulated as follows: given a region (or vessel) containing the reactant, knowing the kinetic laws of the evolution of heat and the mechanism of heat transfer within the region, and given the initial and boundary conditions, we are required to determine the basic parameters of the phenomenon (the critical conditions and the induction period). The actual expressions for the evolution and extraction of heat used in the classical theory are based on the simplest model of these phenomena, applicable to gaseous systems.

Generalising and making more concrete some initial premises adopted by Semenov, Frank-Kamenetskii, and

Todes, we shall formulate the essential outlines of the classical model in the following way:

1. The reaction taking place in the region under study occurs in one stage and is irreversible.

2. Heat transfer in the reaction zone occurs by conduction. There is no motion of the reacting substance, and therefore no convective heat transfer.

3. The starting material and the reaction products are in the same state of aggregation, i.e. the reaction is not accompanied by any phase transition.

4. The boundary of the region is impermeable to matter. Heat exchange at the boundary obeys Newton's law.

5. The physical parameters of the material (thermal conductivity, specific heat, density), the characteristics of the chemical reaction (activation energy, pre-exponential factor, enthalpy), and the conditions under which the reaction proceeds (pressure, temperature of the surrounding medium, shape and size of the region, emissivity) remain constant throughout the reaction.

This model, the simplest possible, has been widely applied to the study of thermal explosions in condensed as well as in gaseous media.

A mathematical statement of the problem, which satisfies the above premises, leads to the familiar equations of the classical theory

$$c\rho\frac{\partial T}{\partial t} = Q\frac{\partial \eta}{\partial t} + \lambda\left(\frac{\partial^2 T}{\partial x^2} + \frac{n}{x}\frac{\partial T}{\partial x}\right),$$

$$\frac{\partial \eta}{\partial t} = k_0 e^{-\frac{E}{RT}}\varphi(\eta).$$

Boundary conditions:

$$x = 0, \frac{\partial T}{\partial x} = 0;\ x = r, -\lambda\frac{\partial T}{\partial x} = \alpha(T - T_0).$$

Initial conditions:

$$t = 0,\ T = T_{init},\ \eta = 0.$$

We shall deal with symmetrical regions, of plane-parallel ($n = 0$), cylindrical ($n = 1$), and spherical geometry ($n = 2$).

Symbols. The following symbols will be adopted:

T temperature in the reaction zone (°K);
T_0 temperature of the surrounding medium (°K);
T_{init} initial temperature of the substance (°K);
η extent of reaction;
x spatial coordinate (cm);
r the characteristic dimension of the region (radius of the vessel)(cm);
t time (s);
Q the exothermicity of the reaction (cal cm^{-3});
E activation energy (cal mole^{-1});
k_0 pre-exponential factor (s^{-1});
λ thermal conductivity of the material (cal cm^{-1} × × s^{-1} deg^{-1});
c specific heat (cal g^{-1} deg^{-1});
ρ density (g cm^{-3});
α thermal emissivity coefficient (cal cm^{-2} s^{-1} deg^{-1}).

The function $\varphi(\eta)$ expresses the law governing the reaction under isothermal conditions:

$\varphi(\eta) \equiv 1$ for a zero-order reaction;
$\varphi(\eta) = (1 - \eta)^m$ for a reaction of order m;
$\varphi(\eta) = (\eta + \eta_0)(1 - \eta)$ for a first-order autocatalytic reaction;
η_0 the criterion for autocatalysis (ratio of initial reaction rate to autocatalytic constant).

This system of equations, when reduced to dimensionless quantities as suggested by Frank-Kamenetskii, takes the form

$$\frac{\partial\theta}{\partial\tau} = \varphi(\eta)\exp\frac{\theta}{1+\beta\theta} + \frac{1}{\delta}\left(\frac{\partial^2\theta}{\partial\xi^2} + \frac{n}{\xi}\frac{\partial\theta}{\partial\xi}\right);\ \frac{\partial\eta}{\partial\tau} = \gamma\varphi(\eta)\exp\frac{\theta}{1+\beta\theta}. \quad (1)$$

Boundary conditions:

$$\xi = 0, \frac{\partial\theta}{\partial\xi} = 0;\ \xi = 1, \frac{\partial\theta}{\partial\xi} = -\mathrm{Bi}\cdot\theta.$$

Initial conditions:

$$\tau = 0, \theta = -\theta_{init}, \eta = 0.$$

Dimensionless variables:

$$\theta = \frac{E}{RT_0^2}(T - T_0) \text{ initial heating up},$$

$$\xi = \frac{x}{r} \text{ coordinate},$$

$$\tau = t\cdot\frac{Q}{c\rho}\frac{E}{RT_0^2}k_0\exp\left(-\frac{E}{RT_0}\right) \text{ time}.$$

Dimensionless parameters:

$$\delta = \frac{Q}{\lambda}\frac{E}{RT_0^2}r^2k_0\exp\left(-\frac{E}{RT_0}\right),$$

is the Frank-Kamenetskii criterion, giving the relationship between the scale factors for the supply and the dissipation of heat (the fundamental parameter in the theory of thermal explosions).

$\mathrm{Bi} = \alpha r/\lambda$ is the familiar Biot criterion of the theory of heat transfer, which characterises the relationship between external and internal heat transfer. The case of $\mathrm{Bi} \to \infty$ corresponds to constant surface temperature, whereas $\mathrm{Bi} \to 0$ denotes absence of temperature gradients in the vessel under consideration.

$$\theta_{init} = \frac{E}{RT_0^2}(T_0 - T_{init}),$$

is the initial temperature excess of the surroundings, which determines the role of the heating-up stage, and

$$\beta = \frac{RT_0}{E} \text{ and } \gamma = \frac{c\rho}{Q}\frac{RT_0^2}{E},$$

are parameters which characterise the "quality" of the thermal explosion as a limiting case of reaction under non-isothermal conditions. For normal, non-degenerate régimes, $\beta \ll 1$ and $\gamma \ll 1$, and the theory of thermal explosions usually deals with the limiting cases $\beta \to 0$ and $\gamma \to 0$.

Solution of the general system of equations (1) presents great mathematical difficulties. Therefore approximate ways of approaching the problem — known as the stationary and the non-stationary theory of thermal explosions — have been developed within the classical theory. Table 1 lists some concrete examples of solutions of the equations for thermal explosions, discussed in the classical theory

TABLE 1.

Cases considered						Type of solution*	Method**	Ref.
θ_{init}	n	Bi	β	γ	$\varphi(\eta)$			
—	—	→0	β	—	1	s	a	1

* s = stationary; n = non-stationary; q = quasistationary.
** a = analytic; n = numerical integration.

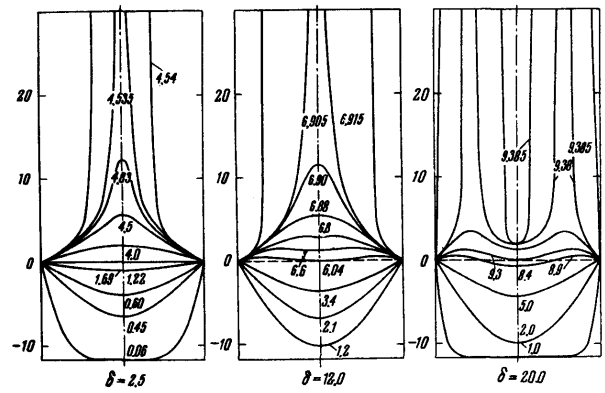

Fig. 1. Non-stationary temperature profiles during ignition with allowance for the heating-up stage [16]:
$n = 1$; $\theta_{init} = 11.7$; $\beta = 0.03$; $\gamma \to 0$. The numbers on the curves give the values of τ.

and also in more recent work. It is evident that generalisation and development of the classical theory have proceeded by making due allowance for the heating-up stage, considering the various modes of heat transfer at the surface, and elucidating the role of isothermal self-acceleration of the reaction (autocatalysis). Also, various approximate procedures have been developed within the framework of the stationary and the non-stationary theories.

We shall now briefly consider the main results of papers devoted to the generalisation and development of the classical theory.

1. Thermal Explosion as an Ignition Régime

Usually, a substance has to be heated to some definite temperature in order to achieve thermal explosion. The classical theory considers that the heating-up stage is unimportant and can be ignored.

Zinn and Mader [15] were the first to solve the thermal explosion equation with allowance for the heating-up stage, by numerical integration on an electronic computer for the case of a zero-order reaction, but they gave no general conclusions (either qualitative or quantitative). Abramov, Gontkovskaya, and one of us made some more detailed calculations [16-19], which revealed the specific effects which arise with a heating-up stage and explained the place of thermal explosions within the more general framework of ignition régimes. They also formulated the conditions under which conventional views on the role of the heating-up stage can be applied to thermal explosions.

The main conclusions of these investigations are based on an analysis of temperature distribution curves in space and time. (The most typical cases are illustrated in Fig. 1). Ignition in the presence of a heating-up stage proceeds in the following way.

In general, the heating-up of the system as a result of an exothermic reaction does not occur simultaneously throughout the volume. A temperature of T_0 is reached initially in the surface layers, and spreads to the inner layers. Temperature maxima appear close to the surface, and in time these grow and move towards the centre: in other words, a heat-evolution wave of increasing amplitude moves from the surface towards the centre of the vessel. The magnitude of the heating effect at the maximum increases faster than linearly with time, leading to ignition, which may occur either at the centre (when the heating-up wave reaches the centre, and the maxima coalesce) or at some distace from it.

This state of affairs is very sensitive to the parameter δ. At low values of δ this model degenerates, and heating-up proceeds practically simultaneously at all points in the reaction volume, so that there are no heating-up waves. As δ increases, the wave character of the heating-up stage becomes more and more distinct, and for very large values of δ the system does not heat up: ignition occurs when the central regions of the material are almost at the initial temperature.

The change in ignition régime as δ increases is conveniently observed from the change in position of the point corresponding to the onset of ignition, whose coordinate we shall denote $\xi_{expl}(\delta)$ (see Fig. 2). The plot of ξ_{expl} against δ shows two critical values of δ: (*a*) δ_{cr}, the lower limit of thermal explosion, is the value of δ which separates the ignition region from the region of non-explosive reaction (this quantity is known from the classical theory, and its value has been calculated by Frank-Kamenetskii); (*b*) δ'_{cr}, the upper limit of thermal explosion, is a value which separates two ignition régimes according to whether

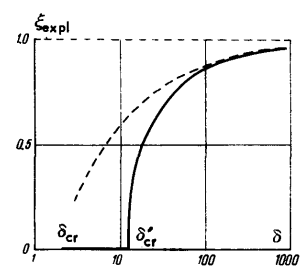

Fig. 2. Variation of ξ_{expl} with δ for the same values of the parameters as in Fig. 1. The broken line gives the limiting curve for ignition [16].

ignition sets in at the centre of not. This is essentially a new characteristic of thermal explosions, revealed by a consideration of the heating-up process — allowance for the parameter θ_{init} in the initial conditions of the system of equations (1) — and was not recognised until recently

Thus, according to the value of δ, we can distinguish the following régimes —

$\delta \ll \delta_{cr}$ the reaction proceeds isothermally (with very fast initial heating)
$\delta < \delta_{cr}$ the reaction proceeds non-isothermally, but non-explosively (with rapid heating-up and a heat-evolution stage)
$\delta_{cr} < \delta < \delta'_{cr}$ thermal explosion (self-ignition)
$\delta > \delta'_{cr}$ transition from thermal explosion to ignition
$\delta \gg \delta'_{cr}$ ignition.

We shall stress two important conclusions relating to this problem.

(*a*) Under the most favourable conditions (constant surface temperature and absence of isothermal autocatalysis) the region of thermal explosions is very narrow. It has been found[17] that the ratio δ'_{cr}/δ_{cr} is ~ 10 for a flat layer, ~ 6 for an infinite cylinder, and ~ 4 for a sphere. This corresponds to a range of about 1–2 critical diameters or a few tens of degrees. Decrease in the coefficient of heat transfer from the surface to the surrounding medium[18] and the appearance of isothermal autocatalysis[19] lead to a wider region of thermal explosion. When $Bi \to 0$, $\delta'_{cr} \to \infty$: obviously, if the system does not contain temperature gradients, ignition can occur only under the thermal explosion régime.

(*b*) Over the whole range $\delta_{cr} < \delta < \delta'_{cr}$ the overall time lag of the ignition τ_{expl} can be separated into a heating-up time τ_{heat} and an induction period τ_{ind}:

$$\tau_{expl} = \tau_{heat} + \tau_{ind},$$

the quantity τ_{ind} being almost independent of θ_{init}, i.e. of whether or not a heating-up stage is present. This separation was found to be possible even when $\tau_{heat} > \tau_{ind}$.

Thus, the framework of classical theory, which assumes $T_{init} = T_0$ ($\theta_{init} = 0$), can also be used when a heating-up stage is present, but only over a certain range of values of δ.

It is interesting to note that the formulation of the problem of thermal explosions with allowance for the heating-up stage is essentially equivalent to a general formulation of the problem in the theory of combustion, and that the equations considered in the thermal theory of ignition[20–23] for a semi-infinite space represent a limiting case of the system of equations (1) when $\delta \to \infty$. An analysis of the phenomenon close to the limiting region $\delta \to \infty$ has been made by Zel'dovich[24]. Problems in the general theory of combustion are being intensively studied at the moment by numerical integration of Eqns. (1) with the help of an electronic computer. This approach has revealed the main features of the phenomenon, and has enabled some quantitative generalisations to be made, but we still lack an approximate mathematical theory for the transition region (and in particular for calculating the value of δ'_{cr}).

2. Steady-State Theory of Thermal Explosions

The steady-state theory of thermal explosions is an approximate method for calculating the critical conditions (the δ_{cr} values) and the temperature distributions. It consists in solving the equation

$$\frac{d^2\theta}{d\xi^2} + \frac{n}{\xi}\frac{d\theta}{d\xi} = -\delta \exp\frac{\theta}{1+\beta\theta}, \qquad (2)$$

with the boundary conditions

$$\xi = 0.\ \frac{d\theta}{d\xi} = 0;\ \xi = 1.\ \frac{d\theta}{d\xi} = -\mathrm{Bi}\cdot\theta.$$

Explosion is treated as the absence of a solution for the steady-state equation (2). The approximation arises mainly from neglect of the combustion of material which occurs during the induction period: in other words, the reaction is assumed to be of zero order.

In the classical theory, Eqn. (2) is solved in two limiting cases —

$Bi \to 0$, β arbitrary (Semenov's theory)
$Bi \to \infty$, $\beta \to 0$ (Frank-Kamenetskii's theory)

The steady-state theory has been developed further in recent years[25–31]. The most interesting achievement is the generalisation of the classical theory[29,30] for the case of an arbitrary value of the Bi parameter, which is particularly relevant to the discussion of thermal explosions in condensed media. The régime $Bi \to \infty$ (constant temperature of the walls of the vessel) usually applies to gases; condensed phases, on the other hand, can have any value of Bi, including both limiting cases and the transition region. The variation of δ_{cr} with Bi for $\beta = 0$ has been obtained in the form of a transcendental equation for the case of planar geometry, in explicit analytical form for cylindrical geometry, and by numerical integration of Eqn. (2) for spherical geometry. It has been shown[29] that for the symmetrical geometries under discussion the variation of δ_{cr} with Bi can be approximated (to an accuracy equal to or better than 10%) in the form

$$\delta_{cr} \simeq \delta_n \varphi(\mathrm{Bi}),$$

where δ_{cr} is the critical value of the parameter δ for Bi = ∞, which depends on the form of the function (according to Frank-Kamenetskii's theory, $\delta_0 = 0.88$, $\delta_1 = 2.00$, $\delta_2 = 3.32$), and

$$\varphi(\mathrm{Bi}) = \frac{\mathrm{Bi}}{2}\left(\sqrt{\mathrm{Bi}^2+4} - \mathrm{Bi}\right)\exp\frac{\sqrt{\mathrm{Bi}^2+4} - \mathrm{Bi} - 2}{\mathrm{Bi}}, \qquad (3)$$

is a universal parameter, independent of the form of the function.

The significance of recent researches[29,30] lies in the fact firstly that they provide means for calculating critical thermal explosion conditions in many practical cases, and secondly that they are able to unify the theories of Semenov and Frank-Kamenetskii by eliminating the apparent contradiction between their respective models of the temperature distribution in the system. This work has allowed a re-evaluation of the original and simplest theory of thermal explosions.

The rules applying to the transition from the Semenov to the Frank-Kamenetskii régime are illustrated in Figs. 3 and 4. The latter diagram is reproduced from a paper by Gray and Harper[32].

Many workers[29,31,33,34] have discussed various approximate methods for calculating the variation of δ_{cr} with Bi. The simplest of these[29] is based on Frank-Kamenetskii's

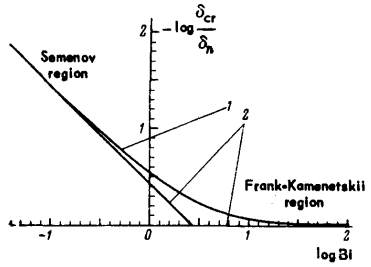

Fig. 3. 1) General form of the function $\varphi(Bi)$; 2) asymptotes according to Semenov and Frank-Kamenetskii[29].

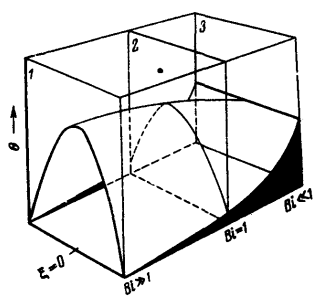

Fig. 4. Steady-state temperature distribution at the thermal explosion limit[32].

concept of an effective internal heat transmission coefficient, and on his rule for combining thermal resistances. The resulting formula

$$\frac{1}{\delta_{cr}} = \frac{1}{\delta_n} + \frac{e}{(1+n)\,Bi},$$

is very convenient and gives tolerably accurate results (~ 15% in the most unfavourable case).

One of the main problems of the steady-state theory is the calculation of δ_{cr} for bodies of complicated geometrical form (the so-called geometrical problems of the theory of thermal explosions). The mathematical difficulties of the calculation, especially for three dimensional regions, are obvious. Starting from various physical and mathematical considerations, a simpler procedure for approximately calculating the critical conditions has been obtained[12,31,34]: according to this, $\delta_{cr} \simeq \mu_1^2/e$, where μ_1^2 is the first eigenvalue of the homogeneous linear equation of thermal conduction

$$\Delta\theta + \mu^2\theta = 0,$$

for the region under consideration, with the appropriate boundary conditions. This method has been used[12,35] to calculate δ_{cr} for a hollow cylinder, a cylinder of finite length, a cylindrical sector, and a cube. The results have been shown to agree satisfactorily with the numerical integration of the original equation of thermal explosion. It is not yet clear, however, whether the method can be applied to the calculation of critical conditions for complicated, unsymmetrical shapes.

Analytical solutions of Eqn. (2) have been obtained for the limiting cases of $\beta \to 0$. The possibility of considering this case followed from Semenov's theory, and was put on a physical basis by Frank-Kamenetskii (the so-called Frank-Kamenetskii exponential transformation). Using Semenov's theory, and the numerical calculations of Parks[36], we can introduce corrections for the quantity β:

$$\delta_{cr}(\beta) \simeq \delta_{cr}(0)(1+\beta),\quad \theta_{cr}(\beta) \simeq \theta_{cr}(0)(1+2\beta),$$

where θ_{cr} is the initial heating preceding explosion. Hence we can estimate the error of the formulae obtained in the steady-state theory for $\beta = 0$:

$$\Delta_1 = \frac{\delta_{cr}(\beta) - \delta_{cr}(0)}{\delta_{cr}(0)} \simeq \beta;\ \Delta_2 = \frac{\theta_{cr}(\beta) - \theta_{cr}(0)}{\theta_{cr}(0)} \simeq 2\beta.$$

For the commonly encountered values of β, the error in the calculation of δ_{cr} is 1–5%, whilst the error in θ_{cr} is 2–10%.

3. Non-Stationary Theory of Thermal Explosions

In its classical form, the non-stationary theory of thermal explosions studies the variation with time in the heating-up of the system and in the extent of chemical reaction by analysing equations set up in terms of quantities which are averaged over the entire volume (or on the assumption that there is no temperature distribution within the reaction zone). The initial temperature is assumed equal to the temperature of the surroundings. Thus

$$\frac{d\theta}{d\tau} = \varphi(\eta)\exp\frac{\theta}{1+\beta\theta} - \frac{1}{\varkappa}\theta,$$

$$\frac{d\eta}{d\tau} = \gamma\varphi(\eta)\exp\frac{\theta}{1+\beta\theta}, \qquad (4)$$

$$\tau = 0,\ \theta = 0,\ \eta = 0,$$

where

$$\varkappa = \frac{Q}{\alpha\dfrac{S}{V}}\frac{E}{RT_0^2}k_0\exp\left(-\frac{E}{RT_0}\right),$$

is Semenov's parameter, V being the volume occupied by the reacting substance, and S the area of the heat-emitting surface.

In the non-stationary theory, explosion conditions are identified with a progressive increase in heating up. The main objective of the non-stationary theory is to study simple reactions which are not autocatalytic under isothermal conditions.

The classical non-stationary theory was developed in papers by Todes and his coworkers[2,4,5]. It gives an analytical solution of the simplest non-stationary problem (the adiabatic explosion), as well as results of the numerical integration of a set of equations of type (4), whence it is possible to analyse the development of heating-up preceding the explosion and to draw important conclusions concerning the kinetic features of the phenomenon. However, the authors used laborious manual computation and inconvenient dimensionless parameters, and were therefore unable to arrive at a satisfactory quantitative generalisation of their results.

The hope of obtaining formulae for calculating the induction period has led to a number of investigation[32,37-39], aimed mainly at an analytical solution of simplified non-stationary equations. A common feature of all these researches is the attempt to express the Arrhenius exponent in terms of a power series. In our opinion, none of these investigations has produced a computational procedure applicable to the non-stationary theory, although

several useful results have been obtained with the help of Gray and Harper's quadratic approximation.

One of the problems which concern the non-stationary theory is the displacement of the thermal explosion limit caused by the combustion of material during the induction period, i.e. the variation of δ_{cr} with γ. For normal, non-degenerate thermal explosion régimes ($\gamma < 10^{-2}$), this variation merely introduces a correction, but it becomes very significant for large values of γ (systems with a relatively small heat of reaction). The variation of δ_{cr} with γ was first calculated by Frank-Kamenetskii, who discussed the non-stationary explosion system close to the limit and showed that

$$\delta_{cr} \simeq \delta_n [1 + 1.39 (m\gamma)^{\frac{2}{3}}].$$

This formula has enjoyed wide popularity, but it has recently been pointed out [40,41] that the value of 1.39 given for the coefficient is erroneous. The correct value of this coefficient in Frank-Kamenetskii's solution is 2.7. A comparison of various reported variations of δ_{cr} as a function of γ is made in Gray and Lee's note [41].

Practically all the papers mentioned above have considered a set of equations in which the temperature distribution in the reaction zone is ignored. A detailed analysis of non-stationary solutions to the general system of equations (1) for thermal explosion régimes ($\theta_{init} = 0$) has been carried out [42] by numerical integration on an electronic computer. This work involved many calculations over a wide range of values of all the parameters, and produced results of relatively high accuracy. This enabled the authors to discuss a number of "fine effects" in the non-stationary model of thermal explosions which had not been given due prominence in the classical theory, and to put forward a quantitative generalisation of the calculated critical conditions and induction periods. Basing ourselves on that paper [42] and on earlier work, we shall note the basic features of the phenomenon revealed by an analysis of the non-stationary equations.

The theory of thermal explosions deals with two clearly distinguishable régimes, comprising reactions occurring under non-isothermal conditions with relatively little heating-up, and reactions undergoing progressive autocatalysis leading to explosion. In the model for a zero-order reaction, $\gamma \to 0$ or $\varphi(\eta) \equiv 1$, the transition from one régime to the other occurs abruptly at $\delta = \delta_{cr}$, and a maximum value of the steady-state heating-up θ_{cr} exists. When combustion of the reactant occurs, the mathematical discontinuity separating these two régimes disappears. The transition from one régime to the other becomes continuous. Continuity of the transition is conveniently demonstrated by the plot of the maximum (with respect to time) heating-up at the centre of the system θ_m against the parameter δ (Fig. 5).

Thus, analysis of the non-stationary equations leads to the conclusion that there are no critical conditions in the mathematical sense. Likewise, there is no heating-up preceding explosion, a characteristic introduced in the steady-state theory. It is evident from Fig. 5 that some régimes can have $\theta_m > \theta_{cr}$ and yet not qualify as explosions. The width of the transition region in terms of δ depends on the value of γ: the larger γ, the wider is the transition region. By the very nature of the phenomenon, thermal explosion corresponds to a narrow transition region (usually $\gamma = 10^{-2}$–10^{-3}), and the critical conditions have a clear physical significance. At high values of γ

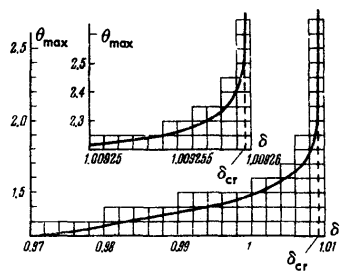

Fig. 5. Variation of the maximum heating-up of the system with the parameter δ when $n = 1$, $\theta_{init} = 0$, Bi = 2, $\beta = 0.03$, and $\gamma = 0.005$ for a first-order reaction [42]. The values of δ_{cr} and θ_m calculated from the steady-state theory are 0.95 and 1.35 respectively.

the phenomenon of thermal explosion becomes degenerate, and critical conditions become meaningless in the physical as well as in the mathematical sense. The transition from normal to degenerate régimes of thermal explosion is also continuous. If we definite the conditions for normal régimes as

$$\delta_*(\gamma) - \delta_{cr}(0) \ll \delta_{cr}(0),$$

where $d^2\theta_m(\delta_*)/d\delta^2 = 0$, we can take the quantity δ_* to be the critical value of the parameter δ in the presence of combustion.

We shall now consider the problem of determining the induction period τ_{ind}, which has been defined [4,11,43] as the time for completion of the heating-up preceding explosion θ_{cr}. It was assumed that the time of reaction $\theta > \theta_{cr}$ is much shorter than the induction period. This definition is inaccurate, since firstly there is no pre-explosion heating-up as such, and therefore the time needed to reach θ_{cr} is not a characteristic quantity, and secondly the time during which the reaction proceeds at $\theta > \theta_{cr}$ cannot be neglected. Even in the most favourable case (under adiabatic conditions) this time amounts to ~ 30% of the total time lag [42]. As the limit is approached, this value increases rapidly and becomes greater than the time of the heating-up preceding explosion.

Surprisingly, this definition of the induction period originated from a curious error made by Todes. When analysing his calculated θ–τ curve (Fig. 5 of Ref. 4, p. 874), Todes stated in the text that the increase in heating-up from the value corresponding to θ_{cr} to the highest value ($\theta_m \simeq 1/\gamma$ in our symbols) "occurs at almost constant time, i.e. practically instantaneously". This conclusion is based on a misunderstanding, and certainly does not follow from the published curve. This erroneous statement then found its way into Semenov's review [11], where it forms the basis of the definition of induction period: "The time elapsing between the beginning of the reaction and the heating-up preceding explosion is called the induction period. It is practically identical with the time between the beginning of the reaction and the explosion" (Ref. 11, p. 275). This error by Todes was pointed out to the present writers by Barzykin.

It would seem more correct to identify the induction period with the time needed to reach the maximum rate of a non-isothermal reaction [42]. This definition of the induction period gives a more accurate impression of the

time needed for the onset of explosion, and gives an insight into the transition region in terms of the time characteristic. The function $\tau_{ind}(\delta)$ has a maximum at the value of δ corresponding to δ_{cr}. As $\delta \rightarrow \delta_{cr}$ (from either side) τ_{ind} rises steeply towards its maximum value τ_{cr}.

The following empirical formulae have been derived[42] for calculating δ_{cr} and τ_{ind} for a first-order reaction, which quantitatively reflect the basic features of thermal explosions: (*a*) the critical condition

$$\delta_{cr} = \delta_n \varphi\,(\mathrm{Bi}(1 + 2.4\,\gamma^{3/4})(1 + \beta),$$

where $\varphi(\mathrm{Bi})$ has the form of Eqn. (3); (*b*) the induction period ($1.1 < \Delta < 10$)

$$\tau_{ind} = \tau_{av}\,(1 - K),$$

where

$$\tau_{av} = \left[1 + 0.62\,\frac{1 - 4\,\Delta^{-3}\sqrt{\gamma}}{(\Delta - 0.95)^{0.9}}\right](1 + 2\beta),$$

$$K = \frac{[1 + 1.5(1 - 0.1\,\Delta)n]\,\mathrm{Bi}}{16(1 + \mathrm{Bi})},$$

and $\Delta = \delta/\delta_{cr}$ is the relative departure from the thermal explosion limit.

The function τ_{av}, obtained by solving the system of equations (4), which disregards the temperature distribution in the reaction zone, expresses the basic variation of the induction period with Δ for different values of β and γ. The function K describes the variation in induction period resulting from geometrical shape and from heat exchange, i.e. the extra information obtained by considering the system of equations (1) in comparison with (4). The quantity K expresses the error involved in calculating the induction period from the averaged set of equations, and is essentially a criterion of the accuracy of the non-stationary theory in the classical treatment. The largest error occurs with $n = 2$, $\mathrm{Bi} = \infty$, and $\Delta \rightarrow 1$: under these conditions $K \simeq 0.23$. A small value of K (which makes averaging possible) is obtained when the heating-up of the system in the pre-explosion period is not too large. We should stress that the averaging can lead to significantly large errors when degenerate régimes are considered (β and γ relatively large) or when $\theta_{init} \neq 0$.

4. Quasistationary Theory of Thermal Explosions

The non-stationary theory is essentially the most general theory of thermal explosions, because its methods (based mainly on numerical integration) give a comprehensive picture of the phenomenon and allow calculation of all the characteristics for different reactions under different conditions. The critical conditions for thermal explosion is simple, non-autocatalytic reactions can also be determined using the approach of the steady-state theory. Thermal explosions in reactions showing isothermal autocatalysis are considered in the quasistationary theory.

The quasistationary procedure for calculating the characteristics was unknown in the classical theory. Todes and Melent'ev discussed the thermal explosion of autocatalytic reactions on the basis of numerical integration of the equations, and showed in particular that the critical condition is of the same form as for a zero-order reaction provided that the rate constant is replaced by the maximum reaction velocity under isothermal conditions. Semenov[11] suggested isothermal computation for calculating the induction period.

The quasistationary theory of thermal explosions has been developed by the present writers[44]; it is based on the specific features of autocatalytic reactions occurring under non-isothermal conditions. The quasistationary theory deals also with régimes under which the initial reaction rate does not satisfy explosion conditions. It is well known that in these circumstances an explosion can develop at high degrees of conversion. The course of the process preceding explosion in autocatalytic reactions can be envisaged[44] as involving in the initial stages on essentially non-stationary thermal régime, which continues until the initial rate of heat evolution is balanced by the heat losses. The resulting equilibrium situation then begins to be displaced by isothermal autocatalysis of the reaction, leading to an increase in the temperature of the system: thus, the higher the rate of heat evolution, the greater is the steady-state heating-up. Under this régime practically the whole of the heat evolved by the reaction is lost to the surrounding medium, the rate at which heat accumulates in the system is small compared with the rate of evolution of heat, and the heating-up increases slowly (quasi-stationarily). When the reaction rate reaches a value which satisfies the condition for explosion, the quasi-stationary régime is disturbed, and gradual autocatalysis of the reaction sets in, leading to an explosion. If, however, the maximum rate of the isothermal reaction does not satisfy the explosion condition, the reaction goes to completion under a quasistationary régime. The induction period in systems showing appreciable isothermal self-acceleration is practically equal to the time of the quasistationary stage of the reaction, and can be calculated by means of the quasistationary model.

A procedure for calculating all the basic characteristics of the thermal explosion in self-accelerating reactions has been proposed[44] involving solution of the system of equations (4) in the quasistationary approximation (in which the term $d\theta/d\tau$ is assumed to vanish), for the case of an autocatalytic first-order reaction $\varphi(\eta) = (\eta + \eta_0)(1 - \eta)$. The conditions under which a quasistationary régime can arise are also discussed, a criterion for a quasistationary reaction being obtained. The region of existence of the quasistationary régime (and therefore the applicability of the quasistationary theory) is illustrated by the $\kappa - 1/\eta_0$ diagram (Fig. 6). The boundary of the quasistationary region (the quantity κ_{qs}) is arbitrary, because the quasi-stationary régime becomes gradually degenerate as we depart from the thermal explosion limit. The value of κ_{qs} depends on γ: the smaller γ, the greater is κ_{qs}, and the wider is the region of quasistationary pre-explosion régime.

The general system of equations (1) has been integrated numerically[45] on an electronic computer for $\varphi(\eta) = (\eta + \eta_0) \cdot (1 - \eta)$ and $\theta_{init} = 0$. It is found that the "fine effects" observed in the non-stationary theory for simple reactions (continuous variation of θ_m with δ, presence of a maximum induction period close to δ_{cr}) occur also in autocatalytic reactions, but are not so clearly developed. Fig. 7 shows the non-stationary "surge" of the induction period, superimposed on the general quasistationary tendency for τ_{ind} to decrease. Since this effect is relatively small, the quantity τ_* calculated by the quasistationary theory can be identified with the induction period at the thermal explosion limit. Calculation shows that τ_{ind} at constant Δ is very insensitive to n and Bi, so that the error involved in applying the averaged system of equations (4) to autocatalytic reactions is insignificant (much less than the quantity K as calculated in the non-stationary theory). Therefore the formula obtained by Khudyaev[46] for the particular case of

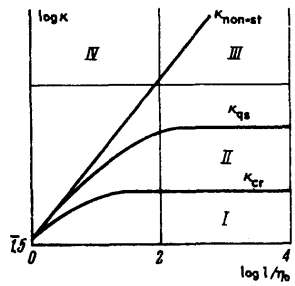

Fig. 6. Different thermal explosion régimes for an autocatalytic reaction, $\varphi(\eta) = (\eta + \eta_0)(1 - \eta)$: I) quasistationary régime below the thermal explosion limit; II) quasi-stationary régime below the thermal explosion limit; III) degenerate quasi-stationary régime; IV) effectively non-stationary reaction.

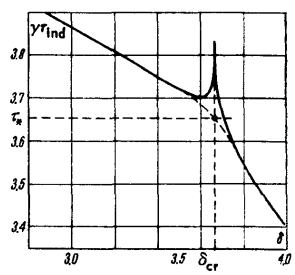

Fig. 7. Variation with δ of the induction period near the limit for $\varphi(\eta) = (\eta + \eta_0)$. $(1 - \eta)$, $n = 1$, $\eta_0 = 0.01$, $\gamma = 0.005$, $\beta = 0$, and Bi = 2.[45]

$n = 1$, Bi $\to \infty$, can be recommended for calculating the induction period of an autocatalytic first-order reaction:

$$\tau_{ind} = \frac{1}{\gamma(1+\eta_0)}\left\{\ln\frac{\sqrt{\tau_1}}{\eta_0} + \frac{1}{2}\ln\frac{(1-\eta_0)\tau_2+\tau_3}{2} + \tau_4 - \sqrt{\Delta}\ln\frac{\sqrt{\Delta}(1-\eta_0)+\tau_2}{1+\eta_0} - \right.$$
$$\left. - \Delta\left(\frac{1}{1+\eta_0} + \frac{1}{1+\tau_1}\right)\right\}$$

$$\tau_1 = 1 \text{ for } \Delta \leqslant 1$$

$$\tau_1 = 2[\Delta - \sqrt{\Delta(\Delta-1)}] - 1 \text{ for } \Delta \geqslant 1;\quad \tau_2 = \sqrt{(1+\eta_0)^2 - 4\Delta\eta_0},$$
$$\tau_3 = (1+\eta_0)^2 - 2(\Delta+1)\eta_0;\ \tau_4 = \frac{1}{2}\left|\sqrt{\Delta} - 1\right|\ln\left|\Delta - 1\right|.$$

At the thermal explosion limit the formula takes the simple form

$$\tau_{cr} = \frac{1}{\gamma(1+\eta_0)}\left[\ln\frac{1+\eta_0}{2\eta_0} - \frac{1-\eta_0}{2(1+\eta_0)}\right].$$

It is interesting to note that, in a simpler case than that considered by Khudyaev, not taking account of the temperature distribution in the reaction zone, τ_{ind} is expressed by a definite integral which cannot be resolved into elementary functions.

The quasistationary theory is now widely used in experimental studies of thermal explosions in condensed phases.

III. THERMAL EXPLOSION RÉGIMES NOT DESCRIBED BY THE CLASSICAL THEORY

In this Section we shall consider some thermal explosion processes whose description does not fall within the scope of the classical theory based on the simple model formulated at the beginning of this Review. These include thermal explosion régimes with applied heating or cooling, in the presence of external heat exchange by conduction, with local application of a heat pulse, etc.

1. Dynamic Thermal Explosion Régimes in the Presence of Heating and Cooling

We shall call thermal explosion régimes involving variation in the temperature T_0 of the surroundings according to a given time law "dynamic régimes", to distinguish them from the static régimes (T_0 = const) considered in the classical theory. The study of dynamic régimes is of considerable interest from many points of view, since it allows us: (1) to develop and generalise the quasistationary theory of thermal explosions, and to supplement it with an analysis of constrained quasistationary régimes involving a shift in the position of balance between the supply and the removal of heat resulting from variation in T_0; (2) to propose dynamic methods for the experimental measurement of thermal explosion characteristics (including rapid, approximate methods), which are sometimes more satisfactory than the static methods; and (3) to solve some applied problems of possible explosion under actual conditions of variation in T_0, which arise in the practical employment of explosive systems (e.g. in the application of explosives for "torpedoing" and for drilling oil-wells[47]).

A theory of thermal explosions under conditions of linearly varying T_0 (both heating and cooling) has been developed[48-51] on the basis of solving the systems of equations (1) and (4) in conjuction with the time law for the change in temperature of the surroundings

$$T_0 = T_{init} + wt,$$

(where w is the rate of change of the temperature). Two cases of particular interest were examined —

$$T_{init} \ll T_{0,cr},\ w > 0 \text{ — heating},$$
$$T_{init} > T_{0,cr},\ w < 0 \text{ — cooling},$$

where $T_{0,cr}$ is the critical temperature for thermal explosion under static conditions (a quantity known from the classical theory).

Under the dynamic régimes T_0 is not a constant, and it cannot therefore appear among the dimensionless parameters of the problem. The quantity $T_{0,cr}$ was found to be a convenient scale factor for the temperature. The fundamental parameter of the dynamic problem

$$\left(\omega = w\frac{E}{RT_{0,cr}^2}\frac{1}{k_0}\exp\right)\frac{E}{RT_{0,cr}},$$

is the ratio of the scale factors for reaction time and for temperature change.

This is, essentially, the dynamic analogue of the parameters proposed by Semenov and by Frank-Kamenetskii. The basic dynamic characteristic is the temperature of the surroundings at which explosion occurs (analogous to the induction period).

Let us briefly examine, on the basis of recent results[48-51], the development of explosions under conditions of heating and of cooling.

On heating, provided that $T_{init} \ll T_{0,cr}$, the system behaves at first as an inert substance, and the temperature in it develops a steady-state lag with respect to T_0. On further heating, the reaction begins to evolve heat, the lag disappears, and the temperature within the system rises above that of the surroundings. For a zero-order reaction this temperature rise in the system leads to explosion. In real systems, there is always a critical rate of heating ω_{cr}, such that when $\omega < \omega_{cr}$ the reaction goes smoothly to completion without excessive overheating, whereas when $\omega > \omega_{cr}$ an explosion occurs.

We should stress that the appearance of critical conditions on heating is fundamentally due to burning off of the material, whereas under the static régime burning off merely introduces a correction. In the neighbourhood of ω_{cr} various types of reaction show a region of quasi-stationary reaction characterised by a considerable extent of pre-explosion transformation (as with autocatalytic reactions in the static case). At large values of ω we find a transition from thermal explosion to ignition (with a clearly defined value of ω'_{cr}), which is in a qualitative sense entirely analogous to the static régime [51]. An approximate analytical procedure, based on quasistationary concepts, has been developed for the calculation of ω_{cr} and other characteristics in the neighbourhood of the limit [48,49].

The pattern of thermal explosion on cooling (when $T_{init} > T_{0,cr}$ always) depends essentially on whether the thermal self-acceleration régime at T_{init} is quasistationary or non-stationary under static conditions. If the former, the initial reaction velocity at T_{init} does not satisfy the explosion condition, and this condition may result from competition between two opposing factors — isothermal self-acceleration of the reaction and the decrease in reaction rate caused by the fall in temperature — in which conditions the extent of the pre-explosion reaction η_{expl} is always less than the extent of reaction corresponding to the maximum rate under isothermal conditions (in other words, the burning-off of material actually does not play a major part). In the second case the explosion condition is satisfied from the beginning, and the thermal balance is predetermined by the competition between the fast development of the pre-explosion process and the decrease in reaction velocity due to the fall in temperature. At high values of T_{init} an explosion invariably occurs, however high the cooling rate. A quasistationary calculation of the characteristics and a numerical integration of the system of equations (4), have been made [50] for the case of $\varphi(\eta) = (\eta + \eta_0)(1 - \eta)$. Studies under a cooling régime are very interesting from the point of view of technique, because heating the substance above the critical temperature followed by cooling allows the critical conditions for thermal explosion to be investigated with a much shorter induction period.

At the moment, the framework of the dynamic theory still lacks the unified and definitive form which characterises the classical thoey. In particular, it needs more mathematical work on the general dynamic set of equations for thermal explosion, based on explicit functions of time both in the equations themselves and in the boundary conditions. The principles needed to develop dynamic methods for studying thermal explosions, which will allow experimental investigations to be completed in a much shorter time (thus overcoming the difficulties arising from long induction periods), have not yet been formulated.

2. Thermal Explosions under Conditions of Conductive Heat Transfer in the Surrounding Medium

The solution of the problem in the classical formulation ignores heat-transfer processes in the external medium. The role of the surroundings is characterised uniquely by the boundary conditions. Yet, there are many thermal explosion régimes under which it is essential to consider the transfer of heat in the external medium. This is particularly true of systems surrounded by non-mobile media (a condensed phase in a solid block, a gas or a liquid in a thick-walled vessel, fine particles of a condensed substance in a gas or a liquid, a localised explosive impurity, etc.). To describe thermal explosions in systems of this type we must consider the equation for heat conduction in the surrounding medium as well as the system of equations for the internal region — of type (1) or of type (4) — in other words, we must solve the conjugate problem.

Grigor'ev and coworkers [52] have discussed this problem by considering the ignition of spherical particles in a hot gas, and have also made a more general study [53] of the critical thermal explosion conditions. They show, in particular, that the conjugate problem is equivalent to a boundary problem in which the conditions at the boundary of the inner region are expressed by integro-differential relations in the form of a Duhamel integral. Critical conditions have been calculated for $n = 0$, 1, and 2, and $\varphi(\eta) = 1 - \eta$, by numerical integration on an electronic computer.

Thermal explosions involving heat loss to the surroundings by conduction are shown [53] to have a number of specific features, summarised as follows:

1. The quantitative aspects of the phenomenon depend essentially on the geometry of the system. Of the three shapes which were considered, only the spherical case leads (under certain conditions) to a steady-state régime, thus allowing the approach of steady-state theory to be used. In the planar and the cylindrical geometries (excluding the limiting case of constant surface temperature) the critical conditions are determined mainly by the burning-off of the material (as in the case of linearly rising temperature).

2. The relationship between internal and external heat transfer is independent of the geometrical size of the system. It follows that the transition from the limiting case of constant temperature at the surface of the reacting substance to the limiting case of absence of temperature gradients in the reaction zone is also unaffected by the size of the system.

3. A reaction which is not autocatalytic under isothermal conditions can occur under a quasistationary régime close to the self-ignition limit during the pre-explosion period: this arises from the decrease in the effective coefficient of heat transfer from the surface of the reactant into the external medium. Hence it is possible, in principle, to develop a quasistationary theory of the phenomenon which deals with régimes under which the position of balance between heat supply and heat losses is a slowly varying function of some parameter. In autocatalytic reactions the shift in equilibrium is caused by an isothermal increase in reaction rate; under dynamic (heating) régimes it is caused by the increase in temperature of the surrounding medium; and the present case it is caused by a decrease in the effective heat-transfer coefficient. In consequence

of the quasistationary régime we find, as usual, extensive pre-explosion reaction, which is a characteristic of the present case.

Studies of thermal explosion in the present of conductive heat transfer in the external medium are still in their early stages: it is not surprising, therefore, that many of the problems have not been satisfactorily solved.

3. Localised Thermal Explosion Régimes

If, owing to special circumstances, the initial reaction in an explosive system does not proceed uniformly throughout the volume, the onset of thermal explosion can show a localised character. In the problems of explosion with a localised focus we can again distinguish (though arbitrarily) between an internal and an external region, and discuss the course of the chemical reaction in the two regions. The localised problem includes two aspects — the explosion of the local centre itself and the focal excitation of a self-propagating reaction in the medium — the former aspect being proper to the theory of explosions. We shall consider two types of focus —

1. A chemical focus, when the temperature of the focus is initially the same as that of the medium, but the kinetic parameters of the reaction are different.

2. A thermal focus, at which the temperature is higher than that of the medium, while the kinetic parameters of the reaction are the same.

The first type of focus includes cases of localised impurities of one explosive substance in another. The second type arises from external (non-thermal) influences on explosive systems.

The cases of localised explosion discussed in the literature[54-58] deal exclusively with the thermal type of focus, considered on the simplest model of a Π-shaped focus. Some workers[54,56,57] have attempted an approximate analytical calculation of the critical conditions: others[55,58] give the results of numerical solution of the equations, generalised to a dimensionless form. The basic parameters of the problem are

$$\delta = \frac{Q}{\lambda}\frac{E}{RT_0^2}r^2k_0\exp\left(-\frac{E}{RT_0}\right)$$ Frank-Kamenetskii's parameter,

$$\theta_0 = \frac{E}{RT_0^2}(T_0 - T_1)$$ initial temperature differential of the focus,

where T_0 is the initial temperature of the focus and T_1 is the temperature of the substance.

The critical explosion condition for the focus is of the form $\delta_{cr} = f_n(\theta_0)$. Merzhanov[58] has reviewed the work devoted to the evaluation of this function. As Table 2 shows, the approximate theories of Zinn[54], Friedman[56], and Boddington[57] lead to an incorrect form of the function $\delta_n^{init}(\theta_0)$, because they do not take into account the most essential feature of thermal explosion with a thermal focus, which is the presence of large temperature gradients in the focus. We have as yet no satisfactory approximate theory of this phenomenon.

The problem of thermal explosion of a thermal focus is of great importance to the theory, now being developed, of the sensitivity of explosive systems to external (non-thermal) influences. The expressions obtained for $\delta_{cr}(\theta_0)$ are adequate for the present level of development of the sensitivity theory and are widely used in tentative calculations of the critical size (or temperature) of the focus.

4. Hydrodynamic Problems of Thermal Explosion Theory

Hydrodynamic problems arise in the discussion of thermal explosion régimes under which the reactant is in a state of motion. The two most interesting aspects of the problem are the forced flow of viscous liquids and convection in low-viscosity liquids. In the former case the main interest lies in the dissipation of the energy of motion, and two types of heat source — chemical and mechanical — have to be considered in the analysis of the thermal explosion. Nothing has yet been published on the theory of thermal explosions with mechanical sources of heat. However, a recent series of papers[59-62] has a bearing on the problem, since it deals with the so-called hydrodynamic thermal explosion. From a theoretical analysis of the flow of a chemically inert, viscous liquid under the influence of a pressure difference it is shown that under certain conditions the heat evolved by internal friction is unable to pass into the surrounding medium, and causes the temperature to rise at an increasing rate: the analogy with thermal explosions is evident. Bostandzhiyan and his coworkers[60] have calculated the critical conditions for hydrodynamic explosion, and discussed the analogy with thermal explosions of chemical origin. It is interesting to note that a hydrodynamic explosion can occur only under forced flow conditions, whereas in free flow there are always steady-state régimes with different amounts of heating-up[59,61]. The ideas and methods of the theory of hydrodynamic explosion can be useful in the analysis of the flow of a chemically reacting liquid, because in this case the basic characteristics of the phenomenon — the critical condition and the induction period — may be independent of the kinetics of the chemical reaction, being determined by hydrodynamic factors.

The second aspect of the hydrodynamic problem is concerned with the convection mechanism of heat transfer in a reacting liquid. This question has been discussed in the literature for many years, but a satisfactory solution is still lacking because serious difficulties arise in describing the process. The simplest problem (in essence not a hydrodynamic one) involving convective heat transport — that of thermal explosion in a gas stream — has been discussed by Merzhanov and Filonenko[63], and the results have been applied in the theory of the combustion of condensed phases.

IV. METHODS OF EXPERIMENTAL INVESTIGATION AND TESTS OF THE THEORY

The basic requirement of methods for the experimental study of thermal explosion processes is that the main parameters which determine the course of the reaction should be clearly defined and reproducible in successive experiments. These include the temperature of the surrounding medium, the shape and size of the vessel (or specimen), the conditions of heat exchange with the surroundings, the pressure, and the density (with condensed phases).

With gaseous systems the most commonly used methods are admission to a heated vessel and adiabatic compression. Frank-Kamenetskii's monograph [12] discusses the problems arising during experimental tests of the classical theory of thermal explosion in various gaseous mixtures.

The present writers, in collaboration with Abramov [64], proposed the use of thermal analysis for the study of thermal explosions in condensed substances, and have subsequently developed the method further [65-67]. The method consists essentially in placing the experimental substance in a cylindrical reaction vessel, heated by a thermostatically controlled heat-transfer agent, the coefficient of heat transfer to which is measured in preliminary experiments. The limiting cases of constant temperature at the inner surface of the vessel and of absence of temperature gradients in the material can be realised in various ways. Heat evolution in the material is recorded by a differential thermocouple. The results are analysed from plots of the heating effect against time, which give information on the critical conditions, subexplosive heating, induction periods, and heating times of the system. If the substance does not contain temperature gradients, the kinetic characteristics of the heat evolution can be calculated from the differential thermograms [68]. Different variants of the method have been developed (for different ranges of temperature and size, for different conditions of heat exchange with the surroundings, for static and dynamic régimes, for high pressures of an inert gas).

The thermographic method has been used in an extensive series of experimental investigations. We shall consider some of the results obtained in experimental tests of the theory in the specific case of the thermal explosion of DINA and tetryl in the liquid phase. The experimental conditions were chosen so that temperature gradients in the reaction zone were negligible [65,66]. The results of the experiment, and those of an absolute calculation based on independent kinetic [69,70] and thermophysical data, presented in Tables 3–5, illustrate the great precision of the theoretical description of the phenomenon. It is interesting to note that the critical conditions for DINA were calculated by Semenov's theory, because the experimental conditions agreed with the model assumed by Senemov. Thus, the simplest model of the thermal explosion phenomenon, proposed by Semenov and still lacking a rigid quantitative basis for the case of gases (owing to the presence of temperature distributions in the reaction volume), was first realised in a thermal decomposition in the liquid phase.

Another method [52,71] for the experimental study of thermal explosions in condensed phases uses a spherical particle of the material in a heated gas. The experiments are carried out at low Reynolds and Grashof numbers, and therefore the heat exchange between particle and gas can be characterised by the heat-transfer coefficient $\alpha = \lambda_g/r$,

where λ_g is the thermal conductivity of the gas and r is the radius of the particle. Under these conditions, calculation shows that temperature gradients within the particle are negligible. The thermal explosion of the particle is detected by an optical method, using the incandescence of the explosion products. The critical conditions and the total time lag before the explosion (including the heating-up stage) can be determined from these experiments. The theory of the method [52] allows adequate analysis of the experimental results. It is important to remember that flameless detonation, which cannot be observed, may occur near the limit. However, the presence of this régime can be discovered by a series of determinations of the critical conditions in different gases. The preparation of the material in the form of spherical particles often presents special problems.

We shall examine the results of a study [52], by this method, of the thermal explosion of pyroxylin. Fig. 8 shows the variation of the critical temperature as a function of particle size in air and in argon, and Fig. 9 shows the variation of the time lag with particle size and with gas temperature, expressed in dimensionless quantities.

From the critical condition the kinetic constants were evaluated, and from these the time lag was calculated. The agreement between calculated and experimental results is satisfactory.

The method based on the thermal explosion of a particle in a heated gas is of interest from the point of view of the study of ignition mechanisms at high temperatures, and of the measurement of effective kinetic parameters for rapid decompositions in condensed phases.

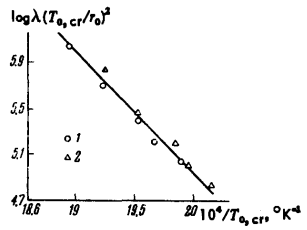

Fig.8. Critical thermal explosion condition for spherical particles of pyroxylin in a heated gas [52]: 1) air; 2) argon.

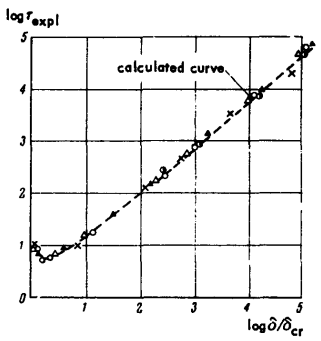

Fig. 9. Comparison of calculated (broken curve) and experimental values (points) of the time lag for the ignition of spherical particles of pyroxylin in a hot gas [52].

We shall not dwell on the other methods for the study of thermal explosions reported in the literature, because they lack proper theoretical foundations.

V. MECHANISM OF THERMAL EXPLOSION IN CONDENSED MEDIA

The very simple model of thermal explosion used as a basis for the classical theory can often be successfully applied to condensed systems. This is shown by the results of experimental investigations, some of which were discussed in the previous Section. However, thermal explosion in condensed media is, in general, a complex physicochemical reaction involving various phase transitions and associated effects in addition to chemical reaction.

We shall now briefly consider these physicochemical aspects of the mechanism of thermal explosions, and discuss the role of bulk gas evolution during thermal decomposition of a condensed material, of evaporation, of the formation of eutectics in the condensed phase, and of polymorphic transformations.

1. Effect of Bulk Gas Evolution during Decomposition on the Course of Thermal Explosion Processes

The role of bulk gas evolution depends on whether the process occurs in a solid or a liquid phase, whether it is fast or slow, and whether autocatalysis by gaseous decomposition products is possible.

One of the most interesting effects associated with gas evolution is convective heat transfer in liquid systems, resulting from the mixing effect of the bubbles of gaseous products on the reactant, and closely bound up with the rate of the chemical reaction.

The experimental work of Abramov and the present authors [64] on the critical thermal explosion conditions for molten tetryl has focussed attention on the specific features of thermal explosions in liquid media and on their relationship to the mechanism of stirring by gas bubbles. It was pointed out that:

1. The critical temperature $T_{0,cr}$ is strongly dependent on the material of the walls of the vessel: $T_{0,cr}$ is higher in a metal vessel than in a glass vessel.

2. The effective (overall) heat-transfer coefficient, calculated from the formula for the critical condition, increases with rise in temperature.

3. Pre-explosion heating-up is 3–5 times greater than the Semenov value:

$$\Delta T_{cr} = (3-5)\frac{RT_0^2}{E}.$$

4. The induction period at the thermal explosion limit is a much more sensitive function of temperature than the kinetic data suggest.

It should be stressed that this behaviour is shown by other liquids as well. In solids and gases, and also in liquids under conditions of rate limitation by external heat transfer, these observations do not apply. Merzhanov and coworkers [64] have given a qualitative explanation of these peculiarities in terms of stirring by bubbles.

Studies of the temperature field in a reacting liquid system at constant wall temperature are of considerable interest. The experimental results obtained by Barzykin and the present writers [75] indicate that in high-viscosity liquid systems the temperature profile does not differ appreciably from that in a solid (maximum heating-up at the centre and practically no heating-up close to the surface). In low-viscosity liquids a constant-temperature core appears in the reaction zone, and practically the whole of the thermal resistance of the system is concentrated in a thin boundary layer.

There is as yet no quantitative theory of thermal explosion in liquids which takes account of mixing effects, and the experimental results obtained under such conditions cannot be subjected to strict quantitative analysis. The most promising field for further studies is to acquire a fund of experimental data and to generalise it by simi-similarity methods, as is often done in the thoery of heat transfer.

Gaseous reaction products are frequently active, and capable of catalysing the reaction in progress. Under these conditions all the characteristics of the thermal explosion are strongly dependent on the conditions of removal of the gaseous products.

This dependence can be observed experimentally by controlling the escape of gaseous products through the pressure of the surrounding medium (constant-pressure bomb experiments). The most typical variation of the critical temperature $T_{0,cr}$ with pressure p is shown in Fig. 10 for a model mixture based on ammonium perchlorate (from

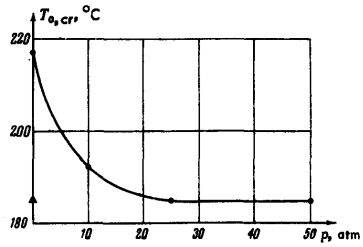

Fig. 10. Variation of critical temperature with pressure of inert gas. The solid triangle gives critical temperature in a sealed vessel without any free volume.

results obtained by Samoilenko, Abramov, and the present authors[75]). It is evident from the diagram that, as the pressure is increased, the critical temperature falls by ~ 30 deg, and thereafter stays constant. This lowering of the critical temperature occurs because the escape of gaseous reaction products is hindered by an increase in pressure, and this increases the catalytic effect of the products on the course of the reaction. The constancy of $T_{0,cr}$ at high pressures is probably due to the fact that at these pressures the gaseous products responsible for autocatalysis pass into the condensed state and cannot leave the reaction zone. It is significant that the value of $T_{0,cr}$ in the region of the plateau is the same as the value observed in a sealed vessel of the same diameter without any free volume. The gaseous reaction products cannot escape from the reaction zone in a sealed vessel, and the resulting complications are thus avoided. This is the simplest model for thermal explosions in a condensed phase: it will probably be widely applied in actual cases.

When discussing the thermal explosion of liquid explosives in open vessels, it is important to remember that the escape of gaseous reaction products produces a decrease in the reaction volume and alters its shape; this, in turn, affects both the formal kinetics of the thermal decomposition and the conditions of heat exchange between the reaction volume and the surroundings. The critical characteristics are altered because the volume occupied by the reacting system decreases a result of the escape of gaseous products, so that the concentration of the starting material and of the condensed products becomes higher than if the volume had remained unchanged. Thus, reaction velocities increase under conditions of changing volume. The conditions of heat exchange between the reaction volume and the external heat-transfer agent change because the ratio of the heat-emitting surface S to the volume of the condensed phase V is affected by the escape of gaseous products. We can distinguish two types of distortion of the model, simple shrinkage and frothing of the material. In the former case the behaviour of the system can be described mathematically[72], and expressions for the critical conditions and for the induction period of reactions of a specified type can be obtained. (These expressions are quite different from the corresponding expressions for the constant-volume case[44]). When frothing occurs the course of the reaction becomes more intermediate, and is fairly difficult to describe mathematically.

2. Thermal Explosion of Volatile Substances

The thermal explosion of substances which can evaporate has received very little attention. The literature of the 1930's and 1940's describes some experiments on the detonation of volatile substances, but the information given is inadequate for understanding the mechanism and developing a theory of the thermal explosion of volatile substances.

When analysing this phenomenon, it is important to remember that evaporation (or sublimation) in the presence of a chemical reaction in the bulk of the condensed phase, with evolution of gaseous products, follows quite a different course from evaporation in inert systems. Normally evaporation occurs from the surface of the material, and its rate is determined by the rate of diffusion of vapour in the gas phase above the surface and by the rate of supply of heat to the surface. In the case of a reacting system the rate of evaporation increases with the rate of gas evolution, because vapour is "entrained" by the mass flow of reaction products. Evaporation now becomes, as it were, a bulk process. Thus, when thermal decomposition and evaporation occur at the same time, an increase in the rate of the former process produces an increase in the rate of the latter. On the other hand, evaporation decreases the rate of the reaction, because: (1) evaporation consumes some of the starting material; (2) evaporation, being an endothermic process, absorbs a definite amount of heat. Evaporation occurring at the same time as thermal decomposition can therefore increase the induction period of the explosion and the critical temperature.

It should be noted that a given substance can behave, according to conditions, either as a volatile or as a non-volatile material. According to Belyaev[73], the determining factor is the relation between the temperature T_0, which characterises the reaction, and the boiling point T_b. If $T_0 > T_b$ or $T_0 \simeq T_b$, the evaporation is considerable, but if $T_0 \ll T_b$ the material behaves as though it were non-volatile. When $T_0 > T_b$ explosion cannot occur in the liquid phase, and the critical conditions are determined by reactions in a gas–vapour mixture.

3. Thermal Explosion of Organic Solids

Many solid organic explosives give rise to condensed decomposition products which form eutectic mixtures with the starting material. Eutectic formation, by converting some of the reactant into the liquid state, causes the reaction rate to increase, since the rate of decomposition of substances in the liquid state is higher than in the solid state.

A characteristic feature of these systems is autocatalysis of the reaction under isothermal conditions, arising from progressive dissolution of the starting material in the condensed reaction products. Solid-phase reaction is appreciable only in the initial stages of the decomposition; thereafter, the reaction occurs predominantly in the liquid phase.

On the assumption that the limiting step is associated with the kinetics of decomposition (and not with the kinetics of eutectic formation), i.e. that a state of quasi-equilibrium exists between the solid and the liquid phase, the kinetic features of the process can be put in mathematical form[74]. Unfortunately, the thermal explosion of

these materials (e.g. Hexogen and tetryl with T_0 below their melting points) has not been investigated experimentally, and there are no published data which illustrate the effects arising from eutectic formation.

4. Thermal Explosion in the Presence of Polymorphic Transformations

Polymorphic transformation (and, in general, any phase transition) affects the characteristics of thermal explosions in two ways: firstly, the transition to a new modification affects the laws governing the thermal decomposition and the thermophysical properties of the material, and secondly a definite quantity of heat is adsorbed (or evolved).

From the experimental results obtained by Abramov, Samoilenko, and the writers[75] for the thermal explosion of ammonium perchlorate, the development of thermal explosion in the presence of a polymorphic transformation shows the following pattern as a fuction of the relation between the experimental temperature T_0 and the phase transition temperature T_*:

1. $T_* < T_0$. The phase transition occurs during the heating-up stage, and its influence of the characteristics of the thermal explosion is not large.

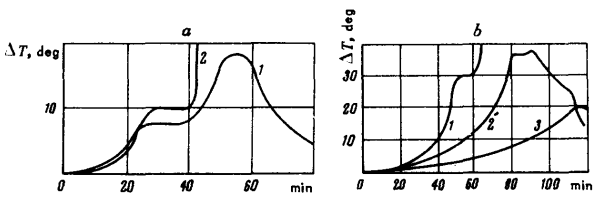

Fig. 11. Heating curves of ammonium perchlorate for different values of r (cm) and T_0:
a) 1) 1, 232°; 2) 1.25, 230°;
b) 1) 1.5, 212°; 2) 1.5, 206°; 3) 1.5, 202°.

2. $T_* - T_0 < RT_0^2/E$. The phase transition occurs during the pre-explosion period. The heat evolved in the reaction initially heats the material to T_*, and then is adsorbed by the phase transition. The critical conditions are determined, ultimately, by the reaction in the new phase (Fig. 11*a*).

3. $T_* - T_0 > RT_0^2/E$. The phase transition temperature is now reached during the substantially non-stationary régime; in this case the critical conditions are determined by the reaction in the old phase. It can happen, however, that the phase transition may halt the development of explosion: in this case the critical conditions are affected by the parameters of the phase transition (Fig. 11*b*), and the process is characterised by abnormally high pre-explosion heating-up.

A description of a process involving simultaneous chemical reaction and phase transition is of great theoretical interest, because the evolution of heat in the old phase makes methods of calculation based on Stefan's problem inapplicable.

---oOo---

The theory of thermal explosions has undergone very important modification since it was first put forward. Present-day theory deals with a wide range of problems, differing in their physical content and practical importance. The development of the theory has been influenced by the overwhelming practical interest in condensed materials, which not only generated a number of specific problems but also brought about the solution of more general problems. Recent advances in computational techniques have contributed very significantly to the development of the theory. The solutions of the basic equations of thermal explosion in their general form, using numerical integration on fast electronic computers, has not only extended the computational equipment of the theory but also contributed to our understanding of the mechanism of the phenomenon. The theory of thermal explosions in its classical formulation has now been worked out in detail in its main aspects, and has been given a definitive form. More complicated thermal explosion régimes, particularly in the presence of physicochemical and hydrodynamic processes accompanying the chemical reaction, have not been adequately investigated, and their study is of the greatest interest in the further development of the theory of thermal explosions.

I. INTRODUCTION

More than forty years ago, in the Laboratory of Electronic Chemistry of the Leningrad Physicotechnical Institute headed by Semenov, an investigation was begun of the mechanism and the kinetics of gas reactions, which subsequently resulted in a general theory of thermally explosive processes. New ideas on branching reactions, the possibility of isothermal chain explosions, on the effect of the dimensions of the reaction vessel and of additions of inert substances on the kinetics of chain reactions were developed on the basis of quantitative investigations of the oxidation of phosphorus vapour. It is interesting that the original aim of this work was not at all to investigate the kinetics of the process, but to study the effect of the oxygen pressure on the efficiency of the chemiluminescence accompanying oxidation. The impetus to make a kinetic study came from the discovery of peculiar and surprising critical phenomena. It was shown[1,2] that intense luminescence arises only within a definite range of oxygen pressures: at lower and higher pressures the reaction does not occur at all, and emission is absent. An experimental and theoretical analysis of this phenomenon by Semenov led to the formulation of the fundamental postulates of the theory of branched chain reactions. Thus it can be stated that a new stage in the development of kinetics and of several related fields of science began with investigations of chemiluminescence.

Although the oxidation of phosphorus was the first process explained in terms of the theory of branched chain reactions, the detailed mechanism of this process has hitherto been unknown, and the kinetic schemes which have been considered are hypothetical in character. Only the fact that the oxidation of phosphorus occurs by a radical-chain mechanism can be regarded as firmly established. It is therefore obvious that the chemiluminescence observed in this reaction is also due to the reactions of free radicals.

This conclusion, that chemiluminescence originates in the reactions of free radicals, applies not only to the oxidation of phosphorus. It applies generally to gas-phase reactions, and is firmly based on the pioneering quantitative investigations of chemiluminescence made by Polanyi, Kondrat'ev, Terenin, and their collaborators. Examination of the work of these and other authors on gas-phase systems shows that in all gas-phase chemical processes the occurrence of chemiluminescence is associated with the recombination (or disproportionation) of free radicals and atoms or with their addition to various species. The energy of these elementary acts is usually sufficient to produce electronically excited (or strongly vibrationally excited) species.

The principal laws of chemiluminescence were established on the basis of gas reactions. Its intensity was shown to be proportional to the rate of the elementary reaction in which excited species are formed. A quantitative study was made of the possible effect of secondary processes (quenching of excited states, transfer of energy) on the intensity of the emission. The investigations of chemiluminescence enabled quantitative information to be obtained on the relative and absolute concentrations of atoms and free radicals in flames and combustion products, on the rate constants of the reactions of these species, on the energy distribution of the products of elementary reactions, on the processes of energy exchange in collisions, on the bond energies in certain molecules, etc. The results of this work are quite well known, have been summarised in several reviews and monographs, and will not be considered in detail here. The purpose of the present review is to discuss the considerably less thoroughly studied question of the possibilities of using chemiluminescent methods in the quantitative investigation of the mechanism and the kinetics of radical and chain reactions occurring in the liquid phase. The possibilities of these methods have been demonstrated mainly in work on liquid-phase oxidation processes undertaken during recent years in the Institute of Chemical Physics of the USSR Academy of Sciences.

II. RELATION BETWEEN CHEMILUMINESCENCE AND MECHANISM OF THE OXIDATION OF ORGANIC SUBSTANCES BY MOLECULAR OXYGEN

It has recently been shown[3] that, in the liquid-phase oxidation of organic compounds by molecular oxygen, chemiluminescence arises in acts of disproportionation of peroxy-radicals. Therefore the intensity of emission in oxidation processes is characteristic not of the overall rate of the process but of the rate of interaction of peroxy-radicals, the intensity being proportional to the rate of this reaction.

In the simplest case, when a pure substance is undergoing oxidation with a fairly high oxygen concentration in the liquid phase, only one kind of radicals — peroxy-radicals of the oxidisable compound — is involved in the reaction. These radicals are formed either by reaction of the oxidisable substance with oxygen, as a result of thermal or catalytic dissociation of peroxy-compounds formed in the course of oxidation, or as a result of dissociation of specially added initiators. The radicals obtained take part in the chain reaction and are destroyed, thus exciting the luminescence.

In the steady state the rate of loss of radicals is equal to the rate of generation of chains. Hence in systems containing one species of free radicals, the intensity of the light is proportional to the rate of the process in which free radicals are formed, i.e. to the rate of initiation. The existence of this relationship enables chemiluminescence intensity measurements to be used as a rapid method for determining the kinetic characteristics of the initiation reaction (investigation of the mechanism of initiation, and determination of the activation energy, order, and rate constant of initiation, of number of radicals formed on the breakdown of one molecule of the initiator)[4-6].

Let us now examine a more complex system, containing two species — active and relatively inactive — of free radicals. Such a system can be obtained experimentally, for example, by adding an inhibitor to the oxidisable substance. In such a system one chemiluminescent reaction remains as before, since reactions of the inactive radicals (in this case inhibitor radicals) are insufficiently exothermic to excite chemiluminescence in the visible spectrum. Since some of the active peroxy-radicals are destroyed by interaction with the inhibitor, the rate of disproportionation of the peroxy-radicals does not equal their rate of formation, and the emission intensity I in such a system

measures not the rate of initiation but the concentration of peroxy-radicals RO_2, where $[RO_2] \propto \sqrt{I}$.

As the concentration of inhibitor interacting with the peroxy-radicals increases, the intensity of the emission diminishes. The concentration dependence of the emission intensity (with a constant rate of initiation) can be used[7-10] to measure the activities and concentrations of inhibitors, to determine the number of chains terminated by one molecule of inhibitor, to determine the rate of initiation, and also to investigate the mechanism of the inhibitor action.

If the reaction involves two species of active radicals, three chemiluminescent recombinations are possible in the system. Such a system can be obtained, for example, by adding a substance capable of reaction with the active radicals. One of the simplest systems containing two species of active radicals arises when small amounts of oxygen are introduced into a solution of an initiator in the oxidisable substance. Some of the alkyl radicals R present in the system are then converted by reaction with oxygen into RO_2. On the introduction of oxygen the intensity of the emission increases, since the oxygen-containing products of the recombination of the peroxy-radicals have emission bands in the visible part of the spectrum. Such bands are usually absent in the products of the recombination of R + R and R + RO_2 radicals. Therefore only one chemiluminescent reaction actually takes place in this system, and the emission intensity, as in the preceding case, measures the concentration of peroxy-radicals. The dependence of intensity on the concentration of dissolved oxygen in such a system can be used to estimate the relative reactivity of the alkyl radicals towards oxygen[11].

The quantum yield of chemiluminescence changes not only on passing from one type of radicals to another (e.g. from R to RO_2). It depends also on the structure of the radical R present in the free peroxy-radical. If peroxy-radicals of two kinds take part in the reaction (as e.g. in the co-oxidation of two compounds R^1H and R^2H), a change in the composition of the mixture is accompanied by a change in the relative concentrations of R^1O_2 and R^2O_2 radicals, and therefore the intensity of the emission depends on composition. When the chemiluminescence yields in simultaneous recombination reactions differ relatively little, the dependence of the intensity of emission on the concentration of one of the reactants is more complicated than in the preceding case. Under favourable conditions in such systems, however, it is possible to evaluate the kinetic parameters of the reaction from measurements of chemiluminescence[12].

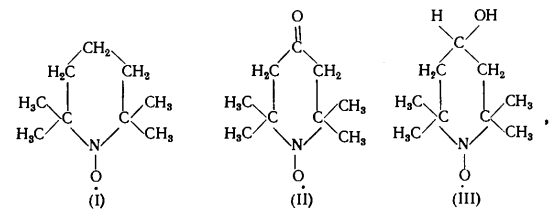
Thus quantitative studies of the laws of chemiluminescence in liquid-phase oxidations show that, in systems in which one chemiluminescent reaction occurs (or in systems in which the yield of chemiluminescence is much higher in one reaction than in the others), the emission intensity is a measure of the rate of recombination of free radicals. Therefore all factors which affect the concentration of radicals — temperature, reagent concentrations, additions of inhibitors, catalysts, etc. — influence the intensity of the luminescence. Furthermore, it is often possible from the emission intensity to follow the conversion of one kind of radicals into another. This opens up the possibility of determining from the emission intensity the relative concentration of free radicals and recording its variation both during the reaction and with change in the experimental conditions. In view of the great sensitivity of the chemiluminescent method, it is quite often the only direct method enabling changes in the concentration of free radicals to be recorded immediately.

III. USE OF CHEMILUMINESCENT METHODS TO INVESTIGATE THE MECHANISM OF THE ACTION OF ANTIOXIDANTS

In the present Section are discussed the results of several investigations in which the above ideas on the mechanism of chemiluminescence in inhibited oxidations have been used to elucidate the mechanism of the action of various inhibitors or antioxidants.

1. Mechanism of the Termination of Oxidation Chains by Stable Nitroxyl Radicals

Phenols and amines used as inhibitors form, on interaction with peroxy-radicals, unstable intermediate products, hydroperoxides, which readily break down to form free radicals, thus diminishing their effectiveness. Therefore great interest attaches to the search for inhibitors which terminate chains without forming branching agents. Among inhibitors of this type are the stable nitroxyl radicals



(I) (II) (III)

the mechanism of whose inhibiting action has been investigated[13].

Experiments were conducted with different concentrations of the nitroxyl radicals and different partial pressures of oxygen in the gaseous mixture bubbling through the oxidising ethylbenzene. During the experiments the concentrations of stable radicals were measured by the electron spin resonance method, and concentrations of peroxy-radicals by the chemiluminescent method. The experiments showed that, with sufficiently high oxygen concentrations, additions of stable radicals do not affect the intensity of the glow. Hence it follows that nitroxyl radicals R'NO· do not interact with the peroxy-radicals. They react vigorously, however, with alkyl radicals because, in the absence of oxygen, the nitroxyl radicals in concentrations exceeding 2×10^{-5} M are used up at the rate of initiation. Thus the inhibiting power of the nitroxyl radicals is determined by the relation between the rates of the two competing reactions

$$R + O_2 \xrightarrow{k_1} RO_2, \quad (1)$$

$$R + \dot{O}NR' \xrightarrow{k_2} \text{stable products.} \quad (2)$$

Fig. 1 shows how the emission intensity and the concentration of nitroxyl radicals (I) vary in the range of low oxygen concentrations when reactions (1) and (2) take place with comparable velocities. From these data the ratio of the kinetic constants $k_1/k_2 = 26 \pm 3$ for the nitroxyl radicals (I)–(III) was found. For the more stable alkyl radical of diphenylmethane this ratio is 1.4 ± 0.2, which can be explained by a lower value of k_1. Thus nitroxyl radicals can effectively suppress the oxidation chains of substances whose alkyl radicals are stabilised by conjugation and interact relatively slowly with oxygen, the effectiveness of the R'NO· radicals increasing as the oxygen concentration decreases.

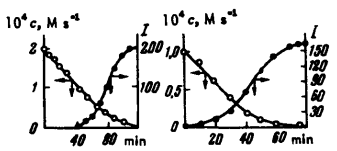


Fig. 1. Variation in concentration of nitroxyl radicals (I) and in intensity of chemiluminescence (in arbitrary units) at two initial concentrations of the nitroxyl radical (the nitrogen bubbling through ethylbenzene contains 9.3% of oxygen).

2. Interaction of the Hydroperoxide of Ethylbenzene with Benzenethiol in the Oxidation of Ethylbenzene

Available data [14-16] indicate that, in the oxidation of organic substances, compounds of the type of benzenethiol can react both with hydroperoxides and with peroxy-radicals. The occurrence of both reactions is readily detected from the kinetics of chemiluminescence [17]. The introduction of benzenethiol RSH into the oxidising ethylbenzene containing azoisobutyronitrile as initiator diminishes the emission intensity I. The dependence of I on [RSH] is of the same form as the corresponding relationship with other inhibitors, which do not react with the hydroperoxide, and it can be used to determine the rate constant for the reaction of benzenethiol with peroxy-radicals. Comparison with other inhibitors shows that benzenethiol reacts with peroxy-radicals just as effectively as does Ionol [4-methyl-2,6-di-t-butylphenol], which is frequently employed as an antioxidant.

Since benzenethiol acts as an inhibitor, it is gradually used up, and the emission intensity increases during the reaction. However, benzenethiol is consumed considerably more rapidly than is Ionol, which reacts solely with peroxy-radicals. This is seen formally from the fact that the mean number of chains terminated by one benzenethiol molecule is 0.3†, whereas Ionol terminates two chains. This difference can be explained by the additional benzenethiol required for reaction with the hydroperoxide. The latter reaction is detected from the chemiluminescence produced when benzenethiol is added to ethylbenzene containing hydroperoxide (~ 0.05 M). No emission is observed before the addition of benzenethiol, since the hydroperoxide dissociates too slowly under the experimental conditions. Additions of the inhibitor 1-naphthol weaken the resulting chemiluminescence. This implies that the hydroperoxide of ethylbenzene reacts with benzenethiol to form active radicals, which in ethylbenzene medium are converted into peroxy-radicals of ethylbenzene.

Thus an examination of the chemiluminescence shows that, in the initial stages of oxidation, when the hydroperoxide concentration is low, benzenethiol acts as an inhibitor. At later stages the additional reaction with hydroperoxide occurs.

3. Synergic Action of Inhibitors in the Oxidation of Hydrocarbons

Fig. 2*A* shows kinetic chemiluminescence curves representing the consumption of two inhibitors and of a mixture thereof in the oxidation of ethylbenzene initiated by azoisobutyronitrile [18]. It is seen that 1-naphthol (curve *1*) is a stronger inhibitor than is Neozone D [*N*-phenyl-2-naphthylamine] (curve *2*). At time $t = 0$, 1-naphthol — a lower concentration of which was taken — diminishes the emission intensity just as strongly as does Neozone D. Consequently the two inhibitors are initially consumed at the same rate. Since the concentration of 1-naphthol is one-fifth, its relative rate of consumption is the higher. With a mixture of the inhibitors in the same concentrations (curve *3*) the 1-naphthol is used up first, and then the Neozone D. This is seen from the shape of the curves.

Quite different behaviour (Fig. 2*B*) is shown by another pair, Neozone D (curve *1*) and the phenolic inhibitor Azolactone‡ (curve *2*). It is seen from Fig. 2*B* that, of these two inhibitors, Neozone D is the more active. With the mixture (curve *3*), however, the weaker phenolic inhibitor is used up first, and then the more active inhibitor. This corresponds to the gently sloping initial portion of the chemiluminescence curve, and at the later stages to the considerably steeper section, identical in shape with the chemiluminescence curve in the presence of pure Neozone D. Nevertheless, the emission intensities at time $t = 0$ for both inhibitor mixtures (Figs. 2*A* and 2*B*) agree well with the calculated values obtained from the known rate constants for the interaction of each inhibitor separately with peroxy-radicals [19]. Hence it follows that the inhibitors do not interact at the instant of mixing.

Investigations [18-22] combining the chemiluminescent methods described above with the usual methods of analysing the consumption of inhibitors during oxidation have enabled the synergic effect (Fig. 2*B*) to be explained by means of the reactions

$$\mathrm{AmH} + \mathrm{RO_2^{\cdot}} \rightarrow \mathrm{Am^{\cdot}} + \mathrm{ROOH}, \quad (3)$$

$$\mathrm{Am^{\cdot}} + \mathrm{PhOH} \rightarrow \mathrm{AmH} + \mathrm{PhO^{\cdot}}, \quad (4)$$

where AmH and Am· are respectively the amine and the free radical, and PhOH and PhO· the phenolic inhibitor and

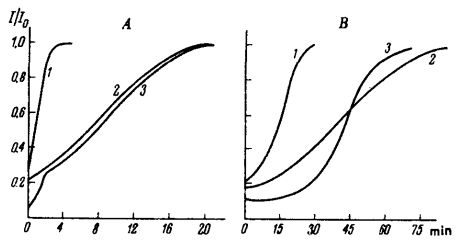

Fig. 2. Kinetic curves of chemiluminescence in the oxidation of ethylbenzene inhibited by additions of:
A): 1) 1-naphthol (0.22×10^{-5} M); 2) Neozone D (10^{-5} M); 3) a mixture of these inhibitors in the same concentrations;
B): 1) Neozone D (1.5×10^{-5} M); 2) the phenolic inhibitor Azolactone (4×10^{-5} M); 3) a mixture of these two inhibitors in the same concentrations.

† The number of chains terminated is determined from the kinetic chemiluminescence curves [10].

‡ 4-(4-Hydroxy-3,5-di-t-butylbenzylidene)-2-phenyloxazolone.

the resulting free radical. It follows from this scheme that the more active inhibitor — the amine — interacts with the peroxy-radicals, but is regenerated by reaction (4). As a result, the amine begins to be used up only after the weak, phenolic inhibitor has been consumed.

4. Mechanism of the Inhibiting Action of Phosphorous Esters

In order to elucidate the mechanism of the inhibiting action of phosphites, the kinetics of chemiluminescence has been investigated[23] in the oxidation of ethylbenzene, initiated by azoisobutyronitrile, in the presence of phosphites having various structures and of substances forming part of phosphite molecules. It has been shown, by the methods already described above, based on the weakening of chemiluminescence and on its kinetics, characterising the consumption of inhibitor, that only phosphites containing phenolic substituents possess high activity towards peroxy-radicals. Alkyl-substituted phosphites and phosphates, as well as phosphorous acid, hardly react at all with peroxy-radicals.

An interesting feature of the kinetic curves of chemiluminescence in the presence of phosphites containing phenolic substituents is that these compounds lower the emission intensity very little, and in this respect behave as weak inhibitors, while being at the same time very rapidly used up, like strong inhibitors, their rate of consumption exceeding by factors of 10–100 the rate of formation of radicals by dissociation of the initiator. If these compounds are stored not in a vacuum but in contact with the atmosphere, increase in the period of storage results in a gradual change in the character of the kinetic curves: the phosphites weaken the emission to an increasing extent, and their rate of consumption constantly decreases, approaching the rate of initiation. Hence it follows that the inhibiting power is possessed not by the phosphites themselves but by the phenols formed by hydrolysis of the former on storage. If a few per cent of a strong inhibitor is formed on hydrolysis, little weakening of the luminescence results, since the concentration of the added inhibitor is less than that of the phosphite by factors of several tens, and the calculated rates of consumption are far too high, since the calculation is based on the concentration of added phosphite.

This hypothetical mechanism is supported by an analysis of the emission curves in the presence of sufficiently high phosphite concentrations. Fig. 3 shows as example the emission curve for *o*-phenylene tri-t-butylphenyl phosphite. The curve contains two clearly marked sections *ab* and *bc*. The maximum slopes of these sections α agree precisely with the values α_1 for catechol (section *ab*) and α_2 for tri-t-butylphenol (*bc*), as shown by the broken straight lines. Thus the inhibiting action of phosphite in oxidation reactions is due to the reactions of their hydrolysis products.

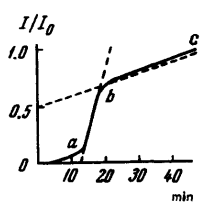

Fig. 3. Variation in relative intensity of chemiluminescence in the oxidation of ethylbenzene inhibited with added *o*-phenylene tri-t-butylphenyl phosphite.

IV. CHEMILUMINESCENT METHODS FOR MEASURING THE RATE CONSTANTS OF THE REACTIONS OF FREE RADICALS

Most methods for determining the rate constants for reactions of free radicals are based on measurements of non-stationary kinetics. Great difficulties are involved in determining kinetic constants by the direct measurement of steady-state concentrations of radicals. Slow chemical processes usually occur with low stationary radical concentrations, and only in rare cases is it possible to find a sufficiently sensitive method of measurement. The determination of the rate constants for reactions of free radicals is usually a complicated and laborious matter. The task is considerably simplified in several cases by the chemiluminescent methods which have appeared recently.

1. Chemiluminescent Method of the Photochemical After-effect

This method is based on measuring the kinetics of chemiluminescence in oxidation occurring under non-stationary conditions as a result of an abrupt change in the rate of initiation[24]. The time variation in the concentration of radicals under non-stationary conditions is described by the equation

$$\frac{d[RO_2]}{dt} = w_i - k_6[RO_2]^2, \qquad (5)$$

where w_i is the rate of initiation and k_6 the rate constant for recombination of the radicals. The form of solution of Eqn. (5) is determined by the initial conditions. If the photochemical reaction is conducted with a constant intensity of the exciting light, i.e. with constant w_i, a steady-state concentration of radicals

$$[RO_2]_{st} = \sqrt{\frac{w_i}{k_6}}, \qquad (6)$$

is established in the system.

After the light has been switched off, $w_i = 0$, and the concentration of radicals will fall as a result of their recombination:

$$-\frac{d[RO_2]}{dt} = k_6[RO_2]^2. \qquad (7)$$

The solution of Eqn. (7) is of the form

$$\frac{[RO_2]_{st}}{[RO_2]} - 1 = k_6[RO_2]_{st}t. \qquad (8)$$

Changing from radical concentrations to intensities, and making use of Eqn. (6), we obtain the expression

$$\sqrt{\frac{I_{st}}{I}} - 1 = \sqrt{k_5 w_i}\, t. \qquad (9)$$

which enables k_6 to be evaluated from the kinetics of the decay of chemiluminescence. Experimental determination of w_i in Eqn. (9) presents no difficulty, and can be effected in various ways.

The mean life of the radicals is

$$\tau = \frac{1}{\sqrt{w_i k_6}}. \quad (10)$$

The recombination rate constants of peroxy-radicals usually lie within the range 10^4–10^8 litres mole^{-1} s^{-1}. The high sensitivity of the chemiluminescent method enables experiments to be conducted at w_i of the order of 10^{-10} M × × s^{-1}. Under these conditions 10 s $\leq \tau \leq$ 1000 s, and the experimental measurement of the kinetics of chemiluminescence can be made with standard equipment using ordinary EPP-09 pen-recorders.

2. Chemiluminescent Method of the Oxygen Aftereffect

The oxygen aftereffect method[24-26], like that of the photochemical aftereffect, is used to determine recombination rate constants of the radicals from the kinetics of the establishment of a steady state recorded from the chemiluminescence. The difference consists in the method used to obtain a non-stationary concentration of radicals. In the oxygen aftereffect method, a non-stationary concentration of peroxy-radicals is produced by rapidly feeding oxygen to a system comprising a compound RH capable of oxidation and an initiator Y.

Before oxygen is admitted, the reactions

$$Y \rightarrow R' + R' + \text{products}, \quad (\text{rate of initiation } w_i)$$

$$R' + RH \rightarrow R'H + R,$$

$$R + R \rightarrow R_2,$$

take place in such a system, and the steady-state concentration of R radicals is

$$[R]_{st} = \sqrt{\frac{w_i}{k_4}}.$$

At the instant at which oxygen enters, the R radicals are converted very rapidly into RO_2 radicals by the reaction

$$R + O_2 \rightarrow RO_2, \quad (11)$$

the rate constant of which is so large that the change occurs in a very short time, and it can be assumed that the concentration of peroxy-radicals at the instant of entry of oxygen is $[RO_2]_0 = [R]_{st}$. Since the recombination rate constant of peroxy-radicals k_6 is in general different from the rate constant k_4, the initial concentration of the radicals $[RO_2]_0$ will be non-stationary. After the admission of oxygen and the conversion of R into RO_2 radicals, therefore, the concentration of the latter will begin to change, tending to the stationary value

$$[RO_2]_{st} = \sqrt{\frac{w_i}{k_6}}.$$

The kinetics of the variation in concentration of peroxy-radicals, and hence in the emission intensity, are described by the equations

$$\ln \frac{[RO_2]_{st} + [RO_2]}{[RO_2]_{st} - [RO_2]} \frac{[RO_2]_{st} - [RO_2]_0}{[RO_2]_{st} + [RO_2]_0} = 2\sqrt{w_i k_6}\, t, \quad (12)$$

$$\ln \frac{\sqrt{I_{st}} + \sqrt{I}}{\sqrt{I_{st}} - \sqrt{I}} \frac{\sqrt{I_{st}} - \sqrt{I_0}}{\sqrt{I_{st}} + \sqrt{I_0}} = 2\sqrt{w_i k_6}\, t, \quad (13)$$

obtained by solving Eqn. (5) with the condition $[RO_2] = [RO_2]_0$ at $t = 0$. The use of Eqn. (13) enables k_6 to be evaluated.

Since

$$k_4[R]^2_{st} = k_4[RO_2]^2_0 = k_6[RO_2]^2_{st} = w_i,$$

the value of k_6 thus obtained can be used to determine k_4:

$$k_4 = k_6 \frac{[RO_2]^2_{st}}{[RO_2]^2_0}$$

or

$$k_4 = k_6 \frac{I_{st}}{I_0}. \quad (14)$$

Thus the oxygen aftereffect method enables not only the recombination rate constant of peroxy-radicals k_6 (a process accompanied by luminescence) but also the rate constant for R radicals (recombination of which involves practically no emission) to be determined from a single experiment.

Fig. 4 shows possible kinetic curves for chemiluminescence with various relationships between the constants k_4 and k_6. Only when $k_4 = k_6$ (Fig. 4, curve *3*) does the oxygen aftereffect method become inapplicable.

The oxygen aftereffect has been measured[24] in the oxidation of cumene and of ethylbenzene. The measurements show that for cumene $k_4 \gg k_6$, as can be seen from the absence of an initial jump in intensity in the kinetics of the chemiluminescence (Fig. 5). In this case it can be assumed that $[RO_2]_0 = 0$, and the kinetics can be described by Eqn. (13) in the form

$$\ln \frac{\sqrt{I_{st}} + \sqrt{I}}{\sqrt{I_{st}} - \sqrt{I}} = 2\sqrt{k_6 w_i}\, t. \quad (15)$$

This equation reproduces the experimental relationship well (Fig. 5). The value obtained for k_6 agrees well with the value determined by the classical method of intermittent illumination[27].

Kinetic curves of the type of curve *2* in Fig. 4 were obtained for ethylbenzene (Fig. 5), and from them recombination rate constants of 4×10^7 (k_6) and 2×10^8 litres mole^{-1} × × s^{-1} were obtained for peroxy-radicals and hydrocarbon radicals respectively.

The oxygen aftereffect method has been employed[28] to investigate the effect of the solvent — glacial acetic acid — on the recombination rate constant k_6 of peroxy-radicals from cumene. It was found that k_6 increases with increase in the acid concentration, being approximately doubled on passing from pure cumene to a 30% solution of cumene in the acid,

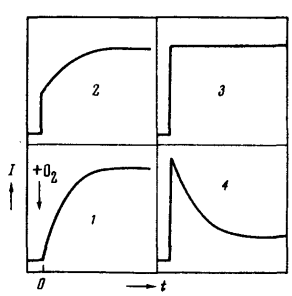

Fig. 4. Diagrammatic kinetic curves of chemiluminescence:
1) $k_4 \gg k_6$; 2) $k_4 > k_6$; 3) $k_4 = k_6$; 4) $k_4 < k_6$.

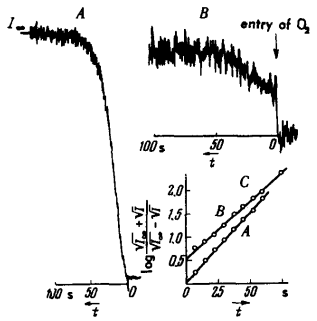

Fig. 5. Kinetics of chemiluminescence after rapid saturation with oxygen:
A) cumene, with dicyclohexyl peroxodicarbonate as initiator at 40° with $w_i = 1.49 \times \times 10^{-8}$ M s^{-1}; *B*) ethylbenzene with azoethylbenzene as initiator at 36° with $w_i = 1.75 \times \times 10^{-8}$ M s^{-1}; *C*) anamorphoses of curves *A* and *B*.

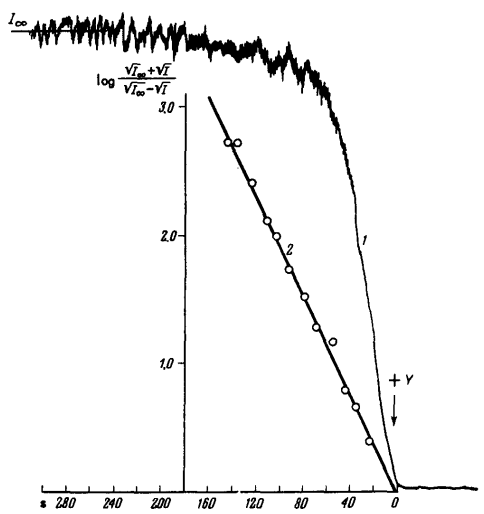

Fig. 6. Kinetics of chemiluminescence *I* after introduction of initiator Y (at instant indicated by arrow) into a solution of butan-2-one in benzene (1 : 4) with $w_i = 3.8 \times 10^{-8}$ M s^{-1} at 60°:
1) kinetic curve; 2) semi-logarithmic anamorphosis of curve 1.

while the rate constant of chain propagation remains practically unchanged. As a result of the increase in k_6, the rate of oxidation of cumene in the 30% solution falls by one-third (with the effect of dilution taken into account).

3. Chemiluminescent Method of Rapid Heating

Apart from the methods already described for producing non-stationary conditions in order to determine the rate constants of radical reactions from the kinetics of chemiluminescence, we can use rapid heating, addition of some reagent (initiator, oxidisable substance, inhibitor, etc.), cessation or change in intensity of initiation accomplished by means of ultrasonic vibrations, penetrating radiation, an electrode reaction, etc. Only some of these methods have hitherto been used in measuring rate constants. Thus the heating method has been used[29-31] in estimating the recombination rate constant for radicals of the initiator azoisobutyronitrile. The method involves adding a small volume (~ 0.1–0.01 ml) of the initiator to a heated inert solvent — chlorobenzene (containing an activator — a substance which intensifies the emission — and oxygen) — and recording the kinetic chemiluminescence curve, which reflects the kinetics of the accumulation of initiator radicals. At the instant of addition of the initiator $[RO_2]_0 = 0$, $I = 0$, and the kinetics of chemiluminescence is described by Eqn. (15).

According to these estimates $3 \times 10^7 < k_6 < 9 \times 10^7$ litres $\times \times$ mole^{-1} s^{-1};[29] a value of $(1.6 \pm 0.8) \times 10^8$ litres mole^{-1} s^{-1} has been given in Ref. 31.

The heating method has been used[32] to investigate the effect of the medium on the recombination rate constant of the peroxy-radicals of butan-2-one. The difference from the work just mentioned consisted in adding a small volume of initiator solution not to a heated inert solvent but to the oxidisable substance (butan-2-one) or to a mixture of the latter and some solvent (benzene, water, nitrobenzene). The kinetics of chemiluminescence in this system is also described by Eqn. (15), which, as can be seen from Fig. 6, is well satisfied.

It was shown[32] that additions of benzene and water produce a decrease in the values of k_6, whereas additions of nitrobenzene produce an increase. The effects are quite marked: addition of 20 mole % of benzene more than halves k_6, and of water diminishes it almost to one-quarter whereas this addition of nitrobenzene produces a sevenfold increase in k_6.

It may be remarked that Refs. 28 and 32 report the first investigations of the effect of a solvent on the rate constants of the elementary reactions of free radicals in oxidation processes. Such studies have not previously been made, since the measurement even of one value of a constant was extremely time-consuming.

V. CHEMILUMINESCENCE OF IRRADIATED PROTEINS, NUCLEIC ACIDS, AND SYNTHETIC POLYMERS

Research papers have recently appeared on the chemiluminescence of irradiated proteins, nucleic acids, and synthetic polymers, which have established a link between free-radical processes and chemiluminescence. Chemiluminescent methods have been employed in this work to identify free radicals, determine the kinetics of radical destruction, reveal the reactions leading to the formation of free radicals, and assess the protective effect against radiation of compounds of various classes.

Chemiluminescence has been detected[33-35] in dry irradiated synthetic polymers and biopolymers, such as poly(methyl methacrylate), polystyrene, bovine serum albumin, human serum albumin, egg albumin, casein, etc. Comparison of the curves for the decay in chemiluminescence and for the fall in concentration of free radicals after irradiation (radical concentrations measured by the electron spin resonance method) showed that the chemiluminescence curves represent quantitatively the fall in radical

concentration. If the emission and radical-concentration curves are superposed at one point by changing the scale of the vertical axis, the curves coincide completely. This permits the chemiluminescent method to be used to investigate the kinetics of radical destruction at small radiation doses, when the sensitivity of the electron spin resonance spectrometer is inadequate.

Similar relationships have been obtained in studying the flash of chemiluminescence accompanying the dissolution of irradiated proteins and polymers[35]. Fig. 7 shows the kinetic curves for emission (full line) and radical concentration (points) in the dissolution of irradiated poly(methyl methacrylate) in dichloroethane. It is seen from Fig. 7 that in this case, too, the time variation of the emission reproduces the kinetics of the loss of radicals.

The luminescence becomes weaker or completely disappears when oxygen is removed. Addition to the solution of inhibitors for free-radical processes (e.g. Ionol) results in a diminished intensity of emission.

It was shown in the above papers that luminescence was associated with the recombination of peroxy-radicals. The coincidence of the kinetic curves for emission and loss of radicals was explained by limitation of the kinetics by processes of dissolution and diffusion of oxygen in the solvent. In view of the complexity of the systems, the experimental results do not yet provide, in the absence of many postulates, quantitative information on the elementary processes of the addition of oxygen or on the recombination rate constants of the radicals.

The investigation of the reactions of free radicals in solution is of special interest to radiation biology. Chemiluminescent methods can also be used in this work. Employment of a highly sensitive flow-type apparatus[36] has enabled a prolonged afterglow to be recorded in aqueous solutions of certain proteins and polymers — serum albumin, haemoglobin, trypsin, poly(ethylene oxide), polyvinylpyrrolidone, etc. — which have been irradiated with small doses of ultraviolet radiation and X-rays[37,38]. The investigation led to the conclusion that the afterglow represented chemiluminescence accompanying the recombination of peroxy-radicals[38].

Investigation of the effect of various substances on the kinetics of the afterglow has shown[39,40] that the rate of extinction of the light is most strongly increased by substances which possess a protective action against radiation (those containing sulphur, phenols). These substances

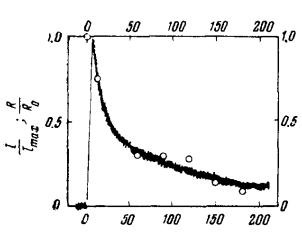

Fig. 7. Kinetics of the variation in the relative intensity of chemiluminescence (full curve) and kinetics of variation in relative concentration of radicals (points on curve) in the dissolution of irradiated poly(methyl methacrylate) in 1,2-dichloroethane.

influence the kinetics still more strongly if they are introduced into the system before exposure. Substances with feebly developed radiation-protective properties, however, exert little influence on the kinetics of the afterglow. Further investigation of the mechanism of the long-lived afterglow will probably help to elucidate several aspects of the primary action of radiation. Determination of the kinetics of the afterglow may also prove useful for a preliminary selection of radiation-protective substances.

A study has been made[41,42] of the afterglow in aqueous solutions of deoxyribonucleic acids (DNA) which have been irradiated at room temperature. Chemiluminescence was observed when the solutions were heated above 40°. The luminescence was shown to be associated with the breakdown of unstable peroxy-compounds of the DNA, formed during irradiation in the presence of oxygen. The kinetics of the decay of the emission, representing the rate of decomposition of the initiator, was used to evaluate the decomposition rate constants of the peroxy-compounds and the activation energy (13 kcal mole^{-1}). This value is identical with the activation energy for breakdown of the least stable DNA hydroperoxide and cytosine hydroperoxide[42]. The initial emission intensity is proportional to the concentration of peroxy-compounds of the DNA, and this relationship can be used to determine the content of peroxy-compounds in the irradiated solutions. Chemiluminescence in these systems is obviously associated with the reactions of free radicals, as is indicated by the weakening of the glow produced by antioxidants. Those inhibitors (e.g. propyl gallate) which considerably diminish the postradiation fall in viscosity of DNA solutions are most effective in diminishing the intensity of the chemiluminescence of DNA. When inhibitors which have a feeble effect on the postradiation fall in viscosity are added after irradiation, the emission intensity also changes insignificantly. These results again show the possibility of employing chemiluminescent methods to assess the radiation-protective effects of different compounds.

I. INTRODUCTION

It is well known that radical formation often occurs by unimolecular decomposition of various compounds with fission of the weakest bond in the molecule, e.g. by decomposition of peroxides at the O–O bond, of azo compounds at the C–N bond, of organometallic compounds at the metal–carbon bond, etc.

In recent years, evidence has accumulated in favour of the possibility of free-radical formation by a bimolecular reaction between valency-saturated molecules:

$$R'X + YR'' \rightarrow R'\cdot + XY + R''\cdot, \quad (1)$$

In 1954, Semenov[1] published the first theoretical discussion, in a general form, of the kinetic features of reactions of this type, and arrived at the seemingly paradoxical conclusion that their activation-energy barrier should be relatively small.

This conclusion was reached on applying the principle of detailed equilibrium to certain reactions of atoms and radicals. Thus, we know[2] that the disproportionation of free ethyl radicals occurs with a very low activation energy. Hence it is a thermodynamic necessity that the reverse reaction (formation of two ethyl radicals from a molecule of ethylene and one of ethane) should also be attended by a negligible activation barrier[3], and that its activation energy should be fully accounted for by the endothermicity of the process (~ 60 kcal mole^{-1}).

I. INTRODUCTION

It is well known that radical formation often occurs by unimolecular decomposition of various compounds with fission of the weakest bond in the molecule, e.g. by decomposition of peroxides at the O–O bond, of azo compounds at the C–N bond, of organometallic compounds at the metal–carbon bond, etc.

In recent years, evidence has accumulated in favour of the possibility of free-radical formation by a bimolecular reaction between valency-saturated molecules:

$$R'X + YR'' \rightarrow R'\cdot + XY + R''\cdot, \quad (1)$$

In 1954, Semenov[1] published the first theoretical discussion, in a general form, of the kinetic features of reactions of this type, and arrived at the seemingly paradoxical conclusion that their activation-energy barrier should be relatively small.

This conclusion was reached on applying the principle of detailed equilibrium to certain reactions of atoms and radicals. Thus, we know[2] that the disproportionation of free ethyl radicals occurs with a very low activation energy. Hence it is a thermodynamic necessity that the reverse reaction (formation of two ethyl radicals from a molecule of ethylene and one of ethane) should also be attended by a negligible activation barrier[3], and that its activation energy should be fully accounted for by the endothermicity of the process (~ 60 kcal mole^{-1}).

A qualitative discussion of the activation energy of the reaction

$$H_2 + Cl_2 \rightarrow H\cdot + HCl + Cl\cdot, \qquad (2)$$

starting from the reverse reaction between the two atoms ($H^{\cdot}$ and $Cl^{\cdot}$) and a molecule of hydrogen chloride, leads to the same conclusion.

Arguing that a termolecular reaction between two atoms and a molecule should involve a low activation barrier, Semenov concluded that the activation energy of the bimolecular reaction (2) must be largely determined by the endothermicity of this reaction.

These ideas were confirmed in Semenov's book [1] by an approximate quantum-mechanical calculation of the activation energy of the reaction

$$H_2 + H_2 \rightarrow H\cdot + H_2 + H\cdot, \qquad (3)$$

using London's method.

The activation barrier to reaction (3), on the assumption of a linear configuration of the atoms in the transition complex, turned out to be lower than the activation energy of the reaction

$$H\cdot + H_2 \rightarrow H_2 + H\cdot.$$

Griffing's molecular orbital calculation [4,5] of the activation energy of reaction (3) confirmed that the activation barrier is small when the hydrogen atoms in the transition complex are arranged in a straight line.

In 1958 Semenov discussed [1] from a general standpoint the experimental data then available on reactions proceeding according to scheme (1) and also according to scheme (1'),

$$RX + \rangle C{=}C\langle \rightarrow R\cdot + X{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}\cdot, \qquad (1')$$

which is a particular case of scheme (1). He showed that many baffling results could be simply explained in terms of the proposed mechanism.

By studying reactions of this type, it was possible to envisage systems in which the formation of radicals would be most likely to follow scheme (1) or scheme (1').

Subsequent researches into reactions of this type have been carried out much more systematically, mainly at the Institute of Chemical Physics of the USSR Academy of Sciences. The present Review deals primarily with the experimental results obtained since the publication of Semenov's book [1] in 1958, with particular emphasis on kinetic investigations.

II. GENERAL CONSIDERATIONS

The reaction between two molecules R'X and R''Y with formation of two radicals according to scheme (1) is in most cases endothermic, because two covalent bonds are broken (R'–X and R''–Y) but only one new bond is formed (X–Y). If, in accordance with Semenov's views, the activation energy of reactions of this type is largely determined by the heat absorbed (in other words, if the activation barrier is small), the reaction will actually take place when D(X–Y) $\gg D$(R'–X) and D(X–Y) $\gg D$(R''–Y), and the heat of reaction (1), $q = D$(X–Y) - D(R'–X) - D(R''–Y), will not be much less than zero.

It can be shown that this condition is satisfied if the bond formed by the reaction is appreciably more polar than the two broken bonds. Thus, using Pauling's postulate of the additivity of normal covalent bond energies, we find that

$$D(R' - X) = \frac{D(R' - R') + D(X - X)}{2} + \Delta_{R'X},$$

$$D(R'' - Y) = \frac{D(R'' - R'') + D(Y - Y)}{2} + \Delta_{R''Y},$$

$$D(X - Y) = \frac{D(X - X) + D(Y - Y)}{2} + \Delta_{XY},$$

where $\Delta_{R'X}$, $\Delta_{R''Y}$, and Δ_{XY} are the departures from covalency of the bonds in the particular molecules.

Thus,

$$q = -\frac{D(R' - R') + D(R'' - R'')}{2} + \Delta_{XY} - \Delta_{R'X} - \Delta_{R''Y} =$$

$$= -\quad (R' - R'') + \Delta_{XY} - \Delta_{R'X} - \Delta_{R''Y} + \Delta_{R'R''}, \qquad (I)$$

where D(R'–R'') and $\Delta_{R'R''}$ are the bond energy and the departure of the bond from covalency in the molecule R'R''.

It follows from formula (I) that, if the bonds which are broken and formed in the reaction are non-polar, the heat of the reaction is equal to the energy of the R'–R'' bond, and is therefore of the order of tens of kilocalories per mole.

In order to make reaction (1) less endothermic (for a given R'–R'' bond), the departure from covalency Δ_{XY} must considerably exceed the sum $\Delta_{R'X} + \Delta_{R''Y}$. For the particular case of reaction (1)

$$X_2 + Y_2 \rightarrow X\cdot + XY + Y\cdot,$$

where the bonds in the original molecules are, of course, non-polar, formula (I) reduces to

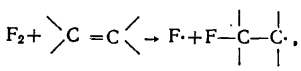
$$q = -D(X - Y) + 2\Delta_{XY}. \qquad (II)$$

We conclude from formulae (I) and (II) that a reaction of the type (1) becomes thermodynamically possible and kinetically real if one of the reactants is strongly oxidising or strongly reducing with respect to the other, so that the atom X in the resulting compound XY transfers an electron to Y (or conversely attracts an electron from the electron cloud of Y) thus making Δ_{XY} large. It follows that reaction (1) will occur in practice if it is a typical oxidation–reduction interaction. Not surprisingly, therefore, known cases of this reaction involve strong oxidising or reducing agents, e.g. oxygen, halogens, and peroxides with saturated and unsaturated hydrocarbons, peroxides with amines and sulphides, organometallic compounds with alkyl halides, etc. On the other hand, it should be noted that scheme (1) does not cover all possible cases of radical formation in redox systems [6-12].

As stated above, application of the principle of detailed equilibrium predicts an activation energy equal to the heat of reaction for strongly endothermic reactions giving rise to atoms and radicals: in other words, the activation barrier is vanishingly small. Furthermore, the theory predicts a linear configuration of the atoms in the transition complex for reactions between two H_2 molecules. This conclusion has been confirmed by quantum-mechanical calculations [1,4].

When extending these conclusions to other systems of more practical importance, we should not expect a linear

activated complex in all cases. Thus, a non-linear structure will probably be more favourable if not only s electrons are involved in the formation of bonds in the transition complex. For example, in the reaction between olefins and halogens



the most favourable configuration of the transition complex is probably one in which the F–F and C–C bonds are mutually almost perpendicular.

Not even the conclusion of a zero activation barrier can be assumed to apply unequivocally to all real systems. Thus, although the overall activation energy E (including the heat of reaction q) decreases on going from strongly exothermic towards thermally neutral processes, there is no reason to suppose that E tends to zero for thermally neutral reactions, i.e. that when $q = 0$ the activation barrier $\epsilon = E - q$ is zero.

The approximate Polanyi–Semenov relation [1]

$$\varepsilon = A - \alpha q, \qquad \text{(III)}$$

is known to hold for free-radical reactions: in other words, ϵ is a maximum for $q = 0$.

Semenov has given evidence [1] showing that expression (III) is generally applicable to the kinetics of elementary reactions and is by no means confined to reactions between radicals and molecules. When the transition complex has a complicated structure, the quantity A, which depends on many factors, such as bond elongation, distortion of valence angles, etc., does not remain constant even in series of related reactions. This introduces a deviation from linearity in the relation between ϵ and q.

The reactions represented by scheme (1) are similar to radical reactions in the simplicity of structure of the transition complex, since in both cases the valence angles are not significantly distorted on formation of the transition complex. We can therefore expect expression (III) to hold, with constant values of A and α, in series of related reactions of this type. Thus, the activation barrier will evidently not be zero, and will be a maximum for thermally neutral reactions.

III. THE STERIC FACTOR IN BIMOLECULAR REACTIONS INVOLVING VALENCY-SATURATED MOLECULES

Table 1 lists the preexponential factors of a number of reactions, calculated by the transition state method. In most cases, the transition complex was assumed to have a linear configuration. As was to be expected, the steric factor P is in many cases much less than unity. For the relatively simple molecules considered in Table 1, and for reactions between a diatomic molecule and a complicated molecule, P lies in the range 10^{-1}–10^{-5}.

TABLE 1.

Reaction	$10^{-10}A$, $cm^3\ s^{-1}$
$H_2+C_2H_5 \rightarrow H+C_2H_6$	3.32 [24]
$H_2+H_2 \rightarrow H\cdots H\cdots H \rightarrow H+H_2+H$	4670
$F_2+H_2 \rightarrow F\cdots F\cdots H\cdots H \rightarrow F+HF+H$	530
$F_2+HBr \rightarrow F\cdots F\cdots H\cdots Br \rightarrow F+HF+Br$	7.80
$F_2+HI \rightarrow F\cdots F\cdots H\cdots I \rightarrow F+HF+I$	6.26

IV. SPECIFIC SYSTEMS

1. Reactions of Molecular Oxygen

The bimolecular reaction

$$RH + O_2 \rightarrow R\cdot + HO_2\cdot, \qquad (4)$$

is a well-known example of initiation of oxidation, and of some other chain reactions [1,13].

Nalbandyan and his coworkers [14] have recently studied this reaction in the particular case of acetaldehyde. They found that hydrogen peroxide is a primary product of the molecular reaction, which suggests the mechanism

$$CH_3C(=O)H + O_2 \rightarrow CH_3\dot{C}O + HO_2\cdot, \qquad (5)$$
$$HO_2\cdot + CH_3COH \rightarrow H_2O_2 + CH_3\dot{C}O.$$

In agreement with earlier data [15,16], the activation energy of the reaction was found to be 30 kcal mole^{-1}, which is not very different from the heat of reaction (5).

Extending Semenov's approach to liquid-phase oxidation, Denisov showed [17–19] that free radicals can be formed in the termolecular reaction between RH and oxygen

$$RH + O_2 + HR \rightarrow R\cdot + H_2O_2 + R\cdot.$$

When $D(R–H) < 90$ kcal mole^{-1} the termolecular reaction is less endothermic than the bimolecular reaction (4). Assuming that the activation energy was fully accounted for by the heat of reaction, Denisov concluded that at high hydrocarbon concentrations (10 M) the termolecular reaction should be faster than the bimolecular reaction for hydrocarbons and other compounds having a bond energy $D(R–H) < 90$ kcal mole^{-1}.

Experimental results for a number of compounds have confirmed the formation of radicals by a termolecular mechanism [18–21]. These results, and those of other authors, are summarised in a review [19] and in a monograph [13].

2. Reactions of Peroxides

The decomposition of the hydroperoxides formed as intermediates in oxidations is a reaction of the type known as "degenerate chain branching". It is now realised that, in addition to the unimolecular decomposition ROOH → → RO$^{\cdot}$ + $^{\cdot}$OH, the bimolecular reactions of hydroperoxide molecules with the following species are very important sources of free radicals

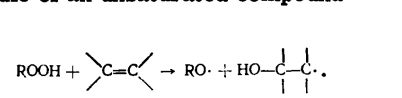
(a) another molecule of the hydroperoxide [22]

$$2\,ROOH \rightarrow RO\cdot + H_2O + ROO\cdot.$$

(b) a solvent molecule [1,23,24]

$$ROOH + R'H \rightarrow RO\cdot + H_2O + R'\cdot.$$

(c) a molecule of an unsaturated compound [19]



A hydrogen-bonded intermediate association complex[22] could be a precursor in the bimolecular interaction of two hydroperoxide molecules:

We can envisage two extreme cases, leading to entirely different reaction kinetics. If the equilibrium lies far over towards the monomeric hydroperoxide molecules, it is easy to see that both the kinetic equation and the reaction rate will be indistinguishable from those corresponding to the bimolecular reaction between two hydroperoxide molecules. In other cases, the concentration of the association complex may be the predominant factor, and in this case the reaction will occur through this complex and follow first-order kinetics.

More detailed experimental results on the formation of radicals from hydroperoxides can be found in the reviews mentioned above[13,19].

3. Reactions of Molecular Fluorine

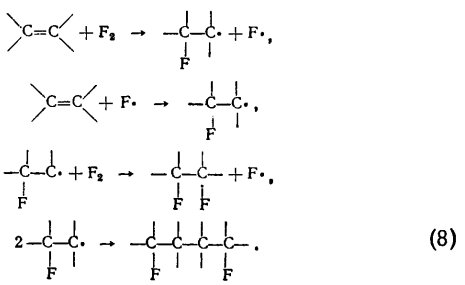
(*a*) Initiation. Radical formation by the reaction between F_2 and hydrocarbons

(6)

(7)

is particularly favourable thermodynamically, because all reactions of these two types are either practically athermic or exothermic. Miller[25-27], as long ago as 1956, pointed out that these reactions have to be included in the fluorination scheme in order to explain the reaction products, particularly in the case of olefins.

As a result of his study of the fluorination products of olefins over a range of temperatures, Miller proposes the following scheme for the reaction between F_2 and olefins[28]



(8)

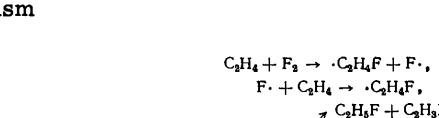
The high rate of formation of radicals explains the relatively high yield (tens per cent) of the dimeric product in reaction (8).

A direct confirmation of the formation of radicals during the reaction between F_2 and olefins was obtained by Kapralova and Shilov[29], who studied these reactions by the electron spin resonance method. They found that, when fluorine is passed over an olefin frozen at the temperature of liquid nitrogen, free radicals are formed on the surface. These radicals were shown to be peroxidic and to result from the interaction of the primary radicals with oxygen, present as an impurity in the fluorine:

According to their rate of reaction with fluorine when frozen at 77°K, ethylene and its derivatives can be arranged in the sequence[30]

The first three members of the series react too fast for accurate measurement even at liquid nitrogen temperature. The temperature at which these reactions take place indicates that the activation energy must be low: the experimental value for the reaction between F_2 and C_2HCl_3 is close to 0.5 kcal mole^{-1}

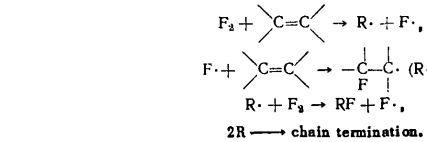
The elementary reaction between fluorine and ethylene has been investigated in the gas phase by the low-pressure flame method[30,31]. The conditions (very large excess of ethylene) are chosen so as to exclude secondary chain propagation reactions ($R^{\cdot} + F_2 \rightarrow RF + F^{\cdot}$) when the rate constant of the primary reaction between F_2 and C_2H_4 is large. The products of the reaction were identified as C_2H_3F, C_2H_5F, and $C_4H_8F_2$, corresponding to the mechanism



(9)

The absence of $C_2H_4F_2$ among the reaction products shows that chain propagation is effectively excluded under the chosen conditions. The rate constant of reaction (9) is $8 \times 10^{14} \exp(-4600/RT)$ cm^3 s^{-1}.

Rodgers[32,33] studied the kinetics of the slow gas-phase reactions of fluorine with 2,3-dichlorohexafluorobut-2-ene and with perfluorobut-2-ene. His kinetic results are consistent with the following chain mechanism for the fluorination:



(7)

From the overall activation energy for the reaction Rodgers, estimated the activation energy for reaction (7), assuming values close to zero for the other reactions. The activation energy of the chain generation reaction was found to be quite large — 16 kcal mole^{-1} for perfluorobutene and 23–25 kcal mole^{-1} for dichlorohexafluorobutene.

Thus, the activation energy of reactions of type (7) is not zero, even for ethylene, whose reaction is exothermic by 16 kcal. When electronegative substituents are introduced into the olefin molecule, the activation energy increases for surface and gas-phase reactions alike. This may be partly caused by a decrease in the enthalpy change accompanying the elementary reaction of fluorine with the olefins, but the available experimental data do not allow us to establish a quantitative relationship. There is a substantial difference in activation energy between the gas-phase reactions of fluorine and the surface reactions, the latter having the lower value of ϵ. This is evidently a manifestation of the specificity of surface reactions, in which the resulting free radical remains bound to the surface.

Very much less is known about elementary reactions of fluorine of the type

$$RH + F_2 \rightarrow R\cdot + HF + F\cdot.$$

The only reaction of this type which has been the object of a kinetic study is the reaction

$$F_2 + HI \rightarrow F\cdot + FH + I\cdot. \quad (10)$$

This reaction was investigated by the low-pressure flame method[30]: the measured activation energy was 3.5 kcal mole^{-1}. However, it is possible that the authors failed to exclude the chain reaction completely, and that the true activation energy is somewhat higher.

Reaction (10) is unique in the value of its heat of reaction. In other cases, e.g.

$$F_2 + H_2 \rightarrow F\cdot + FH + H\cdot, \quad (11)$$

$$F_2 + HCl \rightarrow F\cdot + FH + Cl\cdot, \quad (12)$$

$$F_2 + CH_4 \rightarrow F\cdot + FH + CH_3\cdot, \quad (13)$$

$$F_2 + C_4H_{10} \rightarrow F\cdot + FH + C_4H_9\cdot, \quad (14)$$

the thermal effect is much smaller. The rate constants and activation energies of these reactions are not known. Several workers[30,34-36] have shown that under certain conditions the fluorination of hydrogen, hydrogen chloride, methane, and butane is very slow or even undetectable at room temperature or above. Under different conditions the fluorination of those same compounds is known to proceed explosively by a spontaneous thermal or chain reaction[37]. A high reaction rate is not sufficient proof that the elementary reactions (11)–(14) occur readily, since the rate of initiation may not play an essential role. On the other hand, the fact that under certain conditions the fluorination is immeasurably slow proves that the rate constant of the elementary reactions (11)–(14) is small and that their activation energy is large.

Published experimental results[30,34-36] in conjunction with the data of Table 1 enable us to estimate a lower limit for the activation energy of these reactions: the value thus obtained is ~ 15–20 kcal mole^{-1}. In fact, the activation energy can, of course, be as much higher as we wish. This is evidence for the existence of a considerable activation barrier in practically athermic reactions of fluorine, proceeding according to scheme (6).

(*b*) Chain Branching. We have already pointed out that the bimolecular reaction of hydroperoxides with various compounds can provide a chain-branching mechanism in chain reactions in which hydroperoxides are formed as intermediates. Reaction (4) can also act as a branching process if RH is an intermediate product and the bond energy D(R–H) is much lower than in the original compound. Branching of this type occurs, for example, in the high-temperature oxidation of methane. In this case the branching product is formaldehyde, which reacts with O_2 according to scheme (4). From the point of view of reaction mechanism, this so-called "degenerate" branching is indistinguishable from initiation. Thus, a degenerate branching reaction is either a unimolecular decomposition or a bimolecular reaction involving a molecule of an intermediate product which is chemically more reactive than the starting compound.

Somewhat similar ideas have been developed[37] in recent years for the non-degenerate branching mechanism, which causes spontaneous ignition by a chain reaction. It has been shown[38-40] that the reactions of molecular fluorine involve a branching chain mechanism, the branching of the chains being realised by chemical reactions of intermediate species.

The difference from degenerate branching resides in the fact that the intermediate species react in an excited state, for which the excitation energy is supplied by exothermic chain development reactions. Thus, the concentration of these intermediate species does not follow the Maxwell–Boltzmann energy distribution. The life of the excited particles, limited by energy dissipation by collisions, is short and of the same order as the time of chain development. If the particle is able to react during this time with formation of atoms or radicals, chain branching occurs. The branching can proceed either as a unimolecular decomposition at the weakest bond or as a bimolecular chemical reaction between excited particles and the initial molecules.

The chain branching which occurs during fluorination of hydrogen[40] is an example of a bimolecular branching reaction. It has been shown that this reaction has definite pressure limits, separating a region of extremely slow reaction from a region of spontaneous ignition. In view of the relative simplicity of the system $H_2 + F_2$, we can unambiguously identify the chain development mechanism as analogous to the Nernst chain in chlorination:

$$F\cdot + H_2 \rightarrow HF + H\cdot,$$

$$H\cdot + F_2 \rightarrow HF + F\cdot + 98 \text{ kcal}.$$

Kapralova and her coworkers[38,40] have suggested that branching results from the chemical reaction of an excited molecule with a starting molecule:

$$F_2 + HF^* \rightarrow F\cdots F\cdots H\cdots F \rightarrow F\cdot + FH + F\cdot. \quad (15)$$

It may be noted that this reaction leads formally to the same result as energy transfer from an excited HF* molecule to a molecule of fluorine:

$$HF^* + F_2 \rightarrow HF + F_2^*,$$

$$F^*_2 \rightarrow 2F\cdot.$$

This type of branching mechanism by energy transfer was proposed by Semenov at a very early stage in the development of the theory of branched chain reactions[41,42], and has since been invoked by various workers[44-46]. However, it is in the chemical reaction that the most effective utilisation of large amounts of energy can be expected[37,43]. Hence, the bimolecular interaction mechanism of scheme (1) can be applied to this system, too.

According to the experimental results, reaction (15) has a much lower probability than dissipation of the energy. However, because of the very long chains in the fluorination of hydrogen, the probability is sufficient to cause non-stationary reaction and spontaneous ignition. The same mechanism can be applied to the fluorination of methane and other compounds, when the resulting molecule does not contain a sufficient amount of energy for unimolecular decomposition at the weakest bond.

Clearly, however, the more complex the resulting molecule, the less probable is bimolecular reaction with F_2, because the probability of energy concentration at the site of attack decreases[37].

4. Reactions between Organometallic Compounds and Alkyl Halides

We have considered some examples of strong oxidising agents reacting according to Semenov's scheme. We shall

now discuss the reactions of organometallic compounds, which are known to be strong reducing agents. When metal alkyls react with halogen derivatives according to scheme (1)

$$R'Hal + MR'' \rightarrow R'\cdot + MHal + \cdot R'', \qquad (16)$$

the considerable energy of the resulting ionic bond M–Hal largely balances the rupture of the relatively weak M–R'' bond and of the R'–Hal bond, so that the heat required by the elementary reaction (16) and its activation energy should both be small. Reactions between alkyl halides and organometallic compounds occur in the familiar Wurtz, Fittig, and Grignard reactions. Although the mechanism of these reactions has been studied in detail in comparatively few cases, the available information shows that the mechanism can vary according to the nature of the metal, the reactants, and the medium. Metals with a low ionisation potential (e.g. potassium) form relatively polar M–C bonds, and this gives the reaction a heterolytic character, particularly in polar solvents. On changing to metals with a high ionisation potential the polarity of the M–C bond decreases, and this, as has been shown above, favours the formation of free radicals, particularly in non-polar hydrocarbon media.

Among the alkali metals, lithium has the highest ionisation potential[47], and therefore the Li–C bond is more covalent than the Na–C and K–C bonds. Thus, free-radical formation is most likely to be found in the reactions of lithium alkyls with alkyl halides.

The free-radical mechanism of the reaction of organometallic compounds with halogen derivatives has been discussed on a number of occasions[48–53].

Bryce-Smith[54] obtained a direct proof of the formation of radicals in his work on the reactions of the metals Li, Na, K, and also butyllithium, butylsodium, butylpotassium, with butyl iodide, bromide, and chloride in the presence of cumene, which reacts with free radicals to give 2,3-dimethyl-2,3-diphenylbutane:

$$R\cdot + C_6H_5CH(CH_3)_2 \rightarrow RH + C_6H_5\dot{C}(CH_3)_2,$$
$$2\,C_6H_5\dot{C}(CH_3)_2 \rightarrow C_6H_5C(CH_3)_2C(CH_3)_2C_6H_5.$$

An appreciable amount of the dimethyldiphenylbutane is formed only in the reactions of lithium and butyllithium with butyl halides. In the reactions of sodium, potassium, butylsodium, and butylpotassium its formation was negligible. Bryce-Smith proposed the following reaction scheme:

$$C_4H_9I + 2M \rightarrow C_4H_9M + MI,$$
$$C_4H_9I + C_4H_9M \rightarrow 2\,\dot{C}_4H_9 + MI,$$
$$2\,C_4H_9 \nearrow C_8H_{18}, \quad \searrow C_4H_{10} + C_4H_8,$$
$$C_4H_9 + HS \rightarrow C_4H_{10} + \dot{S},$$
$$\left.\begin{aligned} C_4H_9M + C_4H_9I &\rightarrow C_8H_{18} + MI \\ C_4H_9M + C_4H_9I &\rightarrow C_4H_8 + C_4H_{10} + MI \end{aligned}\right\} \text{ionic path.}$$

Bryce-Smith stresses that free-radical formation is very probable when the colliding molecules take up a linear configuration R...Li...X...R, so that the alkyl groups are as remote from each other as possible. Formation of free radicals was demonstrated in a similar way by Okhlobystin and his coworkers[55], who studied the reaction of organomagnesium compounds with alkyl halides in hydrocarbon solvents. In their work on the reaction between butylmagnesium iodide and butyl iodide and chloride in cumene, they detected the formation of the dimethyldiphenylbutane, together with butane and butene, among the reaction products. They explained their results by the scheme

$$C_4H_9MgI + C_4H_9I \rightarrow 2\,\dot{C}_4H_9 + MgI_2,$$
$$2\,C_4H_9 \rightarrow C_4H_8 + C_4H_{10},$$
$$C_4H_9 + C_6H_5CH(CH_3)_2 \rightarrow C_4H_{10} + C_6H_5\dot{C}(CH_3)_2,$$
$$2\,C_6H_5\dot{C}(CH_3)_2 \rightarrow C_6H_5C(CH_3)_2C(CH_3)_2C_6H_5.$$

The mechanism of the reaction is substantially changed on passing to a polar solvent[56–58]. Thus, the reaction RMgX + R'X in ethers yields mainly RR', apparently without formation of free radicals. When the reaction is carried out in tetrahydrofuran and dimethoxyethane, alkyl exchange is observed[57]: $RMgX + R'X \rightleftharpoons R'MgX + RX$.

In general, therefore, scheme (1) by no means exhausts the mechanism of the interaction of organometallic compounds with halogen-containing molecules. Thus, the large and important class of reactions between the transition-metal halides and aluminium alkyls does not usually involve radicals as intermediates[59,60], although schemes similar to (1) have frequently been postulated[61].

The mechanism of these reactions, leading to well-known polymerisation catalysts, falls outside the scope of the present Review.

The kinetics and mechanism of the reactions between ethyllithium and a number of alkyl halides have been investigated[62–67] at the Institute of Chemical Physics of the USSR Academy of Sciences. The formation of free radicals was most unequivocally demonstrated in the reaction between ethyllithium and triphenylchloromethane[62]. The relatively low rate of recombination of triphenylmethyl radicals[68] contributed to their formation in concentrations sufficient to enable the reaction to be studied by electron spin resonance. It was found that the concentration of $(C_6H_5)_3C'$ radicals passes through a clearly defined maximum immediately after the reactants are mixed, and then drops to an equilibrium value.

The initial formation of a concentration of radicals in excess of equilibrium proves that these radicals are a primary product in the reaction:

$$(C_6H_5)_3CCl + LiC_2H_5 \rightarrow (C_6H_5)_3C\cdot + LiCl + \cdot C_2H_5. \qquad (17)$$

Kinetic investigation led D'yachkovskii and his coworkers[62] to conclude that the activation energy of reaction (17) is 4–5 kcal mole^{-1}. These workers studied the fate of the ethyl radicals, and concluded that they are formed as complexes with C_2H_5Li molecules: this makes their reactivity quite different from that of free ethyl radicals.

Similar conclusions were reached from a study[63] of the mechanism of the reaction between ethyllithium and ethyl iodide in hydrocarbon solvents. The experimental results — formation of ethane, ethylene, and butane in the reaction, formation of C_2H_5D if the reaction is carried out in deuterated solvents, and decrease in the yield of ethane in the presence of free-radical acceptors — confirm the formation of free ethyl radicals during the reaction. At the same time, a quantitative estimate of the yield of C_2H_5D and certain other facts show that only a fraction of the $C_2H_5^{\cdot}$ radicals are free: the remainder appear to be bound in a complex with ethyllithium. The explanation of this result is evidently to be found in the fact that ethyllithium is present in solution, and reacts with a molecule of alkyl halide, in the form of associated complexes[69–73]. Hence, when a C_2H_5 radical is formed from

a C_2H_5Li molecule, it is already bound to molecules of ethyllithium which form the complex.

The stability of the bond between a C_2H_5 radical and the C_2H_5Li molecules is still unknown, but it is evident that the reactivity of a radical which is bound in this way must be considerably lower than the reactivity of a free $\cdot C_2H_5$ radical formed from a C_2H_5I molecule.

Our work on the kinetics of the reactions of C_2H_5Li with ethyl iodide, bromide, and chloride, and with some other organic chlorides[66,67], has led us to conclude that the rate-determining stage is the first elementary act

$$(C_2H_5Li)_n\, C_2H_5Li + IC_2H_5 \rightarrow \cdot C_2H_5 (C_2H_5Li)_n + LiI + \cdot C_2H_5.$$

The most important kinetic results are summarised in Table 2. The most obvious conclusion from the data for different chlorides is that the reaction rate decreases and the activation energy increases as the energy of the C–Cl bond increases.

As D(R–Cl) is varied from 48 to 80 kcal mole^{-1}, the rate constant for the reaction at 90° decreases by a factor of approximately 10^5. The variation of the activation energy E with D(R–Cl) is not far from linear. Since the heat of reaction q is almost completely determined, in the reactions of different chlorides with ethyllithium, by differences in the C–Cl bond energy, the linear dependence of E_{act} on D(R–Cl) implies that E_{act} must be linearly related to q, i.e. that the Polanyi–Semenov rule is obeyed.

The numerical values of the coefficients A and α in the expression $\epsilon = A - \alpha q$ could be estimated only approximately, because of uncertainty in the value of $D(Li–C_2H_5)$ in solution. Adopting the value obtained for the gas phase[75] without allowance for molecular association, the variation of ϵ with q was described by the formula $\epsilon = 13 - 0.33q$. It is interesting to note that the values of A and α obtained in this way are not very different from the corresponding values for radical reactions.

The reactions of ethyllithium with ethyl iodide, bromide, and chloride were examined to establish the effect of the nature of the halogen on the rate of reactions of this type. In this series, the increase in the energy of the C–Hal bond is accompanied by a corresponding increase in the energy of the Li–Hal bond, so that the heats of these reactions remain approximately constant:

	D(C–Hal) (Ref. 47), kcal mole^{-1}	D(Li–Hal) (Ref. 47), kcal mole^{-1}	q, kcal mole^{-1}
C_2H_5I	51	83,6	13.4
C_2H_5Br	65	100	12.5
C_2H_5Cl	80	112,5	13.5

At the same time, the activation energy of the reaction increases considerably from C_2H_5I to C_2H_5Cl, varying linearly with the energy of the C–Hal bond. Similar changes in activation energy are observed in many series of reactions of different types, in which the energy changes associated with the rupture and with the formation of bonds are mutually compensating, so that the thermal effect does not change appreciably. Typical of these are the reactions between atomic sodium and alkyl halides[76,77], the reactions between the CF_3 radical and methyl chloride, bromide, and iodide[78], the unimolecular decomposition of alkyl halides[79,80] by the scheme $C_2H_5Hal \rightarrow C_2H_4 + HHal$, and others[81].

Thus, this type of behaviour would appear to be common to the kinetics of elementary reactions. It can be formulated in the following way: if, in a series of related reactions, the heat of reaction is approximately constant because the change in the energy of the bond undergoing fission is compensated by the corresponding change in the energy of the bond which is formed, then the activation barrier opposing the reaction increases with increase in the energy of the bonds involved in the reaction.

TABLE 2.

Reaction	log A	E, kcal × mole^{-1}	D(C–Hal) (Ref. 47), kcal mole^{-1}	20+log k_{90}
$C_2H_5Li+C_2H_5I$	6.74	13.6	51	3.561
$C_2H_5Li+C_2H_5Br$	7.08	16.3	65	2.286
$C_2H_5Li+C_2H_5Cl$	7.00*	19.0*	80	0.590
$C_2H_5Li+C_4H_9Cl$	6.97	18.8	76	0.673
$C_2H_5Li+iso\text{-}C_3H_7Cl$	7.00*	17.6*	74	1.400
$C_2H_5Li+t\text{-}C_4H_9Cl$	7.00*	13.7*	70	3.750
$C_2H_5Li+C_6H_5CH_2Cl$	4.55	10.5	61	3.225
$C_2H_5Li+C_6H_5Cl$	7.59	14.1	59	4.087
$C_2H_5Li+(C_6H_5)_3CCl$	4.32	5.0	48	5.853

* The value log A = 7.00 was assumed, and E was calculated on this assumption.

This rule has been explained[67] in terms of the increase in the steepness of the potential energy curves on passing to more stable bonds.

The existence of the relationship $\Delta E = \beta \Delta D$ points to some connection between the values of A for series of similar reactions in which the condition $\epsilon = A - \alpha q$ is obeyed, e.g. for the series of reactions between C_2H_5Li and chlorides, bromides, and iodides.

4. Methods of detecting CTF 315

1. INTRODUCTION

Processes leading to the formation of macromolecules can be divided into two classes — chain reactions, which include many different methods of polymerisation, and non-chain reactions, which include condensation polymerisation and stepwise reactions.

As early as 1934 Semenov defined [1] polymerisation as a non-branching chain process, and predicted the possibility of chain transfer in a polymerisation system in general, and through a polymer in particular.

More recently, as a result of advances in the chemistry of hetero-chain polymers, various highly specific — both chemically and kinetically — phenomena have been discovered.

In 1940 Flory recognised the degradation caused by the starting materials on a polymer formed by condensation polymerisation [2]. Subsequently, Korshak and his coworkers [3-5] showed that considerable interchain exchange by transesterification and transamidation occurs during the formation of polyesters and polyamides by condensation polymerisation. This phenomenon has been put to use for the synthesis of mixed polymers of the polyester, polyamide, and polyamidoester types.

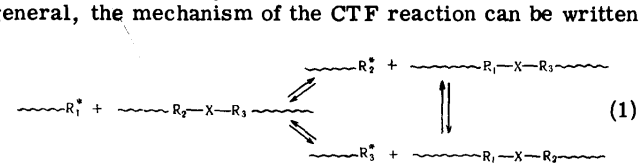
The possibility of interchain exchange was ascribed initially to condensation polymerisation processes only [3-5], and was even taken to be one of the fundamental differences between polycondensation and polymerisation processes.

However, interchain exchange is governed only by the structure of the macromolecule and by the type of active centre, and is evidently a characteristic of all hetero-chain polymers irrespective of the method of preparation. Such exchange can therefore occur in both polycondensation and polymerisation, and also with the resulting hetero-chain polymeric molecules, independently of their method of preparation.

Studies of the polymerisation and copolymerisation of trioxan [6-12] have led to the conclusion that an interchain exchange of a similar type, proceeding by a transacetalation mechanism, occurs in this system.

In 1962 Enikolopyan [8] demonstrated the possibility of interchain exchange during polymerisation by a mechanism which was subsequently called chain transfer through the polymer with fission (CTF).

Chemically, the CTF reaction consists in the exchange interaction of two molecules — one of which is an active centre and the other an inactive macromolecule — by a homolytic or heterolytic substitution mechanism. In general, the mechanism of the CTF reaction can be written



(1)

where X is a hetero-atom (O, S, N, P, Si, metal, etc.) and $\sim R_i^*$ is an active macromolecule (cation, anion, or radical).

The mechanism suggested is fairly universal, and we may assume that it applies to interchain exchange and also to the so-called "degradation" reactions between a polymer chain and the starting materials (or materials of similar nature) during condensation polymerisation. As shown by Korshak and coworkers [3,4], who made a systematic and extensive study of this reaction, interchain exchange proceeds much faster in the presence of catalysts of an acidic or basic nature. The end-groups of the starting material may have a catalytic effect on the process, but the rate of interchain exchange in this case is lower than with specially added catalysts. The exchange reaction is very strongly inhibited when it occurs between macromolecules with blocking end-groups (e.g. alkylated end-groups).

These facts strongly suggest that the reactions in question occur via some ionic states, probably as nucleophilic substitution reactions according to scheme (1).

It can be seen from the scheme that the CTF reaction should produce, during homopolymerisation, a redistribution in size of the growing macromolecules [9], and during the interaction of chemically different polymeric chains, block copolymers [10]. This reaction is one of the most general methods for modification of the main chain and side-chains of a polymer. It can be used to prepare mixed hetero-chain and carbon–hetero-chain macromolecules.

If $\sim R_i^*$ is a compound of low molecular weight the result of the CTF reaction should be a polymer with specified end-groups. This opens up wide possibilities for the synthesis of polymers and oligomers with reactive end-groups. The great practical importance of the CTF reaction in which $R_i^*\sim$ is a material of low molecular weight arises also from the possibility of synthesising thermostable polymers having a lower temperature limit of polymerisation. This method has been successfully applied to the problem of producing thermally stable polyoxymethylene.

An interesting feature of the CTF reaction is the ability of the active centre of the macromolecule to attack its own chain:

$$R_i - R_j - R_k^* \rightleftarrows R_i^* + \begin{pmatrix} R_k \\ R_j \end{pmatrix}. \qquad (2)$$

In this case a cyclic macromolecule may be formed [12]. We may also expect the formation of some very peculiar polymers having a "ring within a ring" structure (polycatenanes). If two polymers of different composition take part in a CTF reaction, copolymers will be formed without a chemical bond being involved.

The most essential feature of polymeric systems in which CTF reactions are proceeding is, as scheme (1) shows, the fact that every "dead" polymeric chain can become "alive". Also, a "dead" polymeric system can be "revived" by introducing a suitable activator. Of all the reactions known in polymer chemistry, CTF alone can bring "dead" chains into the polymerisation process without significant modification. Thus, the concept of a "live" system is more general than the definition of Szwarc [13] implies.

A detailed thermodynamic, kinetic, and chemical analysis of the CTF reaction, made in the Polymerisation Kinetics Laboratory of the Institute of Chemical Physics of the USSR Academy of Sciences, has established the uniqueness of the process, which can therefore be considered to be a new, fifth elementary act among polymerisation processes.

The present review aims to systematise and summarise existing data on the CTF reaction, and to discuss the potential applications of this reaction to polymer modification.

2. KINETIC AND THERMODYNAMIC FEATURES OF CHAIN TRANSFER WITH FISSION (CTF)

The specific feature of polymeric systems as compared with chemical substances of low molecular weight, is from the thermodynamic standpoint, their statistical nature, i.e. the existence of a definite distribution in size and composition of the macromolecules. This must undoubtedly be reflected in the nature of the processes occurring in polymer systems.

Thus, the size distribution alone will alter the entropy of the system, irrespectively of the nature of the polymeric molecules, of their state in the system, and of their interactions with each other and with the medium. Consider a reaction leading to a change in the size distribution of the macromolecules. We shall assume that the change involves only equivalent bonds: since the internal energy of the system depends on the total energy of the bonds, which is assumed to remain unchanged, and also on the interaction of the macromolecules with each other and with the medium (which depends on the total number of segments, again assumed unchanged), the reaction does not affect the internal energy of the system.

$$R_i + R_j \rightarrow R_{i+k} + R_{j-k}. \qquad (3)$$

The total entropy of the system can be split into the configurational entropy, the entropy of the segments, and the entropy of interaction of the macromolecules with each other and with the medium; the statements made above in relation to the enthalpy of the system apply also to the entropy, with the exception of the configurational entropy, whose value depends on the length of the macromolecule according to the expression

$$S_{R_j} = R \ln (a^j), \qquad (4)$$

where j is the length of the macromolecule, and a is the number of possible positions in space of a segment with one end fixed.

Since the entropy of the system is equal to the sum of the entropies of the components, the configurational entropy also must be unaffected by our reaction.

It follows from the statistical nature of a polymeric system that we must take the distributional entropy of the system into account. Strictly speaking, any physical system can be regarded as statistical from the point of view of the distribution of the various forms of energy. However, energy redistribution occurs so rapidly that, with few exceptions, the energy can be assumed to adopt an equilibrium (Boltzmann) distribution. This is not so in polymeric systems, where the distribution concerns units in macromolecules. Obviously, a redistribution of this type cannot occur unless a kinetically favourable mechanism is available. If such a mechanism is possible, the reaction will lead to the establishment of an equilibrium distribution, whose nature can be readily inferred on the hypothesis of maximum entropy. Thus, the driving force of exchange reactions of this type is an entropic one.

Taking the distributional entropy into account, we obtain for the reaction

$$\Delta S = R\left\{\ln \frac{(i+j)!}{(i+k)!\,(j-k)!} - \ln \frac{(i+j)!}{i!\,j!}\right\} = R \ln \frac{j!\,i!}{(i+k)!\,(j-k)!}. \qquad (5)$$

Solving the problem of maximum distributional entropy [14] for the conditions

$$\sum_l R_l = N; \quad \sum_l l R_l = M,$$

we find, as for the Boltzmann distribution,

$$R_l = \frac{N^2}{M}\left(1 - \frac{N}{M}\right)^{l-1} \simeq \frac{N^2}{M} e^{-\frac{N(l-1)}{M}}. \qquad (6)$$

The composition distribution of the macromolecules presents a more complicated problem, because the structure of the copolymer must affect both the internal energy of a macromolecule and its entropy. Thus, even in the presence of a mechanism leading to redistribution, maximum distributional entropy may not be achieved owing to the increase in internal energy or to the decrease in entropy of the macromolecules themselves.

Clearly, redistribution of the sequences A...A and B...B within a chain involves breaking A–A and B–B bonds and the creation of two A–B bonds, or *vice versa*. For each exchange of this kind the expenditure (or gain) of energy is given by

$$\Delta E = 2\left(\epsilon_{AB} - \frac{\epsilon_{AA} + \epsilon_{BB}}{2}\right), \qquad (7)$$

so that the redistribution will be influenced not only by the distributional entropy but also by the change in internal energy. In the limiting case when

$$\epsilon_{AB} \ll \frac{\epsilon_{AA} + \epsilon_{BB}}{2}, \qquad (8)$$

there will obviously be no redistribution at all, in spite of the evident loss of distributional entropy.

Chain transfer with fission is the kinetic mechanism which allows attainment of the most probable distribution, corresponding to maximum entropy. Alternative mechanisms are possible, of course, but the reactions encountered in polymer chemistry either involve fundamental changes in the system [15-17] or operate only on macroradicals or macroions, i.e. on the "live" part of the macromolecule, without affecting the "dead" parts (reversible polymerisation).[18]

The special kinetic status of CTF was first pointed out by Enikolopyan and his coworkers [8,9]. From a study of interchain exchange in a system consisting of R molecules of mean degree of polymerisation $\bar{P}$ with all end-groups active, i.e. of the reaction

$$R_i + R_j \rightarrow R_{i+e} + R_{j-e}, \qquad (9)$$

they arrived [9] at the kinetic equation for the concentration of the $j$mer

$$\frac{dR_j}{dt} = -2kR_jR - 2kR_j\sum_1^N iR_i + 2k\sum_{i=j}^N\sum_{e=j}^N R_iR_e + 2k\sum_1^j\sum_{j-i}^j R_iR_e + 4k\sum_{i=j}^N\sum_1^N R_iR_e, \qquad (10)$$

the coefficient k being independent of j, i, and e.

At equilibrium

$$\frac{dR_j}{dt} = 0. \qquad (11)$$

The equation gives for R_j

$$R_j = \frac{R}{\bar{P}}\, e^{-j/\bar{P}}. \qquad (12)$$

This implies that, independently of the initial distribution, CTF leads to a Semenov–Flory distribution [1,21]

as calculated for equilibrium polymerisation and polycondensation. It can be shown that under these conditions

$$\frac{\bar{P}_w}{\bar{P}_N} = 2.$$

The attainment of this distribution was experimentally demonstrated by studying the cationic exchange between low-molecular-weight dimethyl ethers of poly(oxymethylene glycol)[19], because the molecular-weight distribution is difficult to determine for high-polymer samples.

Disproportionation of the dimethyl ether of dioxymethylene glycol (degree of polymerisation $P = 2$) on treatment with 0.06% sulphuric acid at 120° causes the appearance of a whole series of oligomers, beginning with dimethoxymethane, in amounts independent of both catalyst concentration and temperature. The fact that the resulting composition is independent of the experimental conditions suggests that the observed distribution is an equilibrium one.

The distribution obtained cannot be compared with the function (5), because the latter was derived for the case of $j \gg 1$; in the case of oligomers we cannot ignore the length of one of the two monomeric units in comparison with the length the entire molecule.

The distribution function for oligomers of low molecular weight was obtained by a statistical method, which led to expression (6), obtained previously by a thermodynamic method (p. 309):

$$R_n = \left(\frac{1}{2}\right)^n = e^{-0.69n}. \qquad (13)$$

This equation satisfactorily describes the experimental results.

Thus, it has been shown both theoretically and experimentally that CTF leads to the most probable molecular-weight distribution.

It should be noted that these results have been obtained on the assumption that the rate constant of CTF is independent of the degree of polymerisation of the attacking active molecule and of the molecule being attacked, i.e. that it does not depend on the site of attack. This assumption can be unambiguously substantiated only on the basis of kinetic data. To this end, the kinetics of the establishment of equilibrium was investigated[20] for the disproportionation of the dimethyl ether of dioxymethylene glycol, using the boron trifluoride–ether complex as catalyst.

Evaluation of the kinetics based on a scheme analogous to (3)

$$R_e^* + R'_m - O - R'_n \rightarrow R_m^* + R'_e - O - R'_n,$$

where R'_i is a free-radical residue of structure $CH_3-[OCH_2]_i-$ and R_i^* is a carbonium ion of corresponding structure or a radical forming part of an oxonium ion

$$R'_i - \overset{+}{O}\begin{matrix} R'_m \\ \diagdown \\ R'_n \end{matrix}.$$

The set of kinetic equations corresponding to the proposed scheme is

$$\frac{dR_n}{d\tau} = R\sum_{i=1}^{n} R_i^* - \sum_{e=1}^{n-1}\sum_{i=1}^{n-e} R_i R_e^* - nR_nR^*, \qquad (14)$$

$$\frac{dR_n^*}{d\tau} = \left(R - \sum_{i=1}^{n-1} R_i\right) R^* - \bar{n}RR_n^*,$$

$$d\tau = 2kdt$$

where R_i is the concentration of $CH_3-[OCH_2]_i-OCH_3$ molecules,

R is the total concentration of all molecules,

R_j^* is the concentration of active centres,

n is the mean number of $-OCH_2-$ groups per molecule,

and k is the rate constant for interaction between an active centre and a neutral molecule (assumed independent of R_e^*, R'_m, and R'_n).

This system can be solved step by step. The following expressions are obtained for the first three terms (n = = 1, 2, 3)

$$R_1 = R\left(\frac{1}{2} - \frac{1}{2}e^{-R^*\tau}\right),$$

$$R_2 = R\left(\frac{1}{4} + \frac{1}{2}e^{-R^*\tau} + \frac{1}{4}e^{-2R_\tau^*}\right),$$

$$R_3 = R\left(\frac{1}{8} + \frac{1}{8}e^{-R^*\tau} - \frac{1}{8}e^{-2R^*\tau} - \frac{1}{8}e^{-3R^*\tau}\right). \qquad (15)$$

The following formula gives the total concentration of the remaining molecules

$$R_{rem} = R\left(\frac{1}{8} - \frac{1}{8}e^{-R^*\tau} - \frac{1}{8}e^{-2R^*\tau} + \frac{1}{8}e^{-3R^*\tau}\right). \qquad (16)$$

These equations fully represent the experimental results, the best agreement being obtained with a rate constant of $k = 0.021$ litre mole^{-1} s^{-1}. The agreement between theory and experiment confirms the authors' original assumption of the equivalence of all the acetal bonds.

The role of CTF in the various stages of the process is one of the most important problems in polymerisation kinetics. It is obvious that, in the absence of a chain-growth reaction, CTF must lead to a Semenov–Flory distribution[1,21], but chain growth will perturb this distribution in such a way that at very low rates of CTF (in the absence of chain termination and chain transfer, and with instantaneous initiation) the molecular-weight distribution will be described by Poisson's law[18]

$$R_j = \frac{\bar{P}^j}{j!}e^{-\bar{P}}. \qquad (17)$$

We shall estimate the relative velocities of these reactions.

The rate of the growth reaction is

$$w_{gr} = k_{gr}RM_0(1-\alpha), \qquad (18)$$

where α is the extent of reaction, R the concentration of active centres, and M_0 is the initial concentration of monomer.

The rate of the CTF reaction is

$$w_{CTF} = k_{tr}RM_0\alpha. \qquad (19)$$

The closeness with which the molecular-weight distribution in the system approaches an exponential distribution will be determined by the ratio of the velocities:

$$\frac{w_{CTF}}{w_{gr}} = \frac{k_{tr}}{k_{gr}}\frac{\alpha}{1-\alpha}. \qquad (20)$$

We must remember, however, that the chain growth reaction alters the length by one unit, whereas the CTF reaction alters it by an amount of the same order as the chain length, so that the velocity ratio should be multiplied by the mean degree of polymerisation $\bar{P}$. Thus the transfer intensity factor is

$$\varphi = \varepsilon\bar{P}\frac{\alpha}{1-\alpha}.$$

It is evident that the relative intensity of CTF increases sharply towards the end of the polymerisation process. A study of the polymerisation of tetrahydrofuran has, indeed, shown that the role of CTF, detected by the increase in viscosity of the system, is particularly

noticeable at the very end of the polymerisation, when the growth reaction has practically ceased[22].

Berlin and his coworkers [12] have considered theoretically the possibility of cyclisation by scheme (2) during CTF. They have derived an equation for the molecular-weight distribution in the system with allowance for the formation of cyclic structures

$$h_j = \frac{\alpha}{\beta} \cdot \frac{1}{j^{5/2}} e^{-j/l}, \qquad (21)$$

$$N_j = \frac{N}{l} e^{-j/l},$$

where l is the mean degree of polymerisation of linear molecules, h_j and N_j are the concentrations of cyclic and of linear molecules of length j, and α and β are the rate constants for cyclisation and interchain exchange respectively.

Analysis of the equations yields a number of interesting conclusions. Fig. 1 shows the variation of the mass of cyclic macromolecules for different values of the parameter

$$\varepsilon = \frac{mN}{h_0}, \qquad (22)$$

where

$$h_0 = \lim_{l\to\infty} \int_m^\infty e^{-j/l} \frac{dj}{j^{5/2}} = \frac{\alpha}{\beta} \frac{2}{\sqrt{m}},$$

is the limiting amount of monomer in the cyclic molecules.

From Fig. 1 it is evident that for $M_0 < h_0$ practically the whole of the polymer is cyclic and for $M_0 > h_0$ the mass of cyclic polymer is practically constant. Estimated values of h_0 and ϵ are 4×10^{21} cm^{-3} and 10^{-3} respectively. Thus, in some cases the polymer can be almost completely converted into a cyclic state.

Consideration of the overall molecular-weight distribution gives for $\overline{P}_w/\overline{P}_N$ the expression

$$\frac{\overline{P}_w}{\overline{P}_N} = \frac{2}{3}\left(1 - \frac{h_0}{M_0}\right)^2 \frac{1}{\varepsilon}, \qquad (23)$$

which shows that cyclisation may be a possible cause of the great polydisperseness of polymerisation products.

Recent experimental studies of the polymerisation of heterocyclic compounds[23-27], and earlier work on condensation polymerisation[28-31], have shown that large rings can be formed under these conditions.

The possibility of CTF in a system leads to redistribution of the macromolecules with respect to composition as well as to length. Plechova et al.[10] discuss the influence of CTF on the composition of copolymers.

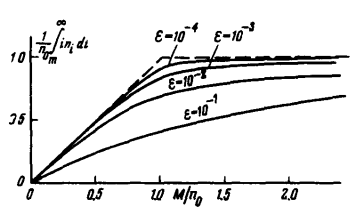


Fig. 1. Variation of mass of cyclic macromolecules with polymer concentration for different values of the parameter ϵ. [12]

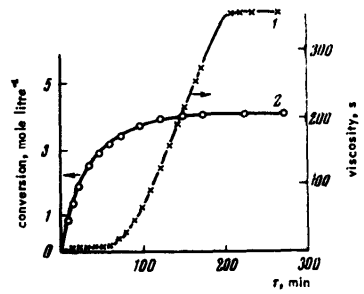

Fig. 2. Dependence of the viscosity of the polymerisation medium (1), and of the extent of reaction (2), on the duration of polymerisation of tetrahydrofuran in diethyl ether at 20° in the presence of the catalytic system

$(C_2H_5)_2O.BF_3$ —— $CH_2-CH-CH_2Cl$ (O)

with $[M]_0 = 7.0$ M, $[cat]_0 = 0.02$ M (after Rozenberg[22]).

The CTF reactions occurring in the case of a binary copolymer can be summarised as follows:

$$\sim\sim A^* + \sim\sim A-B \sim\sim \xrightarrow{k_1} \sim\sim A-A \sim\sim + \sim\sim B^*$$
$$\sim\sim A^* + \sim\sim B-B \sim\sim \xrightarrow{k_2} \sim\sim A-B \sim\sim + \sim\sim B^* \qquad (24)$$
$$\sim\sim B^* + \sim\sim A-B \sim\sim \xrightarrow{k_3} \sim\sim B-B \sim\sim + \sim\sim A^*$$
$$\sim\sim B^* + \sim\sim A-A \sim\sim \xrightarrow{k_4} \sim\sim A-B \sim\sim + \sim\sim A^*$$

It is clear that the composition of the copolymer undergoes a change: sequences (blocks) of units of a given kind can be split, and conversely separate blocks of a given unit can become "fused" into a single block. Thus, CTF can cause redistribution of the units of a copolymer among blocks and affect the number of blocks in the macromolecule.

By analogy with the number average degree of polymerisation, we can introduce the parameters S_A and S_B, the mean lengths of the blocks ~A...A~ and ~B...B~. If the average number of blocks of a given type in the macromolecule is l, it readily follows that

$$S_A = \frac{m_A}{l}, \quad S_B = \frac{m_B}{l},$$

where m_A and m_B are the respective numbers of A and B units in the molecule.

Solving the set of differential equations for the variation in l and $[A^*]$, we obtain for equilibrium the following equation

$$l^2 - \kappa[m_A - l][m_B - l] = 0, \qquad (25)$$

where

$$\kappa = \frac{k_2 k_4}{4 k_1 k_3}.$$

When $\kappa = 1$ the expression for l takes the form

$$l = \frac{m_A m_B}{m_A + m_B} \qquad (26)$$

and

$$\overline{S}_A = 1 + \frac{m_A}{m_B}, \quad \overline{S}_B = 1 + \frac{m_B}{m_A}. \qquad (27)$$

This means that monomer units in the copolymer which are present in small numbers as compared with the other component are distributed singly.

Eqn. (26) can be obtained by a purely statistical approach[32,33].

Thus the occurrence of CFT in a system must cause a redistribution of the monomer units in the system irrespective of the initial distribution.

In the absence of CTF the average length of the blocks is completely determined by the copolymerisation constants according to the formulae

$$\bar{S}_A = r_1\varepsilon + 1; \quad \bar{S}_B = \frac{\varepsilon}{r_2} + 1. \qquad (27')$$

Discrepancies between the experimental composition of a copolymer and that calculated from the formulae (27') have been reported in papers on the copolymerisation of dioxolan with styrene[34] and of 3,3-bischloromethyl--oxacyclobutane with β-propiolactone[35]: obviously, this can be ascribed to the occurrence of CTF in these systems.

Analysis of copolymerisation kinetics with allowance for CTF leads to expressions for the rate and for the composition of the copolymer which differ from the classical expressions.

For small extents of reaction, when the consumption of monomer can be ignored, and $k_2 = 0$, we obtain

$$\alpha + \frac{k_{12}\varepsilon}{k}\left(1 - \frac{k_{21}}{K_{11}}\right)\ln\left\{1 + \frac{k_1 x}{k_{21} + k_{12} n \dfrac{k_{21}}{k_{11}}}\right\} = K_{11}C_0 t, \qquad (28)$$

where

$$\alpha = \frac{m_A}{A}; \quad n = \frac{B}{A}.$$

In the absence of CTF, the parameter α varies linearly with time:

$$\alpha = k_{11}Ct_0\,\frac{1 + k_{12}/k_{11}\cdot n}{1 + k_{12}/k_{21}\cdot n}, \qquad (29')$$

whereas if transfer through the polymer is substantial

$$\alpha = k_{11}kC_0 t. \qquad (29'')$$

The physical significance of these relationships is clear: CTF leads to a greater number of active centres of type A* than in the case of ordinary copolymerisation; this increases or decreases the rate of accumulation of the component A according as $k_{11} \gtrless k_{21}$, since

$$\frac{1 + k_{12}/k_{11}\,n}{1 + k_{12}/k_{21}\,n} \gtrless 1.$$

It is evident that the change in the rate of polymerisation of each of the components in the presence of CTF (as compared with the classical scheme of copolymerisation) will cause departures from the Mayo–Lewis composition equation[36,37].

Thus the instantaneous composition of the copolymer in the presence of CTF is given by the equation[36]

$$n = \frac{1}{2}\left[\frac{\varepsilon r_1 r_3 - r_2 r_4}{r_3} - \frac{\varepsilon + r_2}{r_3}\left(\frac{1}{\alpha} - 1\right) + \sqrt{\left[\frac{\varepsilon r_1 r_3 - r_2 r_4}{r_3} - \frac{\varepsilon + r_2}{r_3}\left(\frac{1}{\alpha} - 1\right)\right] + 4\left[\frac{r_4}{r_3} + \frac{r_1\varepsilon}{r_3}\left(\frac{1}{\alpha} - 1\right)\right]}\right], \qquad (30)$$

where r_1 and r_2 are the copolymerisation constants, and

$$r_3 = \frac{k_1}{k_{21}}; \quad r_4 = \frac{k_2}{k_{12}}; \quad n = \frac{m_A}{m_B}; \quad \varepsilon = \frac{A_0}{B_0}, \alpha = \frac{m_B}{B_0}.$$

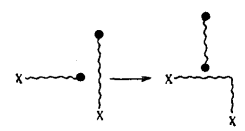
In the absence of CTF ($r_3 = r_4 = 0$) Eqn. (30) becomes identical with the classical equation for the instantaneous composition of a copolymer. If either of the parameters r_3 and r_4 is non-vanishing, the composition given by formula (30) can deviate very significantly from the classical composition. The difference increases with increase in α.

A remarkable consequence of the occurrence of CTF in a system is the special form of the "live" state of the system. The "live" state of polymers, discovered and investigated by Szwarc[13], depends on the absence of any reactions which destroy active centres or cause chain limitation in general, and thus can occur only in absolutely pure systems. This state is characterised by a molecular-weight distribution of the Poisson type[18], a linear increase in degree of polymerisation with extent of reaction, and rigid adherence to the expression

$$\bar{P}_N = \frac{\Delta M}{C}, \qquad (31)$$

where C is the total quantity of active centres, ΔM the amount of polymerised material, and $\bar{P}_N$ the mean degree of polymerisation.

As was stated above, CTF leads to an exponential molecular-weight distribution irrespective of the detailed mechanism of polymerisation. The broken macromolecules take part in CTF without disturbing the distribution, as is the case with normal "live" polymers. Molecules having "dead" end-groups on both sides can acquire active terminations as a result of CTF. As can readily be shown, this should produce chains both ends of which are active:



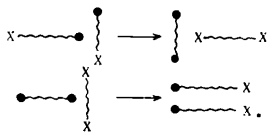
(32)

Therefore, all molecules, both "live" and "dead", will take part in reactions of chain growth, since there will be a constant exchange of end-groups between the macromolecules. Thus, in a way, all molecules in the system are "live", whatever the nature of their end-groups.

Studies of the variation in molecular weight with extent of reaction in the polymerisation of trioxan[38,39] have shown that the viscosity molecular weight increases linearly with extent of conversion, suggesting that the polyoxymethylene molecules are live[38]. However, later experiments revealed a temperature dependence of the slope of the linear plot of $\bar{M}_w$ against extent of reaction, which was unrelated to differences in the degree of initiation[38]. This provides unambiguous proof of the presence of chain--limiting reactions in the system, probably by transfer to impurities with a rate constant much higher than the growth rate constant. The linear variation of the viscosity--average molecular weight with extent of reaction can be retained only in the presence of intense CTF, which allows all the molecules to take part in chain growth and maintains proportionality between number-average and weight--average molecular weights. Thus, this special form of the "live" state of the molecules manifests itself in the polymerisation of trioxan.

It is interesting to consider the nature of the distribution of end-groups among the chains. If the macromolecules can have only two types of end-groups (active and inactive), the system will be composed of three types of molecule: — both end-groups active (A), only one active (B),

and both inactive (C) — transition of molecules of one type into another type occurring by the scheme



(32′)

The set of equations describing this process is

$$\frac{dA}{dt} = \frac{dC}{dt} = -2\frac{dB}{dt} = \frac{1}{2}kB\sum jB_j - 2kA\sum_j jC_j,$$
$$2A + B = a;$$
$$2C + B = b, \qquad (33)$$

where a is the total concentration of active groups, and b of inactive groups.

Assuming that CTF results in the establishment of an equilibrium molecular-weight distribution, and also an equilibrium distribution of end-groups, the former being observed not only in the system as a whole but also in each group of molecules, we obtain

$$\frac{A}{A+B+C} = \frac{a^2}{(a+b)^2};\quad \frac{B}{A+B+C} = \frac{2ab}{(a+b)^2};\quad \frac{C}{A+B+C} = \frac{b^2}{(a+b)^2}. \qquad (34)$$

It should be noted that this distribution of end-groups can be obtained from purely statistical considerations, by assuming that the probability of finding any group at one end of a chain is equal to its fraction of the total number of ends, whilst the probability of finding any two groups at the two ends of a chain is equal to the product of the separate probabilities for each of the groups. The fraction of macromolecules of a given type is determined by the probability of their formation.

A kinetic analysis of the exchange between molecules having more than two types of end-group is fairly complicated, but it leads to a similar result.

As the above considerations show, the kinetic and the probability approaches to the distribution of macromolecules with respect to length, composition, and type of end-groups give identical results, because of the entropic nature of CTF.

3. CTF AS AN EXCHANGE REACTION

It is possible to set up a simple and convenient model of CTF reactions on the basis of low-molecular-weight compounds simulating the functional groups which can undergo CTF (fragments of the main chain or of a side-chain of the polymer). These model exchange reactions must satisfy a number of requirements arising from the specific chemical features of CTF reactions in macromolecular compounds.

The reactions must be reversible. This is because a necessary condition for this reaction to occur during polymerisation is that the new active centre formed after the act of transfer must be able to carry on the polymerisation and CTF process. When CTF occurs, the rate constants for M_1^* with respect to M_1–M_1 and M_2–M_2, and also for M_2^* with respect to M_1–M_1 and M_2–M_2, will be different for the different homopolymers, but it is necessary that all these reactions should take place — which means, in practice, that the reaction must be reversible — in order that CTF can occur.

A second important requirement of the model reactions of exchange interaction is adherence to the principle of conservation of functional groups. This means that the functional groups initially present must not undergo any chemical change during the reaction: only radicals bound to the functional groups are exchanged.

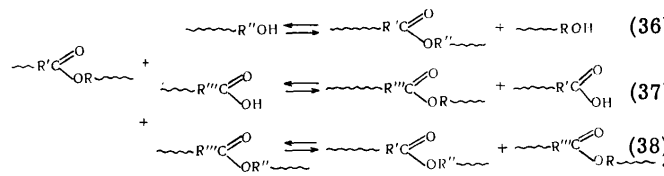
In view of the latter requirement, we must exclude those exchange reactions which, though formally resembling model exchange reactions, follow a quite different mechanism, involving changes in the functional groups during the process. For example, reactions which do not satisfy the above conditions, although formally very similar to model reactions for CTF, are the Meerwein–Ponndorf–Verley reaction of ketones and the Oppenauer oxidation of alcohols[40]

(35)

Another example of a reaction of this type is transamination, discovered by the Soviet biochemists Braunshtein and Kritsman[41].

At the present time, hardly any papers have been published on the detailed mechanism of exchange reactions, but some general features observed in studies of transesterification processes and in particular the alcoholysis of carboxylic esters[42–58] justify the statement that these are fairly typical of nucleophilic substitution processes at a carboxy-group[59,60].

We shall consider some model reactions of exchange interaction. The examples below are given merely as an illustration, and are by no means comprehensive. One of the most thoroughly investigated model reactions is transesterification. It can be conducted in three ways — (1) by reaction between an ester and an alcohol (alcoholysis), (2) by reaction between an ester and an acid (acidolysis), and (3) by reaction between two esters (esterolysis):



(36)

(37)

(38)

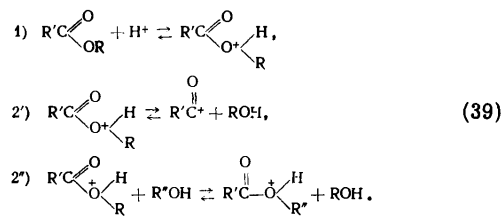
Reactions (36) and (37) simulate the reaction between a polyester macromolecule and a low-molecular-weight impurity (acid or alcohol); reaction (38) simulates the interchain exchange of two polyester macromolecules.

The rate of reactions (36) and (37) is considerably increased by acidic or basic additives[44,46,61], while reaction (38) is accelerated by acidic catalysts[45,61]. Studies of alcoholysis have shown[49] that a heavier hydrocarbon radical displaces a lighter one, but on occasions a heavier alcohol radical is displaced by a lighter one in fairly high yield, as in the alcoholysis of bornyl acetate by ethanol and by butanol[47]. The structure of the radical R′ has a major effect on the rate of exchange. Thus, the exchange is strongly retarded by the presence of double bonds in the α and β positions with respect to the carboxy-group, as in crotonic and cinnamic esters[44]. Conversely, electron-acceptor groups in the α position to the carboxyl increase the rate of exchange[44].

It has recently been shown[56] that the yield of alcoholysis products is practically unaffected by the number and complexity of the substituents in the acid part of malonic esters.

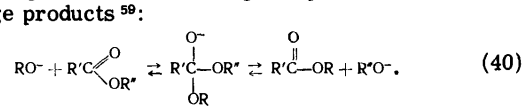
The relative reactivity of various radicals in the alcoholysis of acetates has been measured[50]. As was to be expected, primary alcohols are the most reactive, followed by secondary alcohols.

Korshak and Vinogradova[61] studied the kinetics of alcoholysis in the exchange between ethyl stearate and cetyl alcohol. The reaction takes place even in the absence of catalysts, but very high temperatures are then necessary. Alkaline (sodium hexadecyloxide) and particularly acid (concentrated sulphuric acid) catalysts allow the temperature to be lowered appreciably whilst increasing the velocity above that of the uncatalysed reaction. The mechanism of the uncatalysed (or acid-catalysed) alcoholysis, like that of the thoroughly investigated hydrolysis of esters under analogous conditions[62], appears to consist in the rapid formation of an acylalkyloxonium ion, which subsequently decomposes to form an acylium cation or reacts with the alcohol:



(39)

The mechanism of alkaline alcoholysis involves initial attack by an alkoxy-anions on the carboxyl carbon atom, which has a partial positive charge as a result of the electron-acceptor effect of the carbonyl group. The resulting anionic intermediate can decompose in two ways — to regenerate the starting compounds or to form the exchange products[59]:



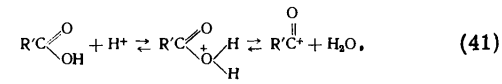
(40)

Some unusual features were observed in a study of the alcoholysis between ethyl stearate and acetic acid[63]. It was shown that the order of the reaction changes from first to second during the course of the reaction.

Acidolysis is accelerated by protonic and aprotic acids[64]. It is very important in synthetic chemistry, and is widely used for the preparation of vinyl esters of carboxylic acids from vinyl acetate[65].

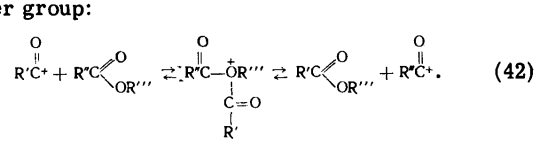
As in the previous systems, the uncatalysed exchange between two esters occurs very slowly and only at sufficiently high temperatures[66]. The reaction becomes much faster in the presence of alkaline, and even more so in the presence of acidic, catalysts[66-68]. The rate of the reaction is proportional to the concentration of the reagents[66].

The mechanism of acid-catalysed acidolysis evidently involves initial formation of an acylium cation



(41)

which can then attack a molecule of the ester with exchange of the ester group:

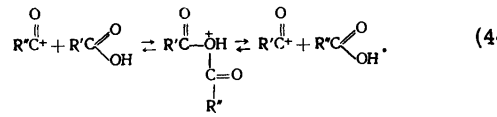


(42)

Regeneration of $O{=}C^{+}R'$ can occur either through the interaction of $O{=}C^{+}R''$ with water

(43)

followed by reaction (41), or directly by reaction between $O{=}C^{+}R''$ and the acid



(44)

In addition to the Soviet work discussed above[61,63,66], we must mention that papers of Flory[2,69], who showed that the alcoholysis of poly(decamethyleneadipate) under the influence of small amounts of an alcohol or a glycol (decamethylene glycol or dodecan-1-ol) follows first-order kinetics in the presence of an acid catalyst. The reaction velocity is proportional to the concentration of the acid catalyst. The activation energy of the alcoholysis is 11.5 kcal mole^{-1}. It was also shown that the exchange reaction in question is approximately 11 times as slow as the polyesterification of decamethylene glycol and adipic acid.

Various workers[70-72] have found that these exchange reactions follow second-order kinetics, the activation energy of the uncatalysed exchange being 20–30 kcal × × mole^{-1} higher than that of the acid- or base-catalysed reaction by factors of 2–3.

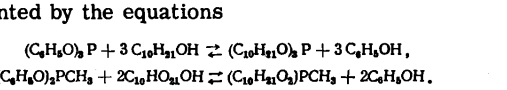
On the basis of the kinetic results obtained in their study of transesterification on model compounds, Korshak and Vinogradova[73,74] arranged the reactions in order of increasing relative reaction rate as follows: esterolysis < < alcoholysis < acidolysis. We should note, however, that in the condensation polymerisation process used in the synthesis of polyesters the relative importance of acidolysis and alcoholysis decreases as the reaction proceeds, owing to the loss of functional groups, while esterolysis becomes increasingly important as a result of the accumulation of polymeric products.

Transesterification occurs readily also with the esters of phosphoric, phosphorous, and phosphonic acids[75-80]. The preparation of dialkyl phosphites from diphenyl phosphites by an exchange reaction between the latter and aliphatic alcohols was worked out by Petrov et al.[75] The reaction proceeds by the scheme

(45)

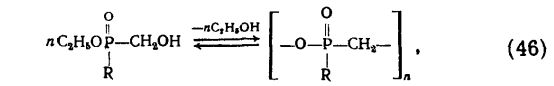
The reaction product is formed in fairly high yield, reaching 93%.

Good yields of exchange products have been obtained also in the transesterification of aromatic esters of phosphoric and phosphonic acids with aliphatic alcohols[76]. The reaction is catalysed by alkali-metal alkoxides and is represented by the equations



Nifant'ev and Fursenko[77] found that the transesterification of phosphites and phosphonites, a very important synthetic reaction used in the preparation of many phosphorus derivatives, can be carried out under much milder conditions (20–40°) and without a catalyst if the 2-fluoroethyl esters of tervalent phosphorus acids are used as starting compounds.

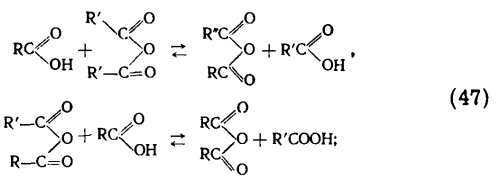
Pudovik and Evstaf'ev [78,79] used transesterification to prepare polyphosphites and polyphosphinites by the reaction of phosphinic and phosphinous esters with glycols. In a recent paper [80], these authors have extended this method to the preparation of phosphorus-containing polymers by homopolyesterification:



(46)

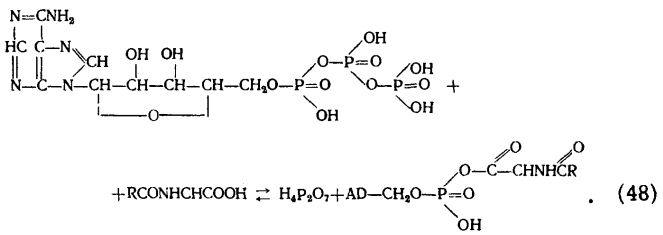
where R = OC_2H_5, C_2H_5, C_6H_5. The kinetics of this reaction is described by a second-order equation, with an activation energy of 23 kcal $mole^{-1}$.

A very important reaction in synthetic chemistry is the exchange interaction of carboxylic acids with acid anhydrides [81-85], leading to formation of the anhydrides of the corresponding acids or to mixed anhydrides:



(47)

The formation of a mixed anhydride is thought [86] to be one of the essential intermediate stages in the synthesis of polypeptides and proteins. Adenosinetriphosphoric acid, which can be said to contain an inorganic acid anhydride group, exchanges with an acylamino-acid to form a mixed anhydride — the acyladenylate of the amino-acid, which can then be used *in vivo* or *in vitro* to construct a peptide link:



(48)

The transetherification of an ether or acetal linkage also has great practical importance in the synthesis of various ethers and acetals [87-94]. These reactions, which proceed according to the scheme

$$ROR + R'OR' \rightleftarrows 2ROR',$$

are catalysed as a rule by acid substances — protonic [94] and aprotic [89] acid, ion-exchange resins [91], and other compounds [89,90] — being particularly important in the synthesis of natural products, especially polysaccharides, in which interchain exchange occurs through the splitting of a glucoside link under the influence of specific enzymes [86].

Exchange reactions between the amide group and acids, amides, esters, and amines are quite rapid. These reactions are of the utmost importance in biosynthesis, and will be dealt with separately.

The disulphide group, and polysulphide groups in general [95], are very reactive towards a number of exchange interactions. The most typical exchanges of this type are the thiol–disulphide and disulphide–disulphide, which can be represented by the general equations

$$RSSR + R'SH \rightleftarrows RSSR' + RSH; \quad (49)$$

$$RSSR + R'SSR' \rightleftarrows 2R'SSR. \quad (50)$$

It is interesting to note that these reactions can be initiated both by anionic and by cationic catalysts. In a few cases the exchange can occur also by a radical mechanism. Thus, for example, exchange was reported [96] between dodecanethiol and propyl disulphide merely on heating, without the addition of any activators.

The thiol–disulphide exchange is very strongly accelerated in the presence of alkaline catalysts [97]. The polarity of the solvent has a considerable effect on the rate of exchange. It has been shown [98] that an exchange which is slow in absolute methanol is accelerated by aqueous methanol, and goes very rapidly in the presence of alkali. The rate of the thiol–disulphide exchange in methanol at 0–35° is proportional to the concentration of disulphide and the alkyl sulphide ion, and the activation energy [99] is 15 kcal × × $mole^{-1}$. Reactants containing sterically hindered groups, such as 2-methylpropane-2-thiol reacting with di-t-butyl disulphide, exchange very slowly, with an activation energy of ~ 22 kcal $mole^{-1}$.

Entirely different behaviour is observed when the thiol–disulphide exchange is carried out in non-polar media. The exchange interaction between aliphatic thiols and disulphides in an aromatic hydrocarbon medium is very slow even at 200°. Its activation energy is 28 kcal $mole^{-1}$. Yet the exchange of aromatic thiols and disulphides under similar conditions is quite fast even at much lower temperatures, and has an activation energy of ~ 10 kcal $mole^{-1}$. The reaction rate is proportional to the square root of the concentration of disulphide, and is independent of the thiol concentration. Gur'yanova and her coworkers [100] proposed a radical exchange mechanism in non-polar media to explain these facts

$$\begin{aligned} RSSR &\rightleftarrows 2RS^{\cdot}, \\ RS^{\cdot} + R'SH &\rightleftarrows R'S^{\cdot} + RSH, \\ R'S^{\cdot} + RS^{\cdot} &\rightleftarrows R'SSR; \end{aligned} \quad (51)$$

The presence of radicals was demonstrated by the accelerating effect of ultraviolet radiation and by reaction with 2,2-diphenyl-1-picrylhydrazyl. The exchange is catalysed by peroxides and azoisobutyronitrile [95]. The decomposition of acyl peroxides occurs in a similar way [34]. A radical mechanism has been postulated also for the exchange of disulphides [101]: unsymmetrical aromatic disulphides undergo rearrangement to symmetrical disulphides in boiling dioxan solutions, under ultravoilet irradiation, or on heating to 170°.

Disulphides exchange very readily in polar media in the presence of hydrogen sulphide or alkyl sulphide anions [97,102,103]. Disulphide exchange can occur also in the presence of protonic or aprotic acids [97,104,105]. The sulphonium ion is assumed to be active species.

Space does not allow us to discuss all the many exchange interactions which can be applied to polymeric molecules for the purpose of modifying them. We shall point out only that the use of nuclear magnetic resonance methods in recent years has helped to demonstrate the occurrence of exchange reactions in the most varied systems [106-109].

4. METHODS OF DETECTING CTF

Exchange reactions involving macromolecular compounds occur by essentially similar processes. Just as with other chemical transformations of macromolecular

compounds [110], the morphology of the polymer plays an important part. This is obviously a highly significant factor in reactions of this type, and exerts a strong influence on the reactivity of polymers.

The occurrence of CTF in a system can be detected in a number of ways. For a CTF reaction to manifest itself in the synthesis of a polymer by condensation or addition polymerisation, the rate constant of the CTF step must be comparable with the rate constant of the polymer formation reaction. This criterion becomes less essential when we are dealing with CTF between two existing homopolymers, since in this case the exchange can be considerably intensified by raising the temperature.

A strict chemical proof of the presence of CTF may be provided by the very fact that block and graft copolymers are formed under conditions offering no conceivable mechanism for their formation other than CTF.

Two methods of synthesis of block copolymers based on CTF have been developed. In the first method the block copolymer is synthesised by the polymerisation of one monomer in a medium of the other homopolymer [111,112], when polymerisation is accompanied by CTF. Block copolymers synthesised by this method and the methods used to identify them are listed in Table 1.

In the second method, block copolymers are synthesised by initiating CTF between the two homopolymers. It is evident that in this case we have no polymerisation as such, and that only CTF processes take place according to the scheme

$$\sim\!\sim R_jOR_i\sim\!\sim + \sim\!\sim R_kOR_l\sim\!\sim \longrightarrow \sim\!\sim R_jOR_k\sim\!\sim + R_lOR_i\sim \quad (52)$$

The results of these syntheses [113] are set out in Table 2.

Pairs of homopolymers were chosen such that one of the polymers was insoluble in the solvent used, thus enabling the occurrence of CTF to be detected visually by the gradual swelling followed by dissolution of the insoluble polymer. Blank experiments without the catalyst (to check whether the insoluble homopolymer was soluble in a solution of the other homopolymer) and without the soluble homopolymer (to check whether the polymer was soluble when degraded by the catalyst) gave no such effect. In both cases, the insoluble polymer was regenerated in almost quantitative yield.

TABLE 1. Preparation of copolymers by cationic polymerisation of a monomer in the presence of other polymers [11].

Poly(tetramethylene oxide)	polyoxymethylene
Polydioxolan	poly-3,3-bischloromethyloxacyclobutane

Obviously, graft copolymers also can be synthesised by a similar procedure, if the functional group by which the chain is transferred is located in a side-branch of the homopolymer. Again, two methods of synthesis are possible — (1) the polymerisation of one monomer in a medium of the other homopolymer, and (2) reaction between the two homopolymers — results of the synthesis of graft polymers by the second method being listed in Table 3 [113].

It might be thought that block and graft copolymers are formed not as a result of CTF but by the copolymerisation of pairs of monomers produced during the establishment of equilibrium with an active polymer chain, which is itself formed by the action of the catalyst on the polymers. However, the results of the third experiment in Table 2 and of the experiments summarised in Table 3 show unambiguously that the block and graft copolymers were formed by a CTF reaction, since the starting homopolymers used could not act as monomer donors under the conditions of the experiments.

Thus, the synthesis of block and graft copolymers by the methods described is a rigorous chemical proof of the reality of CTF as an elementary act.

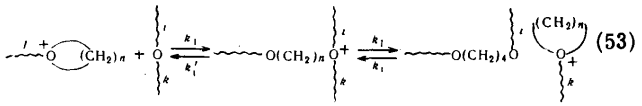
This act can be quite clearly identified even in homopolymerisation processes. A universal method of identification is the change in the molecular-weight distribution of the polymer during polymerisation. Some difficulties in the identification of this elementary act may arise when the polymerisation process is reversible, because under these conditions, too, the most probable molecular-weight distribution will establish itself in the system. These difficulties can be readily overcome by noting that in the case of reversible polymerisation the most probable distribution occurs only in the "live" part of the polymer.

An interesting effect is observed in the cationic polymerisation of oxygen-containing cyclic compounds. Thus, in the polymerisation of tetrahydrofuran [22] or trioxan [114], and perhaps also of other analogous compounds, a large increase in the viscosity of the reaction medium is found towards the end of the polymerisation process. Fig. 2 shows the variation in viscosity of the medium and in the extent of conversion as a function of time during polymerisation. This effect is not difficult to explain on the basis of CTF concepts.

TABLE 3. Preparation of graft copolymers by the interaction of homopolymers [113].

Soluble polymer	Insoluble polymer
Poly(butyl vinyl ether)	polyoxymethylene
Poly (butyl vinyl ether)	poly-3,3-bischloromethyloxacyclobutane

Thus, as was shown above (p. 310), the relative contribution of CTF to the polymerisation process should increase continuously as the reaction proceeds. Since a cyclic ether (acetal) is considerably more basic than a linear polyether, the rate of chain growth is higher, as a rule, than the rate of CTF. In this case the mechanism of CTF is complex, consisting of two consecutive acts: an active centre attacks the polymeric macromolecule with formation of an oxonium ion, and the resulting polymeric oxonium ion then decomposes:



(53)

The rate of the CTF process depends on the ratio of the constants for these elementary reactions: clearly, all the active centres should be in the form of polymeric oxonium ions towards the end of the reaction, so that the reaction medium consists of an aggregated system with labile bonds between polymer chains. Of course, this effect must cause a substantial increase in the viscosity of the medium. The viscosity of a system undergoing polymerisation drops to the normal value on treatment with a nucleophilic reagent[22], i.e. when the labile bonds are broken. The occurrence of this effect during homopolymerisation can itself be taken as evidence for CTF in the system under study.

Clear indications of interchain exchange and related interactions between a polymer chain and the starting materials or compounds of similar chemical nature have been obtained in the study of reactions leading to the formation of macromolecules by condensation polymerisation. As already pointed out, these reactions appear to proceed by a mechanism analogous to CTF. We shall call these reactions interchain exchange reactions in the case of condensation polymerisation.

Since fairly high temperatures are normally used for condensation polymerisation, the contribution of interchain exchange to the formation of macromolecules is considerably increased. We shall consider a few examples which illustrate interchain exchange processes occurring in condensation polymerisation reactions. These relate mainly to interchain exchange reactions of ester and amide groups.

We know from the theory of condensation polymerisation[3,4] that equivalent amounts of reactants are of great importance in the preparation of polymers of high molecular weight. Since functional groups of a single type do not interact, we can expect that a twofold excess, say, of one of the reactants will make it impossible to obtain a high-molecular-weight polymer: only low-molecular-weight reaction products should form in this case. Actually, however, it is possible to obtain products of fairly high molecular weight even in this case[115-117].

Thus, in the preparation of a polyester from a dicarboxylic acid and a diol with a twofold excess of one of the components, HOR'OOCR"COOR'OH or HOOCR"COOR'OOCR"COOH respectively are formed in the early stages of the reaction. Growth of the resulting "intermediates" becomes possible if exchange reactions by a transesterification mechanism (acidolysis or alcoholysis) take place:

$$2\,\mathrm{HOOCR''COOR'OOCR''COOH} \xrightleftharpoons{-R''(COOH)_2} \mathrm{HOOCR''[COOR'OOCR'']_{\frac{1}{2}}COOH},$$

$$2\,\mathrm{HOR'OOCR''COOR'OH} \xrightleftharpoons{-R'(OH)_2} \mathrm{HOR'[-OOCR''COOR'-]_2OH}. \quad (54)$$

The dicarboxylic acid or diol evolved is removed in a vacuum at a high temperature in order to displace the equilibrium. In practice, as a rule, a slight excess of diol is used, since this is the more volatile constituent and is more easily removed from the reaction medium.

The exchange interaction between amides and acids (or esters) can be used for the synthesis of polyamides.

Rafikov et al.[118] observed the formation of a polyamide from *NN'*-diacetylhexamethylenediamine and adipic acid:

$$n\mathrm{CH_3ONH(CH_2)_6NHCOCH_3} + n\mathrm{HOOC[CH_2]_4COOH} \rightleftarrows \mathrm{[-NH[CH_2]_6NHCO[CH_2]_4CO-]_n} + 2n\mathrm{CH_3COOH}. \quad (55)$$

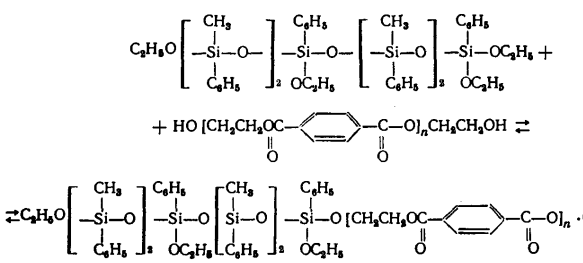
They also studied[118] the reaction between *NN'*-diacetylhexamethylenediamine and diethyl adipate. As before, the product of the reaction is polyhexamethyleneadipamide:

$$n\mathrm{CH_3CONH[CH_2]_6NHCOCH_3} + n\mathrm{C_2H_5OOC[CH_2]_4COOC_2H_5} \rightleftarrows \rightleftarrows \mathrm{[-NH[CH_2]_6NHCO(CH_2)_4CO-]_n} + 2n\mathrm{CH_3C(=O)OC_2H_5}. \quad (56)$$

Lastly, polyamides can be prepared by the exchange interaction of two diamides. Thus, Beste and Houtz[119] observed the formation of a polyamide from diacetylhexamethylenediamine and the diamide of sebacic acid:

$$n\mathrm{CH_3CONH[CH_2]_6HNCOCH_3} + n\mathrm{H_2NCO[CH_2]_8CONH_2} \rightleftarrows \rightleftarrows \mathrm{[-NH[CH_2]_6NHCO[CH_2]_8CO-]_n} + 2n\mathrm{CH_3CONH_2}. \quad (57)$$

The alcoholysis of polyesters has been suggested as a practical reaction for the regeneration of dimethyl terephthalate from poly(ethylene terephthalate) by treating the polymer with methanol[120]. Andrianov and his coworkers[121] demonstrated the interesting potential uses of alcoholysis in synthetic chemistry by preparing block and graft copolymers of poly(ethylene terephthalate) and polyorganosiloxanes:



(58)

The inclusion of ethoxy end-groups and side-groups in the polyorganosiloxane molecule leads to the formation of a mixed block-graft copolymer. The resulting copolymer has superior mechanical and dielectric properties and reasonably high thermal stability.

Kursanov et al.[122] demonstrated the occurrence of exchange interaction between two polyesters by an isotopic method. They studied the reaction between diethyl 2,3-dideuterosuccinate and poly(hexamethylene sebacate). The presence of deuterium in the polyester after reaction with the deuterated succinic ester is a proof of the occurrence of interchain exchange between polyester molecules.

A direct proof of ester exchange was given by Goodman and Nesbitt[123], who studied the interaction of poly(ethylene terephthalate) with tetramethylene dibenzoate and of poly(tetramethylene terephthalate) with ethylene dibenzoate. As a result of interchain exchange, they obtained ethylene and tetramethylene dibenzoates respectively.

The same workers showed that the cyclic trimer of ethylene terephthalate polymerises with formation of a linear polymer of high molecular weight. However, the reaction does not occur if the material is thoroughly dried. This suggests that the active initiator of the reaction is a hydroxy-acid, a hydrolysis product of the cyclic trimer. The mechanism of chain growth is an unusual trans-esterification reaction (acidolysis or alcoholysis) between the hydroxy-acid and the cyclic trimer.

The so-called hydrolytic polymerisation of lactams[4] involves a similar mechanism (transamidation). In general, from the point of view of the present Review, the polymerisation of any heterocycle can be treated as an exchange interaction irrespective of the type of active centre involved in the polymerisation.

Yet another general method of demonstrating the reality of interchain exchange reactions during condensation polymerisation depends on the formation of, say, a polyester from substances which contain neither free carboxyl nor free hydroxyl groups. Thus, a method of preparation of poly(ethylene terephthalate) from bis-2-acetoxyethyl terephthalate or bis-2-benzoyloxyethyl terephthalate has been described in the patent literature[124].

Several methods for identifying interchain exchange reactions are based on studies of the molecular weight, the molecular-weight distribution, or some other physical property of the products of condensation polymerisation[125]. Thus, when two samples of poly(decamethylene glycol) are mixed and heated[19], a fall in viscosity is observed: this is because the weight-average molecular weight decreases, although the number-average molecular weight remains constant under these conditions.

Using a very similar experimental approach, Rafikov et al.[126] separated by fractionation a narrow fraction of poly(ethylene adipate) from an unfractionated specimen. When this narrow fraction was heated in a sealed bulb at 170° the molecular-weight distribution became the same as in the original, unfractionated sample.

It is evident from the scheme discussed above that the acids and alcohols of low molecular weight generated by transesterification should lower the molecular weight of the polyester. Indeed, these phenomena have been thoroughly investigated in numerous publications by Korshak and his coworkers[125-136] and by others[69,137].

As in the case of polyesters, the exchange reactions accompanying the interaction between a polyamide and substance of a low molecular weight cause a lowering of the molecular weight of the former. Fig. 3 illustrates the results of the exchange reaction between polyhexamethyleneadipamide and adipic acid[128]. Similar results were obtained on reaction of this polymer with stearic acid[128] and of polycaprolactam with *p*-chlorobenzoic acid[138].

Korshak and Gribova[132] observed the aminolysis of polyurethane on heating it with aniline. They also showed that polyurethanes, like polyamides, can undergo, as well as aminolysis, exchange reactions with carboxylic acids, alcohols, and isocyanates[139].

A considerable lowering of molecular weight and softening temperature is observed when a polymer containing polysulphide links is treated with a thiol. Thus a liquid polymer of molecular weight ~ 5000 is formed when 5 mole % of butanethiol is added to an alkaline aqueous

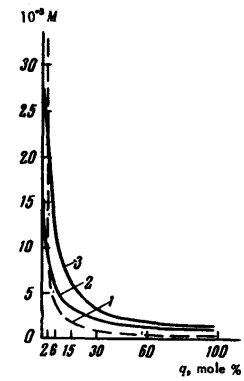


Fig. 3. Acidolysis of polyhexamethyleneadipamide by adipic acid (*q* mole %). Molecular weight:
1) calculated; 2) determined from viscosity;
3) determined from end-groups.

suspension of a macromolecular polysulphide[140]. Similar behaviour is observed with other substances which can denote alkyl sulphide ions, such as low-molecular-weight disulphides. Aromatic thiols, in particular thiophenols and mercaptobenzothiazole are effective donors[95]. Aliphatic thiols are less effective. Thiols with branched radicals have a very low activity[141] because of steric hindrance.

An interesting method, based on the change in physical properties of the resulting polymer, was used by Korshak and his coworkers[142] to demonstrate the occurrence of interchain exchange in condensation polymerisation. A polyamidoester of the composition

$$[-OCH_2CH_2NHCO[CH_2]_8CO-]_n,$$

(I)

was obtained by the condensation polymerisation of 2-aminoethanol with sebacic acid. Condensation polymerisation of *NN'*-bis-2-hydroxyethylsebacamide with sebacic acid was also carried out. The product in this case should have had the structure

$$[-OCH_2CH_2NHCO[CH_2]_8CONHCH_2CH_2OCO[CH_2]_8CO-]_n.$$

(II)

The two polymers were examined by electron diffraction, and found to have exactly the same identity period of 17 Å. This corresponds to the polyamidoester structure given by formula (I), whence we may conclude that polymer (II) has been converted into polymer (I) as a result of interchain exchange.

Kresse[143] used the lowering of the melting point of a copolyester (as compared with that of a mechanical mixture of the two separate polyesters) to detect interchain exchange. In exactly the same way, a copolymer was prepared from a mixture of three polyamides — poly(hexamethyleneazelaamide), polyhexamethyleneadipamide, and polycaprolactam — formation of the copolymer being demonstrated by monitoring the gradual fall in the melting point of the mixture of polyamides on heating[144]. The melting point continues to change until an equilibrium distribution of monomer units is established in the copolymer, as is clearly shown in Fig. 4, which is a plot of the flow temperature of the three-component system as a function of time of heating[144]. The authors also suggested[144] that

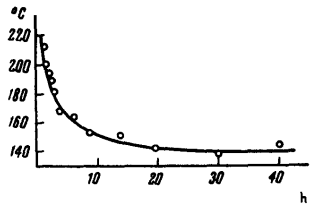

Fig. 4. Variation of the flow temperature of polyhexamethyleneazelaamide–polyhexamethyleneadipamide–polycaprolactam copolymers as a function of time of heating of the homopolymers [144].

the stability of solution of the resulting products can be used to characterise structural changes in the polyamide macromolecules during heating of the homopolyamides.

Technically valuable products have been obtained through the preparation of a copolyamide by heating a mixture of the two homopolyamides polyhexamethyleneadipamide and polycaprolactam [145,146]. It is interesting to compare the difference in melting point between copolymers of a given composition prepared either from the corresponding monomers or from the homopolymers [146,147]. As can be seen from Fig. 5, the melting points of the copolymers differ quite markedly, indicating that the distribution of monomer units is different in the two cases.

Results in good qualitative agreement with this conclusion have been obtained [148] from a study of the tensile strength of mixtures of homopolyamides as a function of time of heating, i.e. essentially as a function of the extent of interchain exchange. As shown in Fig. 6, progress of the reaction is accompanied by a gradual decrease in the tensile strength of the copolyamide. On the basis of the mechanism suggested above for CTF, we may assume that the high initial strength of the copolyamide stems from the large blocks formed in the block copolymer in the initial stages of the reaction; as the reaction proceeds, these blocks are broken up, and this appears to lower the tensile strength of the copolymer.

Thus, as shown by Korshak and his coworkers [149], a block copolymer is formed rapidly on heating mixtures of homopolyamides, the size of the blocks decreasing as interchain exchange proceeds. The system ultimately reaches an equilibrium state characterised by the appropriate distribution of monomer units in the copolymer. The

change in composition of a mixture of polyamides is shown in Fig. 7.[148]

The progress of interchain exchange between two homopolymers can be followed by choosing a solvent in which one of the homopolyamides is insoluble. Thus it was found [149] in a study of the reaction between polyhexamethyleneadipamide and polyhexamethyleneisophthalamide that the latter polymer is insoluble in formic acid. When this mixture was heated, the usual fall in melting point was observed, and at the same time the amount of insoluble polyhexamethyleneisophthalamide decreased with time, as shown in Fig. 8. It is evident from these results that only a relatively crude indication of the extent of interchain exchange can be obtained from the change in melting point of a mixture of polymers, particularly in the initial stages, when the block copolymers formed consist of large blocks and have melting points little different from that of a mechanical mixture of the homopolymers.

Unambiguous evidence for the presence of interchain exchange was obtained in the study of naturally occurring molecules containing peptide links. A characteristic feature of these reactions is the fact that they proceed in aqueous media, where the peptide links can undergo hydrolytic reactions. These reactions occur under the influence of enzymes.

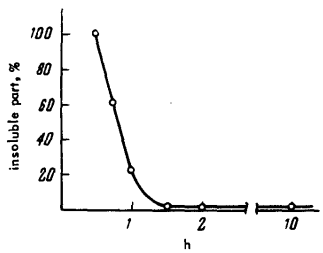

Fig. 8. Change in the relative amount of formic-acid-insoluble material in a polyhexamethylene-adipamide–polyhexamethyleneisophthalamide melt as a function of time of heating [149].

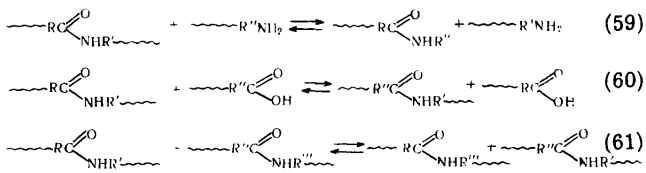
It was shown that various proteolytic enzymes, highly specific in action, can induce transpeptidation reactions as well as hydrolysis, whilst displaying their individual specificity. The term transpeptidation reaction refers to an interchain exchange reaction involving peptide links.

The discovery of transpeptidation is of the greatest interest, because these reactions can play an important role in the synthesis of proteins. In general, transpeptidation reactions can be represented by the following schemes



The earliest report of the possibility of reactions of this type is due to Bergmann [150], who discovered the reaction

$$\text{Hippuroylamine} + \text{Aniline} \xrightarrow{\text{papain}} \text{Hippuroylaniline} + NH_3. \qquad (62)$$

It may be thought that the hippuroylaniline was formed by initial hydrolysis of the hippuroylamine followed by reaction between the free hippuric acid and aniline. However, special experiments showed that the rate of reaction (62) is greater than that of the analogous reaction in which hippuric acid was used as the substrate [150]. Therefore, hippuric acid is not an intermediate in this process. In this way a new type of reaction brought about by proteolytic enzymes — exchange interaction — was postulated.

These results were subsequently confirmed by a series of investigations by Fruton and his coworkers [151-153], who showed that papain, activated by cysteine, catalyses the replacement of the amide nitrogen in *N*-benzoylglycinamide or benzyloxycarbonyl-*L*-methioninamide by ^{15}N, introduced in the form of $^{15}NH_4^+$. Exchange of the amide group can occur also when the amide reacts with hydroxylamine, leading to the formation of the corresponding hydroxamic acid [152,153]. Preliminary hydrolysis of the amide, followed by reaction between the free hydroxyl and the hydroxylamine, is out of the question, since it has been shown experimentally that free amino-acids do not form hydroxamic acids with hydroxylamine to a significant extent. Similar results were obtained when different enzyme systems — ficin and chymotrypsin [154,155], and also cathepsin [152,155] — were used as exchange activators.

Many investigations showed that the ability to undergo exchange is an almost universal property of the amides of various amino-acids. The amide group has a general tendency to exchange with various compounds, in particular with hydroxylamine and ammonia, and the latter can be used in the form of nitrogen-labelled ammonium salts. The exchange reaction takes place in the presence of enzymes of vegetable [155,156] and animal [157,158] origin, and of bacteria [159,160].

Exchange of the amide group has been used in synthetic chemistry to build up polypeptide chains. It has been shown [161] that benzoyltyrosylglycinamide is formed when benzoyltyrosinamide reacts with glycinamide in the presence of chymotrypsin. In a similar way, benzyloxycarbonylglycyltyrosinamide can be obtained from benzyloxycarbonylglycinamide and tyrosyinamide in the presence of papain. The action of cathepsin on glycylphenylalaninamide was shown to yield a whole range of polypeptides of different molecular weights. Polypeptides are formed also from glycyltyrosinamide, alanylphenylalaninamide, and other amides [162,163] in the presence of this enzyme. Experiments by Orekhovich and Kaganova [164] provided additional suuport for the participation of amides in the biosynthesis of peptide links. By treating a tyrosine ester with glutamine or asparagine in the presence of crystalline chymotrypsin these workers obtained a peptide containing a tyrosine residue and glutamic or aspartic acid. If the amides are replaced by aspartic or glutamic acid, formation of a dipeptide does not occur. Many reactions of this type have been reported [165-173] and systematised in a number of reviews and monographs [53,86,174-180]. These include, for example, the formation of plasteins [169-173], which are insoluble peptides with molecular weights up to 400 000.

The examples given above clearly show that transpeptidation reactions are undoubtedly involved in the biosynthesis of peptide links, but their exact role in the general process of protein biosynthesis is still far from clear. Systematic quantitative experiments may, perhaps, solve this problem. This work should also go some way towards the solution of two other important aspects of the general problem of the biosynthesis of proteins: the influence of transpeptidation reactions on the sequence of amino-acid residues in the protein molecule and also the importance of these exchange interactions in the dynamic state of proteins, peptides, and amino-acids in the living organism.

---o0o---

It is evident from what has been said above that reactions involving chain transfer with fission are of common occurrence in processes giving rise to the formation of heterochain polymers. Tney play a most important role in the formation of macromolecules, and they determine the properties of the resulting polymer to quite a large extent. Thus, they open up wide prospects for the controlled modification of heterochain polymers.

By including CTF among the primary steps in polymerisation, we gain a much deeper understanding of the thermodynamic and kinetic peculiarities of this process. Furthermore, many experimental facts could not be interpreted otherwise than in terms of CTF.

The discovery of transpeptidation justifies the hypothesis that interchain exchange reactions play an essential role in the biosynthesis of proteins.

The present Review will not have been written in vain if it can focus attention on the importance of CTF in processes leading to the formation of heterochain polymers, and on its potentialities in synthetic chemistry.

CHEMICAL REACTIONS AT TEMPERATURES CLOSE TO 77°K

G. B. Sergeev

CONTENTS

I. Introduction 323
II. Preparation and reactions of radicals at low temperatures 324
III. Chain reactions in the solid phase at temperatures close to 77°K 328
IV. Rapid spontaneous chemical reactions at low temperatures 331

I. INTRODUCTION

A new branch of chemistry, the study of chemical processes at low temperatures, close to the boiling point of liquid nitrogen, arose in recent years and has rapidly developed. Comparatively recently chemical reactions at low temperatures appeared to be unlikely. This view arose from the fact that the Arrhenius factor, which takes into account the necessity to overcome the activation barrier, increases sharply as the temperature is reduced. Furthermore, at low temperatures most substances are in the solid state where the mobility of the species is extremely low and molecular collision necessary for reaction is difficult to achieve.

Initially, the attention of chemists, who began to work at low temperatures, was drawn mainly to the problem of formation and stabilisation of radicals. Gradually the range of problems investigated widened and at present the study of the fundamental steps in the reaction of various species in the solid phase at low temperatures is one of the central problems of modern chemical kinetics. N.N.Semenov and his school and many other Soviet scientists have made a major contribution to the development of these studies.

The present review deals with certain results of studies on chemical reactions at low temperatures obtained in the Department of Chemical Kinetics at Moscow State University, directed by N.N.Semenov. In the course of these investigations the phenomenon of a spontaneous, explosive course of many chemical reactions at temperatures close to the boiling point of nitrogen and the effect of phase transitions on chemical processes were discovered, the possibility of chain reactions in the solid phase at this temperature was demonstrated, and the special role of unstable molecular complexes of the donor–acceptor type and their aggregates in low-temperature chemical reactions has been observed.

The Review consists of three principal parts. In the first section certain problems of the preparation and reactions of radicals in the solid phase are considered. The second section deals with the characteristic features of

low-temperature chain reactions — photochemical hydrobromination of certain olefins and halogeno-olefins. In the third section a wide variety of chemical reactions occurring at low temperatures are described, and the peculiarities of the mechanism of fast spontaneous chemical reactions are examined, using the halogenation of olefins as an example.

II. PREPARATION AND REACTIONS OF RADICALS AT LOW TEMPERATURES

The problems of the formation, stabilisation, and destruction of radicals at low temperatures have been discussed in many reviews and monographs [1-5]. In order to elucidate certain general features of these processes, the mechanism and characteristic features of the photolysis of frozen aqueous solutions of hydrogen peroxide have been investigated in the Department of Chemical Kinetics of Moscow State University for many years [6-10]. The data obtained permit a deeper understanding of the specific features of the photolysis and radiolysis of aqueous solutions of other substances and suggest an approach to the problem of the detailed role of structured water in biological systems.

Hydrogen peroxide was the first substance for which the special role of phase transitions and chemical reactions at low temperatures was discovered by an electron spin resonance (ESR) study of the destruction of H_3O_2 radicals [6-8]. Depending on the rate of freezing, 25% aqueous solutions of hydrogen peroxide can be obtained at 77°K in a crystalline or vitreous state. When such specimens are irradiated at 77°K with ultraviolet light from a mercury quartz lamp, ESR measurements reveal the presence of HO_2 radicals which have a characteristic asymmetric spectrum and are formed in the reactions

$$H_2O_2 + h\nu \rightarrow 2\,OH,$$
$$OH + H_2O_2 \rightarrow H_2O + HO_2.$$

In vitreous specimens the destruction of radicals does not begin until 143°K and the radicals are completely eliminated by 158°K. In 25% hydrogen peroxide solutions this is the temperature of the glass–crystal phase transition. The destruction of radicals is associated with the fact that at the instant of phase transition changes in structure, leading to considerable mobility of the molecules, usually occur. For example in hydrogen peroxide solutions in the temperature range 153–158°K the viscosity of the glass increases so much at the instant of phase transition that a thermocouple inserted into the specimen may be withdrawn [with difficulty (Ed. of Translation)].

In crystalline specimens radicals are not destroyed at 158°K. When the specimens are irradiated with ultraviolet light below the phase-transition temperature, for example at 163°K, it is again possible to obtain a considerable concentration of HO_2 radicals. On further increase in temperature, destruction of radicals in a characteristic stepwise manner was observed (Fig. 1). The data in Fig. 1 show that in the temperature range 163–183°K a definite proportion of radicals are destroyed at each discrete temperature. The radicals are completely eliminated only at 220°K at the instant of fusion of the eutectic mixture.

A similar process involving the destruction of radicals at the instant of phase transition was also observed at 103°K in the photolysis of hydrogen sulphide frozen at 77°K. [7] Subsequently studies of the role of phase transitions in radical destruction processes were developed

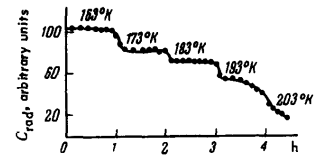

Fig. 1. Effect of temperature on the recombination of HO_2 radicals.

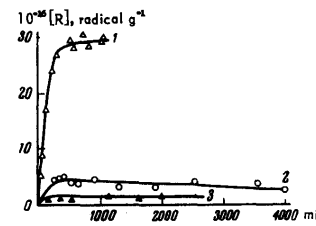

Fig. 2. Accumulation of radicals in dilute hydrogen peroxide solutions at 77°K; concentration of hydrogen peroxide (M): 1) 2×10^{-1}; 2) 4.3×10^{-2}; 3) 4.1×10^{-3}.

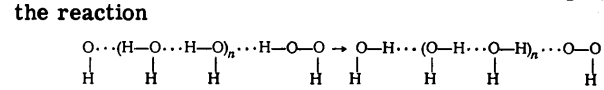
extensively in the Institute of Chemical Physics of the USSR Academy of Sciences and were summarised in Semenov's report to the Eighteenth Congress of the International Union of Theoretical and Applied Chemistry [1].

In recent years many interesting features have been observed in the photolysis of very dilute aqueous solutions of hydrogen peroxide with and without various additives. Fig. 2 shows the variation of the yield of radicals with irradiation time for various hydrogen peroxide concentrations. For the concentration 4×10^{-3} M, the ESR spectrum observed results from the superposition of the spectra of OH and HO_2 radicals. As irradiation is continued, the amount of the HO_2 admixture falls. For the solution in which the concentration is 4×10^{-2} M, the HO_2 spectrum is first observed and then the spectrum of hydroxyl radicals begins to be superimposed. The above changes in the composition of radicals are probably associated with the disappearance of the peroxide and the photolysis of HO_2 in the reaction

$$HO_2 + h\nu \rightarrow H + O_2.$$

The possibility of the photolysis at 77°K of HO_2 radicals is indicated by data obtained in a comparative study of the photolysis and radiolysis of 55% hydrogen peroxide solutions in water [9]. The concentration of HO_2 radicals during radiolysis is higher than during photolysis. When specimens subjected to preliminary irradiation from cobalt-60 were illuminated with ultraviolet light, the concentration of HO_2 radicals fell and approached the value obtained during photolysis alone. The decrease in the line-width of the ESR spectrum, which is observed on increase in the concentration of radicals, is also evidence in favour of the reaction $HO_2 + h\nu \rightarrow H + O_2$. In concentrated solutions the HO_2 radicals formed are initially distributed in pairs. With increase in the duration of illumination, part of the HO_2 radicals are photolysed and their distribution approaches statistical uniformity, which is reflected in a narrowing of the ESR spectral line.

Since diffusion of OH radicals in ice at 77°K is unlikely (OH radicals are stabilised), in order to account for the occurrence of the reaction $OH + H_2O_2 \rightarrow H_2O + HO_2$ at concentrations 10^{-3} M (55 000 H_2O molecules per H_2O_2 molecule), the hypothesis was put forward that there is a possibility of a non-diffusional bond transfer along the system of hydrogen bonds[10]. If the three-dimensional distribution of H_2O_2 molecules in a frozen dilute solution is statistically uniform and the formation of HO_2 radicals occurs in consequence of non-diffusional bond transfer, for example, by the reaction



then any significant breakdown of the structure of hydrogen bonds should result in bond transfer over much smaller distances. One would then expect that OH radicals would be stabilised at H_2O_2 concentrations in excess of 2×10^{-2} M. To check this hypothesis, we carried out experiments on the photolysis of a rapidly frozen solution of hydrogen peroxide (0.16 M) in 8 M sodium perchlorate. This solution froze into a transparent glass in which the hydrogen bond structure may be appreciably degraded. When such solutions are illuminated with ultraviolet light, the ESR spectrum of the OH radical is obtained. The initial rate of formation of radicals is smaller by a factor of approximately 100 than in the photolysis of aqueous solutions. In solutions of similar concentration but without sodium perchlorate only HO_2 radicals are observed. Thus the results of the photolysis of hydrogen peroxide in sodium perchlorate solutions appear to confirm the validity of the earlier hypothesis of non-diffusional bond transfer along the hydrogen bond system in ice.

In the photolysis of dilute aqueous hydrogen peroxide solutions the initial rate w_0 of formation of HO_2 radicals varies linearly with the concentration of hydrogen peroxide. This means that almost all the OH radicals formed in the primary step enter into the reaction $OH + H_2O_2 \rightarrow H_2O + HO_2$. However, in the photolysis of frozen hydrogen peroxide solutions to which isopropanol, which does not absorb light in the wavelength range investigated, had been added, the initial rate of formation of radicals is higher by a factor of fifty. It is difficult to explain this phenomenon. Possibly at low temperatures apart from the reactions

$$H_2O_2 + h\nu \rightarrow 2\,OH,$$

$$OH + H_2O_2 \rightarrow H_2O + HO_2,$$

the following reaction may occur in the given case:

$$OH + HO \rightarrow H_2O + O.$$

Oxygen atoms are not detected at low temperatures by the ESR method[4]. In this case in the presence of the alcohol in the system of the two competing reactions

$$O + H_2O_2 \rightarrow OH + HO_2 \quad (\text{or } O + H_2O_2 \rightarrow O_2 + H_2O)$$

and

$$O + \text{iso-}C_3H_7OH \rightarrow OH + CH_3{-}\dot{C}(OH){-}CH_3,$$

the second predominates, which results in an increased yield of stabilised radicals.

Another explanation of the observed peculiarities of the photolysis of dilute hydrogen peroxide solutions can be obtained on the assumption that on rapid freezing of such solutions hydrogen peroxide may be precipitated as a separate phase. Differential thermography showed that, in rapidly frozen solutions in which the hydrogen peroxide concentration is greater than 0.4 M, the peroxide is indeed evolved as a separate phase. In such a case the difference in the rate of accumulation of radicals when sodium perchlorate and the alcohol are added can probably be accounted for by the cage effect. It is a maximum for sodium perchlorate and a minimum for the alcohol. It must also be postulated that the alcohol is incorporated into the peroxide crystals.

In conclusion it must be emphasised that the study of the photolysis of very dilute frozen aqueous solutions of hydrogen peroxide in the presence of additives made it possible to elucidate a number of new interesting facts which, however, require further study. In the Department of Chemical Kinetics at Moscow State University extensive studies are being made on the photochemical and non-photochemical reactions with participation of halogens and hydrogen halides. To obtain more detailed data on the possibility of the occurrence at low temperatures of reactions of the type $X + RH \rightarrow R + HX$ (X = halogen atom) and to elucidate the characteristic features of the photolysis of binary mixtures of halogens with various organic compounds, a study was made of the formation of radicals at 77°K when mixtures of bromine and chlorine with certain hydrocarbons and alcohols are irradiated with ultraviolet light[11,12]. Compounds with weak C–H bonds and readily undergoing vitrification at low temperatures were mainly investigated. It was assumed that both these factors facilitate the formation of radicals.

The choice of alcohols was also associated with the familiar fact of the formation of molecular complexes with halogens by oxygen-containing compounds[13]. The aim was to elucidate the role of such compounds in the formation of radicals at low temperatures.

In the photolysis experiments the halogen and the organic compound were mixed in specified proportions in a vacuum apparatus. The mixture was frozen with liquid nitrogen in the tip of a quartz tube and illuminated at 77°K with filtered ultraviolet light from a PRK-7 lamp for a specified period. The specimen was then transferred to the resonator of electron spin resonance apparatus and the ESR spectra were recorded at 77°K.

After frozen mixtures of chlorine with isopentane, pentane, iso-octane, and cyclohexane had been illuminated with ultraviolet light at a wavelength $\lambda > 280$ mμm, ESR spectra revealed the presence of radicals. The experimental conditions and the results are presented in Table 1.

Fig. 3 shows as an example the ESR spectra obtained for mixtures of chlorine with isopentane and cyclohexane. The number of hyperfine structure components and their splitting in these spectra are consistent with those described in the literature[14,15] and are evidently due to alkyl radicals of the type $(CH_3)_2{-}\dot{C}{-}CH_2{-}CH_3$ and C_6H_{11}. It should be noted that we were the first to observe at 77°K the additional splitting of each of the six components in the spectrum of the cyclohexyl radical due to β-protons lying in a plane different from the one containing the protons responsible for the main spectrum. Probably the presence of chlorine (m.p. 172°K) makes the system more rigid. The hydrocarbons used in the experiments are transparent to light at a wavelength of 280 mμm. Solid chlorine absorbs light and radicals are formed as a result of the following reactions:

$$Cl_2 + h\nu \rightarrow 2\,Cl,$$

$$Cl + RH \rightarrow HCl + R.$$

TABLE 1. Results of the photolysis of hydrocarbons in the presence of chlorine and bromine at 77°K.

Experimental conditions			Results

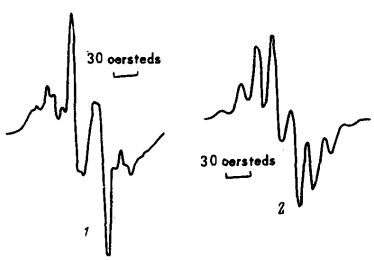

Fig. 3. ESR spectra of the radicals formed on illumination of chlorine–hydrocarbon mixtures at 77°K: 1) in cyclohexane; 2) in isopentane.

The data in Table 1 show that the yield of radicals depends on the amount of chlorine added, the number of radicals formed decreasing as the concentration of chlorine is reduced. This variation confirms the above mechanism for the formation of radicals. The yield of radicals is higher, the weaker is the C–H bond in the hydrocarbon.

It is interesting that in the photolysis of mixtures of hydrocarbons with bromine radical formation is not observed. The absence of radicals in this case is probably due to the high energy required for the reaction

$$Br + RH \rightarrow HBr + R.$$

Radical reactions with participation of bromine atoms are as a rule markedly endothermic [16], and therefore proceed with difficulty at low temperatures.

In contrast to hydrocarbons, in alcohols (methanol, ethanol, isopropanol) radicals were observed not only on addition of chlorine but also in the presence of added bromine. The mixtures were illuminated with light at a wavelength $\lambda > 280$ mμm. When the wavelength was changed from $\lambda < 280$ [sic] to $\lambda > 320$ mμm, radicals were not observed. The photolysis of alcohols with added halogens results in a complex mixture of radicals. This is because a number of secondary reactions involving the photolysis of the radicals occur during the irradiation. In their main outline these processes are similar to those observed in the photolysis of alcohols with added hydrogen peroxide. The radical reactions in methanol and ethanol during irradiation have been investigated in detail by Fok in the Department of Chemical Kinetics at Moscow State University [17,18]. In isopropanol secondary radical reactions are not observed and therefore the isopropanol–halogen system was chosen to investigate the kinetics of the accumulation of isopropanol radicals as a function of the amount of bromine or chlorine added. Experiments were made with alcohol : halogen = 10 : 1, 100 : 1, 1000 : 1, 10 000 : 1. The results obtained are presented in Table 2 and in Fig. 4.

In contrast to hydrocarbons, with alcohols there is a complex relation between the limiting yield of radicals and the amount of halogen added. The data in Fig. 4 show that the maximum yield of isopropanol radicals occurs at an alcohol : halogen ratio of 100 : 1. The initial rate of formation of radicals is also a maximum at this ratio. The occurrence of this relation and the very fact that considerable concentrations of radicals are obtained in the presence of bromine probably indicate that the mechanism of radical formation in alcohol–halogen systems is different from that in hydrocarbon–halogen mixtures.

The dissociation energies of C–H bonds in alcohols are comparable to the dissociation energies of similar bonds in branched-chain paraffins [19]. The activation energy for the reaction Br + ROH → RCHOH + HBr is about 9 kcal $mole^{-1}$

in the case of methanol[20]. As a result of this high activation energy, direct removal of hydrogen from the alcohol molecule by a bromine atom is unlikely at low temperatures. In our view in alcohol–halogen systems radicals are formed under the action of light as a result of the condensation of the molecular charge-transfer complexes (formed during the process), which significantly alters the absorption spectrum of the system. The existence of such complexes at low temperatures is indicated by literature data. For example, Groth and Hassel established that bromine and methanol form a 2 : 1 compound which melts at 213°K.[21] X-Ray diffraction analysis showed that the alcohol molecules are linked into chains by hydrogen bonds and bromine forms cross-links between the chains.

Additional confirmation of the existence of molecular compounds in frozen mixtures of isopropanol with bromine and chlorine was obtained by the present author by a spectrophotometric method. In order to obtain the ultraviolet spectra, the halogen, alcohol, and their mixtures were frozen in the form of thin films on to a quartz plate cooled with liquid nitrogen. Fig. 5 shows as an example the absorption spectra of isopropanol, bromine, and their mixture. It is seen that, when bromine and alcohol are frozen out simultaneously, there is a marked displacement of the bromine band in the region of 384 mμm towards shorter wavelengths and a new band appears in the region of 232 mμm. Such changes in ultraviolet spectra are characteristic of charge-transfer complexes[13]. The displacement of the absorption band towards short wavelengths associated with complex formation explains the finding noted above that radicals are not formed when the wavelength of the light irradiating the mixture is changed from $\lambda > 280$ to $\lambda > 320$ mμm.

One of the possible modes of formation of isopropanol radicals consists in the excitation of the complex on absorption of light and electron transfer from the alcohol oxygen atom to bromine. Such transfer may result in the formation of the radical $CH_3-\overset{\displaystyle H}{\underset{\displaystyle O^{\cdot}}{\overset{|}{\underset{|}{C}}}}-CH_3$ which under the action of light rapidly isomerises to the isopropanol radical $CH_3-\overset{\displaystyle \cdot}{\underset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}-CH_3$, whose ESR spectrum has a seven-component hyperfine structure.

The formation of molecular charge-transfer complexes is determined to a first approximation[13,19] by the ionisation potential of the donor and the electron affinity of the acceptor. Since the difference between the electron affinities of bromine and chlorine is small (1.3 and 1.2 eV)[22] and radicals are formed in alcohols as a result of the photolysis of molecular complexes, their yield should depend only slightly on the nature of the added halogen. The data in Table 2 confirm this conclusion. In contrast to alcohols, hydrocarbons do not form molecular complexes with halogens. Here the formation of radicals depends mainly on the energy relations of secondary reactions and also on the mobility of the halogen atoms, which is determined by their size and the excess energy which they receive during photolysis. The formation of radicals in mixtures of alcohols with halogens occurs in a fundamental step which consists in the photolysis of an intermediate which is stable only at low temperatures. Radicals are formed as a result of electron transfer, and the cage effect is then probably excluded. The suggested mechanism

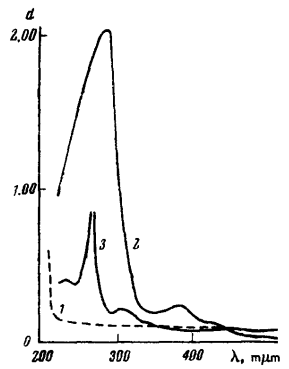

Fig. 5. Ultraviolet absorption spectra at 77°K:
1) isopropanol; 2) bromine; 3) bromine–alcohol mixture.

differs from those described in the literature for the photolysis of frozen alcohols[4,17,23]. The mechanism of radical formation by the photolysis of molecular complexes is probably common to all systems in which donor–acceptor interaction is possible.

The problem of reactions with participation of radicals during the formation of the latter is of fundamental importance both for the problem of the stabilisation and accumulation of radicals and for the possibility of carrying out various low-temperature reactions. For the solution of these problems, the author has used simultaneously electron spin resonance and gas–liquid chromatography. The results obtained in the study of the radiolysis of isopropanol will be given as an example.

The alcohol, purified from traces of acetone on a semi-preparative chromatograph, was freed from dissolved air and irradiated with X-rays for 3 h at 77°K and 90°K. The irradiated specimens were then transferred to the resonant cavity of the ESR apparatus for the determination of the concentration of the isopropanol radicals formed. After the ESR spectra had been measured, the irradiated alcohol specimens were heated to room temperature and analysed. The products were determined with a gas–liquid panchromatograph fitted with a macro-argon detector. The stationary phase was poly(ethylene glycol) with a molecular weight of 400. A large amount of acetone was detected in the reaction products. Preliminary calibration of the detector with artificial mixtures made it possible to make quantitative measurements. The results are presented in Table 3.

The isopropanol radicals obtained in the radiolysis can probably recombine on heating:

$$CH_3-\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}-CH_3 + CH_3-\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}-CH_3 \rightarrow CH_3-\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}-\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}-CH_3,$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad CH_3\ CH_3$$

with formation of pinacol, and disproportionate

$$2\,CH_3-\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}-CH_3 \rightarrow CH_3-\overset{\displaystyle O}{\overset{\|}{\underset{|}{C}}}-CH_3 + CH_3-\overset{\displaystyle OH}{\overset{|}{\underset{|}{CH}}}-CH_3,$$

with formation of acetone and isopropanol. Pinacol could not be detected in the reaction products. Probably its amount is smaller than 10^{-8} g per microlitre, the minimum

TABLE 3. Amount of radicals and acetone in irradiated isopropanol.

Temperature, °K	Amount of radicals in 1 μl, g	Amount of acetone Q_T from radicals in 1 μl, g	Amount of acetone Q_A found by analysis in 1 μl, g	Difference $Q_A - Q_T$ in 1 μl, g
77	$1.1 \cdot 10^{15}$	$5.3 \cdot 10^{-8}$	$2.2 \cdot 10^{-7}$	$17 \cdot 10^{-8}$
90	$1.6 \cdot 10^{15}$	$7.7 \cdot 10^{-8}$	$2.7 \cdot 10^{-7}$	$19.3 \cdot 10^{-8}$

quantity of pinacol which could be detected in the artificial mixtures. Thus the data in Table 3 show that, when the frozen alcohol is heated, the isopropanol radicals mainly disproportionate. This is consistent with the known fact that disproportionation reactions of free radicals require a smaller activation energy than their recombination[24].

Comparison of the data in columns 3 and 4 of Table 3 shows that a large part of the acetone forms during radiolysis in the solid phase. Under the present experimental conditions the yield of radicals varies linearly with dose. Assuming that acetone forms in the solid phase as a result of radical disproportionation and that its yield follows a similar linear relation, it is possible to estimate from the data in Table 3 by the Arrhenius equation the energy of disproportionation of isopropanol radicals as 150 cal mole^{-1}. This value is consistent with the literature data for similar reactions[24] and shows that the simultaneous application of ESR and gas chromatographic methods in combination with low temperatures opens up great possibilities for quantitative investigations of fundamental reactions.

III. CHAIN REACTIONS IN THE SOLID PHASE AT TEMPERATURES CLOSE TO 77°K

Chain reactions with participation of free radicals occur widely in both gas and liquid phases[16,25]. The occurrence of such reactions at low temperatures is of considerable theoretical and practical interest. The possibility of accumulation at the boiling point of liquid nitrogen of considerable non-equilibrium concentrations of radicals and the appearance of stable products under these conditions suggested that chain reactions can also occur in the solid phase. It might have been expected that such reactions would proceed most readily upon irradiation.

We chose for investigation the photochemical hydrobromination of olefins and halogeno-olefins. In gas and liquid phases these reactions occur under the action of light and are typical chain reactions with a chain length of thousands of units[16]. It has been established that photochemical hydrobromination of olefins in the solid phase at 77° proceeds vigorously and explosively[26-28]. The products are alkyl bromides.

The experiments were made in a vacuum apparatus. A mixture of hydrogen bromide and the appropriate olefin was condensed in the reaction vessel, cooled with liquid nitrogen, and then illuminated for a specified period. The reaction was followed by differential thermal analysis. The extent of reaction was usually determined from the change in pressure after heating the irradiated mixture to room temperature. The extent of reaction increased with the duration of irradiation at 77°K. A number of special experiments established that the reaction is initiated by bromine atoms which are formed on photolysis of hydrogen bromide[26]. The formation of radicals during the preliminary illumination of mixtures of hydrogen bromide with unsaturated compounds was detected by the ESR method (in the photolysis of hydrogen bromide–cyclohexene mixtures). The resulting ESR spectrum was similar to that quoted by Abell and Piette[32].

Exact determination of the quantum yield at low temperatures in mixtures of hydrogen bromide and olefins is difficult, because the mixtures are polycrystalline and scatter light to a marked degree. In measurements involving ferric oxalate intensitometry only the number of quanta incident on an amount of mixture which virtually did not transmit light was estimated. The lower limit of the quantum yield obtained in this way for the hydrobromination of ethylene proved to be 150.

The chain length was also estimated on the basis of chromatographic data. In the gas-chromatographic analysis of the products of the low-temperature photochemical hydrobromination of ethylene[29] a considerable amount of 1,2-dibromoethane was detected in addition to ethyl bromide, the ethyl bromide : 1,2-dibromoethane ratio being 500 : 1. The presence of 1,2-dibromoethane in the reaction products shows that the reaction has a radical mechanism. If it is supposed that at low temperatures the reaction proceeds by the same mechanism as in the gas phase, 1,2-dibromoethane may form as a result of the recombination of radicals which propagate the chain hydrobromination of ethylene according to the following mechanism:

$$HBr + h\nu \rightarrow H + Br,$$
$$Br + C_2H_4 \rightarrow C_2H_4Br,$$
$$C_2H_4Br + HBr \rightarrow C_2H_5Br + Br,$$
$$C_2H_4Br + Br \rightarrow C_2H_4Br_2.$$

The chain length can be defined[16] as the number of molecules of the main product formed as a result of chain reaction per active centre. On the basis of the above mechanism, the chain length can be estimated as 250 units from the ethyl bromide : 1,2-dibromoethane ratio obtained.

Since in the determination of the quantum yield the amount of reaction products was found after heating the mixture, it is important to emphasise that the hydrobromination reactions occur in the solid phase below the melting points of the starting components. This is clearly shown in Fig. 6 in which we have plotted thermographic curves for the hydrogen bromide–ethylene system obtained when mixtures subjected to preliminary irradiation with various doses of ultraviolet light at 77°K were heated. The occurrence of reaction in the solid phase is also indicated by the considerable increase in the yield of ethyl bromide with time in an irradiated mixture. For example,

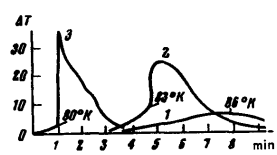

Fig. 6. Thermographic curves for equimolar mixtures of hydrogen bromide and ethylene; temperature of preliminary light irradiation 77°K:
1) Light irradiation dose $D = 0.6$ (arbitrary units), extent of reaction 15%; 2) $D = 0.9$, extent of reaction 14%; 3) $D = 39.5$, extent of reaction 37%.

the extent of reaction increases by 25–30% if the mixture is kept in the dark for 1 h at 77°K before measurements. At high light intensities the reaction is explosive and may occur when actually exposed to the light beam at 77°K. The shape of the thermographic curve is then similar to that of curve *3* in Fig. 6.

An interesting feature of the hydrobromination of ethylene at 77°K is that the rapid reaction is preceded by an induction period, the explosion itself always occurring after exposure to the same radiation dose[28]. This finding is clearly shown by the data presented in Table 4. Thus the induction period τ is inversely proportional to the intensity I, while the dose $D = I\tau$ = const., i.e. the development of the explosive chain reaction at low temperatures requires the accumulation of a specified concentration of active centres, which is clearly determined by the dose and not the intensity.

Another interesting feature of the photochemical hydrobromination is its marked dependence on the conditions of heat exchange with the surrounding medium. If, for example, the heat exchange is reduced, the rapid reaction begins after smaller radiation doses, and conversely if the heat exchange is increased, there is no reaction at all at the temperature of liquid nitrogen for low radiation doses. Here reaction occurs at higher temperatures. The above features of the photochemical hydrobromination of ethylene are associated with the possibility of stabilisation of active centres and show that in low-temperature chain reactions the properties of chain and thermal explosions are closely interlinked.

At low temperatures the frozen mixtures of hydrogen bromide with olefins are polycrystalline and it was of considerable interest to elucidate which features of photochemical chain hydrobromination are characteristic of the crystalline state and which are characteristic of the vitreous state. Transparent glasses are formed when allyl chloride and its liquid mixtures with hydrogen bromide are rapidly cooled to 77°K. When such glasses are exposed to ultraviolet irradiation at 77°K and then warmed, chain hydrobromination occurs in the solid phase below the melting point of the mixture. The quantum yield of the

TABLE 4. Dependence of the induction period τ in the hydrobromination of ethylene on the intensity of illumination (I) at 77°K*.

0.10	45.7	1.1	30	15.2	4.6
0.04	no explosion, on subsequent heating reaction occurs at higher temperatures				

* All the values in the table are averages from several experiments: ΔT is the temperature rise at the end of the induction period, ΔT_M the maximum temperature rise, η the extent of reaction, and $D_{expl} = I\tau$ the radiation dose resulting in explosion. The radiation dose is expressed in arbitrary units. The amount of radiation received by the specimen at maximum intensity I_0 from a PRK-7 lamp in 1 s was adopted as one unit.

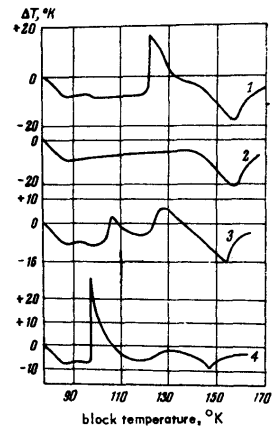

Fig. 7. Temperature variation of the difference between the specimen and block temperatures ΔT (deg) for allyl chloride and its mixtures with hydrogen bromide: 1) vitreous allyl chloride specimen; 2) crystalline specimen; 3) vitreous specimen irradiated with ultraviolet light at 77°K for 5 s; 4) similar specimen irradiated for 180 s.

low-temperature photochemical hydrobromination of allyl chloride is about 50. The occurrence of the reaction in the solid phase was confirmed with the aid of infrared spectra obtained in a special cuvette where the low-temperature photolysis could be carried out and the infrared spectra recorded.

Fig. 7 presents the results of a study of the hydrogen bromide–allyl chloride system by differential thermal analysis[30]. It is evident that the allyl chloride frozen to a glass crystallises at 110°K and melts at 136°K. The equimolar mixture of hydrogen bromide and allyl chloride behaves similarly.

When vitreous hydrogen bromide–allyl chloride specimens irradiated at 77°K are warmed, the thermograms (Fig. 7) reveal the occurrence of a new exothermic process at about 88°K. This process is associated with the hydrobromination since the temperature rise at 88°K is directly proportional to the amount of 3-bromo-1-chloropropane. The formation of 3-bromo-1-chloropropane as the main reaction product was confirmed by gas-chromatographic analysis. The effect of the duration of illumination on the form of the thermographic curves for the vitreous equimolar hydrogen bromide–allyl chloride mixtures is shown in Table 5.

The data in Table 5 show that the temperature of the start of reaction is independent of the duration of the preliminary illumination of the mixture at 77°K. This fact constitutes the most interesting peculiarity of the photochemical chain hydrobromination in the vitreous systems. In crystalline mixtures of allyl chloride and hydrogen bromide the temperature range in which the reaction takes place (the reaction occurs only on heating) depends on the duration of the preliminary irradiation of the mixture at 77°K. In its main outline the reaction is of the same type as in frozen mixtures of ethylene and hydrogen bromide.

The surprising finding that the temperature of the onset of reaction is independent of the duration of the preliminary

TABLE 5. Results of a thermographic study of the hydrogen bromide–allyl chloride system as a function of the time of the preliminary irradiation at 77°K*.

t	T_1	ΔT_1	T_2	ΔT_2	T_f	ΔT_f	t	T_1	ΔT_1	T_2	ΔT_2	T_f	ΔT_f

							240	89.5	39				

* t is the duration of irradiation (minutes) of the specimens at 77°K, T_1, T_2, and T_f are the temperatures of hydrobromination, crystallisation, and fusion respectively, ΔT_1 and ΔT_2 are the maximum temperature rises during the reaction and during crystallisation, and ΔT_f is the height of the fusion peak (°K).

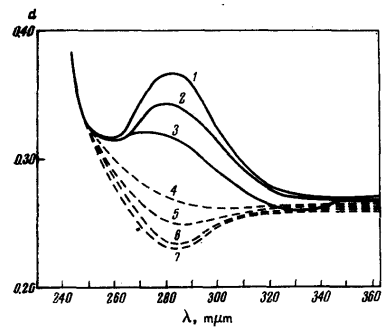

Fig. 8. Ultraviolet absorption spectra at 73°K: 1) non-irradiated mixture of hydrogen bromide and allyl chloride; 2) after irradiation with filtered light (313 mμm) for 25 min 41 s; 3) ditto after irradiation for 49 min 30 s; 4) mixture of hydrogen bromide and allyl chloride after heating to 103°K, spectrum recorded at 73°K; 5) mixture without complex after irradiation for 60 min with filtered light (313 mμm); 6) duration of irradiation 120 min; 7) duration of irradiation 180 min.

irradiation can be explained by supposing that 86–88°K constitutes the low-temperature limit of the softening of the hydrogen bromide–allyl chloride glass. In the glass-softening range there is a change[31] in properties of the system such as heat capacity, viscosity, specific volume, thermal conductivity, etc. In the given case the decrease in the viscosity of the system probably plays the main part, increasing the mobility of the reacting species and facilitating the initiation of the reaction by the active reaction centres stabilised at 77°K and produced during the preliminary irradiation. The rapid increase of the viscosity in the softening range is actually responsible for the virtually complete independence of the temperature of the onset of reaction of the dose of preliminary irradiation. The "healing" of the cracks formed in the glass at 77°K is a qualitative indication that the softening of the hydrogen bromide–allyl chloride glass occurs at temperatures below 90°K. The glass softening range was also determined thermographically from the jump in heat capacity. The thermograms of allyl chloride and of non-irradiated hydrogen bromide–allyl chloride mixtures reveal a weak endothermic process which begins at about 87°K.

The hydrobromination of olefins and halogeno-olefins occurs in systems where there is a possibility of donor–acceptor interaction which leads to the formation at low temperatures of unstable molecular compounds[33]. The role of such complexes in the formation of radicals under the action of light at low temperatures has already been mentioned in the first part of this review. Certain aspects of the participation of such complexes in low-temperature chain reactions are examined below, using the hydrogen bromide–allyl chloride system as an example[34].

Fig. 8 shows ultraviolet spectra of the hydrogen bromide–allyl chloride system. Spectrophotometric study of hydrogen bromide–allyl chloride films frozen on to a quartz plate at 80°K revealed an absorption band with a maximum at 283 mμm. When such mixtures are heated to 103°K and then cooled again to 80°K, this band vanishes irreversibly. The result shows that during condensation on to the cooled quartz plate hydrogen bromide and allyl chloride form a compound which is stable only at the temperature of liquid nitrogen.

Hydrogen bromide is an electron acceptor whereas allyl chloride can behave as an electron donor. In hydrogen bromide–propane mixtures, which were investigated at the same time, the 283 mμm band was not observed. The experimental data obtained suggest, when considered together, that the 283 mμm band of the hydrogen bromide–allyl chloride mixtures is probably due to a charge-transfer complex which forms during the condensation of the starting materials.

In a study of the effect of the amount of hydrogen bromide and allyl chloride on the intensity of the 283 mμm absorption band it was found that an increase in the concentration of either the donor or the acceptor causes a decrease in the intensity of the absorption band. The total amount of mixture was kept constant in these experiments. This type of variation of the intensity of the absorption band with mixture composition indicates that a 1 : 1 complex forms.

In order to elucidate the role of complexes in low-temperature reactions, a comparative study was made of the dependence of the extent of reaction on the duration of irradiation with filtered light (filter with a transmission maximum in the region of 313 mμm) of hydrogen bromide–allyl chloride mixtures with the absorption at 283 mμm characteristic of the complex, and mixtures in which there was no appreciable absorption in this region, the hydrogen bromide–allyl chloride system being heated to 103°K before irradiation with ultraviolet light at 77°K. As stated above, such heating breaks down the complex. Figs. 9 and 10 show the variation of the optical density at 283 mμm and of the extent of reaction with the duration of irradiation. The results obtained indicate the participation of unstable molecular compounds of hydrogen bromide and allyl chloride in the hydrobromination reaction. Data derived from thermographic analysis and infrared spectra show that the decrease of the optical density during irradiation is not associated with an appreciable occurrence of hydrobromination at 80°K. On the other hand, on raising the temperature (Fig. 10) the extent of reaction reaches almost 100%, and a high quantum yield indicates that a chain reaction takes place. Thus the data taken together suggest that at temperatures 77–80°K active centres are formed, probably mainly as a result of the photolysis of unstable molecular complexes.

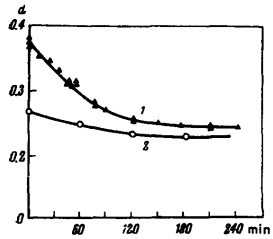

Fig. 9. Variation of optical density with the duration of irradiation in the system hydrogen bromide–allyl chloride at 73°K:
1) irradiation of mixture with complex;
2) irradiation of mixture without complex;
3) curve obtained by graphical subtraction of curve 2 from curve 1.

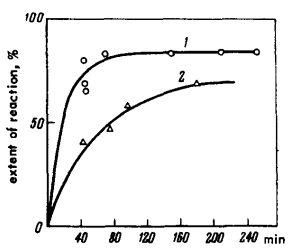

Fig. 10. Variation of the degree of reaction with the time of irradiation in the photochemical hydrobromination of allyl chloride:
1) reaction in the system with complex;
2) reaction in the system without complex.

At 77°K the active centres which initiate the hydrobromination of olefins can also form as a result of the reaction $HBr + h\nu \rightarrow H + Br$. The results obtained in a photometric study of the hydrogen bromide–allyl chloride system make it possible to estimate the contributions of various reactions to the formation of active centres. On the basis of these data, the formation of active centres under the action of light in the solid phase at 80°K can be represented thus:

$$\pi\overset{n}{\nearrow}\!\!\searrow C_3H_5Cl + HBr \rightarrow H + Br\,',$$

where π is the complex and n the number of active centres formed from the complex.

The curves in Figs. 9 and 10 permit an approximate estimate of the relative contributions of various modes of reaction. Comparison of the yields in the initial stage of the photolysis (Fig. 10, curve *1*) and after 1.5 h when all the complex has been almost completely used up indicates the greater effectiveness of the reaction occurring with participation of the complex compared with the reaction in the system without the complex. For example, during the period of existence of the complex $\tau = 0.2t$, where t is the time of irradiation of the mixture corresponding to 85% conversion, the reaction proceeds to the extent of 62%.

On the basis of the above mechanism and using the initial condition $\pi = \pi_0(HBr) = (HBr)_0$, a system of differential equations was set up, and solved with the aid of MN-7 non-linear modelling apparatus. Analysis of the curves obtained showed that, in the initial reaction stage, the formation of active species with the participation of the complex is several times faster than the formation of active species from hydrogen bromide, although the concentration of the complex is smaller than that of hydrogen bromide approximately by a factor of ten. Thus, in contrast to gas and liquid phases, where chain initiation occurs as a result of the photolysis of hydrogen bromide, in the solid phase at low temperatures the active centres are formed mainly under the action of light from unstable intermediate compounds of the donor–acceptor type.

The development of a chain reaction in the solid phase is also affected by particular features of the chain termination reactions. Study of the dependence of the degree of hydrobromination of ethylene η on the light irradiation dose in liquid (112°K) and solid (77°K) phases showed that the degree of reaction in the solid phase is smaller for the same light irradiation dose[30]. In the liquid phase η increases linearly with dose, while in the solid phase it decreases as the dose is increased, which is probably an indication of a decrease in chain length with increase in the concentration of stabilised active centres. Chain termination in the solid phase probably occurs as a result of recombination of the active centres responsible for chain propagation with stabilised active reaction centres.

The possibility of accumulation at low temperatures of considerable concentrations of active centres exerts a significant influence also on the chain propagation reactions. In frozen hydrogen bromide–ethylene mixtures the accumulation of stabilised active centres is accompanied by a slow reaction whose rate depends on the concentration of the centres. Under certain conditions, when the rate of heat generation by the reaction exceeds the rate of heat removal from the system, a vigorous exothermic process takes place by a thermal explosion mechanism.

Semenov regarded the rapid photochemical hydrobromination of ethylene at 77°K as an unusual kind of chain explosion, in which the increase in the number of stabilised active centres entering into reaction is due to the heat of the reaction itself.

The possible mechanism of the reaction can be represented as follows. Most of the active centres formed under the action of light at 77°K are stabilised, and only in rare cases, for example on recombination of two active centres near a third centre, can an individual reaction chain of several hundreds of units arise. The occurrence of such a reaction chain is accompanied by an intense thermal wave (the hydrobromination of olefins is an exothermic reaction), which causes new, stabilised active centres to enter into the reaction. Semenov called such a mechanism the development of a straight chain which undergoes branching occurring with the aid of elementary thermal waves. Thus the results obtained in the study of low-temperature photochemical hydrobromination of olefins, together with data on low-temperature polymerisation, enabled Semenov to formulate the hypothesis of the important role of energy chains in the occurrence of chemical reactions at low temperatures.

IV. RAPID SPONTANEOUS CHEMICAL REACTIONS AT LOW TEMPERATURES

In the first two sections low-temperature reactions initiated by light were examined. This section deals with

TABLE 6. Results of a thermographic study of certain chemical reactions at low temperatures*.

System	T_f, °K component I	T_f, °K component II	T(rapid reaction), °K	Principal products	Yield, %
Chlorine–ethylene	104	172	106,119,171	1,2-dichloroethane	97
Chlorine–propene	88	172	91,111,147	1,2-dichloropropane	92

Chlorine–styrene	242	172			
Chlorine–thiophen	245	172			
Bromine–propene	88	266	117,158,193	1,2-dibromopropane	98
Bromine–isobutene	133	266	120,133,188	1,2-dibromo-2-methylpropane	96
HBr–isobutene	133	186	84,119,150	2-bromo-2-methylpropane	98
HCl–isobutene	133	159	100,119,133,155	2-chloro-2-methylpropane	93
N_2O_4–propene	88	262	238	nitro-nitrate and nitroso-nitrate	
N_2O_4–isobutene	133	262	200	ditto	
N_2O_4–but-1-ene	143	262	233	»	
N_2O_4–hex-1-ene	133	262	241	»	
N_2O_4–cyclohexene	169	262	207	dinitrocyclohexane and nitro-nitrates	
N_2O_4–cyclopentadiene	188	262	183	ditto	
Nitric oxide–oxygen	109	54	88	nitrogen dioxide	100
Nitric oxide–chlorine	109	172	108,143,157	nitrosyl chloride	100
HBr–chlorine	186	172	91,168	hydrogen chloride and hydrogen bromide	100
HCl–nitrogen dioxide	159	262	193	nitrosyl chloride, chlorine, and water	97
Bromine–toluene		266	131,203	hydrogen bromide and substituted toluene	95

* The initial component ratios are 1 : 1, except for nitric oxide with oxygen and chlorine for which the ratios are 2 : 1. In the reaction temperature column the temperatures at which the main bulk of the substance reacts are underlined. Chlorine reacts with thiophen and styrene at the instant of condensation. The nitro-compounds were analysed spectroscopically.

certain peculiarities of the kinetics of a large number of various spontaneous rapid chemical reactions at very low temperatures, discovered in the Department of Chemical Kinetics. Table 6 presents part of the results obtained in a thermographic study of certain chemical reactions at low temperatures[35-38]. In order to eliminate the possibility of reaction in the gas phase at the instant of condensation, the starting materials were frozen in the reaction vessel in the form of individual layers. The technique of the thermographic investigation has been described[36,40].

It is evident from the data in Table 6 that the following reactions can take place at low temperatures: addition of halogens, hydrogen halides, and nitrogen tetroxide to double bonds; inorganic addition reactions ($NO-O_2$ and $NO-Cl_2$ systems); inorganic exchange substitution reactions ($HBr-Cl_2$ system); substitution in aromatic compounds (bromine–toluene system); inorganic redox reactions (NO_2–HCl system).

The technique involving the freezing of the initial components as individual layers prevents their coming into contact at elevated temperatures and makes it possible to verify the possibility of the spontaneous occurrence of the reactions at low temperatures. However, the mixing of the initial reactants is then so poor that the reactions must be hindered. It may be expected that in homogeneous mixtures the reactions would occur at much lower temperatures. To test this hypothesis, a study was made of certain reactions in condensates prepared by freezing out from molecular beams[41]. The molecular beam method for the study of chemical reactions at low temperatures was developed by Semenov and Shal'nikov[42]. Recently this method was successfully used to study low-temperature

TABLE 7. Low-temperature halogenation and hydrohalogenation of unsaturated compounds in mixtures prepared by the molecular beam method*.

System	T_f, °K component I	T_f, °K component II	T(rapid reaction), °K	Principal products	Yield, %

Chlorine–cyclohexene	169	172	98	dichlorocyclohexane	90
Bromine–cyclopentadiene	188	266	98		
HBr–cyclopentadiene	188	186	103		

* The reaction temperatures indicated are averages from a large number of experiments. The discrepancies are within the range of 5 deg.

polymerisation[43]. Condensation under molecular beam conditions yields a mixture which is closest to the molecular state; even the freezing of mixtures subjected to preliminary mixing in the gas phase can involve considerable separation into layers. Table 7 quotes as an example the results obtained in a study of certain halogenation and hydrohalogenation reactions of unsaturated compounds. The apparatus and technique have already been described[41].

Comparison of Tables 6 and 7 shows that in thoroughly blended mixtures the reactions can take place entirely at much lower temperatures. Bromination of ethylene and propene occurs at temperatures close to the melting points of the olefins. In the chlorine–cyclohexene system the reaction occurs in the solid phase at 98°K. This is the temperature of the glass–crystal phase transition. When these substances are frozen into two separate layers, the chlorination occurs at 169°K, i.e. near the melting points of the initial components. It is interesting that, due to their high reactivity, propene and bromine cannot be condensed on a surface cooled with liquid nitrogen at deposition velocities of 10^{17} mol. s^{-1}. This can only be done by reducing the rate of deposition by a power of ten.

Examination of Tables 6 and 7 reveals certain interesting peculiarities of chemical reactions at low temperatures.

1. Many chemical reactions of various types can occur spontaneously (in the absence of special initiation) in the condensed phase even at temperatures as low as the boiling point of liquid nitrogen.
