I. INTRODUCTION

In recent years the oxidative dehydrogenation reactions, whereby olefins and diene monomers can be made from the corresponding more saturated hydrocarbons, have been attracting increasing attention. The essential feature of the oxidative dehydrogenation reaction consists in the partial oxidation of the hydrogen in the organic molecules without affecting the hydrocarbon skeleton. In the usual dehydrogenation of saturated hydrocarbons the conversion of the latter into unsaturated hydrocarbons is limited by the position of the equilibrium in the reversible reaction

$$C_nH_{2n+2} \rightleftarrows C_nH_{2n-2} + 2H_2. \quad (1)$$

The extent of dehydrogenation of hydrocarbons can be sharply increased if the equilibrium is displaced by binding the hydrogen in the form of water, for example:

$$C_nH_{2n+2} + O_2 \rightleftarrows C_nH_{2n-2} + 2H_2O \quad (2)$$

or as hydrogen iodide:

$$C_nH_{2n+2} + 2I_2 \rightleftarrows C_nH_{2n-2} + 4HI. \quad (3)$$

Iodine is much more active as a dehydrogenating agent than oxygen and oxidative dehydrogenation using iodine can be of practical interest in those cases where the dehydrogenation is coupled with an effective iodine regeneration process. The iodine consumed in reaction (3) can be regenerated, for example, by the oxidation of the resulting hydrogen iodide with oxygen:

$$2HI + {}^1/_2O_2 \rightarrow H_2O + I_2 \quad (4)$$

or, as is usually done, the hydrogen iodide is first trapped by solid acceptors, for example, metal oxides, with formation of the corresponding iodides:

$$MO + 2HI \rightleftarrows H_2O + MI_2. \quad (5)$$

On heating in a stream of air, metal iodides readily decompose with evolution of elemental iodine:

$$MI_2 + {}^1/_2O_2 \rightarrow MO + I_2. \quad (6)$$

In contrast to normal dehydrogenation, oxidative dehydrogenation reactions are exothermic.

II. OXIDATIVE DEHYDROGENATION OF OLEFINS

A considerable amount of the available literature on the oxidative dehydrogenation of olefins refers to the conversion of n-butenes into divinyl and of isopentenes into isoprene. The oxidative dehydrogenation of mono-olefins into diolefins is a typical heterogeneous catalytic reaction.

Under certain conditions a high selectivity of the reaction

$$C_4H_8 + {}^1/_2O_2 \rightleftarrows C_4H_6 + H_2O \qquad (7)$$

is attained on suitable catalysts. Small amounts of furan, carbon monoxide, carbon dioxide, acetone, propene, ethylene, formaldehyde, and other substances are formed as side-products. Reaction (7) is an oxidative process and not dehydrogenation with subsequent oxidation of hydrogen. Hydrogen is either completely absent from the reaction system or is not oxidised under the experimental conditions. The oxidation of butane under these conditions is much slower than that of butenes and it is converted preferentially into carbon monoxide and carbon dioxide. Under the normal experimental conditions for the oxidative dehydrogenation of n-butenes into divinyl, thermal reactions virtually do not occur in a Pyrex reactor; a steel reactor favours the formation of carbon dioxide.

1. CHEMICAL COMPOSITION OF THE CATALYSTS

A fairly large number of catalyst recipes have been proposed for the dehydrogenation of mono-olefins in the presence of oxygen: molybdates or tungstates of bismuth [1-7], cobalt, vanadium, tin, titanium [8], tellurium [9], phosphoric acid on alumina [3,5,10], phosphates of bismuth, iron [11,12], strontium, nickel, chromium, calcium [13,14], tungsten, vanadium [15], and indium [16], phosphomolybdate and phosphotungstate of bismuth [17,18], mixed oxides of antimony and tin [3-5,19-24], mixed oxides of titanium [25], mixed oxides of tin and arsenic with selenium and tellurium [19], mixed oxides of iron with aluminium and chromium [26], basic halides of iron, cobalt, magnesium, and manganese [27,28], gold and platinum [29], and others [30].

The application of certain solid catalysts is combined with the introduction into the reaction zone of halogen-containing [31-42] or sulphur-containing [43-46] compounds, which decompose under the reaction conditions with formation of halogens or sulphur dioxide. Thus mixed and pure oxides of iron, cobalt, nickel, manganese, vanadium, molybdenum, bismuth, tin, cadmium, and copper, magnesium phosphate, and many other compounds are recommended for the oxidative dehydrogenation of mono-olefins in the presence of halogen- or sulphur-containing compounds.

Despite the large number of catalysts tested, relatively few data have been published which would permit their comparison. Some typical results of tests of catalysts under optimum conditions are presented in Table 1. The data in Table 1 permit only a very restricted quantitative comparison of the catalysts, since the conditions of the tests, the composition of the raw material, and the method of preparation and treatment of the catalysts were not the same in most of the studies quoted. The yield of diolefins on a molybdenum–bismuth catalyst in the oxidative dehydrogenation of individual butene isomers increases in the series *trans*-but-2-ene, *cis*-but-2-ene, and but-1-ene, and in the dehydrogenation of isopentenes it increases in the series 2-methylbut-1-ene, 2-methylbut-2-ene, and 3-methylbut-1-ene.

High yields of divinyl (65–74%) with a selectivity of 83–91% were attained on many catalysts of various compositions. The same catalysts as those for the dehydrogenation of n-butenes proved to be preferable for the oxidative dehydrogenation of isopentenes to isoprene. The fact that on certain catalysts (mixed oxides of antimony and tin, phosphates) high yields of diolefins are attained at temperatures not higher than 400°C is also striking. The highest yields of diolefins and the highest selectivity are observed in the presence of iodine- and sulphur-containing compounds. Evidently, these additives themselves play a significant if not the main role in the dehydrogenation reaction. Fairly high yields of divinyl were obtained on quartz and silica gel, these catalysts being markedly inferior to those listed in Table 1 only as regards selectivity.

Kolobikhin and Emel'yanova [53] investigated the effect of the proportions of bismuth and molybdenum and also of the total content of bismuth and molybdenum oxides in the catalyst on its dehydrogenating capacity. The catalysts were made by impregnating silica gel for 1 h at room temperature with a complex solution of bismuth nitrate and ammonium molybdate in nitric acid. The optimum composition of the catalyst corresponded to the atomic ratio Bi : Mo = 0.7–0.9 and 18–20 wt.% of bismuth and molybdenum oxides. The silica gel was treated with steam and had a specific surface of 64 $m^2 g^{-1}$ and a pore volume of 0.82 $cm^3 g^{-1}$. An analogous study of bismuth–tungsten catalysts [54] showed that catalysts with the atomic ratio Bi : W = 0.67–1.5 exhibited the highest activity. The addition of phosphorus up to atomic proportions Bi : P : W = 12 : 1 : 12 increases the yields of divinyl.

Table 1. Oxidative dehydrogenation of certain unsaturated hydrocarbons on catalysts of various chemical compositions.

Catalyst	Initial hydrocarbon	Temperature, °C	Moles per mole of hydrocarbon: of oxygen	Moles per mole of hydrocarbon: of nitrogen, water, or other diluent	Yield of diolefins, %: with respect to starting material	Yield of diolefins, %: with respect to product	References

* The iodine- and sulphur-containing compounds were introduced into the reaction together with the initial hydrocarbon. The table indicates the number of moles of the additive per mole of the hydrocarbon.

** Composition of the catalyst not published.

*** Yield of styrene.

According to the data of other workers [55,56], the optimum composition of the molybdenum–bismuth catalyst is in the range Mo : Bi = 1–2 and probably depends on the nature of the carrier and the method of preparation of the catalyst. The extent of formation of carbon dioxide increases with the bismuth content in the specimen. Therefore the highest selectivity is attained in the presence of an excess of molybdenum in the catalyst (Mo : Bi = 2–4).

Kolobikhin and coworkers [57] investigated the effect of the pore structure in the carrier for the bismuth–molybdenum catalyst. They tested four silica gels of various brands with specific surfaces between 680 and 64 $m^2 g^{-1}$. As the specific surface of the silica gel increased, there was a corresponding increase in the conversion of n-butene but the selectivity with respect to divinyl fell. The decrease of the selectivity can probably be explained by the diffusion-dependent inhibition of the reactions on finely porous specimens [58], the divinyl formed undergoing secondary reactions.

2. KINETICS

a. Reaction Temperature

Depending on the properties of the catalyst and the reaction conditions, the maximum yields of divinyl and isoprene in the oxidative dehydrogenation of the corresponding mono-olefins were observed at 370–570°C. [1,18,59–62] With increase of temperature above the optimum value, the yields of the secondary reaction products, mainly carbon dioxide and also furan and carbonyl compounds [62], also rise.

According to the data of Tsailingol'd et al. [63], in the temperature range 410–490°C the temperature dependence of the rate constants for the overall conversion of n-butenes on the bismuth–molybdenum catalyst is defined by the expression

$$\lg k = -\frac{13900}{4.545T} + 3.18 \qquad (8)$$

Thus the apparent activation energy is 13.9 kcal $mole^{-1}$. According to the data of other workers, this quantity is much higher. Thus, according to Adams [1], it is 26 kcal $mole^{-1}$ for but-1-ene at 345–500°C. The apparent activation energies for the oxidative dehydrogenation and combustion of isopentenes at 475–525°C are approximately 21 kcal $mole^{-1}$. [64] At 340–390°C about 40 kcal $mole^{-1}$ was obtained for the oxidative dehydrogenation of but-1-ene [56]. As the temperature is increased above 390°C, the activation energy falls appreciably, probably because of the diffusion-dependent inhibition of the reaction [58].

b. Duration of Contact

Examination of data on the reaction of n-butenes on bismuth molybdate deposited on silica gel as a function of space velocity [53] shows that, other conditions being equal, the maximum yield of divinyl depends on the composition of the catalyst. On a specimen containing 35% of the active substance the same conversion is attained for a shorter contact time than on a specimen containing 13% of bismuth molybdate. With increase in contact time, the difference between the yields of divinyl and the selectivities of all the specimens decrease.

When the time of contact is increased above the optimum value, the yields of divinyl decrease due to secondary reactions, as happens on raising the temperature.

c. Concentrations of the Starting Materials

When the molar ratio oxygen : hydrocarbon is raised from 0.1 to 1, the yields of divinyl and isoprene in the dehydrogenation of the corresponding mono-olefins increase, but there is also an increase in the amount of oxygen-containing side-products formed: carbon dioxide, furan, and carbonyl and carboxy-compounds [53,54,62,65]. A necessary condition for the maximum yield of divinyl is the presence of oxygen in the effluent gases. The lower the oxygen to butenes ratio the greater is the decrease of the activity of the catalyst with time [53].

According to the data of Mel'nik and Tyuryaev [66], the initial "instantaneous" activity of the catalyst is independent of the concentration of oxygen, which determines only the extent of the subsequent fall of activity with time. The decrease of the yields of divinyl with time can be accounted for mainly by the change in the phase composition of the bismuth–molybdenum catalyst and not only by the deposition of carbonaceous substances. Indeed at low oxygen to butenes ratios the amount of divinyl and carbon dioxide formed in the first minutes of the reaction is greater than the amount which could form if all the oxygen supplied were utilised [66]. The decreased activity of the molybdenum–bismuth catalyst on reducing its oxygen content was demonstrated also by direct experiments with partial reduction of the catalyst [63]. On partial reduction, the higher oxides of bismuth and molybdenum are converted into lower oxides, as a result of which the activity of the catalyst decreases. According to the results of another investigation [67], the lattice oxygen is consumed during the reaction even when oxygen is present in a large excess in the reaction mixture.

Thus the oxygen of the catalyst itself participates in reactions involving the formation of divinyl and carbon dioxide. The oxygen in the gas phase has a dual function in the oxidative dehydrogenation process: to maintain the active oxidised form of the catalyst and to prevent coke formation. In order to ensure the presence of oxygen in the effluent gases in the usual flow-type reactor with a stationary catalyst bed, it is necessary to supply a considerable excess of oxygen at the inlet, but this leads to a decrease of selectivity due to formation of oxygen-containing compounds. Therefore reaction systems with internal mixing are preferred [68] for the oxidative dehydrogenation of olefins. Indeed, in a reactor with a suspended catalyst layer, more effective oxidative dehydrogenation of butenes was achieved than in a reactor with a stationary catalyst bed [68].

All that has been said so far about the effect of the concentration of oxygen applies to the region of low oxygen concentrations, up to the ratio oxygen : butenes = 0.8–1.0. When the oxygen : butenes ratio is increased to values in excess of unity, a change of oxygen concentration no longer has an appreciable effect on the yields of divinyl on the bismuth–molybdenum catalyst.

Tsailingol'd and coworkers [63] investigated the kinetics of dehydrogenation on the bismuth–molybdenum catalyst by a flow-circulation method at 410–490°C. The concentration of oxygen was varied in the range between 0.30 and 6.7 mole % and that of n-butenes between 2.55 and 18.60 mole %. An increase of the concentration of oxygen above 1–2% (at n-butene concentrations in the range 4–5 mole %) did not have an appreciable effect on the rate of the reactions, i.e. in this concentration range the reaction

was of zero order with respect to oxygen. The order of the reaction with respect to oxygen at lower contents of the latter in the system was not established. When the oxygen concentrations are not too low, the rate ω_1 of the overall conversion of n-butenes is given by the expression:

$$\omega_1 = \frac{k_1 P_{C_4H_8}}{1+aP_{C_4H_8}}, \quad (9)$$

where k_1 is the rate constant for the overall conversion and a a constant which varies with temperature.

Adams and coworkers [1] investigated the kinetics of the dehydrogenation of individual n-butene isomers on the bismuth–molybdenum catalyst in a flow-type reactor. The overall conversion of each n-butene is described by a first-order equation with respect to the butenes. The rate of reaction at 460°C is several times higher than those of but-2-enes, of which the *cis*-isomer is more reactive than the *trans*-isomer.

The kinetics of the oxidative dehydrogenation of mono-olefins with a carbon chain of more than four atoms is described by equations more complex than Eqn. (9).. The principal differences are the dependence of the reaction rate on the concentration of oxygen and inhibition by products. Thus, according to Adams [69], we have for pent-1-ene

$$\omega_1 = \frac{aP_{\text{hydrocarb}}P_{O_2}^{1/2}}{1+bP_{O_2}^{1/2}+dP_{\text{diene}}}, \quad (10)$$

where a, b, and d are constants.

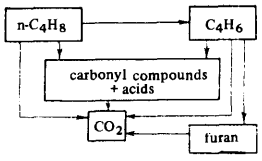
d. Effect of Reaction Products and Diluents

Dilution of butenes with water in proportions of 1 : 10 leads to increase yields of divinyl on the bismuth–molybdenum catalyst. The selectivity then changes much less [54]. Dilution with water in order to optimise the process is recommended also for other catalysts [13,25,70].

With constant concentrations of butenes and oxygen, an increase of the concentration of water from 0 to 40 mole % at 410–470°C does not have an appreciable effect on the rate of reaction on the bismuth–molybdenum catalyst [63]. The same results are obtained when the concentration of carbon dioxide is changed approximately by a factor of 20 and that of divinyl by a factor of six. The dehydrogenation of mono-olefins with a large number of carbon atoms in the chain is inhibited by the products—diolefins [see Eqn. (10)]. According to Alkhazov and coworkers [71], the addition of isobutene also has an inhibiting effect in the dehydrogenation of isopentenes.

The rate of oxidation of divinyl to carbon dioxide on bismuth molybdate is described by a first-order equation with respect to divinyl and a zero-order equation with respect to oxygen [63], amounting under conditions of oxidative dehydrogenation to approximately one-twentieth of the rate of conversion of but-1-ene into divinyl [1], and is thus comparable to the rate of conversion of butenes into carbon monoxide and carbon dioxide. Therefore the carbon dioxide obtained in oxidative dehydrogenation must be regarded as formed partly from divinyl.

The formation of side-products in oxidative dehydrogenation on the bismuth–molybdenum catalyst can be represented by a parallel-consecutive reaction scheme [62]:



Depending on the nature of the catalyst, one or other side-product predominates. Thus, on the iron–zinc catalyst [72], cracking is the principal side-reaction.

e. Isomerisation

The oxidative dehydrogenation of butenes on the bismuth–molybdenum catalyst is accompanied by a change in isomeric composition: the amount of but-1-ene decreases and that of but-2-enes either increases or changes little, while the *cis*-but-2-ene : *trans*-but-2-ene ratio decreases [73]. This is due to the different reactivities of the individual isomers, which decrease in the series but-1-ene > *cis*-but-2-ene > *trans*-but-2-ene. The rate of oxidative dehydrogenation of isopentenes decreases in the series 3-methylbut-1-ene > 2-methylbut-1-ene > 2-methylbut-2-ene [52].

The change in the isomeric composition of mono-olfeins can also be attributed to isomerisation reactions which occur on many catalysts. The rate of the isomerisation reactions depends on the nature of the catalyst. According to Roginskii and coworkers [74,75], the degree of isomerisation of but-1-ene to but-2-ene on the bismuth–molybdenum catalyst without carrier is very low, while for bismuth phosphomolybdate on a carrier the isomerisation is fairly extensive under the conditions of oxidative dehydrogenation.

Table 2. Relative reactivities of olefins in their oxidation on bismuth molybdate at 460°C.

Initial olefin	Main product	Reactivity with respect to the main product referred to	
		one molecule	one hydrogen atom in the allyl position
Propene	acrolein	0.11	0.037
cis-But-2-ene	butadiene	0.26	0.043
trans-But-2-ene	butadiene	0.19	0.032
Isobutene	methacrolein	0.50	0.08
But-1-ene	butadiene	1.00	0.5
2-Methylbut-2-ene	isoprene	2.7	0.3
Pent-1-ene	pentadiene	1.38	0.69
4-Methylpent-1-ene	methylpentadiene	1.6	0.8
Pent-2-ene	pentadiene	0.43	0.086
2-Ethylhex-1-ene	C_8H_{14}	2.8	0.7
3-Methylbut-1-ene	isoprene	2.7	2.7
3-Methylpent-1-ene	methylpentadiene	1.9	1.9
3-Ethylpent-1-ene	C_7H_{12}	1.4	1.4

Studies of the dependence of the isomerising capacity of bismuth–molybdenum catalysts on the Mo : Bi ratio have shown that the rate of isomerisation is highest on molybdenum oxide [55,56]. Isomerisation is not observed under the conditions of oxidative dehydrogenation on a catalyst comprising Group VIII oxides [76].

f. Effect of the Structure of the Hydrocarbons

The unequal reactivities of the individual isomers in oxidative dehydrogenation were pointed out above. Table 2 presents the results of Adams [69] obtained in a study of the comparative reactivities of individual C_3–C_8 hydrocarbons. The reactivities are expressed in relative units with respect to but-1-ene. The reactivity of the allyl C–H bonds increases in the series primary < secondary < tertiary.

Substitution at any vinyl carbon atom increases the reactivity of the olefin. An increase of chain length increases the reactivity of the secondary allyl hydrogen atom (but-1-ene < pent-1-ene < 4-methylpent-1-ene), but reduces the reactivity of the tertiary allyl hydrogen atom (3-methylbut-1-ene > 3-methylpent-1-ene > 3-ethylpent-1-ene).

In the oxidation on bismuth molybdate of molecules which contain less than four carbon atoms in the chain (propene, isobutene) unsaturated aldehydes are formed instead of diolefins. In the reaction of mono-olefins which are readily dehydrogenated to diolefins, carbonyl compounds are formed as side-products. Considerable amounts of mono-unsaturated aldehydes are obtained in the oxidation of mono-subtituted isobutenes.

Certain deviations from the above behaviour can be quite naturally explained. For example, cyclopentene is converted only into total-oxidation products, probably due to the exceptionally high reactivity of cyclopentadiene. Conjugated diolefins are formed from the same molecule at a much higher rate than conjugated olefinic aldehydes.

As the number of carbon atoms in the molecule increases, the degree of inhibition by reaction products (diolefins and aldehydes) also becomes more pronounced. Inhibition by products is shown mainly in a reduction of activity without a significant change in the selectivity of the catalyst.

3. THE MECHANISM OF OXIDATIVE DEHYDROGENATION

a. Similarity of the Oxidative Dehydrogenation of n-Butenes to the Oxidation of Propene to Acrolein and Oxidative Ammonolysis

There exists a profound analogy between the oxidative dehydrogenation of butenes,

$$C_4H_8 + {}^1/_2O_2 \rightleftarrows C_4H_6 + H_2O\,, \qquad (7)$$

the oxidation of propene to the unsaturated aldehyde acrolein,

$$C_3H_6 + O_2 \rightleftarrows C_3H_4O + H_2O\,, \qquad (11)$$

and oxidative ammonolysis of propene with formation of acrylonitrile:

$$C_3H_6 + 1.5O_2 + NH_3 \rightleftarrows C_3H_3N + 3\,H_2O\,. \qquad (12)$$

All the above reactions take place readily on bismuth molybdate. Over a considerable concentration range their rates on this catalyst are described by a first-order equation with respect to the initial mono-olefin and a zero-order equation with respect to oxygen [77,78]. In all the reactions the activity of the catalyst falls in the presence of a deficiency of oxygen, the temperature variation of the yields of acrolein and divinyl in reactions (7) and (11) is approximately the same, the apparent activation energies for these reactions are similar [1], and the kinetic isotope effects in the conversion of deuteriated propene into acrolein and acrylonitrile are also equal [77].

Reactions (7), (11), and (12) have common features: (a) the initial hydrocarbon molecule contains at least one C=C double bond which is not dissociated during the reaction; (b) at least one of the aliphatic C–H bonds dissociated in the reaction is allylic. Transition-metal oxides catalyse these reactions which are sometimes referred to as allyl oxidative reactions.

By the time extensive studies on the oxidative dehydrogenation of olefins began, the oxidation of propene to acrolein had been largely investigated and this plays a definite role in the elucidation of the mechanism of oxidative dehydrogenation. The similarity of the kinetics of reactions (7), (11), and (12) shows that they have a common rate-limiting stage. The first order with respect to the olefin and the zero order with respect to oxygen when $P_{O_2} > (P_{O_2})_{min}$ are evidence that the olefin must take part in the rate-limiting stage.

b. The Mechanism of the Oxidation of Propene to Acrolein

Adsorption of the reactants. According to modern data, the reaction between propene and oxygen takes place on the surface of the catalyst. Both reactants are fairly readily adsorbed on the surface of catalysts such as molybdenum or bismuth oxides. The adsorption of oxygen is at least partially accompanied by dissociation by the active surface centres L:

$$O_2 + 2L \rightleftarrows 2L{-}\dot{O} \qquad (13)$$

The adsorption of propene on the bismuth–molybdenum catalyst is accompanied by dissociation and probably takes place on two surface adsorption centres.

It may be supposed, for example [78], that the transition state preceding dissociation is produced on interaction between a propene molecule and two active centres in which a surface π-complex between one active catalyst centre and the double bond of the propene, on the one hand, and a hydrogen of the methyl group and a second catalyst active centre, on the other, is formed:

$$H_2C{=}CH{-}CH_3 + L_1 + L_2 \rightleftarrows \left\{\begin{matrix} H_2C{=}CH-CH_2 \cdots H \\ \vdots \qquad\qquad \vdots \\ L_1 \qquad\qquad L_2 \end{matrix}\right\} \qquad (14)$$

The transition structure produced as a result of the weakening of the C–H bond in the methyl group is capable of dissociation:

$$\left\{\begin{matrix} H_2C{=}CH{-}CH_2 \cdots H \\ \vdots \qquad\qquad \vdots \\ L_1 \qquad\qquad L_2 \end{matrix}\right\} \rightarrow \underbrace{H_2C \cdots CH \cdots CH_2}_{L_1} + \underset{L_2}{H} \qquad (15)$$

Experimental confirmation. The above picture is in broad outline confirmed by the experimental data obtained in the study of the chemisorption of propene and the oxidation and oxidative ammonolysis of propene labelled with radioactive carbon and deuterium. It is virtually no longer possible to investigate the adsorption of propene at 300°C due to its decomposition on the surface of the bismuth–molybdenum catalyst [79]. Sachtler and De Boer [80] studied the oxidation on the bismuth–molybdenum catalyst of [1-^{14}C]-, [2-^{14}C]-, and [3-^{14}C]-propenes to acrolein. The product was decomposed photochemically into ethylene and carbon monoxide:

$$H_2C{=}CH{-}CHO \rightarrow H_2C{=}CH_2 + CO\,. \qquad (16)$$

The results obtained suggest that the carbon atom of the aldehyde group originates with equal probability both from the methyl and methylene groups of the initial propene. The studies on the oxidation of [1-^{13}C]-propenes on a deuteriated bismuth phosphomolybdate catalyst [81] and of [1-D]-propene and [3-D]propene on bismuth molybdate [77] also led to the conclusion that both terminal carbon atoms are equivalent.

Further reactions. The surface hydrocarbon complex $L_1(CH_2 \cdots CH \cdots CH_2)$ is capable of further reactions, in particular of losing another hydrogen atom or of

combining with oxygen. The formation of acrolein can occur as a result of the following reactions, for example:

$$L_1(CH_2 \cdots CH \cdots CH_2) + L-\dot{O} \rightarrow L_1(CH_2 \cdots CH \cdots CH) + L-OH, \quad (17)$$

$$L_1(CH_2 \cdots CH \cdots CH) + L-\dot{O} \rightarrow L_1(CH_2{=}CH{-}CHO) + L, \quad (18)$$

$$L_1(CH_2{=}CH{-}CHO) \leftrightarrows CH_2{=}CH{-}CHO + L_1, \quad (19)$$

or the surface unsaturated-hydrocarbon complex passes through intermediate stages involving isomerisation to surface radicals, for example:

$$L_1(CH_2 \cdots CH \cdots CH) \rightarrow L_1-\dot{C}H-CH=\dot{C}H_2 \xrightarrow{+L-\dot{O}} CH_2{=}CH{-}CHO. \quad (20)$$

The above hypotheses concerning the possible mechanism of the conversion of the adsorbed allyl radical into acrolein are consistent with the measurements of the kinetic isotope effects in the oxidation with oxygen of propenes deuteriated at the terminal carbon atoms [77]. The observed isotope effects proved to be greater than they should have been if the oxygen atom attacked directly the terminal carbon atom of the allyl radical, since in the latter case the question whether or not the attacked carbon atom contains H or D would have been insignificant.

The rate-limiting stage. On the basis of the kinetic data and the analogy between reactions (7), (11), and (12), it is assumed that dissociative adsorption of the olefinic hydrocarbons constitutes the slowest stage in these reactions. The zero order of reactions (7), (11), and (12) with respect to oxygen means that the rate of adsorption of oxygen at $P_{O_2} > (P_{O_2})_{min}$ is sufficiently high to compensate the time required for the conversion of the oxygen of the catalyst surface.

Thus in order to catalyse the allyl oxidation reaction, the catalyst must be capable of dissociating the C–H bond in the methyl group, while protecting at the same time the double bond in the initial olefin from oxidation. If the adsorption of the latter is so strong that it results in the dissociation of the double bond, degradative oxidation products are formed: acetaldehyde, formaldehyde, carbon dioxide, and others.

c. The Mechanism of the Oxidative Ammonolysis of Propenes

As stated above, the first stages of the oxidative ammonolysis and oxidation of propene to acrolein may be regarded as identical. According to Adams [77], the mechanism becomes different after the removal of the second hydrogen atom from the adsorbed hydrocarbon radical. In the presence of ammonium the unsaturated surface radical $L-\dot{C}H-CH=CH_2$ loses yet another hydrogen atom from the same carbon atom instead of combining with oxygen [reaction (20)]:

$$L_1-\dot{C}H-CH=CH_2 \xrightarrow{+L\dot{O}} L_1-\ddot{C}-CH=CH_2. \quad (21)$$

In turn the ammonia adsorbed in the presence of oxygen also undergoes oxidative dehydrogenation:

$$L_3(NH_3) + L-\dot{O} \rightarrow L_3(NH_2) + L-OH, \quad (22)$$

etc., until the formation of chemisorbed NH and N radicals, which is followed by the addition reaction, whose product is acrylonitrile:

$$L_1-\ddot{C}-CH=CH_2 + L_3-\ddot{N} \rightarrow CH_2-CH-CN + L_1 + L_3. \quad (23)$$

According to the views of Gel'bshtein and coworkers [78], acrylonitrile is formed consecutively via an intermediate stage in which acrolein is formed:

$$L_1(CH_2{=}CH{-}CHO) + L_3(NH) \rightarrow L_1(H_2C{=}CH{-}CN) + L_3(H_2O), \quad (24)$$

with subsequent desorption:

$$L_1(H_2C{=}CH{-}CN) \rightarrow L_1 + H_2C{=}CH{-}CN. \quad (25)$$

The kinetic equation derived on the hypothesis of the consecutive formation of acrylonitrile via acrolein as an intermediate [78] is qualitatively confirmed by experimental data. The formation of degradative reaction products (acetaldehyde, formaldehyde, hydrogen cyanide, acetonitrile, carbon dioxide, and others) may take place on catalytic centres where the adsorption of propene is stronger and is accompanied by the dissociation of the double bond.

d. The Mechanism of the Oxidative Dehydrogenation of Mono-olefins

In order to be capable of oxidative dehydrogenation to a diolefin, the initial olefin molecule must contain not less than four carbon atoms. By analogy with propene, the adsorption of n-butenes can be represented in the following manner:

$$\begin{matrix} CH_2{=}CH{-}CH_2{-}CH_3 \\ (\text{or } CH_3{-}CH{=}CH{-}CH_3) \end{matrix} \searrow \underbrace{H_2C \cdots CH \cdots CH}_{L_1}{-}CH_2 + \underset{L_2}{H}. \quad (26)$$

The C–H bonds at the secondary allyl carbon atom are more readily dissociated than those at the primary carbon atom, and therefore the dissociative adsorption of but-1-ene is faster than that of but-2-ene. In the oxidative dehydrogenation of n-butenes the second hydrogen atom is removed from the methyl group of the adsorbed hydrocarbon molecule and not from the allyl group as in the oxidation of propene to acrolein [Eqn. (17)] [77]:

$$\underbrace{H_2C \cdots CH \cdots CH}_{L_1}{-}CH_3 + \underset{L}{\dot{O}} \rightarrow \underbrace{H_2C \cdots CH \cdots CH}_{L_1}{-}\dot{C}H_2 + \underset{L}{OH}, \quad (27)$$

and further

$$\underbrace{H_2C \cdots CH \cdots CH}_{L_1}{-}\dot{C}H_2 \rightarrow L_1(H_2C{=}CH{-}CH{=}CH_2) \rightarrow L_1 + H_2C{=}CH{-}CH{=}CH_2. \quad (28)$$

The removal of a hydrogen atom from the methyl group probably takes place much more readily than its removal from the allyl group, i.e. the possibility of the formation of a conjugated diolefin is much greater than that of the formation of the corresponding aldehyde. Considerable amounts of aldehydes are formed only from olefins branched at the vinyl atom [69].

Apart from the formation of a diolefin or an aldehyde, there is also a possibility of the recombination of the allyl radical with a hydrogen atom initially removed from the mono-olefin molecule. In this case the initial olefin or one of its isomers (with respect to the double bond) is formed [Eqn. (26)]. However, isomerisation on catalysts such as bismuth molybdate takes place much more slowly than oxidative dehydrogenation.

As in the formation of unsaturated aldehydes and oxidative ammonolysis, the dissociative adsorption of the initial olefin must be adopted as the slowest stage in the oxidative dehydrogenation of mono-olefins to diolefins. Apart from the similarity of the kinetics of these three reactions, further evidence in favour of the above view comes also from the unequal reactivities of the individual n-butene isomers. The rate of oxidative dehydrogenation increases in the series *trans*-but-2-ene < *cis*-but-2-ene < but-1-ene, but, starting with the stage in which the adsorbed allyl radical is present, the individual n-butene isomers are no longer distinguishable [Eqn. (26)].

The rate of dissociative adsorption is determined by the stability of the C–H bond dissociated on formation of the allyl radical from the initial olefin molecule. In agreement with the energies required for the removal of the allyl hydrogen atom by radicals, the rate of oxidative dehydrogenation increases in the series primary > secondary > tertiary allyl hydrogen atoms in the mono-olefin molecule. An increase in rate in the above series is also observed in the formation of the allyl carbonium ion, in conformity with the available data[82], according to which the hydrocarbon radicals adsorbed on the surface of oxidation catalysts are positively charged.

e. Effect of the Nature of the Catalyst

At the present time differences in the catalytic activity of oxides due to their chemical nature are still little understood. The available literature data on the variation of the activity and selectivity of certain catalysts for oxidative dehydrogenation of olefins with the chemical composition were examined in section II, subsection 1. The relation between catalytic activity and catalyst composition in other oxidative reactions, in particular in the oxidation of propene to acrolein and oxidative ammonolysis, is described in Refs. 82–85, for example. Certain new results will be examined here.

Belen'kii and coworkers[86] compared the effects of the molybdenum : bismuth ratio on the catalytic activity in the oxidation of propene to acrolein and in the oxidative dehydrogenation of butenes and isopentenes. The optimum composition of the catalyst proved to be the same for all three reactions and corresponded to the atomic ratio Mo : Bi = 2. These results provide yet another confirmation of the validity of the hypotheses concerning the identity of the active centres of the catalysts in these reactions.

According to other data, the Mo : Bi atomic ratio in the most active catalysts varies between 1 and 2 and apparently depends on the method of preparation of the catalyst and the presence of other substances, in particular a carrier.

Several chemical compounds are formed in the system molybdenum–bismuth. The phase $Bi_2O_3.2MoO_3$, which corresponds to the atomic ratio Mo : Bi = 1, shows the highest activity, among the mixed oxides of molybdenum and bismuth, in the oxidation of propene to acrolein and oxidative ammonolysis to acrylonitrile[79,87,88] Bleijenberg et al.[89] did not observe the formation of the phase with the composition Mo : Bi = 1, and yet specimens with precisely this component ratio proved to be the most active in oxidative dehydrogenation[56]. The 1 : 1 atomic ratio corresponds also to the optimum composition of bismuth–tungsten catalysts[90], while in the best antimony–tin catalysts the atomic ratio is Sn : Sb = 1 : 8. The catalytic activities of various bismuth tungstates differ from one another less than those of bismuth molybdates. The most active form of the tungstate is in fact less active than that of bismuth molybdate.

There are as yet very few data concerning the nature of the active centres responsible for chemisorption and catalysis in the oxidative dehydrogenation of olefins. According to the views of Sachtler and De Boer[80], a bond between one of the carbon atoms and a surface oxygen atom forms in the dissociative adsorption of olefins on oxides. According to Trapnell[91], dissociative adsorption of hydrocarbons takes place on metal ions with an unfilled *d* shell. In the latter case two-point dissociative adsorption of the olefins can occur, for example at a doublet consisting of molybdenum and bismuth atoms. This hypothesis appears justified if it is remembered that catalysts with the atomic ratio Mo : Bi = 1 are active. The centre responsible for the dissociation of the double bond and degradative oxidation can have the same composition (a molybdenum or bismuth atom) but differs by the higher energy of the donor–acceptor interaction with the olefin molecule.

Stroeva and coworkers[92] investigated the relation between the composition of bismuth–molybdenum, cobalt–molybdenum, and antimony–tin catalysts and their electrical properties, on the one hand, and their activity in the oxidative oxidation of the C–H bond, on the other. If follows from the results that, for all three binary systems, the physicochemical nature of the promoting effect of the second oxide is different. In the system MoO_3–Bi_2O_3 the promoting effect is accompanied by the formation of a chemical compound with the atomic ratio Mo : Bi = 1. According to the above authors' views, the active centre is a doublet consisting of molybdenum and bismuth atoms. In the system MoO_3–Co_3O_4 the promoting effect of cobalt is associated with an increase of the specific surface: cobalt molybdate has no catalytic properties and behaves as a carrier. The active centre can consist of two molybdenum atoms. In the system Sb_2O_4–SnO_2 the possible role of tin consists in an increase of the concentration of antimony cations in the most oxidised state and also in an increase of the internal surface of the catalyst. The active centre can consist of two antimony atoms.

Batist et al.[56] suggest that the formation of the intermediate allyl structure on the surface of the bismuth–molybdenum catalyst occurs at the vacant anionic site which is produced as a result of the removal from the surface of the hydroxyls formed in selective oxidation reactions [reactions (17), (21), and others]:

$$2\,OH^- \rightarrow H_2O + \square_d + O^{-2}, \qquad (29)$$

where $\square_d$ is a vacant anionic site. The adsorbed allyl radical is bound to a molybdenum ion via a π-bond. According to Batist et al.[56], the promoting effect of bismuth is associated with an increase in the susceptibility of the catalyst to dehydroxylation and reduction.

In a number of studies attempts were made to establish correlations between the catalytic and other physicochemical properties of the catalysts associated with the mobility of their ions and electrons. Sachtler and De Boer[80] compared the activities, selectivities, and capacities for reduction of the catalysts, and Gel'bshtein, Margolis, and coworkers[78,87,80] compared the catalytic properties and electron work functions.

According to the data of Kolchin et al.[87], the maximum electron work function of mixed bismuth and molybdenum oxides is observed at an atomic ratio of 6 : 4, i.e. corresponds approximately to the highest activity of the catalyst. However, according to other data[78], there is no parallel variation of the electron work function and catalytic activity of the oxidation of propene to acrolein and oxidative ammonolysis. Kolchin et al.[90] arrived at the same conclusion in a similar study of bismuth–tungsten catalysts.

According to the data of Sachtler and De Boer[80], the conversion of propene and the selectivity with respect to acrolein are roughly correlated with the susceptibility of the catalysts to reduction. The susceptibility to reduction (Table 3) was defined as the reciprocal of the absolute temperature at which a rate of reduction of 7.4×10^{-3} moles of hydrogen per gramme of catalyst per hour ($T_{7.4}$) is attained. Under the conditions of the experiments, the principal oxidation products were acrolein, carbon monoxide, and carbon dioxide. With increase in the susceptibility of the catalysts to reduction, the overall degree of conversion of

propene increases and the selectivity with respect to acrolein falls.

The existence of a relation between catalytic activity and the susceptibility of the catalyst to reduction may be attributed to the fact that the susceptibility of the oxide to reduction reflects the mobility of its constituent oxygen, which participates in the catalytic steps in the oxidation of propene. Low mobility is the reason for low activity of the catalyst. On the other hand, if the mobility of oxygen is too high, the formation of the products of the total oxidation of the hydrocarbon is facilitated: for selective oxidation of the C–H bond, the mobility of oxygen should have a definite optimum value.

Table 3. Dependence of the degree of oxidation of propene on the susceptibility of the catalyst to reduction.

Metal of the oxide	Susceptibility to reduction $10^3/T_{7.4}$, deg^{-1}	Yields of propene oxidation products at 520°C, %		
		overall conversion	acrolein	selectivity with respect to acrolein
Mo deposited at 98°C	1.17	2	2	70
Mo deposited at 20°C	1.29	16	9	59
Mo–Bi	1.51	66	55	84
W–Bi	1.52	55	32	58
Mo–Co	1.54	28	9	32
Sn–Sb–Mo	1.70	29	13	46
Mo–Cu	1.73	55	28	50
Mn	2.02	~100	~0	~0

Sachtler and De Boer[80] obtained a kinetic equation based on the theory of absolute reaction rates with the following main assumptions: (a) carbon and oxygen compete in the adsorption process; (b) the rate of adsorption of oxygen greatly exceeds the rate of its consumption by reaction (11); (c) carbon dioxide and carbon monoxide are formed from acrolein. This kinetic equation is qualitatively consistent with the experimental observation that the activity and the selectivity vary with the susceptibility of the catalyst to reduction.

III. OXIDATIVE DEHYDROGENATION OF SATURATED HYDROCARBONS

In contrast to mono-olefins, the oxidation of saturated hydrocarbons with oxygen gives low yields of dehydrogenation products. Therefore much attention has been given to oxidative dehydrogenation under the action of reagents more effective than oxygen, in the first place iodine. When iodine was applied, fairly high yields were obtained and fairly high selectivity with respect to the dehydrogenation products was achieved.

We shall examine initially oxidative dehydrogenation with oxygen.

1. DEHYDROGENATION IN THE PRESENCE OF OXYGEN

The dehydrogenation of saturated hydrocarbons in the presence of oxygen, like that of olefins, in an oxidative, and not a dehydrogenation, reaction accompanied by subsequent oxidation of hydrogen. Depending on the experimental conditions, different proportions of oxygen-containing compounds and cracking products are formed together with the dehydrogenation products. Oxidation reactions are of the radical-chain type and take place mainly in the bulk-phase of the reaction system. In contrast to olefins, solid catalysts which have an effective selective dehydrogenating effect in the oxidative dehydrogenation of saturated hydrocarbons are unknown. The catalysts used were capable only of a comparatively slight increase in the yield of the dehydrogenation products.

a. Low- and High-Temperature Oxidation of Hydrocarbons

Most hydrocarbons are oxidised at about 300°C and below, and in many respects the mechanism of this oxidation is radically different from the mechanism of oxidation at higher temperatures. The products of the low-temperature oxidation of hydrocarbons are mainly aldehydes, ketones, alcohols, carbon monoxide, and carbon dioxide; in the high-temperature oxidation the principal reactions are cracking and dehydrogenation. Under the conditions usually employed, the transition from the low- to the high-temperature mechanism usually occurs in the range 350–500°C. This range depends relatively little on the individual hydrocarbon, so that the oxidations of many saturated hydrocarbons probably occur by similar mechanisms. In the temperature range for the transition from one mechanism to the other the temperature coefficient of the rate of oxidation is anomalous: with increase in temperature, the rate of reaction passes through a minimum in the transition region.

There are numerous data[93–107] concerning the amounts of unsaturated hydrocarbons formed as a function of the experimental conditions. Some of these are quoted in Table 4. With increase in the butane oxidation temperature from 300° to 700°C, the yield of oxygen-containing compounds decreases, that of ethylene and propene increases, and that of butenes passes through a maximum[107]. The extent of formation of oxygen-containing organic products also falls markedly as the oxygen : carbon ratio decreases. For example, with the ratio oxygen : butane ≤ 0.1, at 500°C virtually the only oxygen-containing compound is water[103]. In the homogeneous oxidation of saturated hydrocarbons small amounts of diolefins sometimes form in addition to mono-olefins[104] and in the high-temperature oxidation of ethane small amounts of acetylene are produced[98].

The yields of diolefins obtained were not limited by the equilibrium: the equilibrium yields of diolefins in the oxidation of saturated hydrocarbon by oxygen at about 500°C, at atmospheric pressure, and with the equivalent composition of the initial mixture can reach 100%.[108]

b. The Mechanism of the High-Temperature Oxidation

The mechanism of the formation of olefins under the conditions of the homogeneous oxidation of saturated hydrocarbons has been the subject of discussion for a long time. The mechanism proposed by Shtern[95] for the oxidation of propane may be regarded as one of the most successful mechanisms for the oxidation of saturated hydrocarbons available at present. According to this mechanism, propene forms as a result of the removal by an oxygen molecule of a hydrogen atom from the propane and the subsequent breakdown of the resulting propyl radical into propene and a hydrogen atom:

$$C_3H_8 + O_2 \rightarrow \text{iso-}\dot{C}_3H_7 + H\dot{O}_2, \qquad (30)$$

$$\text{iso-}\dot{C}_3H_7 \rightarrow C_3H_6 + \dot{H}. \quad (31)$$

Nevertheless this reaction path appears unlikely because of the high activation energy (about 40 kcal mole^{-1}) of stage (31). Therefore Semenov [109] suggested the following mechanism for the conversion of propane into propene:

$$C_3H_8 + O_2 \rightarrow \text{iso-}C_3H_7 + H\dot{O}_2, \quad (32)$$

$$\text{iso-}\dot{C}_3H_7 + O_2 \rightarrow CH_3{-}\underset{\dot{O}{-}O}{CH}{-}CH_3. \quad (33)$$

After isomerisation the peroxy-radical formed breaks down with formation of propene:

$$CH_3{-}\underset{\dot{O}{-}O}{CH}{-}CH_3 \rightarrow CH_3{-}\underset{\dot{O}{-}OH}{CH}{-}\dot{C}H_2, \quad (34)$$

$$CH_3{-}\underset{\dot{O}{-}OH}{CH}{-}\dot{C}H_2 \rightarrow C_3H_6 + H\dot{O}_2. \quad (35)$$

However this mechanism too met with objections [95], since it leads to a no less serious inconsistency with experiment. In particular the ratio of the rates of formation of organic products with and without oxygen should have been much greater than is found experimentally [95].

Table 4. Formation of olefins in the oxidation of certain saturated hydrocarbons.

Initial hydrocarbon	Moles of oxygen per mole of hydrocarbon in the starting material	Temperature, °C	Pressure, atm	Dehydrogenation to mono-olefins, %		References
				with respect to starting material	with respect to product	
Ethane	0.3	680	1	50	62	101
Propane	0.23	700	1	15	25	101
Propane	0.17	540	1	16	56	102
Propane	0.5	465	0.4	20	49	95
Propane	1	350	0.4	13	25	95
n-Butane	0.1	500	0.55	7	35	103
n-Pentane	1	500	1	10	25	104
Isopentane	0.5	400	1	9	30	105
Cyclohexane	2.7	400	1	15*		106

* Yield of cyclohexene

The majority of present day investigators assume that the second stage of the reaction involves the removal by an oxygen molecule of a hydrogen atom from the alkyl radical [103-105,110-112]:

$$\dot{C}_nH_{2n+1} + O_2 \rightarrow C_nH_{2n} + H\dot{O}_2. \quad (36)$$

Appleby and coworkers [103] obtained the following equation for the reaction of n-butane at low oxygen : butane ratios:

$$-\frac{d[C_4H_{10}]}{d\tau} = k[C_4H_{10}]^{3/2}[O_2]^{1/2}. \quad (37)$$

The kinetic data were obtained by a flow method at 485-525°C (τ is the contact time): Eqn. (37) was derived by the stationary-state method using the following mechanism:

$$C_4H_{10} + O_2 \rightarrow C_4H_9 + HO_2, \quad (38)$$

$$C_4H_9 + O_2 \rightarrow C_4H_8 + HO_2, \quad (39)$$

$$HO_2 + C_4H_{10} \rightarrow H_2O_2 + C_4H_9, \quad (40)$$

$$2HO_2 \rightarrow H_2O_2 + O_2, \quad (41)$$

$$H_2O_2 \xrightarrow{\text{wall}} H_2O + {}^1/_2O_2, \quad (42)$$

$$2HO_2 \xrightarrow{\text{wall}} H_2O + 1\,{}^1/_2O_2, \quad (43)$$

$$C_4H_9 \rightarrow CH_3 + C_3H_6, \quad (44)$$

$$CH_3 + C_4H_{10} \rightarrow CH_4 + C_4H_9, \quad (45)$$

$$C_4H_9 \rightarrow C_2H_5 + C_2H_4, \quad (46)$$

$$C_2H_5 + C_4H_{10} \rightarrow C_2H_6 + C_4H_9. \quad (47)$$

c. Effect of the Solid Surface

Eqns. (38)-(47) show that the above mechanism of oxidative dehydrogenation and cracking presupposes chain termination on the walls. In actual fact, however, in hydrocarbon oxidation reactions both chain initiation and chain termination probably occur on the walls of the reactor. The available experimental literature data on the effect of the wall on the reaction of saturated hydrocarbons in the presence of oxygen are extremely few and non-systematic. However, it is possible to arrive at the reliable conclusion, on their basis, that the surface of the wall does indeed influence the reaction and that, depending on the experimental conditions and the nature of the wall, the latter can both slow down and accelerate the reaction. The initiating effect of the surface can be associated, for example, with the fact that it facilitates the removal of a hydrogen atom from the hydrocarbon molecule as a result of the chemisorption of oxygen:

$$L - \dot{O}_2 + C_4H_{10} \rightarrow L{-}O_2H + \dot{C}_4H_9, \quad (48)$$

$$L - \dot{O}_2 + \dot{C}_4H_9 \rightarrow L - O_2H + C_4H_8, \quad (49)$$

The possible mechanism of the further conversion of the mono-olefin into the diolefin was examined in section II, subsection 3d.

Martin and Niclause [113,114] investigated the effect of the reactor walls on the pyrolysis of propane and isopentane in the presence of added oxygen (up to 2%). The experiments were performed in a static reactor at initial hydrocarbon pressures of 25-50 mmHg at 480-550°C. The pyrolysis of propane takes place with formation of the following main products: propene, ethylene, methane, and hydrogen. In the pyrolysis of isopentane cracking products are mainly formed. When the surface : volume ratio ($S:V$) for the reactor is increased, the rate of reaction falls, which suggests that the walls of the Pyrex reactor have an inhibiting effect. The pyrolysis was accelerated by washing the reactor with the chromic acid mixture and by preliminary treatment with steam but was retarded when the walls were covered with potassium chloride or lead oxide (PbO).

Selwitz and Stanmyer [105] compared the conversion of isopentane into isopentenes at 400°C in reactors made of quartz, stainless steel, and quartz covered by a thin layer of silver. The smallest yield of isopentene was observed in the reactor whose walls had been covered by a layer of silver, and, what is more, the latter was markedly corroded during the reaction.

According to the data of Sultanova and Nagiev [115], quartz packing somewhat accelerates the dehydrogenation of diethylbenzenes to divinylbenzenes in the presence of hydrogen peroxide, which is decomposed under the conditions of the reaction with formation of oxygen. The favourable effect of the quartz surface on the dehydrogenation is also stated in a patent [116], where it is recommended that n-butene be brought into contact with alternating layers of activated charcoal and quartz. Although only about 8% of the hydrocarbon is then converted into n-butenes, fairly high selectivity (64%) is attained.

Various investigators attempted to increase the yields of the products of oxidative dehydrogenation by using other solid catalysts. Vanadium oxide "or its mixtures with oxides of tin, cobalt, chromium, manganese, uranium, tungsten, lead, bismuth, or zinc" have been suggested as catalysts in certain patents [117,118]. Under optimum conditions (temperature 400°C, n-butane : O_2 : diluent = 1 : 1 : 9) about 10% of butenes and only 1.9% of divinyl is obtained. However, the selectivity with respect to olefins is about 85%. Some patents [119,120] recommend calcium and nickel phosphates, on which yields of 6% of divinyl and 2% of butenes were attained. Ferric, manganic, or germanium oxides and calcium or lithium chlorides have been recommended as catalysts for the oxidative dehydrogenation of saturated hydrocarbons in the presence of oxygen [121].

The authors of some patents [122,123] assert that 17% of the initial n-butane is converted into divinyl in the course of 100 min on a fluidised bed of sodium phosphomolybdate with discontinuous contact. The formation of such large amounts of diolefins is probably related less to the nature of the catalyst than to reactor design or other factors which influence the process.

It follows from the data examined that in most cases the yields of olefins obtained on solid catalysts are close to those in an empty reactor (Table 4), but the selectivity in the presence of a solid catalyst is much higher. This suggests that the role of the solid catalyst may consist in the suppression of side-reactions. This may apply primarily to cracking reactions.

d. Effect of Radical-Forming Additives

The oxidative dehydrogenation of saturated paraffins, like that of olefins, can be greatly accelerated under the influence of small amounts of certain additives, which readily give rise to free radicals. Thus, on addition of iodine to a reaction mixture containing a saturated hydrocarbon and oxygen, the yields of dehydrogenation products increase sharply [108,124-126]. Apart from iodine, oxidative dehydrogenation by oxygen is activated also by other halogens or substances which decompose with formation of halogens: hydrogen and ammonium halides [127] and alkyl halides [128]; or the reaction can be activated by passing the reaction mixture through fused halides, for example lithium, lead, cadmium, etc. iodides [129-131].

The addition of ozone at temperatures in excess of 400°C also accelerates the yields of saturated hydrocarbon dehydrogenation products [105]; on the other hand, at lower temperatures ozone retards the dehydrogenation. Added butenes also have an inhibiting effect on the dehydrogenation of butane [76,103]. The oxidative dehydrogenation of saturated hydrocarbons in the presence of oxygen and small amounts of radical-generating substances will be examined in detail in subsection 3.

2. DEHYDROGENATION IN THE PRESENCE OF IODINE

The method of oxidative dehydrogenation with iodine was proposed in a number of patents, mainly in 1958–1959. [30,132]

a. Dehydrogenation Without an Acceptor and Oxygen

Raley and coworkers [133] investigated the reaction of iodine with saturated hydrocarbons ranging from C_2 to C_5, cyclopentane, and methylcyclopentane at temperatures between 495° and 685°C, iodine : hydrocarbon molar ratios between 0.4 and 4.6, and various contact times. Under these conditions the principal reactions involved dehydrogenation:

$$C_nH_{2n+2} + 2I_2 \rightleftarrows C_nH_{2n-2} + 4HI, \quad (3)$$

$$C_nH_{2n+2} + I_2 \rightleftarrows C_nH_{2n} + 2HI, \quad (50)$$

and

$$C_nH_{2n} + I_2 \rightleftarrows C_nH_{2n-2} + 2HI. \quad (51)$$

Hydrogen iodide is formed in an amount which is almost equivalent to the iodine which has reacted. Organic iodides and polymers were observed as side-products.

The equilibrium yields of propane and isobutane dehydrogenation products in the reaction with iodine are quoted by Benson and coworkers [134,135] and those for n-butane by Kozorezov [136] and Basner et al. [137]. When the temperature is raised above approximately 450°C, the diolefins : mono-olefins ratio increases appreciably, but below 600°C mono-olefins predominate. As the contact time is increased until equilibrium is attained, the yields of dehydrogenation products also increase, while the diolefins to mono-olefins ratio falls (Table 5). [133]

Table 5. Effect of the duration of contact at 550°C.

Reactants	Iodine : n-butane = 1.3			Iodine : isopentane = 1.6		
Duration of contact, s	0.7	1.3	equilibrium	1.3	2.6	equilibrium
Degree of conversion of C_nH_{2n+2}, %	51	76	82	69	90	92
C_nH_{2n-2}/C_nH_{2n}	0.38	0.28	0.24	0.42	0.28	0.27
Yield of C_nH_{2n-2}, %	14	16	16	19	18	20

If the initial saturated hydrocarbon contains six and more carbon atoms in its chain, aromatic hydrocarbons are formed together with olefins [138-140]:

$$C_nH_{2n-2} + I_2 \rightleftarrows C_nH_{2n-4} + 2HI \quad (52)$$

and

$$C_nH_{2n-4} + I_2 \rightleftarrows C_nH_{2n-6} + 2HI \quad (53)$$

(for $n \geqslant 6$). With increase of the iodine : hexane ratio from 0 to 2 at 500°C the degree of conversion into dehydrocyclisation products increases [138]. At low iodine : hexane ratios (up to 0.1–0.15) the dominant products are hydrocarbons with five or less carbon atoms. The same dehydrogenation products as in the reaction of saturated hydrocarbons with iodine (mono- and di-olefins, aromatic compounds, and others) can be obtained when iodine is replaced by bromine [141].

b. Kinetics of the Dehydrogenation Reaction

Teranishi and Benson [142] investigated the kinetics of the dehydrogenation of isobutane with iodine in a static reactor at 250–310°C. No induction period was observed. The reaction kinetics are described by the equation

$$\frac{[\text{iso-}C_4H_{10}](1-B)}{2S} = a_1 + a_2\frac{[HI]}{[I_2]^{1/2}} + b\frac{[HI]}{[I_2]}, \quad (54)$$

where $B = [\text{iso-}C_4H_8][HI]^2/K[\text{iso-}C_4H_{10}][I_2]$ and K is the equilibrium constant for the overall reaction

$$\text{iso-}C_4H_{10} + I_2 \rightleftarrows \text{iso-}C_4H_8 + 2HI, \quad (55)$$

$S = -d[I_2]^{1/2}/dt$ and a_1, a_2, and b are constants. An equation similar to Eqn. (54) also describes the kinetics of the dehydrogenation of propane with iodine [143].

c. The Mechanism of the Dehydrogenation Reaction

The dissociation energy of the iodine molecule is low (36 kcal mole^{-1}) and at high temperatures iodine breaks down partially into atoms:

$$I_2 + M \rightleftarrows 2\dot{I} + M. \quad (56)$$

In the reaction with a saturated hydrocarbon molecule the iodine atom abstracts a hydrogen atom, yielding an alkyl radical:

$$n\text{-}C_4H_{10} + \dot{I} \rightleftarrows HI + n\text{-}\dot{C}_4H_9. \quad (57)$$

Depending on the conditions, the alkyl radical undergoes different further reactions. At temperatures up to 500°C and above cracking occurs predominantly in the presence of low iodine concentrations:

$$n\text{-}\dot{C}_4H_9 \rightarrow \dot{C}_2H_5 + C_2H_4, \quad (58)$$

while at higher iodine concentrations butenes are mainly formed:

$$\dot{C}_4H_9 + \dot{I} \rightarrow C_4H_8 + HI. \quad (59)$$

At temperatures much lower than 500°C the amount of dissociated iodine is small and butenes can be produced via the intermediate formation of iodides, for example [133]:

$$\dot{C}_4H_9 + I_2 \rightarrow C_4H_9I + \dot{I}, \quad (60)$$

$$C_4H_9I + \dot{I} \rightarrow \dot{C}_4H_8I + HI, \quad (61)$$

$$\dot{C}_4H_8I \rightleftarrows C_4H_8 + \dot{I}. \quad (62)$$

The kinetic data of Benson and coworkers [142,143] are consistent with the hypothesis that the slowest stage of the reaction is the removal of a hydrogen atom from the saturated hydrocarbon molecule:

$$\dot{I} + RH \rightleftarrows \dot{R} + HI. \quad (63)$$

Eqn. (54), which describes satisfactorily the experimental data for the dehydrogenation of propane and isobutane by iodine, was obtained on the assumption of a steady state for the alkyl radical and alkyl iodide.

According to Raley et al. [133], the conversion of mono-olefins into diolefins is similar to the conversion of saturated hydrocarbons into mono-olefins. The rate of the mono-olefins → diolefins reaction is much higher than that of the saturated hydrocarbons → mono-olefins reaction and the equilibrium yields of diolefins at temperatures of the order of 500°C are lower than those of mono-olefins. This can explain the experimental finding that the diolefins to mono-olefins ratio decreases as the system approaches equilibrium (Table 5).

According to the data of Back and Cvetanovich [144] the conversion of but-1-ene into divinyl at 65°C in the presence of iodine can occur with intermediate formation of iodides and iodine-containing radicals:

$$\dot{I} + C_4H_8 \rightarrow C_4H_8I. \quad (64)$$

C_4H_8I is a radical or π-complex from which a hydrogen atom is removed:

$$C_4H_8I + \dot{I} \rightarrow C_4H_7I + HI. \quad (65)$$

Then follows the rapid stage

$$C_4H_7I + \dot{I} \rightarrow \dot{C}_4H_7I_2, \quad (66)$$

and subsequently

$$\dot{C}_4H_7I_2 + \dot{I} \rightarrow C_4H_6I_2 + HI, \quad (67)$$

$$C_4H_6I_2 \rightarrow C_4H_6 + I_2. \quad (68)$$

Thus according to modern theories, the high-temperature conversion of saturated hydrocarbons into diolefins in the presence of iodine involves a chain mechanism with intermediate formation of hydrocarbon radicals and mono-olefins. The rate of conversion of mono-olefins into diolefins is much higher than that of saturated hydrocarbons into mono-olefins. At lower temperatures there is also the possibility of the intermediate formation of iodides and iodide radicals.

d. Dehydrogenation in the Presence of Acceptors and Solid Catalysts

The iodine which has reacted can be regenerated by means of solid acceptors in accordance with Eqns. (5) and (6). If an acceptor is introduced into the reaction zone, then, as a result of the adsorption of hydrogen iodide, the equilibria of reactions (3) and (51) are displaced towards the formation of diolefins which leads to an appreciable increase in their yields.

The dehydrogenation of n-butane by iodine in a flow reactor at 520–524°C using butane diluted with nitrogen in the proportions butane : nitrogen = 1, in the presence of manganese dioxide as an acceptor, was investigated by Kolobikhin and coworkers [145]. Apart from divinyl and n-butene, cracking products, organoiodine compounds, and resinous and solid products were observed. Hydrogen and isomerisation products do not form in appreciable amounts. As the iodine : butane ratio is increased from zero to 1.43, the yields of divinyl likewise increase and those of butenes and cracking products pass through a maximum. On further dilution with nitrogen from 1 : 1 to 1 : 4, the yields of divinyl change slightly but those of butenes decrease appreciably [146].

The productivity of apparatus for oxidative dehydrogenation with iodine can be enhanced by using reactors with a fluidised acceptor bed [147]. Here the spent acceptor is continuously removed from the reaction zone. On raising the temperature from 480° to 580°C in apparatus with a fluidised acceptor bed the degree of conversion of n-butane increased and the maximum selectivity with respect to dehydrogenation products was observed at 550°C. An increase of the contact time above the optimum value favours cracking and complete oxidation of hydrocarbons by the oxygen of the acceptor.

The dehydrogenation of isopentane in the presence of iodine and manganese oxides shows approximately the same features as the dehydrogenation of n-butane [148].

An increase in the yields of the dehydrogenation products in the presence of iodine can also be achieved by the introduction of solid catalysts which do not behave as acceptors of hydrogen iodide (platinum, palladium, ferrous iodide, cupric iodide, and others) [138,149], whose activity is attributed to their capacity to catalyse the decomposition of hydrogen iodide:

$$HI \rightarrow H_2 + I_2, \quad (69)$$

e. Dehydrogenation in the Presence of Oxygen

Introduction of oxygen into a reaction system containing a saturated hydrocarbon and iodine leads to an appreciable

increase of the yield of diolefins [133,145,148,150,151]. Oxygen-containing organic products are then formed only in small amounts. If oxygen is present in the system, a smaller amount of iodine is required for the attainment of the same yield of divinyl.

The accelerating effect of oxygen on the formation of diolefins is associated primarily with the oxidation of hydrogen iodide by reaction (4), which leads to the regeneration of iodine. There are reasons to believe that the role of oxygen is not restricted to the oxidation of hydrogen iodide. This problem will be discussed in greater detail in subsection 3.

f. Chemical Composition and the Porous Structure of the Acceptor

Apart from manganese oxides, mixtures of iron oxide with potassium iodide [152] and of manganese and calcium oxides [153], nickel oxide [154], copper [155], etc. have been proposed as hydrogen iodide acceptors. The oxides, hydroxides, or carbonates of various metals can also serve as acceptors of hydrogen bromide if bromine is used instead of iodine in the oxidative dehydrogenation [156].

Tyuryaev and coworkers [157,158] made a comparative study of various acceptors. Among the acceptors tested—the oxides of calcium, barium, strontium, zinc, nickel, iron, cobalt, copper, and manganese—the highest yields of isoprene were obtained on barium, calcium, and manganese oxides. Among metal carbonates, the most effective absorbers of hydrogen iodide are sodium and barium carbonates. The manganese oxide giving the highest yield of isoprene is Mn_3O_4. However, on repeated use, all the oxides tested (Mn_2O_3, MnO_2, and Mn_3O_4) exhibit approximately the same properties in the dehydrogenation processes [148]. This is because the reaction of hydrogen iodide with the oxides results, regardless of the composition of the latter, in the formation of manganese(II) iodide, which yields Mn_3O_4 in the regeneration process under the influence of oxygen:

$$3\,MnI_2 + 2O_2 \rightarrow Mn_3O_4 + 3\,I_2. \qquad (70)$$

Calcium oxide is a more active acceptor than calcium carbonate [159]. When the experiments are repeated on any of the above acceptors, the composition of the latter changes to the steady-state composition corresponding to the ratio $CaO : CaCO_3 = 1 : 3-4$ (by weight).

There is a simple relation between the nature of the oxide and the acceptor capacity: the yields of isoprene vary in parallel with the decrease of the free energy of the reaction in which the acceptor combines with hydrogen iodide [157].

Metal oxide acceptors can be prepared by impregnating porous carriers [150,151,153,160]. Kolobikhin and coworkers [160] compared the following materials as carriers for manganese oxides: KSM and steam-treated silica gels, aluminosilicate, and γ-alumina. The yields of divinyl and the selectivity fall with decrease in pore size and with increase of the specific surface, and they depend on the nature of the carrier. Under the experimental conditions [160] the test specimens were regenerated at different rates and the degree of regeneration was not the same. Therefore the reduction of divinyl yields observed on decrease of acceptor pore size can be the result of the overall effect of two factors: incomplete regeneration of the acceptor and decrease of the rate of absorption of hydrogen iodide by the acceptor. Both phenomena may be associated with an increase of inhibition of the process by factors dependent on internal diffusion.

The present author [161] compared the effects of two acceptor specimens: one porous and one with low porosity. The first consisted of calcium oxide deposited on KSK silica gel and the second was obtained by mixing calcium oxide with a small amount of kaolin (Table 6). Whereas high yields of divinyl were obtained on both specimens, very little isoprene was produced in the presence of the porous specimen. It is difficult to explain by internal-diffusion-dependent factors such striking difference in the behaviour of n-butane and isopentane on changing the porous structure of the catalyst, in view of the slight difference in the dimensions of the n-butane and isopentane molecules compared with the dimensions of the pores of the coarsely porous silica gel. We shall return to this problem later.

Table 6. Effect of the porosity of the acceptor on the oxidative dehydrogenation of saturated hydrocarbons.

Catalyst	Specific surface, $m^2 g^{-1}$	Pore volume, $cm^3 g^{-1}$	Hydrocarbon	Yields under optimum conditions, %	
				of di-olefins*	of mono-olefins*
CaO with added kaolin	0.7	0.05	n-butane	69	<1
			isopentane	41	<1
CaO on KSK silica gel	100	0.4	n-butane	67	8
			isopentane	1	26

* With the same number of carbon atoms as the initial saturated hydrocarbon.

3. DEHYDROGENATION IN THE PRESENCE OF OXYGEN AND SMALL AMOUNTS OF IODINE

a. Some Experimental Data

The effect of oxygen on the oxidative dehydrogenation of saturated hydrocarbons in the presence of nearly equivalent amounts of iodine was examined in subsection 2e. Here we shall examine the features of the process in the presence of small amounts of iodine, sufficient only for the initiation or inhibition of reaction. As will be seen below, under these conditions the dehydrogenation reaction has certain specific features.

The variation of the degree of conversion of n-butane with temperature, duration of contact, and the concentrations of iodine and oxygen was investigated by Kuz'michev et al. [108]. The maximum yields of divinyl were obtained at 530°C. At higher temperatures the yields of cracking and combustion products increase and there is more coke formation. In the absence of iodine the main reaction is oxidative cracking†. On addition of small amounts of iodine, the cracking and overall conversion curves pass through a minimum. A sharp increase in the yield of divinyl is observed on raising the iodine : n-butane ratio to 0.05–0.06. On further increase of the concentration of iodine, the change in the yield of divinyl is less pronounced, while the yield of butenes continuously increases. The addition of small amounts of oxygen accelerates mainly the cracking reaction. A considerable increase in the yield of divinyl is observed only for oxygen : n-butane ratios in excess of 0.5.

† Cracking is the main reaction also at much lower temperatures [108].

Adel'son and Nikonov [162,163] did not observe a minimum on the curve relating the degree of conversion to the concentration of iodine in the dehydrogenation of isopentane. The present author investigated [164] the comparative effects of the addition of iodine and hydrogen iodide and bromide on the reaction of n-butane in the presence of oxygen. It was shown that, with the same amount of added halogen, the yields of divinyl decrease in the series HI > I_2 > HBr.

b. The Possible Mechanism of Dehydrogenation in the Presence of Added Halogen

When the hydrocarbon, iodine, and oxygen are present simultaneously, the reaction of the hydrocarbon with iodine takes place more readily than with oxygen. Therefore, according to the existing hypotheses [125,133,165], oxidative dehydrogenation in the presence of both oxygen and iodine has the same mechanism as without oxygen (see subsection 2c), the role of oxygen consisting in regeneration by reaction (4). However, it is quite likely that its role is not limited to interaction with hydrogen iodide but that oxygen participates actively in the intermediate stages of the formation of dehydrogenation products. Then in the presence of equivalent proportions of oxygen and the saturated hydrocarbon small amounts of added iodine can be regarded as reaction initiators. Iodine is known to initiate certain hydrocarbon oxidation reactions at high temperatures [95].

With equivalent proportions of the hydrocarbon and oxygen in the absence of iodine, the main reaction is cracking. The minimum in the degree of conversion at iodine : n-butane ratios between 0.01 and 0.02 can be accounted for by the dual function of iodine: inhibition of the cracking reaction and participation in oxidative dehydrogenation. If the role of iodine was restricted to the initiation of the reaction between the saturated hydrocarbon and oxygen, the addition of iodine would not significantly alter the relative yields of various products but the overall conversion would then certainly be increased. If the role of iodine consisted only in the inhibition of cracking, then, after a decrease in the rate of the latter to a minimum, further addition would not increase the yield of dehydrogenation products. Probably in oxidative cracking unstable intermediate compounds are formed, which are the first to be attacked by the added iodine. On increasing the amount of iodine, the latter acts in addition as a reactant in oxidative dehydrogenation.

At a low iodine concentration the variation of the yield of divinyl with the concentration of oxygen consists of two steps: a significant increase in the yield of divinyl is observed at oxygen : n-butane ratios ranging approximately from zero to 0.1 and from 0.55 to 0.8. It is difficult to explain the second rise in the divinyl yield curve (at high oxygen concentrations) from the standpoint that the role of oxygen is limited to oxidation of the hydrogen iodide produced, since oxygen is in considerable excess relative to the hydrogen iodide present. There are also other grounds to believe that the role of oxygen is not restricted to oxidation of hydrogen iodide. Thus, according to the data obtained by the present author, the introduction of oxygen favours the decomposition of iodine-containing hydrocarbon derivatives into unsaturated compounds. Therefore, apart from the cracking reaction, the role of oxygen consists also in participation in dehydrogenation by oxidising hydrogen iodide and probably in interaction with hydrocarbon molecules or intermediate iodine-containing species.

To investigate the kinetics of dehydrogenation in the presence of added iodine, the present author [166] used a reactor with internal stirring. The order of the divinyl formation reaction and of the overall reaction proved to be 0.4–0.55. This suggests that a hydrocarbon molecule or a hydrocarbon radical participates in the slowest stage and therefore the rate-limiting stage is not the dissociation of iodine [reaction (56)] or oxidation of hydrogen iodide [reaction (4)]. It was also shown that the oxidation of hydrogen iodide is faster than oxidative dehydrogenation [164].

Since reaction (4) is fast, when added iodine is replaced by hydrogen iodide, the reaction system contains almost the same quantity of molecular iodine as when the latter is added directly into the reactor. However, in the presence of hydrogen iodide there is the additional possibility [apart from the dissociation of iodine molecules by reaction (56)] that iodine atoms and also HO_2 radicals will enter the system:

$$HI + O_2 \rightarrow \dot{I} + H\dot{O}_2. \qquad (71)$$

Therefore the yields of divinyl in the presence of hydrogen iodide are higher than with the same amounts of iodine. When iodine is replaced by bromine, the rate of dehydrogenation decreases appreciably because of the higher dissociation energy of the Br–Br bond (46 kcal $mole^{-1}$) compared with the dissociation energy of the I–I bond (36 kcal $mole^{-1}$).

c. Effect of a Solid Surface on Dehydrogenation in the Presence of Oxygen and Added Iodine

When the walls of the quartz reactor are lined with sodium chloride or alumina or a steel reactor is used, the yields of divinyl are appreciably reduced [167]. In order to determine whether the observed effect is due to the inhibiting effect of alumina and sodium chloride or whether, on the other hand, it is caused by the activation of dehydrogenation by the quartz surface, the effect of the volume to surface ratio for the reactor on the degree of conversion of n-butane was investigated. The results show that the walls of the quartz (and also Pyrex) reactor appreciably accelerate the dehydrogenation. For example, when the volume : surface ratio of a quartz reactor was increased from 0.015 to 0.34 cm, the yield of divinyl decreased from 18 to 9%.

The comparative effects of certain solid catalysts on the yields of dehydrogenation products are shown in Table 7. [161,167] Depending on its nature and porous structure, the catalyst accelerates or inhibits the dehydrogenation reaction. The yields of divinyl on silica gel with a specific surface of 24 $m^2 g^{-1}$ are much higher than on quartz. However, on increasing the specific surface to 120 $m^2 g^{-1}$, the efficiency of the process is somewhat reduced. On alumina the yields of divinyl fall appreciably on increasing the specific surface of the catalyst. Other relations are observed for isopentane and n-hexane. The maximum yields of isoprene are obtained on non-porous catalysts, in agreement also with data on the effect of the porosity of the acceptors (Table 6). On the other hand, even alumina with the highest specific surface has a favourable effect on the dehydrocyclisation of n-hexane.

Apart from the substances listed in Table 7, other active catalysts have been proposed for the dehydrogenation of saturated hydrocarbons in the presence of added iodine: halides of alkali and transition metals and silver on silica gel or α-alumina [168–172], Fe_3O_4, and lithium hydroxide [173].

d. Possible Role of the Solid Catalyst

Since, as in the absence of iodine (subsection 1c), it is unlikely that the acceleration of dehydrogenation in the presence of solid catalysts is due to a major change in the reaction mechanism, as usually happens in heterogeneous catalysis, it follows that in the presence of the catalyst the rate of reaction does not change much relative to the rate in the empty reactor and that the selectivity of the process does not change appreciably (Table 7). For the latter reason, it is also difficult to suppose that the role of the catalyst consists in chain termination for the competing reaction. The more likely hypothesis is that the reaction mechanism remains largely unchanged; the reaction takes place in the bulk-phase but the active surface accelerates the slowest stages.

Table 7. Effects of solid catalysts on oxidative dehydrogenation (hydrocarbon : oxygen : nitrogen = 1 : 1 : 10, temperature 530–540°C).

Catalyst	Specific surface, $m^2 g^{-1}$	Pore volume, $cm^3 g^{-1}$	Yields, % of divinyl from n-butane $\varphi = 0.03$* w.r.t. starting material	Yields, % of divinyl from n-butane $\varphi = 0.03$* w.r.t. product	Yields, % of isoprene from isopentane $\varphi = 0.08$ w.r.t. starting material	Yields, % of isoprene from isopentane $\varphi = 0.08$ w.r.t. product	Yields, % of benzene from n-hexane $\varphi = 0.04$ w.r.t. starting material	Yields, % of benzene from n-hexane $\varphi = 0.04$ w.r.t. product

* φ is the iodine : hydrocarbon molar ratio.

** At the same flow rate as in the experiments with catalysts.

Kolobikhin et al.[172] believe that the accelerating effect of solid catalysts on the oxidative dehydrogenation of n-butane in the presence of oxygen and added iodine is associated with the catalysis of the oxidation [according to the overall Eqn. (4)] of the hydrogen iodide formed in the dehydrogenation. Indeed, solid materials such as broken quartz, silica gel, and other silicon-containing substances catalyse the oxidation of hydrogen iodide with oxygen[174–177]. However, this finding alone is insufficient to explain the activating effect of catalysts; one might expect the acceleration of the oxidative dehydrogenation by catalysts for the oxidation of hydrogen iodide only if the hydrogen iodide oxidation stage was the slowest in oxidative dehydrogenation, but this is not confirmed experimentally (see subsection 3b). Indeed the present author's data[164] show that there is no parallel variation of the activity of the catalyst in oxidative dehydrogenation and the acceleration of the oxidation of hydrogen iodide.

It follows from Tables 6 and 7 that the wide differences in the effect of the porous structure on the reactions of n-butane, isopentane, and n-hexane are associated mainly with the secondary reactions of unsaturated products[161]. The present author investigated[161] the reactions of divinyl and isoprene on quartz, silica gels, and alumina. Divinyl and isoprene are converted mainly into coke-like and tarry products. At 530°C, with the ratios divinyl : iodine : oxygen : nitrogen = 1 : 0.03 : 1 : 10 and a duration of contact of 0.6 s, 22% and 42% of divinyl react respectively in the empty reactor and in the presence of silica gel. Therefore the increased yield of divinyl in the dehydrogenation of n-butane in the presence of silica gel, relative to the empty reactor (Table 7), cannot be due to the inhibition of the decomposition of the divinyl formed. Under these conditions almost complete reaction of divinyl was observed on γ-alumina, which probably accounts for the absence of divinyl from the n-butane reaction products on this catalyst.

Isoprene enters into secondary reactions much more readily than divinyl and this probably explains the decrease of its yield with increasing porosity of the catalysts, this being observed both in experiments with small amounts of iodine (Table 7) and in the presence of acceptors (Table 6). Thus the effect of the solid catalyst on oxidative dehydrogenation in the presence of iodine and oxygen is complex and probably consists in the acceleration of the slow stage of the process and in the participation of the catalyst in secondary reactions of the products.

---o0o---

In recent years significant advances have been achieved in the field of oxidative dehydrogenation of hydrocarbons. Conditions have been found under which the formation of dehydrogenation products in considerable yields is the dominant process in the reaction between the hydrocarbon and an oxidising agent. The oxidising agents may be oxygen or halogens and also substances which give rise to them on decomposition.

On interaction with oxygen, the dehydrogenation of mono-olefins to more unsaturated hydrocarbons takes place in the presence of heterogeneous catalysts. There are virtually no such catalysts for the dehydrogenation of saturated hydrocarbons. The use of iodine-containing substances even in small amounts makes it possible to dehydrogenate fairly readily not only olefins but also saturated hydrocarbons. An increase in the degree of unsaturation of the product is favoured by the introduction into the reaction zone of hydrogen iodide acceptors.

Solid catalysts which are not acceptors and which are capable of accelerating appreciably the oxidative dehydrogenation of saturated hydrocarbons are also known, but their effect on the process is radically different from that of the catalysts for the oxidative dehydrogenation of olefins. While the latter is a typical heterogeneous-catalytic reaction, the homogeneous chain-radical mechanism probably persists in the presence of catalysts suitable for oxidative dehydrogenation of saturated hydrocarbons and the role of the solid surface may consist in the acceleration of the slowest stages of the process.

9. Infrared spectra of substituted 1,3-dioxans 23
10. Synthesis of 1,3-dioxans from terpene hydrocarbons 23

In their review Arundale and Mikeska[1] made a thorough compilation of extensive data on the reaction of olefins with aldehydes and the use of the reaction products in organic synthesis. In recent years numerous papers have appeared in the scientific literature dealing with the mechanism and the chemistry of the Prins reaction and also the possibility of using ion-exchange resins as catalysts, first demonstrated in our laboratory[2].

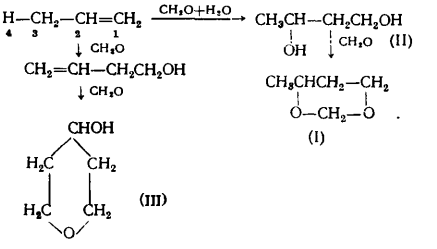
We attempted to review the literature for the period 1953–1965.

1. SYNTHESIS OF 1,3-DIOXANS FROM OLEFINS IN THE PRESENCE OF ACID CATALYSTS

a. Condensation of Olefins with Formaldehyde† in the Presence of Acid Catalysts

In the presence of acid catalysts the main products are 1,3-dioxan and 1,3-glycol. The highest rate of condensation is observed in the reaction of isobutene with formaldehyde. Tertiary olefins with high molecular weights, straight-chain olefins, and also higher aldehydes are less reactive. Apart from the acid catalysts used earlier for the reaction (sulphuric, acetic, hydrochloric, and hypochlorous acids), nitric acid[3] and KU-2 cation-exchange resin[2] have been employed.

In the reaction between propene and formaldehyde investigated by Farberov and coworkers[4,5] optimum conditions are attained at sulphuric acid concentrations of 1–5 wt. %. In the presence of acid of this concentration the main products are 4-methyl-1,3-dioxan (I) (85% yield), butane-1,3-diol (II) (3–5% yield), 1-hydroxytetrahydropyran (III) (7–8% yield), and traces of allylmethanol:



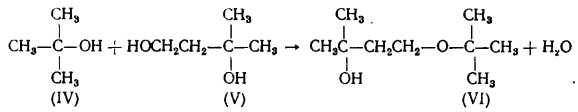
According to the hypotheses put forward by Nesmeyanov and Kabachnik[6], olefins of this type are characterised by

† In some cases formaldehyde is denoted by fa.

the presence of σ, π-conjugation, as a result of which they are capable of two types of reaction, at 1,2- and 1,4-bonds. On the other hand, with isobutene virtually only 1,2-addition takes place (evidently because of the higher rate of this reaction). 4-Acetoxytetrahydropyran was obtained in the condensation of propene in the presence of acetic acid[7]. Isobutene readily condenses with various aldehydes, a complex mixture of products, from which 26 different compounds were isolated, being formed in addition to the main reaction products 1,3-dioxan and 1,3-glycol[8,9].

There exist two views concerning the mechanism of the formation of the dioxan and diol under the conditions of the Prins reaction. In later studies it was assumed that the dioxan and diol may form simultaneously[10]. The mechanism of the Prins reaction will be discussed in detail below.

In the condensation of isobutene with formaldehyde a considerable amount of t-butyl alcohol (IV) forms, and under the conditions of the Prins reaction the latter can react with the 3-methylbutane-1,3-diol (V) produced to give 2-hydroxy-2-methyl-4-t-butoxybutane (VI):



Trenke and Nemtsov[11] were the first to draw attention to this reaction. They hydrolysed the hydroxy-ether obtained in an acid medium both in the presence and in the absence of formaldehyde. t-Butyl alcohol and 3-methylbutane-1,3-diol were obtained in the first case. Hydrolysis in the presence of formaldehyde gave 4,4-dimethyldioxan and t-butyl alcohol; at 98°C the hydrolysis is extensive and rapid in both cases.

Methyldihydropyran and the isomeric methylenetetrahydropyran were also found in the products of the condensation of isobutene and formaldehyde[11,12]. Under the reaction conditions methyldihydropyran reacts with formaldehyde to form a compound containing the pyran and dioxan rings–methyltrioxaperhydronaphthalene[12-14]. In the same papers it is stated that the reaction products contain 4-methyl-4-vinyl-1,3-dioxan and methyldioxanyldioxan.

Under the conditions of the Prins reaction there is also the possibility of the occurrence of the Cannizaro–Tishchenko side-reaction, in which formic acid is formed from formaldehyde and water:

$$2\,CH_2O + H_2O \rightarrow HCOOH + CH_3OH\,.$$

The loss of formaldehyde by this reaction was investigated by Farberov and Speranskaya[15].

The concentration of sulphuric acid used as the catalyst and the reaction temperature have a profound effect on the yield of the main products. The study of the effect of the concentration of the acid on the rate of reaction showed that the latter is proportional to the acid concentration[10]. However, in order to improve the selectivity of the process, it is preferable to use dilute acid solutions (up to 5 wt.%)[4,5]. The Prins reaction also takes place at room temperature, but useful rates of conversion of isobutene are attained only at 70–100°C.[16]

It has been stated in recent communications that, apart from sulphuric acid, cation-exchange resins can be used as catalysts in this reaction[2,17-20]. The application of Amberlite IR-120 and KU-2 resin (the latter produced in the USSR)[21] resulted in a 56% yield of dimethyldioxan with respect to the unreacted olefin. Ion-exchange resins as catalysts have a number of advantages, which are particularly important in the industrial application of the process.

Compared with isobutene, straight-chain butenes are much less reactive. In the condensation of a mixture of butenes, containing 20% of isobutene and 37% of straight-chain butenes, with formaldehyde during 5 h at 70°C, 70% of isobutene and only 3% of butenes reacted[17], but-2-ene reacting somewhat faster than but-1-ene[9,22]. In 3 h at 90°C 4-ethyl-1,3-dioxan was obtained from but-1-ene in 34% yield and a mixture of *cis*- and *trans*-isomers of 4,5-dimethyl-1,3-dioxan was obtained from but-2-ene in 74% yield. According to Farberov's data[4], straight-chain butenes are approximately equally reactive.

The condensation of pentenes with formaldehyde was investigated very recently using KU-2 cation exchanger as catalyst[23]. Substituted 1,3-dioxans are formed. The dioxan fraction (b.p. 152–154°C, yield 66.3%) isolated from the reaction products consisted of 4,4,5-trimethyl-1,3-dioxan and 5-ethyl-4-methyl-1,3-dioxan. t-Pentyl alcohol was also isolated from the products. The reactivities of the isomeric pentenes have been compared.

b. Condensation in the Presence of Heterogeneous Acid Catalysts at High Temperatures

This method has been described only in the patent literature[24-31]. It consists essentially in passing the olefin, aldehyde, and an inert diluent at 250–400°C over heterogeneous catalysts. Under these conditions, diene hydrocarbons are produced:

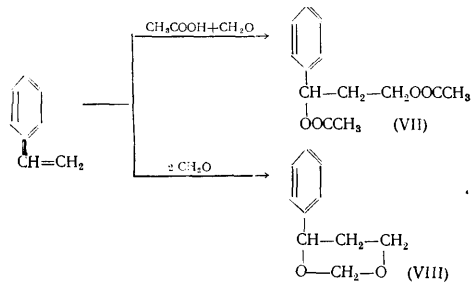
The best results were obtained when olefins with a tertiary carbon atom were used.

The reaction is carried out in the presence of a large excess of olefin (olefin : formaldehyde = 8 : 1), probably in order to suppress side-reactions, which lead to the formation of high-molecular-weight oxygen-containing products. In addition, the reaction products are diluted with a large volume of an inert diluent (nitrogen, carbon dioxide, lower saturated hydrocarbons) to suppress the polymerisation and condensation reactions. In this method the catalysts are mineral acids deposited on activated alumina, silica gel, magnesium oxide, or boron trioxide, synthetic catalysts for the cracking of petroleum, etc. The reactions take place at the normal or elevated (up to 7 atm) pressures. 4,4-Dimethyldioxan is also obtained in the condensation of isobutene with formaldehyde, using silica gel or aluminosilicates as catalysts at 500°C.[32] The acidity of the catalyst has a decisive effect on the yield of the main product in this case. Thus at $H_0 = 1.5$–3.8 (silica gel) a 97% yield of 4,4-dimethyldioxan was obtained.

2. SYNTHESIS OF 1,3-DIOXANS FROM ARYL-SUBSTITUTED OLEFINS

The literature dealing with the condensation of aryl-substituted and cyclic olefins was not reviewed by Arundale and Mikeska[1]. The condensation of styrene with formaldehyde in the presence of a mixture of sulphuric and glacial acetic acids was first investigated by Prins[33]. As a result of the condensation, he obtained the diacetate of

1-phenylpropane-1,3-diol and a certain amount of 4-phenyl-1,3-dioxan:

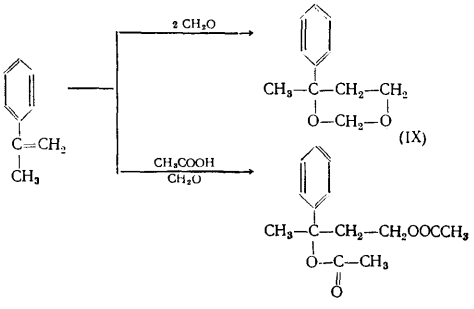


However, Prins erroneously regarded these compounds as derivatives of 2-phenylpropane-1,3-diol. Their true structure was established later[34].

It is noteworthy that, when the reaction is carried out in acetic acid solution, the yield of 4-phenyl-1,3-dioxan (VIII) is reduced due to the formation of the acetates of 1-phenylpropane-1,3-diol (VII). When 1,4-dioxan is used as the solvent, the yield of 4-phenyl-1,3-dioxan is increased to 78%.[35] With hydrochloric acid as the catalyst[36], the reaction can be carried out also in an inert hydrocarbon solvent. 4-Phenyldioxan was obtained in 88% yield by the condensation of styrene with a 37% solution of formaldehyde in the presence of sulphuric acid[35].

Backer[37] noted that the reaction of α-methylstyrene with formaldehyde in a mixture of 100% sulphuric and glacial acetic acids at 40°C is accompanied by extensive polymerisation of α-methylstyrene. Polymerisation can be partially suppressed if the reaction is performed at 0°C, but at this temperature the conversion of α-methylstyrene is low.

The reaction of α-methylstyrene with formaldehyde in the presence of a mixture of sulphuric and acetic acids has the following mechanism:



If orthophosphoric acid is used as the catalyst, the yield of 4-methyl-4-phenyl-1,3-dioxan (IX) can be increased to 75% with respect to the aldehyde.

4-Acetoxy-2-phenylbut-1-ene was obtained in 70% yield in the condensation of α-methylstyrene with formaldehyde in the presence of acetic acid[38]. Farberov[4] showed that the condensation of α-methylstyrene with formaldehyde is quite possible in the presence of 1–1.5% sulphuric acid. Here the yield of 4-methyl-4-phenyl-1,3-dioxan was 85%. In their study of the products of the reaction of anethole with formaldehyde by the NMR method, Smissman et al.[39] noted only the formation of the *cis*-isomers of 1,3-dioxan.

A detailed study of the condensation of α-methylstyrene with formaldehyde was made by French chemists[40], who used various methods for the identification of the chemical compounds (infrared spectroscopy, preparative chromatography, etc.) and isolated and described 15 compounds formed in this system. The reaction of α-methylstyrene with 37% aqueous solution of formaldehyde in the presence of KU-2 resin as the catalyst has been investigated[41].

3. SYNTHESIS OF 1,3-DIOXANS FROM HALOGENO-OLEFINS

Monohalogeno-olefins can react with formaldehyde to form halogeno-1,3-dioxans. 4-Chloromethyl-4-methyl-1,3-dioxan and 3-chloromethylbutane-1,3-diol are formed in the condensation of methylallyl chloride with paraformaldehyde in the presence of sulphuric acid or $BF_3.O(C_2H_5)_2$.[42]

Farberov and coworkers[43] investigated in detail the reaction of chloropropenes with paraformaldehyde under various conditions. The first attempts to prepare halogeno-substituted aryl-1,3-dioxans from halogenostyrenes proved unsuccessful. Beets and Drukker[44] failed in their attempt to condense α- and β-bromostyrenes with formaldehyde in the presence of 5% sulphuric acid. When 50% sulphuric acid was used, 4-aryl-5-halogeno-1,3-dioxans were obtained in 60–90% yield[45].

The work of Japanese and Italian chemists dealing with the condensation of β-bromostyrene and β-bromo-*p*-nitrostyrene with paraformaldehyde was published comparatively recently[46-48]. These studies are of great theoretical interest, since they led to the correction of certain aspects of the mechanism and stereochemistry of the Prins reaction. It is known that the electrophilic addition to carbon–carbon double bonds takes place in the *trans*-position, and this also holds for the Prins reaction.

It was shown in the above investigations that under certain conditions the Prins reaction is stereospecific, i.e. involves *cis*-addition. Thus *cis*-5-bromo-4-phenyl-1,3-dioxan was obtained in the condensation of *trans*-β-bromostyrene with paraformaldehyde.

While the condensation of monohalogeno-olefins with formaldehyde in the presence of dilute mineral acids leads to the formation of halogenated 1,3-dioxans, polyhalogeno-olefins give halogeno-substituted hydroxy-acids or alcohols, depending on the nature and concentration of the catalyst. Halogeno-substituted hydroxy-acids and their esters are obtained in the condensation of di-, tri-, and tetra-chloroethylene with formaldehyde in the presence of dilute sulphuric acid[49]. The condensation of the same olefins with paraformaldehyde in the presence of hydrochloric acid yields chloropropanols[50]. When paraformaldehyde is condensed with trichloroethylene in the presence of aluminium chloride as the catalyst, $\alpha\beta$-dichloropropionic acid, 2,3,3,3-tetrachloropropan-1-ol together, and di(2,3,3,3-tetrachloropropyl) ether are obtained[51].

4. SYNTHESIS OF 1,3-DIOXANS FROM CYCLIC OLEFINS

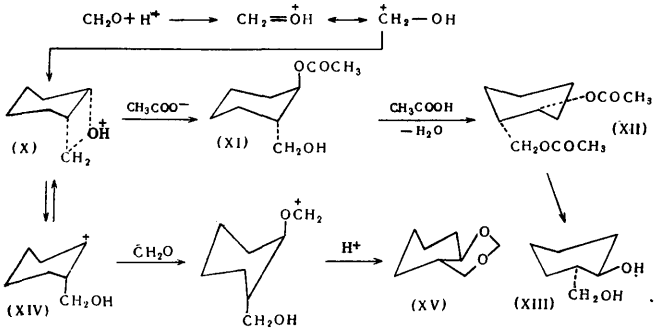
Arundale and Mikeska[52] were the first to show that in the presence of 45–55% sulphuric acid it is possible to condense cyclic olefins with formaldehyde to form 1,3-dioxans. When the reaction is carried out in the presence of sulphuric and acetic acids, the products include, together with 1,3-dioxans, a complex mixture, the main components of which are the diacetate of 2-hydroxymethylcyclohexanol, 3,4-tetramethylene-2,5-dihydrofuran, and 1-hydroxymethylcyclohexene[53-59].

Blomquist and Wolinsky[58] and Smissman and Mode[60] showed that the condensation of cyclohexene with formaldehyde in the presence of acid catalysts is a special case

of the electrophilic addition of an aldehyde to an olefin double bond[61-63]. The above workers noted that only the *trans*-isomers are formed in the reaction of cyclohexene with formaldehyde.

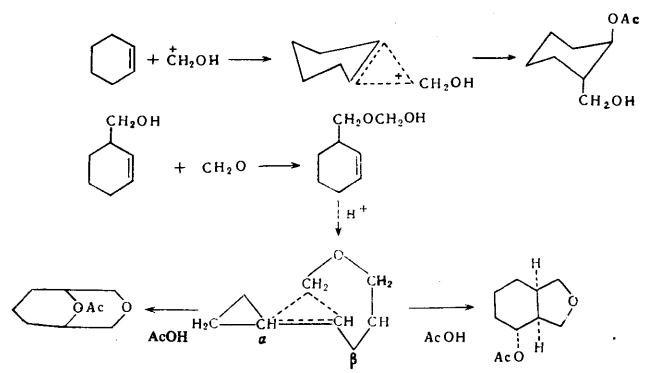
The high stereospecificity of the Prins reaction leads to the formation exclusively of *trans*-2-hydroxymethylcyclohexanol and also substituted 3-oxabicyclononanes in which the substituent in the hydrocarbon ring is in the *trans*-position relative to the heterocycle formed by *cis*-closure.

Blomquist and Wolinsky proposed a mechanism for the Prins reaction, which accounts for its stereoselectivity[58]. As a result of the protonation of formaldehyde and the attack by a solvated carbonium ion on the olefin double bond, a hybrid oxonium–carbonium ion, (X) ⇌ (XIV), is formed. The acetate ion attacks the oxonium–carbonium ion (X) from the least screened side, which leads to the formation, via a diaxial monoacetate stage (XI), of *trans*-diequatorial diacetate (XII), whose hydrolysis yields the diol (XI); the attack of formaldehyde on the carbonium ion (XIV) and subsequent cyclisation yield *trans*-1,3-dioxan (XV):



However, this mechanism does not explain the formation of side-products.

Dolby[59] proposed another mechanism for the Prins reaction. The intermediate product, which in Dolby's view controls the stereochemistry of the reaction, is a three-membered cyclic ion, analogous to the intermediate products suggested by other workers for electrophilic addition at the double bond:



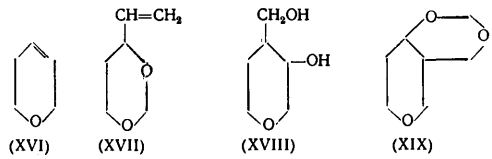
Smissman and coworkers studied the mechanism and the stereospecificity of the Prins reaction using the condensation of anethole with formaldehyde in the presence of an acid catalyst as an example[64,65].

The Prins reaction has been extended to the condensation of olefins not only with aldehydes but also with ketones. Fodor and coworkers[66] showed that 2-(α-hydroxyisopropyl)cyclohexanol forms (after hydrolysis) in the reaction of cyclohexene with acetone in the presence of sulphuric acid.

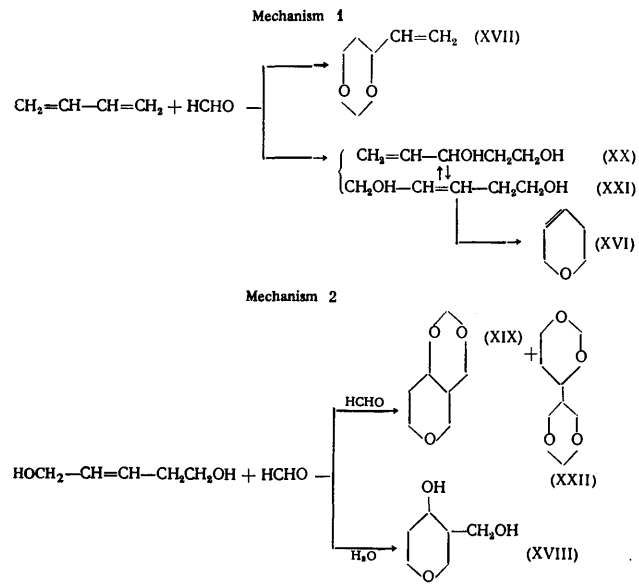
The condensation of cyclohexene and other cyclic olefins with formaldehyde in the presence of KU-2 cation-exchange resin has been investigated[67].

5. SYNTHESIS OF 1,3-DIOXANS FROM DIOLEFINS

A very small number of papers dealing with the condensation of diolefins with formaldehyde has been published. In 1955 Hanschke[68] showed that the condensation of butadiene with two moles of formaldehyde in the presence of sulphuric acid at 80°C yields a mixture of products, from which he isolated and identified 5,6-dihydro-2*H*-pyran (XVI), 4-vinyl-1,3-dioxan (XVII), tetrahydro-4*H*, 5*H*-pyrano[3,4-*d*]-1,3-dioxan (XIX), and the corresponding glycol (XVIII).



Extensive studies on the Prins reaction have been made in recent years at the French Petrochemical Institute. At the end of 1964 Hellin et al.[69] at this Institute published a paper describing the butadiene–formaldehyde system under the conditions of the Prins reaction. They studied the reaction at 80°C in aqueous sulphuric acid with the molar ratio formaldehyde : butadiene = 2; the duration of the reaction was varied from 30 min to 4 h. The authors quote the following two reaction mechanisms:

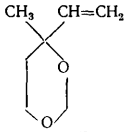


In mechanism 1 two isomers of pentenediol (XX) and (XXI) are formed as a result of 1,2- or 1,4-addition to butadiene. Of these isomers, the second, which has two primary hydroxyls and a double bond within the chain, [isomer (XXI)] is the more likely. Dihydro-5,6-α-pyran (XVI), which is one of the main products of the Prins reaction, forms on intramolecular conversion of pent-2-ene-1,5-diol (XXI) into an ether.

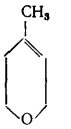
The multiplicity of the possible modes of the reaction leads to the formation of higher condensation products. In particular, diols with a double bond (see mechanism 2)

can react directly with formaldehyde to form large molecules—*trans*-trioxaperhydronaphthalene (XIX), dioxanyldioxan (XXII), and *trans*-hydroxyethyltetrahydropyranol (XVIII). The simultaneous presence of trioxaperhydronaphthalene and dioxanyldioxan confirms the above view rather than the possible occurrence in this case of the Prins reaction with 4-vinyl-1,3-dioxan.

The reaction with isoprene is even more complex[70]. The primary products are 4-methyl-4-vinyl-1,3-dioxan (XXIV) and 4-methyldihydro-5,6-pyran (XXV),

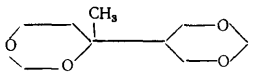


(XXIV)

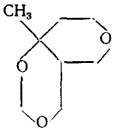


(XXV)

whose subsequent reactions lead to the appearance of more complex products: 5-(4′-methyl-1′,3′-dioxan-4′-yl)-1,3-dioxan (XXVI), *cis*- and *trans*-10-methyl-1,3,7-trioxaperhydronaphthalenes, and the corresponding diols:



(XXVI)



(XXVII)

In the USSR the reaction of diene hydrocarbons with formaldehyde in the presence of hydrochloric acid was investigated by Ustavshchikov and Fel'dblyum[71]. The reaction was studied mainly using butadiene (divinyl). The main reaction products were isolated and characterised. The reaction of the closest butadiene homologues, piperylene and isoprene, were studied in less detail. The reaction was carried out for 3–5 h at 20°C with the molar ratios diene : CH_2O : HCl = 1 : 1 : 2. It was established, on the basis of the rate of disappearance of formaldehyde, that piperylene and isoprene react approximately 1.5 times faster than divinyl.

In the reaction with divinyl the main products are 4-vinyl-1,3-dioxan, 3-chloromethyl-4-chlorotetrahydropyran, and the formals of the isomeric unsaturated chlorohydrins, for example 1-chloropent-2-en-5-ol. The cyclic formal of 3-hydroxymethyltetrahydropyran-4-ol was also isolated in small amounts.

In contrast to divinyl, piperylene and isoprene are mainly hydrochlorinated under the reaction conditions with formation of isomeric chloropentenes; 1,3-dioxans and the corresponding dichloro-derivatives of alkyl-tetrahydropyrans are also formed.

On the basis of their results, the authors proposed the following mechanism for the reaction between dienes and formaldehyde. Apparently the initial step is the protonation of the oxygen atom of formaldehyde:

$$\overset{+}{H} + O{=}CH_2 \rightleftarrows HO\overset{+}{C}H_2 .$$

The hydroxymethylcarbonium ions attack the diene molecules with formation of the carbonium ions A and B,

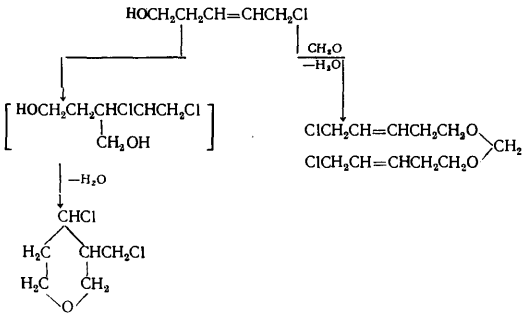
$$CH_2{=}CH{-}CH{=}CH_2 + \overset{+}{C}H_2OH \longrightarrow \begin{cases} \overset{+}{C}H_2{-}CH{=}CH{-}CH_2CH_2OH & (A) \\ CH_2{=}CH{-}\overset{+}{C}H{-}CH_2CH_2OH . & (B) \end{cases}$$

whose reaction with formaldehyde or a chloride ion leads to the formation of 1,3-dioxan or chlorohydrin respectively:

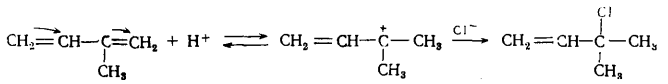
$$\overset{+}{C}H_2{-}CH{=}CH{-}CH_2CH_2OH \xrightarrow{Cl^-} ClCH_2{-}CH{=}CH{-}CH_2CH_2OH$$

$$CH_2{=}CH{-}\overset{+}{C}HCH_2CH_2OH \xrightarrow[-H^+]{CH_2O} CH_2{=}CH{-}\underset{\displaystyle O{-}CH_2{-}O}{\overset{\displaystyle |}{CH}}{-}CH_2{-}CH_2$$

Dioxan has actually been isolated as one of the reaction products. The chlorohydrin probably undergoes secondary reactions by the mechanism



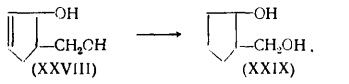
When the diene is isoprene or piperylene, the protons can also react directly with the latter, which leads to the formation of carbonium ions derived from hydrocarbons and the final products are chloropentenes:



However, the mechanism of the formation of the other products is the same.

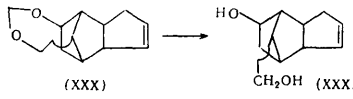
Beets and Drukker[44] investigated the reaction of cyclopentadiene with formaldehyde. When the reaction was carried out in an autoclave at 185°C without catalysts, only a resinous product was obtained. When cyclopentadiene was treated with an excess of 36% aqueous solution of formaldehyde in the presence of sulphuric acid, the authors obtained 2-hydroxymethylcyclopent-4-enol (XXVIII) in 20% yield and the corresponding dioxan. The cyclopentadiene reacted completely; also present were high-boiling products, from which the pure components could not be isolated. When the amount of formaldehyde per mole of diene was reduced from 2.72 to 1.23 moles, the yield of the corresponding dioxan fell and the amount of hydroxylated high-boiling products increased.

2-Hydroxymethylcyclopent-4-enol (XXVIII) was also obtained on heating cyclopentadiene in acetic acid solution with formaldehyde in the presence of catalytic amounts of toluenesulphonic acid. Its structure was demonstrated by conversion into the saturated diol (XXIX) by catalytic hydrogenation:



(XXVIII) (XXIX)

Zimmermann and Reiners described the Prins reaction with dicyclopentadiene[73]. They carried out the reaction in formaldehyde solution in the presence of sulphuric acid at 80°C. The dioxan (XXX) probably forms under the reaction conditions. The diol (XXXI) was obtained by the reaction of the same compound with an excess of methyl alcohol and a small amount of sulphuric acid:



(XXX) (XXXI).

6. SYNTHESIS OF 1,3-DIOXANS FROM ENYNE AND DIENYNE HYDROCARBONS

The first studies on the condensation of enyne and dienyne hydrocarbons with formaldehyde in the presence of sulphuric acid were made by Matsoyan and Saakyan[74]. It was established that formaldehyde reacts selectively with dienes, the reaction involving exclusively the substituted double bond of the divinylacetylene hydrocarbon. During the condensation substituted 1,3-glycols are formed in small amounts as side-products, but they are difficult to purify.

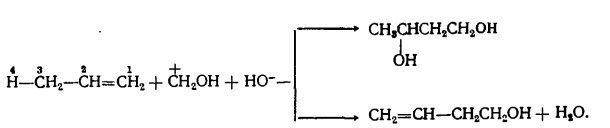
The reaction of formaldehyde with tertiary vinylacetylene alcohols was carried out using KU-1 and KU-2 cation-exchange resins as the catalysts[75]. It was shown that in this case the main products are 1,3-dioxans and a small amount of 1,3-glycols of the vinylacetylene series. The authors of the present review made a detailed study of the optimum conditions for the condensation of ethynyldimethylvinylmethanol with formaldehyde in the presence of KU-2 cation-exchange resin[76].

7. THE MECHANISM OF THE PRINS REACTION

Franzen and Krauch[77] believe that the initial step in the reaction is the addition of a proton to the oxygen atom of the carbonyl group with formation of the carbonium ion $R-\overset{+}{C}-OH$, which then attacks the double bond at the site of the highest electron density. The new carbonium ion can react further in three ways. In the interaction with an excess of the aldehyde, dioxan is produced, the reaction with water leads to the formation of a glycol, and, finally, the removal of a proton results in the formation of an unsaturated alcohol. The glycol and dioxan are formed independently of one another; although the glycol can, in fact, be produced from 1,3-dioxan, under the reaction conditions this happens rarely.

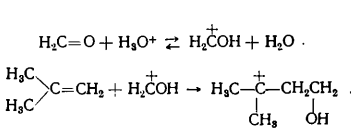
The third reaction, i.e. the removal of a proton, is observed only in the addition of formaldehyde. A proton is removed (in accordance with the Hofmann rule) from the carbon atom adjacent to the carbonium centre which has the smallest number of substituents. The removal of a proton from the CH_3 group can be facilitated by the presence of a hydroxyl. The formation of the glycol greatly depends on the basicity of the medium, since at high pH values the 1,3-glycol decomposes into an olefin and an aldehyde.

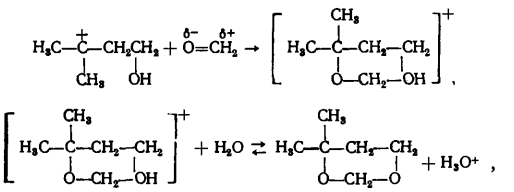
According to Farberov's hypotheses[4,5], the diol results from the reaction at 1,2-bonds and the unsaturated alcohol from the reaction at 1,4-bonds:



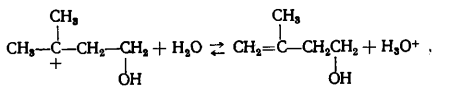
Generalising the results obtained, the following general mechanism of the Prins reaction can be put forward[20,78], for isobutene and formaldehyde as examples:

a. main reaction:

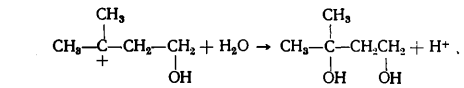




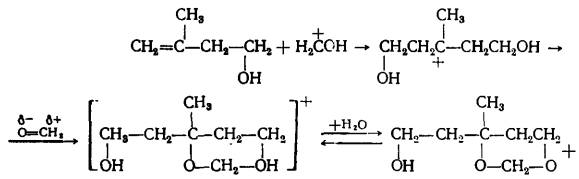
b. side-reactions:



(1)

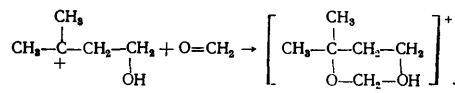


(2)



(3)

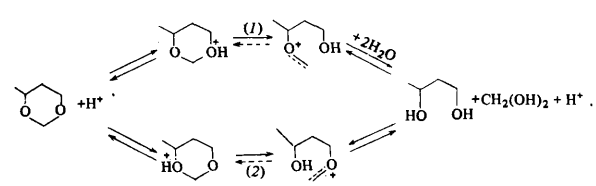
Kinetic studies show that the reaction on ion-exchange resins is of third order, and the rate-limiting stage is the reaction of the secondary carbonium ion with the aldehyde[20]



8. PROPERTIES AND APPLICATIONS OF 1,3-DIOXANS

1,3-Dioxans are widely used as the starting materials for the synthesis of varnishes[79], resins[80], detergents[81], antibiotics[46,47], and insecticides[82]. In practice the most important are the syntheses of diene hydrocarbons based on them. Since hydrolysis is an intermediate stage of the conversion of alkyldioxans into dienes, a number of papers dealing with this problem has appeared in recent years in the scientific literature. In the hydrolysis (methanolysis) of alkyl-1,3-dioxans in the presence of small amounts of sulphuric acid and an excess of methyl alcohol, it proved possible to isolate diols in yields of up to 80%.[83] However, the hydrolysis of alkyldioxans in which the oxygen atom is linked to a tertiary carbon atom is much more difficult. The yield of the diol is at best not more than 50%. Using a cation exchanger instead of sulphuric acid in the methanolysis of 4-methyl-1,3-dioxan, the diol was obtained in quantitative yield[84].

The kinetics of the hydrolysis of a number of substituted 1,3-dioxans in water and aqueous dioxan have been investigated at 60–70°C.[85-87] The hydrolysis of 1,3-dioxans can take place in two ways:



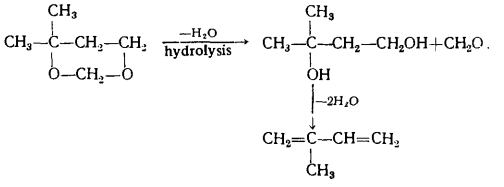
Kinetic measurements show that the first mode of reaction is the more likely.

Dehydration of glycols leads to the formation of the corresponding diene hydrocarbons, but since the yield of glycols is low because of hydrolysis, this method is unsuitable for the industrial manufacture of diene hydrocarbons. Therefore another procedure was chosen, which permits the synthesis of diene directly in one stage—the catalytic dissociation of alkyldioxans in the presence of suitable catalysts. The choice of the catalyst capable of selective dissociation of the alkyldioxan with a high activity was difficult because reactions of this kind had not been investigated in chemical engineering.

The patent literature describes methods of synthesising dienes on the basis of dioxans[1], but in the scientific literature this process had not been elucidated until the publication of the work of Farberov and coworkers[88]. In the course of their studies over a number of years on the synthesis of isoprene from isobutene and formaldehyde, they investigated in detail the catalytic dissociation of 4,4-dimethyl-1,3-dioxan to isoprene in the gas phase over a solid catalyst.

Best results were obtained when Group II metal phosphates were used as catalysts, in particular calcium phosphates. These catalysts are very active and selective, exhibit high productivity, and are fairly stable. An essential condition is that the process be carried out in the presence of water vapour, which is probably connected with the dehydration of acid calcium phosphates.

Bearing in mind that an increase in the concentration of water vapour in the reaction mixture results in an acceleration of the catalytic dissociation of dimethyldioxan, Farberov proposed a mechanism, according to which water participates directly in the reaction. As a result of the reaction with water, dimethyldioxan is hydrolysed on the catalytic surface to the diol, which is then dehydrated to give isoprene:



As a result of a detailed study of the conditions of the catalytic dissociation of dimethyldioxan [at 375°C, 1 : 14 (molar ratio) dilution with water vapour, volume flow rate of dimethyldioxan 0.7 ml per ml of catalyst per hour] isoprene yields of 75–85% with respect to the dioxan passed through and 80–85% with respect to the dioxan decomposed were attained. The method thus developed served as the basis of the industrial manufacture of isoprene of a high degree of purity.

9. INFRARED SPECTRA OF SUBSTITUTED 1,3-DIOXANS

The available data on the infrared spectra of 1,3-dioxans reveal a very complex structure of the bands, the number of characteristic bands being variable[21,89,90]. 1,3-Dioxans substituted in position 4 constitute a system characterised by four bands[85]: two very intense bands in the region 1166 ± 20 cm^{-1} and 1037 ± 15 cm^{-1} and two other less intense bands in the region 1090 ± 25 cm^{-1} and 985 ± 10 cm^{-1}.

10. SYNTHESIS OF 1,3-DIOXANS FROM TERPENE HYDROCARBONS

Until recently the behaviour of the extensive class of terpene hydrocarbons in the Prins reaction was virtually uninvestigated, although the possibility of the condensation of aldehydes with olefins was first demonstrated by Prins for α-pinene and camphene as examples[91]. However, Prins did not investigate these reactions in detail and merely indicated the physicochemical characteristics of some of the condensation products (without stating the yield). Serious studies on the condensation of α-pinene, camphene, dipentene, and β-pinene were begun by Japanese chemists. Watanabe, who studied the condensation of formaldehyde with α-pinene in a mixture of acetic and phosphoric acids and acetic anhydride, obtained a mixture of the acetates of α-terpineol, (±)-isoborneol, and 6-acetoxymethyl-$\Delta^{1,8(9)}$-*p*-pentadiene, whose structure was demonstrated by its further conversion into (±)-carbomenthone[92].

On the other hand, when a mixture of α-pinene, formaldehyde, and 60% perchloric acid was stirred for 6 h at 95–100°C, 1-methyl-4-(4′-methyl-1′, 3′-dioxacyclohex-4′-yl)cyclohexene (I) and bisdioxan $C_{14}H_{24}O_4$ (II) were obtained. The structure of the products (I) and (II) was confirmed by hydrogenation[92].

Using various catalysts (98% sulphuric acid, 85% phosphoric acid, 60% perchloric acid), Watanabe and coworkers isolated a mixture of 8-hydroxymethylcamphene and spiro-[2,2-dimethylnorbornane-3,1′-(2′, 4′-dioxacyclohexane)], with an overall yield of 56.3%, in the condensation of camphene with formaldehyde[93].

A complex mixture of products was also obtained in the condensation of dipentene with formaldehyde in the presence of perchloric acid. Apart from the initial products, a fraction boiling at 104–109°C at 7 mmHg was isolated from the reaction mixture freed from impurities by steam distillation. After chromatography on silica, a product was isolated and identified by infrared spectroscopy as a mixture of 1-methyl-4-(4′-methyl-1′, 3′-dioxacyclohex-4′-yl)cyclohexene and 8-isopropyl-1-methyl-2,4-dioxabicyclo[4,4,0]decane, which the authors regard as the primary products of the reaction between dipentene and formaldehyde[94,95]. A complex mixture of products also resulted in the condensation of limonene with paraldehyde in the presence of zinc chloride[96].

The authors of the present review investigated the condensation of α-pinene, dipentene, and camphene with formaldehyde in the presence of KU-2 cation-exchange resin[97].

While the present review was with the editors, a number of communications by the authors of the review dealing with the Prins reaction in the presence of KU-2 cation-exchange resin was published[98–101].

Electrical and Photoelectric Properties of Organic Polymeric Semiconductors

V.S.Myl'nikov

CONTENTS

I. Introduction 25
II. Low-molecular-weight organic semiconductors 25
III. Electrical properties of organic semiconducting polymers 26
IV. Photo-semiconducting properties of organic polymers 28
V. Conclusions and prospects 32

I. INTRODUCTION

Organic compounds containing systems of conjugated multiple bonds are now termed organic semiconductors: the conductivity of these substances is electronic, increases exponentially with temperature, and is greater (as a rule) than the conductivity of normal organic compounds.

During the past 10 years, in addition to extensive studies of the semiconducting properties of low-molecular-weight organic compounds, we have witnessed a significant volume of work on the synthesis and characterisation of a new class of organic semiconductors: the macromolecular compounds. The rising interest in semiconducting polymers is due, on the one hand, to recent advances in the physics and technology of inorganic semiconductors, which have led to a search for new materials showing semiconductor properties, and on the other hand to the successful preparation of polymers with a wide variety of physicochemical properties, resulting in widespread applications of polymers in technology. The attractive prospect of developing simple models, leading to a deeper understanding of some biophysical processes (which take place, as a rule, in complex macromolecular systems) has undoubtedly been an additional stimulus to developments in the physics of electronic phenomena in organic systems.

The present review deals with the most important experimental and theoretical data relating to organic semiconducting polymers having an electronic (as distinct from an ionic) conduction mechanism. Since studies on low-molecular semiconductors have led the way to an understanding of the semiconductivity of polymers, we shall briefly review the basic ideas of organic low-molecular semiconductor physics without attempting to cover the literature in detail. The later sections will discuss, separately, the electrical properties of organic semiconducting polymers and photoelectric processes in these materials.

We thought it desirable to devote a whole section to the photoelectronics of organic polymers because the subject is of very recent origin (5 years at the most), and has not so far been reviewed in any way. The aim of this review is to familiarise the reader with the physical aspects of organic polymeric semiconductors.

II. LOW-MOLECULAR-WEIGHT ORGANIC SEMICONDUCTORS

The following basic laws have been shown to apply[1-8] to low-molecular-weight organic semiconductors (dyestuffs, aromatic hydrocarbons):

1. The dark conductivity (σ_d) varies with temperature (T) according to the law

$$\sigma_d = \sigma_0 \exp(-E_d/2kT)\dagger \qquad (1)$$

where σ_0 is a constant for the particular semiconductor, k is Boltzmann's constant, and E_d is the thermal activation energy for dark conduction. E_d usually varies between 0.5 and 3 eV, and the value of σ_d at room temperature can vary between wide limits (10^{-1}–10^{-20} ohm^{-1} cm^{-1}). The thermal activation energy for dark conduction corresponds to the energy of the long-wave edge of the optical absorption curve, and decreases with increasing number of π-electrons in the molecule.

† The form of the exponent depends on the conduction mechanism assumed.

2. Ohm's law is obeyed, in general, up to fields of 10^3 V cm^{-1}, beyond which the current increases faster than linearly with voltage.

3. Polymorphic modifications of a given compound can have substantially different conductivities and activation energies for conduction, and charge carriers of different sign[9,10]. There is evidence of conduction anisotropy (anthracene) in different crystallographic directions.

4. The conductivity increases with increase of pressure up to 100 kg cm^{-2}, but not beyond.

5. Carrier mobilities in organic low-molecular-weight compounds are usually very low (< 1 cm^2 V^{-1} s^{-1}). Hall mobility data for organic semiconductors are extremely rare owing to serious difficulties in the measurement of the Hall effect (the high ohmic resistance of the compounds and possibly also some specific aspect of the conduction mechanism). More recently, a pulse method of measuring mobility in a "sandwich" type of cell has come into use. By this method it has been shown that the mobility in anthracene increases on lowering the temperature, suggesting the possibility of applying the band model (in which this dependence is ascribed to a decrease in the concentration of scattering centres with decrease of temperature).

6. Impurities and defects have a considerable effect on the semiconducting properties of organic semiconductors, but the results of different workers show large discrepancies.

7. The thermoelectric power is independent of temperature, suggesting that the free carrier concentration is independent of temperature.

8. The photoconductivity spectra (particularly in thin layers) and the photo-e.m.f. spectra are usually very similar to the absorption spectra. In thicker layers the photoelectric sensitivity decreases at the absorption maximum. Many experimental results show that a highly developed surface or defects must be present before photoconductivity can appear. These observations suggest that charge carriers are formed either at the surface, when an exciton diffuses towards it, or by the simultaneous interaction of a molecule with two photons or two excitons.

9. The relaxation time of the photoeffect varies over a wide range, from 10^{-6} s to tens of minutes.

10. The photoconductivity (σ_{ph}) increases exponentially with temperature (T) according to the law

$$\sigma_{ph} = \sigma_0 \exp(-E_{ph}/kT) , \qquad (2)$$

where σ_0 is a constant for a particular semiconductor and E_{ph} is the thermal activation energy for photoconduction. The value of E_{ph} usually falls between 0.1 and 0.3 eV, pointing to the presence of bound states from which the carriers must be thermally activated in order to move in the applied electric field. The nature of these states is not fully clear.

11. Current carriers can be injected into organic crystals from various electrodes.

12. The sign of both light and dark carriers in most organic semiconductors so far examined corresponds to positive holes.

13. Vapours and gases can have an appreciable effect on the conductivity and photoelectric sensitivity of the semiconductors.

14. The quantum yield of the photoeffect is not large (10^{-1}–10^{-7} electrons per quantum).

15. Changes in photoconductivity have been observed in a weak magnetic field[11,12].

16. The possibility of forming charge-transfer complexes enables the electronic parameters of the semiconductors to be varied between wide limits.

17. On the basis of the experimental facts listed above, the mechanism of semiconductivity in low-molecular-weight organic compounds is usually associated with overlap of the wave functions of π-electrons from neighbouring molecules. Two basic approaches are usually followed. Some authors have attempted to apply to organic semiconductors the band model which satisfactorily describes electronic phenomena in inorganic semiconductors. Others support the "relay" or "hopping" mechanism of conduction. The distinguishing feature of molecular organic semiconductors is the fact that the interaction forces between separate molecules (van der Waals forces) are much weaker than the interaction forces between the component parts of each molecule, so that the molecules can retain their individuality in the crystal lattice. This gives rise to the exciton type of light absorption, and to the formation of narrow bands of singlet and triplet states in the crystal. These exciton states are satisfactorily described by molecular wave functions rather than by the one-electron Bloch functions used in the band theory. Excitons are neutral entities, and can only be treated as transition states in the formation of free carriers. However, these states are important in conduction when an electron migrating through a crystal can be treated as bound to one of the molecules or missing from it. The nature of these states is determined by the specific features of the lattice of a particular organic semiconductor. An analogous approach can clearly be used to discuss high-molecular weight organic semiconductors, to which the remaining sections are devoted.

III. ELECTRICAL PROPERTIES OF ORGANIC SEMICONDUCTING POLYMERS

The conductivity of organic polymeric semiconductors increases exponentially with temperature according to Eqn. (1). Historically, the earliest publications on organic polymeric semiconductors related to materials obtained by pyrolysis. The electrical conduction of pyrolysed polymers was first observed by Kmetko on heat-treated cellophane[13] and by Winslow and coworkers[14,15] by pyrolysing poly(divinylbenzene) and poly(vinylidene chloride)[14,15].

When organic compounds are heated to 400–650°C, high-molecular-weight compounds are formed from highly unsaturated aromatic molecules[16]. When the temperature is raised still further, large planar networks of atoms packed in fairly random piles are formed, and at very high temperatures (3200°C) these condense into large, highly ordered planes and produce the graphite structure. Thus, graphite can be considered to be the limiting case of a polymeric semiconductor. In spite of fairly detailed studies of these compounds, fully satisfactory mechanisms for the change in their electrical properties with structure and heat treatment have not yet been put forward[17]. Materials prepared at temperatures in excess of 1200°C are usually classified as polymeric carbons. At room temperature, polymeric carbon is an n-type semiconductor with a very narrow forbidden gap (0.07–0.01 eV). The conductivity type changes with temperature, which may be ascribed to the presence in the polymeric lattice of valency-unsaturated non-bridging carbon atoms. Because of this unsaturation, electrons can be extracted from the inner carbon atoms with formation of positive holes as current carriers[18,19].

Materials prepared by heat treatment up to 1200°C are normally classified as pyropolymers. They are usually characterised by a narrow forbidden gap. There have been reports of pyropolymers with conductivities covering the

range from semimetals to dielectrics (10^3–10^{-13} ohm^{-1} cm^{-1}), of n- or p-conductivity type, and mobilities between 10^{-6} and 100 cm^2 V^{-1} s^{-1}.[20]

Pyropolymers prepared from organic compounds containing atoms of oxygen, nitrogen, chlorine etc. are particularly interesting. Among the first semiconducting polymers, and the most thoroughly investigated, are the compounds obtained from poly(acrylonitrile)[21]. Published results[21-27] justify the conclusion that electrical conduction in pyrolysed poly(acrylonitrile) is determined by an ionic and an electronic contribution. The ionic contribution, which accounts for the conductivity of the initial polymer, is predominant in specimens prepared at 150–300°C, and decreases with increasing temperature of heat-treatment. At the same time the electronic contribution increases, as required by the increasing number of conjugated double bonds. The increase in electrical conductivity resulting from treatment at 400°C is due to an increase in the effective mobility of current carriers, not to an increase in carrier concentration. Studies of the temperature dependence of electrical conductivity and of thermoelectric power have led to the conclusion that the regions of polyconjugation in poly(acrylonitrile) specimens treated at low temperatures have the properties of impurity semiconductors, changing to semimetal properties as the temperature of heat-treatment is raised. The unpaired electrons which are manifest in the ESR spectra behave as donor impurities[28-30]. It has been shown that the value and the temperature dependence of the electrical conductivity are determined essentially by activated jumps between polyconjugated regions, whereas the thermoelectric power is characteristic of the polyconjugated regions themselves. Estimates of the carrier mobility give values of the order of 10^{-3} cm^2 V^{-1} s^{-1}. These results were obtained by assuming that the band theory can be applied to the system. Although the validity of the band model as applied to organic polymers is by no means established, experiment shows that the formalism of this model gives a fairly consistent picture of the mechanism of charge transfer when applied to poly(acrylonitrile). Work[31,32] on the effect of hydrostatic pressure and tension on the resistance and thermo-e.m.f. of poly(acrylonitrile) filaments is particularly interesting. It was shown that the concentration of free carriers remains constant on raising the pressure, whereas the activation energy of electrical conduction decreases. It follows that the change in conductivity with temperature is determined by the activated nature of the mobility and is associated with the height of the potential barriers separating the regions within which electrons are delocalised. Longitudinal extension increases the distance between molecules and should therefore increase the height of the potential barriers, lower the mobility of the current carriers, and increase the resistance, as is experimentally observed. Kustanovich and coworkers[33,34] have shown that the electrical properties of pyrolysed filaments of poly(acrylonitrile) are determined by gases adsorbed on the surface: this suggests that results obtained in the presence of air should be critically re-examined.

In principle, results obtained on pyrolysed polymers should be difficult to interpret because the structure of the resulting products is usually poorly characterised, and there can be no doubt that heat treatment leads to the appearance of new formations which behave as impurities and are difficult to control. In this context, it is interesting to note reports[35,36] of changes in the electrical properties of poly(acrylonitrile) under the influence of infrared radiation.

An extensive series of papers by Berlin and coworkers and by other authors is devoted to the electrical and magnetic properties of polymers containing acyclic conjugated systems (polyvinylenes)[37-46] and polymers with aromatic rings in the conjugated chain[47-56]. These workers examined the change of conductivity with temperature, and its relationship to paramagnetic absorption and to the structure of the polymer. Most of the polymers investigated had fairly high resistivities ($\sigma_d < 10^{-7}$ ohm^{-1} cm^{-1}) and gave an electronic paramagnetic absorption signal with a g-factor corresponding to the free electron. In spite of the considerable effort devoted to studies of the relationship between the ESR signal and the electrical properties of highly conjugated polymers[37-39,50-72], the relation between current carriers and the concentration of paramagnetic centres is still far from clear. Blyumenfel'd and Benderskii ascribe the ESR signal and the electrical conductivity to the formation of polar charge-transfer complexes either between two neighbouring molecules or by the trapping of charge at a crystal imperfection[57-64]. Another approach is based on the suggestion by Berlin[65-68] that high-molecular-weight fractions containing stable biradicals are formed during the synthesis or the subsequent heat treatment, and that these are the source of current carriers.

Many workers have studied the influence exerted on the semiconducting properties by polymer structure, both supermolecular (crystallinity, degree of order, etc.) and molecular (chemical structure of the macromolecule itself). As a rule, the electrical conductivity increases on increasing the number of π-electrons in the molecule and when atoms with electron-donating properties are introduced into the chain[73-77]. When groups or heteroatoms which interrupt the conjugation are introduced into the macromolecule, the electrical conductivity decreases as a result of the increased activation energy for conduction[50,53,78-84]. Experiments with poly(phenylacetylene) have shown that the activation energy for dark conduction is independent of the molecular weight and corresponds to the radiation maximum in the luminescence spectra[61,62]. This is evidence for the generation of carriers by thermal ionisation of luminescence centres.

However, the electrical properties of polymers depend not only on the degree of conjugation in the macromolecule but also on the physical structure of the polymer. Hatano and Kambara[85,86] found that the resistance of crystalline polyacetylene is lower than that of the amorphous material by 5–8 orders of magnitude. It should be noted, however, that the oxygen content was rigidly controlled in this work. The electrical properties of a series of chelate polymers were shown to be determined, in the first instance, by the degree of order in the polymer and by the nature of the electronic interactions, rather than by the structure of the individual macromolecule[87,88]. The conductivity can be raised by introducing into the macromolecule groups tending to make it more flexible and thus favouring denser packing[54,87,89,90]. Many workers have noted conduction anisotropy with respect to the alignment axis of the macromolecules[28,29,31,91,92], an increase in conductivity with pressure[93-95], and a major influence of adsorbed vapours and gases on the electrical conductance (particularly oxygen)[42,87,96-101]. The effect of oxygen on the electrical conductivity involves either a change in the concentration of current carriers or a modification of the height of the potential barriers between macromolecules or polyconjugation regions. Most high-resistance polymeric semiconductors show a linear dependence (compensation effect) of the activation energy E_d on the logarithm of the pre-expo-

nential factor σ_0 in Eqn. (1)[48,57,58,102,103]. Sazhin and coworkers[104-107] have studied the temperature dependence of electrical conductivity and its relationship to supermolecular structure on a series of polymeric dielectrics.

Compounds containing a metallocyclic ring in the main chain form an important group of semiconducting organic polymers. Poly(copper phthalocyanine) was synthesised by Epstein and Wildi[108-109]. The resistivity of the polymer at room temperature is 10 orders of magnitude lower than that of non-polymeric copper phthalocyanine (10^7–10^8 ohm cm). Interesting Hall effect measurements are reported in the same paper, from which valuable conclusions may be drawn as to the conduction mechanism. It is found that the change in resistance with temperature of a polyphthalocyanine which has not been heat treated reflects both a change in mobility and a change in the carrier concentration. The mobility value was 10 $cm^2\ V^{-1}\ s^{-1}$, and it is interesting to note that it was obtained by direct measurement (Hall effect). Indirect methods of measuring mobility in polymers usually yield values many orders of magnitude lower. Direct methods of measuring mobility (such as the transit-time method) also give low values in polymers (10^{-3}–10^{-4} $cm^2\ V^{-1}\ s^{-1}$)[110]. The Hall constant for polyphthalocyanine heat-treated at 450°C did not change with temperature, pointing to a constant carrier concentration. In this case the activation energy for electrical conduction can be identified with the mobility activation energy.

Berlin, Frankevich and others also investigated polyphthalocyanines[98,97,111-114]. They noted a strong effect from vacuum and oxygen treatment on the electrical properties of the samples, and proposed a method for measuring carrier mobility in polymers by simultaneously monitoring the desorbed acceptor molecules and the electrical conductivity of the polymer[96]. They find that copper polyphthalocyanine is an n-type semiconductor with a mobility of 10^{-2} $cm^2\ V^{-1}\ s^{-1}$ and a concentration of current carriers of 10^{18}–10^{19} cm^{-3}.

Polymeric chelate materials with semiconductor properties have been prepared also from tetracyanoethylene[115-127]. By measuring electrical conductivity at high frequencies it was found that the resistance and the activation energy for electrical conduction decrease with increase of frequency. Hence, the barriers between macromolecules must be taken into account when discussing the conduction mechanism[119-121]. Polymeric chelate compounds are among the most promising materials for technological applications. In polymers of the coordination type we can expect high mobilities and broadening of the energy levels into wide bands. Semiconducting chelate polymers have been prepared from ferrocene[16,48,128-131], poly(vinyl alcohol)[32] and other compounds[77,133-144].

A large group of semiconducting polymers consists of compounds with conjugated triple or cumulative bonds in the main chain[145-163]. A poly-yne with the appearance of a black powder containing 98% of carbon and retaining the structure of polyacetylene up to 200°C has been prepared and investigated[146,152,153]. The polymer shows n-type conduction, the donor centres being copper atoms included in the molecular carbon chain of the polyallene structure. On raising the temperature of heat treatment the polymer changes conductivity type, which the authors ascribe to thermal dissociation and removal of copper and hydrogen atoms from the carbon chain. Under these conditions the terminal carbon atoms behave as electron acceptors. Infrared and X-ray diffraction analysis[147-153] have shown that these carbonaceous products of acetylene condensation are open forms of carbon in which linear macromolecules with a poly-yne and partly a cumulene structure are aggregated in molecular packs of parallel carbon chains. Some of the macromolecules are "cross-linked" into a spatially disordered conjugated polyene structure. Studies of the electrical properties of poly-yne derivatives before and after heat treatment, in cases where the structure consists of parallel molecular chains aggregated into packs with a high degree of azimuthal order[148,149], have shown that these materials also are semiconductors.

Radiation-thermal treatment of polymers appears to be a promising method of preparing materials with semiconducting properties[92,164,165]. For example, the method has been used to prepare semiconducting materials from polyethylene[70,98,165-169], with conductivities between 10^{-14} and 10^2 $ohm^{-1}\ cm^{-1}$, activation energies for conduction between 0 and 1.5 eV, and thermoelectric power between 1 and 500 $\mu V\ deg^{-1}$. Ohm's law is obeyed up to fields of 10^3 V cm^{-1}. At the boundary between low-pressure polyethylene and polyethylene subjected to radiation-thermal treatment, p–n junctions have been obtained with a rectification ratio of 10 in the region of 400–600 mV[165]. The model adopted for the conduction mechanism involves polyconjugation regions 50–100 Å long alternating with barriers 5–20 Å thick which determine the activation energy of the conduction process[98]. Current rectification has been observed also at the junction between polyethylene crystals and metals[170].

The formation of charge-transfer complexes between a polymer and electron-donor molecules[98,102,168,169,171-185], resulting in an increase in conductivity by 4–6 orders of magnitude, offers very attractive possibilities for the preparation of low-resistance polymers. In addition to the compounds mentioned above, semiconducting materials which have been investigated include those prepared from poly(diphenyldiacetylene)[186], polypyrroles[187], polybutadiene[188], poly(azophenylenes)[189], polyaniline[190,191], poly(vinyl acetate)[192] and various other materials[103,193-199]. The semiconducting properties of organic polymers (in the dark) have been discussed in a number of review articles[16,99,102,200-208]. Lastly, we shall note that proteins and nucleic acids have been shown to have quite specific electrical properties of the semiconductor type in a number of investigations[209-224] which cannot be discussed in detail in the present article.

IV. PHOTO-SEMICONDUCTING PROPERTIES OF ORGANIC POLYMERS

Whereas studies of the electrical conductivity, thermoelectric power and ESR spectra of organic polymers are relatively abundant, reports of photoelectric phenomena in organic macromolecular compounds began to appear only during the past 5 years, and are far from numerous. We must stress that the study of photoelectric processes in polymers gives a fuller description of electronic phenomena in these systems than is available from studies of electrical conductivity, since a light beam allows us to probe strictly defined energy states of the electrons. Furthermore, the photo-semiconductors (which behave as insulants in the dark) become accessible to study. These materials are of interest in electrophotography—the only technological area in which organic photosemiconductors have yet found a genuine practical application. It is significant that the number of patents on electrophotographic layers made from organic materials is ever increasing. The patent literature dealing with this subject has been reviewed by Sidaravichyus[225] and by Newman[226,227]. The

most widely used electrophotographic layers are those of poly(vinylcarbazole). However, their physical parameters have been investigated and they have been found to be a hundred times less sensitive than such inorganic materials as selenium sensitised by zinc oxide[228-232]. On the other hand, they have a high resolution (absence of grain structure) and higher contrast than is found in selenium, they are unaffected by the material and size of the substrate, they are technologically attractive, and they offer a number of other advantages. The best promise of improving the sensitivity of organic polymer layers lies in the addition of chemical sensitisers[233] and in the search for new materials[234,235].

The formation of photoelectrically sensitive materials by u.v. irradiation of the copolymer of vinylidene chloride (85%) and vinyl chloride (15%), known as Saran Wrap, was first reported by Oster and coworkers[236,237]. The photoconductivity was attributed to the formation of free radicals under illumination because conditions which induce or eliminate the ESR signal affect the photoconductivity in the same sense. It should be noted that the preparation of polymeric materials with semiconducting properties by irradiation with monochromatic light has some important advantages over alternative methods such as pyrolysis: (1) by appropriate choice of wavelength, it is possible to initiate chemical reactions selectively; (2) the light beam can be confined to particular areas of the target. By virtue of these effects, Oster and coworkers were able to prepare p–n junctions at the interface between differently irradiated areas.

The search for photoelectrically sensitive polymers has been pursued by the present writer for many years in A. N. Terenin's laboratory. Approximately 400 organic polymers have been examined so far [poly(phthalocyanines), polyphenylenes, poly(cyanamides), poly(acetonitriles), polyferrocenes, poly(phenylacetylene) and its copolymers, polymers of malonic and adipic acid, stilbene polymers, poly(vinylphthalimides), polymers of quinizarine with metals, many different chelate polymers, etc.].

Some of these materials, when tested for d.c. photoconductivity, showed a small increase in conductivity with a slow relaxation when illuminated, but it was not possible to distinguish a photoelectric effect unambiguously from the bolometer effect.

By using the capacitor method of photo-e.m.f. measurement[238] with modulated light (300 Hz), polymers with a photocurrent relaxation time of 10^{-2} s were found, and the photoelectric processes in these compounds were examined in detail[100,239-252]. The polymers in question were compounds with triple bonds[239] and poly(metal acetylides)[240]. The compounds were synthesised in Korshak's laboratory by Sladkov and coworkers[145-154,253-256]. An internal photoeffect was observed in 50 of the 70 compounds examined, whose structure can be represented by the formulae

$$R'\!\left(-C\equiv C-R-C\equiv C-\right)_n R'; \quad R\left(-C\equiv C-\right)_n R,$$

where R and R′ are organic radicals containing functional groups or hetero-atoms. The polymers are finely divided powders of colour varying from white to black, poorly soluble or quite insoluble in organic solvents.

Under illumination, the capacitor photo-e.m.f. is observed in the u.v. or visible region of the spectrum[239,243]. In the most of the poly-ynes, the photocurrent carriers have a positive sign. Previous irradiation of the polymers with u.v. light has been shown to increase the photo-e.m.f. This effect is ascribed to ionisation of the conjugated molecules under the influence of u.v. light and formation of centres acting as traps for the photo-electrons. This mechanism is confirmed by some preliminary experiments by the ESR method[249,250]. With poly(pp'-diethynylazobenzene) at 77°K, a partially reversible ESR signal photo-induced by u.v. light can be observed. By comparing the behaviour of the ESR signal with that of the photo-e.m.f. under u.v. light we conclude that the photo-induced ESR signal is due to the capture of photoelectrons by the positively charged local centres formed in the polymer structure by the action of u.v. light. The spectral distribution of photo-e.m.f., measured on a number of polymers, is characterised by smoothly increasing curves (towards higher energies) with a threshold at 2.0 eV.

The dark resistance of the poly-ynes is 10^{12}–10^{14} ohms, decreasing by 2–3 orders of magnitude under the light of a mercury lamp[242,249]. The variation of the photocurrent i_{ph} with illumination (L) is of the form $i_{ph} = \alpha L^n$, where n can vary between 0.5 and 1.0. The photocurrent is proportional to the voltage raised to the power n, where $n > 1$. A typical range of relaxation times for the photocurrent in poly-ynes is between 10^{-5} s and several seconds. From the initial rise and decay of the photocurrent we can extract an exponential component with a time constant of approximately 10^{-5} s.[241] We should stress that poly-ynes and polyacetylides are the only polymers for which such short-lifetime photoconduction processes have yet been reported. With time constants of this order there can be no doubt that the photo-effect in these polymers is electronic in nature. After the initial exponential stage, the relaxation of photoconductivity changes to a hyperbolic law in a time interval of between 10^{-5} s and several seconds[241].

As for the photo-e.m.f., the spectral distribution of the photoconductivity in poly-ynes and of the influence of u.v. light on these materials was investigated[242]. The photoconductivity spectra are displaced towards longer wavelengths as compared with the photo-e.m.f. spectra. The main photoconductivity maximum for poly(pp'-diethynylbenzene) is found, as in most other photoelectrically sensitive semiconductors, beyond the edge of the absorption curve, pointing to a difference between the rates of surface and volume recombination of the photocurrent carriers. The activation energy for poly(pp'-diethynylazobenzene), measured from the photoconductivity spectrum, was 1.82 ± 0.02 eV. The same value was recently obtained in Japan for the activation energy of dark conduction in this polymer[162]: this suggests that the same electronic transitions are responsible for both the dark conduction and the photoconduction in the polymers. As with the photo-e.m.f., the photosensitivity of poly-ynes undergoes a partially reversible change under the influence of u.v. light. Spectrally [with poly(pp'-diethynylazobenzene), say] this change consists in a redistribution of the ratios of the intensity maxima in the photoconductivity spectrum and a shift towards longer wavelengths of the short-wavelength maximum. The change in photoconductivity under u.v. irradiation, like the change in photo-e.m.f., is associated with the capture of the photoionisation electrons by the resulting traps, as shown by the ESR measurements discussed above.

Using the copolymer of p-diethynylbenzene and p'-nitrophenylacetylene, the absorption spectra in solution and in thin film form have been compared with the photoconductivity spectra. Photoconduction is observed in the absorption band of the polymer, and its trend is similar to that of the absorption spectrum[243].

A photoeffect has been found in 15 poly(metal acetylides)[240,250] having a chain structure expressed by the general formulae R–C≡C–M and M–C≡C–R–C≡C–M,

where R is an organic radical and M is a metal (Cu, Ag). Most of the work was done on copper derivatives, and in particular on poly(copper phenylacetylide), abbreviated CPA. These polymers are insoluble, fine powders of different colours, from yellow to dark red, and are coordination compounds[245]. The poly(copper acetylides) had a resistance of 10^9–10^{10} ohm in the dark, decreasing to 10^7–10^8 ohm on illumination with monochromatic light. Growth of the photocurrent to the steady-state value was accomplished in 10–15 s. As with the poly-ynes, the variation of the photocurrent with illumination is given by the formula $i_{ph} = \alpha L^n$, where n varies between 0.5 and 1. Ohm's law is obeyed up to fields of 10^2 V cm^{-1}, beyond which the photocurrent increases faster than linearly with applied voltage. The sign of the photocurrent carriers in all the poly(copper acetylides) is positive[240].

A comprehensive study of the spectral distribution of photo-e.m.f., photoconductivity, absorption, and luminescence in CPA has been described[245]. The photo-e.m.f. spectrum was found to be similar to the absorption spectrum, but the photoconductivity spectrum is displaced towards the long-wave region as compared with the others and has a maximum beyond the absorption edge. The latter fact denotes an important contribution from surface recombination of the carriers, arising from an extensive system of surface states. The increase in photo-e.m.f., accompanied by a decrease in luminescence yield, due to previous illumination, was investigated spectrometrically but remains puzzling.

Work done so far justifies the assumption that the absorption, photoeffect, and luminescence maxima in CPA are similar in nature. The bands are characteristic of fundamental electronic transitions in the polymer. Migration of charge carriers in CPA is assisted by the lowering of the potential barriers between molecules caused by π-complex bridging between the electron-acceptor copper atoms and the acetylene bonds. Changes in the luminescence and photoeffect spectra under u.v. irradiation are due to the rupture of weak coordination bonds in the polymer, which alters the relationship between polymer homologues. Bond breaking facilitates the dissociation of excitons at the resulting defects, leading to an enhanced photoeffect and a lower luminescence yield. This mechanism is supported by numerous experiments on the luminescence of CPA at 77°K[245], in which it was shown by spectroscopic measurements that the degradation of CPA under u.v. light proceeds up to the stage of formation of isolated molecules of diphenylbutadiyne dispersed throughout the polymer structure. Under these conditions we may postulate energy transfer from the semiconducting substrate (CPA) to the diphenylbutadiyne molecules.

Vapours and gases can strongly affect the semiconductor properties of polyacetylides[100,244]. Dry oxygen produces a reversible decrease in the electrical conductivity and photoconductivity by 3–2 orders of magnitude, and lowers the photo-e.m.f. by a factor of 3–5, which is unusual for a p-type semiconductor such as CPA. Gas adsorption on a semiconductor surface may lead, in the first instance, to the formation of a double layer resulting from the adsorbed molecules, and secondly to the creation of new recombination centres or trapping levels. An investigation of the effect of oxygen on the spectral distribution of photosensitivity has identified the quenching effect of oxygen with the formation of effective recombination centres which decrease the lifetime of majority carriers (holes). The recombination centres created by oxygen are primarily surface states, as shown by special experiments on the effect of u.v. light in vacuum, in which it was found that oxygen is photodesorbed from the CPA surface in a vacuum[100,248].

Water vapour reversibly suppresses the electrical conductivity and photoconductivity, and enhances the photo-e.m.f. of CPA[244]. The effect of water vapour on the photosensitivity spectrum has been examined, and shown to be associated with the formation (following adsorption) of an electrical double layer on the CPA surface, resulting from capture of the majority carriers (holes) on surface states.

Electron-acceptor molecules such as quinone and chloranil in the gas phase did not appreciably affect the photo-e.m.f., but suppressed the photoconductivity and the conductivity of CPA[249]. When the specimen was exposed to these molecules in solution, the photo-e.m.f. increased by an order of magnitude but its spectrum did not change appreciably. Evidently, new centres are formed by contact with the solvent, and these enable the quinone molecules to be adsorbed and act as electron traps owing to their high electron affinity. The presence of highly developed surface states, indicated by the above results on the effect of gases and vapours on the electrical properties of CPA, implies catalytic activity towards oxidation reactions[251].

From the view point of applying the concepts of semiconductor physics to biological polymers, some curious results have been obtained in a study[252] of the effect of nucleic acids and amino-acids on the photosemiconducting properties of CPA. In particular, it was shown that deoxyribonucleic acid and ribonucleic acid increase the conductivity and photoconductivity of the polymer by 2–3 orders of magnitude without affecting the spectral sensitivity. The photo-e.m.f. is increased several-fold. An investigation of the effect of purine and pyrimidine bases, which enter into the composition of nucleic acids, showed that only adenine exhibits the effect. The mechanism of these phenomena is probably similar to the process which has been termed chemical sensitisation in inorganic semiconductors[257]. It should be noted that studies of the interactions between biological polymers and model synthetic polymers have opened up new pathways for investigating the specific biological properties of these compounds.

The mechanism of the photoeffect in polymers is probably as follows. The primary act consists in the excitation of a molecule by the absorption of a photon[239,249,250]. The excited state (or exciton) migrates until it collides with a structural or chemical defect, on which a pair of free photocurrent carriers is formed. The electron is retained by the positively charged centres, but free holes can migrate through the entire system of macromolecules. In CPA it would appear that pair formation does not require an activation energy, as shown by the temperature dependence of the photoconductivity at very high frequencies[258]. Potential barriers at the boundaries between macromolecules can be expected to limit the photoelectric sensitivity of the material very markedly. Hence the role of random bonds associated with cross-linking of the macromolecules becomes important.

An effect not previously observed in organic semiconductors—the spectral sensitisation of the photoeffect by dyes—has been found and spectroscopically investigated in poly-ynes and polyacetylides[246–250]. The effect is well known in inorganic semiconductors[259,260], and consists in the appearance of photoelectric sensitivity in the absorption band of a dye adsorbed on the surface of a photoconductor. The sensitisers used in conjunction with poly-ynes and polyacetylides include Methylene Blue, Pinacyanol, chlorophyll, phthalocyanines, erythrosine, hematin, Rho-

damine B and others. The sensitised photoconductivity spectrum and photo-e.m.f. spectrum are similar to the absorption spectrum of the dye in solution (10^{-3} M), which suggests that the monomeric form of the dye takes part in the sensitising act. Dimers and more highly aggregated forms of the dye also take part in the sensitising process. Because of the influence of adsorption forces, the sensitised photosensitivity spectra are displaced by 10–15 nm as compared with the absorption spectra of the dyes. The effectiveness of spectral sensitisation can be as much as 30–40% of the intrinsic photoelectric sensitivity. Adsorption of the dye alters the intrinsic photoelectric sensitivity of the polymeric substrate. For example, the intrinsic photo-e.m.f. was increased by a factor of 30 by adsorption of erythrosine. A detailed study of the spectral curves for intrinsic and sensitised photoeffects (photoconductivity and photo-e.m.f.) has been made using Methylene Blue, chlorophyll *a*, and Pinacyanol. With Methylene Blue it was shown, by a spectrometric method, that the efficiency of spectral sensitisation is a maximum at a solution concentration of the dye of 10^{-3} M. The sign of the photocurrent carriers is the same in the intrinsic and in the sensitised region. The results indicate that the sensitised photoeffect in organic semiconductors follows the same pattern as in inorganic semiconductors. Dyestuffs of the most diverse classes—strong electron acceptors such as Methylene Blue, and readily oxidised compounds such as chlorophyll—are equally effective in sensitising the photoeffect in organic semiconductors. Dyes of the following types are found to act as sensitisers: cationic (Pinacyanol, Methylene Blue), anionic (erythrosine), and neutral (chlorophyll, phthalocyanine, hematin), some of which belong to the photographic sensitiser class (Pinacyanol) and others to the desensitiser class (Methylene Blue). As with inorganic semiconductors, sensitisation occurs through the monomeric, dimeric, and higher polymeric forms of the dye. Some of the dyes examined as sensitisers do not themselves show photoelectric sensitivity in the solid phase, but those that are photoelectrically sensitive show a large increase on adsorption. Therefore, the most likely sensitisation mechanism involves energy transfer from an excited dye molecule to electrons in the filled band or on levels close to it and promotion of these electrons to empty traps, thus promoting the free motion of positive holes. Data obtained from ESR and data on the influence of vapours and gases on the photoelectric properties of polymers suggest that these localised traps are mainly on the surface. The observed change in the intrinsic photoelectric sensitivity of the polymer is related to the nature of the traps generated by the adsorbed dye.

The phenomenon of chemical and spectral sensitisation of the photoeffect, recently described for poly(vinylcarbazole)[261] and polyacenaphthylene[262], is analogous to that found in polyacetylenes. The high photoelectric sensitivity of poly-ynes and polyacetylides has enabled these materials to be made into electrophotographic layers of sensitivity comparable to that of inorganic photosemiconductors[234].

Bradley and Hammes[263,264] have reported photoconductivity in thin (~ 1 μm) organic layers produced by polymerisation in the glow discharge of monomers containing nitrogen, sulphur, selenium, and certain metals. Irradiation with unfiltered white light raised the room-temperature dark conductivity (which was of the order of 10^{-17}–10^{-13} ohm^{-1} cm^{-1}) by a factor of 10^3. The activation energy for photoconduction in these films is 0.25 eV, pointing to thermal activation with formation of free carriers from excited molecules in an intermediate, non-conducting state, rather than band-to-band transitions. All the polymers gave short-circuit photocurrents, evidently due to a photovoltaic effect at the interface between the film and the transparent electrode. The charge carriers were identified as electrons from the polarity of the photocurrent.

It is interesting to note that addition of a trace of iodine during polymerisation in the discharge increased the electrical conductivity and photoconductivity by three orders of magnitude. The authors point out that their results are characteristic of amorphous organic semiconductors in general rather than of any specific polymer structure. The importance of this observation is obvious if we remember that the authors did not control the composition or the structure of their films, produced by polymerisation in a discharge. Clearly, it is impossible to discuss the observed semiconducting properties in terms of the structural parameters of the macromolecule or of the sample as a whole. However, systems of this type can already be of practical interest. For example, these films have been used successfully as high-temperature photodetectors (up to 200°C).

Rozenshtein, Davydov, and others observed photoconductivity in polymeric Schiff's bases made from benzil and *p*-phenylenediamine[265], polyazines[266,267], and poly(diphenyldiacetylenes)[268]. The activation energy for photoconduction in these compounds was shown to lie between 0.1 and 0.3 eV. With poly(diphenyldiacetylene) the activation energy for photoconduction was found to increase with wavelength of the light, due to the existence of an energy distribution of trapping levels. The intensity–current characteristic is of the usual form ($i_{ph} = \alpha L^n$), with n lying between 0.5 and 1. Ohm's law is obeyed up to field intensities of 10^2–10^3 V cm^{-1}. All the polymers have a resistivity higher than 10^{12} ohm cm in the dark. The poly(Schiff's base) gave appreciable photopolymerisation effects, making the interpretation of results difficult.

Drabkin and Rozenshtein proposed the use of the photoconductivity method to investigate changes taking place during heat treatment of polyacrylonitrile[269]. By comparing the time–temperature curves for the increase in the number of conjugated bonds with those for the photoconductivity the authors were able to show that the formation of conjugated bonds is a sufficient condition for the onset of electronic conduction on the polymer. However, it has been stated[36] that photoconductivity in polyacrylonitrile is possible even without conjugated bonds. In particular, photoconductivity was demonstrated in a complex between the polymer (not heat treated) and dimethylformamide solvent. These results point to the need for careful removal of the last traces of solvent from polymer films before attempting to examine the films. The many conflicting data reported by different workers on the semiconducting properties of the same material may be due to varying specimen purity. On the other hand, the formation of charge-transfer complexes between donor-acceptor molecules and polymers is a very promising way of lowering the resistance of polymeric materials and increasing their photosensitivity[180–184,233,270,300].

A group of workers have synthesised poly [1,3-diphenyl-5-(4-vinylphenyl)-2-pyrazoline][271] and polyacenaphthyls and their nitrile derivatives[272], and studied their photoconductivity. The photoconductivity spectrum of the first polymer[271] is reported in the region from 300 to 600 nm. The superlinear law relating the photocurrent to illumination ($n = 1.2$) reported by these workers is unusual in organic semiconductors. Some of the polymers examined have proved useful in electrophotography.

A report by Drechsell and Görlich[273] of photoelectric sensitivity in a polyvinylene film, prepared from poly-(vinyl alcohol) by elimination of water in the presence of dehydrating agents, is noteworthy. The Hall constant of the resulting material was measured, and used to calculate the carrier density (of the order of 10^{16} cm^{-3}) and mobility (10^{-3} cm^2 V^{-1} s^{-1}). The conductivity type was electronic. This polymer is of interest primarily as a possible infrared detector, since photoconductivity occurs in the region of 0.6–6.4 μm according to the photoconductivity spectrum published by the authors. Mrosowski and coworkers[274,275] had previously suggested the possible use of pyrolysed films of cellophane or poly(acrylonitrile) as infrared detectors. However, their results do not show unequivocally that the observed effect was not bolometric.

Beck[101] discusses the photoconductivity of polyphenylene and polyvinylenes. At room temperature, and depending on the polymerisation conditions and on the oxygen content, the observed resistivities fell in the range 10^{1}–10^{15} ohm cm, with activation energies between 0.025 and 0.96 eV. A small decrease in resistance was observed in the unfiltered light of a filament lamp. In the discussion of the kinetics of the photocurrent the author distinguishes between a primary (fast increase in photocurrent with time of irradiation) and a secondary photoeffect (long-term increase in photocurrent). According to Beck, the primary photoeffect corresponds to the $^0E \rightarrow {}^1E$ transition, and the secondary photoeffect to the $^1E \rightarrow {}^3E$ transition, where ^0E is the ground state of the molecule, ^1E is an excited singlet state, and ^3E is a triplet state of the molecule. This distinction is evidently unjustified, since there are no grounds for identifying the excited state of the molecule with the state giving rise to conductivity. Even less justified is the conclusion that the secondary photocurrent is associated with a triplet state of the molecule. The so-called secondary photocurrent is due, in all probability, to the physical condition of the polymer and to defective contacts. Beck[101] proposes a tunnel mechanism for the transition across molecular potential barriers, and gives an estimate of 0.6 cm^2 V^{-1} s^{-1} for the carrier mobility.

A photoeffect has been observed in polyethylene under the action of u.v. light[276,277]. The quasi-classical method of calculation of the ionisation potential of polyethylene in the solid state gives a value of 4.5 eV. Absorption spectral studies revealed the presence of structural and impurity absorption, but no threshold was found in the region of 4.5 eV. The observed photo-e.m.f. and photoconductivity are probably due to impurities, and further work is needed to explain the nature of charge carriers and traps in this material. The mechanism of formation of free charges in polyethylene is likened to charge separation in an assembly of n–p–n structures connected in series. The extent to which such a mechanism can be justified is not yet clear. We note that photoconductivity has been observed also in the radiation-thermal treatment products of polyethylene[167,278].

Photoelectric sensitivity in biological polymers has been observed in an extensive series of investigations[221,224,279-282]. Liang and Scalco observed photoconductivity in adenosine[279], in the sodium salt of deoxyribonucleic acid[280,281], and in polyglycine[286]. The sodium salt of deoxyribonucleic acid had an anomalously high thermal activation energy for photoconduction, 0.9 eV, as compared with the values commonly observed in organic semiconductors. The authors ascribe the high activation energy for photoconduction to the existence of two contributions: (1) the energy required to generate free carriers, and (2) the energy which the carrier must have in order to overcome the potential barriers opposing its motion. We should note that the light source used by these workers—a tungsten filament lamp—had an energy maximum at about 1 μm, whereas the materials examined have an absorption maximum in the u.v. region, showing that the observed photoconduction is due to impurities. The nature of the photoconductivity (whether ionic or electronic) has also not been finally established. Nelson[221] observed photoconductivity in hemoglobin and in gelatin stained with dyes. He suggested that, following light absorption by the protein, energy is transferred by a radiationless resonance mechanism to the dye, which acts as the most easily ionised centre. Studies of photoelectric phenomena in biologically important polymers are only just beginning, and they cannot fail to yield important information on the properties of these polymers in the near future. The writer believes that combined investigations of the photoeffect and luminescence in these compounds will be the most valuable in this field.

A decrease of resistance under illumination is reported in a number of papers dealing with organic polymers, besides those mentioned above. The phenomenon is mentioned in the case of polyacene quinone polymeric radicals[73], poly(*p*-diethynylbenzene)[156], chelate polymers[88], polyazopolyarenes[283], poly(tetrafluorethylene) irradiated by X-rays[284], and others[285]. Extremely interesting work has been reported also on the photoelectric sensitivity of polydisperse organic systems with dyes in the polymer matrix[286,287], or inorganic ions and semiconductors[288].

V. CONCLUSIONS AND PROSPECTS

The vast fund of data on the electrical phenomena taking place in organic polymeric semiconductors, accumulated during the past 5–8 years, is indicative of the rapid development of this branch of knowledge. It must be admitted, that serious obstacles exist to further scientific progress and to the large-scale penetration of these materials into technology. From the scientific point of view these difficulties arise primarily from our uncertain knowledge of the structure of most of the materials examined. This is specially true of polymers prepared by pyrolysis, radiolysis, and similar methods. During the modification of the starting polymers by these methods, far-reaching structural changes undoubtedly occur. Yet, only very few papers deal with the structure of the macromolecule and with the physical structure of the final product. As a rule, authors confine themselves to a statement that their materials have a heterogeneous structure with polyconjugation regions separated by unspecified barriers. Views regarding the size, crystallinity, degree of packing etc. of these formations are extremely hazy. In spite of this, far-reaching conclusions are drawn as to the relationship between the chemical structure of one macromolecule and the electrical properties of the polymer as a whole: in these circumstances, such conclusions are hard to justify. It should be noted that even attempts to correlate the semiconductor properties of low-molecular organic semiconductors (dyes) with the specific chemical structure of their molecules have encountered serious difficulties[289,290]. It is now well established that supermolecular structure is the decisive factor which determines the specific photosemiconducting properties of dyes, whereas the molecular structure (presence of π-electrons) leads only in principle to the appearance of semiconductor properties[9,10,291].

The position is slightly more favourable with polymers prepared by direct synthesis, since in most cases the

chemical structure of the macromolecule is accurately known. But even with these materials the inadequacy of the information as to the role of the physical structure of the resulting polymers in determining their semiconducting properties is readily apparent. Little is known of the influence of defects and foreign impurities on the semiconducting properties of organic polymers. Inorganic semiconductor materials with prescribed properties became available only by rigorous purification followed by doping with the correct impurities. Some problems in solid-state electronics have been solved only by preparing inorganic semiconductors with a total impurity content of 10^{-9}–10^{-10}%. With organic semiconductors, the figure (in the most favourable cases) is higher by 8–9 orders of magnitude.

Thus, whilst not denying the value of a search for new semiconducting organic polymers, the writer believes that there is an urgent need for more detailed studies of their specific physical structure from the point of view of solid-state properties. It is obvious in principle that a periodic chain consisting of carbon atoms attached to an equal number of hydrogen atoms must have an electronic spectrum with allowed and forbidden energy bands. If hydrogen atoms in the chain are replaced by side-groups, the latter can play the part of impurities. Electropositive or electronegative substituents can be treated as acceptor or donor impurities respectively. In contrast to covalent crystals, in which impurity atoms can take up or give up one or several electrons, fixation or emission of a fractional electronic charge is possible in our systems. Transfer of a complete charge may require the cooperation of several bonds acting in the same sense. Many defects of various kinds, found in polymers, can also play the part of donor or acceptor impurities.

As the previous discussion shows, there are essentially two possible charge-transfer mechanisms: the hopping (or jumping) mechanism and the band mechanism. The low mobility values in polymers are a strong argument [292-297] in favour of the former mechanism, which consists of a series of consecutive, activated jumps by the current carriers from one macromolecule to the next. The activation energy for conduction in this case defines the probability of these jumps, and a temperature rise may be thought to increase either the effective mobility or the effective concentration of the current carriers. If the energy barriers are sufficiently permeable, there is also a finite probability of non-activated tunnelling transition by the electrons. According to theoretical work, the hopping mechanism is in principle incompatible with observation of the Hall effect: this may be the reason for the many failures to detect a Hall effect in polymers.

The band model assumes that the charge carriers move in generalised energy bands available to all the π-electrons in the polymer. The width of these bands decreases as the overlap of the wave functions of the π-electrons decreases, and in the limit the bands shrink to conduction energy levels or, in the terminology of the band model, to a very large effective mass of the charge carriers. The band model is based on the strict periodicity of crystalline materials, with allowance for the potential of a real crystal in determining the effective mass of the current carriers. However, many of the polymers in question are amorphous or largely heterogeneous materials. Thus a great deal of interest attaches to the possible application to these systems of the theory of liquid and amorphous semiconductors, in which the electronic properties are determined by short-range rather than by long-range order [296,297]. It has been shown on more than one occasion that long-range order is a sufficient but certainly not a necessary condition for the formation of energy bands [296,297].

Useful results have been obtained also by combining the ideas of the hopping and the band mechanism when dealing with the heterogeneous structures of organic semiconducting polymers. The band model is applicable to an individual macromolecule or to the polyconjugation regions, since these are strictly regular systems, and the conduction electrons can be treated as perfectly free. On the other hand, the migration of charge carriers between macromolecules or regions of polyconjugation is best described by the hopping mechanism.

Pohl introduced the concept of eka-conjugation [73,74] to describe a type of electron delocalisation for which even at room temperature the number of excited states is considerable. He estimates that eka-conjugation will appear if 10–15 pairs of conjugated bonds are present. The nature of the excited states is discussed in terms of excitons and ion–exciton complexes, mutually interacting, and thus substantially assisting the transfer of charge carriers.

In any case, we must remember that the number of organic semiconducting polymers is already of the order of one thousand, and is increasing all the time. It is obviously unreasonable to expect a single theory of electrical conduction to apply equally well to them all.

The problem of the generation of photocurrent carriers in organic polymeric semiconductors is also not finally resolved. By analogy with low-molecular organic semiconductors [1-8,60,64], the photoeffect is assumed to be a multi-stage process [239,248,249]. The primary step is the formation of a singlet or a triplet molecular exciton. These excitons give rise to transfer excitons (two ions) or to a free pair of carriers, either spontaneously or by interaction with defects or other excitons. The latter process depends on the relative contribution of the hopping and the band conduction mechanism. Direct optical transitions to conduction states are improbable under these conditions, which explains the absence of these particular bands in the absorption spectra of the condensed phase.

In addition to an increased concentration of current carriers, envisaged in the above mechanism of carrier generation, we can assume in principle that the role of light is to lower the potential barriers between individual macromolecules or polyconjugation regions. As a result, the effective conductivity increases. This mechanism may operate in polymers whose carrier concentration is unequivocally temperature-independent. The formation of non-equilibrium carriers can also lead to a lowering of the barriers through their polarisation effect. Both processes (increase in concentration and change of barrier height) will then operate together. It should be noted that a detailed analysis of the mechanism of photocurrent generation in semiconducting polymers is complicated by the insolubility (or poor solubility) of most of the compounds examined. Thus, the absorption spectra of the individual macromolecules (in solution) cannot be compared with the absorption spectra and photoeffect of polymers of uniform molecular weight in the condensed phase, which would offer valuable information on collective interactions in polymeric semiconductors. Hence, the development of synthetic routes to soluble semiconducting polymers is a problem of the first importance. At the same time, this approach would clarify the role of intercrystalline and other defective layers, which at present have a major effect on the results since much of the work has been done on compressed discs or powders. There is little doubt also that the availability of soluble polymeric semiconductors would have important repercussions in thin-film electronics.

In general, the problems involved in the practical application of organic semiconductors are of interest for their own sake, and much could be written about them. We wish to state the following. When organic polymers were first introduced into electronics, their basic role was that of insulators. With the appearance of semiconducting polymers, these materials are now considered as potential technological material for semiconductor electronics. Furthermore, the problem of developing materials showing superconducting properties at room temperature[298,299] on the basis of conjugated systems has now been formulated and is being studied. This broad field of applications for polymeric materials is not fortuitous: it derives from the extreme variety of their physicochemical properties and of the methods available for modifying them. Whilst the superconductivity concept has met serious objections, both experimental and theoretical, and needs to be extensively reconsidered, there can be no doubt about the application of semiconducting polymers. The first steps in this direction have already been taken with the preparation of electrophotographic layers[225-234]. Their main shortcoming at the moment is a relatively low photosensitivity, but as was mentioned above there are some effective methods of raising the sensitivity by introducing chemical and spectroscopic sensitisers into the polymers. Radiation detection from the vacuum u.v. to the far infrared becomes possible in principle by using these systems.

The position as regards the application of organic semiconductors is reminiscent of the 1920-1930's, when practical uses for inorganic semiconductors were first suggested. It should not be forgotten that almost 30 years had to elapse before inorganic semiconductors could make an impact on technology over a broad front, whereas studies of organic polymeric semiconductors go back less than 10 years.

Also, there is a tendency to use organic semiconductors as a direct replacement for inorganic semiconductors. In view of the specific properties of the organic materials, this is not always the best approach. Thus, we know that the most successful uses of inorganic semiconductors (in transistors, detectors of various kinds, etc.) depend on the high mobility of charge carriers which characterises these materials. Organic semiconductors, on the other hand, are inferior in this respect. Hence, we must look for specialised areas of application. One possibility is in the electronics of low currents. In organic semiconductors, non-linearity of the current–voltage characteristics sets in at relatively low fields (10^2–10^3 V cm^{-1}), and the materials can be used as non-linear elements (rectifiers, varistors, thermistors, etc.). In conjunction with photochemical methods, they can be used to develop new printing processes. A valuable property of these materials is their ability to transmit excitation, which may find application in entirely new systems of information transmission. As the nature of elementary processes in organic semiconductors becomes clearer, we can look forward to a better understanding of various facets of physical processes in living organisms (mechanism of photosynthesis, energy migration and storage processes in biological systems, carcinogenic activity, catalysis by ferments, colour vision, etc.).

The main problem in the physics and chemistry of organic polymeric semiconductors is the preparation of materials with prescribed electrical properties. Recent advances in polymer synthesis, and the use of newer and more rational physical methods of structure modification, justify the hope that the problem will be solved. There can be no doubt that, as our understanding of electronic processes in organic polymeric semiconductors becomes deeper, ever-widening fields of application in science and technology will be discovered.

I. INTRODUCTION

In most cases the usual sorbents do not exhibit high selectivity with respect to substances (ions) which do not differ markedly in their properties. The combination of ion-exchange or other chromatographic methods with the phenomenon of complex-formation in solution proved extremely useful and led to the discovery of many new efficient procedures for the separation of substances. This is also the idea of precipitation chromatography, which is based on another powerful chemical interaction, the formation of sparingly soluble compounds, in combination with the usual chromatographic methods. The introduction into the chromatographic medium of suitable precipitants as well as complex-forming agents permits selective and very rigorous control of the behaviour of the individual components of mixtures in their separation. The wide possibilities in choice of precipitants, including complex-forming precipitants, make precipitation chromatography one of the most universal methods in chemistry.

A fairly large number of published studies, has accumulated, in which the principles of precipitation chromatography were used. However, the literature on this problem is widely scattered and has been little systematised, and this retards the development and improvement of the method which is essentially very promising. In most monographs on chromatography, precipitation chromatography is either not mentioned at all (although a number of studies using essentially this method is often noted[1-3]) or the method is described very briefly purely on the basis of the paper by Gapon and Gapon (1948).[4-6] The textbook of chromatography published in Poland is an exception[7]: in the chapter devoted to precipitation chromatography 33 papers are quoted, and demonstrate the extremely wide variety of applications of this method. The special monograph of Ol'shanova et al.[8], the only one so far, mentions only about 60 papers on precipitation chromatography. A few more references are quoted in the thorough review on hydrolytic and precipitation chromatography by Hayek[9], but the selection of papers appears somewhat one-sided, as a result of which a number of very interesting developments in the method are not brought to the notice of the investigator.

In view of the existing situation in this field, the author thought it useful to include, together with a review of the basic principles and trends in the development of precipitation chromatography, a scientific and patent bibliography as complete as possible.

II. BRIEF HISTORICAL OUTLINE

The first known study involving elements of precipitation chromatography is in all probability that of Runge[10]. With purely decorative aims, he carried out chemical colour reactions (including reactions with formation of precipitates), by treating with salt solutions filter paper impregnated with various substances. Runge published his own work in 1855 as an album of novel paper chromatograms.

Tsvet[11], the founder of the chromatographic method, noted in 1906 and in 1910 that in many cases of the Schönbein–Goppelsroeder[12] "capillary analysis", put forward in 1861, the formation of a chromatogram on impregnating papers with pigment solutions can be accounted for by the precipitation of the pigment as a result of a concentration gradient of alcohol in the solvent (due to evaporation of the alcohol). However, since precipitation from solutions in these experiments is not caused by the formation of a new substance by a chemical reaction, Goppelsroeder's "capillary" chromatograms cannot be classified as precipitation chromatograms in the generally accepted modern sense of this term (see below). On the other hand, one would be fully justified in classifying as precipitation-chromatographic many reactions carried out in spot analysis[13], particularly in the "fractional" method of analysis which Tananaev proposed in 1920.[14] There are many studies in this field.

For a long time the application of the principles of precipitation-chromatographic separation was only desultory. A certain breakthrough took place in the 1930's. At the beginning of the 1930's Tsvet's chromatographic method was revived, but it was used as before for the separation of organic and biological substances. Towards the end of the 1930's Schwab and coworkers[15,16] suggested that the method be applied also in inorganic chemistry and used alumina extensively as sorbent for this purpose. It was then noted[16-19] that the sorption of certain inorganic ions on alumina exhibits the features (at least partially) of precipitation sorption. Then, following Flood's suggestion[20], paper impregnated with aluminium or chromium hydroxide

began to be used in the analysis of heavy metals[21-27]. The work of Erlenmeyer and coworkers[28-30] stimulated the use as chemical sorbents of organic substances such as hydroxyquinoline, dimethylglyoxime, etc., which form insoluble complexes with many metals[31-36].

In 1948 precipitation chromatography was formulated as an independent chromatographic method. The credit for this is deservedly given to the Soviet physical chemist Gapon. Together with his coworkers, he introduced precipitation chromatography as one of the classified varieties of the chromatographic method[37,38], formulated the basic principles of the precipitation-chromatographic separation of substances[39], and began the first systematic studies in this field[40-46]. Immediately after the appearance of the first fundamental paper by Gapon and Gapon[39], a considerable increase in publications on precipitation chromatography took place both in the Soviet Union and abroad. Starting with 1953, the number of annual publications is not less than 15–20.

III. PRECIPITATION-CHROMATOGRAPHIC MEDIA

In order to separate substances by the precipitation-chromatographic method, a substance capable of reacting with them (or with some of them) to form sparingly soluble reaction products is introduced into the solid phase in the chromatographic medium. Such a substance or ion is called the precipitant. However, the main bulk of the solid phase usually consists of the "carrier". The functions of the latter include imparting the necessary filtering capacity to the system and localisation in the solid phase both of the precipitant and the precipitates produced.

Carriers. Various sorbents (ion exchanger, molecular sorbents) are usually employed as carriers. Frequently solids which are completely inert chemically and physicochemically are also employed as carriers; they serve as fillers, which are introduced mainly to improve the hydrodynamic conditions. In this case powders of sparingly soluble inorganic or organic substances, for example zinc sulphide, dimethylglyoxime, and hydroxyquinoline are used as precipitants. The powdered carriers and sparingly soluble precipitants usually have an average degree of dispersion equivalent to diameters of 0.01–0.1 mm.

The sorbent-carriers retain the precipitates in the form of ions (on ion-exchange resins, zeolites, alumina, and other exchangers), molecules (for example, various organic bases on activated charcoal[47]), or even colloidal particles (for example, the colloidal precipitate of aluminium hydroxide on filter paper[21-27]). One of the principal requirements which must be met by sorbent carriers is also that the carriers should retain the reaction products (precipitates) as well.

In column precipitation chromatography the following carriers are usually employed: alumina ("anhydrous" or "activated for chromatography" and also alumina converted into the anion-exchanger form by treatment with acid), silica gel[34,39,40,44,45,48-57], starch[29,30,32,34,35,48,49,51], Kieselguhr[28,29,34,58,59], glass powder[51-53,60-63], and activated charcoal[47,64-75]. Cellulose[42,49], barium sulphate[29,34,44], gypsum[52], calcium and magnesium carbonates[52,76,77], bentonite[48,78,79], certain metal oxides (zinc[73,75,80-82], magnesium[83,84], lead, lanthanum, and bismuth[82-85], and others), and even ordinary sand[52,53,79,86,87] have also been used.

Application of ion exchangers charged with precipitant ions. This process is interesting because it is thereby possible to remove from solution ions of both charge types at the same time, for example:

$$R^-Ag^+ + NaCl \rightarrow R^-Na^+ + AgCl\downarrow.$$

Gans[88] suggested in 1909 that processes of this kind be used in sorption techniques, referring to an even earlier suggestion by Rümpler[89]. Subsequently this idea was embodied in the so-called silver zeolites, which are widely used for the purification of seawater under special conditions[90]. With the introduction of the synthesis of ion-exchange resins, the application of a cation exchanger in the silver-form was suggested[91] for this purpose, by analogy with the silver zeolite. Somewhat later Gaddis[92] used a weakly basic anion exchanger in the sulphide form instead of gaseous hydrogen sulphides in systematic qualitative analysis. Gaddis's idea was supported and developed further by Kunin[93,94] in 1949, and this was followed by other suggestions concerning the application of ion-exchange resins in the precipitation-chromatographic method: by Aleskovskii and Kheifets[95-98], Glueckauf[99,100], and Kielczewski[101]. Recently ion-exchange resins have been increasingly used in studies on precipitation chromatography (Refs. 102–113 and others).

However, a drawback of such ion-exchange precipitation systems should be noted. This concerns those cases where the solution contains a mixture of ions not all of which form precipitates with the precipitant. In such cases, exchange with the counterions in the solution causes more of precipitant ions to be displaced from the resin than can be consumed in precipitation in the "working" part of the column bed. This can be made clearer by means of an example: suppose that a resin is charged with silver and that the solution contains sodium chloride and nitrate. Sodium displaces from the resin an equivalent amount of silver ions which precipitate chloride ions. Since the ionic concentrations are linked by the relation $[Ag^+]+[Na^+] = [Cl^-] + [NO_3^-]$, it follows that $[Ag^+] > [Cl^-]$. The excess of the unreacted precipitant is washed out of the column with the stream of solvent. Thus the higher is the amount of non-precipitable and non-exchangeable ions (in this example nitrate) the lower is the efficiency of the precipitation-chromatographic column. Ion exchangers are therefore completely ineffective for trapping (precipitating) micro-impurities, for example in the purification of salt solutions. For this purpose, sparingly soluble precipitants are employed.

Sparingly soluble precipitants. In the practical application of precipitation chromatography sparingly soluble precipitants are most frequently used, particularly in paper chromatography. To obtain a precipitate on filter paper, the latter is usually impregnated initially with a solution of one of the reactants, containing as a rule the cation of the precipitate to be formed (since the paper exhibits a higher sorption capacity with respect to cations than with respect to anions). Then the paper is immersed in the solution of the other reactant, whose anion forms the required sparingly soluble compound with the cation present on the paper. It is desirable to wash out the excess of the unreacted salts with pure solvents[20,27,114]. Sometimes the the paper is immediately immersed in a suspension of the previously prepared precipitate[22-27]. Paper is impregnated with sparingly soluble organic precipitants in alcoholic etc. solutions with subsequent drying to remove the solvent[115-118].

Powders of sparingly soluble precipitants are sometimes introduced into the column in a pure form[33,36,76,77,119-125] but most often they are introduced in a mixture with a

filler[28,34-36,60,68]. In most cases the mixture of powders is loaded into the columns in a dry form only ("dry columns"). A homogeneous material can be loaded into columns also in the form of an aqueous suspension (with heterogeneous mixtures there is a risk of layer formation in the preparation of suspensions). An advantage of "wet" columns over "dry" columns is that in the former there are no trapped air bubbles which prevent the operation of part of the charge.

In some cases more than one precipitant is introduced into the chromatographic medium in order to increase the number of absorbing substances[27,48]. On the other hand, certain properties of the chromatographic medium are sometimes improved by using a carrier of more complex composition. For example, Hopf[32] initially impregnated paper with starch and then with the precipitant (violuric acid), probably in order to increase the concentration of the precipitant on the paper. In another study[126] a mixture of finely ground alumina and cellulose pulp, obtained by boiling cotton wool in dilute nitric acid, was used to produce a sorbent with the highest possible surface area and a good filtering capacity. The alumina adhered satisfactorily to the cellulose pulp, the combined carriers being subsequently charged with the precipitant (phosphate).

The carrier (filler) can also take a more active part in the precipitation absorption process. Thus, according to Napol'skii[87,127], the addition of magnesium or calcium oxide to dimethylglyoxime helped maintain in the column the optimum acidity of the medium for the precipitation of nickel (pH $\geqslant$ 6):

$$\begin{cases} NiSO_4 + 2\,H_2Dm \rightleftarrows Ni(HDm)_2\downarrow + H_2SO_4\,, \\ H_2SO_4 + MgO \rightarrow MgSO_4 + H_2O\,. \end{cases}$$

In some cases columns consisting of several beds with different precipitants were used[30,87,97,128-131] to ensure selectivity of absorption and a clear-cut separation of a number of substances[132].

It is noteworthy that a fairly widely used method of preparation of the precipitation-chromatographic medium, in which a readily soluble precipitant is introduced into the carrier, is erroneous. For example, columns with mechanical mixtures of a carrier and a readily soluble precipitant are used fairly frequently, the fraction of the precipitant amounting sometimes to 10–50% of the charge[39,40,44,48,108,133-137], or paper is impregnated with a solution of a readily soluble salt and then dried without washing[138-145]. In experiments with the usual carriers having low sorption capacity (paper, alumina, etc.) such a technique is undesirable, since soon after the start of filtration of the solution the excess of the precipitant, not fixed on the carrier by sorption forces, is washed out of the latter. Only in rapid processes (for example in spot reactions) can the substance react more or less completely with the precipitant. On the other hand, under the usual conditions of the chromatographic process, such technique is ineffective. It is even less applicable in quantitative analysis based on the size of the precipitation bands, which requires uniform distribution of the precipitant in the chromatographic medium (see below). The advantages of sparingly soluble precipitants in systems resembling those used in precipitation chromatography were pointed out by Clarke[146,147] as early as 1937. Investigators who used the precipitation-chromatographic method for quantitative analysis arrived at the same conclusion[62,114].

Among other principles of carrier and precipitant selection, one may note the tendency (in those cases where it is possible) to choose white or pale coloured carriers and precipitants, which form coloured precipitates with the ions evolved. In most real cases this can be fairly readily achieved and the investigator then secures the valuable advantage of being able to follow the process during the separation period and to correct the operation as required. To make observations on precipitates whose colour does not differ from that of the background, a phosphor may be introduced into the column before the experiment[48].

IV. PRECIPITATION-CHROMATOGRAPHIC METHODS OF SEPARATION

A fairly wide variety of procedures for the separation, purification, and concentration of substances is already used in precipitation chromatography. However, the possibilities of precipitation chromatography are still far from being exhausted and eventually the number of methods should probably increase considerably. The present situation in this field must be regarded as merely the initial stage of development.

One of the simplest chromatographic procedures based on precipitation chromatography consists in selective absorption of one of several substances in a solution passed through a suitably prepared column or impregnated paper. This method is widely used both in the concentration of substances from dilute solutions[62,87,146-148] and for the removal from solutions of specific interfering impurities[64-68,71-75,80,104,105,149,150]. In both cases precipitation chromatography has significant advantages over other methods used for the same purposes. In the first case (concentration) the minimum concentration at which a given substance can be absorbed from solution is usually very low as a result of the very low solubility products of the precipitates formed. This permits virtually quantitative isolation from solutions of components present even at microconcentrations[103,151]. On the other hand, ion-exchange resins and the usual sorbents are not very suitable for the removal of microimpurities from salt solutions at high concentrations because of insufficient differences in sorbabilities[73], while precipitation systems readily overcome this difficulty.

The advantages of precipitation under chromatographic conditions compared with static conditions are evident: the technique is simpler, the number of operations required is smaller, the time needed is shorter, the efficiency of separation is higher, and the risk of losses and contamination during the separation process is lower. We may quote the following examples of the significant simplification of technique. It has been suggested that in partition paper chromatography of alkali and alkaline earth metals the interference of polyvalent ions be eliminated as follows[152]. Polyvalent anions are precipitated from the solution as sparingly soluble lead salts at the beginning of the chromatographic band (not far from the start), where two drops of lead acetate solution are deposited before the start of the experiment; at the same time the test cations pass freely through the lead spot and move further along the paper in the usual order. Precipitation in chromatographic columns and not under static conditions is particularly desirable in those by no means rare cases[153,154] where colloidal precipitates are formed, since precipitation-chromatographic media quite often show a satisfactory capacity for the retention of colloids.

Many studies have been described in the literature on the separation of two and more substances by the selective absorption of some and the free passage of other mixture components[47,101,112,155,156]; in this way it is possible to separate ions and substances with similar properties[44,47,54,59,76,77,87,127,157-161].

Adequate selectivity of absorption under real conditions can be ensured both by the selection of the appropriate precipitant and, in the case of ion-exchange carriers, by the choice of an ion exchanger with the required acidity or basicity [92,99,100]. For this purpose (to ensure the specificity of absorption), Hesford [47] suggested that activated charcoal be saturated with bases differing in their dissociation constants: aqueous ammonia, methylamine, diethylamine, urea, ethanolamines, alkylamines, hexamines, pyridine, and others. Strong bases were used to separate most of the cations, forming insoluble hydroxides, from alkali and alkaline earth metals, while weak or complex-forming bases were used for the isolation or separation of particular cations.

Substances retained in the columns are then eluted with solutions of acids, alkalies, or complex-forming agents. Another separation procedure is based on the choice of a selective solvent, which elutes only one or some of the components to be separated which are retained in the column [47,63,111]. For example, on the alumina and cellulose pulp columns [126] mentioned above, silver and iron(III) ions were absorbed in the form of the phosphates and then eluted successively with 0.1 *N* acetic acid (silver) and hot 2 *N* hydrochloric acid (iron). The separation was quantitative. Kielczewski used an unusual procedure [110] for the separation of silver and copper(II) on an anion-exchange resin saturated with arsenate. After both silver and copper had been absorbed on the resin, hydrochloric acid was passed through the column. This resulted in the elution of copper, while the silver arsenate precipitate was converted into silver chloride, so that silver remained in the column. Subsequently silver was eluted with aqueous ammonia (complex-forming solvent).

Precipitation-chromatographic methods on paper differ little from the usual paper chromatographic procedures. Both linear and circular chromatograms are produced. A definite volume of the test solution is usually deposited with a capillary on impregnated paper and the chromatogram is then eluted with a pure solvent until the stabilisation of the zone boundaries. Sometimes dilute solutions can be applied to the paper continuously, i.e. by simple impregnation of the paper with solution at one end [162,163]. The thin-layer precipitation chromatographic technique [55-57] is in many ways similar to paper chromatography.

When a clear-cut detection of all the zones is required on paper or in a column, the primary chromatogram obtained (as a result of the passage of the initial solution) is washed with water or weak aqueous solutions of mineral salts; sometimes it is washed also with organic solvents [54,118,164-166]. If necessary the zones can be revealed by means of solutions or vapours of the usual reagents [22-24,109,139-145,167], or, especially in columns, by means of adsorption indicators introduced with the test solution [137,168-171].

When the primary precipitation chromatogram is washed with organic solvents, the components of the mixture on impregnated paper are frequently separated by elution [115-117, 172,173]. Possibly, it is more correct to regard these as cases of partition rather than precipitation chromatography.

One of the varieties of precipitation chromatography is a separation procedure in which absorption in the solid phase is due to an oxidation–reduction reaction with formation of a sparingly soluble reaction product [8,109]. An example of the application of this method is the use of manganese zeolites [174] for the removal of iron(II) and manganese(II) from water (in cases where the possibility of the preliminary aeration of water is limited and in certain others). The manganese zeolite is a source of oxygen which oxidises the divalent iron and manganese ions to the trivalent state, this being accompanied by the precipitation of the hydroxides. Oxidant additives (sodium permanganate) were used earlier in [175] gas mask filters. A small amount of the oxidant in the gas mask (about 3%) served to oxidise certain gases, for example arsine, which are poorly sorbed by activated charcoal and soda lime (the principal components of the gas mask filter). It has recently been suggested [176] that precipiation-chromatographic columns with a silver precipitant be used to trap arsine (from the gas phase):

$$AsH_3 + Ag^+ \rightarrow Ag_3As\downarrow + Ag^0 + AsO_3^{3-}.$$

The reducing properties of certain ion exchangers, including electron-exchange resins, have found application in the extraction (concentration) of noble metals from solutions [106,107,177].

We may mention yet another method—the procedure for the preparation of stable sols with the aid of precipitation-chromatographic columns [43,44,94,178,179]. In general this method cannot be regarded entirely as precipitation chromatography, since for this purpose one selects a special carrier, which, while retaining the precipitant, should not retain in the column the resulting colloidal precipitate. For example, the following processes have been achieved on ion exchangers [179]:

$$R(OH)_3 + AlCl_3 \rightarrow RCl_3 + Al(OH)_3\downarrow,$$
$$R'H_2 + Na_2SiO_3 \rightarrow R'Na_2 + H_2SiO_3\downarrow.$$

The sols obtained are very pure.

Yet another application of precipitation chromatography is the procedure for the quantitative determination of organic acids on paper impregnated with a hydroxide [180,181]. The quantitative analysis is based on the measurement of the area (or weight) of the section of the paper freed from the hydroxide precipitate as a result of dissolution by the test acid.

V. DIFFUSIONAL PRECIPITATION CHROMATOGRAPHY

The difference between the unusual variety of precipitation chromatography and the normal procedure is that here the principal mass-transfer mechanism is diffusion and not filtration of the solution. The specificity of the reaction medium consists in the fact that the latter does not permit the filtration of the solution and convective mixing of the substances. Such media include moisture-saturated porous materials [44,130,182,183], solutions in capillaries [184-186], and gels. The last are used most often, and therefore such chromatograms are also called "precipitation chromatograms in gels" [185-188]. The brief, accurate, and general name given in the heading of this section was proposed by Olenovich et al. [189].

The technique of this method is very simple. A fused gel of gelatin, agar-agar, or a similar substance, to which the precipitant had been introduced earlier in the form of a solution, is poured into test tubes or Petri dishes. When the gel has set, the test solution is poured onto its surface (in Petri dishes in the form of individual drops). The diffusion of the components of the solution into the gel is accompanied by the precipitation of the various deposits, which results in the continuous development of the chromatogram [185-196].

Some investigators have used paper impregnated with gel together with the precipitant [197,198]. Diffusional precipitation chromatograms can also be obtained in capillary tubes sealed at one end and filled with a precipitant solution (without gel) [185,186,199]. Such capillaries are simply immersed in the test solution with their open ends downwards.

A modified technique is used for special purposes: counter-diffusion of reacting substances in a pure gel medium [182,183,200-202].

VI. THEORY OF PRECIPITATION CHROMATOGRAPHY

1. Problems of Precipitation Sorption

The term "precipitation sorption" includes any processes where the absorption of a substance in an already existing solid phase involves the formation of a new solid phase due to the production of a sparingly soluble compound by a chemical reaction. This precipitation sorption is a complex process. In one of its stages the solute reacts with the precipitant which leads to the precipitation of a sparingly soluble compound. The following, no less important stage is the fixation of the newly formed precipitant in the solid phase. The nature of this fixation can be extremely varied—ranging from mechanical retention to adhesion or molecular fixation. The successful absorption of a substance in a precipitation-chromatographic system depends not only on the correct choice of the precipitant but also on the choice of the carrier which is capable of firm retention of the precipitates formed.

The present author [203] derived an equation for the isotherm of ionic precipitation absorption taking into account only the solubility of the precipitate (i.e. assuming that the precipitate is completely and firmly retained in the solid phase). It was found that the isotherm exhibits virtually maximum convexity. According to the familiar postulates of chromatographic theory, a number of important conclusions follow from this finding. When the isotherm is convex, dynamic precipitation sorption takes place with the formation of the so-called steady-state front, i.e. under conditions of parallel transfer of the sorption front. In those cases where the influence of the sorption kinetics or various longitudinal flow perturbations is weak, the effect of the convexity of the isotherm (tending to sharpen the front of the sorption wave) is particularly pronounced. As a result, exceptionally distinct zone boundaries are particularly frequently observed in precipitation chromatography [8,39,44].

Precipitation sorption on sparingly soluble precipitants. Earlier it was noted that in the practical application of precipitation chromatography, substances which are sparingly soluble in the solvents used but can react with the ions subjected to chromatography, forming even less soluble products, are employed very often as precipitants (the present author suggests that such precipitants be referred to as sparingly soluble). For example, zinc sulphide can absorb copper, cadmium, silver, and other ions, since the sulphides of these metals are even less soluble in water than zinc sulphide. The inclusion of such heterogeneous displacement reactions in precipitation-sorption processes is consistent with the generally accepted definition of a bulk-phase chemisorption reaction: "the absorption process due to a heterogeneous chemical reaction gradually spreads throughout the bulk of the solid, ... producing a new substance in the form of a new phase" (Lepin' [204]).

The absorption of ions on sparingly soluble precipitants is sometimes difficult to distinguish formally from ion exchange. Hayek [9] suggested that two varieties of formal ion exchange be distinguished: ion exchange on relatively high-molecular weight substances without appreciable change of structure, for example:

$$Ca_5(PO_4)_3OH + F^- \rightleftarrows Ca_5(PO_4)_3F + OH^- ,$$

and with change of structure of the initial substance, for example:

$$AgCl + Br^- \rightarrow AgBr + Cl^- .$$

The present author believes that the inclusion only of reactions of the second kind (with change of structure, i.e. with formation of a new solid phase) among precipitation processes is quite acceptable. For example, on the basis of the same considerations, one is quite justified in including among precipitation chemisorbents also the large class of sparingly soluble complex-forming precipitants (of the type of dimethylglyoxime and hydroxyquinoline), despite the apparent complexity of their molecules.

Precipitation sorption on ion exchangers. The application of ion exchangers in precipitation chromatography is based on a three-stage process [8,205,206]: (1) displacement of the precipitant ion from the resin by ion exchange; (2) its reaction with the ion undergoing chromatography leading to the formation of sparingly soluble compounds; (3) fixation of the precipitate on the resin. It has been established [205,206] that on synthetic resins with a high exchange capacity, the ion exchange and formation of a sparingly soluble compound can be clearly distinguished both in time and in space. The ion-exchange displacement of the precipitant ion A linked to the resin matrix R:

$$R^-A^+ + B^- + M^+ \rightleftarrows (R^-M^+ + A^+) + B^- ,$$

results in the binding of the ion B in the precipitate,

$$A^+ + B^- \rightarrow AB\downarrow$$

only after the liberated ions A have diffused to the surface of the resin grain. The explanation is that, as a result of the Donnan potential, the free electrolyte BM virtually does not enter the resin phase [94,207]. Helfferich [208], who considered the problem of the kinetics of ion-exchange processes accompanied by any chemical reaction, recently arrived at similar conclusions. Thus the view that the precipitates are formed and fixed within resin grains [103,105,110] must be regarded as erroneous.

The problems of the equilibrium in the system ion exchanger—sparingly soluble electrolyte—water have been examined in a number of studies [207,210-215]. Grigorov and Tarshis [209] demonstrated the equivalence and the reversibility of ion exchange accompanied by a chemical precipitation reaction. To show this, three successive ion-exchange cycles, including the reaction of barium chloride (or potassium sulphate) solution with the ion exchanger in the silver (or barium) form and the regeneration of the resin with a solution of silver nitrate (or barium chloride), were carried out. Despite the increasing amount of the precipitate (silver chloride or barium sulphate), the amounts of the ions undergoing exchange remained virtually constant in all three cycles. In general the possibility of the regeneration of the column without eluting the absorbed substance [106,107,113] is one of the valuable features of precipitation chromatography. For example, after a number of repetitions of the absorption–regeneration cycles on an electron-exchange resin, it is possible to accumulate reduced silver in amounts up to 300–400% of the weight of the resin [107].

Koblyanskii and Kameneva [216] observed higher rates of ion exchange in a cation-exchange column if the exchange was accompanied by the formation of a precipitate; this is

explained by the displacement of the ion-exchange equilibrium to the right. On the other hand, the general form of the elution curves revealed a dependence both on the solubility product of the precipitate formed and on the constant for the exchange of the corresponding pair of ions. The present author [205,217] showed that conditions of parallel transfer are established in the motion of the precipitation-sorption wave in cation-exchange and anion-exchange columns regardless of the constants for the exchange of the corresponding ions. He also developed a mathematical theory of dynamic precipitation sorption on ion exchangers.

Elsewhere [205,206] he discussed the problem of the mechanism of the fixation of the precipitate on the surface of the resin grains. The following probable mechanism of the fixation by adhesion of the peptised precipitate AB on the resin R was proposed:

$$R^-A^+ + B^- + M^+ \rightarrow R^-M^+ \cdot (B_n^- \cdot AB) + nM^+ ,$$

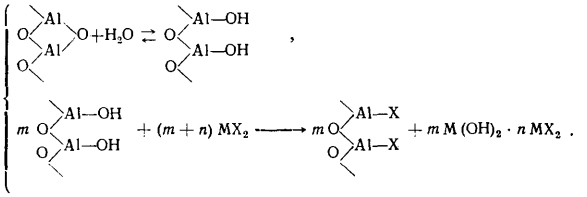
where part of the ions M remain in the diffusion layer at the precipitate particles.

Precipitation sorption on alumina and certain other inorganic sorbents. Because of its wide use in the chromatography of inorganic ions, alumina has attracted the attention of many investigators who attempted to elucidate the sorption mechanism. Gapon [38,218,219] believed that the absorption of cations on basic alumina and the absorption of anions on acid (treated with acid) alumina is due to ion exchange at the aluminate group:

$$(Al_2O_3)_mAlO_2 \cdot Na + A^+ + B^- \rightleftarrows (Al_2O_3)_mAlO_2 \cdot A + Na^+ + B^- ,$$
$$(Al_2O_3)_mAlO \cdot NO_3 + A^+ + B^- \rightleftarrows (Al_2O_3)_mAlO \cdot B + A^+ + NO_3^- .$$

The sorption of polyvalent anions on basic alumina and polyvalent cations on acid alumina was explained in the same papers [218,219] by the reversal of the charge on the sorbent surface by the polyvalent ions.

Without rejecting the possibility of the absorption of ions by ion exchange on alumina, most investigators nowadays believe that a hydrolytic absorption mechanism [9,17-19,84,85,220,221] is more likely for heavy metal salts on basic alumina, for example [81]:



Heavy metals are sorbed as precipitates of hydroxides or basic salts, for example $Cu_2(OH)_3Cl$ from $CuCl_2$ solutions [83,84,222,223], $Co_2(OH)_3Cl$ from $CoCl_2$ solutions [84], and $Cu_4(OH)_6SO_4$ from $CuSO_4$ solutions [84].

The capacity for hydration, which determines the absorption capacity of alumina, depends on the heat-treatment of the latter in its preparation from the hydroxide [223-225]. This capacity is a maximum for γ-alumina (the cubic form) obtained by heat treatment at about 600°C and is absent in the α-form (the rhombohedral form) formed on heating above 1200°C.

It has been noted [84,85] that the same hydrolytic mechanism accounts for the absorption of heavy metals on certain other basic substances, for example on magnesium or lanthanum oxides (as well as on anion exchangers in the hydroxide-form). The absorption of strong electrolytes from aqueous solutions on charcoals is regarded as hydrolytic [175,226-228]. This is indicated by the similarity (with certain unimportant exceptions) of the sorption series for heavy metals on basic alumina [15,16,19,85,133,221,229,230], lanthanum oxide [85], partially dehydrated ferric hydroxide [125], and on charcoal [231], both to one another and to the series of the solubility products of the hydroxides of these metals [232].

The sorption of heavy metals on alkaline silica gel is attributed to the formation of sparingly soluble polysilicates [233]. Here the polysilicate macroion of silica gel serves as a precipitant ion for certain metals. The same sorption series was obtained as for the solubilities of the silicates [233,234].

Certain anions are also sorbed on alumina by a precipitation mechanism [82]. In those cases where alumina is used as a carrier with a sorbed precipitant it is not always possible to observe the fixation of the newly formed precipitates on the carrier [39,43,44]. If the precipitate was nevertheless retained in the column, it was found [205,206] that the individual crystals of the precipitate are fixed on the surface of the grains of alumina (both basic and acid). Since the nature of these adhesion forces is not entirely clear, it is so far necessary to choose empirically the conditions under which the precipitation-chromatographic process can be successfully taken to completion (without loss of the precipitates).

2. Conditions for the Formation of Precipitation Chromatograms

The main factor which determines the separation of substances in precipitation chromatography is the difference between the solubilities of the precipitates formed [39]. Being a variety of the chromatographic method, precipitation chromatography is a dynamic process with multiple repetition of the fundamental step [8,53]. Schematically the formation of precipitation chromatograms can be described as follows [235]. When fresh portions of solutions enter a given element of the column (or impregnated paper), the component which reacts with the precipitant to yield the least soluble precipitate displaces the appropriate components from the previously formed more soluble precipitates. The displaced components move further with the solvent stream and are again precipitated in those layers of the column where there is either the free precipitant or a more soluble precipitate with other components. Frequent repetition of such redistribution of material in the direction of the stream leads to the formation of a developed precipitation chromatogram.

Two evident conditions must be satisfied for the formation of a precipitation chromatogram. In the first place the precipitate must be fixed in some way in the solid phase of the chromatographic medium and should not be eluted with the solvent stream [54,78,109,236] and in the second place the precipitates formed must be retained at the site of their precipitation [8,40,53,147,236-238].

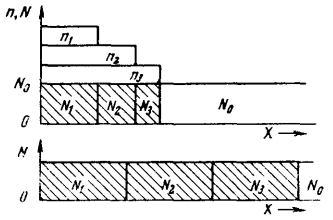
3. Structure of Precipitation Chromatograms

The sequence of the zones in precipitation chromatograms depends on the order of precipitation of the corresponding substances [8]. In the determination of the sequence of the zones one examines in the first place the relative solubility products of the precipitates and in addition the relative concentrations in the initial solution of the substances being separated [8,239]. The present author has given a rigorous mathematical derivation of the general

relations whereby the sequence of the zones in precipitation chromatograms can be predicted[240].

Gapon[43,44] proposed an approximate method for the determination of the zone sequence from reduced solubility products. Although this method is not quite rigorous (for this reason certain exceptions to the rule are observed)[44], in the majority of cases it gives a qualitatively correct picture. In Gapon's method the solubility products of the precipitates are compared after being raised to a power equal to the smallest common multiple of the number of precipitant ions in the precipitate molecule [the factor by which the number of precipitant ions in the precipitate molecule has to be multiplied to give the smallest integral common product (Ed. of Translation)]. For example, in the comparison of the solubilities of iron(III), copper(II), and silver(I) their solubility products are raised to the second, third, and sixth power respectively. The zone sequence (beginning at the start) should correspond to the sequence of increasing values of the quantities thus obtained.

In contrast to the other varieties of chromatography (molecular, ion-exchange), for precipitation chromatography with considerable differences between the solubilities of the resulting precipitates, theory predicts[205,239,241] a simple structure of the chromatogram with virtually only one component of the initial mixture (see Figure) in the solid phase of each zone. In the primary chromatogram some zones, in particular the first (at the start), may still contain admixtures of other components of the initial mixture in the form of a free solution, but in the washed chromatogram every zone contains only one component each. The zones follow one after another without discontinuities, usually with very distinct zone boundaries.



In the ideal case the ratios of the concentrations of the precipitant in the carrier (N_0) and the densities of precipitation (N_1, N_2, N_3, ...) should be equivalent. Under real conditions this requirement is satisfactorily met on finely dispersed sorbent-carriers[52,53,62,205,236].

The washing of the primary chromatogram with an indifferent solvent leads to the widening of the primary zones (particularly those further removed from the start), but only up to a certain limit, beyond which further washing virtually does not change the chromatogram[238,242]. This limit is determined by the amount of substance introduced and the precipitating capacity of the medium[235].

The distribution of the precipitates in the washed chromatogram has been little investigated by direct analysis. In some cases[78] insufficiently complete separation was observed in zones close to the start, although the zones were clearly distinguished by colour. The present author investigated[205,241] the reasons for the incomplete separation in certain specific systems. It was established that in highly dispersed inorganic ion exchangers charged with a precipitant ion, the contamination of initial zones by other components of the initial mixture can be accounted for by the adsorption coprecipitation of ions on the precipitates of the main substance; this occurs to a small extent. On sparingly soluble precipitants and in particular on ion-exchange resins charged with precipitants there is also a poor separation of mixtures in the chromatographic medium due to kinetic causes (continuing precipitation of impurity components from the free solution after formation of the primary chromatogram, when there is not sufficient time for the complete consumption of the precipitant during the brief period when the primary chromatogram is formed). To improve the separation in this last case, it is recommended that the primary chromatograms be washed immediately when the filtration of the initial solution is completed.

4. Quantitative Analysis by Precipitation Chromatography

In view of the very great simplicity of precipitation chromatograms (see Figure), simple quantitative determination of the components from the size of their zones in the chromatograms is possible. One of the conditions for quantitative analysis by precipitation chromatography, together with those enumerated above (see Section VI, Subsection 2), is the uniformity of distribution of the precipitant in the chromatographic medium[8,62,205,236,238].

Washed chromatograms. When washed chromatograms, which virtually do not contain the substances being analysed in a free form (see Figure), are used, a simple linear relation between the quantity of the component introduced and the size of its zone is obtained. The size of the zone is defined as follows: in column chromatography the volume or height of the zone[34,35,50,123,243], in paper or thin-layer linear chromatography the length[21,24-26,55,57,162,244-256], the area[166,257-273], or the weight of the zone[274-277] after the latter has been cut out, and in circular chromatography the area of the circular and annular zones[114,278,279].

Quantitative analysis by precipitation chromatography has proved so simple and convenient that in certain cases it has been used as a simple final step in analytical determinations. For example, it has been suggested[255,262] that partition and precipitation chromatography be combined, the first method being used to separate the ions and the second for their quantitative analysis, after the individual components have been transferred with the aid of appropriate solvents from the chromatograms where they had been separated to paper impregnated with the precipitants.

Although usually quantitative analysis by precipitation chromatography is used for the analysis of a single precipitable substance, there have also been studies on the quantitative determination of components in complex chromatograms[34,35,123,244,248,251,254,258,272,273]. The present author's investigation in this field[205,241] showed that, despite the partial retention of certain mixture components in zones other than their intrinsic zones (see above), the relations between the sizes of washed zones in complex chromatograms and the concentrations of the corresponding components in the initial solutions (for a constant sample volume)

remain linear or nearly so. As a result, quantitative analysis of complex mixtures by frontal precipitation chromatography is possible without preliminary separation.

In the chromatography of various ions on media with sparingly soluble precipitants a steady increase in the length (or area) of the zones with increasing solubility products of the precipitates was observed[62,78,114]. Kulaev[141,143,144] relates the velocity of the precipitation front directly to the solubility product, which of course is unjustified. The present author believes[205,241] that the above relation is due to differences in the rates of the reactions of the solution components with the precipitant. The rate of the displacement reaction is higher the greater is the difference between the solubility products of the starting material and the final product.

Primary chromatograms. Some investigators have used primary unwashed chromatograms for the quantitative analysis of a single precipitable component[51,78,135,137,168,170,280-285]. The zone size–concentration calibration graphs are then curves concave towards the zone size axis. The reason for the non-linearity of the calibration graphs is that part of the solution does not react with the precipitant, since it is retained by capillary forces behind the precipitation front in the free volume of the column[205,236]. Thus Stefkin[286] obtained a linear calibration graph over a fairly wide range of concentrations (0.016–0.5 M) even though he used unwashed chromatograms, but the latter were obtained by filtration at a reduced pressure: the solution was then drawn downwards in its entirety, without begin retained in the free volume of the column.

An equation for the relation between the size of the precipitate zone and the concentration of the initial solution and certain other factors was derived by Cetini and Ricca[238] and more rigorously by the present author[205,236]. The present author used this equation[205,236] as a basis for a more accurate and simpler method of quantitative determination of a single precipitable substance from the primary precipitation zone using linear calibration graphs in transformed coordinates (the reciprocal of zone size plotted against the reciprocal of concentration).

The present author[205] has also proposed a method of quantitative determination of a single precipitable substance from a primary circular zone, in which a very simple technique is employed. To determine the concentration of the solution, it is necessary to immerse a "wick" of impregnated paper into the test solution and then terminate the impregnation with solution at any convenient time: after drying the paper, it is necessary to measure the ratio of the radii of the solvent front and the precipitation zone (or the ratio of the areas of the corresponding circles). Mathematical analysis showed that linear calibration graphs are obtained when the square of the ratio of the radii or [the ratio of (Ed. of Translation)] the areas of the circles are plotted against the reciprocal of concentration. However, it should be noted that the use of primary chromatograms for quantitative analysis becomes ineffective at relatively high concentrations, and therefore in the general case it is more desirable to employ washed chromatograms.

The maximum dilution method. This method, proposed by Shemyakin and coworkers[5] is used in some cases for the quantitative determination of single precipitable substances[109,111,141,144,169,287-292]. The method consists in a number of successive dilutions of the test solution until the latter gives a negative qualitative response with respect to the ion being determined when tested on a precipitation-chromatographic medium. In preliminary experiments it is necessary to determine the minimum detectable amount and also an empirical "correction for losses", which is about 3–10%.[8] The method has very little accuracy[141], is laborious (particularly in the column version), and is suitable only for approximate determinations of microconcentrations[292].

5. Secondary Phenomena

The various processes involving changes in precipitation chromatograms after formation are combined under the common name "secondary phenomena in precipitation chromatography"[8,41-44,183,293-296]. In laboratory practice secondary phenomena are encountered very rarely (only in special cases) when washed chromatograms are obtained. However, in unwashed (primary) chromatograms, where the chromatographic layer contains free solutions at fairly high concentrations in addition to the precipitate, there is an extremely wide variety of secondary phenomena. In contrast to the requirements of analytical practice, where usually only washed chromatograms are dealt with, the study of secondary phenomena in precipitation-chromatographic processes under natural conditions (for example, in the investigation of certain ore-formation and soil-formation processes) is of exceptional importance.

The major proportion of secondary phenomena in precipitation chromatography consist in the effects of diffusion processes[294,295], which are frequently accompanied by various chemical reactions. In the precipitation chromatograms of the iodides of mercury, bismuth, and lead secondary complex-formation reactions combined with diffusion processes have been noted[43,44,295].

Very frequently (and both in washed and unwashed chromatograms) recrystallisation of the precipitates is observed, leading to the growth of bigger crystals at the expense of a large amount of small crystals[44,205,206]. The recrystallisation of precipitates is a favourable process from the standpoint of the firm fixation of the precipitate in the chromatographic media. Both the solubility and the extent to which the precipitates are dislodged are greatly reduced. However, the subsequent elution of the absorbed substance from the column becomes more difficult.

The disruptive effect of precipitates in porous media noted in some cases deserves attention[41,297].

6. Theory of Diffusional Precipitation Chromatography

In diffusional-precipitation systems the velocity of the precipitation front depends on a number of factors: the ratio of the diffusional capacities of the outer and inner electrolytes[298], the concentrations of the outer electrolyte[185,186,190,205,299,300], the inner electrolyte (precipitant)[205,300], and the gel[185], and also the solubility of the precipitate formed[198]. The relative contributions of all these factors in fact determine the form of the diffusional-precipitation chromatogram.

It has been shown[205,298,300] that analytical solutions available from the theory of diffusion[301] and thermal conductivity[302] cannot be applied directly to diffusional-precipitation systems. At the same time an adequate mathematical description of diffusion complicated by precipitation is so far lacking.

The simplest theoretical examination of precipitation diffusion, postulating a linear process[205,303], leads to the

conclusion that the ratio of the square of the depth of the precipitation zone to the time elapsed is constant if the concentration of the outer electrolyte remains constant. The validity of this hypothesis has been firmly established by numerous experimental investigations [303,304].

Diffusional precipitation with a non-constant source was investigated by Watanabe [305] and Mofávek [306]. The equations obtained by Mofavek describe the process more accurately [205,300].

Krishnamurti and Dhareshwar [198] observed empirically a relation between the height of the precipitation zone x and the solubility of the precipitate S. Using the diffusional precipitation (in an agar gel) of silver salts with ten anions of different valence types as an example, the relation was found to be of the form

$$x = k + k' \lg S \ ,$$

where k and k' are constants characterising a number of precipitation systems with a common precipitant ion.

In his study of the rate of penetration into the gel of the precipitation front for different (constant in time) concentrations of the outer solution c_0 the present author observed the following relation [205,300]:

$$x = (a + b \lg c_0) \sqrt{t} \ ,$$

where a and b are constants which depend on the concentration of the precipitant in the gel and t is the time. Using this equation, it is possible to improve the accuracy of, and make more convenient the quantitative analysis of solutions by the diffusional-precipitation method [196,299], which is simple and not at all laborious [205,300].

It has been noted [185] that the change in the density of the gel has little effect on the velocity of the precipitation front. Probably the Traube–Shikata rule [307], first established for the diffusion of dyes in gels, namely $\sqrt[3]{c_g D} =$ const. (c_g is the concentration of the gel and D the diffusion coefficient), holds in diffusional-precipitation systems.

Since a washed chromatogram cannot be obtained in diffusional-precipitation systems, one cannot expect the separation of the mixture components into individual zones: the liquid phase of the gel will contain all other initial-solution components, which form with the precipitant more soluble reaction products. Here we have the same situation as in the usual primary chromatograms: the visual separation of the chromatogram into zones (according to the colour of the precipitates) is not by itself evidence of sufficiently complete separation of the mixture.

The distribution of concentrations in diffusional-precipitation chromatograms is much more complex than in the usual chromatograms. The distribution along the column of precipitate of even a single substance is fairly complex, the chromatogram including bands of different colour and degree of transparency (depending on the size and amount of the precipitate crystals [308]). The zones of adjacent precipitates are sometimes separated by a region of the gel free from precipitate [185-187,192,195]. The effect of the precipitant concentration and the concentrations in the outer solutions, and the gel on the size of this region was investigated by Milone et al. [192].

Various repetitive structures, the so-called Liesegang rings [309,310], are fairly frequently superimposed onto the general pattern. However, it has been shown [205,298,311,312] that the presence or form of such structures in no way affect the principal features of the motion of the diffusional-precipitation zone front.

VII. APPLICATIONS OF THE METHOD

Examples of various applications of precipitation chromatography have already been noted above. Certain common precipitates for the separation of inorganic ions are indicated in the bibliography [327-355].

Among the traditional ways of using the precipitation-chromatographic method, one of the most important is qualitative chemical analysis [13,14,92,102,117,133,136,142,146,147,195,313,314]. A classical example of sensitivity and specificity is the qualitative test for nickel, which is carried out on a dimethylglyoxime column: the minimum detectable amount is 0.2 μg in the presence of a ten thousand-fold excess of cobalt [76,77].

Quantitative analysis by precipitation chromatography is used mainly for inorganic ions. The method has been employed for the analysis of metals and alloys [34,35,86,119,120,140,245,246,249,250,271], minerals [119,120,196], natural waters [163], various biological materials [86,152], and food products and materials used in the food industry [109,134,168,169,287-290,315]. Apart from inorganic ions, the substances separated and analysed have included organic acids [165], lower aliphatic amines [54], phenols [267,273], reducing sugars [261], and various pharmaceutical preparations [48,187,188,316].

Precipitation chromatography has found wide application in the thorough purification of salt solutions (removal of microimpurities), for example in the purification of salts for the preparation of phosphors [64-66,68,72,73,80,104,105,149,150,317-319]. The residual content of heavy metals in the products does not exceed 10^{-5}–10^{-6}%. The methods proposed are very economical, simple, and convenient. For example, it is possible to purify hundreds of kilograms of zinc or cadmium sulphates, giving "chemically pure" materials, by simple filtration through 1 kg of sorbent containing about 48 g of dimethylglyoxime [75].

James and Welch [103] used successfully anion-exchange resin columns charged with precipitant ions for trapping fragment elements from solutions without carriers, and they have noted that the method is superior to the usual coprecipitation procedure as regards efficiency and selectivity. Golovatyi and coworkers [62] demonstrated the possibility of the quantitative concentration of inorganic ions from solutions diluted by a factor of 75–100 relative to the minimum detectable amount (as shown by the colour reaction). The principles of precipitation chromatography have been used for a long time in the purification of water [90,91,174].

Precipitation and diffusional-precipitation chromatography are used to elucidate and model ore-formation processes [182,183,190,297,320-326].

After this article had been submitted to the editors, new papers have been published on precipitation chromatography in the column version [356-363], in particular in ion-exchange resin columns [364-371], and also on paper precipitation chromatography [372-391]. The above publications include also certain earlier papers, which the present author missed previously.

As before, the greatest number of publications deal with the quantitative analysis of inorganic ions on impregnated paper [373-384,389-391]. Small amounts of substances can be detected with the aid of columns [358,361,364]. Precipitation chromatography is used for quantitative inorganic analysis [388], purification of salts [356], quantitative separation of inorganic ions [366-368,386], and radiochemical separation on ion-exchange resins [369-371], including the separation of genetic isotope pairs (for example, $^{90}Sr + {}^{90}Y$, $^{140}Ba + {}^{140}La$). Some papers also deal with the problem of the theory of precipitation sorption [359,360,362,363,365].

Structure Formation in Disperse Systems in an Electric Field

L.G.Gindin and A.E.Vol'pyan

The application of an electric field to disperse systems usually results in the aggregation of the particles of the dispersed phase and their organisation into characteristic structures oriented along the lines of force. Processes of this kind are observed both in finely dispersed colloidal systems and in coarsely dispersed systems–emulsions, suspensions, powders. Despite the extremely varied phenomenological picture of the structure-formation processes, which in many respects is due to the nature of disperse systems, the mechanisms and dynamics of their development also have much in common. Analysis of the fundamental mechanism and the kinetics of these processes constitute the theoretical aspect of the problem of structure formation in disperse systems in an electric field.

Apart from the purely theoretical interest, the problem does not lack practical importance. It is sufficient to say that structure-formation processes underlie phenomena such as, for example, the breakdown of liquid dielectrics and the dehydration of petroleum in an electric field.

In this review an attempt is made to give a brief outline of the historical development of the problem, to characterise its present state, and to suggest the possible ways in which it may develop further. As far as we are aware, the structure-forming effect of an electric field on disperse systems was first described by Rafinesque[1] and Hohlfeld[2], who observed the formation on the surface of a charged object of thread-like structures made up of smoke particles.

The investigations of Munk af Rosenschöld[3,4], who must be regarded as the original discoverer of the coherer and who anticipated Branly by half a century, were carried out in the 1830's. In his experiments a tube filled with wood charcoal powder in an electric circuit completed the circuit under the influence of electric discharges occurring in its vicinity; when the tube was shaken, the circuit was reopened. In the 1880's studies on the electrical conductivity of metallic powders were renewed and led to the discovery of coherers or fritter-detectors of electromagnetic

waves. The work of Calzecchi-Onesti[5] and Branly[6,7] must be mentioned as foremost among the investigations in this field. Branly's coherer consisted of a glass tube filled with metal filings and incorporated into the circuit. Since at that time coherers were the only detectors of electromagnetic waves available, they were thoroughly investigated. Towards the middle of the 1890's it became evident that, firstly, the coherer effect arises only when the conducting material is dispersed in a dielectric (gaseous, liquid, or solid), secondly, the concentration of the conducting material must be fairly high, and, finally, the effect is not entirely reversible: the greatest conductivity jump is observed when the field is first applied.

In the literature of that period three views were put forward concerning the nature of coherers. Lodge[8-10] believed that the reason for the increase of the conductivity of the powder under the action of the field is the formation of a current-conducting path (bridge) due to the aggregation of particles under the influence of electrostatic forces; these forces "strip" insulating films from the surface of the particles, in particular oxide films. According to Auerbach[11], the role of the field is purely mechanical. The field induces a relative disposition of the particles such that it ensures a higher conductivity of the powder. By virtue of surface forces, the resulting structures are maintained also after the removal of the field. Branly[12-17] believed that the layers of insulating dispersion medium between the powder particles are "modified" on application of the field and become conducting.

The adhesion of the particles under the action of electrical pulses was confirmed by numerous investigators. Thus in his study, under the microscope, of the effect of electric discharges on copper, iron, brass, and silver powders, Arons[18] observed the formation of bridges from the powder particles. Particularly stable bridges were produced in copper powders. Sundorph[19] investigated iron and nickel powders. After the powders began to conduct current readily under the action of the field, he succeeded in isolating with the aid of a weak magnet a thin bridge connecting the electrodes. In Tommasina's experiments[20,21] bridges made up of metallic particles reached lengths of 20 cm in distilled water. Using horizontal electrodes, he observed the formation of a multiplicity of vertical chains of particles which immediately collapsed as soon as one of the chains reached the opposite electrode and closed the circuit. Thus the formation of conducting bridges in the powders was demonstrated experimentally.

The problem of coherers gave rise to a number of related problems. These include in the first place the problem of the breakdown in an electric field of aerosols and emulsions. Clark and Lodge[22] noted the common features of structure-formation processes in powders and aerosols in an electric field. The industrial methods for the removal of dust from air and dehydration of petroleum (Cottrell's method and others) originate from this phenomenon also.

Studies of the conductivity of natural air gaps are also closely associated with the problem of coherers. Harden[23] observed that, when a spark jumps in a discharge unit, certain particles are brought into motion in the 6 μm electrode gap and the process terminates in the formation of a bridge. This phenomenon was investigated in greater detail by Sundorph[24]. Using apparatus with movable electrodes, he observed the formation of bridges up to 50 μm in length in a constant field. Similar phenomena were later studied by Hoffman[25], Szèkely[26], Pearson[27], and Pectow[28]. All these studies confirm the characteristic structure formation under the action of an electric field in systems whose disperse phase is a product of the breakdown of the electrode.

At the beginning of the twentieth century coherers lost their practical value with the appearance of the Braun detector; they became of less interest, and studies in this field almost ceased. The literature on coherers has been reviewed by Aschkinass[29], Branly[17], and Righi and Dessau[30].

Starting with the 1920's finely dispersed systems began to attract attention to some extent as a consequence of the interest in problems of colloidal chemistry which arose at the time. The first investigations of the threadlike structure formed in the preparation of aerosol by the electric arc dispersion method were performed during this period[31-33]. Kuczynski[34], Muth[35], and Krasny-Ergen[36] investigated structure formation in emulsions in a high-frequency field. Kuczynski and Muth described the "construction" of chains from emulsion drops along the lines of force of the field. Krasny-Ergen calculated the minimum field strength necessary to overcome the thermal motion interfering with the organisation of drops into structures; his calculations agreed with Muth's experimental data. Pauli and coworkers[37,38] observed an increase of the conductivity of a gold hydrosol after prolonged passage of a current, due to the formation of chain structures.

Kruyt and Vogel[39] made a detailed study of structure formation in hydrosols in an alternating field. They studied gold, platinum, silver, copper, silver iodide, vanadium pentoxide, and paraffin hydrosols and also an aqueous emulsion of tetralin. According to their data, structure formation begins with the precipitation of particle aggregates on the electrode, after which branching structures, chains made up of particles similar to those observed in Pauli's experiments, grow from these deposits towards one another. When the chains are joined, the conductivity of the system increases by a factor of several tens. The higher the field strength the more rapid is the growth of the chains and the larger the gap between the electrodes which they can bridge. Under the microscope it is seen that the structured sol consists of a liquid traversed by a multiplicity of very thin intertwined and knotted threads forming a net-like structure. After the removal of the field the structure breaks down into individual fragments, consisting of many particles. The formation of chains is interfered with by bubbles produced, according to Kruyt and Vogel[39], as a result of the evaporation of water under the action of Joule heat. It was established, that on going from noble metals to copper, the capacity for the formation of threads falls. They rarely appear in copper sols and do not appear at all in silver iodide and vanadium pentoxide sols. In water–paraffin and water–tetralin systems the formation of bead-like aggregates from the dispersed dielectrics is again observed. Later the formation of similar structures was observed by Stauff[40], Us'yarov and coworkers[41-42] (in an alternating field), and also Pearce and Mech (in a constant field)[43]. Kruyt and Vogel distinguished bead-like structures (Perlschnurbildungen) formed from dielectrics and chains (Ketten) formed from metallic particles in accordance with the type of bond linking the units together: the bead-like structures broke down completely after the removal of the field, while the chains broke down into fragments consisting of many particles. According to Kruyt and Vogel, polarisation forces play a major part in the formation of chains; after the deformation and breakdown of the ionic shells of the micelles, van der Waals's cohesion forces begin to act. Subsequently recrystallisation processes develop at the site of direct contact between the nuclei, which accounts for the relative stability of the chains after the removal of the field.

We shall now consider the studies on aerosols performed during that period. These include primarily the work of

Beischer[44] on the stability of structures formed in aerosols of Fe_2O_3, ZnO, As_2S_3, NH_4Cl, iron, anthracene, and aminoazobenzene under the action of the field. The stability of these structures was determined from the maximum length of the chain formed in a field of about 300 V cm^{-1}, remaining attached to the electrode, without breakdown, after the removal of the field. The results were semiquantitative, since the true cross-sectional area of the chains was unknown. According to Beischer, the principal factor determining the stability is the adhesion of the particle aggregates. However, in some cases forces of a different type make a contribution: magnetic and electrostatic attraction forces (ferromagnetic aerosol of iron and the pyroelectric aerosol of aminoazobenzene) or crystal lattice bonding forces (ammonium chloride aerosol, which has a high vapour pressure at room temperature). Beischer regarded chains as tertiary formations. The primary formations are crystal nuclei and the secondary formations their spherical aggregates, which give rise to chains.

In his study of oil mists in an electric field, Winkel[45,46] failed to observe chain structures, a finding which in his view can be used to determine the state of aggregation of the disperse phase of aerosols.

Using the ultramicroscope, Artemov[47,48] studied the coagulation of the ammonium chloride aerosol in air of different humidities using a constant field. In the absence of moisture oriented branched aggregates are formed on the electrode. As the humidity increases, the aggregates grow in size and at 70% humidity drops of solution are deposited on the surface of the electrode instead of the aggregates. Artemov obtained similar results for anthraquinone and aminoazobenzene with water replaced by an appropriate solvent.

The coalescence of small droplets into larger ones is typical of mists in an electric field[49-51]. When the field is sufficiently strong, the drops are stretched into threads, which, on further increase of field strength, again break up into individual drops[52]. In many cases oriented coagulation of aerosols in an electric field takes place as a result of adsorption by the aerosols of the ions formed in air under the action of the field. Fuks[49] developed a theory of the aggregation processes in charged aerosols. Harvey et al.[53] described the formation of chain and three-dimensional network structures under the action of the field in silver and gold aerosols.

The studies on the breakdown of liquid dielectrics occupy a special place. It is known that the dielectric strength of transformer oil is lower the longer it is maintained under a potential. This phenomenon has been attributed for a long time to the aggregating effect of the field on the colloidal particles present and gradually accumulating in the oil. It has been shown in a number of studies that cellulose fibres are the most harmful in this respect, particularly in the presence of traces of water. While dry fibres lower the breakdown strength by 20%, moist fibres lower it by a factor of more than ten[54]. The explanation is that fibres which have adsorbed water are oriented along the lines of force of the field and form a bridge which is responsible for the breakdown. In the absence of fibres water has relatively little effect on the dielectric strength of the oil even when present at high concentrations.

Piper and coworkers[55] showed that, when an electric field is applied to the model phenol–liquid paraffin system, the electrical conductivity increases sharply as soon as a bridge structure consisting of acicular phenol crystals is produced.

At the beginning of the 1950's Frenkel', Gindin, Putilova, Moroz, and Shpanskaya published a series of papers on structure formation in disperse systems in a constant electric field. These studies originated from the problem of the corrosion of metals by liquid dielectrics. In the study of the mechanism of the corrosion processes in dielectrics it was found that the processes are electrochemical. It was established that electrochemical cells operate in hydrocarbon solutions of iodine or aliphatic acids and the current generated by them exceeds by several powers of ten the current which would be expected on the basis of the electrical conductivity of the initial solutions. To account for this phenomenon, it was suggested that salt bridges are formed between the electrodes during the operation of the cells, lowering thereby the internal resistance[56-58]. At the same time one of the present authors studied the suspensions of aluminium in kerosene as a possible reactive fuel and he decided to attempt to observe similar bridges in aluminium suspensions.

The first papers of the above cycle are in fact devoted to these suspensions. When a constant electric field is applied to a suspension of aluminium in petrol, the particles of the suspension begin to move, the rate of motion increasing with field strength E. Marked asymmetry of the motion is observed. Most of the aluminium particles are directed towards the cathode and cover the latter by a fairly thick layer of loose aggregates which grow in the direction of the anode. In the early stages of the process the latter remains clear. However, after a time it becomes coated by particles which have migrated from the cathode and which give rise to new aggregates growing to meet those formed earlier. Frequently the aggregates bound to the cathode suddenly break away from the latter and disintegrate into individual particles, giving the impression of small "explosions". At a certain stage of the process almost the entire space between the electrodes is filled by aggregates oriented along the lines of force of the field. Nevertheless the system is still a dielectric. However, when the field strength is increased to about 4000 V cm^{-1} (E_{cr}), electrical breakdown occurs and the system becomes conducting. This breakdown is readily observed from the sharp increase (by a factor of about 10^5) of the current in the circuit, the decrease of the field strength (from 4000 to 1 V cm^{-1}), and other effects. After the particles have fallen off, a single bridge in the form of a thin thread joining the electrodes is observed between them[59-61]. Subsequently the most important stages of the process were filmed[62,63]. Frame I in Fig. 1 shows the instant preceding the electrical breakdown. Frames II, III, and IV are pictures immediately after the breakdown associated with the formation of the bridge. The effects of the material and shape of the electrodes, the shape and size of the aluminium particles, and also the nature of the dispersion medium on the electrical breakdown were investigated[59-61]. If the bridges are not disconnected from the current source, they can exist for a long time. However, they persist even after the current has been switched off. The formation of the bridge and analysis of its behaviour suggest the presence of two types of bonds between its units. The first type is electrostatic and is observed in the stages of bridge formation preceding the electrical breakdown. The second type is a metallic bond produced at the instant of breakdown; by virtue of this bond the bridge continues to exist after the current ceases to flow. The voltage–current characteristics of the bridges[62,64] are in most cases monotonic up to the highest currents which the bridges can withstand. The initial sections of the characteristics are linear (Ohm's law holds) and then their angle of inclination to the E axis begins to decrease (the resistance increases) (Fig. 2, curve *1*). Such character-

istics are typical for metallic conductors whose temperature rises due to Joule heat.

The branches of the voltage–current characteristics obtained with rising (ascending branch) and falling (descending branch) voltage coincide in most cases (Fig. 2, curve *1*). However, sometimes this is not so (Fig. 2, curve *2*) and a characteristic hysteresis loop forms; this happens only when characteristic "flashes" occur on the current and voltage oscillograms, indicating a rearrangement of the structure of the bridges in the electric field. These and other observations confirm the hypothesis[60]

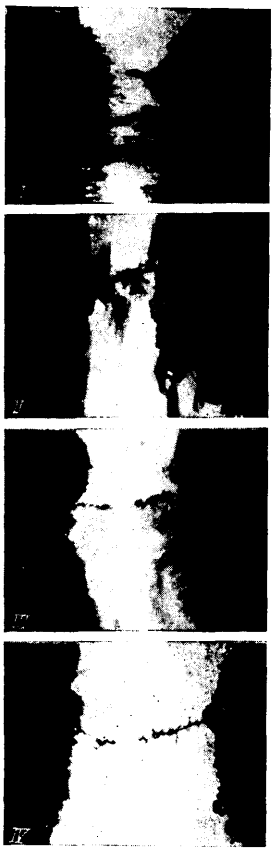

Figure 1. Film frames showing various stages in structure formation.

that the higher stability of the bridge conducting current compared with the bridge in the absence of current is due to the fact that, when the metal contact between the bridge unit breaks down, a fairly strong electric field arises and restores this contact. The bonds between the particles and the cathode, the formation of which is intrinsically responsible for the initiation of bridge formation, and the bonds between the particles themselves before electrical breakdown result from the electric polarisation of the particles. It must be emphasised that the aluminium particles are covered by thin layers of non-conducting oxide, which prevents the direct electrical contact of the particles with one another and with the electrode. Because of this, the suspension continues to be a dielectric even when the entire space between the electrodes is filled by the structures. The conversion of the system from a dielectric into a conductor occurs only when the electric field strength E reaches a value E_{cr} at which the insulating films in one of the numerous aluminium chains filling the space between the electrodes breakdown and the bridge becomes a metallic conductor. Hence follows the physical significance of E_{cr} as a measure of the breakdown voltage of the non-conducting oxide film, calculated over all the units of the bridge.

Indirect confirmation of the validity of this interpretation of E_{cr} is provided by the fact that suspensions of noble metals, for example platinum, become conductors at extremely low values of E.[65–68] Because of the very rapid precipitation of platinum particles, bridges of this metal, like those of aluminium, can be obtained only by "pulling" from the powder: a field of definite strength was established between the electrodes, after which the latter were allowed to touch the surface of a platinum powder; when the electrodes were raised, a bridge was drawn out. In contrast to the observations on the aluminium powder, the

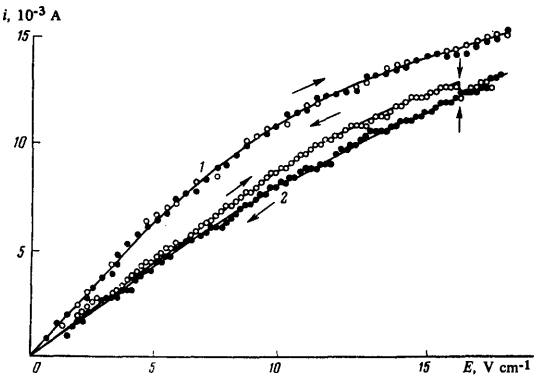

Figure 2. Voltage–current characteristics of the bridges.

platinum powder conducted current even at a minimal value of E. Evidently, it is sufficient for the platinum particles to be merely in contact with one another for the powder to behave as a conductor, since there are no bulk-phase oxide films on the surface of these particles.

Suspensions of copper, whose oxides are semiconductors, occupy an intermediate position between those of aluminium and platinum. Copper suspensions show an appreciable conductivity even at values of E much less than E_{cr} necessary for breakdown. As soon as the space between the electrodes becomes filled by structures made up of copper particles, a current appears in the circuit. A typical voltage–current characteristic for the system in this state is presented in Fig. 3, from which it follows that the conductivity of the system increases smoothly with field strength. Approximate calculations show that, when the overall field strength is only 100 V cm^{-1}, a field strength of the order of 10^4 V cm^{-1} is attained at the oxide film. Ioffe and Ioffe[69] showed that, for this value of E, the conductivity of Cu_2O increases exponentially with $\sqrt{E}$. In Fig. 3 the same relation is presented as a plot of ln σ against $\sqrt{E}$. Evidently the points lie on a straight line and therefore the relation holds in our case too. This

observation shows that before electrical breakdown we are dealing with conductivity due to the contacts between the individual copper particles when the conductivity of the system as a whole is determined by that of the surface semiconductor Cu_2O films on the particles. This is to some extent confirmed by the relation established between E_{cr} and the duration of oxidation of the copper powders

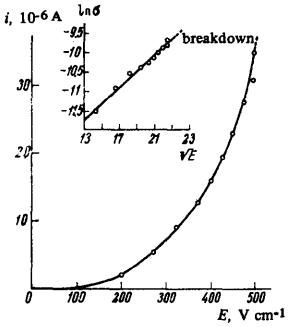

Figure 3. Electrical conductivity of suspensions and powders of oxidised copper before electrical breakdown.

(Fig. 4). The parabolic relation between these quantities is probably a consequence of the parabolic law governing the growth of oxide films. On the basis of this relation, one can set up rapid methods for the determination of the degree of oxidation of metallic powders (taking into account, of course, the characteristic features of the oxidation of each metal) [70].

Apart from the suspensions and powders of aluminium, platinum, and copper, dispersions of other metals have been investigated, namely of iron, cobalt, nickel, chromium, molybdenum, tungsten, antimony, bismuth, tin, lead,

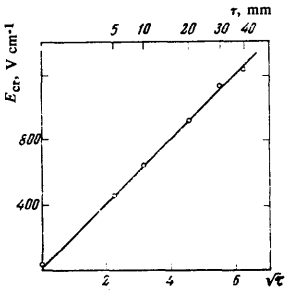

Figure 4. Variation of E_{cr} with the duration of oxidation of copper powders.

zinc, and silver. According to the behaviour of their disperse systems in an electric field, the metals can be divided into the following four groups:

1. Lead and bismuth. The suspensions of powders of these metals show some features resembling the dispersions of aluminium—almost complete absence of the conductivity of the structures before electrical breakdown.

2. Iron, cobalt, nickel, chromium, molybdenum, and tungsten. In their behaviour in an electric field, these metals resemble copper—weak conductivity before breakdown, increasing with E.

3. Tin and zinc. When an electric field is applied to suspensions of these metals, dendrite-like structures are produced, whose conductivity increases with the field even more than for the metals of the preceding group. However, the formation of a stable bridge and the electrical breakdown of the suspensions associated with it cannot be observed. Instead there is sparking with a crackling noise, accompanied by the evolution of gas bubbles—evidently products of the electrical cracking of the dispersion medium (petrol). The conductivity of the powders of these metals, due to the three-dimensional structure when $E \geqslant E_{cr}$, is replaced, like that of the metal powders of the preceding group, by the conductivity of the bridge; however, the electrical breakdown of zinc and tin powders, associated with the formation of a bridge, is not characterised so much by a jump in conductivity as by its stabilisation, i.e. the powders resemble cuprous oxide in this respect (see below).

4. Silver and antimony. Dispersions of these metals behave in an electric field in many ways similarly to the dispersions of platinum. The distinguishing features of these metals, like those of platinum, are a very low value of E_{cr} and the fact that no stable dendrite-like structures are formed in them. Although the problem requires further study (mainly quantitative), it is now clear that in general the behaviour in an electric field of the suspensions and powders of the metals investigated is determined by the nature, and in the first place by the conductivity, of their oxide films [71].

Suspensions of semiconductors such as boron carbide and cuprous oxide have also been investigated [65-68]. When a constant field is applied, the suspended particles of the carbide are deposited on the electrodes, preferentially on the anode. With increase in E, bridges begin to form in the space between the electrodes. As E rises, the number of such bridges increases, this being accompanied by a smooth rise of the current. When the apparatus is gently tapped, the bridges begin to fall off without disintegrating into smaller particles. On attainment of E_{cr}, the current increases sharply (by 2–3 powers of ten). After faulty, incomplete bridges have fallen out of the interelectrode space, a single bridge remains, which is responsible for the jump in the conductivity of the system; the form of this bridge is fairly characteristic: it is thin in the middle but thickens towards the ends attached to the electrode.

In cuprous oxide suspensions the formation of a bridge is also accompanied by a sharp rise of the conductivity of the system, but the attainment of E_{cr} is shown in cuprous oxide suspensions not so much by an increase of current (the latter increases only by a factor of two) as by its stabilisation.

Suspensions of soaps (the stearates of barium, zinc, nickel, cobalt, and copper and barium oleate) in aviation fuel and in liquid paraffin and also suspensions of a protein (egg albumin) in petrol have been investigated [65-68,72] in addition to the suspensions of metals and semiconductors. Outwardly the structure-formation processes in these systems are to some extent similar to those observed in suspensions of metals and semiconductors. When the cuvette with a suspension of soap and protein is included in a high-voltage circuit, the suspended particles begin to move rapidly. Then the particles of soaps (at $E = 7500$ V cm^{-1}) and hydrated protein form characteristic ribbon-like struc-

tures, the number of ribbons increasing with field strength. The formation of ribbons from protein begins at both electrodes but soap ribbons are produced predominantly from one electrode only; when the ribbons break away accidentally, their portions tend to migrate to the opposite electrode, where they become attached and initiate the growth of new ribbons. Sometimes the ribbons also grow in width, their edges coming into contact. The length of the ribbons reaches 1 mm and more, their width is 4–40 μm, and their thickness is of the order of 1 μm. The instant when the electrodes are joined together by the ribbons is shown by a sharp (approximately by 1–2 powers of ten) increase of the conductivity and a corresponding decrease of field strength. The study in polarised light of freshly prepared zinc stearate ribbons showed that they have an anisotropic structure, which, however, disappears after a time. When a field is applied to a suspension of dry albumin in petrol, the protein particles are drawn into the space between the electrodes and, becoming arranged along the lines of force of the field, form structures in which they do not adhere to one another but are merely in contact. It may be suggested that the conductivity of the ribbon-like structures from the soaps and the protein (under the usual dielectric conditions) is ionic and is of the surface and not bulk-phase type: in a later study[73] conductivity of this type was observed for lithium stearate suspensions in a mineral oil; it was explained by the presence of traces of moisture on the surface of the soap fibres.

Skanavi[74] noted that: "the suspension of a metal in a liquid dielectric constitutes to some extent a simplified model of a contaminated liquid. Therefore studies of this kind are not only of specialised interest, but they permit an approach to a more detailed examination of the problem of the mechanism of electrical breakdown and in particular the formation of conducting bridges or channels in contaminated liquid dielectrics... Before the electrical breakdown of a contaminated liquid containing conducting particles, a low-resistance bridge, joining the electrodes, is formed".

Similar views were later expressed by Kok and coworkers[75-80]. Incidentally, they suggested that, in order to enhance the dielectric strength of insulating oils, surface-active additives preventing the formation of bridges be used. They derived a relation between the "threshold" field strength at which the stable bridges are formed and the size of the colloidal particles of the admixture in the dielectric. The results of experiments on the electrical breakdown of liquid argon, nitrogen, and oxygen, proved to be close to the calculations.

Using the idea of the formation of conducting bridges from individual particles under the action of an electric field, Florek and Skowronski[81] constructed a discharge unit for the purification of liquid dielectrics.

Deinega and Vinogradov[82-85] investigated the effect of the electric field on greases—concentrated dispersions of soaps in mineral oils. They established that at the phase boundaries in these systems there exists an electrical double layer and that the sign and magnitude of the charges of the disperse phase and the dispersion medium can change under the action of surface-active substances and certain other factors. They observed that the particles of the disperse phase can have charges of opposite signs at the same time (electrical inhomogeneity, mosaic structure of phase boundary). If the disperse phase has charges of the same sign, then, after application of a constant field, a layer of dispersion medium forms near one of the electrodes; if the particles have charges of both signs, layers of dispersion medium are produced at both electrodes. In both cases the structural framework consisting of disperse phase particles undergoes elastic compression. At the same time the resistance of the grease to shear stress is reduced. The results of shear tests under conditions of steady flow of the grease are independent of the preliminary exposure of the latter to an electric field. Thus it was shown that the electric field induces reversible changes in the structure of greases, which in turn alter significantly their rheological properties.

We shall now review the studies of structure-formation in an electric field in suspensions of graphite and carbon black in dielectrics. It appears that the first study in this field was made by McDowell and Usher[86], who described the formation, under the action of an electric field, of chain-network structures from carbon black particles in toluene and other liquid dielectrics. The overall form of the structure-formation process in unstabilised carbon black suspensions is similar to that observed in noble metal sols[39], and therefore we shall not consider it. McDowell and Usher showed that the stabilisation of the suspension by the introduction of surface-active substances can reduce the capacity of the carbon blacks to form structures in an electric field.

Subsequently these systems were extensively studied by S. S. Voyutskii, V. A. Kargin, A. Voet, A. A. Bondi, and others†. In particular, the work of P. A. Rebinder and his school in the field of rheology and electrical properties of dispersed carbon blacks in liquid hydrocarbons must be mentioned. Voyutskii and Kargin with their coworkers[87] investigated conductimetrically the structure-formation in carbon black suspensions in a mineral oil. They believe that the observed increase of the conductivity of the system with temperature is due to an increase of the area of contact between the particles in the coagulation structures. Structure formation in graphite and carbon black suspensions in benzene, toluene, liquid paraffin, and kerosene under the action of an electric field was investigated by Yampol'skii[88]. When the structures are broken up by shaking or stirring, the mechanical strength and the electrical conductivity of the system are reduced sharply, but are gradually restored when the system is left at rest. The introduction of a surface-active substance (oleic acid, cetyl alcohol) greatly lowers the conductivity due to the growth of insulating adsorption-solvation shells on the surface of the graphite particles. Rebinder, Yampol'skii, and Wu Shu-ch'iu[89-91] investigated the behaviour of carbon black suspensions in liquid paraffin over a wide range of field strengths—from 0.025 to 500 V cm^{-1}. It was shown that the voltage-current characteristics of such systems are S-shaped: initially the conductivity of the system is constant, then it increases, and again tends to a constant value on further increase of E. These findings can be explained by a successive decrease of the thickness (breakdown) of the dispersion medium layers until at sufficiently high field strengths the thickest layers are penetrated. However, after electrical breakdown there remain extremely thin (about 10^{-7}–10^{-8} cm) residual layers of dispersion medium, which conduct current by a tunnel mechanism. Voet[92-98] and Bondi[99] hold similar views.

The combination of rheological and conductimetric studies on carbon black dispersions is of great interest. It has been established[89-91] that the stability of the structures to shear stress increases reversibly with field strength. The

† Here we are not concerned with studies of the electrical properties of carbon black dispersions in solid or highly viscous media (polymers) and in particular with the extensive series of studies on such compositions by B.A.Dogadkin, V.E.Gul', and their coworkers.

curves relating the electrical conductivity of the structured carbon black suspensions to rate of shear in an electric field are U-shaped, which can be explained by the effect of two competing factors: the decrease of conductivity due to the breakdown of the structures and its increase due to the increased frequency of collisions between the charged fragments of the carbon black chains[92-98].

This, in general, is the modern state of the problem of structure-formation in disperse systems in an electric field. In its further development the investigators will undoubtedly encounter the fundamental problem of the nature of the contact between the structural elements at various stages of structure formation. As mentioned earlier[61], the contact in stages preceding electrical breakdown (in the systems investigated by the present authors) is mainly due to forces associated with electrical polarisation, but, after typical breakdown, as in suspensions of aluminium, the particles are joined by metallic bonds (interatomic cohesion forces). However, the problem becomes complicated on going from metals to other substances, for example boron carbide: the question is whether the electrical polarisation forces at the instant of breakdown are weaker than adhesive forces or whether they are replaced by cohesive forces‡.

It is evident that very thin layers of dispersion medium between the elements of the structure always exist and their thickness depends on the lyophilicity of the disperse phase. However, as a result of the electrical breakdown, the particles are welded together and the dispersion medium layers undoubtedly disappear, but then the disperse structure ceases to be of the coagulation (reversible) type. Since before electrical breakdown many of the systems investigated exhibit appreciable conductivity, under these conditions the layers are so thin that they have little effect on the conductivity of the structure, either due to the tunnel effect or due to the breakdown of their continuity, particularly at lyophobic sites in the area of contact between the particles.

In conclusion we may note that structure formation in disperse systems in an electric field can be logically regarded as one of the aspects of the general problem of the formation of three-dimensional structures in disperse systems, which, as rightly pointed out by Rebinder, is one of the newest problems in modern colloidal chemistry. According to his classification[101-103], before breakdown the structures (at any rate those investigated by the present authors) are of the coagulation thixotropic type, but the role of electrical polarisation forces predominates. On the other hand, the structures produced after breakdown (bridges) are of the condensation (or crystallisation) type, but with the distinguishing feature that in the presence of a current the forces associated with the electric field constitute an additional stabilising factor for such structures.

I. INTRODUCTION

The extent and rate at which investigations have been made in the field of the radiation chemistry of solid inorganic compounds has been continuously increasing in recent years. The amount of information accumulated in the specialist literature on these problems is now very large. Data published up to 1962 were reviewed systematically by Sviridov[1], but there are no later reviews.

The aim of the present review was to arrange systematically and to discuss data on the radiation-induced reactions in the group of salts investigated in the greatest detail—alkali metal nitrates, nitrites, chlorates, bromates, and perchlorates. Particular attention has been devoted to the most recent investigations and the views formulated on their basis. Data published up to the end of 1966 are included in the review.

II. RADIOLYSIS OF NITRATES

Of all the inorganic salts with oxygen-containing anions, the nitrates have been investigated most vigorously, the study of alkali metal nitrates being the most detailed[2-11] and that of the nitrates of silver[2,12], alkaline earth metals[2,13,14], and lead[2,15-17] less so.

1. Products of Radiolysis

a. Optical spectra of irradiated nitrates. One of the first studies on optical absorption by irradiated sodium nitrate was that by Pringsheim[18]. At the temperature of liquid nitrogen an absorption band with a maximum at 335 nm was observed and at room temperature another band with a maximum at 355 nm appeared in addition. The author attributed the first band to an electron-excess centre and the second to NO_2^- ions. Absorption maxima at about 350 nm were also observed by Johnson[17] in the reflection spectra of irradiated potassium and lead nitrates. Cunningham made the most detailed study of this problem in the case of potassium nitrate[4]. Fig. 1, which is taken from his paper, shows the absorption spectrum of a potassium nitrate crystal irradiated at 4.2°K. In the range of doses less than 10^{20} eV g^{-1} six absorption bands were observed both at 4.2°K and at 77°K with maxima at 520, 355, 325, 290, 268, and 250 nm. The study of the behaviour of these bands on irradiation with light at a definite wavelength and on changing the temperature, and also comparison with the behaviour of ESR signals on treatment of this kind enabled the author[3,4] to identify these absorption bands. Thus the absorption at 250 nm was

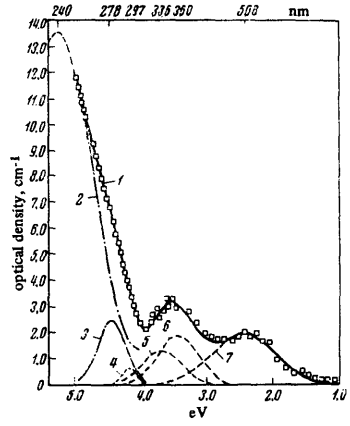

Figure 1. Optical absorption spectrum of potassium nitrate irradiated with γ-rays at 4.2°K;[4] the symbols denote experimental values; curve *1* was obtained by adding together curves *2–7*.

attributed to NO_3 radicals, that at 268 and 520 nm to NO_2^{2-} radical-ions, and that at 325 nm to NO_3^{2-}.

The centre responsible for the band at 290 nm, which is stable at the temperatures of liquid helium and liquid nitrogen, but is annealed on heating to room temperature, was not identified. Nor was the absorption band at 355 nm, which Pringsheim[18] attributed to nitrite ions, assigned.

However in a later study [19] Cunningham assigned this absorption band (*C*-centre) to the oxyhyponitrite ion $N_2O_3^{2-}$.

On irradiation of potassium nitrate with a dose in excess of 10^{20} eV g^{-1}, an additional absorption band was observed at 410 nm. Like the ESR signal[3] attributed to NO_2, which also appears at doses greater than 10^{20} eV g^{-1}, this absorption band was assigned to NO_2.

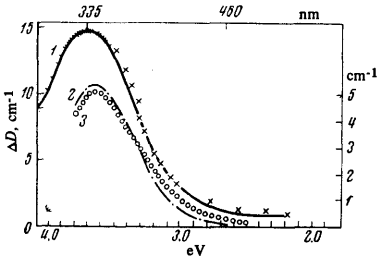

Figure 2. Light absorption by sodium nitrate [19]: *1*) irradiation with X-rays at 77°K for 75 min (right-hand scale); *2*) irradiation with γ-rays at 77°K for 30 min (left-hand scale); *3*) as for 2 after irradiation with $\lambda > 510$ nm light at 77°K for 40 min.

The spectrum of sodium nitrate [19] irradiated at 77°K was found to contain one absorption band with a maximum at 335 nm (Fig. 2). However, analysis of the shape of the curve and experiments involving bleaching with ultraviolet light enabled the author to identify two species responsible for this band (NO_2^{2-} and NO_3^{2-}) and to detect absorption at 410 nm, which is attributed to NO_2. It is interesting that

Table 1. Optical centres in irradiated nitrate systems.

Postulated absorption centre	λ_{max}, nm	Matrix	*T*, °K	Refs	Remarks
NO_3	250	KNO_3	4.2and77	4	Pulse radiolysis

$\bar{e}_{stab}$	335–340	$NaNO_3$	77and300	18	

Cunningham [19] observed an inhibiting effect by Ag^+ ions, introduced into the potassium nitrate and sodium nitrate lattices, on the increase in the intensity of the absorption bands assigned to nitrate ion conversion products.

Table 1 lists the optical centres in irradiated nitrates. For comparison, data obtained on the irradiation of liquid solutions of nitrates are included.

b. ESR Spectra of irradiated nitrates. The ESR signals in irradiated nitrates of potassium [3,5,7,21,22] and sodium [23–28] have been investigated in relatively great detail. There is also information about the ESR spectra of irradiated nitrates of silver [12] strontium [13,29], lead [16,29], and barium [29]. All the nitrates investigated were found to contain NO_2. NO_3 radicals were detected in potassium nitrate [3,5], sodium nitrate [25], and lead nitrate [16], and NO_3^{2-} species were found in potassium nitrate [3,5,21,24], lead nitrate [29], barium nitrate [29], strontium nitrate [13,29], and silver nitrate [12]. In the nitrates of silver [12], lead [29], and, to a slight extent, barium [29] the signal due to the unpaired electron is also split by the cations, i.e. in these nitrates the entire molecule and not only the anion serves as the electron trap. Therefore, especially in silver nitrate, the paramagnetic molecule $(AgNO_3)^-$ appears instead of NO_3^{2-}.

Table 2. Characteristics of the ESR spectra of the paramagnetic species in irradiated potassium nitrate single crystals

Postulated radical	*g*-Factor			Hyperfine structure constants, G			References	Remarks
	g_x	g_y	g_z	A_z	A_x	A_y		
1	2			3			4	5
NO	2.008	2.010	2.005	3.5	4.0	31	3	77° and 4°K
NO_2	1.9996	1.9932	2.0055	62.9	50.3	48.7	21	Formed on heating to room temperature between two exposures to radiation at 77°K or in the presence of potassium nitrite
NO_3		1.999			113		3	Potassium nitrate powder, dose 3×10^{20} eV g^{-1}
NO_3^{2-}	2.025	2.025	2.008	9	9	9	3	4°K, dose 3×10^{18} eV g^{-1}. Absent at 77°K; on annealing at 77°K for 2 h decreases by a factor of two
NO_3^{2-}	2.0057	2.0057	2.0015	63.4	31.8	31.8	5	77°K, dose 4×10^{19} eV g^{-1}, *H* parallel to *a*
NO_2^{2-}	2.006	2.006	2.002	61	32	32	3	4° and 77°K. Crystal axis *c* parallel to rotation axis and perpendicular to *H*
NO_3	2.006	2.006	2.001	0	0	0	3	4°K
NO_3	2.0232	2.0232	2.0031	4.3	3.5	3.5	5	77°K, rapidly decomposes at this temperature
O_2^-		1.958			0		3	Singlet. Appears on heating to 77°K or in measurements at 4°K on a crystal irradiated at 77°K

Furthermore, in silver nitrate there is also an ESR signal due to Ag^{2+} ions [12], the characteristics of which are not given in Table 4. The presence of NO, NO_2^{2-}, and O_2^- in irradiated potassium nitrate has been indicated only by Cunningham [3]. Thus different workers have identified different paramagnetic species in the same nitrate (potassium nitrate) and under the same or similar conditions. These discrepancies are illustrated by the characteristics of the spectra attributed to the paramagnetic species in irradiated potassium nitrate (listed in Table 2).

Although the ESR spectra of irradiated sodium nitrate have been studied in a number of investigations [23–28], only the spectrum attributed to nitrogen dioxide has been reliably interpreted. In two studies [25,28] NO_3 radicals have been identified in addition to NO_2. Table 3, which lists the characteristics of the ESR signals in sodium nitrate, shows that different spectra are attributed to NO_3 radicals. It has been shown [26] that the matrix has virtually no influence on the characteristics of the ESR spectrum due to NO_2. Therefore there is no doubt about the presence of NO_2 in other nitrates also, as can be seen from Tables 2–4. Certain contradictions in the identification of the individual paramagnetic species are readily seen from a comparison of the data in Tables 2–4.

1. If the spectroscopic characteristics of particular paramagnetic species remain the same or similar in the lattices of different nitrates (which probably in fact is the case), the ESR spectrum attributed to NO_2^{2-} in potassium nitrate by Cunningham[3], to NO_3^{2-} in potassium nitrate by Zeldes[22], to NO_3^{2-} in silver nitrate by Mosley and Moulton[12], and to NO_3^{2-} in potassium chloride containing nitrate by Jaccard[30] should be assigned to one of these paramagnetic species. This also applies to the interpretation of the spectra attributed to NO_3^{2-} in potassium nitrate by Cunningham[3] and in strontium nitrate by Zdansky and Sroubek[13] and to NO_3 species in potassium nitrate by Livingston and Zeldes[5] and in lead nitrate by Golding and Henchman[16]. This problem was examined in fair detail by Atkins and Symons[31]. On the basis of a comparison of the characteristics of these spectra with those of isoelectronic radicals, they assigned the first spectrum with $g_x = g_y = 2.006$, $g_z = 2.002$, $A_x = A_y = 32$–37 G, and $A_z = 61$–68 G to NO_3^{2-} radicals, and the second, with very slight splitting, to NO_3.

Table 3. Characteristics of the ESR spectra of sodium nitrate.

Irradiation temperature, °K	Paramagnetic species	$g_{\parallel}$ <111>	$g_{\perp}$ <111>	$A_{\parallel}$ <111>	$A_{\perp}$ <111>	References	Remarks
300	NO_2	2.0059	1.9982	48.0	58.4	24	
77	NO_2	2.0058	1.9964	50.5	59.1	26	
170	NO_2	2.0056	1.9966	51.1	58.4	27	
300	NO_2	2.0050	1.9970	53.0	57.8	27

300	?	2.006	2.0097	0	0	25	ditto
300	?	2.0064	2.0147	0	0	25	Stable above 530°K
300	?	2.006	2.0237	0	0	25	Disappears at 400°K
77	NO_3	2.0004	2.0053	0	0	25	At 300°K converted irreversibly into three preceding species
77	NO_3	2.0022	2.0217	4.11	3.51	28	
77	?	2.0030	2.0225	0	0	28	

2. The spectrum which Cunningham[3] and Jaccard[30] attributed to NO radicals is assigned by Atkins and Symons[31] to NO_2^{2-} species. However, Cunningham[7] showed by chemical analysis and by the ESR method that NO species accumulate as the dose is increased. The two methods gave satisfactory agreement. The data are presented in Fig. 3. Because of this, and also in consequence of the very high anisotropy of the hyperfine splitting, Cunningham's view on this problem is probably more correct.

The identification of the radicals NO_3, NO_3^{2-}, and NO_2^{2-} requires additional investigations.

c. Composition of stable products. The generally adopted method for the determination of the final radiolysis products of nitrates involves the determination of the nitrite by diazotisation after dissolution of the irradiated nitrate in water. In the vast majority of cases the solutions of irradiated nitrates were analysed for nitrite only. In those studies where the gases evolved from the solution were analysed (see, for example, Refs. 2, 7, 19), it was shown that the gaseous radiolysis product is oxygen. The ratio $G(NO_2^-):G(O_2) \simeq 2$ is maintained in all cases, except for the initial stage in the radiolysis of lead nitrate[17].

However, it should be noted that there is a possibility of chemical reactions of the radiolysis products on dissolution of irradiated nitrate in water. Cunningham[7] showed that radical products such as O^-, NO_2, and NO may make a contribution to the yields of the radiolysis product determined as nitrite by the diazotisation reaction. On dissolution in water these products alter the concentration of nitrous acid by the following reactions:

$$O^- + H_2O \rightarrow OH + OH^-,$$
$$OH + NO_2^- \rightarrow NO_2 + OH^-,$$
$$2NO + O_2 \rightarrow 2NO_2,$$
$$2NO_2 + H_2O \rightarrow HNO_3 + HNO_2.$$

Table 4. Characteristics of the ESR spectra of irradiated non-alkali metal nitrates.

Paramagnetic species	irradiated salt	g-Factor			Hyperfine structure constants, G			Refs	Remarks
		g_x	g_y	g_z	A_x	A_y	A_z		
NO_2	$AgNO_3$	2.009	1.9978	2.0039	50.7	48.5	69.6	12	Irradiation at 77°K. Intensity increases with disappearance of the Ag^{2+} signal on heating the crystal from 77° to 140°K
NO_2	$Sr(NO_2)_2$	1.9975	1.9975	2.0054	59	59	50	13	Room temperature. Formed at about 10^7 r or at about 10^5 r if the nitrate contains nitrite
NO_2	$Pb(NO_3)_2$	1.995	1.995	2.004	57	57	50	16	Room temperature
NO_3	$Pb(NO_3)_2$	2.029	2.029	1.998	1	1	2	16	ditto
NO_3^{2-}	$AgNO_3$	2.002	2.007	2.000	35.8	37.1	67.4	12	77°K. The unpaired electron is not localised at NO_3^-, but there is a hyperfine structure also due to the nucleus of the neighbouring cation
NO_3^{2-}	$Sr(NO_3)_2$	2.0081	2.0081	2.0027	0	0	0	13	Room temperature
NO_3^{2-}	$Sr(NO_3)_2$	2.0019	2.0060		68.8	37.3		29	90°K

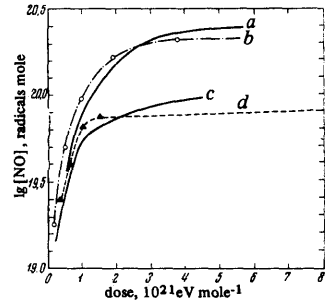

Figure 3. Formation of NO in potassium and sodium nitrates irradiated at 77°K:
a) and *c*) curves based on chemical analysis; *b*) and *d*) curves obtained by the ESR method[7].

It follows from this that $G(NO_2^-)$ determined by the diazotisation method includes the yields of other products: $G(NO_2^-) = G(NO_2^-)_{true} + \frac{1}{2}G(NO_2) + \frac{1}{2}G(NO) - \frac{1}{2}G(O^-)$. It can probably be regarded as established that the main radiolysis products at room temperature, at any rate for potassium and sodium nitrates, are NO, NO_2^-, NO_2, and oxygen. As shown by Cunningham[7], the presence of nitrogen in the gaseous radiolysis products noted by Hennig et al.[11] is a result of the desorption of air adsorbed on the surface of the nitrates during irradiation.

2. Kinetics of Radiolysis

Since nitrogen-containing radiolysis products of nitrates were determined by the diazotisation method in all the investigations except that of Cunningham[7], and since there are no data in the literature on the accumulation of all the decomposition products of NO_3^-, we shall henceforth examine the kinetics of the radiolysis of nitrates on the basis of the yield of nitrite, but one must remember that $G(NO_2^-)$ includes several components (see above).

a. Dependence of the radiochemical yield on the dose absorbed. This problem was investigated in greatest detail by Johnson and coworkers[2,32]. Using the decomposition mechanism for the nitrates of potassium, caesium, sodium, barium, lead, and silver,

$$MNO_3 \xrightarrow{h\nu} MNO_2 + O \quad , \tag{1}$$

$$O + NO_2^- \rightarrow NO_3^- \quad , \tag{2}$$

$$O + NO_3^- \rightarrow NO_2^- + O_2 \quad , \tag{3}$$

and applying the method of steady-state concentrations to atomic oxygen, they derived a second-order equation for the accumulation of nitrite:

$$a[NO_2^-]^2 + [NO_2^-] = bD \quad , \tag{4}$$

where a and b are constants for the given salt and D is the dose absorbed. Eqn. (4) describes satisfactorily the experimental data for caesium, sodium, barium, and lead nitrates (Fig. 4).

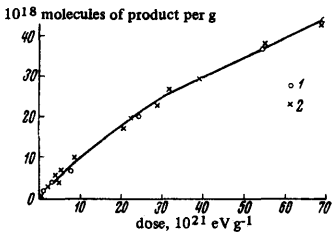

Figure 4. Formation of nitrite[2] in sodium nitrate: *1*) $[NO_2^-]$; *2*) $\frac{1}{2}[O_2]$; curve calculated from Eqn.(4).

From the above mechanism of radiolysis [Eqns. (1)–(3)], the following equation for the description of the accumulation of nitrite in potassium nitrate was obtained taking into account the changes in the concentration of NO_3^- ions[2]:

$$a \lg(1-\alpha) + \frac{\alpha}{1-\alpha} = bD \tag{5}$$

(where $\alpha = [NO_2^-]/[NO_3^-]_0$, a and b are constants, and D is the dose absorbed).

Cunningham and Heal[33], who used doses in excess of 10^{33} eV g^{-1}, described the kinetics of the radiolysis of potassium nitrate by the equation

$$\alpha = 1 - e^{bD} \tag{6}$$

where α is the fraction of nitrate decomposed, D the dose absorbed, and b a constant. A suitable equation for the kinetics of the radiolysis of silver nitrate could not be derived from the decomposition mechanism based on reactions (1)–(3).

The independence of $G(NO_2^-)$ of the dose for the individual nitrates, noted in numerous studies[1,8,10,17,34–36], is observed only for low doses, which are different for different nitrates. It is not difficult to see that all three kinetic equations [Eqns. (4)–(6)] degenerate at low doses to an expression of the form

$$[NO_2^-] = bD \quad , \tag{7}$$

which is consistent with the initial linear sections of the NO_2^- ion accumulation curves.

b. Effect of dose rate and LET†. The effect of dose rate on the radiolysis of nitrates has been investigated in numerous studies[10,33,35,37]. $G(NO_2^-)$ for the nitrates of potassium, sodium, caesium, and lead[37] was not found to change on varying the dose rate from 10^{17} to 10^{20} eV g^{-1} s^{-1}, as observed in other investigations[10,33,35] in the region of other dose rates and for other forms of radiation. The independence of the yield of nitrite of dose rate over a wide range (from about 10^{15} to 10^{20} eV g^{-1} s^{-1}) permitted an unambiguous interpretation of the results on the effect of the type of radiation on $G(NO_2^-)$. Table 5, taken from Hochanadel's paper[10], lists the values of $G(NO_2^-)$ obtained in the radiolysis of nitrates by different types of radiation. The similarity of the values of $G(NO_2^-)$ obtained

Table 5. Effect of LET on $G(NO_2^-)$ in nitrates[10].

Irradiated salt	3.4 MeV α-particles		^{60}Co γ-rays		44.5 keV X-rays	
	25°	120°	30°	150°	15°	150°
$LiNO_3$	0.7		0.02—0.2	0.03—0.4	0.02	
$NaNO_3$	1.3	1.1	0.27	1.0	0.4	1.1
KNO_3	2.2		1.5	3.0	2.0	3.0
$CsNO_3$	1.4		1.6	2.3	1.4	1.2
$Ba(NO_3)_2$	1.6		1.8	1.6	1.8	1.8

under the action of X-rays and γ-rays at 150°C and those obtained under the action of α-rays at 25°C led the author to the conclusion that thermal spikes are formed in the tracks of α-particles. The increase of the radiochemical yield of nitrite with increase in LET was attributed to a local temperature rise in the tracks of heavy particles. It should be noted, however, that it has been demonstrated quite recently that thermal spikes are not formed in the radiolysis of certain salts by protons[38].

c. The role of the cation. Even in the first studies on this problem, a definite relation between $G(NO_2^-)$ and the nature of the cation in nitrates was noted. The present generally accepted explanation is derived by considering the effect of the free space of the lattice on the probability of the reverse reactions. This problem is discussed in greater detail below.

d. Effect of other factors. The values of $G(NO_2^-)$ obtained by different workers show very appreciable discrepancies[1]. One of the possible reasons for the differences may be the different degrees of dispersion of

† Linear energy transfer (Ed.of Translation).

the nitrates irradiated[2,8]. The size of the crystals irradiated has a direct effect on the retention of gaseous radiolysis products within the lattice. On the other hand, the amount of gases retained influences the rate of the reverse reactions of the radiolysis products (see Section VI).

The influence of hetero-phase semiconductor oxide impurities[8] on the rate of radiolysis of potassium nitrate and sodium nitrate has also been investigated. Since the change in the rate of radiolysis under the influence of the oxides is correlated with the electron work functions of the latter, the effect of the additives on radiolysis was attributed to their donor-acceptor properties in relation to the nitrates. The decrease of the rate of radiolysis of sodium nitrate in the presence of Ag^+ ions in the sodium nitrate lattice was also attributed by Cunningham[19,34] to the acceptor properties of Ag^+. Accordingly, the introduction of Tl^+ ions, which, as shown by Boldyrev et al.[39] are electron donors, accelerates the radiolysis of potassium nitrate. Although the amount of experimental data is as yet insufficient to arrive at unambiguous conclusions concerning the mechanism of the effect of the admixtures, one may conclude that, like the degree of dispersion of the crystals, the purity of the salt irradiated has a significant influence on radiochemical stability.

3. Mechanism of Radiolysis

Although the nitrite ion accumulation curves are described satisfactorily by the kinetic equations based on reactions (1)–(3), the work of Cunningham[4,7,19,34] and the ESR spectroscopic data for irradiated nitrates, examined above, convincingly demonstrate a significantly greater complexity of both the primary and the secondary radiochemical processes in the irradiation of nitrates.

The primary processes must be regarded as ionisation and excitation processes:

$$NO_3^- \xrightarrow{h\nu} NO_3^-{}^*,\ NO_3,\ \bar{e} \qquad (8a)$$

$$M^+ \xrightarrow{h\nu} M^{2+} + \bar{e} \qquad (8b‡)$$

We may note that NO_3 can probably form not only as a result of reaction (8a) but also in the subsequent reaction

$$M^{2+} + NO_3^- \rightarrow (M^{+*} + NO_3) \rightarrow M^+ + NO + O_2\,, \qquad (9)$$

which is confirmed by the effect of the nature of the cation on the yield, noted above. Because of the high degree of excitation of the cation, reaction (9) probably does not stop at the stage where NO_3 is formed and continues to a more profound decomposition of the anion. The NO_3 radicals formed in reaction (8a) are unstable even at 77°K (at room temperature the presence of NO_3 is suggested only for lead nitrate[16]) and can decompose by the reactions

$$NO_3 \rightarrow NO_2 + O\,, \qquad (10a)$$

$$NO_3 \rightarrow NO + O_2\,, \qquad (10b)$$

or can serve as traps for thermalised electrons:

$$NO_3 + \bar{e} \rightarrow NO_3^-{}^* \rightleftarrows NO_2^- + O\,. \qquad (11)$$

Since the steady-state concentrations of NO_3 and thermalised electrons are insignificant, one may assume that reaction (11) is unlikely. Cunningham[3,7] found that NO is the primary product and NO_2 appears only for high values of the absorbed dose. It has also been stated in other papers[21,22] that NO_2 is a secondary product. Therefore reactions (10a) and (11) are unlikely, in contrast to reaction (10b). Since the electron affinity of NO_3 is greater than the energy of the N–O bond[40], the oxygen atom produced by fragmentation should have an excess kinetic energy of about 0.2 eV, if it is assumed that the energy associated with the electron affinity of the NO_3 radical is localised at a definite bond. On the other hand, in a solid the cage effect should be shown to the greatest extent. For these reasons, the excitation energy of $NO_3^-{}^*$ is often scattered by the crystal lattice and part of the $NO_3^-{}^*$ species break down into nitrite and atomic oxygen.

The secondary electron, thermalised in non-elastic collisions, may be stabilised in a trap of any type. Such traps may be the defects initially present in the lattice, ionisation products of the cation or anion, radiolysis products produced in secondary (see below) processes (O, O_2, NO_2, etc.), and finally normal lattice sites. In the last case it is reasonable to expect that in alkali metal and alkaline earth metal nitrates thermalised electrons are stabilised by anions and not cations, since the N^{5+}/N^{4+} redox potential is much higher than for M^+/M. Consequently the second primary product, in addition to NO_3, is electron-stabilised by anions[3-5,12,13,19,21,25,29]:

$$NO_3^- + \bar{e} \rightarrow NO_3^{2-}\,, \qquad (12)$$

but in silver nitrate, where the cation is an effective electron acceptor, we have $AgNO_3 + \bar{e} \rightarrow [Ag(NO_3)]^-$.

In potassium and sodium nitrates the absorption band and the ESR spectrum attributed to NO_3^{2-} vanish completely on heating the irradiated crystals to 300°K. At this temperature only the optical absorption bands attributed to $N_2O_3^{2-}$ and NO_2 are stable[4,19]. Consequently, apart from NO_3 radicals, species with an excess of electrons should make a contribution to the formation of the final radiolysis products:

$$NO_3^{2-} \rightarrow NO_2^- + O^-\,, \qquad (13)$$

$$NO_3^{2-} \rightarrow NO_2^{2-} + O\,. \qquad (14)$$

It is so far difficult to estimate the relative contributions to the yields of final radiolysis products by reactions (8)–(11) and (12)–(14). It is extremely probable that these two groups of reactions lead to different results. As already mentioned above, the relative importance of the individual reactions within each group is also different.

The present authors believe that steric factors should have a considerable effect on secondary processes involving the interaction of the products of reactions (8)–(14). Fig. 3 shows that the concentration of NO in sodium nitrate reaches a limiting value at a dose of only 1×10^{21} eV mole^{-1}, while in potassium nitrate the corresponding dose is approximately twice as high, the steady-state concentration of NO in sodium nitrate also being lower than in potassium nitrate. This shows that the reactions of NO depend on the lattice parameters. According to Cunningham, such reactions may be

$$NO + O \rightarrow NO_2\,, \qquad (15)$$

$$NO + O_2^- \rightleftarrows NO_3^-{}^* \rightleftarrows NO_2^- + O\,, \qquad (16)$$

$$NO + NO_3 \rightleftarrows N_2O_4^* \rightleftarrows 2\,NO_2\,, \qquad (17)$$

$$NO + NO_2^{2-} \rightarrow N_2O_3^{2-}\,, \qquad (18)$$

$$O + O = O_2\,. \qquad (19)$$

Reaction (17) occurs only in the presence of high doses, when there is a possibility of the formation of NO and NO_3 at adjacent sites[7].

‡ Here and henceforth M^+ denotes the normal cation (Na^+, K^+, Sr^{2+}, Ba^{2+} etc.) and M^{2+} an ionised cation, i.e. one which has lost another electron (Na^{2+}, K^{2+}, Sr^{3+}, Ba^{3+}, etc.). [See, however, the scheme on p.68, reaction (2c). (Ed.of Translation)].

The mechanism of the radiolysis of alkali metal nitrates examined above can probably be extended to the nitrates of alkaline earth metals. In the nitrates of heavy metals or variable-valence metals quite different electronic-ionic processes occur, whose importance is evident from the examination of the effect of impurities on the radiolysis of the nitrates[8,19,24,39].

III. RADIOLYSIS OF NITRITES

Alkali metal nitrites are extremely stable under the action of radiation[41]. The only products observed on irradiation of sodium nitrite are the paramagnetic species NO_2 and $N_2O_4^-$.[41-44] The signal detected after irradiation at 77°K (a strongly anisotropic triplet) has been attributed[42,43,45] to NO_2 molecules located in the *bc* plane of the crystal. These species disappear on heating the crystals to room temperature.

However, sodium nitrite irradiated at 20°C at doses of about 100 Mrad also gives a distinct ESR signal consisting of an anisotropic triplet on which a quintet is superimposed. It has been shown[41-44] that the first signal originates from NO_2 molecules in the *ac* plane of the crystal and the second is due to $N_2O_4^-$ ions formed as a result of the transition of NO_2^- ions or more probably NO_2 molecules into neighbouring cationic vacancies with rotation by 180° and formation of an N–N bond between these species and neighbouring normal anions. Optical absorption spectra in the visible and in the infrared regions[45-47] confirm this view.

IV. RADIOLYSIS OF CHLORATES, BROMATES, AND IODATES

1. ESR and Optical Spectra of Irradiated Salts

At the present time ESR spectra have been investigated in relatively high detail only for potassium and sodium chlorates irradiated with comparatively low doses ($< 10^6$ rad). The data concerning the signals from caesium and rubidium chlorates are extremely limited, while for bromates and iodates there is only a general indication of the possibility of detecting signals due to paramagnetic species in these salts and a brief description of the form of such signals in the spectra of powdered materials[48].

The ESR spectra of irradiated alkali metal chlorates are complex (Figs. 5 and 6). There exist different views in the literature concerning the interpretation of each signal in the spectrum (see Table 6). In later studies on the ESR spectra of irradiated sodium chlorate[49,54-56] it has been shown that at irradiation doses up to about 10^5 roengtens three paramagnetic centres are evident, their number increasing on further irradiation. The attention of the investigators has been drawn most to the complex signal, observed in almost all the studies, consisting of four anisotropic quartets.

Some workers[51,53,54] attribute this signal to the $ClO-ClO_3^-$ group, while Gamble[49] assigned it to ClO_3 radicals. The analysis of the signal in the latter study[49] shows, however, that its parameters (hyperfine structure and *g*-factor) differ appreciably from those of the spectra of ClO_3 captured in various matrices[50] and therefore the models of this centre proposed by Hasty[51] and Ramasastry et al.[52] must be preferred (see Figs. 5 and 6).

Studies of the ESR spectra at low temperatures (irradiation of crystals with fast electrons and recording of the spectra at 77°K) led to a new spectrum[50], which can be more definitely assigned to ClO_3 (Fig. 6). This radical proved to be extremely unstable; it breaks down on storage and under the action of light at 77°K after 35 and 15 min respectively.

The distinct central singlet in the spectra of irradiated chlorates has been attributed[52-54] to O_3^-. Probably this interpretation is correct, although it has been suggested[51,57,58] that the signal is due to the radical-ion O_2^-.

The characteristic doublet observed in a number of studies has been assigned by all the investigators to ClO_2, the remaining lines of the ESR spectrum of this radical (it gives rise to a quartet) being masked by other signals which are in no way related to it. However, it should be noted that the parameters of this signal attributed to ClO_2 by Fayet and Thieblemont [55] differ from those found by Ramasastry et al. [52]

Apart from the identification of different species enumerated above, a number of investigators have observed in the spectra of chlorates irradiated at room temperature lines due to various unidentified centres [49,52,55]. The results obtained by Subbotin [54] show that the ESR spectra of the powdered salts irradiated at room temperature are qualitatively similar for all the alkali metal and alkaline earth metal chlorates. Data on the accumulation kinetics and the behaviour of the signals from a number of chlorates after annealing and on the relation between the rate of accumulation and the crystal lattice parameters were obtained for the first time [48,50] from the ESR spectra of alkali metal chlorates, the specimens being irradiated and the spectra recorded at 123° and 77°K. The irradiation of the salts at low temperatures with high doses (up to 10^8 rad) made it possible to obtain for the first time signals from bromates and iodates and to observe signals from potassium chlorate not detected previously. Nuclear quadrupole resonance signals due to ^{35}Cl nuclei in potassium and sodium chlorates have been described in certain brief communications [59-61]. The deformation of the lattices of these salts in the vicinity of the radiolysis products leads to the appearance of broad signals which have not been interpreted hitherto.

The information about the absorption spectra of irradiated salt layers of the type MXO_3 (X = halogen) are also extremely limited. Heal, who investigated the absorption spectra of thin single-crystal potassium chlorate plates irradiated with X-rays up to high doses (10^{23} eV g^{-1}), [62] established the presence in the spectra of three absorption bands—at 260 nm, 310 nm, and in the region of about 450 nm. By analogy with the positions of the absorption bands of oxychlorine anions in aqueous solutions (cf. Ref. 63), he attributed these bands respectively to ClO_2^-, ClO^-, and Cl_2O_6 and confirmed their presence by analysing the solution of the irradiated salt. In contrast to Heal's data, other investigators [52,64-66] observed only one band in the spectrum of irradiated potassium chlorate, with a maximum at 461 nm, which is stable at room temperature. When crystals irradiated with X-rays are exposed to light, an additional band appears at 340 nm (and at the same time also a new signal in the ESR spectrum), which has been attributed [65] to Cl_2^-. Under the same conditions, two absorption peaks, displaced towards the short-wavelength region of the spectrum, have been observed [64] in the spectrum of sodium chlorate.

A more detailed study of the colouring of sodium and potassium chlorates at room temperature [67,68] showed that in the spectrum of irradiated sodium chlorate there are three absorption regions: at wavelengths less than 260 nm and with maxima at 302–310 and 420 nm. The observed spectrum is believed [68] to consist of individual bands with maxima at 228, 260, 310, 360, and 420 nm for sodium chlorate and at 216, 260, 310, 360, and 450 nm for potassium chlorate. It is reasonable to assign the absorption at 260, 310, and 360 nm to ClO_2^-, ClO^-, and ClO_2 respectively. It is believed [68] that the absorption band at 216–220 nm is due to the transition of an electron from ClO_3^- to a lattice defect (analogue of the α-band in alkali metal chloride crystals), and the absorption in the region 420–450 nm is attributed to Cl_2O_6 and O_3^- or to simultaneous absorption by these species. The nature of the thermal and optical bleaching of the absorption bands studied in the same investigations [67,68] confirmed the hypothesis put forward concerning the structure of the absorption centres [67].

The models of the centres (enumerated above) responsible for the optical absorption in irradiated chlorates are the most likely. Apart from those described, there are, however, other hypotheses about the structure of the absorption centres [51,54].

2. Composition of Stable Radiolysis Products

In the first studies on the radiolysis of chlorates [64,68] the presence of oxygen, Cl^-, and ClO_2^- in the products was established. The composition of the radiolysis products was investigated in detail by Heal [62]. By analysing the solutions of irradiated potassium chloride and by absorption spectroscopy of the crystals, he determined the following stable products: O_2, Cl^-, ClO^-, ClO_2^-, ClO_4^-, and small amounts of Cl_2O_6 and ClO_2.

The initial radiochemical yields G_0 of the main radiolysis products of alkali metal chlorates and bromates based on the work of a number of investigators [69-77] are compiled in Table 7. Fig. 7 shows the accumulation curves for the radiolysis products of potassium chlorate [62].

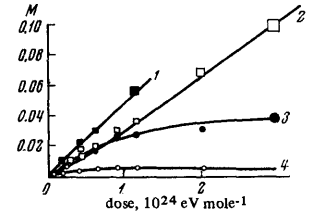

Figure 7. Accumulation curves for the main radiolysis products in potassium chlorate at room temperature [62]:
1) O_2; *2*) Cl^-; *3*) ClO_2^-; *4*) ClO^-.

Studies on the radiation chemistry of bromates [70-75] established that their irradiation in a nuclear reactor with mixed radiation (γ-rays, fast and slow neutrons) and with cobalt-60 γ-rays leads to the accumulation of the radiolysis products Br^-, Br_2, BrO^-, and BrO_2^-, i.e. the composition of the reduction products of bromate ions is similar to that of the products found in the radiolysis of chlorates. The products also contain O_2, but the presence of BrO_4^- has not been finally established. Chase and Boyd [78] also detected BrO^-, BrO_2^-, Br^-, O_2, and BrO_2 (the last tentatively) in aqueous solutions of alkaline earth metal bromates.

3. Kinetics of Radiolysis

A constant rate of accumulation of Cl^- and O_2 and a complex shape of ClO_2^- and ClO^- accumulation curves are characteristic of chlorates. Characteristic features of potassium chlorate, which has been investigated in greater detail, are also the insignificant effect of temperature in the range 77–300°K on $G(-ClO_3^-)$ and the probable formation of appreciable amounts of ClO_4^- or Cl_2O_6.

A group of studies on the Szillard–Chalmers effect in this class of compounds[79-81] is related to the investigations of the radiolysis of chlorates. Among the products in chlorates irradiated with neutrons, Cl^-, ClO_2^-, ClO^-, Cl_2, and ClO_4^- have been noted.

The radiolysis of alkali metal bromates has been investigated in greatest detail by Boyd and coworkers[72-75,82] (Table 7). The accumulation of Br^- is linear in the initial stage of the radiolysis (approximately up to 1×10^{23} eV g^{-1}); then it begins to take place with a gradually decreasing rate for all the bromates, except lithium bromate, the degree of deviation from linearity increasing in the series from lithium bromate to caesium bromate. In the temperature range 77–358°K the rate of radiolysis depends only very slightly on the irradiation temperature. The rate of accumulation of Br^- in caesium bromate is almost independent also of the irradiation dose rate.

One of the principal conclusions arrived at by Boyd et al.[72] is the correlation which they established between the "free space" in bromates and radiation stability. Such correlation holds also for a number of other inorganic salts[38].

Table 7. The yields of the main radiolysis products of salts of the type $MHalO_3$.

Irradiated compound	Products					References	Remarks
	G (Hal^-)	G ($HalO^-$)	G ($HalO_2^-$)	G (O_2)	G ($-HalO_3^-$)

$KBrO_3$	0.63	0.20	0.54	—	1.3		
$RbBrO_3$	0.96	2.23	0.31	—	2.4		
$CsBrO_3$	0.61	—	—	—	3.4		
$LiBrO_3$	0.58	0.26	0.47	—	1.4		

Boyd[73] established that certain kinetic parameters of the radiolysis of lithium bromate under the action of neutrons differ from those which they described for γ-irradiation. In particular, the radiation yields are much higher (Table 7). For all the other bromates, the yields of products on γ-irradiation and irradiation in a reactor are very similar. The higher yield for lithium bromate is associated with the high efficiency of neutron capture by ^6Li nuclei. Thus, when mixed reactor radiation is used, the isotope composition influences the rate of radiolysis.

Among alkali metal bromates, the radiolysis of caesium bromate has been investigated in greatest detail[75]. Some information about the kinetics of product accumulation in the radiolysis of alkaline earth metal bromates has been published by Chase and Boyd[78] who noted a change in the yields with dose for all the products resulting from the secondary reactions involved in the thermolysis and annealing of the radiolysis products.

4. Mechanism of Radiolysis

The above data provide a basis for a mechanism of the radiation-induced decomposition of alkali metal chlorates. The following fundamental reactions are likely to occur in the radiolysis of the chlorates:

1. $ClO_3^- \xrightarrow{h\nu} ClO_3^{-*}$ → $ClO^- + O_2$, (a); → $ClO_2^- + O$, (b); → $Cl^- + {}^3/_2O_2$, (c); → $ClO + O_2^-$, (d); → $ClO_2 + O^-$, (e)
2. $ClO_3^- \xrightarrow{h\nu} ClO_3 + \bar{e}^*$, (a)
   $M^+ \xrightarrow{h\nu} M^{2+} + \bar{e}^*$, (b)
   $M^{2+} + ClO_3^- \rightarrow M^{3+*} + ClO_3^*$, (c)
3. $\bar{e}^* \rightarrow \bar{e}$, → $ClO_2 + O$, (a)
4. ClO_3^*, ClO_3 → $ClO + O_2$, → $Cl + O_2 + O$, (b)
5. $ClO_3 + e \rightarrow$ products 1a–1e (a)
   $ClO + ClO_3^- \rightarrow (ClO{-}ClO_3^-)$, (b)
6. $O_2^- + O \rightarrow O_3^-$, (a)
   $O_2 | \square a + \bar{e} \rightarrow O_2^- | \square a$, (b)
7. $O + O \rightarrow O_2$, (a)
   $Cl + Cl \rightarrow Cl_2$, (b)
8. $ClO_2^- \rightarrow Cl^- + O_2$, (a)
   $ClO^- \rightarrow Cl^- + O$, (b)
9. $ClO_2^- + O \rightarrow ClO_3^-$, (a)
   $ClO^- + O \rightarrow ClO_2^-$, (b)
10. $ClO_3^- + O \rightarrow ClO_4^-$, (a)
11. $ClO_3 + ClO_3 \rightarrow Cl_2O_6$, (a)
    $Cl_2O_6 + e \rightarrow ClO_3^- + ClO_3$. (b)

In the primary stage both excitation [reaction (1)] and ionisation [reaction (2)] of anions take place. The dissociation of excited ClO_3^{-*} species can result in the formation of various oxychlorine products [reactions (1a)–(1e)]. However, the formation of oxychlorine anions [reactions (1a)–(1c)] is more likely than reactions (1d) and (1e) because of the higher electron affinity of chlorine oxides compared with oxygen[40].

The following experimental findings confirm the occurrence of ionisation in chlorates: (1) the presence at low temperatures in irradiated sodium and potassium chlorates of a signal originating most probably from ClO_3;[50] (2) the formation on radiolysis of small amounts of Cl_2O_6 [76] produced as a result of bimolecular interaction between ClO_3 species [stage (11a)]. After the ionisation step, the excited electron loses its energy [the electron thermalisation stage, reaction (3)], and is then captured by a trap.

Reactions (2b) and (2c), the ionisation of the cation and subsequent conversion into M^{2+*} under the influence of the powerful field of the electron in the neighbouring anion, probably also occur. The excited radical ClO_3^* produced at the same time breaks down; among its possible decomposition products, only ClO_2 radicals have been observed so far.

In view of the high electron affinity of ClO_3 ($E = 3.96$ eV according to Ref. 40), the recombination of these species

[reaction (5)] can also lead to bond dissociation within the radical. The possibility of this occurring is largely determined by the ratio of the electron affinity of ClO_3 to the dissociation energy of Cl–O bonds in the chlorate. The latter is 2.38 eV in potassium chlorate [11]. The adoption of the $ClO–ClO_3^-$ pair as one of the paramagnetic centres in chlorates presupposes reaction (5b).

In the ESR spectra of irradiated chlorates one of the singlets has been assigned to the oxygen radical, which justifies the introduction of reaction (6a), but according to the latest studies stage (6b) is the more likely.

By analogy with bromates, one may assume that the annealing of the radiolysis products which occurs also in the radiolysis process itself at moderate and high temperatures involves both thermal conversion of unstable products [reactions (8a) and (8b)] and the reverse oxidation of oxychlorine products by atomic oxygen [reactions (9a) and (9b)] formed on decomposition of excited species [reactions (1), (4), and (5)].

It is at present difficult to determine the subsequent fate of the ClO_3 radicals formed in stage (2) (decomposition or dissociative recombination with an electron). However, the first data obtained on the thermal and optical bleaching of ClO_3 at low temperatures [50] suggest that reaction (5) is the more likely process, although reaction (11a) and the subsequent reaction (11b) are possible.

In view of what has been said, one might think that neutral oxychlorine radicals (ClO, ClO_2) and anions (ClO^-, ClO_2^-) are formed in chlorates by different reactions [reactions (2) and (4) and reactions (1) and (5) respectively]. Since the presence of the ClO_4^- anions in the radiolysis products of chlorates has been demonstrated in a number of studies and Sharman and McCallum [80] assert that ClO_4^- anions are formed by the further oxidation of chlorine in the chlorate anion, one must introduce tentatively reaction (10).

The formation of radicals and final products in the radiolysis of alkali metal bromates has been investigated in much less detail than for the chlorates. Only the problem of the accumulation of bromide and oxybromine anions with a low degree of oxidation of bromine has been adequately dealt with in the literature. The mechanism put forward [73,74] for the radiolysis of bromates appears to be less definite and justified than the set of fundamental stages which can be postulated for chlorates. It may be supposed (the comparison of the compositions of the molecular radiolysis products of chlorates and bromates confirms this) that the mechanism of the radiolysis of $MBrO_3$ is largely similar to that of the radiolysis of chlorates. The differences in the mechanism of radiolysis of these two groups of salts can be definitely established only by a thorough comparative study of the optical and ESR spectra of the salts.

V. RADIOLYSIS OF PERCHLORATES

The radical products of the radiolysis of potassium and ammonium perchlorates have been determined and investigated by the ESR method by a number of workers [83–90]. The presence of the paramagnetic species ClO_2 and O_3^- in potassium perchlorate irradiated at room temperature has been established [3,84] and certain kinetic characteristics of their accumulation and thermal breakdown have been determined [83]. By irradiating the specimens and recording the spectra at low temperatures, it is possible to observe two additional signals, one of which has been attributed [83] to O_3^-, while the other has remained uninterpreted. A study in the temperature range 77–100°K revealed two further ESR signals, which have been assigned tentatively to ClO_4 radicals [90].

The relatively stable ClO_3 and NH_3^+ species have been observed and definitely identified in irradiated ammonium perchlorate, while Boyarchuk et al. [85] also observed at low temperatures an unstable singlet which they attributed to electrons localised at lattice defects.

Among all the radicals enumerated, only the behaviour of NH_3^+ in ammonium perchlorate has been investigated in fair detail. The spectroscopic and kinetic characteristics of other paramagnetic centres have not been studied, nor have the ESR spectra of any other perchlorates. Optical absorption by radiolysis products in solid perchlorates has been investigated only for ammonium perchlorate [63,91]. Absorption bands with maxima close to 260, 300, and 360 nm, indistinct absorption near 420 nm, and absorption at wavelengths below 220 nm have been detected in the spectrum of ammonium perchlorate irradiated at 77° and 300°K. Comparison with the spectra of irradiated chlorates, aqueous solutions of the corresponding compounds, and the results of the analysis of the stable products of the radiolysis of ammonium perchlorate, led the authors to assign these bands to ClO_2^-, ClO^-, ClO_2, O_3^- (Cl_2O_6), and Cl_2^- respectively.

Heal [92] identified Cl^-, ClO_3^-, and O_2 as the stable radiolysis products of potassium perchlorate, after dissolving the irradiated salt in water. However, Baberkin et al. [69] have stated that the chloride appears only after heating the irradiated specimens above 370°K. Heal [92] has suggested the formation of hypochlorite and chlorite ions, whose presence in irradiated alkali metal and alkaline earth metal perchlorates was demonstrated later [93–96]—these studies showed that ClO_2 and metal oxides are also formed. The variation of the degree of accumulation of the main radiolysis products with the dose absorbed differs little from linearity. The deviations from linearity at high irradiation doses are due to secondary reactions involving the annealing and thermolysis of the products. The radiochemical yields of the radiolysis products of various metal perchlorates are listed in Table 8, which shows that the main radiolysis products of the perchlorates are chlorate and oxygen. The remaining products are formed with relatively low yields. It has been shown [93–95] that $G(-ClO_4^-)$ for potassium and sodium perchlorates is almost independent of temperature over a wide range of the latter.

Table 8. Radiochemical yields of the radiolysis products of perchlorates at room temperature.

The relative content and the kinetics of the accumulation of stable radiolysis products, observed after dissolving irradiated ammonium perchlorate in water, differ from those quoted for alkali metal perchlorates. It has been shown[63,91,97,98] that the main radiolysis products are Cl^-, ClO_3^-, and Cl_2; the question of the presence of ClO_2^- and ClO^- in aqueous solutions of irradiated ammonium perchlorate remains open (see Table 9).

The accumulation of products is non-linear because of the thermolysis during irradiation (even at room temperature) of oxychlorine radiolysis products, but the overall yield $G(-ClO_4^-)$ in the radiolysis process remains constant. Attention has been drawn to the effect of LET on the yields of the radiolysis products[63,91].

The composition of the gaseous radiolysis products was established mass-spectrometrically only for ammonium perchlorate[63,99]. In irradiated crystals O_2, HCl, and N_2O retained by the lattice have been observed[99]—N_2O, NO, O_2, and H_2O are evolved from the crystals during radiolysis[63].

Table 9. Initial yields of the radiolysis products of ammonium perchlorate at room temperature.

Type of radiation	$G(ClO_3^-)$	$G(ClO^-+Cl_2)$	$G(Cl^-)$	$G(-ClO_4^-)$	References

^{60}Co γ-rays	1. 3	1.65	2.5	—	98

The post-radiative changes in the properties (mainly thermal stability) of ammonium perchlorate have been examined in a number of studies[100-105]. Stable final radiolysis products which catalyse thermal decomposition must probably be regarded as responsible for the increased rate of thermolysis of irradiated ammonium perchlorate. The data available at the present time on the composition and properties of intermediate and to some extent final radiolysis products are insufficient for the construction of soundly based mechanisms for the radiolysis of perchlorates at various temperatures. Therefore the mechanisms proposed for the individual intermediate stages of the radiolysis of perchlorates[63,83,91,94-96,106] must be regarded as tentative.

The principal postulates put forward in the construction of these mechanisms are as follows. It is suggested that the primary radiolysis products are mainly Cl^-, O_2, and ClO_3^-. The predominant formation of ClO_3^- as the primary product in the radiolysis of ammonium perchlorate has been pointed out[63,91]. Data on the effect of semiconductor impurities on the radiolysis of ammonium perchlorate[63,107,108] suggest that the products are formed on dissociative addition of an electron to ClO_3 and ClO_4 radicals. The important role of the interaction between the radiation and the cation, which leads to the formation of species with two and more positive charges, has been pointed out[106].

VI. ANNEALING AND INTERCONVERSIONS OF RADIATION-DAMAGED REGIONS

A number of investigators have undertaken, particularly in recent years, the study of processes involved in the restoration of the properties and the stoichiometric composition of irradiated materials, under the influence of various factors on the irradiated compounds. Frequently in studies of this kind thermolysis and interconversions of the radiolysis products are observed together with the intrinsic annealing. Studies in this field consist of two groups in each of which the problem is formulated in a slightly different way.

Most of the investigations deal with the study of the annealing phenomena in preparations (mainly inorganic oxygen-containing salts stable to radiation) irradiated with slow neutrons. Problems concerning isotope separation using the Szillard–Chalmers effect and the time-variation of isotope distribution between the individual chemical species in irradiated materials have been mainly examined (for reviews, see Refs. 109–111).

A comparatively small number of publications concern the changes in the concentrations of the radiolysis products in solid salts during post-radiative annealing. Most of these studies have been carried out on potassium nitrate and certain heavy metal nitrates. The available literature data are concerned almost exclusively with the kinetics of thermal annealing[10,14,15,38,94,112-118], while the post-radiative changes in the products under the influence of other factors have been investigated very little.

Annealing in nitrates is regarded approximately as the oxidation of nitrogen–oxygen products (mainly NO_2^-) by radiolytic oxygen[112,113]. The rate and extent of this process are significantly influenced by all types of treatment of the salt: pressing[113,114,116], grinding[115], introduction of heterovalent ions into the lattice[39]. Annealing is greatly accelerated at the polymorphic transition temperatures[117]; in some nitrates it appears to involve a more complex mechanism than simple oxidation of NO_2^- by oxygen trapped in the lattice. There must be various mechanisms of the effects of the preliminary treatment on thermal annealing[114,115].

Among cases of non-thermal annealing, a decrease of the amount of radiolytic NO_2^- in lead nitrate on pressing[114] and irradiating the preparation with ultraviolet light has been observed.

Unstable radiolysis products of oxyhalogen salts can also undergo changes during annealing of the irradiated compounds[72,75,76,94,119-121]. According to some investigators[72,75,111,121-123], two groups of reactions then occur–recombination of oxychlorine or oxybromine products with oxygen (i.e. the intrinsic annealing) and their thermolysis to the chlorides. In alkali metal and alkaline earth metal bromates these reactions take place during the irradiation process itself even at room temperature and result in variable yields of the products during radiolysis.

VII. RELATIVE STABILITY TO RADIATION IN SERIES OF SIMILAR SALTS

It has now been firmly established that the stability of inorganic compounds (including oxygen-containing salts) to radiation is determined both by their macroproperties, in particular the structural and energy properties[94-96], and the nature and type of damage to the crystal lattice[107,124].

One of the most clearly established relations between stability and macroproperties of similar salts is that, on substitution of the cation in series of salts with the same anion, the radiation yield of the products changes smoothly and in parallel with the variation of the most important characteristics of the crystal lattice ("free space" and lattice energy, electronic fraction of the ions, etc.). The study of relations obtaining in radiolysis in series of similar compounds over a wide range of temperatures[48,50,125]

and in the annealing of nitrates [118] and also the study of the radiolysis of aqueous perchlorate systems [106] permit a more detailed examination of this problem. In particular, three temperature regions may be isolated in which the origins of stability series and the very nature of the relations obtaining in series of compounds may be different.

At low temperatures (77°K) the accumulation in alkali metal bromates and chlorates of radical products of the ionisation of anions takes place with a yield which increases in the series in parallel with the increase of the electronic fraction of the anion [50]. At the same time other radicals, whose yield increases in the opposite sense, i.e. in parallel with the increasing electronic fraction of the cation and the "free space" in the lattice, become stabilised under these conditions.

At higher temperatures (between 120° and 150°K) the radicals of the first type disappear, while the yields of those of the second type increase. Probably, starting with the above temperatures, the overall rate of accumulation of products in series of compounds with a variable cation or anion (for example, in the second case in the series $KClO_3$–$KBrO_3$–KIO_3) increases in parallel with increasing "free space" and electronic fraction of the cation. A similar relation is also observed in the accumulation of final, molecular radiolysis products, which are analysed chemically.

Similar relations (as regards stable products) have been established by a number of workers for alkali metal and (in a number of cases) alkaline earth metal halides, azides, nitrates, chlorates, bromates, perchlorates, and permanganates [38,50,78,106,126] and they are probably common to inorganic salts irradiated close to room temperature. Until recently it has been assumed that the direct origin of series relations of this type is associated with the change only in the *"free space" of the crystals* in the series of salts. As the "free space" increases, the cage effect and the probability of the reverse reactions of the intermediate radiolysis products decrease, which in fact entails an increase of the radiation yields of the products.

However, recently it has been suggested that the change in "free space" cannot be regarded as the only origin of related series in the temperature range investigated. According to some investigators [3,4,93,106], the interaction between radiation and the salt cations must make a significant contribution to the yields of the radiolysis products. This view was confirmed experimentally for the first time for silver nitrate and alkali metal perchlorates by Mosley and Moulton [12] and Wang Wen-hsin et al. [106] respectively. The interaction between radiation and cations which takes place with a probability proportional to the electronic fraction of the latter leads to the formation of additionally ionised cations (mainly M^{2+}), whose coulombic field may be sufficient to remove an electron from a neighbouring anion [106]. The energy evolved on addition of an electron to M^{2+} may result in the decomposition of neighbouring radicals and anions.

Finally, in radiolysis at elevated temperatures (different for different salts) it is desirable to take into account the effect of annealing processes, occurring during irradiation, on the yields of products and the occurrence under these conditions of radiation stability series. According to Zakharov et al. [118], the rate and extent of annealing in alkali metal nitrates increase appreciably in the series ranging from sodium nitrate to caesium nitrate, which means that they vary in parallel with the increase of "free space", i.e. with the improved conditions for the diffusion of radiolysis products. The activation energy for the annealing in nitrates is much higher than the activation energies for the processes occurring in radiolysis. Therefore the variation of radiation stability in series of these salts at elevated temperatures must be less pronounced and possibly (if not prevented by thermolysis) actually the reverse of the variation of radiation stability at low temperatures [118].

The rates of annealing (re-oxidation) and thermolysis of the oxyhalogen products in perchlorates, chlorates, and bromates also depend on the "free space" [78,94]. This must affect the radiation stability series for the salts at elevated temperatures.

Autocatalytic and Impedance Phenomena and the Effect of the Physical State of the Solid Product on the Acceleration and Retardation of Reversible Topochemical Reactions with Participation of Solid and Gaseous Reactants

E.S.Vorontsov

CONTENTS

I. Introduction 73
II. The mechanism of autocatalysis 74
III. Catalysis by a solid product 78
IV. The impedance phenomenon 80
V. Unblocking of the initial solid phase 81
VI. The Pilling-Bedworth rule and the principle of the acceleration or retardation of reversible topochemical reactions with participation of gaseous and solid reactants 82

I. INTRODUCTION

During the last 2–3 decades significant advances have been made in the chemistry of solids [1–16]. However, it is noteworthy that many problems of the kinetics and mechanism of heterogeneous reactions involving solids are only in the initial stage of development. Furthermore, the development and research in this field and the accumulation of experimental data make it necessary to revise or correct the classical hypotheses in this branch of science.

The present review deals with the most important kinetic features of reactions of the type

$$A(solid) + C(gas) \rightleftarrows B(solid), \quad (1)$$

$$A(solid) + C(gas) \rightleftarrows B(solid) + D(gas). \quad (2)$$

Reactions of the first type include the formation of metal oxides, sulphides, selenides, and halides, the hydration of oxides and their conversion into carbides, and the reverse reactions. Processes of the second type include numerous reactions involving the reduction of oxides to the metals by gaseous reducing agents and the reverse reactions, as well as certain other interactions. Reactions (1) and (2) are heterogeneous and take place at an interface. Therefore the physical state and the topography of the surface of the initial solid phase A and the product B play a very important role in the kinetics of these processes.

The intrinsic chemical step is complicated by a number of physical phenomena which accompany it: the rearrangement of the crystal lattices of the interacting phases and their recrystallisation and sintering, the diffusion of the reactant C and the product B in the gaseous medium and their motion through pores and cracks in the solid phases A and B, the adsorption and desorption of gases, and the supply and removal of heat. Therefore the processes can take place both under kinetic and diffusion-dependent conditions.

In the examination of the kinetics of reactions (1) and (2) under isothermal conditions (this is the case most frequently encountered in technology), we shall distinguish two factors which have been called "autocatalysis" and "impedance".

Autocatalysis consists in the reaction, having begun after a certain induction period, developing at an increasing rate, the process gradually coming to a stop only at more advanced stages as a result of the disappearance of the initial reactant. The accumulation of the product of an autocatalytic reaction can be described graphically by an S-shaped curve and mathematically the relation between the extent of reaction α and time t can be expressed by the Kolmogorov–Erofeev equation, for example [17]:

$$\alpha = 1 - \exp(-kt^n). \quad (3)$$

The self-acceleration of the reaction and a rate maximum on the kinetic curve have been observed experimentally in numerous investigations [18–27].

Another no less interesting feature of reactions (1) and (2) is that the formation of the product B results in the separation of the reactants in space and the appearance of factors hindering the process, whose magnitude increases as the solid product accumulates. This phenomenon has been called impedance. Factors hindering the reaction can arise even at the very beginning, whereupon the rate will steadily decrease (provided, of course, that there are no abrupt changes in the nature of the process itself, the

conditions of the process, or the physical state of the interacting phases). The time-dependent inhibition of the process can be described mathematically either by a parabolic or a logarithmic relation[28,29]:

$$\delta^n = kt, \tag{4}$$

$$\delta = \ln(kt), \tag{5}$$

where δ is the thickness of the layer of product, t the time and n the exponent of the parabola.

Despite the abundance of the available experimental data, the nature and mechanism of autocatalysis have not yet been completely elucidated. In the literature there are contradictory interpretations of this phenomenon[30-33]. The occurrence of extrema on the kinetic curves can be explained in different ways[13]. The extensive experimental data on impedance have not been adequately systematised.

The aim of the present review is to reveal certain contradictions in the interpretation of the mechanisms of autocatalysis and impedance. The comparison of these phenomena in a single review should facilitate a deeper understanding of their nature and mechanisms. Analysis of the experimental data which have accumulated in this field during the last decades permits the formulation of an empirical principle broader than, for example, the Pilling–Bedworth rule[34] which has existed since 1923.

II. THE MECHANISM OF AUTOCATALYSIS

Usually the acceleration of reactions (1) and (2) is attributed to the increase during the process of the area of the A–B interface. According to the theory of the initiation and growth of a new phase developed by Gibbs, Volmer, Frenkel', Roginskii, and others, it is now believed that, after the formation of the nuclei of the new phase B, further reaction is localised at the interface between the phases A and B.[35] The process develops from the nuclei into the bulk of the specimen. Todes gave a mathematical description of this mechanism. If the particle is very small, the nucleus can completely fill it up before the second nucleus is produced—this is a case of mononuclear transformation in a chemical reaction[36].

Clearly reactions of types (1) or (2) extend into the bulk of the compact crystal, having begun on its surface. However, the theoretical foundations of the role of the A–B interface in autocatalysis, and the details of the model of this surface and its application to any type of topochemical reaction have given rise to a number of contradictions and therefore they require revision and correction. For example, Esin and Gel'd, gave the following explanation of the role of the A–B interface, on the basis of Langmuir's studies, in connection with the discussion of the mechanism of the reduction of an oxide to the metal by a gaseous reducing agent[37]. It is assumed that in the reaction

$$a\mathrm{A(solid)} + c\mathrm{C(gas)} \rightleftarrows b\mathrm{B(solid)} + d\mathrm{D(gas)} \tag{6}$$

the rates of the forward (V_1) and reverse (V_2) processes depend on the total areas of the solid phases:

$$V_1 = k_1 S_A p_C^c, \tag{7}$$

$$V_2 = k_2 S_B p_D^d. \tag{8}$$

On attainment of equilibrium, $V_1 = V_2$ and

$$k_1 S_A p_C^c = k_2 S_B p_D^d, \tag{9}$$

whence

$$K = \frac{k_1}{k_2} = \frac{S_B p_D^d}{S_A p_C^c}. \tag{10}$$

It follows from Eqn. (10) that the equilibrium constant K depends on the ratio of the total areas of the solid phases, but this is inconsistent with experiment.

To eliminate this "contradiction", Esin and Gel'd[37] conclude that the reactions of the gases C and D with the solids A and B do not take place on the entire surface of each phase but only at their contact boundary. They believe that such localisation of the process in a narrow contact zone between two solid phases has a number of advantages.

However, one should bear in mind that the appearance of a solid product can give rise to diffusion-dependent inhibition and can result in a change of the process conditions from kinetic to diffusion-dependent. Then the kinetic laws should cease to apply and should be replaced by diffusion laws. The application of the law of mass action to reactions of types (1) and (2) in its usual kinetic form is possible only when the interaction of the gas with solid phases is not complicated by either external or internal diffusion. This means that the gas phase is mixed sufficiently vigorously and has free access to the surface of the solid reactant, i.e. the supply of the molecules of C and D to the substances A and B is not rate-limiting.

Furthermore, one should bear in mind that, as equilibrium is approached, the difficulties associated with the formation of the new phase become increasingly significant. The size of the critical nucleus is inversely proportional to the degree of chemical supersaturation raised to the third power. This means that at equilibrium the fundamental forward and reverse steps (for example, oxidation and reduction) can take place on both surfaces (A and B) without the formation of a new solid phase.

This conclusion becomes particularly convincing if the following version of equilibrium is postulated. We assume that the reaction volume contains the solid phases A and B, which are separated in space, and that the gas mixture (C + D) has the equilibrium composition. Clearly in this case there is no A–B interface but a dynamic equilibrium nevertheless exists.

Therefore one can assume that at equilibrium the reaction surface is not the A–B interface but the surfaces of the phases A and B (for example an oxide and a metal) which are accessible to the gas. Since on attainment of equilibrium the number of forward reaction steps becomes equal to the number of reverse steps, it must be assumed that the reaction surface areas S_A and S_B are equal regardless of the ratio of the total areas of the phases A and B:

$$S_A = S_B \tag{11}$$

Here by S_A and S_B we understand not the macroscopic areas of the phases A and B but those surfaces of both solid phases on which the forward and reverse reaction steps can take place. It is possible to explain in this way the independence of the equilibrium constant for the topochemical reaction of the ratio of the surface areas of the solid phases. Therefore the explanation by Esin and Gel'd[37] of the role of the A–B interface in autocatalysis is not very convincing.

For processes which are the reverse of reactions of type (1) (thermal dissociation processes), Jacobs and Tompkins give the following explanation of autocatalysis[38]. The Gibbs free energy (ΔG) of formation of a nucleus of the new solid phase A must include not only the difference between the thermodynamic potentials of the products and reactants ($\Delta G'$) but also the energy γ of the strain in the crystal lattices of the solid phases at the sites where they are in contact. Accordingly, the following equation holds:

$$\Delta G = m\Delta G' + \sigma\gamma \tag{12}$$

where σ is a geometric factor (equal to $4\pi r^2$ for a spherical

interface) and m the number of molecules involved in the formation of the nucleus. Eqn. (12) can be put in a different form:

$$\Delta G = am^{2/3} - bm . \quad (13)$$

Here a is proportional to the strain energy and b denotes the free energy change per molecule with the sign reversed.

If $\Delta G' < 0$, ΔG is a decreasing function of m when $\gamma = 0$ or there is a maximum when $\gamma > 0$ (Fig. 1). The maximum value of ΔG corresponds to the critical size of the nucleus (m_{cr}). Apparently as a result of the strain due to the formation of the new phase, small particles of A are unstable and tend to be reconverted into B, while large particles are more stable in relation to the reverse transition. Jacobs and Tompkins[38] believe that because of this subsequent reactions take place preferentially at the interface between the two solid phases and not via the formation of a large number of submicroscopic particles A. The phase A formed in the reaction steadily increases in size, extending from the nuclei into the bulk of the crystal.

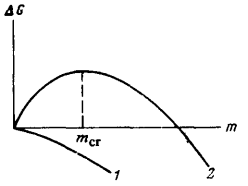

Figure 1. The ΔG–m curve for $\Delta G' < 0$: *1*) $\gamma = 0$; *2*) $\gamma > 0$.

The authors explain the autocatalytic nature of the reaction by a general hypothesis, according to which the nuclei are formed initially, this being followed by a period of their relatively rapid growth. If the activation energy for the growth at the interface is less than the activation energy for the formation of the nucleus, then the growth of the already existing nuclei predominates over the formation of new ones and the phase formed acquires the form of individual compact grains. In the opposite case a large number of very small nuclei are formed, none of which attains a size sufficient for observation with the naked eye.

The above mechanism of the development of the process differs little from the classical hypotheses of Volmer and Frenkel'[39,40]. It has the advantage that it can embrace in a general form a wide range of topochemical reactions, including reactions (1) and (2). At the same time it is readily seen that a more concrete application of the theory to reactions (1) and (2) requires the correction of some of its postulates. This applies in particular to the structural model of the A–B interface and the question of the site where the reaction takes place.

Autocatalysis due to the growth of the A–B interface requires in the first place that such an interface be present. However, it is known that, with the exception of molecular crystals, most solid crystalline chemical compounds exhibit appreciable deviations from stoichiometry (see, for example, Ref. 41). Furthermore, there is a possibility of the occurrence in the process itself of unstable transitional structures which, from the thermodynamic point of view, can be embraced by the concept of the solid solution. Therefore there may be no definite interface between the solid phases.

Furthermore, the volumes of the interacting phases are not as a rule equal. Because of this and because of the difference in the rates of migration of the elementary species through the layer of the solid products, the solid phase formed is usually very porous, amorphous, or finely dispersed. In this connection, it is interesting that as early as 1940 Erofeev examined photographs of nuclear grains and found that crystallisation processes are separated in space from the interface. An amorphous product, which becomes crystalline only at a certain distance from the contact surface, is in contact with the initial substance. In some cases the solid crystalline product is not observed at all or is observed only a considerable time after the reaction. Thus the crystallisation process is separated from the intrinsic chemical reaction both in space and in time[17].

If the volume of the new solid phase is smaller than the volume of the initial solid consumed in the formation of the former, then, if the process takes place under conditions which impede sintering and recrystallisation, the reaction usually results in the formation of a finely dispersed porous product. Thus the reduction of single-crystal and polycrystalline oxides by gaseous reducing agents can yield pyrophoric metal as the product[42]. The dissociation of calcite, $CaCO_3 \rightarrow CaO + CO_2$, leads to the formation of a product which has a bulk porosity of up to 54%.[43] A continuous growth of porosity occurs in the multistage reduction of ferric oxide to the metal, $Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow \rightarrow FeO \rightarrow Fe$, in the dissociation of oxides, sulphides, oxalates, and carbonates, and also in the dehydration of hydrates. In this connection the studies of the overall and differential porosity, the size of the primary crystals, and the total surface areas of the solid phases merit attention[15,44–48].

In concrete cases various mechanisms of the formation of pores obtain. For example, the formation of metal nuclei and submicroscopic pores in oxides or oxide nuclei and pores in carbonates can be represented in two different ways: (a) an unstable transition structure is formed in the bulk of the parent phase; the formation in the latter of a three-dimensional hetero-phase fluctuation, which already has different lattice parameters and smaller distances between its constituent species, should result in its separation from the parent medium, if not over the entire surface then at least partially (Fig. 2*a*); (b) when a nucleus forms on the surface of the initial phase due to an orientation effect (epitaxy), it draws its "constructional material" from the surrounding medium. The loss of mass in the immediate vicinity of the nucleus should initiate the formation of a pore (Fig. 2*b*).

It is important to note that in both cases, regardless of mechanism, the appearance of the nucleus of the new phase is accompanied by the formation of two new interfaces: between the initial solid phase and the new solid phase and between the new solid phase and the gas. This may be accompanied by the regeneration of the interface between the initial solid phase and the gas. This factor along requires the correction of Eqn. (12), as was done in our earlier review by the present author[35].

A mechanism for the formation of pores in the dehydration of hydrates was proposed by Garner[49] (Fig. 2*c*). Wagner[50] put forward a mechanism for the development of a pore in the reduction of wustite (Fig. 2*d*). The primary defect of this mechanism is that it accounts only for the development but not the formation of the pore. It is quite clear that in the reduction of wustite to iron pores not only develop but new ones are actually formed.

Pores are not necessarily formed only when the volume of the new phase is smaller than that of the initial phase but also when the opposite relation between phase volumes holds. For example, in the conversion of copper, nickel, and iron wires into the corresponding oxides, sulphides, and selenides the cations move faster than anions. As a result, there is, as it were, a dispersal of the mass of the metal from the surface towards the periphery; pores are formed which can coagulate and give rise in the limit to a cavity with the same geometrical shape and dimensions as the initial specimen[51].

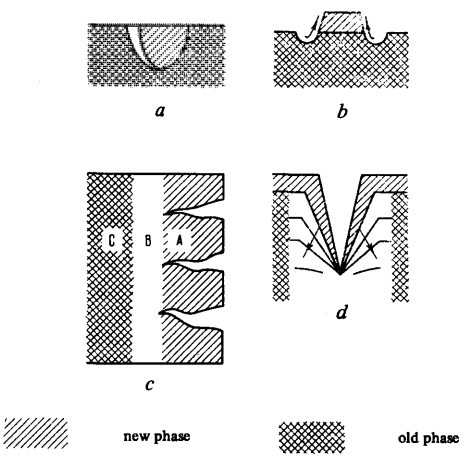

Figure 2. Mechanisms of the formation and growth of pores in topochemical processes:
a) the formation of a nucleus and pore within the parent phase[61]; *b*) the formation of the nucleus of the new phase on the surface of the old; *c*) the formation and growth of pores in the dehydration of hydrates[49] [*A*) new phase; *B*) transition layer; *C*) old phase]; *d*) the development of the pore in the reduction of wustite[50].

The formation of pores renews or maintains contact between the gaseous and solid reactants[42,52], shortens the diffusion path[42], and sets up the conditions necessary for the penetration of electric fields into the bulk of the crystal, which gives rise to the possibility, for example, of the reduction of oxides to metals at temperatures so low that the reoxidation of the latter cannot take place to a significant extent[53].

The experimental data on pore formation throw doubt on the exceptional role which has been attributed to the A–B interface in the development of autocatalysis. A typical autocatalytic reaction is the thermal decomposition of oxalates. For example, Jacobs and Kureishy[14] obtained S-shaped kinetic curves for nickel oxalate both in the powder and compressed states.

Let us consider the dissociation of oxalates:

$$Ag_2C_2O_4(\text{solid}) \rightarrow 2Ag(\text{solid}) + 2CO_2(\text{gas}), \quad (14)$$

$$PbC_2O_4(\text{solid}) \rightarrow Pb(\text{solid}) + 2CO_2(\text{gas}), \quad (15)$$

$$MgC_2O_4(\text{solid}) \rightarrow Mg(\text{solid}) + 2CO_2(\text{gas}). \quad (16)$$

It follows from the ratio of the densities of MnC_2O_4 and M that reactions (14)–(16) should be accompanied by considerable pore formation in the solid product. If one neglects the sintering effect, it is possible to calculate that the porosity of the product formed in reaction (15), for example, may reach about 67% and that of the product formed in reaction (17) may be up to 70%.

Clearly in this case the fundamental decomposition steps on the oxalate–metal surface are hindered. There is no space available for carbon dioxide molecules to desorb into and they cannot dissolve in the atomic lattice of the metal and diffuse through the latter. On the other hand, at the oxalate–gas boundary the reaction is facilitated by the fact that the carbon dioxide molecules can pass freely into the gas phase. Here the decomposition is accompanied by the regeneration of the solid phase–gas interface, breakdown of the crystal, and self-dispersion[13,35].

It is not fortuitous therefore that in recent years investigators have studied the kinetics of thermal decomposition reactions in conjunction with measurements on the changes in the total surface of the solid phase and the porosity occurring in the course of the process. This is evident in the work of Dollimore[15], Gordeeva and coworkers[47], Danes[48], and the present author and Bystrova[43].

The fundamental chemical step in the dissociation of the carbonate, $MCO_3 \rightarrow MO + CO_2$, is the breakdown of the complex anion CO_3^{2-} into a CO_2 molecule and the monatomic anion O^{2-}. It is not difficult to show that this step too is incomparably easier on the carbonate–gas interface than on the carbonate–oxide interface. On the crystal surface, carbon dioxide molecules can be desorbed freely into the gas phase. Their evolution from the outer layers gives rise to vacancies in the anionic sublattice, as a result of which favourable conditions are created for the diffusion of carbon dioxide from the following layers of the crystal lattice. The rearrangement of the crystal lattice of the carbonate into that of the oxide and the formation of a three-dimensional nucleus of the new phase are in no way restricted. On the other hand, on the carbonate–oxide surface the desorption of carbon dioxide molecules is difficult. Their mobility is limited by forces associated with orientation correspondence. The diffusion of carbon dioxide through the calcium oxide lattice involves considerable difficulties. Gel'd et al.[54] showed that calcium carbonate and calcium oxide are virtually immiscible. The diffusion of carbon dioxide on the calcium carbonate–calcium oxide interface also appears unlikely, in the first place because such a surface may not actually exist and in the second place because the forces associated with orientation correspondence must give rise on this surface to a structure almost as compact as that in the bulk of the crystal.

Self-diffusion of carbon dioxide in the calcite lattice is impossible. This was demonstrated by Haul and Stein[55] by the radioactive tracer method. However, the development of the process due to the evolution of carbon dioxide from the bulk of the crystal or on the calcium carbonate–calcium oxide interface, which is associated with diffusion-dependent inhibition, could not give rise to the high rates of reaction which are observed in practice. Thus the complete dissociation of a small cube of polycrystalline calcite with an approx. 10 mm edge at 1140°C requires only 6–7 min.[43] These studies permit the conclusion that both the rapid development of the process and its acceleration are due in this case to the establishment of conditions of uninhibited (or almost uninhibited) evolution of carbon dioxide, i.e. the continuous regeneration of the "initial solid phase–gas" interface.

Under certain thermodynamic conditions and when the mobility of the particles is sufficiently high, a similar mechanism can also be postulated for the dissociation of oxides, sulphides, and other compounds. Of course, the

fundamental steps will be different. For example, in the dissociation of an oxide the fundamental chemical interaction consists in the removal of an electron (or electrons) from the oxygen to the metal. The subsequent stages involving the formation of O_2 and desorption of oxygen should take place more readily on the surface of the crystal, where favourable conditions for the initiation of the new phase do in fact arise. Consequently, the acceleration of the process can be accounted for no less successfully by the occurrence of the reaction on the crystal–gas interface, the "corrosion" of the crystal, and the development of this interface, and also by an increase in the number of defect sites [13,35].

It is noteworthy that in certain studies on the dissociation of carbonates the "degree of conversion–time" curve was not found to be S-shaped. This was observed in experiments with magnesium carbonate by Gordeeva et al. [47] and in experiments with lead carbonate by Kadlets and Dubinin [56]. In the "Proceedings of the Fifth International Symposium (Munich)" Wanmaker reported a similar conclusion concerning strontium carbonate [15].

In this connection it must be noted that these investigators worked with finely dispersed powdered salts. In Wanmaker's study [15] a relation between the rate of reaction and the dimensions of the particles was observed and the absence of an induction period was explained by the rapid generation of the nuclei of the new phase. One should also bear in mind that the increase in size of the particles, the recrystallisation of the initial preparation, can give rise to a considerable increase of the induction period and change the nature of the kinetic curve.

Thus the classical hypotheses concerning autocatalysis, which attribute exceptional importance to the A–B surface in this phenomenon, unduly reduce the role of the gas phase in the development process and also the role of the contact between the solid phase and the gas. Analysis of the literature data [11–27] shows that the phenomenon of autocatalysis is shown most clearly in interactions between solid and gas where the volume of the new solid phase is less than the volume of the substance consumed in its formation. The product must be fairly porous, so that diffusion-dependent inhibition can be excluded, if only in the initial phase, since the ascending branch of the autocatalytic curve corresponds to conditions determined by the reaction kinetics. The present author believes that the formal extension of the classical hypotheses concerning the mechanism of autocatalysis to the interaction of powders with a gas is therefore particularly inadmissible, and yet this is still encountered in modern literature.

We shall now consider the reduction of oxides to metallic iron, the process most frequently encountered in industry. In most practical cases a number of zones are observed in the reduction of crystalline oxides to the metals. Thus the reduction of fused magnetite, carried out by the present author together with Bystrova, leads to the appearance of metal and oxide zones which are clearly distinguishable even with the naked eye [52]. Under the microscope a transition zone, magnetite grains bordered by iron, is observed. The higher the degree of reduction the narrower is the transition zone and the clearer the boundary between the metal and the oxide. The occurrence of zones in the reduction of higher iron oxides has been observed in numerous studies (see, for example, Refs. 42, 57, 58).

When the oxide is finely ground, the process consists of several stages, the lowest oxide not being reduced until the reduction of the higher oxide is complete. Under certain thermodynamic conditions, the reduction of ferric oxide Fe_2O_3 is characterised by the presence of three stages in the reaction:

$$Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe\ . \qquad (17)$$

The phenomenon of a number of stages is difficult to achieve and therefore it has been little investigated. It has been observed, for example, in the work of Rostovtsev et al. [59], who explain the presence of several stages by the synchronisation of the reaction in all the grains of the specimen or the sample, and the phenomenon of autocatalysis observed at the same time is accounted for by the classical mechanism, according to which a reaction an interface develops within each grain. Of course, on the basis of this mechanism it appears logical to assume the synchronisation of the reaction in all the grains of the ore. Otherwise the superposition of the maximum rate in one grain onto the minimum rate in another can lead to cancellation of effects. However, this interpretation of the process mechanism gives rise to the following objections.

1. In the first place the applicability of the classical mechanism of the reaction under the conditions of the experiments actually performed has not been demonstrated.

2. In an atmosphere of pure reducing agents, used in the experiments of Rostovtsev et al. [59], only one phase (the metal) can be stable. Therefore, under kinetic conditions (in the absence of diffusion-dependent inhibition), there could not be several stages.

3. In the synchronous reduction of grains in the absence of retardation of the supply of the reducing gas the duration of the process should be a small fraction of the duration actually observed. Furthermore, it would depend only on the size of the grains and not on the weight of the specimen.

In a conductimetric study of the oxidation and subsequent reduction of thin copper and iron wires it was shown that the time required for the complete reduction is smaller by a factor of tens and hundreds than the total oxidation time [60,61]. The reduction of oxidised iron and copper wires 0.20–0.50 mm in diameter in a stream of hydrogen at 500–900°C requires times ranging from 30 s to several minutes. In Rostovtsev's study the reduction of a finely ground hematite powder, the grain dimensions of which were smaller than the diameter of the oxidised wires in the work of the present author and Ermakov [61], took tens of minutes and sometimes actually exceeded 1 h.

Comparison of these kinetic characteristics throws doubt on the synchronous mechanism of the reaction in all the grains of the specimen. In this connection it appears that the classical explanation of the occurrence of maxima and minima on kinetic curves cannot be universal. One should also remember that in the discussion of the mechanism of autocatalysis in modern literature the concept of the A–B interface, its structural model, are not considered in a sufficiently concrete form. The surface of a pressed oxide powder accessible to reaction with the reducing gas may prove to be extremely large. Thus for spherical particles 0.01 mm in diameter, the total surface per cm^3 of such a powder is about 300 cm^2. [62]

If account is also taken of the presence of defects in the crystal structure of the powder grains and the possibility of the regeneration of this structure and the "oxide–gas" interface during the reduction process, as described above, it becomes clear that, under the conditions of Rostovtsev's experiments [59], the principal site where the reaction takes place may be not the "oxide–metal" interface but the "oxide–gas" interface. However, such a hypothesis requires the revision of the mechanism of autocatalysis and the mechanism responsible for the presence of several stages in Rostovtsev's experiments [59].

In the absence of diffusion-dependent inhibition in the crystal lattice of the solid phase, which is probably the case in the reduction of fine powders, it is essential to take into account in the kinetic analysis of the process the ratio of the rate of penetration of the reducing gas (V_1) through the external geometrical surface of the specimen into its deeper zones (towards the reaction surface) and the rate of the adsorption-chemical step (V_2). The rate V_1 depends on the difference between the concentrations of hydrogen in the centre of the gas stream and within the specimen, and is a maximum at the initial instant of reduction. The second rate (V_2) is associated with the area of the reaction surface and the degree of chemical supersaturation; at the beginning of the process it can be a minimum or even zero.

The penetration of the reducing gas into the specimen and the reverse diffusion of the product gas show to some extent the features of Knudsen molecular flow. Some hydrogen molecules encounter the reaction surface of the oxide comparatively rapidly, while others fail to react and pass into the bulk of the specimen.

According to Roginskii's theory, chemical supersaturation in the system is necessary for the process to occur at a finite rate. Under the conditions of the experiments analysed, it cannot be achieved instantaneously over the entire surface of the solid phase, i.e. throughout the bulk of the specimen. As the process develops, oxidising and inert gases are flushed out of the specimen by the hydrogen and the rate of consumption of the reducing gas increases both due to the increase of the degree of chemical supersaturation and also due to the involvement in the reaction of an increasing number of new sections of the oxide surface.

It appears that in this case it is more correct to attribute the rate of reduction corresponding to the ascending branch of the catalytic curve to the increase in the area of the "oxide–gas" interface and not of the "metal–oxide" interface. On the other hand, as the specimen is "saturated" by hydrogen, the rate of "diffusion" of this reducing gas decreases. Thus the values of V_1 and V_2 approach one another. Therefore the process is initially of the purely kinetic type but after a certain time it becomes of a mixed or even diffusion-dependent type.

In this connection, the phenomenon of several stages can be accounted for by the transition of the process from kinetic to diffusion-dependent conditions. In fact, if the rate of diffusion did not limit the rate of the further development of the process, chemical supersaturation could be fairly rapidly attained not only with respect to the first but also the second and third stages of the reduction. However, then we could not have several stages in the process. The ultimate result of the approach of the rate of the adsorption-chemical step to the rate of supply of the reducing gas is that the chemical reaction maintains in the specimen a gas composition which is close to the equilibrium composition for the given stage. If for some reason the rate of supply of the reducing gas increases, there is also an increase in the degree of chemical supersaturation in the system and hence in the rate of reaction.

The process could be self-regulated. However, the gradual disappearance of the initial oxide phase leads to a decrease in the area of the reaction surface and a lowering of the overall rate of the process, and the ultimate result is that the rate of penetration of the reducing gas again begins to prevail over the rate of its consumption in the given reaction stage: supersaturation with respect to the next stage is established.

In this way it is possible to explain the mechanism of autocatalysis and the phenomenon of several stages in the reduction of powdered oxides without resorting to the concept of the "metal–oxide" interface as the reaction surface, the doubtful hypothesis of the synchronisation of the reaction in all the specimen grains being eliminated. This mechanism is in good agreement with theory and experiment. A mathematical interpretation would be desirable for its further justification[63].

The above analysis of the conditions of autocatalysis and the stepwise reaction phenomenon in the reduction of higher oxides shows that an explanation, other than that given in the literature, of the minima and maxima on the kinetic curves for the relevant processes is possible. The formation of the A–B interface cannot by itself accelerate the process. It is also necessary to eliminate the inhibition of the transport of the reactants, i.e. to ensure that they come into contact. In many cases the successful occurrence of the process is probably associated with sufficiently high mobility of the fundamental species. In the low-temperature oxidation of metals the formation of very thin passive films several ångströms thick, which separate the reactants in space, leads to almost complete cessation of the process. If in this case autocatalysis does in fact take place, it is quite clear that the maximum rate is achieved on attaining a degree of reaction which is difficult to determine quantitatively even by the most refined experimental methods.

On the other hand, when the mobility of the species and the porosity of the product are sufficiently high and satisfactory contact is achieved between the reactants, the maximum rate can be attained at high degrees of reaction, which are readily determined experimentally. For example, in the reduction of cuprous and cupric oxides with carbon monoxide the highest rate was observed at high degrees of reaction, amounting to 20–70%, depending on the experimental conditions[64].

All that has been said does not exclude a certain role of the A–B interface and of the product B and its physical state in the kinetics of the reaction.

III. CATALYSIS BY A SOLID PRODUCT

In recent years the problem of catalysis by a solid product has been discussed frequently. Some authors believe that catalysis by a solid product is a specific feature of topochemical processes[25,32,65–70], while others deny that the product has any effect on the rate of reaction[30,31,56,71–74]. Each investigator bases his view on particular experimental data. In all the above investigations the area of the reaction surface could not be estimated. This is not only because of the difficulty of an accurate determination of the surface area of solids. It should be borne in mind that in powdered preparations the true surface area, which may be very high, in some cases cannot be entirely involved in the reaction at once and in crystalline specimens the area of the reaction surface changes during the process due to the "corrosion" of the crystals.

The present author believes that a categorical formulation of the question of the inevitable catalytic effect of the solid product on the topochemical reaction, in isolation from the experimental conditions and the physical state of the solid phases, is pointless. This follows if only from the vast experimental data which show that the appearance of the product can both accelerate the process (catalysis) and retard it (impedance). Therefore the assertion by Sakovich and Boldyrev[32] that the solid product formed in the reaction must *always* (author's italics) have a catalytic effect on the further process when there is an interface

between it and the initial material can be scarcely regarded as valid.

We shall now consider certain examples. In their study of the decomposition of silver oxide, Pavlyuchenko and Gurevich determined the rate of reaction from the change in the pressure of the oxygen evolved per unit time[31]. They observed that, when silver oxide was mixed with powdered silver obtained by the decomposition of the oxide, the rate of reaction did not change. However, complete removal of the product by careful treatment of the partially decomposed silver oxide with mercury did not retard but actually accelerated the process. Probably in this case catalysis by the product could not occur, being suppressed by the blocking effect of the silver produced. It is known that in some cases at high degrees of chemical supersaturation the reaction MO → M leads to the appearance of a very thin layer of metal which separates the initial phase from the gaseous medium and inhibits the process[50,75-77]. Earlier it was observed[70] that the mercury additive does not affect the rate of decomposition of AgO, the presence of copper has no effect on the decomposition of CuO[73], etc.

However, one cannot compare the effect of a product mixed mechanically with the initial preparation, and therefore making a very imperfect contact with the former, with the effect of a product formed as a result of the reaction, and as a rule corresponding to the parent phase as regards orientation and dimensions[78]. According to certain investigators, the catalytic effect of the product can occur only in those cases where there is sufficiently satisfactory contact between it and the initial substance. For catalysis, it is necessary to have a distinct interface between the solid phases. Boldyrev[25,79] frequently drew attention to this condition.

Boldyrev investigated together with Ermolaev the catalytic effect of solid products in the reduction of nickel and copper oxides with hydrogen[25]. The dimensions of the NiO and CuO particles were in the range 0.01–0.06 mm. It was found that, if NiO is subjected to partial preliminary reduction with hydrogen, the rate of its subsequent reduction under the same conditions is very much higher than the rate of reduction of the initial oxide. On treatment of the partially reduced NiO with a solution of mercuric nitrate, the rate-of-reduction curve was almost identical with the curve for the pure oxide. According to the authors, this proves the catalytic effect of the product.

Possibly this is so. However, can one regard such proof as unambiguous? Probably not. Above, the present author showed that the "corrosion" of crystals during the process and the reproduction of the initial solid phase–gas interface, the porosity, and also the defects in the crystal lattice can greatly accelerate the reaction. It is noteworthy that in the experiments of Boldyrev and Ermolaev the effect of these factors was not excluded. The "washing out" of the reaction centres and microcrystals by treatment of the partially reduced oxides with a mercuric nitrate solution can give rise to capillary forces so high that the defects are undoubtedly "healed", i.e. the initial preparation is "aged". This last condition must always be taken into account in the analysis of the kinetics of topochemical reactions[5]. Consequently the retardation of the process can be caused not only by the removal of the product (the catalyst) but also by other factors.

From the above standpoints, one can scarcely regard the catalytic effect of the product in experiments on the decomposition of pyrite as unambiguously proved[80]. Here there is a break in the kinetic curve, beyond which the rate of dissociation increases sharply. X-Ray diffraction studies confirm that, before the appearance of the break, a solid solution was formed, while beyond it crystals of the product were deposited. However, it remains obscure whether the acceleration of the process is due to the catalytic effect of the product or due to autocatalysis caused by an increase in the area of the reaction surface.

The essential feature of the mechanism of the accelerating effect of the product on the topochemical reaction is that the step involving the addition of a fundamental particle to an already existing small crystal of the new phase requires a smaller expenditure of energy (per gramme atom or per particle) than the formation of the three-dimensional nucleus of the new phase itself. In other words the activation energy for the two-dimensional growth of the new phase must be smaller than the analogous quantity for the three-dimensional growth of the solid product. Even a small difference between the two activation energies can give rise to an appreciable difference between the rate constants for the three-dimensional (k_V) and two-dimensional (k_S) growth of the new phase, since both k_i and E_i are related by the exponential expression

$$k_i = k_i^0 e^{-\frac{E_i}{RT}} . \qquad (18)$$

These postulates constitute the basis of the explanation of a number of features of the mechanism of topochemical reactions, for example in the work of Esin and Gel'd[37], Boldyrev[11], and others. Thus the following microscopic picture of the mechanism for the thermal decomposition of an oxide is suggested[21,81]. On the metal–oxide interface, electrons pass from the O^{2-} anion to the metal. As a result of the "relay" transition of electrons, an oxygen ion and not an oxygen atom will appear in the neighbourhood of the metal. An oxygen atom will appear on the outer surface of the oxide in the neighbourhood of the gas phase. The accumulation of such atoms should result in the formation of molecular oxygen and its desorption. A negatively charged crystal of a metal grows by attracting cations from the oxide lattice.

Apart from definite advantages, the mechanism has certain disadvantages. It is invoked in order to explain the catalytic effect of the product and therefore it is based on the presence of a distinct interface between the oxide and the metal. The growth of the metallic phase at this interface without the removal of oxygen anions should involve considerable steric hindrance. But the mechanism does not explain where and how the oxygen anions are removed.

The diffusion of oxygen, which is a slow process, could complicate the reaction. On the other hand, the occurrence of the process under kinetic conditions is evidence of unhindered removal of oxygen. This can be explained on the basis of the difference between the volumes of the new and old phases, leading to continuous regeneration of the pores, the oxide–gas interface, and the defects in the surface layer of the oxide. Probably this mechanism, taking into account the formation of pores and defects, may prove quite acceptable also for the reduction of oxides to metals by gaseous reducing agents.

Turning again to the relative values of the activation energies for the growth of the new phases in the bulk (E_V) and on the surface (E_S), it must be emphasised that in principle one cannot exclude also the possibility that

$$E_S > E_V \qquad (19)$$

In a slightly different form this confirms the principle of correspondence as regards orientation and dimensions, formulated on the basis of the systematic examination of the experimental data: "the phase reaction on the surface of a solid involves the formation of a new crystal lattice which corresponds, as regards orientation and dimensions,

to the crystal lattice of the initial surface if the energy (E) of deformation of the two-dimensional lattice of the new phase is smaller than the work (A) required for the formation of its three-dimensional nucleus... Otherwise, when $E > A$, the process takes place independently of the structure of the surface of the initial phase"[82]. Here it is appropriate to recall yet again Erofeev's data[17] on the formation of an amorphous product on the A–B interface. The above scheme probably does not exhaust the possible different versions of the mechanism of process catalysis by a solid product.

The accelerating effect of the gaseous product in some cases is striking. Thus the thermal decomposition of potassium azides takes place more rapidly in the presence of potassium vapour than in a vacuum[83]. The experimental data obtained by Tumarev and Pushkarev[84], who investigated the reduction of powdered cupric oxide (–0.050) [particle size 0.050 mm? (Ed. of Translation)] and a gaseous reducing agent (carbon monoxide) are of considerable interest. The product obtained was used as an activator. Three types of experiments were tried: (1) a 0.5 g layer of the activator was placed under a CuO sample (4 g), (2) 0.5 g was mixed with the sample, and (3) a 0.5 g layer was placed on top of the sample. In all cases the presence of the activator resulted in the reduction of cupric oxide at temperatures below 100°C, i.e. under conditions where the process did not develop in the absence of the product. The activator placed underneath the oxide sample proved to have the greatest effect, while the layer of activator on top of the sample to be reduced had no catalytic influence. The authors concluded that the catalysis is due to the activation of the reducing gas by the solid product. They postulate the desorption of the gas from the surface of the catalyst, which retains its activity during a period sufficient for transition to the reaction zone. It would be interesting to test how a change in the distance between the activator and the sample being reduced affects the interaction. Mass-spectrometric (or some other) analysis of the gas which has just passed through the layer of activator would be valuable.

The present author believes that in this case we are dealing with an unusual version of a chain reaction mechanism: an increase in the amount of the solid product results in an increase of the number of activated species in the gas phase which in turn accelerates the conversion of the initial solid phase into the product. Of course under these conditions the area of the reaction surface and its regeneration must be such that unhindered utilisation of an increasing amount of activated species from the gas phase is permitted. The attainment of a maximum rate and the subsequent retardation of the process must be treated here as a stage in which the capacity of the oxide surface to utilise all the active species from the gas has been exhausted.

Tumarev and Pushkarev's experiments confirm the present author's view, stated earlier, on the role of the gas phase, the porosity, and the oxide–gas interface in the mechanism of the reduction of oxides to the metals by gaseous reducing agents[35,61,63]. At the same time, Boldyrev's assertion[79] that the catalytic effects of the product can be shown only when the contact between the latter and the starting material is sufficiently good, probably cannot apply to all cases of acceleration of topochemical processes by the new solid phase.

When autocatalysis in the reduction of oxides to the metals is approached from the standpoint of electronic hypotheses, it is noteworthy that the formation of the metallic phase may be accompanied by a sharp increase in the number of free electron-acceptor energy levels. This in turn may facilitate and accelerate the reducing gas chemisorption stage, and may increase the amount of adsorbate on the surface of an oxide with mixed (electronic-ionic) conductivity[8,12,15]. Here the assertion[79] that contact between the solid phases is essential for catalysis to take place appears to be quite appropriate.

Analysis of the possible reasons for the acceleration of reactions (1) and (2) shows that they may be different, for example, in the dissociation of oxalates and carbonates, on the one hand, and the reduction of oxides, on the other. While in the first case the breakdown of the crystals, self-dispersion and regeneration of defects, can have a decisive effect on the course of self-acceleration, in the second case one must take into account the electronic factor in the chemisorption of the reducing gas. Thus analysis of the literature data leads to the following conclusions.

1. The classical mechanism of autocatalysis, which is based on the increase of the area of the interface in the course of the process is inadequate and cannot be universal.

2. Autocatalysis due to the increase in the area of the reaction surface and catalysis by a solid product are so mutually interconnected that in most experiments it is difficult to separate them and to investigate them in a pure form.

3. The gas phase, the development of porosity, and the regeneration of contacts between the initial solid phase and the gas play a major role in the development of autocatalysis.

4. Catalysis by the product can occur only when its inhibiting effect on the process is suppressed.

In connection with this last feature of the topochemical reactions analysed, the impedance phenomenon will be examined in greater detail.

IV. THE IMPEDANCE PHENOMENON

Numerous experimental data have now accumulated, showing how the physical state of the product influences the kinetics of the relevant topochemical reactions. It has been observed that in some cases the formation of the product lowers the rate of reaction. This is explained by the blocking of the initial solid phase, the separation of the reactants, and the occurrence of diffusion-dependent retardation. In other cases the product does not prevent appreciably contact between the reactants and cannot significantly retard or stop the process.

The available experimental data will now be quoted and initially those cases will be considered where the formation of a product separates the reactants and sharply reduces the rate of reaction.

1. All metals, except the noble metals, are thermodynamically unstable under the usual atmospheric conditions and should be oxidised. However, most of them, except for the alkali and alkaline earth metals, virtually do not oxidise. It has been shown that the reason for this stability is the formation of a thin protecting film of oxide, which separates the reactants and prevents further interaction of the metal with atmospheric oxygen[85].

2. High-temperature oxidation of metals yields in many cases a dense layer of scale, which lowers the rate of the process. The direct interaction between the oxidising gas and the metal is replaced by a slow diffusion-dependent process.

3. The blocking of the initial phase has proved to be particularly successful when the system is alloyed to

impart to it heat-resistant properties. Arkharov showed[86] that in this case high-temperature oxidation leads to the formation of a dense protective layer, consisting of spinel-type oxides with the smallest possible lattice constants.

4. Isothermal carbonation of calcium oxide crystals takes place with great difficulty, since the product (calcite) has a smaller density than the initial preparation and a continuous coating is formed. One may refer to the example quoted by Rostovtsev[87]: lime obtained by the heat treatment of calcite required exposure for three days to an atmosphere of carbon dioxide at 850°C in order to reabsorb two thirds of the carbon dioxide evolved.

5. In experiments on the reduction of polycrystalline specimens of fused magnetite with hydrogen the process was found to be retarded from its very beginning[52]. Despite its porosity, the coating produced presents a definite obstacle to the penetration of the reducing gas into the reaction zone. In this case Knudsen molecular diffusion of the gases (the reactant and the product) occurs. However, even such migration of gases can prove to be the rate-limiting step of the process.

6. In the reduction of natural magnetite single crystals Edstrom observed considerable inhibition of the process due to the formation of a compact layer of wustite as the product[42].

7. The reduction of oxides sometimes leads to the formation of the metal as a thin compact layer, although the appearance of a porous product would be expected from the relative volumes of M and MO. Thus in the reduction of cuprous oxide with carbon monoxide vigorous formation of metallic copper is observed from the very beginning of the process, so that, over a very short period, the initial solid phase becomes covered by a compact copper film, which protects the entire specimens from further action of carbon monoxide; the reduction of Cu_2O ceases[75].

A similar phenomenon was observed in the reduction of wustite with hydrogen[50,76]. Electron-optical studies showed that the iron film formed did not have any pores. In this case the reaction is very slow. According to the authors it was possible only by virture of the diffusion of oxygen through the thin metal film. Calculation of the activation energy for such diffusion gives 53 000 ± 4000 cal g-atom O.

8. The sintering or recrystallisation of spongy metal in the reduction can retard the reaction. This was observed, for example, in the experiments of Chufarov and Lokhvitskaya[22] in the reduction of magnetite with hydrogen and also in a comparative conductimetric study of the rates of oxidation of copper and the reduction of its oxides[60].

Here one should also bear in mind the possibility of a lowering of the catalytic effect of the product with increase in temperature. For example, the iron catalyst for the synthesis of ammonia is prepared by the fusion of iron oxides with K_2O, CaO, Al_2O_3, and SiO_2 additives with subsequent reduction of this mixture of oxides with hydrogen to the attainment of an active state[88]. As the reduction temperature is raised, the catalyst surface is deactivated.

At any rate the experimentally observed negative temperature coefficients of the rates of the topochemical reactions analysed probably cannot be attributed solely to the sintering and recrystallisation of the product.

9. It should also be noted that any autocatalytic process is completed with a continuous decrease of rate, which corresponds to the descending branch of the "rate–time" kinetic curve. The retardation of the process is not due only to the narrowing of the reaction front but also to an increase in the thickness of the outer layer of product[89]. In many cases one can observe how autocatalysis is replaced by impedance.

The above examples have been quoted to illustrate the role of impedance in the kinetics of reactions of types (1) and (2).

V. UNBLOCKING OF THE INITIAL SOLID PHASE

The weakening of the impedance or its suppression play an important role in the kinetics of the processes analysed. We shall now examine the experimental data which show that the loosening of the product and also the improvement of the contact between the reactants facilitate the process and accelerate it. Here the following data are relevant.

1. When the oxide film protecting the metal from the effect of the gas phase is scratched, the contact between the reactants is restored. This phenomenon is used to dissolve the metal and to isolate the protective film in a "pure" form, which constitutes one of the experimental proofs of the existence of protective films[29].

2. Periodic cracking of the scale under the influence of stresses arising in it during the high-temperature oxidation of metals is reflected in breaks on the kinetic curve. The breaks can be explained by the acceleration of the process due to the renewal of contact between the metal and the gas phase each time the scale cracks[90,91].

3. The oxidation of alkali and alkaline earth metals is accompanied by the formation of a loose layer of products. Even at room temperature under the usual atmospheric conditions the initial solid phase is completely converted into oxide after a relatively short time. Here one may refer to numerous experimental data: a typical example is the oxidation of barium at 17°C in "room" atmosphere[92].

4. In 1941 Arkharov established that the rate of oxidation of iron increases with the appearance of a wustite layer in the scale[93]. The appearance of structures with cationic vacancies (wustite or the porous modification of hematite) facilitates the diffusion of iron ions and accelerates the oxidation process. The heat resistance principle formulated by Arkharov is based on the prevention of the formation of the wustite phase and the creation of conditions for the formation of dense oxides of the spinel type[86].

5. Carbonate dissociation processes take place much more rapidly than the reverse reactions. The thermogram for the dissociation of calcium carbonate and the carbonation of calcium oxide, recorded by Potapenko for the same specimen[94], is very instructive in this respect. Heating and cooling of the preparation in a stream of carbon dioxide results in two temperature arrests, at about 918° and 888°C, the extent of the first being much greater than that of the second. Consequently at a given rate of supply or removal of heat, the amount of carbonate decomposed is greater than the amount formed. This is the result of the different rates of diffusion of carbon dioxide through the coating, which proves to be looser during dissociation (calcium oxide) than during carbonation (calcium carbonate).

6. In the reduction of oxides and ores to the metals the reaction product is frequently porous with an extremely large surface area. The methods of preparation of pyrophoric metals by reducing polycrystalline specimens at low temperatures are widely known. The reduction of iron ore usually results in the formation of "spongy" iron.

Bogdandy et al.[46], who investigated the mechanism of the reduction of porous iron ore, concluded that in most cases contact between wustite and the reducing gas is not impaired by a layer of metallic iron. On the basis of microscopic studies, Edstrom[42] explained the faster reduction of ferric oxide compared with other iron oxides by the earlier and more abundant formation of pores in the products.

7. A comparative conductimetric study[61,95] of the rates of oxidation and reduction of iron revealed marked loosening of the metal after the completion of the cycle incorporating the forward and reverse reactions. Because of this, the time consumed in the reduction of wire specimens until the recovery of the initial resistivity proved to be much lower than in the oxidation. Sometimes this difference is as much as 100%.

8. The crystallisation process in the dehydration of hydrates is accompanied by the formation of cracks (pores), usually perpendicular to the interface between the solid phases[96]. These pores facilitate the subsequent development of the process.

9. Some investigators have shown that the removal of the product blocking the initial solid phase and separating the reactants accelerates the process. For example, Pavlyuchenko and Gurevich observed that the removal of the product accelerates the decomposition of silver oxide[31].

Thus numerous experimental data suggest that in reactions between solid and gaseous substances the unblocking of the solid phase blocked by the condensed product may significantly facilitate the process. We now see the great importance of the physical state of the product in the kinetic analysis of reactions (1) and (2). Therefore a systematic arrangement of all these data, i.e. their generalisation in a single rule or principle is extremely desirable. This has been done only in the field of chemical corrosion of metals.

VI. THE PILLING–BEDWORTH RULE AND THE PRINCIPLE OF THE ACCELERATION OR RETARDATION OF REVERSIBLE TOPOCHEMICAL REACTIONS WITH PARTICIPATION OF GASEOUS AND SOLID REACTANTS

In 1923 Pilling and Bedworth[34] formulated a rule for the isothermal oxidation of metals, the significance of which is that the formation of a compact film of oxide on the metal inhibits the subsequent interaction of the latter with the gas, while the appearance of a loose (porous) product does not hinder the process. The type of product formed depends on the relative volumes of the metal oxidised and the oxide produced.

Mathematically the rule formulated by Pilling and Bedworth can be described by two formulae:

$$\frac{V_O}{V_M}=\frac{Md_M}{And_O}<1 \qquad (20)$$

and

$$\frac{V_O}{V_M}=\frac{Md_M}{And_O}>1\,, \qquad (21)$$

where V_O is the volume of the oxide formed in the interaction of one gramme-atom of the metal, V_M the gramme-atomic volume of the metal, A the atomic weight of the metal, M the molecular weight of the oxide, n the number of metal atoms in the oxide molecules, and d_M and d_O are the densities of the metal and the oxide respectively. Eqn. (20) is valid for the oxidation of alkali and alkaline earth metals. Here the formation of a loose film does not lead to the separation in space of the reactants M and O_2:

$$M+\tfrac{1}{2}O_2\rightarrow MO\,. \qquad (22)$$

According to other hypotheses[29], a very thin pseudomorphous film of oxide forms between the solid phases and cannot cause serious diffusion-dependent inhibition of the process. Therefore the law governing the growth of the oxide layer is linear.

Eqn. (21) holds in the oxidation of most of the technically important metals (aluminium, zinc, copper, nickel, manganese, iron, chromium, cobalt, tungsten, etc.). It leads to a parabolic or a logarithmic relation between the weight of the oxidised metal (or the thickness of the oxide film) and time [Eqns. (4) and (5)].

The Pilling–Bedworth rule is of limited applicability for the following reasons:

1. It takes into account only the ratio of the volumes of the solid phases, disregarding their structural features.

2. Apart from the true volume of the oxide, there exists also the apparent volume. The difference between the rates of diffusion of ions in the high-temperature oxidation of metals, for example, results in the apparent volume of the oxide becoming much larger than the volume calculated from the ratio of the densities of M and MO.

The experiments of Wagner[97] and Ol'shanskii[51] on the conversion of silver and copper into their sulphides showed that the process occurs via the preferential diffusion of the cations through the layer of the solid product. This leads to the appearance and coagulation of pores. In the limit cavities may form, which are, as it were, negative imprints of the oxidised specimen.

The formation of iron scale under industrial conditions is accompanied by the appearance in the inner layers of macropores which are visible even with the naked eye.

3. The occurrence of internal stresses in the oxide layer due to the different densities of the metal and the oxide, phase transitions, temperature oscillations (deviations from the specified temperature of the process), and other factors leads to the cracking of the scale, which may result in the degeneration of the parabolic relation to a linear relation, for example, as shown in Fig. 3.

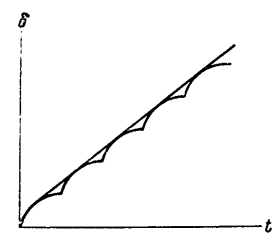

Figure 3. Transformation of a parabolic relation into one of a pseudolinear type.

4. It is possible to select such process conditions that, when Eqn. (21) holds, the product is loose (porous) and, conversely, when the inequality (20) holds, the product may become compact.

The development of the theory of the oxidation of metals suggests that the mechanisms of chemical and electrochemical corrosion have much in common, in addition to certain differences. Thus, according to the data of a number of investigators[51,98,99], chemical oxidation of a metal should be regarded as due to the operation of electrochemical cells in which the role of the metallic conductor and the electrolyte is fulfilled by the oxide phase which exhibits

mixed (electronic and ionic) conductivity. Electrochemical oxidation is also treated as the result of the operation of electrochemical corrosion cells[29].

However, in one case (in chemical oxidation) the reaction between iron and oxygen yields a compact oxide film. As a result, the reactants are separated in space, the process is retarded, and is possible only via the diffusion of elementary species. In another case (in electrochemical corrosion of iron) the product (rust) may be porous despite the fact that its volume is greater than that of the metal oxidised.

5. Finally, it is possible to set up such temperature conditions that the loose oxide begins to sinter, and, despite Eqn. (20), the process is retarded and the linear relation in kinetic plots is converted into one of a parabolic or logarithmic type; on the other hand, on loosening or sublimation of the compact oxide, it is possible to obtain a linear relation between the weight of the metal which has reacted and time.

The above considerations lead to the following conclusion. Under the conditions of isothermal oxidation of the metal, the protective film does not always have the density and the structure of the compact oxide of the same composition. Consequently, the main factors which influence the acceleration or inhibition of the process are not those defined by formulae (20) and (21) but the physical state of the product and the mechanism of the reaction. This conclusion is even more convincing if one goes beyond the limits of chemical corrosion into the wider field of topochemical reactions described by formulae (1) and (2). This is demonstrated by numerous experimental data, described in sections IV and V of the present review and in the literature[9,11,13,15].

Thus one may conclude that the modern state of the theory of topochemical processes analysed in the present article is not yet consistent with the experimental data which have accumulated. The Pilling–Bedworth rule and also Arkharov's heat-resistance principle have played a major role in the determination of the general trends in the acceleration or retardation of topochemical reactions; however, their applicability is restricted to the field of chemical corrosion of metals.

Dankov's principle of orientational and dimensional correspondence applies directly to the mechanism of the reactions considered. Its great theoretical and practical value is generally known. However, it does not determine directly the mode of acceleration or retardation of the relevant reactions.

One must of course bear in mind that no one rule or principle can pretend to be fully universal and cannot embrace all the wide variety of factors which influence the kinetics of topochemical reactions. How wide is the range of these factors, which include all the chemical and physical phenomena accompanying the development of the process, can be assessed if only from the thermal decomposition of solids[5]. At the same time the systematised experimental data on the blocking and unblocking of the initial solid phase in its interaction with the gaseous medium show how great is the role of impedance in the kinetics of topochemical processes. Analysis of the phenomenon of autocatalysis shows that the maximum rate can be attained at high degrees of reaction only when sufficient contact between the reactants is maintained throughout the entire period of self-acceleration and the chemical reaction takes place under kinetic conditions. It becomes clear that there exists in this field a more general kinetic principle, including as a special case the Pilling–Bedworth rule, of recognised value in the field of chemical corrosion of metals but which requires correction on going to the wider field of topochemical reactions.

Analysis of experimental data permits the formulation of the kinetic principle for topochemical reactions with participation of solid and gaseous reactants under isothermal conditions in the form of the following postulates:

1. When reactions of the type

$$A(solid) \rightleftarrows B(solid) + C(gas),$$

$$A(solid) + C(gas) \rightleftarrows B(solid) + D(gas)$$

are thermodynamically possible, the continuous formation of the product is possible only when the phases [i.e. the initial phase (A) and the gaseous phase] are in contact. An increase of the contact surface by dispersing phase A may accelerate the process, reduce its duration, and increase its extent.

2. The blocking of the initial solid phase by the product B (or A in the reverse reaction) leads to the separation in space of the reactants and the occurrence of hindrance to the process, which undergoes a transition from kinetic to diffusion-dependent conditions. Then both the rate of diffusion of elementary species through the crystal lattice of the compact product and the rate of Knudsen molecular flow may prove to be the rate-limiting component of the topochemical reactions considered.

3. When the solid phase is unblocked as a result of the cracking of the layer of product, by the formation in the latter of pores, or by its artificial loosening or even removal (for example by sublimation), the reaction may be significantly facilitated even under diffusion-dependent conditions, and under favourable circumstances (effective unblocking) may result in a return to kinetic conditions. Then, if during some period spontaneous growth of the reaction surface or an accelerating effect of the product is observed, the process may become autocatalytic.

In conclusion it must be emphasised that the above postulates are of the kinetic type and have nothing in common with the thermodynamic principle of the displacement of equilibrium (the Le Châtelier–Braun principle[100]), according to which the removal of the product should favour a higher degree of conversion regardless of the time consumed.

The necessity for a clear formulation of the principle governing the acceleration or retardation of topochemical reactions is dictated by the following considerations. In the first place the kinetic rules and principles available at the present time (the Pilling–Bedworth rule and the Arkharov principle) are restricted to the field of chemical corrosion. However, the experimental data which have accumulated show a considerable influence of the physical state of the product on the kinetics of a wider range of topochemical processes. Secondly the formulation of the principle should indicate the general pathways involved in the acceleration (and, where required, also retardation) of isothermal reactions of the given type. Thirdly one can encounter in the literature directly opposed views: some authors believe that the product inevitably accelerates the process, while others reject this. The above general principle shows that, depending on the process conditions and the physical state of the interacting solid phases, three cases are possible: (1) the product does not influence the rate of the process; (2) the product accelerates the reaction (catalysis); (3) the separation of the reactants by the product inhibits the process (impedance).

7. Astatine in organic compounds 95
8. Biological behaviour of astatine 96

Astatine is the rarest element on our planet. The Earth's crust contains ~70 mg, among the short-lived members of the natural radioactive families[1]. Astatine became available to investigators only after it had been obtained as a result of nuclear synthesis, therefore it is justifiable to classify it among the synthetic elements.

Despite the fact that the chemical properties of astatine began to be studied a quarter of a century ago, much concerning the behaviour of this element is uncertain and at present we know relatively little about it. This is due primarily to the absence of stable and long-lived isotopes of astatine, which makes it inevitable that all investigations be made at the ultramicro-level with all the associated difficulties. Moreover, it must be borne in mind that astatine is capable of forming a large number of valence states, some of which exhibit high reactivity.

By exhibiting non-metallic properties in some instances and metallic in others, astatine is one of the most interesting elements of the Periodic System.

I. HISTORY OF DISCOVERY

Mendeleev first predicted the existence of the 85th element of the Periodic System. At the start of the nineteen-twenties Wagner[2], starting from the physical basis of the Periodic Law, again predicted the existence of a fifth member of the halogen subgroup. At this time intensive searches for it in natural materials began. Reports of the discovery of element 85 appeared one after another[3-7]. Definite chemical properties were ascribed to the newly discovered element and it was given sonorous names: alabamine[6], helvetium[7], anglo-helvetium[8], leptine[9], daccine[10]. A more thorough verification of the separation and methods of identification of element 85, which were used in studies noted earlier, led to the conclusion that its existence was not proved[11-14]. The mass-energy dependence for heavy nuclei[15] shows that in element 85 the proton : neutron ratio is such that considerable stability cannot be expected for the nucleus of the element, and consequently of its isotopes of long half-life also. In natural materials element 85 is encountered solely in trace amounts as a short-lived daughter product in the natural radioactive series. The search for this element in natural materials by use of chemical methods of separation developed for its nearest analogue, iodine, was unsuccessful. Above all this was due to the time consumption of the methods for separation from the natural materials and the absence of sufficiently long-lived isotopes of element 85. Karlik[16] and Hulubie[17] reviewed critically the unsuccessful searches for the missing halogen and the erroneous reports of its discovery.

The first reliable report of the discovery and identification of element 85 appeared in 1940 in a paper by Corson and coworkers[18], who obtained it in the bombardment of a bismuth target by helium ions in the 60-in cyclotron of California University, by the reaction:

$$^{209}\mathrm{Bi}\,(\alpha,\,2n)\,^{211}\mathrm{At}.$$

Subsequently, the discoveries of this element gave it the name astatin[19] from the Greek αστατος (unstable): this name well describes its nature. Until 1960 the name астатин [astatin] was widely used in the Russian chemical literature but the name of this element has now been shortened to астат [astat].

2. ISOTOPES OF ASTATINE

Twenty isotopes of astatine are now known. Their main radioactive characteristics and the nuclear reactions by which they were obtained and identified are shown in Table 1.

It must be noted here that almost all the known isotopes of astatine are also formed by reactions of deep fission of thorium and uranium by high-energy protons[21-23].

Fig. 1 shows a plot of the relation between the α-particle energies and the mass numbers (and number of neutrons) of the isotopes of astatine[24]. As Table 1 and Fig. 1 show, the most long-lived isotopes of astatine have a number of neutrons close to 126, which corresponds to the formation of a completed nuclear shell[25,26]. The form of the curve in Fig. 1 shows that the light isotopes should have very short half-lives and disintegrate with the expulsion of high-energy α-particles. Moreover, in possessing a considerable neutron deficiency they will certainly be unstable to the capture of an orbital electron. On passing to the neutron-surplus region ($A - Z = 126$) the curve has a break, which shows a sharp decrease in the strength of the bonding of the nucleons in the nucleus—all the isotopes of astatine with $A > 211$ have very short half-lives. The heaviest isotopes of astatine ($A \geqslant 219$) show some stability towards α-decay. However, in this range transitions by β-decay are also possible[27,28]. Several authors have suggested that astatine, like elements 43 and 61, cannot have β-stable nuclei at all[29].

Figure 1. Energy of the α-particles of the isotopes of astatine plotted against mass number (and number of neutrons).

Table 1. Isotopes of astatine[20].

Isotope	Half-life	Type of decay	Energy of α-particles, MeV	Method of production
^{200}At	0.8 min	α	6.42 (~60%) 6.47 (~40%)	Au + ^{12}C
^{201}At	1.5 min	α	6.348	Au + ^{12}C, ^{14}N, ^{16}O
^{202}At	3 min	α (12%) e.c. (88%)	6.133 (64%) 6.231 (36%)	Au + ^{12}C, ^{14}N, ^{16}O
^{203}At	7.1–7.4 min	α (14%) e.c. (86%)	6.09	Bi (α, 10n) Pt + ^{14}N Au + ^{12}C, ^{14}N, ^{16}O
^{204}At	9–9.3 min	α (4.5%) e.c. (95.5%)	5.95	Bi(α, 9n) Au + ^{12}C, ^{14}N, ^{16}O
^{205}At	22.7–26.2 min	α (18%) e.c. (82%)	5.90	Bi (α, 8n) Au + ^{12}C, ^{14}N, ^{16}O Pt + ^{14}N
^{206}At	22–29.5 min	α (0.9%) e.c. (>99%)	5.7–5.9	Bi (α, 7n) Au + ^{12}C, ^{14}N, ^{16}O
^{207}At	1.8–2 h	α (~10%) e.c. (~90%)	5.75	Bi (α, 6n) Au + ^{14}N daughter ^{207}Rn
^{208}At	1.7 h	α (0.5%) e.c. (99.5%)	5.65	Bi (α, 5n) daughter ^{212}Fr
^{209}At	5.5 h	α (~5%) e.c. (~95%)	5.642	Bi (α, 4n) daughter ^{209}Rn
^{210}At	8.3 h	α (0.17) e.c. (>99%)	5.519 (32%) 5.437 (31%) 5.355 (37%)	Bi (α, 3n) daughter ^{210}Rn
^{211}At	7.2–7.5 h	α (40.9%) e.c. (59.1%)	5.862	Bi (α, 2n) daughter ^{211}Rn
^{212}At	0.22–0.305 s.	α	7.60 (20%) 7.66 (80%)	Bi (α, n)
^{212m}At	0.120 s.	α	7.82 (80%) 7.88 (20%)	Bi (α, n)
^{213}At	≪1 s.	α	9.2	decay product of ^{225}Pa
^{214}At	2×10^{-6} s.	α	8.78	daughter of ^{218}Fr in ^{226}Pa series
^{215}At	short	α	8.04	natural daughter of AcA
^{215}At	10^{-4} s.	α	8.00	daughter of ^{219}Fr in ^{227}Pa series
^{216}At	3×10^{-4} s.	α	7.79	daughter of ^{220}Fr in ^{228}Pa series
^{217}At	0.018 s.	α	7.05	daughter of ^{221}Fr in ^{233}U series
^{218}At	1.5–2.0 s.	α	6.6976 (94%) 6.653 (6%)	natural daughter of RaA
^{219}At	0.9 min	α (97%) β (3%)	6.27	natural daughter of AcK

In some papers devoted to the study of astatine isotopes it was noted that ^{208}At has an isomer with a half-life of 6.3 h.[30] The isomers ^{204m}At (25 min) and ^{206m}At (2.9 h) have also been observed[30]. A more thorough check of the half-lives of ^{208}At, ^{206}At, and ^{204}At from the periodically separated daughter polonium did not show the presence of the long-lived isomers noted above[31]. Probably the information on the existence of the isomers is due to methodological errors.

The chemical properties of astatine are most conveniently studied on its relatively long-lived isotopes with mass numbers 209, 210, and 211. These isotopes are usually obtained by irradiating bismuth with α-particles.

The excitation function of ^{209}Bi(α, 2n)^{211}At has been studied in sufficient detail[32,33]. Its threshold is 21 MeV, and the yield of ^{211}At reaches a maximum at an α-particle energy of 26 MeV. It is important to note that for the production of pure ^{211}At free from other isotopes as impurities the energy of the helium ions should not exceed 29 MeV—the threshold of the (α, 3n) reaction. These conditions must be observed when the activity of the astatine is measured by recording α-particles, since ^{210}At decays

by 99% into the 138-day ^{210}Po, which also emits α-particles. True, the decay of ^{211}At by 59.1% is effected by capture of an orbital electron with the formation of ^{211}Po but the latter has the half-life of only 0.52 s, and almost any act of decay of ^{211}At leads to the loss of an α-particle. The α-particle spectrum of ^{211}At has a very characteristic appearance: a line at 5.862 MeV for the α-particles of ^{211}At itself and a line at 7.43 MeV for the α-particles of ^{211}Po. A guarantee of the purity of a specimen of ^{211}At is the ratio of the intensities of the 5.862 and 7.430 energies, which should be 40/60.

The isotope ^{210}At was first obtained[32] by the reaction ^{209}Bi(α, $3n$)^{210}At. As already noted above, the threshold of this reaction is 29 MeV and the maximum yield occurs at 40 MeV. The isotope ^{210}At disintegrates by only 0.17% with expulsion of α-particles with energies of 5.519 (32%), 5.437 (33%), and 5.355 (37%) MeV. The decay proceeds mainly through the capture of an orbital electron and the scheme of the conversions is rather complex[34].

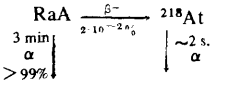
The reaction ^{209}Bi(α, $4n$)^{209}At is most often used for the production of large quantities of the isotope ^{209}At. True, specimens obtained by this method are necessarily contaminated by other isotopes of astatine. A small quantity of completely pure ^{209}At can be isolated as a daughter product from ^{213}Ra, obtained in the irradiation of thorium with protons of energy 350 MeV [21,30].

The isotope ^{209}At decays by capture of an orbital electron and expulsion of α-particles with energy 5.642 ± 0.005 MeV. The α-decay branch totals 5%.[30] Gamma radiation of ^{209}At, which is accompanied by electron capture, consists of four lines.

The principal nuclear properties and the schemes for the γ-transitions for some isotopes of astatine have been reviewed in detail[20].

3. ASTATINE IN NATURE

Starting from the processes of radioactive decay in the uranium series, Hahn[35] predicted the possibility of the formation of isotopes of astatine in the β-decay of polonium[35]. Karlik and Bernert[36], and then Walen[37], observed, in studying the radioactivity of the daughter products of radon, that an insignificant part of RaA (^{218}Po) disintegrates by the scheme:



The presence in a freshly formed specimen of RaA, in addition to α-particles with energy of 5.99 MeV due to the decay of this isotope of polonium, of α-particles with energy 6.63 MeV, served as proof of the formation of ^{218}At in the β-decay of RaA.

The discovery of β-branching in the decay of RaA served as an impetus for studying the polonium fractions of other natural radioactive series with the aim of discovering new natural isotopes of astatine. Karlik and Bernert[38] reported the β-decay of AcA (^{215}Po). They found that AcA undergoes 5×10^{-4}% β-decay, to form ^{215}At, which decays with a period of 10^{-4} s, expelling α-particles with energy 8.4 MeV. Avignon[39] made a more careful investigation and defined the energy of the ^{215}At α-particles (8.00 MeV) and the β^-/α ratio (0.9×10^{-7}) more accurately. This isotope was also observed[40] as the product of the successive α-disintegrations of ^{227}Pa.

On the basis of the regularities in the α- and β-decays in the natural radioactive series it was suggested that as a result of rare instances of α-decay ^{227}Ac forms a little chain parallel to the main series[9]. Hyde and Giorso[41] isolated from the ^{227}Ac source 20 mC francium, in which, ^{219}At was then identified by chemical means. It was shown that ^{219}At has a half-life of 0.9 min, and disintegrates 97% with the expulsion of α-particles with energy 6.27 MeV and 3% undergoes β-decay. This work[41] is the only instance of the chemical identification of an isotope of astatine from a natural source. It has been reliably established that in natural radioactive sources only three short-lived isotopes of astatine, ^{215}At, ^{218}At, and ^{219}At can be detected; these are members of radioactive families. This explains why interest in the search for and investigation of natural astatine has decreased somewhat recently.

4. METHODS OF OBTAINING AND ISOLATING ASTATINE

In the production of astatine in cyclotrons by the (α, xn) reaction a layer of bismuth (50–100 mg cm^{-2}) is applied to an aluminium substrate either as the molten metal or by sputtering. When bismuth oxide is to be irradiated a copper support is employed in the openings of which the Bi_2O_3 is pressed. To avoid loss of astatine at the time of irradiation due to sublimation the back of the support is cooled with water†.

The astatine which is formed as a result of the irradiation of bismuth by α-particles is the main product of the reaction ($\sigma \simeq 10^{-24}$ cm^2) and the contribution of the radioactive isotopes of the other elements is insignificant ($\sigma \simeq 10^{-26}$ cm^2).[42,43] To separate the astatine formed from the main mass of metallic bismuth and from polonium use is frequently made of the high volatility of astatine. The distillation is done in a current of nitrogen (at a few mmHg) or in a vacuum with the target heated to 300–600°C. The astatine vapour is condensed on the surface of a glass trap cooled with liquid air or dry ice. Radiochemically pure astatine is obtained by redistillation[18,44]. The yield of ^{210}At is 5–15%. This is due to the incomplete separation of astatine from bismuth in the gas phase at 600°C. At a higher temperature bismuth starts to distil.

It has been suggested[30] that the retention of astatine in the bismuth target is due to the formation of involatile compounds of it with bismuth inside the target irradiated with α-particles. This is confirmed by the fact that distillation at 700–800°C in air leads to the removal of up to 80% of the astatine from the bismuth target[30]. Evidently on heating in air the compound of bismuth with astatine decomposes with the formation of bismuth oxide and free astatine. From these results Appelman[45] developed the following scheme for the separation of astatine from the bismuth target.

The irradiated bismuth target is put in a stainless steel beaker and heated to 270°C to remove volatile impurities. The subsequent distillation of the astatine is carried out at 800°C. The distillate is collected on a water-cooled platinum plate suspended above the molten target. For the final purification of the astatine the platinum is put in a quartz tube and the impurities are removed at 130°C and a pressure of 10^{-4} mmHg, after which the astatine is redistilled at 500°C. The pure astatine is condensed in a

† When the astatine is produced by deep fission or irradiation of thorium by high-energy protons, such precautions are not needed since usually the intensity of the beam of protons is not so great as to cause strong overheating of the target. [It appears that the terms "deep fission" and "division" used in this review refer to *fission* and *spallation* respectively of Western literature (see especially Ref.50) (Ed. of Translation)].

U-tube cooled with dry ice. The astatine is washed from the walls of the tube with 0.5 ml dilute nitric acid. In this instance the yield reaches 30% and the concentration of astatine in the solution is $\sim 10^{-8}$ M.

The distillation method is also used for the separation of astatine from other targets, for example, gold[46]. Here the irradiated target is dissolved in molten lead or bismuth, after which the astatine is distilled off.

In addition to distillation, astatine is also separated from the target by the so-called "wet method". In this the irradiated bismuth or bismuth oxide can be dissolved in perchloric acid containing a little iodine as a carrier for the astatine, and the bulk of the target is thrown out of solution by precipitating bismuth phosphate. The astatine passes into the filtrate at AtI[47]. However, the preparation contains some polonium.

Neuman[48] made use of its extractibility by isopropyl ether for the separation of astatine from bismuth. The bismuth target is dissolved in nitric acid, the solution evaporated, but not to dryness, since a little nitric acid does not interfere with subsequent operations, and concentrated hydrochloric acid is added to bring the solution of 8 M in HCl. Then the solution is cooled and the astatine extracted with isopropyl ether, saturated with 8 M HCl. The organic phase is washed with 8 M HCl and then the astatine is back-extracted by NaOH solution containing a little iron(III). Iron hydroxide retains the remaining impurities completely and the loss of astatine here does not exceed 5%. The yield is $\sim$ 90%.

An interesting method of extraction separation of astatine from polonium and bismuth has been described[30]. The extractant used to separate astatine from concentrated hydrochloric acid solutions is di-isopropyl ether containing a little of a 20% solution of tributyl phosphate in isobutyl ether, and the extraction was effected in the presence of iron(II) as a reductant. Traces of polonium, bismuth, and lead are washed out of the organic phase by a mixture of 2 M nitric and 4 M hydrochloric acid. The back-extraction is carried out with alkali.

In the production of astatine by the deep fission of thorium the formation cross-section of the isotopes of astatine is two or three orders of magnitude less than the total formation cross section of the products of division and deep fission[49,50]. In the present instance to obtain radiochemically pure astatine effective purification from most of the elements of the Periodic System is necessary.

A method for separating astatine from lead, bismuth, and thorium irradiated with high-energy protons has been described[23]. According to this method, 1 g metallic thorium irradiated with protons of 660 MeV energy, is dissolved in 5 ml concentrated nitric acid by heating in a flask with a reflux condenser. 40 ml 8 M hydrochloric acid saturated with chlorine are added to the nitric acid solution. The extraction is performed with 60 ml di-isopropyl ether in an extractor with a mechanical stirrer. The organic layer is washed twice with 15 ml 8 M hydrochloric acid. The astatine is back-extracted from the ether with 40 ml 0.1 M solution of sodium stannite in 2 M NaOH. 10–15 mg sodium tellurite, 4–5 mg lanthanum chloride, and 1–2 mg sodium chloroaurate were added to the alkaline solution. The solution is separated from the residue by filtration through a glass filter. The precipitation of tellurium with sodium stannite is repeated twice. In this way polonium, gold, mercury, and several other metals which are co-precipitated with metallic tellurium from the alkaline solution in the presence of a reductant or of difficultly soluble hydroxides which are formed are separated from the solution. The alkaline filtrate is acidified with 20 ml concentrated hydrochloric acid containing $\sim$ 4 mg tellurium. The precipitation of tellurium, and astatine with it, from acid solution is carried out with vigorous mixing. After coagulation of the precipitate 5 mg tellurium are twice added to complete the precipitation of the astatine. The precipitate of tellurium containing the astatine is separated from the solution by centrifuging, washed with 6 M hydrochloric acid, and dissolved in a few drops of concentrated nitric acid. 20 ml 6 M hydrochloric acid is added to the solution obtained and the tellurium precipitated with tin(II) chloride. After coagulation of the precipitate the precipitation of tellurium (5 mg) is repeated once more. The precipitate is centrifuged off, washed with concentrated acid and dissolved in 5 ml 8 M HCl whilst passing gaseous chlorine. The astatine is separated from the tellurium by extraction into di-isopropyl ether. The ethereal layer (6 ml) is washed twice with 1.5–2 ml 8 M hydrochloric acid and the astatine is re-extracted with water (twice with 5 ml). After extraction a solution of radiochemically pure astatine is obtained $\sim$ 0.01 M in HCl and containing traces of solvent is obtained.

To separate astatine from tellurium and to obtain a concentrated preparation the chromatographic method can be used[51]. A solution of 8 M HCl saturated with chlorine which contains tellurium and astatine is passed through a layer of Dowex 50 × 8 cation-exchange resin. The tellurium is not retained on the resin; the astatine is adsorbed and is subsequently eluted with chlorine water. The yield of astatine in this method is 60 ± 10%, the degree of purity $\sim 10^{7}$.

Lefort and coworkers[22,52] give the following scheme for the separation of astatine which is formed as a result of the fission of ^{232}Th under the action of protons with energy 160 MeV. The thorium target is dissolved in concentrated hydrochloric acid with the addition of small amounts of hydrofluoric acid. The solution is diluted to 3 M HCl and the astatine coprecipitated by tin(II) chloride with elemental tellurium. To remove the polonium coprecipitated during this the tellurium is dissolved by heating in the minimal quantity of concentrated nitric acid and again precipitated with a milder reductant—sulphur dioxide from dilute hydrochloric acid solution. The precipitate, which contains the astatine, is dissolved in a little concentrated nitric acid, made alkaline until 2 M in NaOH; the astatine is separated from the tellurium and traces of polonium and other radioactive contaminants during their coprecipitation with elemental tellurium after addition of sodium stannite. The filtrate is acidified with nitric acid to 0.3–0.5 M. To prevent the capture of astatine by colloidal tin at the moment of change of the acidity of the medium, small portions of hydrofluoric acid are added. Astatine is isolated from the acid solution by spontaneous deposition on silver foil. This gives an α-radioactively pure preparation of astatine. To bring the astatine into solution, the silver foil is dissolved in concentrated nitric acid and the silver precipitated as chloride. To avoid retention of astatine by the silver chloride precipitate, the latter operation is done in a darkened place.

5. PHYSICAL PROPERTIES OF ASTATINE

Owing to its short half-life, astatine cannot be obtained in ponderable amounts; because of this the physical properties of this element and of its compounds have been incompletely studied. The information was mainly obtained by interpolation and extrapolation of data for its nearest analogues or on the basis of theoretical calculations.

The predicted melting and boiling points are 411° and 299°C respectively [53] [sic (Ed. of Translation)]. The radius of the At^{7+} ion calculated on the basis of theoretical data is 0.62 Å. [54] The crystalline ionic radius of At^- evaluated by several investigators [55-57], is close to 2.3 Å. The radius of At^- in gaseous molecules is calculated to be [57] 1.97 Å. Calculations of the ionisation potentials give the following values: first 9.6, [58-60], second 18.2, [58-59], third 30, fourth 41, fifth 51, sixth 78, and seventh 91 eV. [59]

The relative electronegativity of the astatine atom is estimated [61] to be 2,2 and the atomic refraction, calculated on the basis of this quantity, is 19.3 cm^3. [62]

Starting from the well-known data on the vibration frequencies of the diatomic molecules F_2, Cl_2, Br_2, and I_2, this quantity was also found by extrapolation for At_2 ($\omega_e \simeq 160\ cm^{-1}$). [60] The graphical dependence of ω_e plotted on the coordinates $\lg \omega_e$ against $\lg n^2 I$ (where n is the principal quantum number, and I the ionisation potential of a molecule of type XX) gives for At_2 a value $I(At_2) = 8.3$ eV. The dissociation energy of an astatine molecule $D(At_2)$, found by a similar method, is 1.2 eV. In the same study [60] the dissociation energy of an ionised astatine molecule $D(At_2^+)$ was found to be 2.4 eV by use of a thermodynamic cycle. By calculations, some thermodynamic characteristics were obtained for atomic astatine [57,63], for At_2 molecules [64], and for several compounds of astatine with alkali and alkaline earth elements [57-63].

It should be noted that although many chemical and thermodynamic parameters have been calculated for a diatomic astatine molecule, the At_2 molecule was not detected in extremely thorough experiments made by a mass spectrometric method [65].

The most modern equipment now allows several physical constants of astatine to be determined experimentally using indicator amounts of the element. For example, the absorption spectrum of astatine was investigated with the aid of a highly sensitive spectrograph with a capillary absorption cell and use of gaseous specimens of astatine weighing 0.2 mg. [66]

Two lines were observed with wavelengths 2244.01 and 2162.25 Å, and were assigned respectively to the transitions

$$6p^5\ ^2P^0_{3/2} - 6p^4\ 7s^4\ P_{5/2} \text{ and } 6p^5\ ^2P^0_{3/2} - 6p^4\ 7s^4 P_{3/2}. \qquad (E)$$

6. CHEMICAL PROPERTIES OF ASTATINE

As noted above, astatine does not have long-lived isotopes, in consequence of which only ultra-small amounts of the element are available for studying its properties. The investigation was mainly carried out with concentrations of 10^{-11}–10^{-15} M. The most concentrated solution of astatine (10^{-8} M) was obtained by Appelman [45]. It is known that 650 atoms of astatine lead to one α-decay per minute. For this reason a 1 M solution would exhibit an activity of 1.54×10^{16} α-particles min^{-1} cm^{-3}. At such a high specific activity an effervescence of the solutions being tested would be unavoidable and there would be intensive radiolysis of the water with the formation of considerable quantities of hydrogen peroxide. Under these conditions it would be impossible to stabilise the astatine in a desired oxidation state. Astatine, like any other element, present in ultra-small concentrations, must react with traces of impurities in the solutions, be sorbed on dust particles to form radio-colloids, etc.

Usually in studying the behaviour of an element present in indicator amounts the carrier method is used. But astatine does not have either stable isotopic carriers or a sufficiently satisfactory non-isotopic carrier. Being the heaviest element of the halogen subgroup it should exhibit the properties of the latter. However, astatine shows electronegative properties more rarely than iodine, and in some instances it is reminiscent of a metal. The position is greatly complicated by the fact that the chemistry of trace amounts of iodine differs greatly from the chemistry of its macro-quantities [67-69]. At low concentrations iodine not only forms new species (for example, in the oxidation of iodide by Cr^{VI} or Ce^{IV} at iodide concentrations of $\sim 10^{-7}$ M in 1 M sulphuric acid three unidentified iodine species unknown in the macrochemistry of iodine were found), but its interaction with traces of dust and micro-impurities was noted [70].

Four states of oxidation of astatine are now known: At^- the astatide ion, At^0 the zero state, At^X some unidentified valence state, and At^{5+} in the form AtO_3^-. Appelman [71] gives the following scheme for the redox potentials of astatine at pH = 1:

$$At^- \xrightarrow{-0.3\,V} At^0 \xrightarrow{-1.0\,V} At^X \xrightarrow{-1.5\,V} AtO_3^- \xrightarrow{-1.6\,V} H_5AtO_6\ (?)$$

1. Astatine in the Zerovalent State, At^0

Like elemental iodine, astatine in the zerovalent state of oxidation exhibits very high volatility. On this property, in particular, is based the method of isolating astatine from a fused bismuth target.

In the gaseous state astatine is readily sorbed by surfaces of various materials. Table 2 shows data on the simultaneous adsorption of astatine on the surfaces of various metals in a high vacuum [44]. In each instance the surface of the metals was previously purified by heating at ~ 400°C in an atmosphere of hydrogen.

Table 2.

Metal	Quantity of adsorbed astatine, relative %		
	20°	325°	
		expt. 1	expt. 2
Aluminium	0.3	0.2	0.3
Nickel	0.2	0.6	0.7
Copper	0.5	0.6	4.3
Platinum	36.3	33.5	6.5
Gold	38.4	0.1	0.7
Silver	24.3	65.0	87.5
	100.0%	100.0%	100.0%

The vaporisation and adsorption of astatine depends on the nature of the substrate. The low volatility from the surface of gold and platinum is evidently explained by the formation of a new valence form of astatine or its reaction with the material of the substrate [44].

Astatine in the zerovalent state in solutions cannot be identified with any definite chemical species. This can be the products of the reaction of astatine with traces of organic impurities, interhalogen compounds of astatine, and elemental astatine [45]. The latter is undoubtedly present in dilute nitric acid solutions. This happens although

a considerable amount of astatine is lost during the evaporation of the solution. In the drying of a nitric acid solution on platinum substrates ~26% of the astatine volatilises[44]. However, the loss of astatine due to its volatility is not so great as the loss of iodine during the evaporation of the solutions which contain micro-amounts of elemental iodine. The retention of astatine on various surfaces during the evaporation of aqueous solutions varies with the nature of the surface, the composition of the solution, and the conditions of evaporation[15].

Sorption on glass from dilute nitric acid solutions is inherent to astatine in the zerovalent state[45]. An increase in the nitric acid concentration leads to a decrease in sorption, probably as a result of a change in the valence state of the astatine[45].

At^0, like elemental iodine, is extracted very well from nitric acid solutions by almost all organic solvents. This property of astatine is widely used in studying its chemistry. Observation of the change in extraction coefficients of astatine from HNO_3 solutions with change in the concentration of the latter on adding other acids, complex-formers, or various oxidants and reductants makes it possible to find the form of the compound extracted, the degree of complex formation, and the oxidation potential.

At^0 is completely extracted from the organic phase on shaking with 0.1 M NaOH. Probably in this instance the At^0 disproportionates to astatide and a higher oxidation state[44]. Acidification of the solution converts astatine into its initial state and it is again extracted by organic solvents with the initial partition coefficient.

At^0 is partly coprecipitated from aqueous solutions with some hydroxides and also with AgI and TlI, probably as a result of its sorption by the developed surface of these precipitates. Increasing the acidity of the solution completely suppresses the adsorption. Washing the AgI and TlI precipitates with acetone completely removes the astatine from their surface.

Astatine(0) can be isolated from solution by precipitation with elemental tellurium, metallic silver, and on various heavy metal sulphides[18,72]. It is also coprecipitated with PdI_2.[47]

Study of the electrochemical behaviour of astatine showed that the critical potential for the deposition of At^0 from nitric acid solutions on a cathode is −1.22 V and at the anode −1.45 V[44] [Both potentials referred to a normal hydrogen electrode (Ed. of Translation)]. Thin gold foils were used as electrodes in these experiments.

The nature of the astatine compounds liberated in electrolysis is unknown.

The extraction of astatine by polar solvents from solutions of mineral acids in the presence of oxidants or reductants is widely employed in studying the chemistry of astatine[44,45,48,73] but the distribution coefficients for At^0 between aqueous and organic phases depend quite strongly on the purity of the reagents used. Impurities, even those found in micro-concentrations, can bring a considerable part of the astatine into a form with another distribution coefficient. Thus, the repeated extraction of astatine from the same solution with an organic solvent leads to a fall in the partition coefficient with each extraction and finally the astatine stops being extracted. Similarly for repeated re-extraction from an organic phase by an aqueous solution the amount of astatine re-extracted falls[44,45]. Consequently in using extraction as a method of studying the chemistry of astatine, conclusions can be drawn about the change in the state of the latter only when there are very large differences in the partition coefficients of the astatine forms being studied[15].

An important contribution to the study of the chemistry of astatine by the extraction method was made by Johnson and coworkers[44], Neumann[48], and Appelman[45,73]. During the action of reductants of the type of SO_2, H_3AsO_3, or metallic zinc on acid solutions which contain At^0 a sharp decrease in the partition coefficients was observed, evidently the astatine(0) is reduced to At^-, which is confirmed by its coprecipitation with silver or thallium iodides. With Br_2 astatine is oxidised to an unidentified valence state[45].

The addition of strong oxidants of the $S_2O_8^{2-}$ type converts astatine into AtO_3^-, which is coprecipitated with $AgIO_3$.[44]

2. Astatide Ion

The astatide ion is the most studied state of astatine because this form is the most similar in properties to the iodide ion. At^- is formed in solutions which contain astatine(0) in the presence of strong reductants such as SO_2, H_3AsO_3, hydrogen at the moment of liberation in acid solution, or Na_2SO_3 in alkali. This is shown by the results of experiments on electromigration and on coprecipitation with iodides at any acidities and in the presence of various anions[18,44]. At^- is not removed from precipitates of insoluble iodides on washing them with acetone (as happened in the coprecipitation of At^0). These results show that At^- is isomorphously coprecipitated with iodides.

The ratio of the diffusion coefficients of I^- and At^- in 1% NaCl solution which contains 1.2×10^{-3} M KI and 4×10^{-3} M Na_2SO_3 is $D_{I^-}/D_{At^-} = 1.41 \pm 0.02$.[74]

It is thought that the astatide ion absorbs ultraviolet radiation of wavelength ~3000 Å.[75]

The work with At^- in acid solution must be carried out with great precaution since there are indications of the formation of volatile astatides[18,44].

3. The Unidentified Valence State At^X

Oxidants such as the vanadate ion, bromine, chlorine, dichromate, concentrated nitric acid, and Fe^{3+} ions oxidise At^0 to some valence form the state of oxidation of which lies between At^0 and AtO_3^-.[15,44,45] This form is not extracted by carbon tetrachloride and is not coprecipitated with iodides.

Some investigators ascribe to this state of astatine the charge 3+,[76] others the form AtO^- [77,78] (by analogy with iodine) or AtO_2^-.[78] Although the existence of the latter for iodine is also not established, this form could be more stable for astatine[76].

The main regularities in the change in the properties of the elements in the Periodic System show that astatine ought to be more "metallic" than the other halogens. This signifies, in particular that astatine should acquire a positive charge more readily than iodine. In several studies it was found that in its properties astatine shows more resemblances to polonium and bismuth—its nearest neighbours in the Table—than to iodine[18,79].

Experimental results have been obtained[44] which show the reversibility of the electrochemical deposition of astatine on a gold cathode from sulphate solutions oxidised with dichromate, which can be held as proof of the existence of astatine in the form of a cation.

The investigation of the behaviour of astatine oxidised by dichromate in solutions of nitric acid showed that it is present as a singly-charged cation[80]. This was shown by experiments on migration, from the results of which it is clear that the astatine ion in this medium moves predominantly towards the cathode[80]. It appeared that astatine in

this form is sorbed on monofunctional sulphonic-cation-exchange resins. This allowed the charge on the ion of astatine oxidised by dichromate in nitric acid solutions to be determined, and it was found to be unity[80].

In a series of chemical properties the astatine cation is similar to the heavy singly-charged cations, for example, thallium and caesium, and is absorbed well by precipitates of caesium tungstophosphate, thallium dichromate, and silver iodate (Table 3)[81,82].

The astatine cation is spontaneously deposited on metallic platinum coated with an oxide film (Fig. 2).[83] The rate of deposition (at a time of deposition $\tau \leqslant 40$ min) is satisfactorily described by the equation for a first-order reaction:

$$\frac{dx}{d\tau} = K(a - x)\frac{S}{V}$$

where a is the initial amount of the element in the solution, S the surface of the platinum, V the volume of solution, and K a constant.

Table 3. Retention of the singly charged astatine cation by various precipitates from nitric acid solutions containing the dichromate ion. (0.005 M $H_2Cr_2O_7$) (solution volume 5 ml).

* $(PW)^{3-} = [P(W_{12}O_{40})]^{3-}$.

The adsorption is affected positively by raising the temperature and negatively by increasing the acidity. The astatine deposited on the platinum is held strongly on the metal surface. However, it can be easily desorbed by anodic polarisation of the platinum.

The spontaneous liberation of astatine at platinum covered with an oxide film with subsequent anodic dissolution allows solutions of astatine to be obtained in almost all strong acids, and, moreover, opens the possibility of using this phenomenon in the production of radiochemically pure astatine[83].

4. States 5+ and 7+

The existence of an astatate ion (AtO_3^-) was inferred on the basis of the results of experiments on the coprecipitation of astatine with silver, lead, and barium iodates from nitric and hydrochloric acid solutions containing strong oxidants: $S_2O_8^{2-}$, Ce^{IV}, IO_4^-, $NaBiO_3$.[44,73] The astatate ion is not extracted by carbon tetrachloride or benzene. The negative charge of this form of astatine produced in oxidation by $Na_2S_2O_8$ in nitric acid was shown by electromigration experiments[44]. It was found[44] that astatine oxidised by a hot $Na_2S_2O_8$ solution is coprecipitated very well with

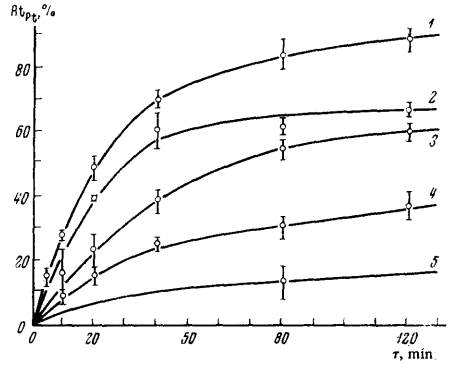

Figure 2. Liberation of astatine at platinum from nitric acid solutions as a function of time. Temperature 23°C; $[H_2Cr_2O_7] = 5 \times 10^{-3}$ M; $S_{Pt} = 4$ cm^2; $V_{soln} = 10$ ml; HNO_3 concentration, M: *1*) 1; *2*) 3; *3*) 5; *4*) 7; *5*) 10.

lanthanum hydroxide. It is assumed that in this instance a compound of the type $La(AtO_3)_3$ insoluble in alkaline medium, is formed.

However, Appelman[72] did not observe the coprecipitation of astatine oxidised by Ce^{IV} in 6 M $HClO_4$ with cerium(IV) hydroxide. It is reported[84] that astatine oxidised by Ce^{IV} is readily extracted by di-isopropyl ether from 4–5 M solutions of nitric, sulphuric, and perchloric acids. Under these conditions micro-amounts of iodine are not extracted. It is known that Ce^{IV} in solutions of strong mineral acids oxidises iodine in indicator amounts to IO_3^-.[67]

Experimental results proving the existence of At^{7+} as perastatate do not exist at present.

Thus Appelman[71], using vigorous oxidants such as H_5IO_6 or Ce^{IV} in 6 M $HClO_4$ did not obtain astatine in a form coprecipitable with potassium periodate. And under these conditions astatine is retained solely by iodates. However, bearing in mind the various forms of periodates[85], a definite conclusion about the absence of a 7+ state cannot be drawn without further studies.

All the above valence states of astatine are formed, as already noted above, at such low concentrations that to stabilise these forms it is necessary to hold the oxidation potential of the solution within strictly defined limits. Therefore to study the chemical properties of any state of astatine the solution must contain an oxidant (a reductant, for the astatide ion), not only for converting the astatine into the required form but also for protecting this form at the time of the experiment from micro-impurities which are unavoidably present in the reagents used.

5. Interhalogen Compounds of Astatine

In studying the chemistry of astatine in solutions which do not contain stabilising agents irreproducible results are

usually obtained. When the stabilising buffer is the halogen pair I^-/I_2, the predominant state will be interhalogen compounds of the types AtI and AtI_2^-. In the presence of elemental iodine the zero valency of the element is represented exclusively by AtI molecules. For the last instance Appelman[73] determined with great accuracy the value of the partition coefficient between carbon tetrachloride and water, 5.5 (Table 5).

Detailed studies have been made[23,48] of the extraction of astatine by di-isopropyl ether from chlorine-treated hydrochloric acid solutions of various concentrations (Fig. 3). On the basis of the results of extraction experiments Neumann[48] drew conclusions about the existence of chloroastatates of composition $AtCl_2^-$ or $AtCl_4^-$. In his review[77], Bagnall states that the composition of the complex probably corresponds to the formula $AtCl_2^-$, that is, the astatine is in oxidation state +1.

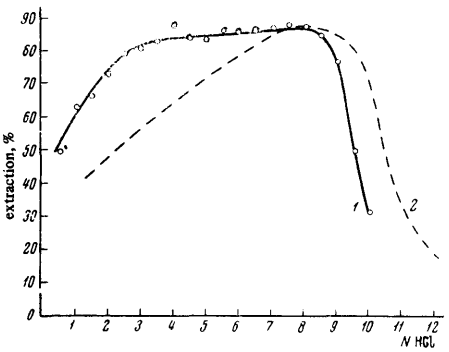

Figure 3. Extraction of astatine from hydrochloric acid solutions by di-isopropyl ether:
1) after the results of Belyaev and coworkers[23]; *2*) after the results of Vinogradov and coworkers[48].

This assumption found confirmation in a study of the adsorption of the astatine cation on platinum covered with an oxide film[83] from nitric acid solutions as a function of the chloride ion concentration. It was found that chloride ion has a negative effect on the adsorption of astatine on platinum (Table 4).

The distribution of astatine between the solution and the platinum depends on the chloride ion concentration:

$$(K_d D - 1) = \frac{1}{K_n}[Cl^-]^n$$

where $K_d = At_{Pt}/At_{soln}$ is the ratio of the amount of astatine on platinum (At_{Pt}) to the amount of (At_{soln}) in solutions which do not contain chloride ion, $D = At_{soln}/At_{Pt}$ the ratio of the amount of astatine in the solution to the amount of it on the platinum in the presence of chloride ion, and K_n the instability constant of the most stable chloro-complex of astatine with n ligands.

In the graph of $\lg(K_d D - 1)$ against $\lg[Cl^-]$ the points calculated from the results in Table 4 lie along a straight line with a slope of 2. Paper electromigration shows that under these conditions astatine is present in an anionic form[81,83]. These results suggest the singly-charged astatine cation adds two Cl^- ions to form an anionic complex of type $[(AtX)Cl_2]^-$. The stability constant of this complex is $(7.4 \pm 0.8) \times 10^5$ M^{-2}‡.

The anionic chloro-complex exhibits one property which is very interesting from the preparative point of view: it is adsorbed on sulphonic cation-exchange resins of the type of KU-2§ and Dowex 50 from solutions of hydrochloric acid and alkali metal chlorides first saturated with chlorine (Fig. 4).[51]

The interhalogen compounds of astatine in various systems in the presence of iodine with the use of liquid extraction by carbon tetrachloride was studied in detail by Appelman[45,73]. Table 5 gives the partition coefficients of the halogens and interhalogen compounds between carbon tetrachloride and the aqueous phase.

On the basis of the distribution results Appelman[45] calculated the formation constants of various astatine complexes (Table 6).

Table 4. Deposition of astatine on platinum in the presence of hydrochloric acid from 1 M HNO_3–5 x 10^{-3} M H_2CrO_4. $S_{Pt} = 4$ cm^2; $V = 10$ ml; $\tau = 40$ min.

[HCl], M	%At on Pt	[HCl], M	%At on Pt
0	53.7±31	$8 \cdot 10^{-3}$	2.1±0.12
$2 \cdot 10^{-3}$	23.5±2.8	$1.3 \cdot 10^{-2}$	0.91±0.13
$3 \cdot 10^{-3}$	12.5±2	$2 \cdot 10^{-2}$	0.52±0.2
$5 \cdot 10^{-3}$	4.9±0.3		

It is interesting to note that astatine always forms a more stable complex than iodine under analogous conditions. The formation constants of identical interhalogen complexes of astatine and iodine differ by a factor of 5–8.[45]

It is well known that molecules which consist of two identical halogen atoms are extracted by carbon tetrachloride considerably better ($D_{I_2} = 86$) than molecules which contain two different atoms ($D_{AtI} = 5.5$, $D_{IBr} = 4.3$, $D_{ICl} = 0.34$). This is because the molecules of the first type are completely non-polar, whereas the interhalogen compounds are dipoles.

The coprecipitation of AtI with elemental iodine in chloroform solutions has been studied[86]. It was shown that the introduction of AtI into iodine crystals obeys Dorner and Hoskins' logarithmic law of distribution. The partition coefficient is

$$\lambda = \frac{\lg(AtI_{soln})/(AtI_{soln} + AtI_{solid})}{\lg(I_{2soln})/(I_{2soln} + I_{2solid})} = 4.$$

Interhalogen compounds are formed in the solid state[87]. Thus CsI_3 which contains $CsAtI_2$ is easily obtained on adding an excess of solid iodine to an aqueous solution of CsI(At). When the system is heated and then cooled, CsI_3 containing astatine is obtained.

‡ When this article was being prepared for press the stability constants of this complex were checked and defined more accurately by the cation-exchange method and β_2 was found to be 2.5×10^5 M^{-2}; moreover, the same method was used to determine the stability constant of a chloro-complex with one ligand, $\beta_1 = 7 \times 10^2$ M^{-1}.[33a]

§ KU-2 is a monofunctional, strongly acid cation-exchange resin with $-SO_3H$ active groups, prepared by treating a swollen styrene–divinylbenzene copolymer with chlorosulphonic acid, then saponifying the sulphonyl chloride (Ed. of Translation).

The thermal decomposition of $CsAtI_2$ obeys the general rule for the decomposition of polyhalogen compounds (in such instances an involatile monohalide is formed—the lighter halogen with the metal), that is, involatile CsI is formed and the astatine is volatilised in the form AtI.[88]

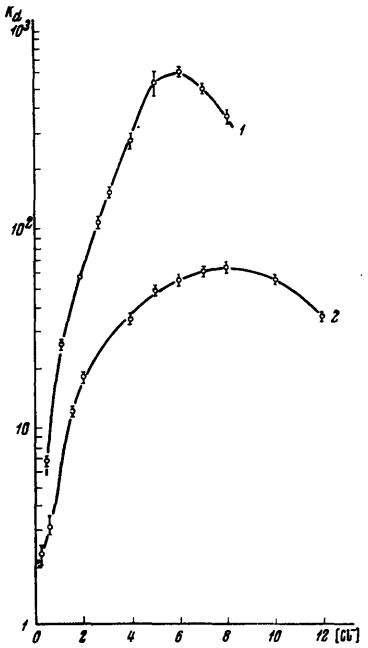

Figure 4. Distribution of astatine, oxidised by chlorine, between the sulphonic cation-exchange resin Dowex 50 x 8 and a solution, as a function of the concentration: *1*) LiCl; *2*) HCl.

Table 5.[73] Partition coefficients of the halogens and interhalogen compounds (21°C), $D = (XY)_{CCl_4}/(XY)_{aq}$.

XY	D	XY	D
AtBr	0.040	AtI	5.5
ICl	0.34 (25°)	Br_2	27
IBr	4.3	I_2	86

Table 6.[45] Formation constants of the various interhalogen complexes of astatine.

Reaction	K_{form} ± 10% (21°)
$At I_{aq} + I^- = AtI_2^-$	2000
$At I_{aq} + Br^- = AtIBr^-$	120
$At I_{aq} + Cl^- = AtICl^-$	9
$AtBr_{aq} + Br^- = AtBr_2^-$	320
$At I_{aq} + IBr_{CCl_4} = AtBr_{aq} + I_{2CCl_4}$	3800
$At I_{aq} + \frac{1}{2}Br_{aq} = AtBr_{aq} + \frac{1}{2}I_{2aq}$	4.2×10^4
$AtICl^- + Cl^- = AtCl_2^- + I^-$	2×10^{-4}

7. ASTATINE IN ORGANIC COMPOUNDS

A rather large number of organoelemental compounds of iodine have now been obtained and their properties studied in more or less detail. This cannot be said about astatine although the existence of stable alkyl and aryl derivatives of this element follows from its position in the Periodic System (the stability of organic derivatives in Periodic Group VII corresponding to valencies of +3 and over increases from chlorine to iodine).

The difficulty encountered in working with the inorganic forms of astatine is greatly increased in studying the organic derivatives of this element.

One of the features of the preparation of organoelemental compounds of radioactive elements is that they can be produced only with vanishingly small amounts of materials. This is due on the one hand to the impossibility of obtaining ponderable amounts of individual radioactive elements (francium, astatine, radon) even with the aid of modern equipment, and of the necessity of using special, quite complicated techniques of investigation. On the other hand, and this is most important, the undertaking of investigations with considerable amounts of certain radioactive substances is accompanied by such radio-chemical changes (both in the substances studied and in the surrounding medium), which rules out the possibility of obtaining correct information about the properties and state of the substances being studied.

One of the important consequences of the fact that in the preparation of organoelemental compounds of the radioactive elements one is dealing with submicro-amounts of substance is the impossibility of finding the qualitative and quantitative composition of the compounds being studied by direct methods of analysis. For this reason indirect methods based on a comparison of the behaviour of the substance being studied with that of known compounds of analogous elements play the determining role in such investigations. Here the most convenient method is observation of the chromatographic behaviour of the elements and their compounds.

Since astatine does not have long-lived isotopes, almost the only method of making its organic derivatives is preparation with a non-isotopic carrier—iodine.

Until recently only a few papers[48,78,89-91] had been published on the preparation of organoastatine compounds.

From data on the extraction of astatine in an intermediate state of oxidation from 0.5 M sulphuric acid with benzene and a 10^{-3} M solution of phenol in carbon tetrachloride and the back-extraction of astatine from these solvents with 0.5 M NaOH, Neumann draws conclusions about the existence of astatobenzene and astatophenol[48]. However, these compounds were not isolated and identified.

Contradictory results were obtained in an attempt to make iodo(astato)form and *p*-iodo(astato)aniline[78].

Aten's statement (based on the known chemical properties of astatine) that astatine is probably most readily introduced into an organic molecule when it is found in a positively charged state in some intermediate product obtained at the time of reaction merits attention[78].

A large number of organic compounds of astatine also of interest for biological investigations has been obtained[89-91]. Astatobenzene, astatinated serin albumen, and *p*-astatobenzoic acid were obtained through diazo-compounds. *p*-Astatobenzoic acid offers the possibility of introducing astatine into various proteins. Direct astatination in the presence of KI_3 gave astatinated egg albumin and γ-globulin and the reaction of astatine with *N*-iodosuccinimide gave astatinated tyrosine.

Methods of making astatinated compounds of the types RAt, $RAtCl_2$, R_2AtCl, and $RAtO_2$ (where R is phenyl or *p*-tolyl radical) have been described[92,93].

Both phenyl and *p*-tolyl derivatives of astatine were obtained by the same scheme:

$$R_2ICl + KI(At) \rightarrow R_2I \cdot I(At) \xrightarrow{170-180^\circ} RI(At) \xrightarrow{Cl_2} RI(At)Cl_2 \begin{cases} \xrightarrow{R_2Hg} R_2I(At)Cl \\ \xrightarrow[NaOCl]{} RI(At)O_2 \end{cases}$$

To prepare $RAtCl_2$, KI(At) solution was added to aqueous R_2ICl solution, to give a crystalline precipitate which was subjected to thermal decomposition at 170–190°C:

$$R_2I.I(At) \rightarrow 2RI(At).$$

A little chloroform was added to the reaction product and after cooling to 0°C the RI(At) was chlorinated until a yellow crystalline precipitate of $RI(At)Cl_2$ no longer separated.

$RI(At)Cl_2$ was used to make R_2AtCl. The crystals were dissolved in chloroform, the solution was heated to boiling and a hot chloroform solution of R_2Hg was slowly added to it. The mixture was heated for several minutes on the water-bath and then cooled. The precipitate was centrifuged off and R_2AtCl was extracted with water from the mixture of products remaining in the solution.

Table 7. Value of R_f for the tolyl derivatives of astatine and iodine in the chromatographic of various solvents on mixtures of silica gel KSM No.5 and gypsum. Fixed layer.

Substance	R_f				
	methanol	water-25% methanol	water-25% ethanol	butanol	acetone
p-$CH_3C_6H_4ICl_2$	0.33±0.02	0.1±0.01	0.68±0.02	0.6±0.02	0
p-$CH_3C_6H_4AtCl_2$	0.32±0.03	0.11±0.02	0.68±0.04	0.61±0.03	0
$(p$-$CH_3C_6H_4)_2ICl$	0.1±0.02	0.23±0.02	0.1±0.03	0.67±0.02	0.55±0.02
$(p$-$CH_3C_6H_4)_2AtCl$	0.1±0.05	0.25±0.03	0.1±0.04	0.68±0.03	0.54±0.03
p-$CH_3C_6H_4IO_2$	0.65±0.05	0	0.75±0.04	0	0
p-$CH_3C_6H_4AtO_2$	0.65±0.05	0	0.72±0.05	0	0

To prepare $RAtO_2$, crystals of $RI(At)Cl_2$ were put in a centrifuge tube, to which were added 2 ml 50% NaOH solution and 0.5 ml acetic acid. The mixture was heated to 70°C and chlorinated to complete conversion of the yellow crystalline precipitate of $RI(At)Cl_2$ into a white amorphous precipitate of $RI(At)O_2$. Then the temperature was raised to 100°C, the precipitate rapidly centrifuged off, and on cooling the solution to 0°C $RI(At)O_2$ crystallised out.

The compounds obtained were identified by thin layer and paper chromatography.

The results of the analysis of the organoastatine compounds agree well, within the limits of error of the experiment, with the results obtained in the analysis of analogous iodine compounds (Table 7).

In a study of the properties of astatinated derivatives a large part has undoubtedly been played by their preparation using a method based on the change of chemical state of the atoms during nuclear transformations. In this instance it is possible to obtain organic compounds of astatine without a carrier. This method, which has played a large part in studying the chemistry of organopolonium compounds[94,95], has not yet been extensively employed for astatine. Apparently this is connected with the difficulty of obtaining a corresponding organic medium containing radon—the initial substance from which "hot" atoms of astatine are formed as the result of *K*-electron capture.

8. BIOLOGICAL BEHAVIOUR OF ASTATINE

It has been found that astatine, like iodine, is selectively concentrated in the thyroid gland[96]. In this connection the study of the biological properties of astatine started immediately after its discovery[96]. For this purpose At^{211} is usually employed, for which, as noted above, any act of disintegration leads to the expulsion of an α-particle, and the daughter ^{207}Bi exhibits so great a half-life that it does not affect the results of the investigation. Preparations of astatine for biological purposes are obtained by a standard method: distillation in a vacuum from a bismuth target and condensation in a trap on a thin ice surface. After melting the ice, an aqueous solution of astatine in minimal volume is obtained. The physiological solution used in injections is prepared by the addition of the appropriate amount of sodium chloride to the aqueous solution of astatine.

In studying the biological properties of astatine very small quantities of it are usually employed ($< 10\ \mu C$). To obtain sufficiently precise information about the distribution of astatine in organisms a very precise analytical method of separating it from biological specimens is needed. This requirement is satisfied by the method of radiochemical determination in biological materials developed by Hamilton and coworkers[72]: the organic substance is destroyed by wet combustion with a mixture of perchloric and nitric acids (9 M $HClO_4$ containing 30 vol.% 16 M HNO_3). Subsequently the solution is evaporated until perchloric acid fumes appear (during which the nitric acid distils off completely), diluted with distilled water to 3 M in perchloric acid, and the astatine separated from this solution for recording by coprecipitation with metallic thallium or by sorption on a silver disk. The separation on silver requires less time (73.5% is sorbed in the first 10 min and 100% after the next 20 min) and this method is more suitable for the serial analysis of biological materials.

Investigation of the radiobiological properties of ^{211}At showed that the α-particles emitted in the disintegration of this isotope produce some decay in the tissues of the thyroid and, unlike iodine, do not harm the neighbouring parathyroid gland[97]. This shows that astatine is perhaps the only means of therapeutic treatment for enlarged thyroid gland.

The radiobiological action of α-particles of astatine on the thyroid gland is 2.8 times greater[98] than deeply penetrating β-particles of ^{131}I.

It has been found that propylthiouracil suppresses the concentration of iodine in the thyroid gland but with astatine the effect is the reverse—its concentration is observed when this preparation is introduced into rats[99].

It is interesting to note that when astatine is introduced in the form of a radiocolloid it is deposited mainly in the

liver[100]. This reflects the general tendency for most elements which are capable of forming colloidal solutions.

In comparing the metabolism of astatine and radioiodine it was found that their excretion by the stomach and kidney is almost the same. In other instances with the exception of the thyroid the metabolism of astatine is completely different from that of iodine. Even on the introduction of a lethal dose of astatine in the form of true solutions into rats and apes, morphological changes in organs and tissues other than the thyroid were not noted[101]. The observation of the accumulation of ^{211}At in the human thyroid in the breakdown of some of the functions of this organ also showed the absence of concentration of astatine in other organs[102].

On the repeated introduction of large doses of astatine into rats and apes their growth is stopped, probably as a result of a change in the functions of the thyroid secretions due to deficiencies of the thyroid hormones[103]. This could also explain the complete destruction of tumours of the mammary gland in rats on the repeated introduction of small doses of astatine[103]. In some studies it is stated that astatine is partly concentrated in the mammary gland[104].

When very large doses of astatine were introduced into rats over 26 months almost complete destruction of the thyroid gland and highly developed tumours of the mucous and mammary glands were observed[105].

The accumulation of astatine by the thyroid gland is under the control of the pituitary body, and leads to the suppression of the concentration of astatine in the thyroid[106]. It was also shown that the thiocyanate ion blocks the accumulation of astatine in the thyroid, probably by forming a sufficiently stable complex. Consequently the thiocyanate ion can be used to remove astatine from this organ[106].

---o0o---

In conclusion it must be noted that the experimental difficulties associated with the study of the chemistry of astatine were evidently due to factors that are now understood: it does not have long-lived isotopes and consequently is found in amounts commensurate with accidental contamination. Reviews on the chemistry of astatine[15,76-79,107-113] appear more frequently than original studies. A recently published paper[114] gives information about the [half-life] periods and α-particle energies of the lightest isotopes of astatine.

I. INTRODUCTION

Thanks to the diverse properties of solvents the electrochemistry of non-aqueous solutions allows processes which are inaccessible for study in aqueous solutions to be brought about and investigated. In particular, there is considerable interest in the experimental investigation of the anodic discharge of hydride hydrogen. The corresponding cathodic process in aqueous solutions—the discharge of H^+—has been studied rather fully. In the investigation of an anodic process it is sufficient to operate with discharge of anions of the type $(M^{+m}H_n)^{-n+m}$, which are precisely what exist in non-aqueous solutions. Since the binding energy of H^- in an anionic complex can depend significantly on the medium, it follows that there are at least indications about the nature of the bonding of this anion with the solvent. The behaviour of the anode during polarisation is also essential —its solubility, the nature and properties of the soluble products which are formed, and in the absence of solubility the order of the strength of the bonding of atomic or molecular hydrogen at its surface. Interest in the process of the discharge of hydride hydrogen, which was first observed by Bardwell[1] for a melt of CaH_2 in KCl–LiCl eutectic and by Ziegler and coworkers[2] for non-aqueous solutions, stimulated us to differentiate AlH_3 and its complexes of the $MAlH_4$ type from the class of compounds $MAlR'_nR''_{4-n}$, the electrochemical properties of which were considered earlier[3]. It was interesting to review the properties, a knowledge of which is needed in investigating the discharge of hydride ions. From the practical viewpoint the solutions of such substances can be used both for the electrodeposition of aluminium‡, and also for obtaining solutions of aluminium hydride[6], the chemical preparation of which is rather complicated.

In the anodic discharge of the AlH_4^- ion, AlH_3 and H_2 should be formed. The subsequent behaviour of AlH_3 and its influence on the kinetics of the anode process depends on the interaction of AlH_3 with the components of the solution, that is, on the nature of the complex formation. We will therefore begin with consideration of the properties of the complexes of AlH_3. Hydroaluminates§ must formally be considered as complexes $AlH_3.MH$. However, they exhibit a series of characteristic differences from the complexes of AlH_3 with organic ligands and are of special interest for electrochemistry. Therefore an examination of several of their properties and methods of preparation is treated under a separate heading. A separate chapter is devoted to the important problem of the structure of the complexes of AlH_3, in which those of the type $AlH_3.MH$ are considered as a special case of the complexes $AlH_3.L$. Finally, the last chapter is devoted to the natural electrochemical properties of the aluminium hydrides.

II. COMPLEXES OF ALUMINIUM HYDRIDE $AlH_3.nL$

In the pure solid state AlH_3¶ is known only as a polymer. $(AlH_3)_x$ is a white involatile substance, usually not free from diethyl ether. Aluminium hydride is insoluble in inert solvents, but soluble with the formation of complexes and depolymerisation in tetrahydrofuran, dioxan, triethylamine[9], diamines[10], and methylcellosolve[11]. The ethereal solution of AlH_3 obtained from $LiAlH_4$ and $AlCl_3$ by the method of Finholt and coworkers[12], is unstable† and on standing it deposits an ether-containing polymer $(AlH_3)_x$[9,14–16], the composition of which depends on the conditions of isolation[9,12,15,17].

† Symbols used in the text: L ligand; M metal; R alkyl, halogen, or hydrogen; NR_3 tertiary amine; Hal halogen; μ dipole moment of the molecule in Debye units; t_b boiling point; t_f melting point; C.N. coordination number; κ electrical conductivity, $\Omega^{-1}\,cm^{-1}$. The thermochemical sign convention is used for denoting the thermal effects.

‡ Kessler and coworkers have reviewed the work of Brenner and coworkers on the electrodeposition of aluminium from hydride solutions. See also Refs.4 and 5.

§ Unfortunately obsolete terminology is often used (for example, in a review[7] which appeared after the present article had been sent to the press).

¶ The monomer AlH_3 and the dimer Al_2H_6 have been obtained in the gas phase at low pressure in the vaporisation of aluminium from a tungsten wire into a vacuum system with partly dissociated hydrogen[8].

† More stable ether addition compounds are known for the aluminium hydrohalides than for AlH_3, for example, $AlHCl_2.O(C_2H_5)_2$, and $AlHBr_2.O(C_2H_5)_2$.[13]

Table 1. Complexes of aluminium hydride.

System	Complex, production or method of detection	Properties
AlH_3-tetrahydrofuran	$AlH_3.2C_4H_8O$ *, 1) C_4H_8O vac. from soln. of AlH_3 in C_4H_8O at -45°C;[18] 2) Infrared[19] and NMR[16] spectra in soln. of AlH_3 in C_4H_8O.	stable at t_{room} only in soln. in C_4H_8O.[9] P_d = 6 mmHg, -5°C; 15 mmHg, +20°C.[18]
	$AlH_3.nC_4H_8O$, $n > 2$ not observed up to -65°C (tensimetric measurements)[18].	
	$AlH_3.C_4H_8O$, 1) C_4H_8O vac. from soln. of AlH_3 in C_4H_8O at t_{room}.[9,20] 2) 1 mole C_4H_8O vac. from $AlH_3.2C_4H_8O$ at -5°C.[18].	White cryst. subst., t_f = 56–57°C[16,20], sol. in e., THF, d., b., cyclohexane, iso-octane[16].
AlH_3-dioxan	$AlH_3.2OC_4H_8O$, $AlH_3.OC_4H_8O.C_4H_8O$, NMR[19] and infrared[9,16] spectra of soln. in d, and $AlH_3.OC_4H_8O$ in THF.	
	$AlH_3.OC_4H_8O$, OC_4H_8O vac. from soln. of AlH_3 in OC_4H_8O.[9,16]	white cryst. subst., does not melt, sol. in THF, d., insol. in b.[16].
AlH_3-trimethylamine	$AlH_3.2N(CH_3)_3$, 1) Treatment with amine of products of reaction in glow discharge: $Al(CH_3)_3 + nH_2 \rightarrow Al(CH_3)_{3-n}H_n + nCH_4$,[13] 2) $N(CH_3)_3 + (C_2H_5)_2O$ vac. from soln. AlH_3** and amine in e. at comp. ratio 1 : 2 or excess of amine[9,16,23,24]. Purification of subl.[23,25] or extr. b.[16]; 3) condensation of amine on $AlH_3.N(CH_3)_3$;[26] 4) tensim. titration of $AlH_3.N(C_2H_5)_3$ with gaseous $N(CH_3)_3$.[27].	white cryst. subst., t_f = 94–95°C[16,23], sol. in e., THF, b., cyclohexane, iso-octane[16,23]. Subl. impure subst., 30–40°C/1 mmHg[23] or at t_{room}.[24] At t_{room} stable in cryst. and in soln., dissoc. in gas[9,13,26,28] $AlH_3.2N(CH_3)_3 \rightleftarrows AlH_3.N(CH_3)_3 + N(CH_3)_3$.
	$AlH_3.N(CH_3)_3$*** 1) e. vac. from soln. AlH_3 and $N(CH_3)_3$ in e. at equimol. ratio of comp. or excess AlH_3. Purif. subl.[9,16,23] or extr.[9,16]. 2) Ruff's method[25,31] $LiAlH_4 + N(CH_3)_3.HCl \xrightarrow[t_{room}]{e.} AlH_3.N(CH_3)_3 + LiCl + H_2$, e. vac., subl. complex.	white cryst. subst., t_f = 74–76°C[16,23,26,29], sol. in e., THF, b., d., cyclohexane, iso-octane[16,23], P_d = 2–3 mmHg[26], subl. impure subst. 35–40°C, in vac.[26,31], 50–60°C, 1 mmHg.[23]
	$AlD_3.N(CH_3)_3$, Ruff's method[31], see above.	t_f = 77–78°C[31]
	$AlH_3.N(CH_3)_2CH_2CH{=}CH_2$, Ruff's method[31], see above.	t_f = 12°C[31]
AlH_3-dimethylamine	$AlH_3.2(CH_3)_2NH$, mixt. in e. AlH_3 with excess amine at -50°C, e. and excess amine vac. at -40°C[32].	at $t > -20$°C, chemical reaction: $AlH_3.2(CH_3)_2NH \rightarrow 2H_2 + AlH[N(CH_3)_2]_2$[32]
	$AlH_3.(CH_3)_2NH$, Ruff's method $LiAlH_4 + (CH_3)_2NH.HCl \xrightarrow[-40°C]{e.} H_2 + LiCl +$ $AlH_3.(CH_3)_2NH$[31]; assumed to be the same as preceding formation of $AlH_2N(CH_3)_2$.[32]	at $t > -10$°C, chem. reaction, see above[32].
AlH_3-methylamine	$AlH_3.2CH_3NH_2$, mixt. comp. in e. at -55°C at ratio 1 : 2 or excess of amine[33].	white solid, at $t > -40$°C, chem. reaction, $AlH_3.2CH_3NH_2 \rightarrow 2H_2 + HAl(NHCH_3)_2$.[33]
	$AlH_3.CH_3NH_2$, mixt. equimol. amount of comp. in e. at 55°C.[33].	white solid, at $t > -40$°C, chem. reaction, see above[33].
AlH_3-ammonia	$AlH_3.2NH_3$, proposed as preceding the formation of $H_2AlNH_2.NH_3$ at liq. nitrogen temp.[34]	at -80°C, chem. reaction $AlH_3.2NH_3 \rightarrow H_2 + H_2AlNH_2.NH_3$[34] at -45°C, chem. reaction, see above.[35]
	$AlH_3.NH_3$, mixt. equimol. amount comp. in e. at -80°C.[35]	
AlH_3-pyridine	$AlH_3.2C_5H_5N$, mixt. comp. in e. at -30°C to -40°C, e. and C_5H_5N vac.[36]	white cryst. subst., at 0°C, chem. reaction $AlH_3.2C_5H_5N \rightarrow HAl(NC_5H_6)_2$[36]
	$AlH_3.C_5H_5N$, mixt. comp. in e. at -30°C at equimol. ratio[36]	white cryst. subst., at t_{room}, chem. reaction, see above[36]
AlH_3-triethylamine	$AlH_3.N(C_2H_5)_3$: 1) e. vac. from equimol. soln. comp. in e.[16,36]. 2) Ruff's method[31] $LiAlH_4 + N(C_2H_5)_3.HCl \xrightarrow{e.} LiCl + H_2 + AlH_3.N(C_2H_5)_3$.	white cryst. subst.[36], t_f = 18–19.2°C,[31,36] melts readily supercools to -60°C,[36] subl. 0°C, high vac.[36], + 30°C/4.5 mmHg[36], sol. in e., b., triethylamine[16,36].
	$AlH_3.2N(C_2H_5)_3$ is not formed even in soln. of AlH_3 in $N(C_2H_5)_3$.[16,36]	
AlH_3-tripropylamine	$AlH_3.N(C_3H_7)_3$: 1) Ruff's method[31]: $LiAlH_4 + N(C_3H_7)_3.HCl \xrightarrow{e.}$ $LiCl + H_2 + AlH_3.N(C_3H_7)_3$; 2) mixt. comp. in e.[36]	white cryst. subst., t_f = 79.6–81.0°C,[27,29] sol. in e. and b.[36], subl. 30–40°C, in high vac.[36].
AlH_3-tributylamine	$AlH_3.N(C_4H_9)_3$, mixt. comp. in e.[36], purification only by recrystn. from b.[36]	t_f = 41.5°C, does not subl., decomp. into comp. at room temp.[36]
AlH_3-*NNN'N'*-tetramethylethylenediamine (L)	$AlH_3.L$: 1) Ruff's method: $LiAlH_4 + L.2HCl \xrightarrow[\text{excess}]{L} LiCl + H_2 + AlH_3.L$[37];	white solid, P_d = 1.5 mmHg, 99.3°C, 10.6 mmHg, 119.3°C, sol. in L[37].
	2) displacement of $N(CH_3)_3$ from the complex: $AlH_3.2N(CH_3)_3 + L \xrightarrow[\text{excess}]{L}$ $2N(CH_3)_3 + AlH_3.L$[37]	
AlH_3-*NNN'N'*-tetramethylpropanediamine ****(L)	$AlH_3.L$, displacement of $N(CH_3)_3$ from complex $AlH_3.N(CH_3)_3 + L \xrightarrow[\text{excess}]{L}$ $AlH_3.L + N(CH_3)_3$, purif. by subl.[10].	white solid, t_f = +140°C, subl. impure subst. 80°C, 0.05 mmHg[10].

* It was shown[21,22] by the isomolar series method (viscosity, density, electrical conductivity) that C_4H_8O forms complexes with $AlBr_3$ and $AlCl_3$, for example, in b. and $C_6H_5NO_2$ the complex $AlBr_3.C_4H_8O$.

** AlH_3 in e. obtained by $3LiAlH_4 + AlCl_3 \rightarrow 3LiCl + 4AlH_3$;[16,23] or $LiAlH_4 + HCl \rightarrow LiCl + H_2 + AlH_3$;[24] the polymer $(AlH_3)_x$, which dissolved in a soln. of $N(CH_3)_3$ in e.[9] was also used.

*** 1 : 1 adducts are known of $N(CH_3)_3$ with H_2AlCl, $HAlCl_2$, H_2AlBr, $HAlBr_2$;[29] aluminium alkyl hydrides also form complexes, for example, $CH_3AlH_2.N(CH_3)_3$, $(CH_3)_2AlH.N(CH_3)_3$.[30]

**** Complexes of AlH_3 with other polyamines are also obtained[10]; however, in these instances a chemical conversion is possible, which hinders the interpretation of the results. The complexes $AlH_3.L$ (L = triethylenediamine), stable up to > 200°C and insoluble in the usual organic solvents, were obtained[38] in tetrahydrofuran from Al, H_2, and L at moderate temperatures and hydrogen pressures.

Table 1‡ gives the methods of preparation and proof of the existence and also certain properties of the complexes of AlH_3. An appreciable proportion of the complexes exist only at low temperatures, above which a chemical reaction starts between the AlH_3 and the ligand.

Depending on the strength of the bonding of the ligands with AlH_3, some ligands can displace others to form more stable complexes, for example, NaH, LiH, and CaH_2 displace $N(CH_3)_3$ from its complexes with AlH_3[27] by reactions of the type:

$$LiH + AlH_3 \cdot N(CH_3)_3 \xrightarrow{(C_2H_5)_2O} LiAlH_4 + N(CH_3)_3 .$$

‡ In Tables 1 and 4 the following abbreviations and conventional symbols are used: vac. removal in a vacuum, soln. solution, subst. substance, sol. soluble, e. diethyl ether, THF tetrahydrofuran, d. dioxan, b. benzene, P_d dissociation pressure, comp. components, mixt. mixture, extr. extraction. The other symbols are understandable from the text.

NNN'N'-tetramethylethylenediamine (L) taken in excess, has a similar action[37]:

$$AlH_3 \cdot 2N(CH_3)_3 \xrightarrow[\text{solvent}]{L} AlH_3 \cdot L + 2N(CH_3)_3.$$

The same reactions take place with *NNN'N'*-tetramethylpropanediamine[10] and trimethylhydrazine[39].

By tensimetric titration of the complex $AlH_3.N(C_2H_5)_3$ with trimethylamine it was found that $N(CH_3)_3$ displaces $N(C_2H_5)_3$,[27] for $AlH_3.2N(CH_3)_3$ was isolated from the reaction mixture. NMR has shown[9] that C_4H_8O does not displace the amine from the complex $AlH_3.N(CH_3)_3$, and C_4H_8O in $AlH_3.C_4H_8O$ can be partly replaced by dioxan. The existence of the mixed complexes $AlH_3.N(CH_3)_3.C_4H_8O$, $AlH_3.N(CH_3)_3.OC_4H_8O$, and $AlH_3.C_4H_8O.OC_4H_8O$, has been found[16,19] in an excess of the complex-forming agent or solvent. The infrared spectra of solutions of $AlH_3.N(CH_3)_3$ in $N(C_2H_5)_3$, C_4H_8O, and OC_4H_8O showed[9] the presence of the compounds $AlH_3.N(CH_3)_3.N(C_2H_5)_3$, $AlH_3.N(CH_3)_3.C_4H_8O$, and $AlH_3.N(CH_3)_3.OC_4H_8O$, stable only in solution in an excess of the corresponding complex-forming substance. It is interesting that C_4H_8O and OC_4H_8O taken in excess give diadducts with AlH_3, but $N(C_2H_5)_3$ does not[9].

To explain the solubility of AlH_3 in diethyl ether, many authors propose the existence of the complexes $AlH_3.n(C_2H_5)_2O$, which were not isolated owing to their instability.

The precipitation of the ether-containing polymer $(AlH_3)_x$ from ethereal solutions of AlH_3, the stability of AlH_3 solutions in tetrahydrofuran and dioxan and of ethereal solutions of AlH_3 in the presence of LiBr or NR_3, and also the depolymerising action of tetrahydrofuran, tertiary amines, LiBr [3,9,16,36] on polymeric AlH_3 suggests that tetrahydrofuran, tertiary amines, and LiBr are stronger complex-forming agents than diethyl ether.

Accordingly, a series can be drawn up with the ligands arranged according to diminishing strength of the bond with AlH_3: alkali or alkaline earth metal hydrides > diamines > $N(CH_3)_3$ > OC_4H_8O, C_4H_8O, $N(C_2H_5)_3$ > $(C_2H_5)_2O$.

The ability of complexes to dissociate

$$AlH_3.L \rightleftharpoons AlH_3 + L$$

is also interesting. For the complexes of AlH_3 with alkali metal and alkaline earth metal hydrides such dissociation seems improbable although the decomposition

$$MAlH_4 \rightarrow MH + AlH_3$$

is proposed as a stage preceding certain chemical reactions[40] or the catalytic decomposition of $MAlH_4$ in ethereal solution[41,42].

Table 2 gives some information about the possibility of the dissociation in a vacuum

$$AlH_3.L \rightleftharpoons AlH_3 + L$$

of complexes with amines§.

The sequence of ligands according to the tendency of their complexes to dissociate from AlH_3 is: diamines < $< N(CH_3)_3 < N(C_2H_5)_3 < N(C_3H_7)_3 < N(C_4H_9)_3$. It should be noted that complexes with an odd number of carbon atoms in the alkyl radical of the amine melt at a higher temperature than those with an even number.

Depending on the ligand L and steric factors the complexes $AlH_3.L$ can add a second molecule of ligand ($AlH_3.L$ + + L ⇌ $AlH_3.2L$).

Quantitative data characterising this ability exist only for complexes with tertiary amines. The cryoscopic method was used[27] to measure the mean molecular weight of mixtures of NR_3 and $AlH_3.NR_3$, in benzene and the formation constants of the complexes, K, were calculated for certain amines: $AlH_3.2N(CH_3)_2CH_2CH{=}CH_2$, $K = 2 \times 10^2$; $AlH_3.2N(C_2H_5)_2CH_3$, $K = 3$; $AlH_3.2N(C_2H_5)_3$, $K = 8 \times 10^{-2}$. For $N(CH_3)_3$ the formation of the 1 : 2 complex is thought to be complete¶.

Table 2. Dissociation temperatures and melting points of the complexes $AlH_3.NR_3$.

Ligand	t_{dis}, °C	t_f, °C	References
$N(CH_3)_3$	100	75—76	20, 23, 27, 31
$N(C_2H_5)_3$	40 slow, 80 rapid	18—19.2	31.36
$N(C_3H_7)_3$	~40 in vacuum	79.6—81	31.36
$N(C_4H_9)_3$	readily dissociates in a vacuum, - does not distil	41.5	36
$N(CH_3)_2CH_2CH{=}CH_2$	—	12	31
$(CH_3)_2N(CH_2)_2N(CH_3)_2$	does not dissociate at 133	—	37
$(CH_3)_2N(CH_2)_3N(CH_3)_2$	does not dissociate at 140	136—140	10

Similar cryoscopic measurements were also made for the mixed complexes: $AlH_3.N(CH_3)_3.N(C_3H_7)_3$, $K = 7 \times 10^{-1}$; $AlH_3.N(CH_3)_3.N(C_2H_5)_3$, $K = 9$; $AlH_3.N(CH_3)_3.N(C_2H_5)_2CH_3$, $K = 5 \times 10^2$.

According to these results the stability order of the amino-complexes is: $N(CH_3)_3 > N(CH_3)_2CH_2CH{=}CH_2 > > N(C_2H_5)_2CH_3 > N(C_2H_5)_3 > N(C_3H_7)_3$. This series is also confirmed by qualitative results.

III. ALKALI METAL TETRAHYDROALUMINATES $MAlH_4$ AND THEIR COMPLEXES $MAlH_4.nL$

1. Methods of Preparation of $MAlH_4$

Rather effective methods for making alkali metal tetrahydroaluminates are now known, including the following which are suitable for industrial preparation:

(a) The reaction of the alkali metal hydride MH with $AlHal_3$ may be carried out in various solvents, the choice of which depends on the nature of M and Hal [12,15,41,43-53]. When MH is insoluble then the reaction proceeds in the presence of aluminium alkyls, the role of which reduces to the conversion of the MH into the soluble complexes $MAlHR_3$.[51,52] $LiAlH_4$, $NaAlH_4$, and $KAlH_4$ are obtained in this way, and the reaction of LiH and $AlCl_3$ in $(C_2H_5)_2O$ serves for the industrial production of $LiAlH_4$.

It is thought[44,49,53] that the reaction of MH with $AlHal_3$ proceeds through the intermediate formation of AlH_3. The coordination unsaturated AlH_3 should, in our opinion, lead also to the formation of soluble complexes of composition

§ For other complexes the dissociation is complicated by the catalytic or thermal decomposition of AlH_3.

¶ This assumption is well based. The molecular weight of this complex in ether (ebullioscopy) and in benzene (cryoscopy) has been determined[8,16,26]. It has been shown that in both the compound is monomeric and not dissociated. The complex is completely stable in solution and in the crystalline form, whereas dissociation occurs in the gas

$$AlH_3.2N(CH_3)_3 \rightleftharpoons AlH_3.N(CH_3)_3 + N(CH_3)_3;$$

$$AlH_3.N(CH_3)_3 \rightarrow (AlH_3)_x + N(CH_3)_3.$$

as vapour pressure measurements and the infrared spectra have shown[9,26,28,37]. The polymers which are formed gradually break down into Al and H_2, that is, complete decomposition of $AlH_3.2N(CH_3)_3$ can proceed over a long time. The excess of $N(CH_3)_3$ shifts the equilibrium to the left.

$n MAlH_4.mAlH_3$. Evidently, at the start of the reaction $m \gg n$ and aluminium hydride predominates; at the end of reaction $m \ll n$ and $MAlH_4$ predominates in the solution. The decomposition of non-recrystallised $LiAlH_4$ usually observed is apparently connected above all with the decomposition of the impurity $MAlH_4.nAlH_3$. The hypothesis of the intermediate formation of the complex $LiAlH_4.AlH_3$ is made also for the reaction

$$3LiAlH_4 + AlCl_3 \rightarrow 3LiCl + 4AlH_3$$

from the results of NMR spectra [54].

(b) Direct reaction of the elements or MH, Al, and H_2 (the Al is specially activated [55-57]) on heating with hydrogen in solvating solvents [58-64], or hydrocarbons in the presence of aluminium alkyls and analogous compounds as activators [60,61,65]. In tetrahydrofuran and diglyme, Li, Na, and K tetrahydroaluminates have been obtained, in hydrocarbons, Na, K, and Cs.

In solvating media the direct preparation is complicated by cleavage of the solvent which at a definite temperature and concentration takes place explosively. Pyrophoric impurities are formed in the cleavage [58-61]. Solvent cleavage is intensified in the sequence Li–Cs, since $KAlH_4$ is obtained strongly contaminated and $CsAlH_4$ cannot be obtained at all in diglyme [60,61]. The explosive cleavage of diglyme by lithium tetrahydroaluminate [66] and of tetrahydrofuran by sodium tetrahydroaluminate [67] have been noted. The limiting temperatures for the coexistence of $LiAlH_4$ with diglyme, $NaAlH_4$ with C_4H_8O, and $NaAlH_4$ with diglyme are 200°, 165°, and 180°C respectively [60,61].

The vacuum distillation of the solvent after the preparation leads to contamination of the products from solutions of $MAlH_4$ in tetrahydrofuran and diglyme. On salting out the $MAlH_4$ from these solutions with ether or toluene, sufficiently pure $NaAlH_4$, $KAlH_4$, and $CsAlH_4$ are precipitated, but $LiAlH_4$ could not be isolated in this way.

In hydrocarbons, the direct preparation gives products with alkyl-substituted $MAlH_4$ as impurities, formed as a result of the reaction of aluminium alkyls with alkali metal hydrides.

The activating action of aluminium alkyls is explained by the formation of intermediate soluble complexes $MH.AlR_3$. [51,52,65] It has been suggested [56,58,65] that during the direct preparation of $MAlH_4$ there is the intermediate formation of AlH_3 from the elements, although this has been doubted [60,61], since the direct preparation of AlH_3 did not take place under conditions analogous to the direct preparation of tetrahydroaluminates [56]. Nevertheless without assuming the intermediate formation of AlH_3 or its subhydrides it is difficult to understand how the metallic aluminium is involved in the reaction.

It should be noted that the complex $AlH_3.L$ (L = triethylenediamine) has been prepared from Al, H_2, and L in tetrahydrofuran at moderate temperatures and hydrogen pressures [38].

In this reaction the formation of AlH_3 and polyhydroaluminates (or their partial alkyl derivatives) as a result of the hydrogenolysis of the compounds AlR_3 and $nMAlH_4.mAlR_3$ is quite probable [68,69]:

$$AlR_3 \xrightarrow{H_2} AlH_3 \xrightarrow{MH} MAlH_4;\ n\,MAlH_4 \cdot m\,AlR_3 \xrightarrow{H_2} n\,MAlH_4 \cdot m\,AlH_3.$$

Partly alkyl-substituted compounds give $MAlH_4$ as a result of the catalytic displacement of α-alkenes on heating [70,71].

From an analysis of the results on the direct preparation it can be concluded that the formation of $LiAlH_4$ from the elements is evidently determined ultimately by the magnitude of the solvation energy, which in tetrahydrofuran is sufficient for the formation of $LiAlH_4$. In diethyl ether and hydrocarbon solvents it is low and the change in free energy in the reaction [72]

$$LiH + Al + \tfrac{3}{2}H_2 \rightarrow LiAlH_4,\quad \Delta G = -3.9 \text{ kcal mole}^{-1}$$

is too insignificant to be the determining factor.

For sodium, potassium, and caesium tetrahydroaluminates the change in free energy is a significant quantity: for $NaAlH_4$ ΔG° = +3.0 kcal mole^{-1}, $KAlH_4$ ΔG° = +14.9 kcal mole^{-1}, $CsAlH_4$ ΔG° = +16.5 kcal mole^{-1}; [72] this also determines the possibility of their production in non-solvating media.

In the series $NaAlH_4$, $KAlH_4$, $CsAlH_4$ there is increasing solvent cleavage in their formation from the elements (125–150°C). The stability of the solvates should decrease in the same order (see below).

(c) Double decompositions of the type:

$$MAlH_4 + M'Hal \rightarrow M'AlH_4 + MHal\ [58,60,61,75]$$

and

$$M'AlH_4 + MH \rightarrow MAlH_4 + M'H\ [74],$$

the occurrence of which is determined by the ratios of the energies of formation of the reactants and final products and by solubility factors.

(d) Reactions for the replacement of an amine by a metal hydride [27]

$$AlH_3 \cdot NR_3 + MH \rightarrow MAlH_4 + NR_3.$$

Here the alkali metal hydride emerges as a stronger donor than the amine. The reaction

$$AlH_3 + MAlR_2H_2 \rightarrow MAlH_4 + R_2AlH,$$

where M = Na, K, has been proposed [65].

(e) The displacement

$$MAlH_4 + M' \rightarrow M'AlH_4 + M$$

where M = Li; M' = K, Rb, Cs [75].

2. Solubility and Complex Formation

The alkali metal tetrahydroaluminates are destroyed by water, ammonia, and other compounds with labile hydrogen. They are insoluble in non-polar solvents: benzene, toluene, aliphatic hydrocarbons. Table 3 gives the available information on solubility (m = moles per 1000 g solvent, c = moles per litre solution). In addition the solubility of $LiAlH_4$ is m = 1.1 in diethyl Carbitol [diethylene glycol diethyl ether] [12], m = 0.5 in dibutyl ether [12], m = 0.025 in dioxan [12], and $m > 1.5$ in methylal [80] (acetals are not reduced by $LiAlH_4$). A new solvent for lithium tetrahydroaluminate is "T-solvent"—tetrahydrofurfuroxytetrahydrofuran. The solubility of $LiAlH_4$ at 90°C is 22%. "T-solvent" boils at 238°C, which allows the reaction to be carried out at elevated temperatures [81].

$LiAlH_4$ is very slightly soluble in tertiary amines [12].

The great scatter in the results on the solubility of $LiAlH_4$ in diethyl ether is striking; it is due to the quality of the material dissolved [82]. Freshly prepared $LiAlH_4$ is more soluble in ether than the available commercial preparations [77]. The solubility of $MAlH_4$ is closely connected with the solvating ability of the solvents [58].

In several instances the solubility of tetrahydroaluminates can be compared with the properties of the complexes formed by $MAlH_4$ with the solvent. Table 4 gives the properties of the known complexes.

A series of complexes of the type $MAlH_4.nER_3$, where m = alkali metal and E = Al, Tl, In; R = alkyl; n = 1–4,

are also known; they were obtained by heating mixtures of the components[68]. The properties of most of these complexes have not been described, apart from $NaAlH_4.Al(C_2H_5)_3$, t_f = 60°C. It is also interesting to note the probable existence of $LiAlH_4.AlH_3$ [54] and $NaAlH_4.AlH_3$.[6]

Table 3. Comparison of the solubility of $MAlH_4$ in various solvents at room temperature.

Solvent	$MAlH_4$				
	$LiAlH_4$	$NaAlH_4$	$KAlH_4$	$CsAlH_4$	$Ca(AlH_4)_2$
Diethyl ether	m = 6.7-7.9[12] m = 6.7[17] m = 10.8[76] c = 7.9[77] c = 0.83[78]	insoluble[49,50**]			
Tetrahydrofuran	c = 3; 20°C[12]	c = 3; 20°[6,58]	poorly soluble[60,61] c = 0.03[58]		$c > 0.25$[6]
Monoglyme	c = 2.0; 20°C[58]	soluble[49]			
Diglyme	c = 1.0; 20°C[58]	c = 2,2; 20°C[58]	soluble[60,61]	soluble[60,61]	
Triglyme	c = 0.8; 20°C[58]	c = 2.8; 20°C[58]			
Tetraglyme	c = 1.8; 20°C[58]				

* The solubility was calculated by the authors[76] from the pressure-composition isotherm.

** $NaAlH_4$ is insoluble in $CH_3OC_2H_5$ and $CH_3OC_3H_7$.[49] The number of solvents for $NaAlH_4$ is limited to tetrahydrofuran and the methyl esters of mono- and poly-glycols.[79]

The instability of the complexes $MAlH_4.n(C_2H_5)_2O$ is illustrated by the solubility of only $LiAlH_4$ in $(C_2H_5)_2O$, the low heat of mixing of ether with $LiAlH_4$ (+1.95 kcal mole^{-1} [76]), and the ease of isolation of $LiAlH_4$ by simple vacuum distillation of ether from the solution.

The practical insolubility of $KAlH_4$, $RbAlH_4$, and $CsAlH_4$ in tetrahydrofuran, the relative ease of isolation of pure $NaAlH_4$ from C_4H_8O by salting-out with ether[58] or toluene[60] and the impossibility of this for $LiAlH_4$, and also the possibility of salting-out $KAlH_4$, $RbAlH_4$, and $CsAlH_4$ from their solutions in diglyme with toluene and the incompleteness of this for $LiAlH_4$ and $NaAlH_4$,[60] show the fall in stability of the solvates in the series $LiAlH_4 \rightarrow NaAlH_4 \rightarrow KAlH_4 \rightarrow RbAlH_4 \rightarrow CsAlH_4$. The essential role in solubility is evidently played not only by complex formation as such, but also the solvation of the alkali metal ions. In the series Cs, Rb, K, Na, Li the solvation of the ions by the ethers should increase. Moreover, it has been shown[93] that single complexes $[AlH_4.nL]^-$ are formed in C_4H_8O and diglyme, irrespective of M (see below). It should also be noted that although $LiAlH_4$ also forms comparatively stable complexes with dioxan and tertiary amines, it is practically insoluble in them[12]. In the strength of bonding of $LiAlH_4$ in the complex the ligands considered above can be arranged in the order:

$$(C_2H_5)_2O < C_4H_8O < OC_4H_8O \simeq NR_3.$$

From the point of view of the bond type and the possibility of existence of polyhydroaluminates, compounds with the general formula $MAlH_4.nAlR_3$, where R is an alkyl

Table 4. Complexes of the alkali metal tetrahydroaluminates.

System	Complex, production or method of observation	Properties
$LiAlH_4$–diethyl ether	$LiAlH_4.2(C_2H_5)_2O$ e. vac. from soln. of $LiAlH_4$ in e. at -60°C to constant weight[83].	$t_f \simeq$ -70°C, P_d = 38 mmHg, 0°C, readily sol. in e., loses e. even at t_{room}[83]
	$LiAlH_4.(C_2H_5)_2O$* (1) e. vac. from soln. of $LiAlH_4$ in e. at -15°C to const. weight[83]; 2) tensimetric measurements in the $LiAlH_4$–$(C_2H_5)_2O$ system[76,83].	e. light vac. (analogously at atm. pressure), being converted into $LiAlH_4$ on slight rise in t.[12,58,83] Isolation from e. on addition of b.[41,58,60] or hydrocarbons, which gives $LiAlH_4$ of higher purity than vac. e.[85]
$LiAlH_4$–tetrahydrofuran	$LiAlH_4.3C_4H_8O$, THF, vac. from soln. of $LiAlH_4$ in THF[16,83,86], for example, 17-20 mmHg, t_{room} or -20-0°C.[83]	colourless cryst. mass, t_f = 29-30°C[16,83,86], P_d = 16 mmHg, 0°C; 40 mmHg, 40°C[83]; sol. in e., THF, b.[83,86]; conc. soln. in e. forms layers, lower layer $LiAlH_4.3C_4H_8O$, upper satd. soln.[83].
	$LiAlH_4.2C_4H_8O$, tensimetric measurements during conversion of $LiAlH_4.3C_4H_8O$ into $LiAlH_4.C_4H_8O$;[83] 2) gas chromatography during addition of THF to soln. of $LiAlH_4$ in e.[87]	P_d = 15 mmHg, 34°C.[83]
	$LiAlH_4.C_4H_8O$, THF, vac. from soln. $LiAlH_4$ in THF 20-40°C[83,86], 40°C/3 mmHg.[16]	white solid, P_d = 1 mmHg, 20°C; 7 mmHg, 34°C[83]; readily sol. in e., THF, almost insol. in b.[16,83], last traces of THF difficult vac.[58,60].
$LiAlH_4$–trimethylamine	$LiAlH_4.3N(CH_3)_3$, mixt., comp. in e. at large excess of amine at -80°C.[88]	amine vac. even at -40°C, > 0°C converted into $LiAlH_4.N(CH_3)_3$.[88]
	$LiAlH_4.2N(CH_3)_3$, mixt. ethereal soln. of comp. at -50°C.[88]	white cryst. subst., in vac. at t_{room} converted into $LiAlH_4.N(CH_3)_3$.[88]
	$LiAlH_4.N(CH_3)_3$, mixt. ethereal soln. comp.[88]	white subst. sparingly sol. in e., insol. in b., decomposes in vac. at 180–200°C with separation of Al.[88]
$LiAlH_4$–triethylamine	$LiAlH_4.N(C_2H_5)_3$[89]	
$LiAlH_4$–triethylaluminium	$LiAlH_4.4Al(C_2H_5)_3$ Heating comp. at 80°C.[68,69]	liq., $\kappa = 3.72 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$, 100°C.[69]
	$LiAlH_4.3Al(C_2H_5)_3$ Heating comp. at 80°C.[68,69]	liq., $\kappa = 2.55 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$, 100°C.[69]
	$LiAlH_4.2Al(C_2H_5)_3$ Heating comp. at 80°C.[68,69]	t_f = 29°C, $\kappa = 1.46 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$, 100°C.[69]
	$LiAlH_4.Al(C_2H_5)_3$ Heating at 100°C.[69]	solid, sol. in pet. ether[69], toluene[68]
$MAlH_4$–hydrides of tervalent elements	$MAlH_4.nEH_3$, n = 0.25-16, for example, $LiAlH_4.\frac{1}{2}AlH_3$, $NaAlH_4.\frac{1}{2}GaH_3$, $LiAlH_4.\frac{1}{2}InH_3$, $NaAlH_4.AlH_3$, $LiAlH_4.GaH_3$[90], combination of $MAlH_4$ in org. solvents, conductimetric and ebullioscopic measurements[90]. Series of substances isolated [from solution] by crystn. in vac.[90].	sol. in polar solvents (THF, e.)[90]
$NaAlH_4$–sodium hydride	$NaAlH_4.2NaH$, 1) $NaAlH_4 + 2NaH \rightarrow Na_3AlH_6$ in ball mill in heptane or xylene, 20–100°C; 2) $2Na + NaAlH_4 + H_2 \rightarrow Na_3AlH_6$; 3) $3Na + Al + 3H_2 \rightarrow Na_3AlH_6$, 150–160°C, H_2 pressure 180–110 atm[65,91].	solid, insol. in org. solvents[91].
$LiAlH_4$–lithium hydride	$LiAlH_4.2LiH$, $LiAlH_4 + 2C_4H_9Li \rightarrow Li_3AlH_6 + 3C_4H_8$ mixt. soln. C_4H_9Li in hexane with soln. $LiAlH_4$ in e. t_{room}[92].	solid, insol. in org. solvents, decomp. without fusion and sublimation 210°C.[92]

* The complex $NaAl(C_2H_5)_4.(C_2H_5)_2O$.[84]

radical or hydrogen, are extremely interesting. The complexes $MAlH_4.nAlR_3$, including $RbAlH_4.4Al(C_2H_5)_3$, have already been isolated and partly characterised[68]. It remains unclear whether the compounds $MAlH_4.nAlH_3$ are actually isolated in the pure state, or whether their existence is only surmised in solutions. It is curious that recently halogen analogues of the first member of the hydroaluminate series $LiAl_2H_7$ have been obtained: $LiAl_2Br_7$ and $LiAl_2I_7$.[94]

3. Some Reactions of Tetrahydroaluminates

For the electrochemistry of $MAlH_4$ it is essential to consider firstly those reactions which characterise the thermal and catalytic stability of $MAlH_4$, the capability of hydride hydrogen to be replaced, and solvent interaction.

Behaviour on heating. The thermal stability of lithium, sodium, and potassium tetrahydroaluminates increases in the order $LiAlH_4$–$NaAlH_4$–$KAlH_4$.[95-99] This suggests that $RbAlH_4$ and $CsAlH_4$ should have even greater thermal stability.

A peculiarity of the thermal decomposition of $LiAlH_4$, $NaAlH_4$, and $KAlH_4$ is the stepwise evolution of hydrogen. Half the hydrogen is lost initially: $MAlH_4 \rightarrow MAlH_2 + H_2$. The temperature of this stage is: for $LiAlH_4$, 154–161°C[96] or 187–218°C[97]; for $NaAlH_4$, $> tf = 184$°C[97], for $KAlH_4$, 292–315°C[99]. The second stage corresponds to the decomposition $MAlH_2 \rightarrow MH + Al + \frac{1}{2}H_2$ and its temperature is: for $LiAlH_4$, 197–227°C[96], or 228–282°C[97]; for $NaAlH_4$ 290–298°C[98]; and for $KAlH_4$, 335–365°C[99]. The remaining hydrogen is lost by decomposition of the alkali metal hydride: $MH \rightarrow M + \frac{1}{2}H_2$, which corresponds to the temperatures: for $LiAlH_4$ 580–586°C[96], or 370–483°C[97], for $NaAlH_4$ 422–432°C[98], and for $KAlH_4$ 425–430°C[99]. The scatter of the results for lithium hydroaluminates is probably due to a difference in the purity of the substances tested.

Mikheeva and coworkers consider that all the stages of the decomposition of $LiAlH_4$ are endothermic[96]. However others[97] have found that the first stage of the decomposition (to $LiAlH_2$) is exothermic. The latter agrees with the thermochemical results. The decomposition of $LiAlH_4$ to LiH is exothermic, which is contrary to the behaviour of the other hydroaluminates[72]. All stages of the decomposition of $NaAlH_4$ and $KAlH_4$ are exothermic. $NaAlH_4$ melts almost without decomposition.

We note also that a reversible phase transformation of unknown nature has been found[97] for $LiAlH_4$ in the range 160–177°C.

Catalytic decomposition of $LiAlH_4$. In accordance with the decrease in free energy in the decomposition $LiAlH_4 \rightarrow LiH + Al + \frac{3}{2}H_2$,[72] $LiAlH_4$ is metastable, in contrast with sodium, potassium, and caesium tetrahydroaluminates. Solid preparations of $LiAlH_4$ darken on long storage, especially in the light, and gradually decompose, especially in the presence of catalytic additions of Ti, Si, Fe, Cu, or B[41]. When aluminium powder is dusted into an ethereal solution of $LiAlH_4$ the latter decomposes violently[58]. Highly disperse aluminium formed in the decomposition of solid $LiAlH_4$ is evidently the cause of the self-acceleration of the process. The decomposition of $LiAlH_4$ has been connected[100] with the initial homolytic splitting of $LiAlH_4$ into LiH and AlH_3. However, we think it much more probable that the initiation of the decomposition of the preparations is connected with the instability of the complexes $LiAlH_4.nAlH_3$ present as impurities (see p. 101/102).

This suggestion fits in well with the fact that the stabilisation of solid preparations of $LiAlH_4$ involves removal of the impurities as much as possible. This is done by dissolution of the preparations in $(C_2H_5)_2O$ and long boiling[100], especially in the presence of LiH[42], and also by bonding the impurities in complexes by the addition (up to 6%) of dioxan, dimethylcellosolve, and trimethylamine[101]. The complexes formed with AlH_3 are capable of regenerating $LiAlH_4$ in ethereal solution in the presence of lithium hydride[42]:

$$AlH_3 \cdot L + LiH \rightarrow LiAlH_4 + L.$$

A stabilising action on $LiAlH_4$ due to complex formation is shown by tetrahydrofuran and diglyme, which form completely stable solutions with $LiAlH_4$ at room temperature[58,60]. Here the stability of the solvates of $LiAlH_4$ is so great that it cannot be freed from solvent (see p. 102/103).

Reaction of $MAlH_4$ with solvents. Alkali metal hydroaluminates are not completely inert to solvents, especially on heating (see p. 102).

Explosive reactions of $LiAlH_4$ with dimethyl ether[102] and perfluorosuccinamide[103] have been noted, in addition to the splitting of tetrahydrofuran, dioxan, diethoxyethane, and dibutyl ether by a mixture of $LiAlH_4$ and $AlCl_3$.[104,105] Information about the splitting of $(C_2H_5)_2O$ by lithium tetrahydroaluminate is not available.

IV. STRUCTURE OF THE COMPLEXES $AlH_3.nL$ AND $MAlH_4.nL$

The complexes of AlH_3 have been better studied than the complexes of the alkali metal tetrahydroaluminates and for $n = 1$, 2 and various L they are known in all states of aggregation. The most reliable and confidently interpreted results were obtained for the gaseous complexes with $N(CH_3)_3$. At $n = 1$ the infrared spectra show the tetrahedral configuration of the molecules of the complex with symmetry C_{3v}.[9,26,106] In this sense they are similar to the anions formed in the aluminium compounds of type $MAlR_4$, where R is halogen or alkyl[3,107-109]. The anion AlH_4^- in $MAlH_4$ also exhibits an analogous structure[77,93,110] with an Al–H distance between 1.61[111] and 1.66 Å,[112] a conclusion reached on the basis of an investigation of the infrared and Raman spectra in ether[77,110] and in the solid state[77]. The valence state of the aluminium atom in such compounds corresponds to sp^3 hybridisation[20,113]. For other compounds of aluminium hydride in which the aluminium has coordination number four such definite conclusions cannot be drawn owing to the absence of corresponding experimental data: not one of them apart from $AlH_3.N(CH_3)_3$ has been studied in the gas phase and only two—$AlH_3.C_4H_8O$ and $AlH_3.N(C_2H_5)_3$ have been studied in inert solvents[9,16,20,114,115]. In the last examples the considerable similarity between these spectra and the spectra of solutions of the complex $AlH_3.N(CH_3)_3$ in the same solvent suggests that the molecules of these complexes have analogous structure[20].

For the complex $AlH_3.2N(CH_3)_3$ information is available about the infrared spectra in the gas[9,26,106] and in inert solvents[16,20,114,115], the Raman spectra of solutions[26,106], and the structure of crystals[24]. These results show definitely that the molecule of the complex is a trigonal bipyramid with three H atoms in the base [sic], an Al–N distance of 2.18 Å and an N–Al–N angle of 180°. Such a

structure corresponds to sp^2-pd hybridisation (three planar sp^2-bonds and two pd-orbitals perpendicular to their plane)[19,20,27], symmetry group D_{3h} [20,26,106] or D_3.[106] From the similarity of the spectra of solutions of AlH_3 in complex-forming solvents and by general analogy such a structure can also be suggested for complexes with $2C_4H_8O$, $2OC_4H_8O$, and the mixed compound $AlH_3.C_4H_8O.OC_4H_8O$.[16]

At the same time some uncertainties about the frequencies still exist even for the complexes with $N(CH_3)_3$. The Al–N stretching vibration in compounds of the 1 : 1 type has been assigned the frequency 533 cm^{-1} on the grounds that it is unchanged on going to $AlD_3.N(CH_3)_3$, whereas all the others show a decrease in frequency of a factor of $\sqrt{2}$.[26] However, the absorption in this region is very weak so that Roszinski and Dautel[9] could not even detect it in deuteriation. This fact is puzzling.

In the 1 : 2 complexes the N–Al–N symmetric stretching vibrations are from the same considerations assigned the frequency 461 cm^{-1} (Raman spectra, inactive in the infrared spectrum) and the asymmetric, 460 cm^{-1} (infrared spectrum, inactive in the Raman spectrum)[26], 466 cm^{-1}, and 460 cm^{-1}.[106] The proximity of these values is strange, since the light aluminium atom takes part in the asymmetric vibrations, and consequently the shift should be more pronounced. This contradiction has been explained[106] by the spectra's being obtained under different conditions—the infrared spectrum in the gas, and the Raman spectrum in $N(CH_3)_3$ as solvent. An attempt has been made[116] to calculate the frequency of the corresponding vibrations theoretically; however, by making a series of necessary assumptions the authors did not obtain values which agree well with those observable experimentally. They all concluded that the frequency of the symmetric vibrations should be found in the 150–200 cm^{-1} region. Actually, in the Raman spectrum absorption is observed[106] at 197 cm^{-1}, which the authors[106] assigned to the deformation vibrations of the Al–N bond and two absorption bands at 142 and 114 cm^{-1}, not assigned to any vibrations owing to the absence of an absorption spectrum for $N(CH_3)_3$ in this frequency range. In fact, one of them could be a deformation vibration since it is known that the N–Al–N bond is very readily deformed[24,106]. Evidently, further investigation is necessary.

In the complexes with tetrahydrofuran and dioxan the position is still more uncertain. The stretching vibration of the Al–O bond in $AlH_3.C_4H_8O$ was assigned the frequency 538 cm^{-1} in benzene solution, by analogy with the corresponding frequency in the complex with $N(CH_3)_3$.[9] However, in the spectra of solutions of AlH_3 in $AlH_3.N(CH_3)_3$ in tetrahydrofuran frequencies above 400 cm^{-1} which could be assigned to the Al–O or Al–N vibrations are not observed[9,16]. On the contrary, the frequency 455 cm^{-1}, provisionally assigned to the Al–O stretching vibrations is observed in the spectra of these substances and of $AlH_3.C_4H_8O$ in dioxan and of $AlH_3.OC_4H_8O$ in tetrahydrofuran[9]. There are, however, grounds for assuming that it is due to the deformation vibrations of the dioxan ring, inactive in the infrared spectrum in pure dioxan and which appears on destroying its symmetry by interaction with AlH_3.[16] Precise determination of the vibration frequencies of the aluminium–donor atom bond would be extremely desirable to solve problems connected with the stability of the complexes.

In this respect the dependence of the stretching frequencies of AlH_3 on the strength of the ligand–aluminium bond is interesting. Zeil and coworkers[20], having comparatively meagre data at their disposal, evaluated the force constant of this bond and found that it decreases in the series of compounds $AlH_3 > AlH_4^- > AlH_3.C_4H_8O > AlH_3.2N(CH_3)_3$. Schomburg and Hoffman[115] compared the displacement of the Al–H vibration frequency with the heat of reaction of AlH_3 with various ligands[117] and observed that they were symbathic. Later this relation was used repeatedly, was generalised, and was taken as a general rule[9,16,114]. However, the conclusions given in the literature need to be reconsidered, since they were obtained by comparing spectra for different states of aggregation and using spectra of crystalline substance, which is scarcely permissible in the absence of reliable assignment of frequencies and clear information about the character of the interaction of the molecules of the complexes in the crystalline state. Table 5 gives the stretching vibration frequencies of the Al–H bond from the spectra obtained under comparable conditions. The concentration of the test solutions is not always given in the original studies, but as far as can be judged in all the instances quoted it does not exceed 0.5 M. The observed difference between the various data are evidently explained by the experimental difficulties with such active substances.

Table 5 suggests that the ligands can be arranged according to the strength of the bond with aluminium in the 1 : 1 complexes in the series: $N(CH_3)_3 > C_4H_8O > N(C_2H_5)_3$. It is also evident that the solvents concerned are sufficiently inert in relation to these complexes, since the frequency

in the gas and in them are very close. The latter relates also to $AlH_3.2N(CH_3)_3$, the only non-mixed 1 : 2 complex, studied in inert solvents: 1706 (C_6H_{12} [115]), 1702 (C_6H_6 [16]), and 1690 (C_6H_6 [114]) (mean 1700) and 1709,[26] 1709,[9] and 1711 cm^{-1} [106] (mean 1710 cm^{-1}) in the gas. For the remaining complexes, which contain more than one ligand molecule per AlH_3 molecule, information exists only for their solutions in the same ligand (Table 6) or in another (Table 7). In all these instances the frequency relates to the Al–H asymmetric stretching vibrations, since they are obtained from the infrared spectra, in which the symmetric vibrations are inactive.

To draw the correct conclusions from Table 6 it is necessary to bear in mind two additional circumstances. Firstly, a second $N(C_2H_5)_3$ molecule is not added even in a solution of AlH_3 in this substance[9,16,26]. Secondly, $(C_2H_5)_2O$ exhibits some anomalies in comparison with other ligands, namely, in benzene solution, with AlH_3 and $(C_2H_5)_2O$ in the ratio 1 : 4, absorption is observed at 1840 cm^{-1}, and at 1800 cm^{-1} there is only a "shoulder". Evidently this must be understood as an indication that in a solution of AlH_3 in

$(C_2H_5)_2O$ a 1 : 2 complex is formed, which in benzene is largely decomposed into the 1 : 1 complex and free $(C_2H_5)_2O$. True, it has been suggested[16] that at coordination number 5 the Al–H frequency should be $\geqslant$ 1750 cm^{-1}, but probably the anomaly once again consists in a departure from this rule, which holds well for other ligands. When this observation is taken into account, then according to Table 6 we obtain the following series of strengths of the bond between the ligands and aluminium hydride in the 1 : 2 L complexes: $N(CH_3)_3 > C_4H_8O > OC_4H_8O > (C_2H_5)_2O > N(C_2H_5)_3$.

This conclusion is confirmed in the NMR spectra for AlH_3 in the 1 : 1 and 1 : 2 complexes with $N(CH_3)_3$ and C_4H_8O, the chemical shift in which is greater for $N(CH_3)_3$.[19]

For the formation of 1 : 2 mixed complexes of type $AlH_3.L.L'$ the position is more complex. It is evident directly from Table 7 that in the addition of various ligands to $AlH_3.N(CH_3)_3$ the compounds which are formed are arranged in the following series according to stability: $C_4H_8O > (C_2H_5)_2O > OC_4H_8O$, where OC_4H_8O and $(C_2H_5)_2O$ change places in comparison with the 1 : 2L complexes. The same order for C_4H_8O and $(C_2H_5)_2O$ is kept also in their addition to $AlH_3.LiH$.

On the basis of the results collected in Tables 5–7 and those on a solution of $AlH_3.C_4H_8O.(C_2H_5)_2O$ in C_6H_6,[114] it can be shown that the shift in the Al–H frequency on the addition of L' to $AlH_3.L$ depends on the nature of L and L', despite conclusions[16] drawn from a comparison of spectra obtained under poorly comparable conditions (Table 8). For comparison, Table 8 also gives the displacement in the formation of complexes of type $AlH_3.2L$. The NMR spectra also confirm that the addition of the second C_4H_8O molecule to $AlH_3.C_4H_8O$ is less favourable than that of $N(CH_3)_3$ to $AlH_3.N(CH_3)_3$.[19] Unfortunately, on account of the absence of information under comparable conditions the shift in frequency during the formation of AlH_4^- from AlH_3 cannot be determined. However, reliable estimates using the results on solutions of $LiAlH_4$ in C_4H_8O and $(C_2H_5)_2O$ show that it lies within the limits 60–100 cm^{-1}, that is, almost equal to the shift brought about by the most strongly bound ligands. The values found for $\Delta\nu$ agree with the facts that $N(CH_3)_3$ is not displaced from the complexes by tetrahydrofuran and dioxan, whereas in an excess of OC_4H_8O the C_4H_8O is partly replaced with the formation of $AlH_3.2OC_4H_8O$.[19] At the same time it should be noted that the symbathic relation between $\Delta\nu$ and the tendency for complex formation is absent. Thus the addition of the first $N(C_2H_5)_3$ molecule brings about almost the same displacement as the addition of $N(CH_3)_3$; however, in the first instance the 1 : 2 compound is not formed completely, whereas in the second it is formed and seems completely stable. Further, the compounds with $2C_4H_8O$ and $2OC_4H_8O$ are formed only in an excess of the ligands[9], but the addition of $(C_2H_5)_2O$ to $AlH_3.N(CH_3)_3$, even in $(C_2H_5)_2O$ takes place only partially despite the high value of $\Delta\nu$. This is so because the absorption at 1724 cm^{-1}, which corresponds to the complex $AlH_3.N(CH_3)_3.(C_2H_5)_2O$, is very weak and the strong absorption corresponding to the $AlH_3.N(CH_3)_3$ molecules is retained[114]. In the literature these facts are attributed to steric hindrance[9,114], but no additional confirmation of this has yet been found. It therefore remains uncertain what aspect of the steric factors are significantly less favourable for $N(C_2H_5)_3$ than for $(C_2H_5)_2O$ or C_4H_8O and OC_4H_8O. The uncertainty is even further aggravated by the fact that the rather stable compounds $AlH_3.2NCH_3(C_2H_5)_2$ and $AlH_3.N(CH_3)_3.N(C_2H_5)_3$ are formed[27].

From the results of Tables 6 and 7, clearly in an excess of ligand the compounds $AlH_3.L$ (L $\neq$ LiH) do not give complexes with $n > 2$. From Table 8 it follows that the most favourable formation of mixed complexes occurs at L = $N(CH_3)_3$. At the same time, according to Ehrlich and coworkers[114] the vibrations of the Al–H bond for solutions of $AlH_3.2N(CH_3)_3$ in C_4H_8O—the strongest ligand after $N(CH_3)_3$—and in $(C_2H_5)_2O$ lie at 1695 cm^{-1} and the same vibrations for solutions of $AlH_3.2N(CH_3)_3$ in benzene, at 1690 cm^{-1}. Hence, clearly, complexes with a coordination number 6

for aluminium are not formed in such mixtures. However, $\nu_{Al-H}LiAlH_4$ in C_4H_8O (Table 7) and the liquid mixture $AlH_3.LiH : C_4H_8O = 1:8$ lies at 1674 cm^{-1}, but in a solution of the mixture $AlH_3.LiH : C_4H_8O = 1:3$ in benzene, at 1724 cm^{-1}.[16] Hence the conclusion (which should be confirmed by a more thorough and detailed investigation) that instances of complex formation in the liquid phase with a coordination number of 6 for Al are clearly possible. This is suggested, in particular, by the infrared spectra of solutions of the alkali metal tetrahydroaluminates, $CsAlH_4$–$LiAlH_4$, in diglyme and of $LiAlH_4$ and $NaAlH_4$ in C_4H_8O.[93] It was found[92] that the spectra agree with the existence of the anion $[AlH_4.2L]^-$. However, they can be interpreted also without this assumption, which needs additional proof.

The next question, directly connected with the stability of the complexes formed, is the change in the state of ligand molecules on coordination with Al. Unfortunately, little information is available here. Of the 1:1 complexes only that with $N(CH_3)_3$, and of the 1:2 complexes those with $N(CH_3)_3$ and C_4H_8O, have been investigated. In $AlH_3.N(CH_3)_3$ a shift in the N–C stretching frequency in the $N(CH_3)_3$ molecule from 1040 cm^{-1} in pure $N(CH_3)_3$ (gas) to 1005 cm^{-1} in complexes (gas)[26] or 1000 cm^{-1} (solution in C_6H_6)[16] is observed. In the solutions of the complex in C_4H_8O and OC_4H_8O this frequency lies at 1018 and 1015 cm^{-1} respectively[16]. The 997–1002 cm^{-1} absorption band was also observed in the liquid 1:1 complexes of $N(CH_3)_3$ with $(C_2H_5)_2AlH$, $(C_2H_5)AlH_2$, $(CH_3)_2AlH$, and CH_3AlH_2.[30] For the 1:2 compounds with $N(CH_3)_3$ the results are less unequivocal: Heitsch and Kniselly[106] did not observe a change in the infrared spectrum of $N(CH_3)_3$ in the gaseous complex, and Dautel and Zeil[16] observed an absorption band at 1015 cm^{-1} in the benzene solution of the complex. They did not observe[19] a chemical shift of the NMR lines for the protons of the CH_3 groups. Evidently these results suggest a comparatively weak change in the state of the $N(CH_3)_3$ molecules. This can be explained by the free electron pair of the nitrogen in $N(CH_3)_3$ already participating in the sp^3-hybridisation of this atom (the angles of the C–N–C bonds are close to tetrahedral)[19]. On the other hand, in the $AlH_3.2C_4H_8O$ complexes a drop in the resonance frequency in the NMR spectrum of the proton in the α-CH_3 group by 10 Hz is observed, whereas in the β-CH_2 groups there is no chemical shift. This is explained by the strong change in the valence state of the O atom, the [bonding] eigenfunction of which in the free ligand is the p-function (possibly, with a small fraction of s-character)[19]. It is quite probable that the change in energy level of the molecule of the ligands plays a considerable part of the role which is ascribed to steric hindrance in the attempts to explain the observed regularities in complex formation.

Generally speaking, the structure of the complexes considered above in the condensed state can undergo definite changes owing to association if this involves a change in the coordination number of aluminium or the setting up of ligand–ligand bonds. Table 9 gives results on the degree of association of several complexes. The possibility of the formation of bonds between these ligands, already coordinated with aluminium, is almost absent. Consequently, the association can be due either to the high values of the dipole moments ($\mu \simeq 3$–5 D[26,115,118]) or the formation of hydrogen bridges, the possibility of which for solid AlH_3 was first shown by Longuet-Higgins[119]. Subsequently this idea was extended by other authors to solutions of its complexes. Let us first consider the liquid state.

The formation of hydrogen bridges should be indicated in the infrared spectra by: (1) broadening of the bands for the Al–H stretching vibration, (2) the shift to lower frequencies of this vibration, and (3) the appearance of certain new lines in the spectrum. In the NMR spectra there should be corresponding displacements. Not one of these phenomena occurs in the solutions in inert solvents, at least up to 0.5 M concentration[19,20,26,31,77,115]. Moreover, Wiberg and coworkers[25] found that at the b.p. of solutions of $LiAlH_4$ in diethyl ether the molecular weight of $LiAlH_4$ increases with concentration and corresponds to $(LiAlH_4)_2$ at 0.08 M, and to $(LiAlH_4)_3$ at 0.8 M, which they explain by the formation of hydrogen bridges, However, a change in the form and a displacement of the absorption bands of the complex up to 3.4 M was not observed in the infrared and Raman spectra[77,110] of these solutions although the degree of association is sufficiently high even in dilute solutions (cryoscopy, Table 9), and a concentration of 0.3–0.5 M is completely sufficient for obtaining clear spectral data. The association of hydrides of the type R_2AlH has been investigated by cryoscopic methods and by infrared and Raman spectroscopy[118,120]. It was found that in the liquid state, dilute solutions, inert solvents, and in the gas these compounds are trimers owing to the formation of hydrogen bridges with aluminium in coordination number 4. Very strong absorption bands for the Al–H of the trimers lie in the 1770 cm^{-1} range and have a half-width of $\sim$ 100 cm^{-1} (concentration of solutions $\sim$ 0.1 M). The addition of strong complex-forming ligands, such as $N(CH_3)_3$, C_4H_8O, and $(C_2H_5)_2O$ leads to the breakdown of the trimers and the formation of 1:1 complexes with the aluminium coordination number remaining at four, this being accompanied by a marked narrowing of the absorption bands and their displacement to lower or higher frequencies (see also Schomburg and Hoffman[115]), depending on the ligand. The latter is understandable, since here there are two effects superimposed—displacement to higher frequencies on breaking the hydrogen bridge, and to lower during coordination of the ligand. However, no narrowing of the absorption bands takes place during the formation of the complexes $AlH_3.2L$ or $AlH_3.L.L'$ from $AlH_3.L$.[9,14] Further, in the addition of L' to $AlH_3.L$ the maximum displacement of frequency to the side of lower frequencies takes place for $L = N(CH_3)_3$ (Table 8), that is, when α is

* The authors[31] found it difficult to explain this departure from Wiberg's results[23,25].

highest (Table 9) and a significant difference in sign of the contribution from the breaking of the hydrogen bridges would be expected. Hydrogen bridges are absent from a solution of AlH_3 in diethyl ether, in which AlH_3 is monomeric[12] although the bonding of AlH_3 in ether is weak. Probably the $(C_2H_5)_2O \rightarrow AlH_3$ donor–acceptor bond, in decreasing the formal positive change on Al, leads to loss by the AlH_3 molecule of the ability to give hydrogen bridges. It therefore seems improbable that bridges can be formed by AlH_3 molecules bound with such strong donors as amines.

Ruff[29], in considering the results of Ulich and Nespital[121] for solutions of complexes of aluminium halides, also considers that the association of these complexes is more similar to the dipole–dipole interaction than to polymerisation through halogen bridges.

The dipole–dipole interaction hypothesis accords with symmetric $AlH_3.2N(CH_3)_3$, the dipole moment of which is close to zero, not being associated in benzene (Table 9), although the coordination number of aluminium does not have the maximal value of 6 (see Refs. 9, 13, 119, 122).

The association of $AlH_3.NR_3$ in benzene decreases with increase in the length of the amine radical (Table 9)[23,25,31]. Such a relation contradicts the hypothesis of hydrogen bridge formation, since with decrease in the radical length the stability of the complexes of AlH_3 with NR_3 increases, corresponding to a decrease in the effective positive charge on the Al in the $Al^{\delta+}-H^{\delta-}$ bond[19], which should hinder the formation of hydrogen bridges, that is, decrease the degree of association.

The main argument supporting the existence of hydrogen bonds in benzene solutions is thought[23,25,31] to be the association of $AlH_3.NR_3$, in contrast with the monomeric nature of $AlH_3.NR_3$ in diethyl ether. This, in the opinion of the authors, is connected with the breaking of hydrogen bonds due to donor–acceptor interaction with ether. However, the monomeric nature can be explained also by inhibition of the dipole–dipole interaction of the $AlH_3.NR_3$ molecules in diethyl ether, because of the somewhat greater dielectric constant of ether in comparison with benzene, and also the weakening due to the decrease in μ of the complex, since in an excess of ether unstable mixed diadducts can be formed, $AlH_3.NR_3.(C_2H_5)_2O$ with $\mu \simeq 0$.

The absence of association (according to ebullioscopic results[88]) of $LiAlH_4$ in C_4H_8O can be explained in a similar manner.

Hence if the possibility of association due to dipole–dipole interaction is considered then it must be acknowledged that in dilute solutions there are no objective reasons for assuming the existence of hydrogen bridges, provided only that the latter do not exhibit any new properties distinguishable from those for bridges in $(R_2AlH)_x$. For compounds of the type $R_2AlH.N(CH_3)_3$ and $RAlH_2.N(C_2H_5)_3$. another method of association is possible—due to the carbon of the methyl (for R = CH_3) and methylene CH_2 group (for R = C_2H_5). Such a possibility follows from the splitting of the NMR lines[30]. We note that the dimerisation of $Al(C_2H_5)_3$, also investigated by the NMR method[123] also takes place because of the CH_2 group. Doubt about the formation of hydrogen bridges has repeatedly been expressed[16,115,123]. In particular, it is thought[16] that: (a) it is difficult to assume that tetrahedral 1 : 1 complexes lose symmetry and acquire sp^3-spd-hybridisation† with five-coordinated aluminium owing to the formation of hydrogen bridges, and (b) the assumption of dimerisation should imply the presence in the solution of an equilibrium between the monomers and dimers which should enrich the spectra with new lines, which is not observed. True, later the same authors concluded that dimers existed[9], arguing mainly from a comparison of the spectra of $AlH_3.N(CH_3)_3$ and $AlH_3.2N(CH_3)_3$ in the crystalline state, in concentrated and dilute solutions in benzene, and in the gas, and the spectra of $AlH_3.N(C_2H_5)_3$ and $AlH_3.C_4H_8O$ in the crystalline state and in concentrated solution in C_6H_6. In particular they observed the appearance of weak absorption bands in the 1550–1650 cm^{-1} range in concentrated solutions and in the crystals and a displacement of the Al–H frequency to 1762 cm^{-1} for $AlH_3.N(CH_3)_3$ and $AlH_3.C_4H_8O$ in comparison with the dilute solutions (Table 5). From what has been said above, clearly these results cannot themselves be considered as any significant argument in support of the formation of hydrogen bridges. The discussion of Roszinski and Dautel[9], leading them to conclude the formation of hydrogen bridges, also cannot be considered as substantiated. They found by comparison of the spectra in various states of aggregation that the spectrum of $AlH_3.N(CH_3)_3$ in the crystal differs considerably from its spectrum in the gas, but the spectra of $AlH_3.2N(CH_3)_3$ agree. Hence it was concluded that the first compound in the crystal is dimerised, but the second is not. On comparing further the spectra in the crystal and in the concentrated solution and establishing their similarity, the authors drew conclusions about association in the solution. There are two weak spots in this approach which lead to quite unreliable conclusions. Firstly, it is not explained why associates do not appear in the spectra of moderately concentrated solutions. Secondly and mainly, there is no basis for ascribing the difference in the spectra in the crystal and the gas to associates when there is no additional information about the crystal structure, since the appearance of new frequencies and a displacement of the known frequencies can be due to the deformations of the molecules in the crystal field (this, to a certain extent, also relates to concentrated solutions). Such deformation is observed, for example, for the tetrahedral anions $Al(CH_3)_4^-$ in the field of the cations[108] in the $LiAl(CH_3)_4$ crystals. Moreover, the solid compound $AlH_3.NR_3$ sublimes comparatively readily, which would be improbable in the presence of hydrogen bonds.

Finally, association in benzene solutions of $AlH_2N(CH_3)_2$ and $AlH_2N(C_2H_5)_2$ takes place[31] most quickly due to Al–N–Al bonds by analogy with $BH_2N(CH_3)_2$, where such a structure was found by X-ray diffraction[124].

As regards the structure of the complexes in the crystalline state, here except for $AlH_3.2N(CH_3)_3$, which has been investigated by X-ray diffraction, much is not clear. Table 10 shows the frequencies of the Al–H bonds for several compounds.

$AlH_3.2N(CH_3)_3$ crystals consist of individual molecules of the complex[24] without directed bonds between them[9,16]. The spectra of $LiH.AlH_3$ crystals accord with an ionic structure in which the nodes of the lattice are occupied by tetrahedral AlH_4^- ions with Li^+ ions distributed between them[77]. Possibly there is some distortion of the regular tetrahedral form of the anion in the field of the cation[93], like that observed in $LiAl(CH_3)_4$,[108] and responsible for some complication of the spectrum observed in later investigations[9]. On the basis of a comparison of the infrared spectra of crystalline alkali metal tetrahydroaluminates, the authors[93] consider that such distortion is maximal for $LiAlH_4$ and minimal for $CsAlH_4$, with the symmetry of the former being decreased to C_{2v} owing to the formation by the lithium of covalent bonds with two hydrogens of

† Three tetrahedral sp^3-orbitals; instead of a fourth orbital, two spd-orbitals with an included angle of 71°.

the AlH_4^-. The structure of $CsAlH_4$ is thought to be much more ionic with retention of the tetrahedral structure of the anion. For $AlH_3.OC_4H_8O$ a chain structure is proposed with

$$Al-OC_4H_8O-Al-OC_4H_8O$$

bonds on the following grounds: (1) the compound is insoluble in inert solvents; (2) it does not melt; (3) the frequencies of the vibrations are close to those of the 1 : 2 complexes; and (4) in the spectrum there is no 455 cm^{-1} band, corresponding to the deformation vibrations of the dioxan ring and inactive in the infrared spectrum under

Table 10. Vibration frequencies of the M–H bond of the compounds AlH_3 in the crystalline state, cm^{-1}.

Complex	Vibration frequency	Reference	Complex	Vibration frequency	Reference
$AlH_3 \cdot OC_4H_8O$	1748	9	$AlH_3 \cdot C_4H_8O$	1802	9
$AlH_3 \cdot OC_4H_8O$	1762	16		1810	16

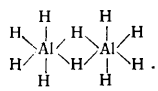
With $(C_2H_5)_2O$ as impurity.

symmetrical loading of the dioxan molecule[16]. For $AlH_3.N(CH_3)_3$ and $AlH_3.C_4H_8O$ association due to hydrogen bridges is proposed, based on the work[9,16] and their criticism given above. To the critical remarks it must be added that the breadths of the absorption bands in all the instances in Table 10 except AlH_3 are similar. On the other hand the absorption band of AlH_3 is very wide and no narrower than the corresponding bands in $(R_2AlH)_3$.[118,120]

The physicochemical properties of $(AlH_3)_x$ also show its high degree of polymerisation, which is usually connected with a high coordination number of aluminium, namely, 6,[9,13,119,122] leading to the formation of a hydrogen-bridged space lattice, which can be provisionally represented in the form of the fragment:

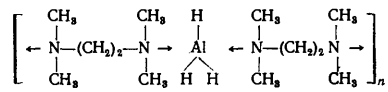


The absorption frequencies of $AlH_3.N(CH_3)_3$ and $AlH_3.C_4H_8O$ —allowing for the fact that they contain a coordinated ligand—lie too high, but for $AlH_3.N(CH_3)_3$ they are still very close to the absorption frequency in the gas (1792 cm^{-1}),[9,26] to support the formation of hydrogen bridges.

Hence it is possible to agree with certain authors[9,16] concerning the polymerisation of AlH_3 due to the formation of hydrogen bridges and to consider their existence at least non-proven in all the remaining complexes of AlH_3. The problem of the structure of the crystals of $AlH_3.LiH.C_4H_8O$ and $AlH_3.LiH.3C_4H_8O$ remains almost completely open.

This section shows rather reliably the existence of compounds of aluminium with coordination number 6, namely, for $(AlH_3)_x$; the same number exists in the complexes which have recently become well-known: Na_3AlH_6 [65,91] and Li_3AlH_6.[82] Six-coordination also may occur in solutions of $AlH_3.MH$ in tetrahydrofuran and diglyme and in a liquid mixture of composition $AlH_3.LiH + 3C_4H_8O$ where the Al–H absorption band is displaced[16] to 1674 cm^{-1}. Most probably, however, it does not exceed 5. In this connection it is interesting to note the remarkable similarity in the structure of the spectra of solutions of $AlH_3.LiH$ in THF and of gaseous $AlH_3.2N(CH_3)_3$ (see Table 11).

However, when the ligand entering the complex is bidentate polymerisation is possible for complexes of AlH_3. Polymeric structures which are well-founded are proposed[10] for complexes of AlH_3 with diamines[10,97]. Thus, a structure with a unit cell containing eight dimeric units:



has been given[10] for the complex of AlH_3 with tetramethylethylenediamine.

The high melting points and sublimation temperatures of such complexes and their thermal stability[10,37] also confirm the presence of a polymeric structure. There is probably an analogous structure in the complex of AlH_3 with triethylenediamine[38].

Table 11. Spectrum of a solution of $AlH_3.LiH$ in tetrahydrofuran[16] and of gaseous $AlH_3.2N(CH_3)_3$.[9,26]

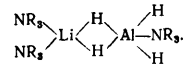
1674	1709
895	894
763	793
426	727
416	460

Polymerisation due to ligand has also been proposed for the complex $AlH_3.OC_4H_8O$.[9,16] The complexes $AlH_3.NC_5H_5$,[36] $AlH_3.LiH.N(CH_3)_3$,[88] $AlH_3.NaH.C_4H_8O$,[108] and $AlH_3.LiH.3N(CH_3)_3$[88] are ascribed a structure based on general considerations and chemical properties. It is thought that in these compounds the aluminium has coordination number five and that in the first three complexes the ligand is coordinated by aluminium whereas the last has the structure



Further investigations are needed to establish the complete structure of these compounds.

V. ELECTROCHEMISTRY OF SYSTEMS CONTAINING ALUMINIUM HYDRIDE

1. Electrical Conductivity of Solutions of $MAlH_4$

To show the nature of solutions of hydroaluminates and to make electrochemical preparations information about the electrical conductivity of such systems is needed. The published data are very limited and contradictory.

Solutions of $LiAlH_4$ in diethyl ether have a very low electrical conductivity; κ for a 1 M solution at 15°C is $(4.43 \pm 0.02) \times 10^{-5}\ \Omega^{-1}\ cm^{-1}$,[125] κ for ethereal solutions of $LiAlH_4$ is less by a factor of ~ 2.5 than for such solutions

of $LiClO_4$.[126] The relation between the electrical conductivity of $LiAlH_4$ solutions and their purity has also been noted[127]. The variation of the electrical conductivity with the $LiAlH_4$ concentration is shown in Fig. 1, curve *a*,[127] and agrees in order of magnitude with other results[125]; however, in another study[126] κ is approximately an order

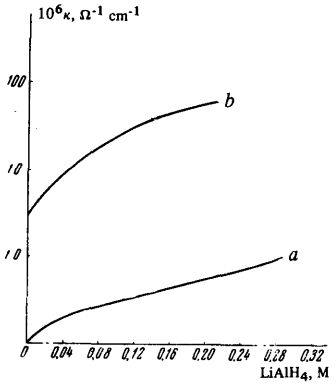


Figure 1. Variation of the electrical conductivity, κ, Ω^{-1} cm^{-1}, with the $LiAlH_4$ concentration: *a*) in pure diethyl ether; *b*) in diethyl ether containing 0.394 M AlH_3.

of magnitude less. Curve *b* shows the variation of κ with $LiAlH_4$ concentration in the presence of AlH_3. Here κ is greatly above the additive value, as with MHal–AlR_3 systems[128]. It is also interesting that the electrical conductivity of ethereal solutions of $LiAlH_4$ and AlH_3 at the same concentrations is similar[127].

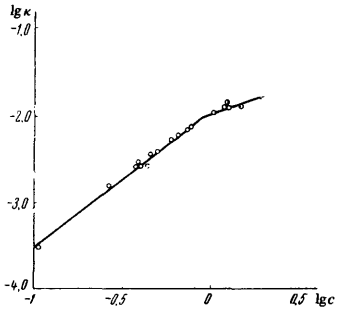

Figure 2. Variation of the electrical conductivity, κ, Ω^{-1} cm^{-1}, of a solution of $LiAlH_4$ in tetrahydrofuran with the concentration *c*, M.

The electrical conductivity of solutions of $LiAlH_4$ in tetrahydrofuran has been measured over the concentration range 0.1–1.5 M at $t = 25° \pm 0.5°C$ (Fig. 2).[129] It was found that such solutions are quite stable even in contact with platinum electrodes.

The variation of the molar conductance with concentration (Fig. 3) does not obey the Ostwald dilution law for weak electrolytes.

Solutions of $NaAlH_4$ in tetrahydrofuran also have high electrical conductivity: $\kappa = 2 \times 10^{-2}\ \Omega^{-1}$ cm^{-1} at $c = 3$ M and 40°C (for 1 mole KCl per dm^3 water $\kappa = 1.10 \times 10^{-1}\ \Omega^{-1}$ cm^{-1} at 25°C [130]).

The electrical conductivity of solutions in tetrahydrofuran greatly exceeds that of solutions in diethyl ether. This is probably because the latter is a weaker complexing agent than tetrahydrofuran in relation to $MAlH_4$, although some effect must be due to the somewhat greater dielectric constant of tetrahydrofuran (7.87) compared with that of diethyl ether (4.34). However, the degree of dissociation of $LiAlH_4$, even in tetrahydrofuran is always small and amounts to 1–10%, which can be estimated from the ebullioscopic value of the molecular weight 38 ± 1 (calculated value 38)[83] and the value of κ on making reasonable assumptions about the mobility of the ions in tetrahydrofuran.

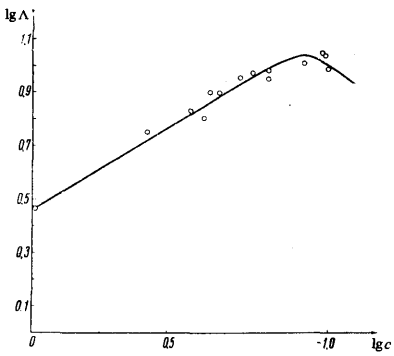

Figure 3. Variation of the molar conductance, Λ_m, Ω^{-1} cm^2 mole^{-1}, of a solution of $LiAlH_4$ in tetrahydrofuran on the concentration, *c*, M.

Most authors assume that $LiAlH_4$ in diethyl ether dissociates into Li^+ and AlH_4^-.[40,125,126,131] However, such a scheme is hardly correct for solutions in tetrahydrofuran. An anomalous dependence of molar conductance[129] of $LiAlH_4$ on concentration‡ can be explained by the complex interaction of the particles of the solute with one another[132,133] or with solvent. The hypothesis of complex formation, probably with participation of the solvent, is confirmed by the fact that the electrical conductivity of dilute solutions of $LiAlH_4$ in tetrahydrofuran has a negative temperature coefficient[129], which could be connected with the breakdown of the compounds formed on raising the temperature. At high concentrations of lithium tetrahydroaluminate in tetrahydrofuran the temperature coefficient of electrical conductivity is greater than zero[129]. Possibly here the increase in electrolytic dissociation of the complexes with rise in temperature exceeds the effect of the breakdown of the complexes into components. On the grounds that the reduction of covalent chlorides (PCl_3, BCl_3, etc.) by lithium tetrahydroaluminate takes place only in the presence of donor solvents, some authors consider that the further dissociation

$$AlH_4^- \rightleftharpoons H^- + AlH_3$$

‡ An increase in molar conductance on increasing the concentration is also observed in solutions of $NaAlR_4$ in diethyl ether (R = alkyl)[84].

is possible[82,125]. The role of the donor here consists in the shift of the equilibrium to the right owing to the bonding of AlH_3 in the complex. It has also been suggested that ethereal solutions of $LiAlH_4$ possibly contain the cations AlH_2^+,[82,134] by the further dissociation

$$2AlH_3 \rightleftharpoons AlH_2^+ + AlH_4^-.$$

The scheme for the breakdown of AlH_4^- with the formation of H^- and AlH_3 seems improbable for energetic reasons although the dissociation of AlH_3 in ether by itself evidently takes place[3]. The latter is confirmed by the conductance of ethereal solutions of AlH_3 (for ~ 0.4 M solution, $\kappa = 3 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$).[127] For reasons stated in relation to the compounds $MAlR_4$ (R = alkyl or halogen)[3] it appears that dissociation of $LiAlH_4$ to the H^- ion does not take place. Dissociation with the formation of H^- has also been rejected in another study[135], where the AlH_4^- ion is considered to be the reducing agent. An increase in the reducing ability of $LiAlH_4$ under the influence of donor solvents should evidently be connected with the formation of $LiAlH_4$ complexes which are more active reductants.

The anions AlH_4^- in an ethereal solution of $LiAlH_4$ are probably only slightly solvated in agreement with the instability of the ethereal complexes of $LiAlH_4$ (Table 4) and with the relatively large size of the AlH_4 ion[40] (r = 2.45 Å, calculated on the Al–H distance of 1.66 Å) and also with the absence of a change in breadth and position of the absorption bands of AlH_4^- in the spectra with change of concentration[77,110]. The Li^+ ions in an ethereal solution of $LiAlH_4$ are thought to be strongly solvated[53]. This accords with the weakening of the ether CO absorption bands in the Raman spectra of such solutions[77].

The greater-than-additive values of the electrical conductivity of ethereal solutions of $LiAlH_4$ mixed with AlH_3 (Fig. 1) shows the formation of alternative ions to those arising from $LiAlH_4$ and AlH_3 separately. In accordance with this[3,136] and by analogy with observations on MHal–AlR_3 systems, it is natural to suggest the formation of $MAlH_4.nAlH_3$ complexes or polyhydroaluminates, in particular, heptahydrodialuminate, $LiAl_2H_7$. The dissociation of such complexes should lead to the formation of polyhydrodialuminate ions:

$$LiAl_2H_7 \rightleftarrows Li^+ + Al_2H_7^-$$

and in view of the larger anions the degree of dissociation and consequently the electrical conductivity should exceed the corresponding values for $LiAlH_4$ and AlH_3§.

The relatively high values of the electrical conductivity for the complexes $LiAlH_4.nAl(C_2H_5)_3$ (n = 2–4) and the rise in conductivity with increase in the number of ligand molecules (Ref. 69, see Table 4) also support the hypothesis of the formation of $LiAlH_4.nAlH_3$ in mixtures of $LiAlH_4$ and AlH_3.

2. Electrode Processes

Claisen's patent deals with the electrolysis of solutions of $NaAlH_4$ and $Ca(AlH_4)_2$ in tetrahydrofuran. Mercury was used as cathode and an aluminium rod as anode. During electrolysis sodium amalgam formed on the cathode and AlH_3 accumulated in the solution but at the anode (according to the authors) hydrogen is released by the overall reaction

$$NaAlH_4 \rightarrow Na_{amal} + AlH_3 + \tfrac{1}{2}H_2.$$

It is thought[6] that the accumulation of AlH_3 in solution is accompanied by the formation of the complex $NaAl_2H_7$:

$$2\,NaAlH_4 \rightarrow Na_{amal} + NaAl_2H_7 + {}^1/_2H_2.$$

After the saturation of the electrolyte with the products the "pure" AlH_3 starts to be precipitated. By the term "pure" the author evidently understands AlH_3 free from chloride impurities, as distinct from the hydride obtainable by a chemical method[12]. For the production of unsolvated AlH_3 by this method the hydride cannot be freed completely from impurities, as is evident from the work described earlier. Therefore a similar electrochemical process has no advantages in comparison with the usual chemical preparation.

Information was recently published on the electrolysis of a solution of $NaAlH_4$ in tetrahydrofuran[137]. Several different metals and low-resistance or p-type Ge and Si have been used as anodes, platinum as cathode (Table 12).

Table 12. Behaviour of a series of anions in $NaAlH_4$ + C_4H_8O.

Anode	Current density, mA cm^{-2}	Current efficiency, %	Gas evolution
Mg	9	70	+
Ga	15	100	—
Si	15	124 (Si^{4+})	—
Ge	10—18	13	+
Na	10	not determined	—
Pt, Cu, Hg, Zn	15—22	0	+

Even from a purely qualitative examination of the anodic dissolution of metals it is clear that a sharp difference exists not only between the "noble" and strongly electropositive metals but also between the latter, for example, Mg and Zn. The existence of "free" ions of polyvalent metals in solution is improbable since they tend to form complexes. Moreover, if it is assumed that the initial electrode act is the discharge of AlH^- ions or molecules of $NaAlH_4$ [sic], the atomic hydrogen liberated could form hydrides with the electrode metal. There is therefore a definite probability that in the anodic dissolution of metals hydrides or hydroaluminates of the corresponding metals will be formed. In this connection it is interesting to compare certain properties of these compounds with the ability of the corresponding metals to dissolve during anodic polarisation in solutions of $NaAlH_4$ or $LiAlH_4$ in ethers (Table 13)[134].

By analogy with the solubility of sodium and lithium tetrahydroaluminates it can be suggested that the tetrahydroaluminates of Mg, Ga, and Be are soluble in tetrahydrofuran. Silicon and germanium hydrides are gases and if soluble in ethers the solubility is insignificant. On comparing these results with Table 12 on electrolysis, clearly anodic dissolution occurs for those metals the hydrides or tetrahydroaluminates of which are soluble in the solvent concerned. With germanium the products of

§ After writing this review we learnt that G.Schrauzer (Thesis, Munich, 1956) found an increase in the molar conductance of solutions of alkali metal tetrahydroaluminates with increase in concentration and the electrical conductivity of solutions of $LiAlH_4$ in tetrahydrofuran exceeded the value for a corresponding solution in diethyl ether. He also considers that the dissociation scheme

$$2AlH_3 \rightleftharpoons AlH_2^+ + AlH_4^-$$

is possible.

the anodic dissolution can be removed as gases. With silicon the problem remains unresolved since little gas is released during electrolysis but on the surface a red-brown film forms; this film rapidly turns white and crumbles in air, disclosing a smooth etch surface. Hence, if the proposed hypothesis about the connection of the anodic dissolution of metals with the solubility of their hydrides or hydroaluminates is true, then it could be expected that in this electrolyte not only the metals listed would be soluble, but also Be and Al. The latter was negated by Claisen's results[6], for he did not observe the anodic dissolution of aluminium. However, it should be noted that the patentee did not measure the current efficiency in respect of the metal but the gas liberated, and firstly it is easy to confuse with the boiling of the solvent at the surface of the electrode, and secondly gas liberation is usually observed at the start of electrolysis during the breakdown of the surface film of oxide on the metal.

The process for soluble anodes can then, with some reliability, be described by the equation:

$$M + n AlH_4^- - ne \rightarrow n AlH_3 + MH_n$$

where M is the metal of the anode. It should be noted that the final products of the anodic reaction may be not only the hydride but also $M(AlH_4)_n$. The probability of the formation of the latter depends on its physicochemical properties.

Table 13. Properties of the hydrides and tetrahydroaluminates of certain elements.

Element	$M(AlH_4)_n$	Decomposition temperature, °C	Solubility in $(C_2H_5)_2O$*	MH_n	Decomposition, temperature, °C	Solubility in $(C_2H_5)_2O$*
Mg	$Mg(AlH_4)_2$	~140	+	MgH_2	>200	+
Ga	$Ga(AlH_4)_3$	0	+	GaH_3	>35	+
Al				AlH_3		+
Be	$Be(AlH_4)_2$	>room	+	BeH_2 or $BeH_2 \cdot LiH$	>room	—
Si				SiH_4		
Ge				GeH_4		
Cu				CuH	>60	—
Hg				HgH_2	—125	—
Zn				ZnH_2	90	—
Ag	$AgAlH_4$	—50	—			
Cd				CdH_2	—20	—
In	$In(AlH_4)_3$	>—40	—	InH_3	80	—
Sn	$Sn(AlH_4)_4$	—40		SnH_4		

* + = soluble.
- = insoluble.

At insoluble anodes during the electrolysis considerable evolution of gas is observed, which shows the discharge of hydride ions (molecules). Therefore in this example the anodic process is simpler and can be described by the equation:

$$AlH_4^- - e^- \rightarrow AlH_3 + \tfrac{1}{2}H_2.$$

The electrolytes considered here are extremely complex. Therefore, despite the experimental difficulties further information is necessary, since the mechanism of the reaction can change sharply according to the nature of the anode material. In addition the study of kinetics at insoluble anodes can give interesting information on the hydrogen overpotential for the discharge of hydride ions.

3. Synthesis of polypeptides on polymers in the liquid phase 118

I. INTRODUCTION

The synthesis of polypeptides is not only one of the present theoretical problems but also a great scientific task and a great economic undertaking. During the last decade in several countries the synthesis of the less complex polypeptides has become attainable not only in laboratories but also on the industrial scale. These are mainly such important biologically active peptides as the hormones oxytocin and vasopressin, which are now easier to synthesise than to isolate from natural sources. The artificial peptide synthesis was developed so that a few years ago three groups of investigators: Katsoyannis and coworkers[1] (USA), Zahn and coworkers[2] (Federal Rupublic of Germany), and Tsou, Wang, and their coworkers[3] (People's Republic of China) succeeded in synthesising the first simplest protein —the hormone insulin, which consists of 51 amino-acids. The complete synthesis of this hormone was effected in 221 stages. This is indeed a great achievement, which itself characterises the modern level of development of peptide synthesis. However, every synthetic chemist knows very well that the multi-stage nature of a synthesis leads to a sharp drop in the yield of the final compound. Thus it is easy to calculate that in carrying out a twenty-stage synthesis with an 80% yield at each stage, the yield of the final product is only 1.2%. In the example of the synthesis of insulin, where the yields were not 100%, the inadequacy of the existing arsenal of methods of peptide synthesis appeared especially sharply.

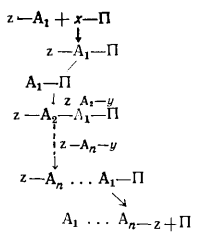
The formation of the peptide bond is only part of the task. A more important obstacle is the purification of the peptide product from impurities formed during the course of the synthesis and which usually have properties very similar to those of the main product. Moreover there is a series of difficulties connected with the low solubility of the peptides in organic solvents, which decreases with increase in the number of amino-acid residues in the molecule. All this placed on the agenda the problem of the creation of more up-to-date methods of synthesising polypeptides. In recent years a way, new in principle, of overcoming the above difficulties has appeared—the construction of peptide chains on three-dimensional polymers in the solid phase and on linear polymers in solution.

II. SYNTHESIS OF POLYPEPTIDES ON POLYMERS

1. Essentials of the Method

In 1959 Merrifield started to develop a new method of synthesising peptides on polymers in the solid phase with the aim of the standardisation and automation of the process. After three years the first report about progress along these lines appeared[4]. Later the synthesis of peptides on polymers was also effected in the liquid phase. The principle of the method is that the first amino-acid $z-A_1$ is attached by a covalent bond to a polymer П. Then amino-acids A_2, A_3, ..., A_n are attached successively to this "anchor" amino-acid. The prepared peptide $z-A_n \ldots A_1-П$ which is formed is separated from the polymer by breaking the peptide–polymer covalent bond at the very end of the synthesis (see Scheme 1, where П is the polymer, z a protective group, A_1, ..., A_n are amino-acids, and x and y are activating groups).

Scheme 1



In the solid-phase synthesis, owing to the insolubility of the peptides attached to the polymer their purification from the starting materials and side-products, even if these impurities are of low solubility, is easily performed by washing with appropriate solvents without danger of loss of peptide. This greatly simplifies the synthesis, shortens the time for carrying out the reaction, and facilitates the purification of the products, so that the standardisation and automation of the processes become possible. The solid phase synthesis allows up to six amino-acid residues to be introduced into a peptide in 24 hours. On using an excess of amino-acid at each stage of the formation of a peptide bond the yield of the peptide usually approaches 100%. Hence the solid-phase synthesis is characterised by simplicity of operation, rapidity, high yields, and the purity of the final products. The synthesis of peptides in the liquid phase on polymers has certain significant differences. Firstly, all the components of the reaction at the time of the synthesis are in the dissolved state but the purification of the polymer–peptide is usually effected by washing free from side-products with water. Secondly, the condensation of amino-acids into peptides is carried out by other methods. In the last stage the peptide separated from the polymer is transferred to an aqueous phase and the polymer remains in an organic layer.

As noted in the very first studies of Merrifield[4,5], the general Scheme 1 is applicable not only to the synthesis of peptides but also to the synthesis of other classes of polymers. Thus, for polynucleotides the individual unit A can be a protected mononucleotide, and for polysaccharides an appropriate protected monosaccharide, etc.

2. Synthesis of Polypeptides on Polymers in the Solid Phase

a. The polymer. In the initial period of the development of the method of peptide synthesis in the solid phase, Merrifield[4,5] carried out considerable work on the selection of a suitable polymer. He tried cellulose, poly-(vinyl alcohol), polymethacrylate, sulphonated polystyrene, and partly chloromethylated copolymer of styrene with 2% divinylbenzene (PSDB–CH_2Cl) which seemed the most suitable for this purpose. Firstly, this polymer is completely insoluble in all the organic solvents used in the synthesis, including neutral, acid, and basic solvents, and at the same time it swells sufficiently in them, which predetermines a rapid penetration of the reagents into the pores of the polymer. Secondly, this polymer has, when swollen, a consistency that is stable and suitable for filtration. Moreover, it contains a functional group capable of reacting with the carboxyl group of the amino-acid or peptide to form an "anchor" covalent bond, which can be split selectively at the end of the peptide synthesis.

b. Protective group and solvent. The success of the synthesis of polypeptides on a polymer basis depends greatly on the choice of a suitable protective group for the amino-acid and of a solvent. In the first studies Merrifield[4,5] protected the amino-components with the benzyloxycarbonyl group (Cbz)†,[6] which is well-known in peptide synthesis and sufficiently readily removable[6]. However, he noted that treatment with hydrogen bromide in glacial acetic acid did not detach all the Cbz groups and that increasing the reaction time led to breaking of some of the "anchor" peptide–polymer ester bonds. For these reasons peptides with shorter chains are formed as impurities and some of the peptide chains are lost. Consequently, it would be necessary either to strengthen the "anchor" benzyl ester bond or to use a more readily removable protective group. Merrifield[4,5] at first followed the first path. For this purpose PSDB–CH_2Cl polymer was nitrated or brominated. As a result of this the loss of peptide due to rupture of the "anchor" benzyl ester bond at the time of removal of the Cbz group became minimal, but the rate of removal of the Cbz groups decreased considerably, especially for the nitrated polymer. On the other hand the polymer–amino-acid bond was strengthened so much that hydrogen bromide in acetic acid had no action on it. Therefore the final peptide was removed from the nitrated polymer by alkaline hydrolysis, and this could lead to a particularly undesirable feature—some racemisation of the peptide. In its properties in peptide syntheses bromination of the polymer occupied an intermediate position.

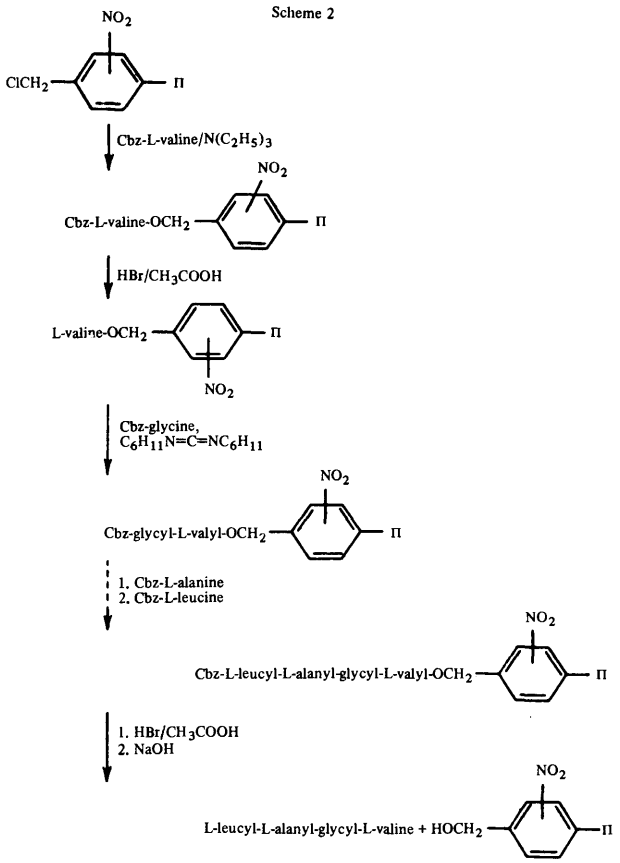
The best solvents in the solid-phase synthesis are dimethylformamide (DMF) and methylene chloride[5], as was shown in studying the synthesis of the tetrapeptide L-leucyl-L-alanyl-glycyl-L-valine on nitrated partially chloromethylated PSDB polymer (Scheme 2, p. 116).

The "anchor" amino-acid Cbz-L-valine was attached by a covalent bond to nitrated PSDB-CH_2Cl polymer by the action of its triethylammonium salt in a suitable solvent; then the protective Cbz group was removed with 10% HBr in acetic acid[7]. After removing all the impurities by washing, DMF was introduced as the best solvent in this synthesis together with Cbz-glycine and the condensing agent, *NN'*-dicyclohexylcarbodi-imide (DCCD). At room

† Cbz is the accepted biochemical abbreviation for the benzyloxycarbonyl (or carbobenzoxy) group (Ed.of Translation).

temperature the reaction lasted 0.5 h. All the side-products, including *NN'*-dicyclohexylurea, were removed by washing with solvents and the Cbz groups were removed as described above. In this cycle the peptide chain is lengthened by one amino-acid. By repeating analogous cycles with Cbz-L-alanine and Cbz-L-leucine the tetrapeptide mentioned above was obtained and was removed from the polymer by hydrolysis with alkali[5], during which partial racemisation of the peptide occurred.

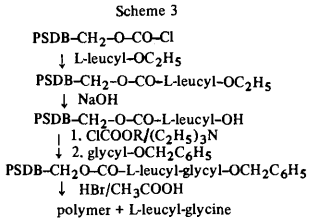
Scheme 2



c. Development of the method. Letsinger and coworkers[8,9] proposed another scheme for the synthesis of peptides in the solid phase. They synthesised a copolymer of styrene with 0.5% divinylbenzene with functional groups which were capable of attachment to the first amino-acid at not the carboxyl, but the amino-group (Scheme 3). This offered the possibility of growing a peptide chain at the unsubstituted carboxyl group of the "anchor" amino-acids by the usual methods. The dipeptide L-leucyl-glycine was obtained in this way.

As we have seen, the strengthening of the "anchor" benzyl ester bond of the polymer–amino-acid did not lead to the desired results. Therefore Merrifield[10] subsequently rejected this path and started to use, instead of a Cbz group, a more readily removable protective group—t-butoxycarbonyl (t-Boc) was introduced into peptide chemistry by McKay and Albertson[11]. In this the solid-phase method not only received a thorough check but was also developed considerably[10,12]. For example, in the synthesis of bradykinin, obtained earlier, particularly by Boissonnas and coworkers[13], polyfunctional amino-acids were included which had been used earlier in solid-phase synthesis: arginine, serine, and proline[10,12]. The solid phase was partly chloromethylated, not nitrated and not brominated, PSDB polymer (Scheme 4). Thanks to the ease of removal of the t-Boc protective groups (1 *N* HCl in acetic acid) the loss of the intermediate peptides was minimised. The use of an excess of t-Boc-amino-acid in the stage of the formation of the peptide allowed the yield of the peptide to be increased and the acetylation with acetic anhydride after each reaction for the formation of the peptide bond previously employed[4,5] to be omitted.

Scheme 3



The final nonapeptide, bradykinin was removed from the solid phase by Gutman and Boissonnas[14] by the action of HBr in trifluoroacetic acid. Note particularly that the synthesis of bradykinin was effected in a special glass apparatus fitted with a system of automatically acting sensors for the initial substances and solvent[15–17]. As a result of the automation of the synthesis the total time required for each cycle was reduced to four hours and the yield of peptide was increased. Thus pure bradykinin with complete biological activity was obtained in 32% yield after 8 days,[10] and in later work[12] in which methylene chloride was used instead of DMF as the solvent, the yield of bradykinin reached 68%.

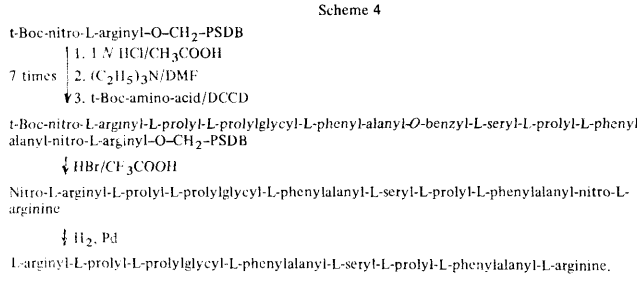
Subsequently Lenart and coworkers[18,19] proposed to remove the prepared bradykinin from the polymer with dry liquid HF in an excess of anisole. In addition to breaking the peptide–polymer ester bond this also removed the NO_2 groups from arginine.

In seeking antagonists for bradykinin, Stewart and Woolley[20,21] used the automatic synthesis of peptides in the solid phase and within an extremely short time obtained 23 analogues of it, including a bradykinin consisting of D-amino-acids. In a completely analogous manner Merrifield[22] added L-lysine and L-methionine to PSDB–CH_2–O–bradykinin and obtained in 65% yield the chemically pure undecapeptide L-methionyl-L-lysyl-bradykinin, with the complete biological activity of natural kinin. During the synthesis the ϵ-amino-group of lysine was protected with a Cbz, not a t-Boc, group. Alkylation of the sulphide group of methionine with the benzyl bromide formed in the action of HBr in CF_3CO_2H on the Cbz group and *O*-benzylserine was avoided by the presence of ethyl methyl sulphide.

The possibility of including any amino-acid in the peptides was of enormous importance for confirming the general applicability of the new method. With this aim general Scheme 4 was used to synthesise in 56% yield the octapeptide 5-isoleucyl-angiotensin II, which exhibits complete biological activity of the natural material, and twice that of

its analogue[23], and also a hexapeptide[24] in which were successfully included four amino-acids not used earlier in the solid-phase synthesis: asparagine, histidine, isoleucine, and tyrosine. It was shown clearly[24] that if the formation of nitriles is avoided[25] asparagine can be added not by the carbodi-imide method but by Bodanszky's nitrophenyl ester method[26], although this method was rejected by Merrifield after some failures[4,5]. This was confirmed by Bodanszky and Sheehan[27], who found that the nitrophenyl ester method can be used on a par with the carbodi-imide method of amino-acid condensation in solid-phase peptide synthesis. True, they did not give any experimental results in support of this. Merrifield's review[28] of the automatic synthesis of peptides considers not only the carbodi-imide but also Nefkens' hydroxyphthalimide method[29] to be applicable and, exceptionally, in some instances Bodanszky's nitrophenyl ester method[26].

Scheme 4



Rothe[30] recently published a brief communication stating that he had succeeded in synthesising, on the basis of a Merrifield solid carrier (true, not automatically), a linear oligomer consisting of 14 monomers of ϵ-aminohexanoic acid. Kusch[31,32] gives more detailed information on the synthesis in a solid polymeric phase of a whole series of analogous linear oligomers of hexamethyleneadipic acid amide:

H–[B–A]–OH, where n = 2–5, and 10,

ω-aminoundecanoic acid:

H(Und)–OH, where n = 2–5 and 10,

and ϵ-aminohexanoic acid:

H–(Cap)–OH, where n = 4 and 8,

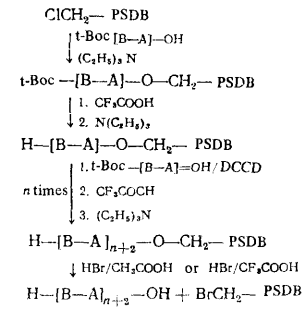
according to Scheme 5, analogous to the general scheme for synthesis on polymers.

The accumulated experience on the synthesis of peptides on solid carriers allowed Marglin and Merrifield[33] to obtain in sufficiently high yields the A and B chains of insulin in 8 and 11 days respectively. However, completely synthetic insulin exhibited insignificant biological activity, since the A chain contained a racemic asparagine residue.

Considerable difficulties are encountered in including in the peptide chain not only asparagine but also serine and also in the removal of *S*-protected groups in peptides. All these problems which arise in the synthesis of long peptides on carriers were discussed in September 1966 in the Netherlands at the Eighth European Symposium on peptides.

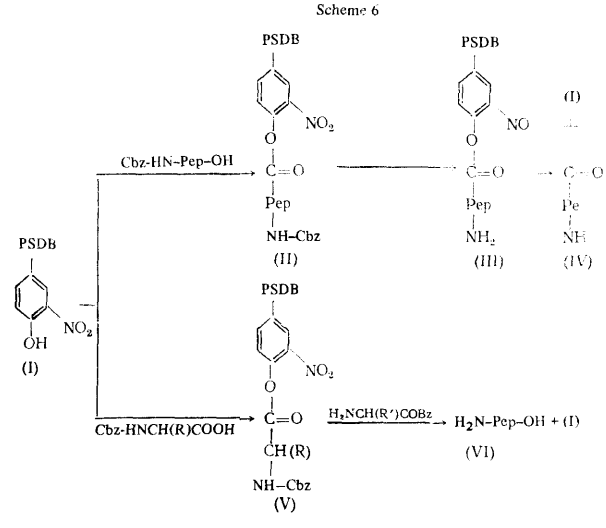
As Katchalski and coworkers showed[34], not only linear but cyclic compounds can be synthesised in the solid phase on polymers. For this purpose poly-(4-hydroxy-3-nitrostyrene) cross-linked with divinylbenzene (I) was obtained, and its active hydroxyl groups were used for preparing high-molecular-weight activated esters of *N*-substituted peptides (II) (Scheme 6).

Scheme 5*



* –A– = –OC.[CH_2]$_4$.CO–;
–B– = –NH.[CH_2]$_6$NH–;
–Cap– = –HN.[CH_2]$_5$.CO–;
–Und– = –HN.[CH_2]$_5$CO–.

Scheme 6



A high yield of activated ester (II) was obtained only on using at least a triple excess of Cbz–HN–Pep–OH‡ and DCCD. After removing the protective Cbz group the formation of the cyclopeptides (IV) occurred, due to intramolecular aminolysis of the ester bond. This method of cyclisation seemed better than the earlier ones since the final cyclopeptides are obtained pure and in higher yields (60–80%).

Polymer (I) (Scheme 6) can be considered as a chemical reagent-activator which is capable of forming with the carboxyl groups of amino-acids or peptides insoluble activated phenyl ethers (II) and (V). Being activated, the

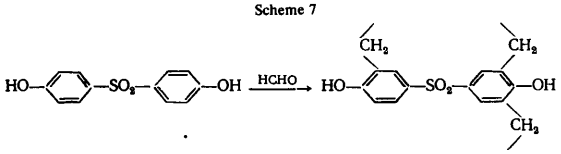
‡ H_2N–Pep–OH is a peptide.

latter can react with compounds which contain unsubstituted amino-groups to form a peptide bond. These considerations were checked experimentally by Katchalski and coworkers [35], and from the insoluble esters (V) Cbz-L-phenylalanine, Cbz-L-proline, etc. were obtained with glycyl–OBz§, S-Cbz-L-cystylglycyl–OBz, etc., the linear peptides (VI) were obtained. At the time of the reaction for the formation of peptides (VI) the initial polymer (I) was liberated and was easily separated from the peptide by centrifuging. By removing the Cbz protective group from the peptide (VI) obtained, it can be introduced again into reaction with the desired insoluble activated polymer with amino-acid (V). On repeating this process a polypeptide of desired structure can be obtained.

Insoluble polymers of phenolic type, one of which contained a mercapto-group in the benzene ring, were made by Shchukina and coworkers [36] and were successfully used for constructing a peptide chain according to Scheme 6.

Wieland and Birr [37] proposed to activate the carboxyl groups of amino-acids with a polymer of phenolic type obtained by the polycondensation of bis-(*p*-hydroxyphenyl) sulphone and formalin according to Scheme 7.

Scheme 7



This insoluble polymer was used to activate Cbz-glycine, t-Boc-L-alanine, etc., which were then used in condensation with the methyl esters of L-phenylalanine and L-valyl-L-phenylalanine.

On detailed examination of all the papers on the synthesis of polypeptides in the solid phase it is easy to note the principal differences in the methods of utilising the polymer phase. In some instances the polymer plays the simultaneous part of a protective group and a peptide carrier from which it is separated at the end of the synthesis, in others the polymer serves as an activating medium and participates in the formation of an amide bond. In the synthesis of peptides by the first path the products were purified by washing the polymer–peptide with solvents and at the end of the synthesis the peptide removed from the polymer was purified in the usual manner. In the second instance the purification of the peptide is possible after any stage, since the peptide which is formed is free from the polymer and present in solution. The synthesis of peptides in the solid phase by the first path, named rightfully after Merrifield, has been greatly standardised and automated. The use of phenol-type polymers for the synthesis of peptides has only started, as we have seen, and will evidently attract even greater attention from investigators in the future.

3. Synthesis of Polypeptides on Polymers in the Liquid Phase

The first studies on the synthesis of peptides on polymers in the solid phase showed certain deficiencies of the method. As we have seen, it can used only when all the reactions are completed rather rapidly and with quantitative yields, since otherwise the final polypeptides separated from the polymer base will be contaminated by peptides of lower molecular weight which are difficult to separate. In turn the rate of formation of peptide bonds and the size of the peptide depends on the permeability of the polymer by amino-acids, peptides, condensing agents, etc. This property is very specific for every concrete instance taken and depends on a series of factors, often not predictable.

With the aim of surmounting the above drawbacks of the solid-phase method, Shemyakin and coworkers [38] proposed the synthesis of polypeptides on linear polymers in the liquid phase. Here the polymer and the growing peptide chain attached to it, just as all the agents, are found in the dissolved state. Partially chloromethylated polystyrene was chosen as the polymeric base (scheme of synthesis analogous to Scheme 2). t-Boc-glycine was attached to it by an ester bond. Then a peptide chain was constructed at room temperature by the method of hydroxysuccinimide esters of t-Boc-amino-acids [39] in DMF. The removal of the excess of the agents and impurities was carried out by washing the precipitated polymer with water and the final tetrapeptide glycyl-glycyl-L-leucyl-glycine, obtained in 65% yield, was detached from the polymer by HBr in CF_3CO_2H.

A second example of the synthesis of peptides, but already cyclic peptides, by the liquid-phase method is the work of Katchalski and coworkers [34]. They synthesised the soluble branched copolymer of L-lysine with 3-nitro-L-tyrosine in which the free amino-groups were blocked by acetylation, and the hydroxyl groups remained free, capable of forming ester bonds with *N*-substituted amino-acids or peptides. However, this polymer had one significant drawback since the high yields of Cbz-*N*-activated esters of type (II) (Scheme 6) could be obtained by using only a considerable excess of Cbz-*N*-peptide. In this connection additional difficulties were created, connected with the removal of the excess of unreacted peptides from a solution. After removing the protective group and the neutralisation of the corresponding hydrobromides an internal aminolysis took place and cyclopeptides were formed in 60–80% yield. In this way cyclo-(glycyl-glycyl), cyclo-(tetra-L-alanyl), etc. were obtained. However, these contained peptide oligomers as impurities, which were not observed in the solid-phase synthesis of cyclopeptides [34].

---o0o---

In the development of the new method of the synthesis of peptides on polymers in the solid phase the first substantial successes have been obtained. This relates especially to syntheses on PSDB–CH_2Cl polymer, with the use of which the conditions for the combination into peptides of many amino-acids have been studied, including polyfunctional amino-acids, and several linear oligomers of the nylon type have been obtained. It is remarkable that already bradykinin, methionyl-lysyl-bradykinin, angiotensin II, 5-isoleucyl-angiotensin, and several analogues of bradykinin of the L- and D-series have been synthesised. The complete biological activity of the above synthesised products of the L-series confirms the extremely important fact that racemisation does not take place during their synthesis in the solid phase. The high rate and the economic nature of the synthesis results from its considerable standardisation and automation. However, as already noted, the method also has some significant drawbacks and limitations concerning the inclusion in the peptides of asparagine, serine, the removal of *S*-protective groups,

§ Bz = benzyl.

etc. All these problems are now being solved by investigators.

As Merrifield noted[4,5], the solid-phase method allows not only peptides to be constructed on a polymer, but also other oligomers, for example, nucleotides, the first papers about the synthesis of which have already appeared[40-43]. All this suggests that the solid-phase method has enormous prospects. It helps investigators to obtain compounds of the most varied degrees of complexity, having inestimable value not only for theory but also for practice.

Owing to the insufficient information it is at present difficult to state definitely the advantages of the liquid-phase method in comparison with the solid-phase. It must be noted that good results were obtained with this method in the synthesis of oligonucleotides[44,45]. Undoubtedly further investigations in this direction will bring new valuable results.

III. Quantum-mechanical studies of conjugated compounds	124
IV. The vibrational spectra of conjugated compounds	129

I. INTRODUCTION

One of the most important problems in theoretical organic chemistry is the study of the electron density distribution in molecules. Systems with conjugated carbon–carbon bonds occupy a unique position in this problem. Modern theoretical methods of organic chemistry have been their greatest successes when applied to such molecules as polyenes, poly-ynes, aromatic systems (benzenoid and non-benzenoid), organic dyes, and cumulenes. The

phenomenon of conjugation, discovered initially by organic chemists, obtained a theoretical basis with the development of electronic theories in organic chemistry (the Robinson–Ingold concepts[1,2]) and with the application of the quantitative methods of molecular quantum mechanics (quantum chemistry). The study of conjugated compounds by the methods of quantum chemistry always shows displacement of the π-electron density from the multiple bonds to the single bonds even in the ground electronic state of molecules, and the formation of multi-centre orbitals.

Since the nineteen-thirties it has been considered that the experimentally observed physical and chemical properties of conjugated compounds confirm the conclusions regarding π-electron delocalisation, reached on the basis of quantum-mechanical considerations. The concept of delocalisation has been severely criticised, however, particularly in recent years. This criticism is to be found in its most fully developed form in papers by Dewar and Schmeising[3-5] and others[6-12]. It has been shown that many of the experimental facts previously adduced as proof of the delocalisation of π-electrons can be no less successfully explained in terms of the concept of hybridisation, which assumes that the two-centre orbitals of the valency π-electrons are preserved in linear conjugated molecules in accordance with the classical structural formulae. The characteristic features of these compounds are attributed to the differences in the properties of the carbon atoms compared with those in saturated hydrocarbons and compounds with isolated multiple bonds. Attempts have also been made to explain the properties of organic compounds in terms of polar effects and the interaction of atoms which are not joined by valency forces.

It is at present expedient, and quite justified, to regard hybridisation, delocalisation, hyperconjugation, etc. as particular "electronic effects", but it should nevertheless be borne in mind that this separation is to some extent arbitrary and is due to the impossibility of obtaining a rigorous solution of the quantum-mechanical problem for a polyatomic molecule. The above structural concepts attribute a dominating influence on the properties of molecules to one of a number of possible electronic effects. As a result, each of the existing concepts is in principle restricted and in the best circumstances can be used to examine only a definite set of properties for a comparatively narrow range of compounds.

The present review examines theoretical and experimental studies of the structure of conjugated hydrocarbons. On the basis of an analysis of published data, the authors have tried firstly to provide a picture of the electron density distribution in linear polyenes, organic dyes, polyynes, and cumulenes, and secondly to define the limits of applicability of existing concepts of the structure of organic compounds, that is, to show the influence of π-electron delocalisation, the valency state of the carbon, and the interaction of atoms which are not joined by valency forces, on the interatomic distances, bond energies, force fields, and electrical fields of conjugated molecules.

II. BASIC CONCEPTS OF THE STRUCTURE OF ORGANIC COMPOUNDS

In the concept of delocalisation, to confirm the conclusion that the π-electron density is displaced, use is made primarily of the fact that the lengths of the single bonds in polyenes and poly-ynes are much less than the lengths of the C–C bonds in the molecules of saturated hydrocarbons. A basis for comparison was provided by the benzene molecule, in which, with complete delocalisation of the π-electrons, all the carbon–carbon bonds have a length of 1.397 Å, which is intermediate between the length of the C–C bond in ethane (1.54 Å) and the length of the bond in ethylene (1.334 Å). Pauling[13], Mulliken[14], and later Coulson[15] estimated the contribution made by π-electron delocalisation to the decrease in the length of the single bonds, on the assumption that the covalent radii of the carbon in the CC and CH bonds are additive. It was found that the decrease in the lengths of the single bonds in conjugated molecules is due both to the change in the hybridisation of the carbon atoms and to the π-electron delocalisation, to almost equal extents. Dewar and Schmeising[3-5], however, suggest that the additivity rule is not observed in this instance. The decrease in the radius of the tetrahedral carbon atom (C_{sp^3}) on changing to trigonal (C_{sp_2}) and digonal (C_{sp}) is greater in C–C bonds than in C–H bonds. Dewar and Schmeising therefore attributed the decrease in the lengths of the single bonds in conjugated molecules entirely to the hybridisation of the atoms, and not to π-electron delocalisation. On this basis, delocalisation was rejected even in such molecules as butadiene and diacetylene. According to Dewar and Schmeising[4], proof of the absence of delocalisation is provided by the fact that the lengths of the C–C bonds are constant within a given hybrid type (C_{sp^3}–C_{sp^3}, C_{sp^3}–C_{sp^2}, C_{sp^3}–C_{sp}, etc.), irrespective of the nature of the nearest substituents. The observed changes in the lengths of the C–C bonds on going from one hybrid type of single bond to another are strictly proportional to the fraction of "s-character" in the orbitals of the atoms forming the bond (Fig. 1).

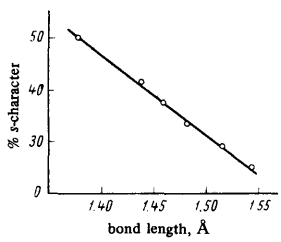

Figure 1. Dependence of bond length on the mean percentage of s-character for single C–C bonds.[4]

A remarkable feature is that the points corresponding to the central bonds of butadiene and diacetylene lie satisfactorily on the straight line. Dewar and Schmeising consider that a linear relationship would not have been expected if delocalisation had a significant influence on the lengths of single carbon bonds. Essentially analogous conclusions were reached as early as 1950 by Tatevskii[16,17], who classified carbon–carbon bonds and established that the bond lengths are constant for each type. A classification of carbon–carbon bonds according to type was also carried out by Herzberg and Stoicheff[18] using spectroscopic data. Later, linear relationships between the length of a bond of any multiplicity and the number of adjacent bonds were observed by Costain and Stoicheff[19] and Bernstein[20]. Moreover, the concept of π-electron delocalisation does not agree with a number of other familiar experimental facts, in particular the similar values found for the lengths

of central bonds with identical hybridisation in the non-planar molecules (in the vapour) of biphenyl and 4,4′-bipyridyl and the planar butadiene molecule[21,22]. Data on bond lengths in the cyclo-octatetraene molecule also do not agree with this concept. Work by Bastiansen and coworkers[23] has shown that in this molecule the single bonds are even slightly shorter than that in butadiene. Moreover, in cyclo-octatetraene (symmetry D_{2d}) the planes of the neighbouring double bonds lie at an angle of ~ 80°, so that the delocalisation of the π-electrons should be very slight, despite the fact that the molecule is an alternant hydrocarbon[24].

Mulliken[25] in his reply to Dewar and Schmeising, agrees that the additive approach to covalent radii is limited, but points out that the classification of carbon atoms in organic compounds as tetrahedral, trigonal, and digonal is also to a considerable extent arbitrary. As shown by Coulson's relationship[26], a condition for the preservation of hybridisation is that the valency angles of the carbon atom remain constant: 109°28′ for sp^3 hybridisation, 120° for sp^2, and 180° for sp. Since the valency angles often differ considerably from these values, a strict subdivision of the hybridisations of carbon into these three types is strictly speaking impossible. This feature was also pointed out by Lide[27].

According to Mulliken[25], the fact that the lengths of bonds with the same hybridisation are constant in conjugated and hyperconjugated molecules does not provide evidence against π-electron delocalisation. The observed facts contradict only the results of the quantum-chemical calculations carried out in the Hückel approximation, and they show complete agreement with the results of modern calculations carried out by various SCF MO LCAO methods[28-32]. The fact that the lengths of C–C bonds of the same hybridisation type are constant, in Mulliken's opinion, is due not to the absence of displacement of the π-electron density from the multiple bonds to the single bonds, but to the fact that the change in the degree of delocalisation in different molecules is small. Some supporters of the hybridisation concept[9-12] reject the existence of delocalisation on the basis of the fact that conjugated molecules do not show an increase in the lengths of the multiple bonds. Mulliken[25] points out that the increases in the lengths of multiple bonds on conjugation, predicted by SCF MO LCAO calculation, do not exceed the experimental errors of even the most precise measurements. Moreover, the lengths of the multiple bonds in conjugated molecules, despite electron delocalisation, may be even shorter than those in non-conjugated molecules. Calculations of overlap populations[33,34] show that the population in the C=C bonds in non-conjugated butadiene is greater than that in ethylene, and this leads to a decrease in the length of the bond; π-electron delocalisation operates in the opposite direction. Thus the double bonds in butadiene may be slightly shorter than the double bond in ethylene, slightly longer than this bond, or almost unchanged, as is in fact observed. Similar conclusions can evidently be reached for the triple bond. For cyclo-octatetraene, Mulliken[14] suggests that the length of the single bond in this molecule is determined not only by the sp^2-hybridisation of the carbon atoms, but also by first-order hyperconjugation.

These arguments are not sufficiently convincing, however. As before, it is difficult, on the basis of the concept of π-electron delocalisation, to explain at least two facts, namely, the linear dependence of the length of the C–C bond on the proportion of "s-character" and the similar values found for the lengths of C–C bonds with the same hybridisation in conjugated and non-conjugated molecules (butadiene, cyclo-octatetraene, biphenyl, etc.). On the other hand, as already noted, the hybridisation concept contradicts the data obtained in all quantum-mechanical studies of conjugated molecules. Dewar and Schmeising[3,4] doubt the reliability of the results of earlier calculations. In their opinion, the increased π-electron density on a single bond, for example in butadiene, is obtained because no allowance was made for the tendency of the electrons to lie on different sides of the nodal plane. A partial correlation related to this tendency is made in calculations by the Pariser–Parr method[35,36], and by Moffit's method[37,38] of atoms in a molecule, by the introduction of empirical corrections into the interelectronic repulsion integrals. The results of calculations for butadiene[28-31] by the methods of Pariser and Parr and Moffit[32,35-37], however, agree with the results of calculations for this molecule carried out by other methods[32-34], indicating that these effects play a secondary role. Moreover, direct calculation with allowance for vertical correlation, carried out by Dewar himself[39] by the split p-orbital method which he developed, gave bond orders for the bonds in butadiene which were very close to the values obtained by the SCF MO LCAO methods[28-31]. Calculations for butadiene by an improved valency bond method, carried out recently by Coulson and coworkers[40], also gave a similar result. Thus the various methods of quantum chemistry are unanimous regarding the problem of π-electron delocalisation in systems of the butadiene and diacetylene type. This however does not yet solve the problem of the lengths of carbon–carbon bonds in organic molecules.

In addition to these two views regarding the reasons for the changes in bond lengths, other ideas have been put forward. For example, Bartell[41-43], opposing both Mulliken and Dewar, considers that the concepts of π-electron delocalisation and hybridisation have no independent significance. In Bartell's opinion, the changes in bond lengths can be attributed to the interaction of atoms which are not joined by valency forces. Bartell considers that evidence in support of his view is provided by the existence of a linear relationship between the length of a C–C bond and the number of nearest substituents in accordance with the change in non-bonded repulsion[43]. The large amount of theoretical and experimental material which has now accumulated, however, shows that interaction between atoms which are not joined by valency forces is not the chief factor determining the lengths of carbon–carbon bonds. Here, reference must first be made to Kitaigorodskii's studies[44-48] of the conformation of organic molecules, carried out over many years. In the mechanical model used for conformational calculations, it is assumed that the optimal conformation is established as a result of a compromise between the tendencies of the molecule on the one hand to keep the values of the valency angles close to the ideal values (109°28′, 120°, and 180° for the sp^3, sp^2, and sp valency states of carbon respectively) and on the other hand to bring the atoms which are not joined by valency forces into equilibrium states. The lengths of the bonds are considered to be absolutely fixed. This approach leads to very good agreement between the calculated and real conformations for a large number of complex, chiefly aromatic, molecules in which the non-bonded repulsion is particularly large. The latest data on the calculation of the optimal conformations of organic molecules by Kitaigorodskii's method are given in papers by Dashevskii[49-51]. Studies[44-51] have shown that the inclusion, in the potential energy expression, of additional terms making allowance for the changes in bond length resulting from the interaction of atoms which are not joined by valency forces is

inappropriate, since the resulting corrections to the bond lengths are insignificant. The results of Coulson's calculations [52,53] of the conformations of "overcrowded" aromatic molecules agree with the conclusion that the bond lengths show little sensitivity to the interaction of atoms which are not joined by valency forces. The same conclusion was reached by Westheimer [54] from an analysis of structural data, and by Wilson [55] from an analysis of the barriers to internal rotation in ethane derivatives.

In addition to data on bond lengths, to which we shall return, results of thermochemical measurements are usually adduced to prove π-electron delocalisation in organic molecules with alternating multiple and single bonds. As early as the nineteen-thirties, Pauling [56] suggested that the heat of formation of a compound can be used as a measure of the strength of the bonding in the molecule. The bond energy was taken as a criterion of bond strength; summation of the bond energies over all the bonds gives the heat of atomisation of the molecule [57]. In organic chemistry the concept of bond energy has been used to determine the additional stabilisation energy of conjugated molecules. The stabilisation or resonance energy was taken as the difference between the heat of atomisation of the real molecule and the additive sum of the bond energies in the corresponding non-conjugated model [14,58]. Another method for estimating the additional energy of conjugated molecules, proposed by Kistiakowsky [59], is based on data on heats of hydrogenation. The resonance energy is obtained by comparing the heats of hydrogenation of the conjugated molecule and a selected model compound, for example, butadiene and but-1-ene, or benzene and cyclohexene. Neither approach can now be considered satisfactory. For the first, the energies of the C–C and C–H bonds are not found to be constant, even in the alkanes [60], and for the second the resonance energy is not entirely an internal characteristic of the molecule, since its magnitude depends on the choice of model compound. The stabilisation energies calculated in this way include effects related not only to electron delocalisation but also to the effects of hybridisation, bond shortening, spatial interactions, etc. Nevertheless, it has been assumed that a predominant part is played by π-electron delocalisation.

In their discussion of resonance energies, as in their discussion of bond lengths, Dewar and Schmeising [3-5] attribute exclusive significance to hybridisation. From calculations based on empirical relationships between bond lengths and bond energies in diamond, methane, and other simple molecules, they concluded that for butadiene the delocalisation energy is equal to almost zero or in the extreme case does not exceed 2 kcal mole^{-1}, and that the total stabilisation energy for butadiene (8.6 kcal mole^{-1}) is due almost entirely to changes in the hybridisation of the carbon. From the same data it follows that the actual delocalisation energy for benzene amounts to not 36 kcal mole^{-1}, but only a quarter of this quantity. Dewar and Schmeising consider that earlier estimates of the delocalisation energy are too high since no allowance was made for the change in the valency state of the carbon atoms and the compression of the σ-bonds.

Mulliken and Parr [61] previously put forward a formula for calculating the heats of atomisation of organic molecules. For C–C and C–H bonds the formula contained empirical constants which did not take account of the changes in the hybridisation of the atoms. Soon after the publication of the paper by Dewar and Schmeising [3], Mulliken [25], introducing additional constants, extended the formula to molecules with C–C and C–H bonds showing different hybridisation. Mulliken's more general formula, like the formula given by Dewar and Schmeising, contains an additional term $E_h = (E'_{CC} - E_{CC}) - 2(E'_{CH} - E_{CH})$, where E and E' are the energies of the bonds formed by sp^3 and sp^2 carbon atoms. The energy E_h acquires a large relative weighting in the total stabilisation energy of the molecule only when the change in the energy of the carbon–carbon bonds with change in hybridisation is much more marked than that for the energy of the C–H bonds. The same assumption was made by Dewar and Schmeising when they suggested that the energies and lengths of the bonds are determined by hybridisation. In Mulliken's opinion, the validity of this assumption is not evident. Mulliken [25] agrees with Dewar and Schmeising that the difference between the heat of atomisation of conjugated molecules and the additive sum of constant bond energies, which is often taken as the resonance energy, is not a true characteristic of delocalisation. He also points out, however, that the approach adopted by Dewar and Schmeising is not rigorous enough to yield unambiguous conclusions regarding the absence of π-electron delocalisation. The same opinion was expressed by Skinner and Pither [62] in a review of thermochemical data for hydrocarbons. Mulliken considers that the theoretical approach to the determination of delocalisation energy appears promising. The calculated energy values can be verified by comparison with the experimental values obtained for the energy barriers to rotation. As an example, Mulliken [61] quotes butadiene, for which the calculated vertical resonance energy amounts to 6.5 kcal mole^{-1}. If this value is corrected for the hyperconjugation for a molecular shape in which the planes of the double bonds are perpendicular, and also for the decompression of the σ-bonds on rotation and the energy of rotation about the single bond in the absence of delocalisation, the calculated potential barrier to rotation amounts to $\sim$ 5 kcal mole^{-1}, which is close to the experimental value [63]. The values of the potential barriers show good agreement with the stability of the planar forms of conjugated systems, produced by π-electron delocalisation. Mulliken's remarks are general in character, however. The theoretical approach to the estimation of resonance energies, expressed, for example, in the LCAO-MO method in units of the resonance integral β, can give only the relative magnitude for different molecules in a series of compounds. As before, the absolute values of the resonance energies remain indeterminate [24]. Experiment shows that even in aromatic systems, steric interactions compete successfully with π-electron delocalisation [44-54]. The frequently encountered departure from coplanarity in aromatic molecules suggests that in linear conjugated systems also, the gain in energy resulting from electron delocalisation constitutes an insignificant fraction of the observed barriers to rotation. Under ordinary conditions, butadiene exists in the *s-trans*-form [64]; the concentration of the *s-cis*-conformation can correspond to only a very small percentage. Calculations by the self-consistency LCAO-MO method [31,32], however, show that the *s-cis*-form of butadiene has a greater stability (from the viewpoint of orbital overlap). Later calculations for this molecule by the SCF MO LCAO method [65] and with allowance for d-orbitals [66] indicate that the stabilities of the two conformations are approximately equal. The fact that butadiene exists chiefly in the *s-trans*-form indicates that a significant part is played by the interaction between atoms which are not joined by valency forces.

Recent papers on bond energies have put forward new calculation schemes, based either [67] on the work of Dewar and Schmeising or on correlations between bond energy and various molecular parameters: the overlap integrals of

the bonding orbitals[68], bond lengths, and bond orders[69,70]. Cox[71,72] extended the relationships obtained by Dewar and Schmeising to organic molecules containing hetero-atoms (O, N, S, and Hal). The data given in these papers, despite the differences in absolute values, change in the same sense as the changes in bond lengths and bond energies. In Table 1 we have compared the most self-consistent values for the energies of bonds of different types. It can be seen from Table 1 that the energy of the single bond in butadiene is almost the same as the energies of bonds of the same type in biphenyl, acetophenone, and biacetyl. The $C_{sp^2}-C_{sp^2}$ bonds in these molecules, however, are known to have significantly different π-orders, so that if a significant part were played by π-electron delocalisation, these bonds should have had different energies. Agreement is also observed between the values of the energies of single bonds of the type $C_{sp^2}-C_{sp}$ in the molecules of phenyl cyanide and vinylacetylene, for which the intermediate

*Bond energies calculated by the authors using the heats of formation of the compounds and the energies of the other bonds given in the Table. All the values of E relate to 25°C; the values $\Delta H^\circ_{\text{formation}}C(\text{gas}) = 170.9$ kcal g-atom^{-1} and $\Delta H^\circ_{\text{formation}}H(\text{gas}) = 52.09$ kcal g-atom^{-1} are assumed[57].

bonds also have different orders. This shows that the delocalisation energy in conjugated molecules makes up only an insignificant part of the so-called stabilisation energy. When the energies of bonds of the same type are used, the calculated heats of formation of linear conjugated systems almost agree with the experimental values. A different conclusion regarding the part played by π-electron delocalisation was reached on the basis of calculations of the conformation of biphenyl[76,77]. Here it was assumed that the angle of rotation of the benzene rings in the molecule ($\sim$ 41° in the vapour[22]) is determined by the competition between conjugation and the interaction between non-bonded atoms. According to Bartell[78], however, the minimum of the potential barrier for biphenyl shows little sensitivity to the potential associated with electron delocalisation. Change in the latter from 0 to 2 kcal mole^{-1} has almost no influence on the conformation of biphenyl, as can be seen from the published diagrams[76,77]. The non-planar structure of the molecule in the gaseous phase is thus evidently due chiefly to the mutual repulsion of the ortho-hydrogens. In the crystalline state, the planar form of biphenyl is favoured, because of the effects of packing ($\sim$ 3 kcal mole^{-1})[79,80]. Thus the height of the potential barrier to rotation cannot give information on π-electron delocalisation, since this effect is due to a considerable extent to the interaction of atoms which are not joined by valency forces[81-84].

Unlike that for linear conjugated compounds, the delocalisation energy for aromatic molecules, calculated with allowance for the type of bond hybridisation, constitutes a significant part of the stabilisation energy. The value obtained for benzene using the data in Table 1 (comparison with classical cyclohexatriene) amounts to $\sim$ 22 kcal mole^{-1}. It is evidently this feature which makes necessary the introduction of additional terms making allowance for distortion of the aromatic rings in the calculations of optimal conformations by the methods of Kitaigorodskii[44-51] and Coulson[52,53].

The relationship between the energies of bonds of various types (values taken from Table 1) and interatomic distance (Fig. 2) is linear (this was noted earlier[67,71]). The points corresponding to the central single bonds in the molecules of butadiene, vinylacetylene, and diacetylene lie satisfactorily on the straight line. Thus these data on the

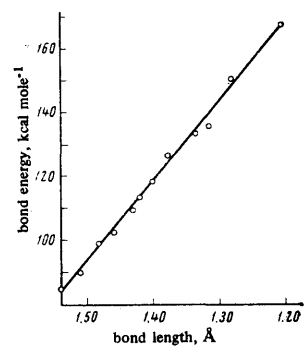

Figure 2. Dependence of the C–C bond energy on bond length.

lengths and energies of the bonds in linear conjugated molecules provide evidence in support of that part of Dewar and Schmeising's treatment which states that these parameters are independent of π-electron delocalisation and can be attributed to the change in the valency state of the carbon atoms. This conclusion does not relate to aromatic compounds. In these compounds, as will be shown below, the π-electron delocalisation is reflected to a marked extent in both the bond lengths and bond energies.

Published explanations of the polarity of conjugated and hyperconjugated molecules are contradictory. Supporters of the delocalisation concept consider that the existence of dipole moments in molecules such as propene and toluene

(~ 0.4 *D*) is due to the displacement of π-electron density. Dewar and Schmeising[3-5] attribute it to the fact that carbon atoms in the sp^3, sp^2, and *sp* states have different electronegativities, according to Walsh[85] and Coulson[86]. On the basis of similar considerations, Petro[87] put forward an additive scheme for calculating the dipole moments of hydrocarbons, in which the C–C and C–H moments were assumed to depend on the type of bond. The possibilities provided by the hybridisation concept in the interpretation of dipole moments are very limited, however. For example, according to this concept the dipole moments of azulene and fulvene should be equal to zero, since all the carbon atoms have the same sp^2-hybridisation, whereas the observed dipole moments are 1.0 *D* and 1.2 *D* respectively[24]. It is just as difficult to explain the polarity of these molecules on the basis of the hybridisation concept as it is to understand, for example, the decrease in the length of the single bonds in cyclo-octatetraene on the basis of the delocalisation concept. The concept of bond delocalisation does not encounter any fundamental difficulties, however, when applied to the dipole moments of non-alternant hydrocarbons (including azulene and fulvene). Hückel's simple MO method and the electron-gas method give very high values for azulene and fulvene (~ 6.5 *D* and 4.5 *D* respectively[88,89]), but the use of improved MO methods with self-consistency gives much better agreement between the calculated and experimental values[24].

Anomalies are observed in the optical properties of hydrocarbons with conjugated multiple bonds. In the electronic spectra this is revealed as a bathochromic shift and increase in the intensity of the absorption bands, and in the Raman spectra it is revealed as a sharp increase in the intensities of the lines due to the vibrations of the multiple bonds. Exaltation of molar refractions is also an optical sign of conjugation in organic compounds. Consideration of these phenomena lies outside the scope of the present review, however, since they are related not only to ground state but also to the excited electronic states of the molecule.

Considerable information on the detailed structure of molecules in the ground electronic state is provided by the radiofrequency spectra. Data on molecular structure recently obtained by NQR, EPR, and NMR methods indicate delocalisation of electrons not only in conjugated and hyperconjugated systems, but even in alkanes. Thus Semin[90], in an NQR study of compounds of the type $Cl-[CH_2]_n-Cl$ ($n = 1-10$) observed a characteristic interaction of the chlorine atoms through the chain of methylene groups. On the basis of calculations in the LCAO-MO approximation, the observed dependence of the NQR signal on the length of the chain was later attributed by Sokolov and Umanskii[91] to partial delocalisation of the σ-electrons of the C–C bond. Proof of delocalisation in hydrocarbons (including alkanes) has also been obtained by EPR[92-96] and NMR[97,98] methods.

In the light of these facts it is evident that none of the existing structural concepts can claim to explain all the varied properties of organic molecules. The non-equivalence of the concepts of hybridisation and π-electron delocalisation in their approach to the study of molecules should be noted, however. In this respect, the concept of delocalisation exhibits the greatest generality. Its conclusions are based on the theory and calculation methods of quantum chemistry. Its range of application is not restricted to individual classes of compound or to definite energy states of molecules. The concept of hybridisation (and the concept of non-bonded interactions), however, is based on a number of empirical relationships and is therefore more particular and simplified.

III. QUANTUM-MECHANICAL STUDIES OF CONJUGATED COMPOUNDS

The success of the application of quantum chemistry to conjugate compounds is due chiefly to the presence of π-electrons, which, in an approximation which is adequate in many instances, can be considered independently. In this section we shall deal with the results of quantum-mechanical studies of linear polyenes, organic dyes, polyynes, and cumulenes.

1. Linear Polyenes

A central problem in the structure of conjugated systems is the question of the change in π-electron delocalisation and the associated change in the lengths of the multiple and single bonds with increase in the length of the chain.

One of the first quantum-mechanical calculations for polyenes was carried out by Lennard-Jones[99,100] using the simple MO method. By using bond length data for ethylene and ethane and determining the resonance integrals for the double and single bonds in polyenes, Lennard-Jones found a decrease in the length of the central bond in butadiene. According to the calculation, the addition of new units to the conjugated chain should lead to gradual equalisation of the bonds. In an infinite polyene the double and single bonds are completely equalised, the length of each being 1.30 Å. Equalisation of the bonds in the central region of a polyene chain also followed from work published simultaneously by Penney[101], who used the valency bond (VB) method. Later, Coulson[102] studied linear polyene radicals $C_{2n+1}H_{2n+3}$ and concluded that as $n \to \infty$, the configurations with alternating bonds will be less stable than those with equalised bonds. In a subsequent paper Coulson[103] extended this conclusion essentially to polyene molecules $C_{2n}H_{2n+2}$, when he found that with increase in *n* for these molecules the orders of the double and single bonds are equalised from the ends of the chain to the centre. In the same paper Coulson for the first time introduced fractional bond orders within the framework of the MO method.

The inadmissibility of the model with equalised bonds for polyenes was soon demonstrated by Mulliken[104,105]. He showed by the simple MO method that for equalisation of the bonds the wavelength of the first absorption band should be proportional to the length of the chain for all conjugated systems, including linear polyenes. The same result was obtained by Kuhn[106] by the simple electron-gas method. It had been known even earlier[107-118], however, that the absorption bands in the spectra of polyenes converge with increase in chain length; with the addition of each unit the bands are displaced towards longer wavelengths by an ever-decreasing amount, tending towards a definite limit (Fig. 3). Kuhn[106,114,115] showed that in order to obtain satisfactory agreement between the experimental and calculated wavelengths in the ultraviolet spectra of polyenes it is necessary to assume strong alternation of the π-electron density in the polyene chain. In the electron-gas method this is achieved by introducing an alternating nuclear potential with maxima in the middle of the double bonds in the classical formula of the polyene. The calculations carried out by Kuhn and coworkers[116] for two- and three-dimensional models showed that the alternation of the electron density in long linear polyenes is the same as that in butadiene.

Dewar[117] studied the electronic structure of polyenes with long chains by the LCAO-MO method. He also showed that in the absence of alternation the calculated frequencies of the absorption bands should tend to zero as $n \to \infty$.

Agreement with experiment can be obtained by assuming that all the double and all the single bonds are equivalent and by assigning different values to the resonance integrals for both types of bond.

Platt[118] attributes the observed regular features in the absorption spectra of linear conjugated systems to the configurational interaction of several possible electronic states. Either the interaction is constant and the compounds have equalised bonds (cyanine dyes) or the interaction varies with chain length, leading to alternation of charge density and hence to alternation of bond lengths. In Platt's opinion, solution by the simple LCAO-MO method

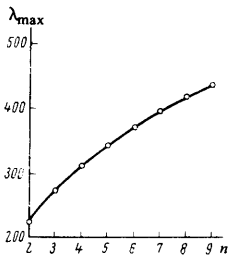

Figure 3. Dependence of λ_{max} (nm) on n for *trans*-polyenes $H_3C-[CH=CH]_n-CH_3$.[113]

leads to equalisation of the bonds in polyenes because no allowance is made for the configurational interaction between the ground and lower excited electronic states. A similar conclusion was reached by Labhart[119] using the free-electron method. He showed that when allowance is made for the compressional energy of σ-bonds the filled π-electron levels of polyenes with alternating bond lengths lie below the levels for polyenes with equal bond lengths. The conclusion that there is alternation of the π-electron charge density on the bonds also follows from the modified potential-box model examined by Bagdasar'yan[120]. Alternation is energetically favourable, since the energy of the electrostatic repulsion of the π-electrons on neighbouring bonds is then minimal.

Ooshika[121,122] was the first to use the semi-empirical Pariser–Parr–Pople SCF MO LCAO method[28,35,36] to solve the problem of the alternation of bond lengths in polyenes. For an infinite polyene chain the π-order of the C=C bond was found to be 0.938, and that of a C–C bond 0.249. These values are very close to the bond orders in butadiene, calculated by Mulliken[25]. Ooshika noted that strong alternation of the bond orders in polyenes leads to an absorption energy difference for an infinite number of double bonds equal to ~ 5.6 eV, although the experimental value is 2.5 eV.[118] Huzinaga and Hasino[123] carried out calculations for polyenes using a modified LCAO-MO method based on a united atom model[124], for which the Coulomb integral depends on the interatomic distance. The authors also obtained significant alternation of the lengths of the double and single bonds (~ 0.1 Å). Thus even in the late nineteen-fifties a large number of quantum-mechanical papers had shown that results agreeing with experiment can be obtained for polyenes only by assuming bond alternation, which is preserved with increase in chain length. Alternation of the bond orders and bond lengths decreases the total energy of the system, making it more stable relative to the system with equalised bonds.

In addition to quantum-mechanical calculations, classical models have been used in the interpretation of the electronic spectra of polyenes. Lewis and Calvin[125] used a model with non-coupled oscillators, but the relationship which they found between the wavelength of the absorption band of the polyene and the number of double bonds did not agree with experimental data[126]. Much better agreement with experiment was obtained by Kuhn[127] and Hirayama[128], who assumed coupled oscillators. In a series of papers by Simpson[129–132] the characteristic features of the structure of polyenes are attributed to the electrostatic interaction of the double bonds. In Simpson's opinion, a significant contribution to the ground state of these compounds is made by an ionic structure with alternating charges, for example, $-\bar{C}=\bar{C}-\bar{C}=\bar{C}$ for butadiene. Simpson's model is, however, extremely far from reality[133].

Among later quantum-mechanical studies of the structure of polyenes, mention must be made of work by Longuet-Higgins and Salem[134,135]. These authors used the simple LCAO-MO method, but they made allowance for the compressional energy of σ-bonds and introduced not the parabolic dependence of the resonance integral β on the interatomic distance, as Lennard-Jones had done[99,100], but an exponential dependence. It was found that with this approach, cyclic and linear polyenes with equalised bonds become dynamically unstable as $n \to \infty$. The theoretical analysis also led Longuet-Higgins and Salem to the conclusion that the molecular π-orbitals in the ground and excited states of an infinite polyene do not form a continuous bond, but are separated by a finite energy barrier. This means that an infinite polyene should behave not as a one-dimensional metal but as an insulator with a low electronic excitation energy. This conclusion is directly related to the chemical problem, examined below, of the mutual influence of atomic groups separated by a chain of conjugated bonds.

Pople and Walmsley[136] calculated the energy of the lower excited state for polyenes by the Pariser–Parr method[35,36] for weak and strong alternation of the bonds. They found that the limit of the long-wave absorption is 2.9 eV for the former, and 4.6 eV for the latter. Thus according to Pople and Walmsley, weak alternation of the bonds shows better agreement with the experimental value of 2.5 eV.[118] Dixon[137] examined the nature of the alternation of bonds in polyenes by the VB method. In contrast to the earlier calculations of Penney[101], the values of the Coulomb and resonance integrals were assumed to be different, depending on the interatomic distance (the method has been described in detail[138]). The lengths of the double and single bonds calculated by Dixon are almost independent of the dimensions of the polyene chain and show good agreement with the experimental bond lengths for butadiene[139,140]. Merz and coworkers[141] used the "molecules in molecules" method, developed by Longuet-Higgins and Murrell[142], to interpret the electronic spectra of conjugated compounds. They concluded that there is considerable localisation of the π-electrons on the bonds in linear polyenes, irrespective of the length of the chain.

A recent paper by Dewar and Gleicher[143] (see also Refs. 5 and 144) described a study of the structure of polyene compounds by the Pariser–Parr–Pople SCF MO LCAO method and the split p-orbital method[145]. Both methods showed that with increase in the chain-length the alternation of the double and single bonds remains almost the same as that in the first members of the vinyl series. At the same time it was shown that the heats of formation of polyenes can be represented in the form of additive sums of the empirical energies of the C=C, C–C, and C–H bonds. In

the opinion of the authors cited, this indicates the absence of π-electron delocalisation and the inappropriateness of using the actual concept of bond delocalisation or resonance interaction to describe the collective properties of molecules, It is difficult to agree with this, however, since even the energies of aromatic hydrocarbons, in which the existence of resonance interactions cannot be doubted, can be described by additive schemes[146]. As will be shown below, bond energies, like bond lengths, cannot serve as reliable criteria of π-electron delocalisation in linear conjugated molecules.

Calculations of the absorption spectra, ionisation potentials, charges on the atoms, and bond orders in polyenes $H[CH=CH]_nH$ (n = 1–10) and in various condensed aromatic compounds have been described by Adams and Miller[147]. The calculations were carried out using a semi-empirical method in a π-electron approximation which differs from the generally adopted Pariser–Parr–Pople SCF MO LCAO method in that the atomic orbitals are expressed in terms of orthogonal orbitals of the Slater type (after Lowdin). The results obtained indicate that there is strong alternation of the π-electron density in polyenes and that the orders of the double and single bonds depend little on chain length.

Thus quantum-mechanical examination using all existing methods shows that polyenes in the ground electronic state form systems with alternating charge density. The problems of the degree of alternation and the change in bond orders with increase in chain length have been less fully investigated. The quantum-mechanical problem of the transfer of influence along a chain of conjugated bonds has been little studied, although there is an extremely widespread opinion that the polyene chain exhibits metallic conductivity[148].

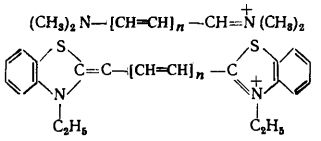
The problem of the alternation of bonds in long polyenes might be solved unambiguously by experimental methods, but the amount of available material is extremely small. We know of only one X-ray diffraction study, by Dreuth and Wiebeng[149], in which the bond lengths in 1,8-diphenyl-1,3,5,7-octatetraene were determined. It was shown that the molecule has the *s-trans*-configuration with the following bond lengths in the chain:

There is very little published information on the structure of excited states of polyenes. This problem was first examined in relation to polyenes by Bayliss[150] and later, in more detail, by Platt[118]. In the excited state of hexatriene according to Bayliss, migration of the charge takes place from the centre of the chain to its ends. The double-bond character of the central bond decreases, and that of the neighbouring single bonds increases. On excitation of the polyene, the alternation of the bonds is preserved, but its sign changes. In Platt's opinion[118], this explains various characteristic features of the absorption spectra of polyenes, in particular the existence of a distinct vibrational structure in the spectra at room temperature.

Recently, Hoffmann[151] carried out calculations on the geometry of polyenes in the first excited state. Using an extended version of Hückel's method which he developed, Hoffmann showed that in the excited state of butadiene the planes of the terminal CH_2 groups are mutually perpendicular. In the excited state of hexatriene, rotation about the central double bond takes place. Octatetraene and polyenes with higher molecular weight remain planar in the excited state.

2. Organic Dyes

From the work examined in the previous section, it follows that the convergence of the wavelengths of the absorption bands observed in the electronic spectra of polyenes with increasing chain length is due to the alternation of bond orders. There is an extensive class of compound, however, whose ultraviolet absorption bands do not show this tendency. These include the symmetrical polymethine (I) and cyanine (II) dyes:



With the addition of a new unit, the absorption band of (I) and (II) is displaced by a constant amount equal to 1000 ± 50 Å [152–162] (Fig. 4). The first attempts to use the methods of quantum chemistry (VB and MO) to interpret the electronic spectra of organic dyes are described in papers by Föster[163] and Herzfeld and Sklar[164–166]. Kuhn[114–116] was the first to show that the observed regular features in the spectra of compounds (I) and (II) can be described satisfactorily by the free-electron method using a model with equalised bonds. The application of the method of molecular orbitals to these compounds is described by Dewar[167].

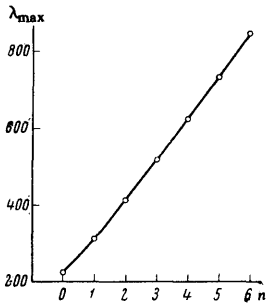


Figure 4. Dependence of λ_{max} (nm) on n for cyanines $(H_3C)_2\overset{+}{N}=CH-[CH=CH]_n-N(CH_3)_2$.[113]

Fukui and coworkers[168] concluded that in order to obtain better agreement with experiment in calculations for symmetrical polymethine dyes by the electron-gas method, it is necessary to assume a slightly modified potential, because of the influence of the terminal groups. A similar conclusion was later reached by Oldzewsky[169,170], who used the potential-box method and introduced barriers associated with the terminal effects of the nitrogen atoms. For a chain of carbon atoms, as in work by Kuhn[114–116], Bayliss[150], and Simpson[171], an equalised potential was used. McGlynn and Simpson[172] calculated the energies of electronic transitions by an improved LCAO-MO method in the Pariser–Parr approximation.

In recent years, new experimental data have been obtained on the electronic spectra of cyanines, oxonols $O=CH-[CH=CH]_n-O$, and merocyanines[173]

$$(CH_3)_2N-[CH=CH]_n-COH.$$

The dependence of λ_{max} on n for oxonols and merocyanines (Fig. 5) shows that these compounds have different structures. Leupold[174] obtained good agreement between the calculated and experimental positions of the long-wave absorption bands for symmetrical polymethines using a modified version of the simple LCAO-MO method (corrections were introduced for the hetero-atoms). The molecular diagrams obtained indicate almost complete equalisation of the bonds, the bond orders being close to the value obtained by the simple MO method for benzene (0.67). Leroy and Nys[175] carried out calculations for various types of cyanine dye by the Pariser–Parr SCF MO LCAO method. By assuming a linear relationship between bond length and bond order, they obtained values for the carbon–carbon bond lengths in cyanine dyes which almost coincided with the CC bond length in benzene (1.397 Å). Thus according to these authors[174,175], dyes of types (I) and (II) are linear analogues of benzene with respect to delocalisation of the bond lengths and bond orders.

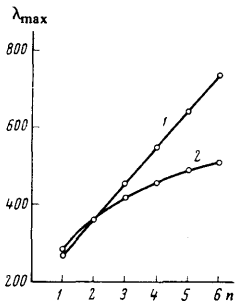

Figure 5. Dependence of λ_{max} (nm) on n for oxonols $O{=}CH{-}[CH{=}CH]_n{-}O^-$ (*1*) and merocyanines $(H_3C)_2N{-}[CH{=}CH]_n{-}CHO$ (*2*). [173]

In a subsequent paper, Leupold and Dähne[176] carried out calculations for oxonols and merocyanines by a method similar to that described earlier[174]. For oxonols, good agreement was obtained between the calculated and experimental bands in the electronic absorption spectra. The CC bond orders for oxonols were also found to be close to the carbon–carbon bond order for benzene. The absorption band maxima calculated for merocyanines[176] showed poor agreement with the experimental values. The experimental data for the electronic spectra of merocyanines[173] and various other unsymmetrical $\alpha\omega$-substituted polyenes[177] show a distinct tendency for the maxima of the long-wave band to approach a finite limit (Fig. 5). This is evidently due to incomplete delocalisation of the π-electrons. Recently, Klessinger[178] carried out calculations for cyanines and merocyanines using the Pariser–Parr–Pople SCF MO LCAO method and showed that these compounds belong to different classes. In the cyanines the bonds are equalised, the π-order approaching 0.67 (benzene) with increase in the chain length. The behaviour of the merocyanines is similar to that of polyenes—considerable alternation of the bonds, which remains almost unchanged with change in the length of the chain, is observed. Alternation of the bond orders in $\alpha\omega$-substituted polyenes is also indicated by dipole moment data[179] and the vibrational spectra (see below). Thus the characteristic features of the electronic structure of linear conjugated molecules in the ground state are clearly revealed in the ultraviolet absorption spectra. Compounds for which the absorption bands in the electronic spectra do not converge with increase in chain length form systems of equalised bonds (cyanines, polymethines, and oxonols). Compounds for which the absorption band maxima tend towards a definite limit with increase in the length of the chain show alternation of electron density (polyenes, merocyanines, and other $\alpha\omega$-substituted polyenes with paired electrons). The limiting wavelength in the electronic spectra is reached more rapidly, the more marked the alternation of the bond orders and hence the smaller the π-electron delocalisation. It is evidently for this reason that the absorption bands in the spectra of *p*-polyphenyls[128], for example, show rapid convergence towards a limit, compared with polyenes. The non-coplanarity of the benzene rings in *p*-polyphenyls, resulting from the interaction of the ortho-hydrogens, leads to greater localisation of the π-electrons within each unit of the chain.

Pouradier[180] analysed a large number of electronic spectra of cyanine dyes, and showed that the distance between the first and second components of the absorption band is approximately constant and amounts to ~ 1200 cm^{-1}, irrespective of the nature of the dye. The splitting was attributed to vibration of the chain in the excited state.

3. Poly-ynes and Cumulenes†

The first calculations for cumulenes were carried out by Pullman and Berthier[181] by the LCAO-MO method with allowance for hyperconjugation of the terminal bonds (after Mulliken[14]).

Quantitative data were obtained on the equalisation of the bonds in cumulenes with odd and even numbers of carbon atoms. It was noted that a bathochromic effect should be observed in the electronic spectra with increase in chain length. Later, again using the simple LCAO-MO method, Longuet-Higgins and Burkitt[182] carried out calculations for the lower polyalkynes (up to and including tetraacetylene) and cumulenes (as far as pentatetraene). The results showed that the poly-ynes and cumulenes show different behaviour with increase in chain length. The equalisation of the orders of the central bonds given by the method of molecular orbitals is slower for poly-ynes than for polyenes. For cumulenes, the bond orders change sharply on going from allene to butatriene, the orders of the terminal bonds decreasing, and the order of the central bond increasing. The bond orders for pentatetraene differ little from those for butatriene; only a slight decrease in the bond orders in the middle of the chain is observed.

The first experimental data on the electronic spectra of poly-ynes and cumulenes were obtained in the nineteen-fifties[183–187]. Comparison of the spectra enabled Krauch[188] to refute the extremely widespread opinion that the electron density distribution is the same for long poly-ynes and cumulenes[189]. If delocalisation of the π-electrons did in fact lead to complete equalisation of the bonds, so that an infinite poly-yne had the cumulene structure, the ultraviolet spectra should have shown a tendency for the absorption bands of molecules of the two classes to approach one another with gradual increase in the number of carbon bonds, but this is not observed. The differences between

† The structures of poly-ynes and cumulenes are considered in the same section of the present review merely for convenience of presentation and not for more significant reasons.

the spectra of these compounds increase with increase in the length of the conjugated chains (Fig. 6). The maxima of the absorption bands for cumulenes, like those of polymethines and cyanine dyes, are displaced regularly by the same amount with the addition of each new unit (for example by ~ 750 Å for tetraphenylcumulenes[187]), whereas the band maxima for poly-ynes, like those for linear polyenes, tend towards a definite limit[183,184].

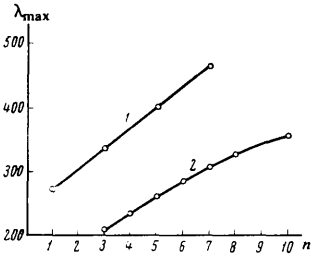

Figure 6. Dependence of λ_{max} (nm) on n for cumulenes

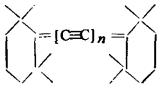

(1)

and poly-ynes $(H_3C)_3C-[C\equiv C]_n-C(CH_3)_3$ (2).[113]

Kuhn[116] examined the characteristic features of the electronic spectra of polyenes and poly-ynes by the free-electron method, using one-dimensional as well as two- and three-dimensional potentials. It was found that all the models give qualitatively similar results for the alternation of the multiple and single bonds in these systems, and that infinitely long polyenes and poly-ynes show approximately the same alternation of bonds as butadiene and diacetylene respectively. It was found that the absorption bands show more rapid convergence towards a limit for poly-ynes than for polyenes. This was reflected in the choice of a larger value for the amplitude of the alternating potential for poly-ynes (3.4 eV) compared with polyenes (2.4 eV). Thus the ultraviolet spectra indicate directly that the electron density distribution is different for poly-ynes and cumulenes. Marked bond alternation, changing little with change in the length of the poly-yne chain, was recently obtained by an SCF MO LCAO method[190] in calculations for the molecules of di-, tri-, and tetra-acetylenes[191,193]. Comparison of the molecular diagrams for these compounds and the molecular diagram for octatetraene[194], obtained by the same method of Julg[190], shows that the electron density distributions in poly-ynes and polyenes are similar.

The structures of cumulenes and poly-ynes have recently been studied by Shustorovich[195-203]. Using the simple LCAO MO method, improved by Longuet-Higgins and Salem[134], Shustorovich obtained data on the barriers to internal rotation in organic cumulenes[195,196], the ionisation potentials and electron affinities[197,198], and the alternation of bond lengths in cumulenes and poly-ynes[199,200]. Shustorovich also examined the electronic structures of cumulenes by the self-consistent π-MO method in the Pople approximation[201]. Despite the large amount of available published material on the electronic spectra of cumulenes, Shustorovich considered only preliminary data on carbene (a compound containing more than 1000 carbon atoms).

Shustorovich concludes that cumulenes and poly-ynes differ only in the structures of the terminal groups, whose influence becomes weaker with increase in the number of carbon bonds. When the chain is sufficiently long, organic cumulenes and poly-ynes are indistinguishable and consist of systems of weakly alternating conjugated bonds. This conclusion, however, does not agree with familiar experimental facts relating to the structures of cumulenes and poly-ynes. It was shown above that available experimental and calculated data on the electronic spectra indicate that there is equalisation of the bonds in long cumulenes on the one hand, and marked alternation of the bonds in poly-ynes on the other. Differences in the structures of these compounds are also indicated by structural data, although such data are at present available only for cumulenes and poly-ynes with a small number of bonds. The bond lengths in molecules of both classes show no tendency to converge (Table 2). If the structures of long cumulenes and poly-ynes were identical, however, the greatest changes in bond lengths with increase in their number should have been observed in these lower members of each series.

Table 2. Bond lengths in cumulenes and poly-ynes, Å.

The conclusion that the alternation of bonds in poly-ynes is weak follows inescapably when the version of the simple MO method due to Longuet-Higgins and Salem[134] is used. The simple MO method of Hückel is in general inapplicable to calculations for linear conjugated molecules, since it leads to equalisation of the bonds and to a linear dependence of λ_{max} on the number of multiple bonds[99,100,103], which does not agree with experiment. Longuet-Higgins and Salem, using a slightly improved version of Hückel's method, concluded that there is alternation of the bond orders in polyenes, although for an infinite polyene they also obtained a very small difference between the levels of the ground and excited states (ΔE = 0.25 eV, experimental value $\Delta E \sim$ 2.5 eV [116,118]). Shustorovich[199,200], using the same method, obtained for an infinite poly-yne the value ΔE = 0.05–0.4 eV (depending on the choice of initial parameters), which is also less than the experimental value (~ 3.4 eV [116]).

Hückel's simple MO method, however, describes effectively the electronic spectra of systems with equalised bonds, that is, the spectra of polymethines and cyanine dyes[167], oxonols[176], condensed aromatic systems[211,212], and cumulenes[182,183]. The fact that Hückel's method is applicable to one large group of compounds and is not applicable to another (polyenes, poly-ynes, and merocyanines) is not accidental. It is evidently related to the existence in the first instance, and the non-existence in the

second, of a correspondence between the actual relationship between the energy and the order of the π-bonding and the linear relationship which follows in Hückel's approximation[213]. As shown below, significantly different relationships between the energies and orders of the bonds are observed in these groups of compounds: for cumulenes, polymethines, etc. the relationship is approximately linear, whereas for polyenes and poly-ynes the relationship is more complex.

The characteristic features of the structures of cumulenes and poly-ynes in the ground and excited electronic states were recently studied in detail by Hoffmann[151] using an extended MO method with allowance for σ-electrons. Hoffmann obtained data on the geometry of cumulenes with odd and even numbers of carbon atoms (n) in the ground and excited states. For both states, oscillation of the barriers to rotation (ΔE) depending on n were observed, and it was found that $\Delta E \to 0$ as $n \to \infty$. It was shown that the difference between the energies of the higher filled and lower vacant molecular orbitals (E) is greater for cumulenes with odd values of n than for those with even values; in both instances the value of E approaches zero with increase in n. Hoffmann's calculations agree with experimental data on the excitation energies and electronic spectra of cumulenes. The known experimental values of E decrease regularly in the order: ethylene, allene, butatriene, and pentatriene[214,215]; a linear relationship is also observed between λ_{max} and the number of double bonds[183, 187,216]. Hoffmann studied the electron density distribution using the total charges on the atoms and the overlap populations (n_{ij}). The data which he obtained indicate equalisation of the bonds in cumulenes. For decanonaene ($C_{10}H_4$) Hoffmann obtained the following values of n_{ij} (from the end of the chain to the middle): 1.27, 1.37, 1.32, 1.35, and 1.33. Hoffmann concluded that the poly-ynes show appreciable alternation of bond orders, changing little with increase in chain length. Thus for the poly-yne $C_{16}H_2$ he obtained the following values for the overlap populations n_{ij} (from the end of the chain to the middle): 1.86, 1.01, 1.78, 1.03, 1.76, 1.03, 1.76, 1.03. Hoffmann's calculations showed that in the excited state, unlike acetylene which has the *trans*-form[217-219], diacetylene remains linear, contrary to Pontrelli's conclusion[220].

The structures of butatriene, vinylacetylene, and divinylacetylene were recently studied by Julg and Pellegatti[221] using an improved MO method[190]. For the π-orders for butatriene they obtained the values 0.91 for the terminal bonds and 1.38 for the central bond.

In addition to the literature cited, further references to early work on the electronic spectra of conjugated hydrocarbons can be found in a detailed review by Mason[113]; extensive references on the chemistry of poly-ynes are given in a review by Sladkov and Kudryavtsev[222], and similar references on the chemistry of cumulenes are given in a review by Cadiot, Chodkiewicz, and Rauss-Godineau[223].

IV. THE VIBRATIONAL SPECTRA OF CONJUGATED COMPOUNDS

Isolated attempts have been made to obtain force constants for molecules by quantum-mechanical calculation. The first attempts were made by Coulson and Longuet-Higgins[224] as early as 1948 for the molecules of benzene and butadiene. Calculations within the framework of the simple MO method gave qualitative agreement between the force constants for benzene and the constants determined from the vibrational spectra. Later, Longuet-Higgins and Burkitt[182] used a method developed earlier[224] to calculate the force constants of the carbon–carbon bonds in the molecules of poly-ynes and cumulenes. They noted that the values of the force constants of the bonds are highly sensitive to the π-order, and that the values of the interaction constants are highly sensitive to the mutual polarisability of the bonds. Misurkin and Ovchinnikov[225] recently calculated the vibrational frequencies of the benzene ring using constants found by the MO method. The discrepancies between the calculated and experimental values amounted to several hundred cm^{-1}. This and other work[226-234] indicates that quantum-mechanical methods cannot yet be used to obtain reliable information on the force field of a molecule. As yet, the only real basis for the interpretation of frequencies is the classical semi-empirical theory of vibrations.

The present chapter examines work on the study of the vibrational spectra of conjugated organic compounds. Its aim is to examine the picture of the electronic structure of the molecules revealed by the existing methods of vibrational spectroscopy, that is methods based on experimental data and theoretical concepts which are different from those of the methods of quantum chemistry.

1. Elastic Properties of Conjugated Chains

A large amount of experimental material[139,140,235-237] has been published on the structure of butadiene. Most authors assume that the butadiene molecule can exist in two isomeric forms, the *s*-trans and the *s*-cis. Although the existence of the *s*-trans-form of butadiene is not now doubted, the question of the realisation of the second isomeric form has not yet been completely resolved. The fact that usually only the *s*-trans-form of butadiene exists under normal conditions has been confirmed directly by studies of electron diffraction[139] and the rotational structure of the bands in the vibrational spectra[140].

The normal vibrations of butadiene were first calculated by Sverdlov and Tarasova[238] using the force constants for propene. The marked discrepancy between the observed and calculated frequencies in this and later work by Sverdlov and Tarasova[239] indicates that the force field of butadiene cannot be represented by the additive combination of the force fields of simpler molecules. Recently, Tatevskii and coworkers[240] tried to describe the vibrational spectrum of butadiene by assuming that the elastic properties of the double bonds are the same in the C=C–C=C system and in ethylene. Earlier, Ferigle and Weber[241,242] made an analogous assumption regarding the properties of the triple bond in the C≡C–C≡C system and in acetylene in a calculation of the vibrations of diacetylene and dimethyldiacetylene. To obtain satisfactory agreement with the experimental frequencies of butadiene, Tatevskii and coworkers[240] had to alter significantly the values of a large number of bond–angle interaction constants and increase the constant for the central bond. For diacetylene and dimethyldiacetylene, however, with this assumption, it was necessary to introduce anomalously high values for the constants for the interaction of the triple bonds with adjoining single bonds and also to increase the constant for the central bond. The assumption that the force constants of multiple bonds are the same in conjugated and non-conjugated molecules is unjustified for a number of reasons, including the fact that the constants obtained by Tatevskii and coworkers[240] for butadiene and by Ferigle and Weber[241,242] for diacetylene do not show the continuity required by actual sets of force constants in the description

of the properties of the molecules of a homologous series. The vibrational frequencies for polyenes and poly-ynes calculated using these constants not only show poor agreement with the observed frequencies but also show regular features which are different from those found for the observed frequencies with increase in the length of the chain[243,244]. Sufficiently reliable data on the force fields of compounds with alternating multiple and single carbon–carbon bonds evidently cannot be obtained on the basis of even a correct study of single molecules.

In a study of the structure of conjugated hydrocarbons, the authors of the present review carried out an analysis of the vibrational spectra of a large number of conjugated molecules of various classes: linear polyenes, poly-ynes, vinylacetylenes, cumulenes, and conjugated nitriles. The vibrational spectra of molecules with known structures were calculated for comparison.

The spectra of C_6H_6 and C_4D_6 were used in a study of butadiene[245,246]. In the calculation of the force constants, allowance was made for the characteristic frequency and form for individual atomic groups of many of the vibrations of butadiene. The set of force constants obtained for butadiene was subsequently tested for the molecules of polyenes with higher molecular weight. The constants were also further verified by calculating the electro-optical parameters and integral intensities of the absorption bands in the infrared spectra of C_4H_6, C_4D_6, and other polyenes.

The set of force constants found for the C=C–C=C system[245] indicates that there is appreciable interaction between the carbon–carbon bonds in the ground electronic state of butadiene. The force constants of the C=C bonds were found to be significantly lower than the analogous constants for ethylene[247], propene[248], and 2-methylpropene[249] (12.00 compared with 14.20‡) whereas the constant for the central C–C bond was found to be greater than that for propene and 2-methylpropene (10.40 compared with 7.02); higher values were obtained for the constants for the interaction of the double bonds (–1.50) and the interaction of the double and single bonds (0.40).

The force constants of butadiene were used to describe the vibrational spectrum of 1,3,5-hexatriene[245]. The frequencies of hexatriene calculated on this basis show satisfactory agreement with the experimental values. Complete agreement with the observed vibrational frequencies for the chain of carbon atoms in hexatriene was obtained by correcting slightly the force constant for the interaction of neighbouring double bonds and by making allowance for the weak interaction of the terminal carbon–carbon bonds. Hence the differences in the frequencies of butadiene and hexatriene are due not to a change in the force field resulting from the greater delocalisation of the π-electrons with increase in the length of the chain, as claimed by Lippincott and coworkers[250], but to the purely kinematic factor.

The problem of the equalisation of the bonds in polyenes containing a large number of units was examined by Ivanova and the authors[243] by analysing the vibrations of molecules of the type $X-[CH=CH]_n-X$, where $X = COOC_2H_5$, and $n = 2-8$. Studies of the chemical properties[244] and electronic and vibrational spectra[177,251–253] indicate that these compounds are linear polyenes with transoid arrangement of the bonds. The vibrations of molecules with two to eight units were calculated[243] using three different types of sets of force constants for the polyene chain: those of butadiene[245], propene[248], and benzene[254]. It was found that the calculation reproduces the characteristic features of the experimentally observed infrared[252,253] and Raman[251,252] spectra only when the force constants of butadiene are used. Thus increase in the length of the polyene chain does not lead to significant redistribution of the force field of the molecule.

The force fields of poly-ynes were studied by Popov and Lubuzh[255]. Attempts to describe the vibrational spectra of diacetylene and a number of other poly-ynes containing up to six triple bonds in the chain, using the constants for simple molecules, did not give satisfactory results, as in the case of the polyenes. The force field of the butadiene system C≡C–C≡C was found by simultaneous solution of the secular equations for diacetylene and dimethyldiacetylene. The values obtained differ significantly from the corresponding constants for saturated hydrocarbons and molecules with an isolated triple bond. Thus the force constant of the C≡C bond in diacetylene was found to be less than the constant for acetylene and methylacetylene (22.20 compared with 24.50 [256,257]), and the constant for the central C–C bond was found to be significantly greater than that for the single bond in methylacetylene (11.80 compared with 8.00 [257]). Significant values were obtained for the constants for the interaction of the triple bonds (–1.50) and the interaction of the triple and single bonds (0.50).

The vibrations of the poly-yne chain in the compounds $R-[C\equiv C]_n-R$, where R = Alk and $n = 2-6$, can be described[225] using force constants whose values are extremely close to those for diacetylene and are independent of chain length. This indicates that in the poly-yne chain, as in the polyene chain, equalisation of the orders of the multiple and single bonds does not take place with increase in chain length. This conclusion regarding the structures of linear polyenes and poly-ynes, based on an examination of their vibrational spectra, agrees with the results of most quantum-mechanical calculations and also with the available experimental data on the electronic spectra (the convergence of λ_{max} with increase in n) and bond lengths (the fact that the lengths of the multiple and single bonds are independent of chain length) for these compounds. It should be noted that the differences in the values of the force constants for the C=C bonds in ethylene and polyenes and for the C≡C bonds in acetylene and poly-ynes are not incompatible with the equality of the lengths of the multiple bonds in the corresponding molecules (with the significant interaction constants in conjugated molecules)[258].

Thus analysis of the vibrational spectra of butadiene[245] and diacetylene[255] and of polyenes[243] and poly-ynes[255] with higher molecular weight showed that molecules with alternating multiple and single carbon–carbon bonds have a characteristic type of force field. The force field of vinylacetylene[259] also belongs to this type. Let us consider the factors which may be responsible for the specific features of the force fields of these compounds. Table 3, taken from our paper[266], compares the most important characteristics of the force field for the chains of carbon atoms in butadiene and diacetylene with the analogous characteristics of molecules for which significant electron delocalisation is not expected (compounds *1–7*) and compounds for which delocalisation has been assumed (compounds *8* and *9*). The data show that change in the valency state of the carbon atoms does not lead to a significant change in the force constants for the single and multiple bonds. The force constants for the multiple bonds remain almost unchanged when an H atom is replaced by a methyl group. The constants for the interaction of even adjacent bonds are very small for compounds *1–7*. Quite different relationships between the force constants are observed in the benzene molecule and in the pentadienyl

‡ Here and subsequently the force constants are given in units $\times 10^6$ cm^{-2}.

ring of ferrocene, that is, with complete delocalisation. In this instance there is a change in the constants for the carbon–carbon bonds and a sharp increase in the constants for the interaction of adjacent bonds, and significant values are observed for the constants for the interaction of bonds without a common atom.

* K_{ij} is the adjacent bond interaction constant, and K_{ik} the interaction constants for bonds without a common atom.

Comparison of the elastic characteristics of simple molecules leads to the conclusion that the force constants of carbon–carbon bonds are parameters which are extremely sensitive to π-electron delocalisation but which have a comparatively low sensitivity to change in the hybrid type of the bond. It is therefore natural to relate the specific features of the force field of butadiene and diacetylene not to the hybridisation of the carbon but to partial π-electron delocalisation.

Relationships between the bond order and force constant (Fig. 7) and between the bond hybrid type (or length) and force constant (Fig. 8) have been obtained for single and multiple carbon–carbon bonds[265]. Curve *2* in Fig. 7, based on the relationship between force constant and hybridisation for a single C–C bond, shows the contribution of the σ-components to the values of the constants for multiple bonds (in the harmonic approximation and assuming additivity of the σ- and π-electrons). Comparison of curves *1* and *2* shows that the increased rigidity of the bond with increase in its order is due chiefly to the π-electrons. The values of the π-orders of the bonds, found from the curves in Figs. 7 and 8, amounted to 0.40 and 0.80 for butadiene, 0.45 and 1.88 for diacetylene, and 0.45, 0.80, and 1.88 for vinylacetylene. A noteworthy feature revealed by comparison of these data is the similarity in the values for the orders of the single bonds in butadiene, diacetylene, and vinylacetylene. This indicates that the multiplicities of the central bonds in these molecules are approximately the same. If the decrease in the lengths of single bonds situated between double and triple carbon–carbon bonds were determined to a significant extent by the values of their π-orders (in accordance with the delocalisation concept) we would expect only a very slight difference in the lengths of the C–C bonds in butadiene, diacetylene, and vinylacetylene (not more than 0.03 Å, if we calculate the covalent radius of carbon from data on the lengths of CH bonds). This is not the case, however. On going from butadiene to diacetylene, the length of the single bond decreases by 0.11 Å, which is almost twice that observed on going from ethane to butadiene (~ 0.06 Å).

Conjugated nitriles, such as cyanogen, cyanoacetylene, and cyanoethylenes, which have a formal resemblance to the corresponding conjugated hydrocarbons, are of considerable interest in the further study of this problem.

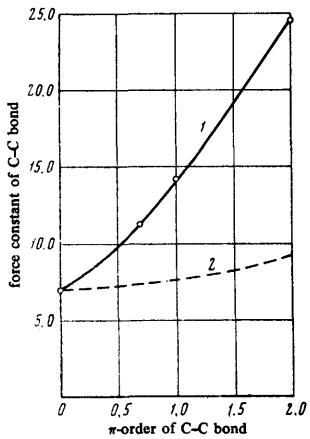

Figure 7. Plot of bond order against force constant for C–C bonds.

Qunatum-mechanical calculations which have been carried out for these molecules do not yet permit an unambiguous conclusion to be reached regarding the electron density distributions. McLean and Clementi[267,268], using the SCF MO LCAO method with allowance for all the electrons, obtained molecular wave functions for hydrogen cyanide (HCN) and cyanogen (C_2N_2). The bond orders for cyanogen calculated on the basis of these results by Mulliken[269] indicate that the delocalisation of the π-electrons in this molecule is as extensive as that in diacetylene. A different

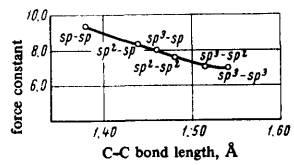

Figure 8. Plot of bond length against force constant for C–C single bonds.

conclusion was reached by Burnelle[270], who also applied the wave functions of McLean and Clementi to the HCN and C_2N_2 molecules. Burnelle concluded that the electron density curves for the HCN and C_2N_2 molecules are almost identical in the region of the nucleus of the nitrogen atom and in the region of the unshared pairs, and also in the zone of the C≡N bonds. Moffat[271] used the LCAO MO method with self-consistency to calculate the orders of the

C=C, C≡C, C–C, and C≡N bonds for an extensive series of nitriles. By assuming that the Coulomb and resonance integrals of the molecules studied are proportional to the corresponding integrals for benzene, Moffat obtained high π-orders for the C–C bonds in acrylonitrile (0.45), cyanoacetylene (0.36), and cyanogen (0.31). Shvarts[272] studied cyanoethylenes by the LCAO MO method and concluded that with increase in the number of nitrile groups attached to the double bond there is a decrease in the π-order of the latter and an increase in the conjugation energy.

The authors of the present review recently carried out an analysis of the vibrational spectra of cyanogen, cyanoacetylene[265], and mono-, *trans*-di-, *cis*-di-, tri-, and tetra-cyanoethylenes[264]. The observed values of the constants show that the force fields of conjugated nitriles differ qualitatively from the force fields of conjugated hydrocarbons. The constants for the bonds in cyanogen, cyanoacetylene, and cyanoethylenes were found to be much closer to the values of the corresponding constants for simple molecules than is the case for butadiene, diacetylene, and vinylacetylene. The values of the constants for the interaction of the multiple bonds are also much smaller. The orders of the central C–C bonds in the above nitriles are smaller by a factor of 3–4 than those for conjugated hydrocarbons. Thus the analysis of the vibrational spectra indicates that the π-electron delocalisation resulting from the intramolecular mutual influence of the nitrile groups and the double (or triple) bonds is not as extensive as that in analogous systems with alternating multiple and single carbon–carbon bonds. In spite of this marked difference in the π-electron delocalisation, the lengths of the single bonds with the same hybridisation in nitriles and in hydrocarbons show almost no differences. Thus here, as in butadiene, diacetylene, and vinylacetylene, we reach the conclusion that the interatomic distances are determined chiefly by the valency state of the carbon atoms, and not by π-electron delocalisation. This is also in accordance with a number of other experimental facts already mentioned. Data on the bond lengths for cyclo-octatetraene, in which the conditions necessary for conjugation are absent, are of particular interest. Our calculation of the force constants for the cyclo-octatetraene molecule[266] confirm that there is very little π-electron delocalisation.

The conclusion that the length of a carbon–carbon bond in linear conjugated systems shows little sensitivity to change in the bond order is not always correct, however. Studies of organic dyes[174,175,178], cumulenes[204,205], and condensed aromatic hydrocarbons[211,212] have shown that the bond orders in these molecules serve as an accurate indication of bond lengths. For example, for ovalene, which has twelve types of non-equivalent carbon–carbon bond, Buzeman[273] obtained excellent agreement between all the experimental and calculated bond lengths. The latter were determined using the π-orders calculated by the simple MO method. It is evident that here, as in many other instances, the agreement is not accidental. Thus at first sight there appear to be contradictory facts, some of which indicate that there is a relationship between bond order and bond length (aromatic compounds, polymethines, cyanines, and cumulenes), whereas others indicate that the bond length is not determined by the bond order (linear polyenes and poly-ynes). The authors of the present review[265] showed that this is due to the specific values of the π-orders of the bonds in the molecule and to the nature of the relationship between the order of a carbon–carbon bond and the change in its length due to π-electrons. The relationship observed[265] is given by curve *II* in Fig. 9. In the construction of curve *II* it was assumed that the lengths of pure σ-bonds of the types C_{sp^2}–C_{sp^2} and C_{sp}–C_{sp} are equal to the lengths of the central bonds in butadiene (1.483 Å) and diacetylene (1.379 Å). The length of a σ-bond of the type C_{sp^3}–C_{sp^3} is equal to the length of the C–C bond in ethane (1.54 Å). The vertical axis on the right gives the differences in the lengths of the multiple and single bonds formed by carbon atoms with the same hybridisation, and the horizontal axis gives the bond orders. As starting compounds we took acetylene, ethylene, benzene, graphite, and ethane, for which the hybridisation, orders,

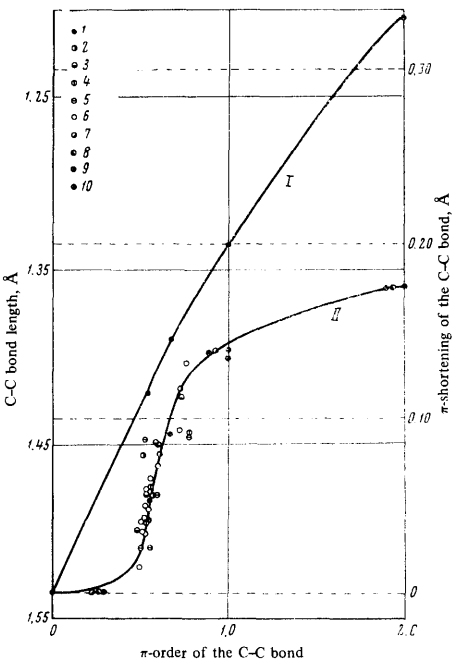

Figure 9. Plot of bond order against bond length (*I*) and bond order against π-shortening of the bond (*II*):
1) Ethane, graphite, benzene, ethylene, acetylene; *2*) naphthalene; *3*) anthracene; *4*) coronene; *5*) pyrene; *6*) ovalene; *7*) butadiene; *8*) diacetylene; *9*) vinylacetylene; *10*) allene.

and lengths of the bonds are known. Thus curve *II* gives the change in the length of the carbon–carbon bond due entirely to the π-electrons. The total change in bond length on going from ethane to acetylene is shown by curve *I* (the familiar Pauling curve). The fact that curve *II* is S-shaped indicates that the lengths of the carbon–carbon bond are not equally sensitive to bond order. The changes in bond order from 0 to 0.4 and in the regions around 1.0 and in around 2.0 lead to small changes in bond length, within the limits of experimental error. It is evidently for this reason that the bond lengths in butadiene, diacetylene, and vinylacetylene (whose bond orders lie in these ranges) differ little from the lengths of the carbon–carbon bonds of the same hybridisation type in molecules in which there is no π-electron delocalisation.

The bond length is most sensitive to change in bond order in the range 0.4–0.9, that is, in the range corresponding to aromatic compounds and organic dyes. Since all the carbon–carbon bonds in these molecules have a

hybridisation close to sp^2–sp^2, the interatomic distances depend almost exclusively on the bond orders, the relationship being almost linear. Curve *II* in Fig. 9 passes through the points corresponding to the molecules of naphthalene, anthracene, coronene, pyrene, and ovalene, and also the points corresponding to the molecules of butadiene, diacetylene (and hence other linear polyenes and poly-ynes), vinylacetylene, and allene.

The observed relationship between bond length and bond order shows that π-electron delocalisation and the associated changes in the orders of the single and multiple bonds in linear polyenes and poly-ynes does not lead to a significant change in bond length. The decrease in the length of the single bonds in these molecules with isolated multiple bonds is determined chiefly by the valency state of the carbon atoms. At the same time, preservation of the lengths of the bonds of a given hybrid type in the molecules of organic compounds cannot be taken as a sufficient basis for rejecting π-electron delocalisation.

This conclusion is equally applicable to bond energies. It can be seen from Fig. 10 that the relationships between bond order and total bond energy (curve *1*) and between bond order and the energy introduced into the carbon–carbon bond by the π-electrons (curve *2*) are analogous to the corresponding relationships between bond length and bond order (Fig. 9). The construction of the curves in Fig. 10 is analogous to that of the curves in Fig. 9; the values of the bond energies are taken from Table 1. The

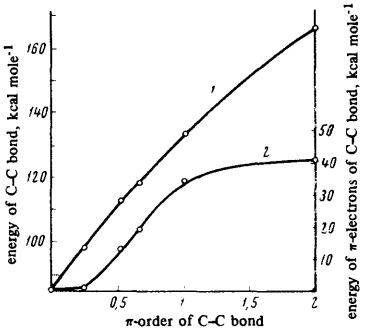

Figure 10. Plot of bond energy against bond order (*1*) and π-bond energy against bond order (*2*).

fact that the bond energy and bond length show identical behaviour with change in bond order is not surprising, since there is a linear relationship between them (Fig. 2). Fig. 10 shows that in conjugated hydrocarbons with open chains the energy of the π-bond is not proportional to the bond order, as follows from the simple Hückel method[213]. This feature evidently explains the overestimation of the part played by π-electron delocalisation in the interpretation of the properties of polyenes and poly-ynes by the Hückel method.

2. Polar Properties of Conjugated Chains

To obtain a more detailed picture of the electron density distribution along a chain of conjugated bonds, it is of considerable interest to study the intensities of infrared absorption bands and Raman lines. According to the modern semi-empirical theory of intensities[274], the electro-optical parameters characterising directly the electronic structure of a molecule are the dipole moments and polarisabilities of the individual bonds and their derivatives with respect to the vibrational coordinates.

The specific form of the electric field of butadiene was determined by the authors of the present review[275] by analysing the intensities of the infrared spectra of the C_6H_6 and C_4D_6 molecules. It was shown that the double bonds in butadiene have dipole moments of ~ 1.3 D, whose positive ends are the $C_{(2)}$ and $C_{(3)}$ central atoms. The parameter which characterises the change in the C=C moment on elongation of the double bonds was also found to have an appreciable magnitude. Since all the carbon atoms in the molecule are in the same valency state (sp^2), the results indicating non-equivalence of the electron density distribution in the C=C–C=C system contradict the views of Dewar and Schmeising[3-5] regarding the structure of butadiene. The observed electro-optical parameters of the terminal $=CH_2$ groups of butadiene (like the $=CH_2$ force constants) differ from the corresponding quantities in non-conjugated molecules (ethylene and propene) to a much smaller extent than the parameters of the central =CH bonds. This suggests that partial delocalisation of the electrons in butadiene and the production of an excess of negative charge on the $C_{(1)}$ and $C_{(4)}$ atoms relative to $C_{(2)}$ and $C_{(3)}$ take place chiefly as a result of the overlap of the π-orbitals of the $C_{(2)}$ and $C_{(3)}$ central atoms. An analogous conclusion regarding the polarity of the multiple bonds and the nature of the electron density distribution was reached by studying the intensities of the infrared absorption bands of other simple conjugated molecules—diacetylene and vinylacetylene[276].

Let us consider briefly the picture of charges on atoms following from quantum-mechanical calculations. Coulson and Rushbrooke[277] previously showed that the π-electron charges on all the carbon atoms in polyenes are the same and equal to 1. Later, McWeeny[278] showed that the formal charge on carbon can be represented as the sum of the local charge of the atom and the charge of the bond. It was concluded that two carbon atoms with equal formal charges can have different local charges, so that the distribution of the charges in alternant hydrocarbons may be unsymmetrical. Maslen and Coulson[279] calculated the charges of the atoms and bonds in linear polyenes (without allowance for the distribution of electrons in the σ-bonds). The following values were obtained for butadiene:

$$\overset{0.82}{C}\overset{}{=}\underset{0.35}{\overset{0.75}{C}}\overset{}{-}\underset{0.14}{\overset{0.75}{C}}\overset{}{=}\underset{0.35}{\overset{0.82}{C}}.$$

Thus the values of the π-electron charges on the $C_{(1)}$ and $C_{(4)}$ atoms are greater than those on the $C_{(2)}$ and $C_{(3)}$ central atoms. An interesting feature is that the charges on the $C_{(1)}$ and $C_{(4)}$ atoms almost coincide with the values of the charges on the carbon atoms in ethylene, calculated by the same authors[279]. The magnitude of the C=C moment, determined by Maslen and Coulson only on the basis of the non-equivalent distribution of the π-electron density along the bond, amounts to ~ 0.45 D.

Fukui and coworkers[280] used the LCAO MO-method to calculate the σ-electronic charges of the atoms in butadiene. The calculations gave the following σ-electron density distribution:

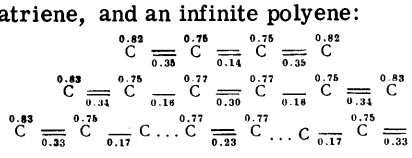
$$\overset{0.18}{C}=\overset{0.11}{C}-\overset{0.11}{C}=\overset{0.18}{C}.$$

The dipole moment of the C=C bond due to the non-equivalent distribution of the σ-electrons of butadiene amounts to ~ 0.45 D and is directed in the same direction.

Thus the data on the electron density distribution in butadiene obtained from quantum-mechanical calculations and analysis of the intensities of the infrared spectra show qualitative agreement.

The polar properties of conjugated compounds containing a larger number of units in the chain were studied by Ivanova, Lubuzh, and the present authors[252,253,255] using the intensities of the infrared absorption bands of $\alpha\omega$-substituted polyenes of the type $X-[CH=CH]_n-X$, where $X = COOC_2H_5$ and $n = 2-7$, and poly-ynes of the type $R-[C\equiv C]_n-R$, where R = Alk and $n = 2-4$. The experimental data on the intensities of the absorption bands of the polyenes at about 1600 cm^{-1} and of the poly-ynes at about 2200 cm^{-1}, and an analysis of the forms of the vibrations, indicate that the observed proportionate increases in the integral intensities of absorption for the polyenes and poly-ynes are due chiefly to the increase in the number of bonds taking part in the vibrations, and not to changes in the polar properties of the chains. Calculations of the intensities of the absorption bands of polyenes led to the conclusion that the values of the polarisation of both single and double bonds depend little on the position of the bonds in the chain. Good agreement between the experimental and calculated values of the relative intensities of the infrared absorption bands of the polyenes at about 1600 cm^{-1} was obtained with the assumption that the polarisation of a single bond is equal to half the polarisation of a double bond and of opposite sign. Thus studies of the frequencies of the normal vibrations and the intensities of the infrared absorption bands show that in molecules with alternating multiple and single carbon–carbon bonds there is alternation of both bond orders and charges on the carbon atoms along the chain, the degree of alternation in both instances being independent of chain length. Thus the frequencies and intensities of alternant hydrocarbons can be explained within the framework of a single model with partly delocalised bonds. Moreover, the data obtained cannot be explained using the hybridisation concept.

The conclusion, which follows from the analysis of the infrared spectra, that there is alternation of the charges on the carbon atoms in a polyene chain, agrees with the results of quantum-mechanical calculations by Maslen and Coulson[279]. The following results were obtained for butadiene, hexatriene, and an infinite polyene:



These data show that the charges on the atoms of the terminal bonds are independent of the dimensions of the polyene chain. The charges on the atoms of the central bonds in the polyenes also remain unchanged with increase in the number of units. The dipole moments of the double and single bonds have opposite directions. It may be noted that quantum-mechanical calculations and analysis of the infrared spectra lead to a polyene model in which the central bond has no dipole. Other data also point to a model in which the central bond exhibits unique properties. Even in long polyenes, the central bond exhibits specific chemical and stereochemical properties[148]. For example, of the large number of possible *cis–trans* isomers of a polyene chain, the one most readily realised is that with the central double bond in the *cis*-configuration. Ease of isomerisation at the central double bond is observed in the molecules of lycopene and the α-, β-, and γ-carotenes. The molecules undergo relatively easy rupture at this point[148].

As already noted, the force fields of conjugated nitriles differ qualitatively from the force fields of conjugated hydrocarbons. In particular, the force constants of the C=C, C≡C, and C≡N bonds and the intermediate C–C bonds in cyanoethylenes and cyanoacetylene (Table 3) have values which are close to the corresponding constants for the isolated multiple bonds and the simple σ-bond. Study of the intensities of the infrared absorption bands of acrylonitrile[281] showed that the mutual influence of the multiple carbon–carbon bonds and the nitrile group produces an electron density distribution which differs significantly both from that for simple molecules and from that for alternant hydrocarbons without leading to appreciable π-electron delocalisation. Calculation of the electro-optical parameters gives a dipole moment of ~ 1.0 D for the double bond in acrylonitrile with the negative charge on the $C_{(2)}$ atom, that is, the direction of the double bond moment in acrylonitrile is the opposite of that for butadiene and vinylacetylene. The double bonds in the C=C–C≡N and C=C–C≡C (or C=C–C=C) systems differ in the values of the π-orders, in the nature of the electron density distribution along the bond, in the ability of the charge to migrate during the vibration (this is much smaller for acrylonitrile than for vinylacetylene and butadiene). In these conjugated nitriles, the displacement of the electron density towards C≡N takes place chiefly within individual bonds. There may be instances when the inductive effect causes the electrons to leave the limits of their "own" bonds. This requires a relationship between the donor and acceptor properties of the interacting atomic groups which is different from that in acrylonitrile and cyanoacetylene. These conditions are satisfied, for example, in the cyanamide molecule, in which the inductive effect leads to delocalisation of the electrons of the unshared pairs of the nitrogen and a change in its valency state[282].

The electron density distribution in acrylonitrile was recently studied by Halper and coworkers[283] using the simple Hückel method with allowance for overlap. The results obtained show good agreement with the results of the analysis of the intensities of the infrared absorption bands. The dipole moment of the C=C bond, determined on the basis of the π-charges on the atoms found by Halper and coworkers[283], amounted to ~ 0.7 D, compared with the value of ~ 1.0 D obtained from the infrared spectra[281].

Study of the electron density distribution in butadiene, diacetylene, vinylacetylene, and polyenes and poly-ynes with higher molecular weights showed that the delocalisation of the electrons in these molecules leads to polarisation of the bonds. In molecules known to contain polarised bonds (cyanogen, cyanoacetylene, and cyanoethylenes), however, the delocalisation of the π-electrons is significantly smaller, and is probably due to different factors. As already noted, the direction of the displacement of the electron density of multiple bonds in these molecules under the influence of the inductive effect of the acceptor nitrile group is the opposite of that for the analogous bonds in compounds with purely carbon–carbon conjugation. Thus the effect of delocalisation and the inductive effect have opposite influences on the π-electron density distribution. It is probably because of this feature, and also because of the polarisation of the bonds on delocalisation and the production of an inductive interaction, that the alternation of the bonds is preserved in linear polyenes and poly-ynes. The degree of alternation, that is, the orders of the multiple and single bonds, is determined by the competition between the two effects. In aromatic compounds, for example, in benzene, the complete equalisation of the bonds is due to

the fact that π-electron delocalisation is possible whereas polarisation is impossible, that is, only one effect operates.

Let us now consider the Raman spectra of conjugated systems. The Raman spectra of the esters of polyene $\alpha\omega$-dicarboxylic acids $C_2H_5OOC[CH=CH]_nCOOC_2H_5$, where $n = 2-8$, and diphenylpolyenes $C_6H_5[CH=CH]_nC_6H_5$, where $n = 5$ or 6, were studied in detail by Shorygin and Ivanova[251,284,285]. It was found that with increase in n, the intensities of the various Raman lines of the polyenes do not increase to the same extent. In the spectra of short polyenes ($n = 2-4$) the number of observed lines assigned to the vibrations of the chain corresponds exactly to that predicted by theory for centrosymmetric molecules. With increase in n, the frequency of the exciting light approaches the range corresponding to the characteristic frequencies of the electronic transitions, and when the frequencies coincide, that is, with excitation in or close to the resonance range, not all of the Raman-active vibrations of the polyene chain are observed, but only two normal vibrations ($\sim$ 1600 cm^{-1} and 1140 cm^{-1}) and their overtones and combination frequencies (as far as the fourth order). An interesting feature is that the maximal deviations of the frequencies of higher order from the multiple fundamental tones, due to anharmonicity, are small and amount to $\sim$ 30 cm^{-1}. The lines at $\sim$ 1600 cm^{-1} and 1140 cm^{-1} are characterised by unusually high absolute intensities. Approximately the same frequencies are observed in the vibrational structure of the first absorption bands and fluorescence bands in a number of other polyenes[286]. These lines are also present in the Raman spectra of polyenes with various substituents in the α- and ω-positions[287]. With increase in the number of double bonds, the frequency in the region of 1600 cm^{-1} decreases regularly, approaching a definite limit, whereas the 1140 cm^{-1} frequency is independent of chain length. Calculations for polyenes[243,245] showed that this behaviour of the Raman frequencies is not due to equalisation of the bonds. The reason for the unique activity of the symmetric vibrations at $\sim$ 1600 cm^{-1} and 1140 cm^{-1} compared with the other vibrations permitted by symmetry for a system of conjugated double bonds is that only these vibrations involve the entire polyene chain, so that they are accompanied by the maximal change in the polarisability of the molecule.

The reason for the marked decrease in the frequencies at $\sim$ 1600 cm^{-1} with increase in the length of the chain ($\sim$ 100 cm^{-1} on going from $n = 2$ to $n = 8$) without change in the nature of the bonds and with preservation of the 1140 cm^{-1} frequency under the same conditions was investigated[281] by comparing the zeroth amplitudes of the double ($\bar{Q}$) and single ($\bar{q}$) bonds. It was found that the ratio $\bar{Q}/\bar{q}$ for the vibrations at $\sim$ 1600 cm^{-1} decreases with increase in the length of the chain, the decrease being greater for the first terms of the vinyl series, but remains almost constant for the vibrations at 1140 cm^{-1}. Since the overall change in the double and single bonds in these vibrations depends little on chain length, the decrease, with increase in n, in the relative participation of the more rigid double bonds in the $\sim$ 1600 cm^{-1} vibration leads to a decrease in the frequency without change in the nature of the bonds. With the condition that the ratio $\bar{Q}/\bar{q}$ is constant, the frequency at 1140 cm^{-1} can remain unchanged in the spectra of various polyenes only if the elastic properties of the bonds are preserved irrespective of chain length[288].

3. Transfer of Influence Along a Chain of Conjugated Bonds

The concept of molecules with alternating multiple and single carbon–carbon bonds as systems transferring the influence of substituents without significant weakening (vinylogy) is widely encountered in the literature. Analysis of the available data on the physical and chemical properties of conjugated compounds, however, indicates that there is little justification for these views. Thus calculations of the vibrations of linear polyenes and poly-ynes[243,245,255] showed that significant interaction takes place only between the closest multiple bonds. With increase in the number of intermediate units, the interaction rapidly becomes weaker and is almost imperceptible for multiple bonds separated by more than two carbon atoms. It is natural to assume that the mutual influence of substituents in the α- and ω-positions will decrease to the same extent. The problem of the transfer of influence through a system of conjugated bonds was examined by Ivanova and the present authors[243,253] in an analysis of the vibrational spectra of the esters of polyene $\alpha\omega$-dicarboxylic acids ($n = 2-8$), unsymmetrical polyenes $X-[CH=CH]_nCOOC_2H_5$ ($X = CH_3$, NO_2, and CHO, $n = 2-4$) and $\alpha\omega$-dinitriles $NC-[CH=CH]_n-CN$ ($n = 4$ or 5). The study showed that the values of the frequencies and intensities of the C=O stretching vibrations in the infrared spectra of the esters $C_2H_6OOC[CH=CH]_nCOOC_2H_5$ are independent of chain length and agree with the corresponding values for the $\alpha\beta$-unsaturated esters of carboxylic acids (RCH=CHCOOR, R = Alk[289]). Change in X and n in $X-[CH=CH]_nCOOC_2H_5$ did not lead to marked changes in the frequencies and intensities of the absorption bands of the carbonyl group in the spectra. This indicates that a conjugated system of carbon–carbon bonds in the ground electronic state of the molecule does not effectively transfer the influence of substituents. This conclusion is confirmed by the agreement shown by the ν_s and ν_{as} frequencies of the C=O vibrations in the spectra of polyene diesters and the C≡N vibrations in the spectra of polyene dinitriles. The absence of splitting of the frequencies of the symmetric and antisymmetric vibrations of equivalent atomic groups in the spectra of symmetrical molecules indicates the absence of mechanical and electronic interaction between the groups[290,291]. The conclusion that substituents at the ends of a polyene chain have an extremely restricted sphere of influence agrees with data obtained by Hutchinson and Sutton[179] on the dipole moments of the series of polyenes $(H_3C)_2N-[CH=CH]_n-CHO$ ($n = 0-4$) and data obtained by Yanovskaya[292] on the ionisation constants of polyene mono- and di-carboxylic acids. The nature of the changes in both dipole moments and ionisation constants with increase in chain length shows that the mutual influence of substituents separated by a conjugated chain weakens very rapidly. It can hardly be detected by dielectric or potentiometric measurements or by vibrational spectroscopy even for polyenes with $n \geq 3$. Quenching of the influence of substituents was also observed by Shorygin and Ivanova[293,294] from the Raman spectra of various other classes of conjugated compound. A long system of conjugated bonds does not transfer the influence effectively even when one end of the chain carries a substituent with clearly defined electron-donating properties (for example, R_2N-) and the other carries a substituent with clearly defined electron-accepting properties ($-NO_2$).

4. Classification of the Force Fields and Electric Fields of Organic Compounds

A considerable amount of material on the force fields of various classes of organic compound has now accumulated. Its analysis has enabled the present authors[266] to classify

force fields (initially on the basis of purely external characteristics) into several types, arbitrarily described as non-conjugated, aromatic, mesomeric, and inductive. It was found that this classification corresponds to the electronic structures of the molecules. Each type of force field is determined by a definite form of electron density distribution. The force constants of bonds and their interaction constants for simple molecules are given in Table 3.

We have already noted the characteristic features of the force fields of saturated hydrocarbons, compounds with isolated multiple bonds, aromatic compounds, and linear polyenes and poly-ynes. The force fields of conjugated molecules containing electron-accepting groups exhibit certain specific features. The data given above for the molecules of acrylonitrile and cyanoacetylene show that the polarisation of multiple carbon–carbon bonds has little influence on the values of the diagonal elements, but leads to an increase in the non-diagonal elements of the interaction of the bonds.

The sets of force constants of each type describe the vibrational spectra of a large number of molecules with the corresponding electron density distribution. The force constants of the non-conjugated type describe the spectra of alkanes, alkenes, and alkynes; those of the aromatic type describe the spectra of benzene derivatives and condensed aromatic compounds; those of the mesomeric type describe the spectra of polyenes, poly-ynes, and vinylacetylenes; and those of the inductive type describe the spectra of a large number of nitriles[295,264,265]. Each type of force field is characterised by definite values of the force constants of the bonds and values of the bond interaction constants. Changes in the constants are mutually related. Thus decrease in the constants of the multiple bonds in linear polyenes and poly-ynes (as a result of π-electron delocalisation) is accompanied by an increase in the constants of the single bonds and the bond interaction constants (as a result of the formation of multi-centre orbitals). Change in the nature of the electron density distribution leads to a change in the complete set of force constants. Within a given type of force field, however, the values of the constants are transferable.

The classification of force fields facilitates the solution of two problems. When the force field is known, its classification in a given type immediately gives information on the electronic structure of the molecule. On the other hand, a knowledge of merely the nature of the electron density distribution in a molecule increases considerably the reliability of the determination of force constants. The existence of a correlation between the structure and force field of a molecule imposes a number of additional conditions on the solution of the reverse spectroscopic problem. An example is provided by the study of the molecules of cyclo-octatetraene (C_8H_8) and butatriene (C_4H_4).[286] The frequencies of the vibrations of these extremely complex molecules were determined using force fields compiled on the basis of data on their electron density distributions. Calculations of the normal vibrations for C_8H_8 and C_8D_8, in agreement with quantum-mechanical calculations[24], confirmed that there is no significant π-electron delocalisation in cyclo-octatetraene, despite the formal resemblance to the molecules of alternant hydrocarbons. In the calculation for butatriene it was assumed that the nature of the electron distribution in one of the planes of the molecule is similar to that in butadiene, and in the other (perpendicular to the first) is similar to that in an isolated double bond. In accordance with this assumption, the force field of butadiene was compiled by superimposing fields of two types—mesomeric and non-conjugated. In the determination of the numerical values of the force constants, the values of the orders of cumulative bonds for butatriene obtained by the MO method[221] were assumed, and use was made of the relationship between the force constant, hybridisation type, and bond order (Figs. 7 and 8). The frequencies of the vibrations of butatriene calculated for these conditions showed good agreement with the observed values. Recently, an attempt was made to calculate, on the basis of the proposed classification of force fields, the frequencies of the vibrations of vinylacetylene and the four methyl derivatives of vinylacetylene using constants selected on the basis of definite assumptions regarding the electron density distribution in the C=C–C≡C system[259]. Agreement between all the calculated and experimental frequencies (more than 120) was obtained only when a force field of the mesomeric type was used. It should be borne in mind, however, that the proposed classification[266] of force fields is to some extent arbitrary. A sharp distinction cannot be made between the force fields of organic molecules, particularly molecules containing hetero-atoms. When there is strong intramolecular interaction between individual atomic groups, the force field of the molecule may appear in a new form or exhibit the features of several types simultaneously. Examples are provided by the molecules of $\alpha\beta$-unsaturated ketones[296] and the cyanamide molecule[282]. Nevertheless, a knowledge of the force fields of the limiting structures is also necessary in complicated cases.

A much more complete picture of the electronic structure of a molecule in the ground state can be obtained by simultaneous analysis of the force field and the electric field. Data are now available on the electric fields of a comparatively large number of molecules of organic compounds of various classes[256,275,281,297-304]. These values were obtained with the same approximation and within the framework of a single calculation scheme by Gribov[274]. Calculations showed that the electro-optical parameters characterise the properties of only the electron cloud of the molecule and in this sense they resemble force constants. A paper by one of the present authors[305] classified the electric fields of organic molecules and established a correlation between the specific features of the electronic structure and the characteristic features of the electric field.

Calculation of the intensities of the infrared absorption bands of saturated hydrocarbons and compounds with isolated multiple bonds[256,298-301] showed that the electro-optical parameters of the $-CH_3$, $=CH_2$, and $\equiv CH$ groups, found for simple molecules, can be used to describe satisfactorily the intensities for more complex alkane, alkene, and alkyne molecules. Thus within a series of these compounds, the electro-optical parameters of the above groups, like their force constants, are transferable. The mechanical and polar properties of the $-CH_3$, $=CH_2$, and $\equiv CH$ groups in the molecules of a given series remain to a considerable extent unchanged, that is, the electron density distribution remains approximately the same. The electric fields of alkanes, alkenes, and alkynes are also characterised by low values for the dipole moments and polarisations of the carbon–carbon bonds. The participation of purely carbon-carbon bonds in the vibrations of the molecules does not make a significant contribution to the intensities of the infrared absorption bands. This leads to the at first sight paradoxical conclusion that the infrared spectra of compounds of these classes are due chiefly to the electro-optical properties of the CH bonds.

The electric fields of linear conjugated molecules belong to a different type. Butadiene[275], diacetylene[276], and vinylacetylene[276], as well as polyenes[252] and poly-ynes[255]

with higher molecular weights are characterised by appreciable dipole moments and polarisations of the carbon–carbon bonds. In the C=C–C=C, C=C–C≡C, and C≡C–C≡C systems the excess of negative charge is found on the $C_{(1)}$ and $C_{(4)}$ atoms. The electro-optical parameters of identical atomic groups in the molecules of conjugated hydrocarbons have similar values. Thus the electric field of vinylacetylene can be made up almost entirely of the parameters of the corresponding atomic groups of butadiene and diacetylene[276,305], and the electric fields of polyenes can be made up of the parameters of butadiene[252]. In this sense the electro-optical parameters of butadiene and diacetylene are transferable and can be used to compile the electric fields of more complex linear molecules with alternating multiple and single carbon–carbon bonds. It was noted above that in the same series of compounds an analogous property is shown by the force constants of butadiene and diacetylene. Thus for conjugated molecules, as for non-conjugated molecules, the transferability of some parameters is accompanied by the transferability of others. A correlation between electric fields and force fields is also observed for the molecules of other classes of organic compound. In all cases each type of electric field corresponds to a definite type of force field.

The results of experimental and theoretical studies of conjugated hydrocarbons enable the following conclusions to be reached regarding their structures and certain other properties.

1. Linear polyenes and poly-ynes consist of systems of conjugated alternating bonds. Increase in the length of the chain does not lead to appreciable equalisation of the carbon–carbon bonds. The lengths and orders of the multiple and single bonds in polyenes and poly-ynes with high molecular weights are approximately the same as those for butadiene and diacetylene respectively.

2. Organic dyes (polymethines, cyanines, and oxonols) contain equalised bonds. With increase in the length of the chain, the lengths and orders of the bonds approach those of the bonds in benzene.

3. Cumulenes consist of systems of double bonds conjugated in two mutually perpendicular planes; increase in the length of the chain does not lead to a change in the lengths and orders of the bonds. In a cumulene with a long chain, all the bonds except the terminal bonds have the same lengths and orders. As for other compounds with equalised bonds, λ_{max} in the ultraviolet spectra of the cumulenes is displaced by a constant amount with the addition of each new unit.

4. The lengths and energies of carbon–carbon bonds are not equally sensitive to bond order throughout the entire range of possible change in this quantity. Preservation of the lengths and energies of the bonds of a given hybridisation type in the molecules of organic compounds cannot be taken as a basis for rejecting π-electron delocalisation.

5. Delocalisation of π-electrons and the associated changes in the orders of multiple and single bonds does not lead to a significant change in the lengths and energies of the bonds in polyenes and poly-ynes. The increase in the energy and the decrease in the length of the single bonds in alternant hydrocarbons are determined chiefly by the valency state of the carbon atoms.

6. The lengths and energies of the bonds in polymethines, cyanines, oxonols, and aromatic compounds depend almost exclusively on the bond orders, the corresponding relationships being almost linear.

7. Delocalisation of π-electrons in polyenes and poly-ynes leads to a non-equivalent distribution of electron density along each bond, with the exception of the central bond. In butadiene, vinylacetylene, and diacetylene, the positive ends of the dipoles of the multiple bonds are the central carbon atoms. With increase in the length of the chain, alternation of the bond orders, and also alternation of the charges on the atoms, are preserved.

8. The mutual influence of atomic groups separated by a chain of conjugated carbon–carbon bonds rapidly becomes weaker with increase in the number of intermediate units.

9. The characteristic features of the force fields and electric fields of conjugated hydrocarbons are determined chiefly by π-electron delocalisation.

10. The methods of quantum chemistry and vibrational spectroscopy lead to the same picture of the structure of conjugated hydrocarbons.

---o0o---

A number of interesting experimental and theoretical papers on the structures of conjugated hydrocarbons appeared after the present manuscript had been submitted for publication. We can now only mention briefly some of these papers, most directly related to the topics discussed above.

Page 121. Traetteberg[306] has made a new study of the structure of cyclo-octatetraene. The value which he obtained for the C–C bond length in this molecule (1.475 Å) is greater than the value found earlier (1.460 Å)[23]; there is now almost no difference between the length of this bond and the length of the single carbon–carbon bond in butadiene.

Page 126. Studies confirming the alternation of the charges on the atoms and the bond orders in polyenes now include the following: calculations by Flurry and Bell[307] using the SCF MO LCAO method in the Pariser–Parr–Pople approximation, including resonance integrals characterising non-neighbouring interactions; calculations by Misurkin and Ovchinnikov[308] using the Hartree–Fock generalised self-consistent field method; calculations for $\alpha\omega$-diphenylpolyenes using Pariser–Parr–Pople method; calculations for polyenes by Adams and Miller[310] using a modified method with self-consistency; calculations for dienes and hexatriene by Allinger and coworkers[311] using the Pariser–Parr method; and calculations for polyenes by Kutzelnigg[312] within the framework of the simple Hückel approximation using a perturbation method.

Alternation of bond lengths was obtained by Haugen and Traetteberg[313] in an electron-diffraction study of 1,3-butadiene ($L_{C=C}$ = 1.343 Å and L_{C-C} = 1.467 Å) and *trans*-1,3,5-hexatriene ($L_{C=C}$ = 1.345 Å and L_{C-C} = 1.450 Å).

Page 127. Dähne and Leupold[314] published a review on the calculation of the electronic spectra of dyes of various classes.

Page 132. Cherniak and Costain[315] showed by microwave spectroscopy that the lengths of the C–C bonds in *trans*-acrolein and 1,3-butadiene are approximately equal (1.470 Å).

Page 134. Data indicating non-equivalent distribution of the π-electron density along the carbon framework of 1,3-butadiene were obtained by Hobgood and Goldstein[316] in an analysis of the NMR spectra.

V.	The most common masking agents	149
VI.	Characteristic examples of the practical application of masking	153

I. INTRODUCTION

Any chemical reaction is characterised not only by stoichiometric conditions but also by thermodynamic and kinetic conditions. Changes in the last two conditions may increase the rate of a reaction or, on the other hand, decrease the rate of the reaction until the reaction is completely suppressed. In recent years the rapid development of science and technology has faced chemists with a number of problems associated with the suppression of undesirable chemical processes[1], and the attention of chemists is now drawn equally to problems of increasing reaction rates and problems of decreasing reaction rates.

One particular example of the retardation of chemical reactions is masking, which is of considerable importance in analytical chemistry. The term masking is used to describe the retardation or complete suppression of a reaction in the presence of substances capable of altering the rate or direction of the reaction as a result of their influence on its kinetic or thermodynamic conditions without the physical or chemical separation of the participants of the reaction into a new phase. The substances introduced into the reaction medium in order to retard or suppress the reaction are called masking agents. A classical example of the masking of a reaction is the non-precipitation of $Fe(OH)_3$ from an alkaline solution containing F^- ions; in this example, F^- prevents the formation of $Fe(OH)_3$, by combining with Fe^{3+} to form the soluble complex FeF_6^{3-} (that is, by bringing about another, thermodynamically more favourable reaction) and thus acts as a masking agent for the reaction of Fe^{3+} with OH^-.

Frequently, instead of the masking of a reaction, one speaks of the masking of the ions (or molecules) taking part in the reaction; usually it is not even emphasised which of the ions taking part in the reaction being masked are in fact masked directly, that is, which of the ions is responsible for the masking of the reaction as a whole. For example, in the masking of the formation of the yellow molybdophosphate complex in the presence of $C_2O_4^{2-}$ in the traditional use of this masking agent to eliminate the interfering influence of PO_4^{3-} in the photometric determination of Si, reference is made to the masking of the PO_4^{3-} ion, rather than to the masking of the MoO_4^{2-} ion, although it is the MoO_4^{2-} ion which is responsible for the masking of the reaction, since it reacts with $C_2O_4^{2-}$ to form a colourless soluble complex. In most instances when a knowledge of the mechanism of masking is not required, this replacement of concepts, with a correct understanding of the essential features of the process, is quite justified, but for greater accuracy and to avoid misunderstanding it is desirable even in these instances to indicate the reaction (or reagent) with respect to which a given ion is masked. The statement (without any additional information) that a given ion is masked should evidently be understood to mean that all the reactions which are possible for this ion in the given reaction medium (before the addition of the masking agent) are masked. Thus if one speaks of the masking of Fe^{3+} by tartrate in the determination of Ni by dimethylglyoxime, one means that the Fe^{3+} is masked with respect to all reactions possible for this ion under the conditions of the determination of Ni, including (and this is the most important) the formation of $Fe(OH)_3$.

Frequently, the masking of ions is erroneously identified with the separation of ions, and it is forgotten that the separation of ions, unlike masking, always involves the transfer of ions into a new phase, that is, their actual removal from the sphere of reaction. For example, the reaction of NH_4^+ with CH_2O with the formation of soluble hexamethylenetetramine $(CH_2)_6N_4$ is a typical example of masking of the NH_4^+ ion, but the decomposition of NH_4^+ by nitrite with the formation of the gaseous product N_2 cannot be regarded as masking of the NH_4^+ ion. According to the same principle, masking does not include examples where the interfering influence of ions is eliminated by precipitating them in the form of sparingly soluble compounds, even when the latter remain in the mother-liquor [for example, the precipitation of Mg^{2+} as $Mg(OH)_2$ in the complexometric titration of Ca^{2+}].

The incorrect view that masking is merely a method for eliminating the interfering influence of substances in qualitative and quantitative analysis is widely encountered. Masking is a process in which the ion or molecule being masked, under the influence of the masking agent, loses its ability to undergo certain reactions characteristic of the ion or molecule. Like any other process, masking may be either desirable or undesirable, that is, it may be useful or harmful. Thus the masking of many qualitative reactions of the cations of analytical groups II and III in the presence of PO_4^{3-} is undesirable and steps have to be taken to prevent it. On the other hand, the masking of accompanying ions in various analytical reactions is useful and desirable, and is used to eliminate the interfering influence of these ions.

Masking has two significant advantages over methods of separation as a method for eliminating the interfering influence of substances: maximal speed, since almost no time is required for the actual masking, and high efficiency due to the absence of the usual errors associated with phase separations. Because of these advantages, the masking of reactions and ions has now become an extremely widespread and powerful means of eliminating the interfering influence of the medium in chemical analysis. This

has been greatly facilitated by the work of Feigl[2,3], who first drew attention to the importance of the study of the masking of reactions and ions in analytical chemistry, and also by Ringbom[4-6], Reilley and Schmid[7], Suzuki[8,9], Tanaka[10,11], Chaberek and Martell[12], Cheng[13], Schwarzenbach[14], and Yatsimirskii[15,16], who have made important contributions to the theory of masking processes.

Although the study of problems in the theory and practical application of masking is not restricted to analytical chemistry, but is also of importance in, for example, biology, and various branches of industry[12], the present state of development of these problems is closely related to the development of general problems in analytical chemistry. The present paper therefore deals chiefly with analytical aspects of the masking of reactions and ions.

II. CLASSIFICATION OF MASKING PROCESSES

Two basic types of masking can be distinguished, according to their fundamental nature: (1) masking due to a change in the thermodynamic conditions for the reaction being masked; and (2) masking due to a change in the kinetic conditions for the reaction being masked.

In all examples of masking belonging to the first type, the essential feature of the masking action of the substances specially introduced (or the factors deliberately altered) is the change in the reaction system from the initial equilibrium state in the newly created conditions; a characteristic feature of this new equilibrium state is that the reaction being masked takes place to the minimal extent. This type of masking can be described as equilibrium (or thermodynamic) masking. In equilibrium masking, the masking action responsible for the change in the direction of the reaction being masked is described qualitatively by le Châtelier's principle, and quantitatively by the corresponding thermodynamic equations, in particular the equation for the law of mass action (when there is a change in the concentration of the substances taking part in the reaction being masked) and the isobar or isochore equations (when there is a change in temperature).

In specific instances, masking action of the first type is brought about by the most varied mechanisms: (a) mechanical introduction of additional quantities of the compound which is the product of the reaction being masked; (b) oxidation or reduction of one or more of the substances taking part in the reaction being masked; (c) the reaction of one or more of the participants in the reaction being masked to form soluble complexes (including chelate compounds); and (d) the reaction of one or more of the participants in the reaction being masked to form other types of soluble compound (molecular adducts, ion associates, covalent compounds, etc.). This list should also include the masking of reactions as a result of a change in temperature and pressure (without the introduction of special masking agents) and also as a result of a change in the composition of the reaction medium (the nature of the solvent, ionic strength, etc.). In the last instance, and also when the direction of the reaction being masked is changed as a result of the addition of an excess of the product of the reaction, the original form of the substances being masked remains unchanged.

The following are some examples: (a) in the cerimetric titration of Fe^{2+}, Sn^{2+}, or Sb^{3+}, the interfering reaction between AsO_2^- and Ce^{4+} can be reliably masked with a large excess of AsO_4^{3-}, which is the product of the reaction of AsO_2^- and Ce^{4+}; (b) in the hydrogen sulphide scheme of qualitative analysis, $Cr_2O_7^{2-}$ is masked by reduction to Cr^{3+} with ethanol; (c) the oxidising reactions of Fe^{3+} are completely masked in the presence of ethylenediaminetetraacetate (EDTA), which combines with Fe^{3+} to form a stable soluble complex; and (d) in the titrimetric analysis of mixtures of H_2SO_3 and HSO_3^-, the acid strengths of these substances are "moved apart" by masking the HSO_3^- with formaldehyde, which reacts with HSO_3^- to form a soluble adduct with stability constant $\sim 10^7$.

The basis of masking action of the second type is the kinetic effect: the masking agent introduced into the reaction medium decreases the rate of the reaction being masked, either directly or by removing one of the participants of the reaction being masked, in another, more rapid reaction. In this instance the masking is not associated with the attainment of stable thermodynamic equilibrium in the system; this distinguishes the second type of masking from the first type, and the second type of masking can be described briefly as non-equilibrium (or kinetic) masking. The masking action produced by the kinetic effect can in principle be described quantitatively by the appropriate kinetic equations.

Comparatively few examples of masking of the second type have been studied (and hence become familiar), although this does not mean that they are not widely encountered. The primary example is masking based on negative catalysis, when the presence of a masking agent (which in this instance plays the part of catalyst) excludes one of the reaction paths which is possible in its absence, leaving slower reaction paths unaffected. An example of catalytic masking is provided by the suppression of the oxidation of AsO_2^- by $Cr_2O_7^{2-}$ ions in the presence of Mn^{2+} in the dichromate titration of Fe^{2+} (Mn^{2+} acts as negative catalyst for the spontaneous reaction of AsO_2^- with $Cr_2O_7^{2-}$). The action of the catalyst masking agent on the reaction being masked involves its intermediate chemical reaction with the reacting substances with the restoration of the original forms of these substances after each cycle of the intermediate reactions; the substances being masked thus remain finally unchanged.

A form of masking which is very similar to catalytic masking is that involving the suppression of induced (conjugated) reactions. The mechanism of the masking action in this instance has its own characteristic features, associated with the differences between induced reactions and purely catalytic reactions, and it makes allowance for the stoichiometry of the induction and the irreversible chemical transformation of the inductor, but, as in the previous example, the substances being masked retain their original forms as a result of the masking. A familiar example of the masking of an induced reaction is the suppression of the oxidation of Cl^- in the permanganometric titration of Fe^{2+} in the presence of Mn^{2+}, which acts as masking agent for the Cl^- ion.

Finally, the second type includes masking based on the difference in the rates of the reaction being masked and the masking reaction with a common participant—the masking agent. This principle forms the basis, for example, of the complexometric titration of Fe^{3+} in the presence of Cr^{3+}, which, unlike Fe^{3+}, forms a soluble complex with EDTA only very slowly, although the stability constants of the complexonato-compounds of Fe^{III} and Cr^{III} are close to one another (10^{25} and 10^{23} respectively); in this example, EDTA acts simultaneously as complexometric titrant for Fe^{3+} and masking agent for Cr^{3+}.

The above general and fundamental classification of masking processes naturally provides for special classifications of importance in various particular instances.

Thus if the masking of ions is one of the stages in the analysis of complex mixtures, it is usually always followed by demasking of the ions; in these instances the selection of rational methods of demasking is facilitated by Suzuki's classification[8,9], based on the state of the ion after masking.

When we are dealing with the masking of individual ions (and not reactions), it is sometimes convenient to distinguish various forms (or techniques) of masking, for example, direct and indirect, single-stage and multi-stage, etc. The suppression of the reaction between PO_4^{2-} and MoO_4^{2-} in the presence of $C_2O_4^{2-}$ is an example of direct masking for MoO_4^{2-} and of indirect masking for PO_4^{3-} (most examples of equilibrium masking can be regarded in this way). The masking of the Cu^{2+} ion by glycerol (which forms a soluble complex with Cu^{2+}) in the qualitative analysis of the cations of analytical group IV is an example of single-stage masking, whereas the masking of the same Cu^{2+} ion by cyanide is an example of double (two-stage) masking, since in this example the Cu^{2+} is first reduced by the cyanide to Cu^{+}, after which it reacts with cyanide to form the soluble complex $Cu(CN)_4^{3-}$, that is, it is masked twice.

Special attention must be made of self-masking and buffer masking. The self-masking of a reaction is masking brought about by the reaction being masked; in this instance the addition of a special masking agent is not required, since its part is played by one of the reacting substances or reaction products (an example in the suppression of the formation of sparingly soluble HgI_2 at high I^- concentrations as a result of the formation of the soluble complex HgI_4^{2-}). Buffer masking differs from ordinary masking in that the substance added to the reaction medium is not the free masking agent but its complex with a given ion; the absence of a large quantity of free masking agent from the reaction medium leads to the strictly selective masking of only that reaction which is capable of being influenced by the very small quantities of masking agent produced by dissociation of the added complex. An example of buffer masking is the masking of Sr^{2+} by a mixture of EDTA and Mg^{2+} in the precipitation of Ba^{2+} as $BaCrO_4$ (the comparatively unstable complex of Mg^{2+} with EDTA formed in this instance does not prevent the quantitative precipitation of $BaCrO_4$, but is capable of creating conditions leading to the complete conversion of Sr^{2+} into a soluble complexonate).

III. METHODS FOR CALCULATING THE EFFICIENCY OF MASKING

1. The Masking of Reactions and Their Conditional Constants

For equilibrium (thermodynamic) masking, that is, for most examples of masking known at present, all the information on the masking process could in principle be obtained by solving the thermodynamic equations for the masked and masking reactions in the given system, containing the ions being masked and the masking agent. For systems of any complexity, however, this involves practically unsurmountable difficulties, since the necessary equilibrium constants are not known. This makes it necessary to examine the masking of reactions using approximate methods of calculation, and in some instances using semi-quantitative and qualitative-descriptive methods.

In analytical chemistry at present, ordinary (thermodynamic) equilibrium constants are being widely replaced by so-called "conditional constants", which were introduced by Ringbom[4,5] and which make allowance for the influence, on the main reaction, of all side-reactions possible in the given system (the reactions of the participants in the main reaction with hydrogen and hydroxide ions, buffer and masking agents, competing ions, etc.).

For a reaction of the type

$$M + A \rightleftarrows MA$$

the conditional constant is defined by the expression

$$K_{M'A'} = \frac{[MA]}{[M'][A']}, \quad (1)$$

where $[M']$ denotes the concentration of not only the free participant in the reaction M, but also all the M in solution which has not reacted with A. Similarly $[A']$ denotes the concentration of not only free A but also all the A which has not reacted with M.

The conditional constant for the reaction $K_{M'A'}$ is related to the ordinary equilibrium constant for this reaction K_{MA} by the simple relationship

$$K_{M'A'} = \frac{K_{MA}}{\alpha_M \alpha_A}, \quad (2)$$

where α_M and α_A are the so-called "α-coefficients" or "side reaction coefficients" proposed by Schwarzenbach[14]. For the reaction being considered, the α-coefficients are defined as follows:

$$\alpha_M = \frac{[M']}{[M]} \quad (3) \text{ and } \alpha_A = \frac{[A']}{[A]} \quad (4)$$

where [M] and [A] are the concentrations of free (not combined with one another or with other substances) participants in the reaction M and A respectively.

The α-coefficients α_M and α_A are functions of the equilibrium constants of the corresponding side-reactions. If, for example, one of the participants in the main reaction M (a metal ion) takes part in a side-reaction with a ligand L with the formation of a series of mononuclear complexes, we have

$$\alpha_{M(L)} = \frac{[M']}{[M]} = \frac{[M] + [ML] + [ML_2] + \ldots + [ML_n]}{[M]}, \quad (5)$$

or

$$\alpha_{M(L)} = 1 + \beta_1[L] + \beta_2[L]^2 + \ldots + \beta_n[L]^n, \quad (6)$$

where $\beta_1, \beta_2, \ldots \beta_n$ are the cumulative stability constants of the complexes of M with L. Similarly, if the second participant in the main reaction A (an anion) reacts with another cation N to form a series of complexes, we have

$$\alpha_{A(N)} = \frac{[A']}{[A]} = \frac{[A] + [NA] + [N_2A] + \ldots + [N_mA]}{[A]}, \quad (7)$$

or

$$\alpha_{A(N)} = 1 + \beta_1[N] + \beta_2[N]^2 + \ldots + \beta_m[N]^m, \quad (8)$$

where $\beta_1, \beta_2, \ldots \beta_m$ are the cumulative stability constants of the complexes of A with N.

In the above particular cases, when the side-reactions involve complex formation, the function giving the α-coefficients in terms of the equilibrium constants of the side-reactions is often called the degree of complex formation, following Yatsimirskii's suggestion[17].

Thus the α-coefficients essentially provide a quantitative measure of the extent to which side-reactions take place in the given system: in the absence of side-reactions, when M reacts only with A, $\alpha_M = 1$ and $\alpha_A = 1$; if, however, M and A take part in side-reactions with L and N respectively, $\alpha_{M(L)} > 1$ and $\alpha_{A(N)} > 1$.

The values of the α-coefficients for any ion can be calculated from the equilibrium constants of the corresponding side-reactions using equations of type (6) and (8), or determined experimentally by potentiometric, polarographic, or spectrophotometric methods, without using the equilibrium constants. The possibility of direct experimental determination of the α-coefficients, combined with the possibility of using the conditional constants in the same way as ordinary equilibrium constants, makes the principle of conditional constants of practical importance in the examination of various analytical problems, in particular the problems of masking action.

The principle of conditional constants is used in all known methods for calculating the efficiency of masking reactions, of which the most commonly encountered are the method which is referred to as the method of conditional constants, and the chelate buffer method.

2. Method of Conditional Constants

In the method of conditional constants, developed by Ringbom[4-6], the masking reactions are regarded as side-reactions with respect to the reaction being masked, so that the latter is taken as the main reaction in the given system. Accordingly, the masking of the reaction can be defined as a process (or technique) leading to a decrease in the conditional constant of this reaction.

Eqn. (2), which can be written in the more general form

$$K_{M'_mA'_n} = \frac{K_{M_mA_n}}{\alpha_M^m \alpha_A^n}, \qquad (9)$$

is the fundamental equation for the quantitative characterisation of masking action in various examples of equilibrium masking. The α-coefficients, which appear in this equation, provide a quantitative measure of the extent to which the masking reactions take place in the given system: in the absence of masking reactions, $\alpha_M = 1$ and $\alpha_A = 1$, but if M and A take part in masking reactions with the masking agents L and N, we have $\alpha_{M(L)} > 1$ and $\alpha_{A(N)} > 1$. In other words, the α-coefficients characterise the ability of ions to be masked by given masking agents (or the ability of the masking agents to mask the given ions), and the conditional constant defines the actual degree of masking of the reaction between these ions in the presence of the corresponding masking agents.

The problem of the value to which the conditional constant of a reaction must be reduced for the reaction to be regarded as masked is of practical importance; this value depends on the concentration conditions and on the degree of masking required. In complexometry, for example, the following limits are acceptable in most instances for the conditional constants of the reactions being masked: for $K_{M'A'} < 10^2$ the interfering reaction is almost completely masked, for $K_{M'A'} > 10^7$ there is almost no masking, and for intermediate values of $K_{M'A'}$ masking is incomplete.

The no less important problem of selecting a suitable masking agent is related to the calculation or determination of the α-coefficients. Eqn. (6) for the calculation of $\alpha_{M(L)}$, in addition to the cumulative stability constants of the complexes of M with L, contains the concentration of free masking agent [L]. If the analytical (total) concentration of L in the solution is much greater than the analytical concentration of the free metal ion M (that is, if $C_L \gg C_M$ and the dissociation of the complex ML is slight), masking of the reactions is observed in practice in most instances, and if L is the anion of a strong acid or of a weak acid which is completely dissociated at the given pH, we have

$$[L] = [L'] \simeq C_L - C_M \text{ (or even) } [L] \simeq C_L) \qquad (10)$$

If, however, L is a weak acid [L] in the general case is given by the equation

$$[L] = \frac{[L']}{\alpha_{L(H)}} = \frac{C_L - C_M}{1 + \frac{[H^+]}{K_m} + \frac{[H^+]^2}{K_m K_{m-1}} + \dots \frac{[H^+]^m}{K_m K_{m-1} \dots K_2 K_1}}, \qquad (11)$$

where $\alpha_{L(H)}$ is the coefficient of the side-reaction of L with H^+, and $K_1, K_2, \dots K_m$ the consecutive dissociation constants of the product of this reaction H_mL. In some instances, particularly for the ions of multivalent metals in strongly alkaline solutions, it is also necessary, in the calculation of the α-coefficients, to make allowance for the possibility of the reaction of M with OH^- with the formation of hydroxo-complexes; this can be done by introducing an additional side-reaction coefficient $\alpha_{M(OH)}$.

The calculation of the α-coefficients using Eqns. (6) and (8) is in general fairly tedious; it is therefore simpler and more convenient to use available α-coefficient values, which are usually provided in the form of graphs and tables. A collection of the values of the α-coefficients for a large number of ligands and metal ions is given in Ringbom's monograph[5]. Table 1 gives as an example the values of

Table 1. Logarithmic values of α_M (EDTA) (concentration of metal ion and EDTA 0.1 M; ionic strength $I = 0.5$).

the α-coefficients, taken from this monograph, for the most widely encountered masking agent EDTA, relative to the ions of various metals at various pH, and Table 2 gives the α-coefficients for the complexing anions most frequently used as masking agents, at various pH.

3. The Chelate Buffer Method

The chelate buffer method, developed by Chaberek and Martell[12] and Tanaka[10,11], is based on the recognition that a buffer action is produced in solutions containing a metal ion and ligand; when the system contains an excess of ligand, the metal ion is buffered (pM buffer), and in an excess of metal ion the ligand is buffered (pL buffer).

For the simplest system consisting of a metal ion M with total concentration C_M and an excess of ligand L with total concentration C_L, in which one chelate compound ML with stability constant K_{ML} is formed at $a = C_L/C_M > 1$, the concentration of free metal ion in the solution is given by the equation:

$$[M] = \frac{C_M}{1 + (a-1) K_{ML} C_M} . \quad (12)$$

If K_{ML} is sufficiently large, we have

$$[M] = \frac{1}{(a-1) K_{ML}} . \quad (13)$$

For a system consisting of a ligand L with total concentration C_L and an excess of a metal ion N with total concentration C_N, in which one chelate compound NL with stability constant K_{NL} is formed at $b = C_L/C_N > 1$, the concentration of free ligand in the solution is given by the equation:

$$[L] = \frac{1}{(b-1) K_{NL}} . \quad (14)$$

It follows from Eqns. (13) and (14) that in solutions containing a metal ion M and an excess of ligand L ($a = C_L/C_M > 1$) or a ligand L and an excess of a metal ion N ($b = C_N/C_L > 1$), the concentration of the metal ion [M] or [L] respectively depends only on the ratio of the total concentrations of the metal ion (C_M or C_N) and ligand C_L, but is independent of their absolute values, that is, these solutions exhibit buffer properties.

The example involving the buffering of a metal ion M in an excess of a masking ligand L (pM buffer) is of greatest importance in the solution of various problems of masking.

Let us examine the behaviour of a pM buffer in the presence of an ion A which reacts with the metal ion M to form, for example, a sparingly soluble compound MA. In the system we have competition between two reactions: the masking reaction:

$$M + L \rightleftarrows ML$$

and the reaction being masked:

$$M + A \rightleftarrows MA$$

and the effect of the competition is described quantitatively by the equation

$$\lg \frac{[L]}{[ML]} = \lg \frac{1}{K_{ML} K_{sp}} + \lg [A] . \quad (15)$$

It can be seen from Eqn. (15) that the ratio [L]/[ML] should be constant at constant concentration of the excess of precipitant ion [A]. The addition of ML to this system necessarily leads to the dissociation of ML and the precipitation of the liberated M as MA, and the addition of free masking agent L leads to the dissolution of part of the MA precipitate and reaction of the liberated metal ion to form the chelate compound ML until the original value of [L]/[ML] in the solution is restored. The ratio [L]/[ML] in the solution will again control [M] only after the disappearance of the solid phase as a result of the gradual addition of L.

The expression $1/K_{ML}K_{sp}$, in Eqn. (15), called the "precipitation constant" and denoted by K_p, provides a quantitative measure of the tendency for the metal ion to be precipitated from the chelate buffer solution: the greater K_p, the greater the quantity of masking agent required to mask the precipitation. Table 3 gives as an example the values of the precipitation constants for the precipitation of the oxalates of various metals in the presence of various masking agents.

If the masking ligand L is a weak acid, pM also depends on pH; for this example, Eqn. (15) becomes

$$\lg \frac{[L]}{[ML]} = \lg \frac{K_m K_{m-1} \cdots K_2 K_1}{K_{ML} \cdot K_{sp}} + \lg [H_m L] + mp\mathrm{H} , \quad (16)$$

where $K_1, K_2, \ldots, K_{m-1}, K_m$ are the consecutive dissociation constants of H_mL.

To calculate the concentration of free metal ion [M] in the pM buffer (that is, in a solution containing the metal ion M and an excess of masking agent L), it is more convenient to use the equation derived in terms of the analytical (total) concentrations of the metal ion C_M and the masking ligand C_L:

$$[M] = \frac{C_M}{1 + K_{ML}(C_L - C_M)}. \quad (17)$$

In the general case, when the masking agent L is a weak acid, it is necessary to use Eqn. (11), which is equivalent

Table 3. Precipitation constants for metal oxalates in the presence of various masking agents [12]*.

* EDTA represents ethylenediaminetetra-acetic acid, NTA nitrilotriacetic acid, HIDA *N*-hydroxyethyliminodiacetic acid, and DHEG dihydroxyethylglycine.

to the replacement of the ordinary constant K_{ML} by the conditional constant $K_{ML'}$:

$$[M] = \frac{C_M}{1 + K_{ML'}(C_L - C_M)}. \quad (18)$$

$K_{ML'} = K_{ML}/\alpha_{L(H)}$ and $\alpha_{L(H)} = (C_L - C_M)/[L]$.

If x denotes the fraction of the metal ion M remaining in solution in the presence of the precipitant ion A, Eqn. (18) becomes

$$[M] = \frac{C_M x}{1 + K_{ML'}(C_L - C_M x)}. \quad (19)$$

Making use of the relationship $[M] = K_{sp}/[A]$, we obtain

$$x = \frac{1 + K_{ML'}C_L}{\left(K_{ML'} + \frac{[A]}{K_{sp}}\right)C_M}. \quad (20)$$

Since $K_{ML'}C_L \gg 1$, we obtain finally:

$$x = \frac{C_L}{\left(1 + \frac{[A]}{K_{ML'}K_{sp}}\right)C_M}. \quad (21)$$

For the formation of a metal hydroxide $M(OH)_n$, Eqn. (21) becomes

$$x = \frac{C_L}{\left(1 + \frac{K_w^n}{K_{ML'}K_{sp}[H^+]^n}\right)C_M}. \quad (22)$$

Let us now consider the pL buffer, which is also of importance in the theory of masking by virtue of its use as masking agent (instead of free ligand) in buffer masking.

In the pL buffer, consisting of a masking ligand L and an excess of an indifferent metal ion N ($K_{NL} < K_{ML}$), the concentration [L] is buffered when its value is low (at a low level) and is determined by Eqn. (14).

When the pL buffer is introduced into a solution containing the metal ion M to be masked, the formation of the chelate compound NL in the pL buffer can be regarded, like the formation of the proton complexes H_mL, as a side-reaction with respect to the reaction being masked (between M and L), so that the conditional constant $K_{ML'}$ in Eqn. (18) is given by

$$K_{ML'} = \frac{K_{ML}}{\alpha_{L(H,N)}}, \quad (23)$$

where $\alpha_{L(H,N)} = \alpha_{L(H)} + \alpha_{L(N)}$.

In the presence of the precipitant ion A the value of b in Eqn. (14) depends on the value of x in Eqn. (21)—that is, $b = C_N/(C_L - C_M x)$—so that Eqn. (14) becomes

$$[L] = \frac{1}{K_{NL}\left(\frac{C_N}{C_L - C_M x} - 1\right)}. \quad (24)$$

Eqn. (18) can be used to construct graphs giving the pH dependence of pM, and Eqn. (21) can be used to construct graphs giving the pH dependence of $\lg x$. These graphs, called pM–pH diagrams, provide a convenient means of predicting the efficiency of the masking of various reactions in the presence of free or complexed ligands as masking agents. Fig. 1 gives as an example the pM–pH diagrams for the masking of the formation of $Fe(OH)_3$ in the presence of EDTA, and also in the presence of Ca–EDTA.

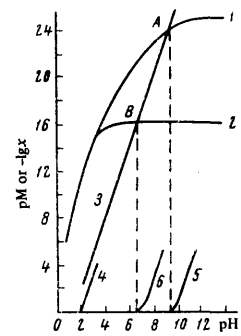

Figure 1. pM–pH and $\lg x$–pH diagrams [10].

Curve *1* gives the pH dependence of pFe in the presence of an excess of EDTA, curve *2* gives the pH dependence of pFe in the presence of a pL buffer consisting of EDTA and an excess of Ca, curve *3* gives the pH dependence of pFe in the absence of masking agent; and curves *4*, *5*, and *6* give the pH dependence of the negative logarithm of the fraction of Fe remaining in solution under the conditions corresponding to curves *1*, *2*, and *3*. The points of intersection of curves *1* and *2* with curve *3* (*A* and *B*) correspond to the start of the precipitation of $Fe(OH)_3$.

4. Other Methods

In addition to the two general methods of calculating the efficiency of masking, described above, various particular methods have been proposed, in which attempts are made to obtain a clearer and simpler description of the equilibrium state in systems containing masking agents and ions being masked, by the introduction of various formally specific masking criteria. Two of these methods deserve mention: Cheng's selectivity ratio method [13], and Hulanicki's masking coefficient method [18].

The first method introduces the concept of "selectivity ratio", defined as

$$\text{S.R.} = \frac{(pM_p)^a}{pM_m}, \qquad (25)$$

where pM_p and pM_m are the negative logarithms of the concentrations of the metal ion resulting from the dissociation of the compound of the metal with the analytical reagent (the product of the reaction being masked) and the complex of the same metal with the masking agent (the product of the masking reaction) respectively.

Calculation of the selectivity ratio, from the pM values determined experimentally or calculated from the thermodynamic or conditional equilibrium constants, makes it possible to predict which of the reactions—the reaction being masked or the masking reaction—predominates in the given system. If the value of the S.R. is less than 7, the masking reaction takes place preferentially in the system (the metal ion is masked), but if the S.R. is greater than 7, masking does not take place and the reaction to be masked takes place normally. Table 4 gives as an example the results of the calculation of the S.R. for the masking action of EDTA on various reactions of the Ag^+ ion.

Table 4. Reactions of the silver ion in the presence of EDTA [13] (concentration of complexes 1 M; pH 10; $K_{Ag\text{-}EDTA} = 2 \times 10^7$; $pM_m = 3.6$).

Reaction	K_{sp} or K_{MA}	pAg^+ (pM_p)	$\frac{(pM_p)^2}{pM_m}$
$2Ag^+ + 2OH^- \rightleftarrows Ag_2O + H_2O$	$2.0 \cdot 10^{-8}$	3.8	4.0
$2Ag^+ + CrO_4^{2-} \rightleftarrows Ag_2CrO_4$	$1.9 \cdot 10^{-12}$	3.6	3.6
$Ag^+ + IO_3^- \rightleftarrows AgIO_3$	$2.0 \cdot 10^{-8}$	3.8	4.0
$Ag^+ + Cl^- \rightleftarrows AgCl$	$1.0 \cdot 10^{-10}$	5.0	7.0
$Ag^+ + Br^- \rightleftarrows AgBr$	$5.0 \cdot 10^{-13}$	6.1	10.3
$Ag^+ + I^- \rightleftarrows AgI$	$8.5 \cdot 10^{-17}$	8.0	17.8
$2Ag^+ + C_2O_4^{2-} \rightleftarrows Ag_2C_2O_4$	$5.0 \cdot 10^{-12}$	3.5	3.4
$Ag^+ + SCN^- \rightleftarrows AgSCN$	$1.0 \cdot 10^{-12}$	6.0	10.0
$2Ag^+ + S^{2-} \rightleftarrows Ag_2S$	$1.0 \cdot 10^{-50}$	16.3	73.8
$Ag^+ + 2S_2O_3^{2-} \rightleftarrows Ag(S_2O_3)^{3-}$	$1.7 \cdot 10^{-13}$	4.6	5.9
$Ag^+ + 2CN^- \rightleftarrows Ag(CN)_2^-$	$5.6 \cdot 10^{18}$	6.4	11.4

In the second method, use is made of the concept of "masking coefficient", which gives the total concentration of the metal M present in the solution in equilibrium with an equivalent concentration of the analytical reagent, for example, the precipitant ion A for the masking of a precipitation of the type

$$mM + nA \rightleftarrows M_mA_n.$$

For this reaction the masking coefficient is given by

$$pM' = \frac{1}{m+n}\left(pK_{sp} - n \lg \frac{m}{n}\right) - \frac{m}{m+n} \lg \alpha_M - \frac{n}{m+n} \lg \alpha_A, \qquad (26)$$

where pM′ is the negative logarithm of the total concentration of the metal ion M in the solution [M′], pK_{sp} the negative logarithm of the solubility product of M_mA_n, and α_M and α_A the α-coefficients—see Eqns. (6) and (8). Eqn. (26) is derived by expansion of the expression for the conditional constant for the solubility product of M_mA_n.

The value of pM′ calculated from Eqn. (26) can be used to predict which reaction—the masking reaction or the reaction being masked—takes place in a given system under given conditions. Since in the usual analytical procedures the metal ion concentrations lie in the range 10^{-3}–10^{-5} M, complete masking of the reaction takes place when pM′ < 3, and complete demasking takes place when pM′ > 5. As an example let us consider the masking of the formation of $Ag_2C_2O_4$ ($pK_{sp} = 10.46$) in the presence of 0.1 M EDTA at pH 5. We find from Tables 1 and 2 that $\lg \alpha_{Ag(EDTA)} = 0.5$ and $\lg \alpha_{C_2O_4(H)} = 0.05$, so that pM′ = (1/3) − (10.46 − 0.30) − (2/3)(0.5) − (1/3)(0.05) = 3.36, − 0.34 − 0.02 = 3.00, that is, under the given conditions the formation of $Ag_2C_2O_4$ is masked completely.

IV. MASKING AND THE SELECTIVITY OF REACTIONS

To characterise quantitatively the increase in the selectivity of reactions due to masking, let us consider a solution containing one analytical reagent A and two metal ions M_I and M_{II}, which react with A to form products with different stabilities ($K_{M_IA} > K_{M_{II}A}$). By applying the principles of conditional constants [4,5], that is, by assuming that the reaction

$$A + M_{II} \rightleftarrows M_{II}A$$

is a side-reaction with respect to the reaction

$$M_I + A \rightleftarrows M_IA$$

we find that

$$K_{M_IA'} = \frac{K_{M_IA}}{\alpha_{A(M_{II})}} \qquad (27)$$

and

$$\alpha_{A(M_{II})} = \frac{[A] + [M_{II}A]}{[A]} = 1 + [M_{II}]K_{M_{II}A} \simeq K_{M_{II}A}[M_{II}]. \qquad (28)$$

Substituting the value of $\alpha_{A(M_{II})}$ from (28) in (27) and taking logarithms, we obtain

$$\lg K_{M_IA'} = \Delta \lg K + pM_{II}, \qquad (29)$$

where $\Delta \lg K = \lg K_{M_IA} - \lg K_{M_{II}A}$.

When a masking agent L is introduced into this solution, the metal ions M_I and M_{II} react with L in masking reactions, which, in accordance with the method of conditional constants, can be regarded as side-reactions with respect to the corresponding reactions involving the formation of M_IA and $M_{II}A$. Eqn. (29) then becomes

$$\lg K_{M_I'A''} = \Delta \lg K' + pM_{II} \qquad (30)$$

where

$$\Delta \lg K' = \lg K_{M_I'A} - \lg K_{M_{II}'A}.$$

Thus if M_{II} is not to interfere in the analytical reaction of M_I with A in the presence of L (that is, if M_{II} is to be masked quantitatively), the conditional constant $K_{M'_{II}A}$ should be sufficiently small. For example, in the complexometric titration of M_I, which requires that $\lg K_{M'_IA''} > 7$, M_{II} is masked completely when $K_{M'_{II}A}$ becomes so small that

$$\lg K_{M_I'A} - \lg K_{M_{II}'A} + pM_{II} > 7.$$

As an example, Fig. 2 gives graphs showing the conditional constants for the reactions of various metals with EDTA in the presence and absence of tren (2,2′,2″-triaminotriethylamine) as masking agent. It can be seen from Fig. 2, for example, that in the titration of Ca with EDTA in the presence of 0.1 M tren at pH 10, Cu and Ni are masked almost completely, Fe is partly masked, and Mn is not masked at all.

Thus the presence of appropriate quantities of suitable masking agents produces the required difference in the conditional constants of the analytical reaction and the reaction being masked, so that the analysis becomes selective; a given masking agent is effective, however, only under definite conditions, in particular at definite pH values. The behaviour of a masking agent under different conditions can be predicted on the basis of a theoretical examination

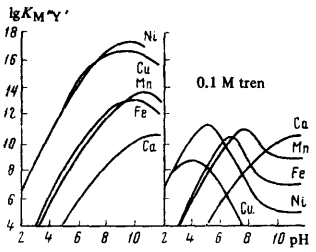

Figure 2. pH dependence of the conditional constants of the complexes of Cu, Ni, Fe, Mn, and Ca with EDTA in the absence and in the presence of an excess of triaminotriethylamine (tren).[5] ($K_{M"Y'} = K_{MY}/\alpha_{M(tren)}\alpha_{Y(H)}$).

of the equilibria established under these conditions. This theoretical approach is greatly facilitated, and the results obtained become extremely clear, if the systems being studied are described by means of diagrams of the type given in Fig. 2 or by means of pA–pH diagrams (pY–pH diagrams for the particular case of complexometry)[7].

V. THE MOST COMMON MASKING AGENTS

A large number of extremely varied inorganic and organic masking agents are now used for the masking of ions and reactions. Table 5 gives common masking agents for the most widely encountered ions of various elements.

Despite the large number and great variety of masking

Table 5. Masking agents for the ions of various elements*.

Element or ion	Masking agent
Ag	CN^-, NH_3, $S_2O_3^{2-}$, SCN^-, TGA, thiourea
Al	F^-, $C_2O_4^{2-}$, CH_3COO^-, OH^-, citrate, tartrate, EDTA, DMP. TEA, Tiron, salicylate, sulphosalicylate, acetylacetonate, malonate, gluconate
As	S_2^{2-}, OH^-, DMP
Au	CN^-, Br^-, $S_2O_3^{2-}$
B	F^-, hydroxy-acids, glycols
Ba	EDTA, citrate, tartrate, NTA, DHEG
Be	F^-, citrate, tartrate, sulphosalicylate
Bi	Citrate, tartrate, EDTA, I^-, Cl^-, NTA, DHEG, thiourea, TEA, DMP, TGA, $Na_5P_3O_{10}$, dithizone
Br	phenols
CN^-	CH_2O, Hg^{2+}, transition metal ions
Ca	EDTA, citrate, tartrate, $P_2O_7^{4-}$, NTA, DHEG
Cd	EDTA, CN^-, $S_2O_3^{2-}$, SCN^-, I^-, citrate, tartrate, NTA, DHEG, DMP, TGA, unithiol, malonate, dithizone
Ce	NTA, EDTA, DHEG, citrate, tartrate, Tiron

agents, they can be grouped into several classes, of which the most important are the aminopolycarboxylic acids, the polyamines, the hydroxy-acids, and the polyphosphates.

The aminopolycarboxylic acids (complexones)[8,9,12-16,19-30] have molecules containing chelating amino- and carboxyl groups, and form stable water-soluble chelate compounds with a large number of metal ions, including the ions of the alkali and alkaline earth metals. They have a number of advantages over other chelating reagents as masking agents: (1) the high efficiency of masking, due to the high stability of the metal-chelates formed by the complexones; (2) the universal nature of the masking, resulting from the ability of the complexones to form comparatively stable chelate compounds with almost all known metals; (3) the wide pH range of masking, related to the high stability of the metal-chelates formed by the complexones and the comparatively low stability of their proton complexes; (4) the possibility of masking at relatively high temperatures, due to the thermal stability of the complexones and their metal-chelates in aqueous solutions; (5) the compatability of the complexones with the other components of usual analytical systems, related to their ability to function in many other capacities (as titrants, pH regulators, photometric reagents, etc.).

The complexone with the most useful properties and widest application is ethylenediaminetetra-acetic acid (EDTA). It reacts with metal ions usually as a sexidentate ligand by coordination through the two nitrogen atoms of the two amino-groups and four oxygen atoms of the four carboxyl groups. The resulting chelates have an octahedral structure with little steric distortion, stabilised by the presence of several five-membered rings and showing a stereochemistry favourable for most common metal ions. In EDTA the common tendency of the carboxyl group to form complexes is strengthened by the chelating effect, resulting in an increase in the stability of the chelate compounds compared with the corresponding complexes formed from the unidentate complexes without ring closure. As a result, EDTA exhibits chelating properties with respect to the ions of almost all metals; this makes it a universal masking agent, but it is not specific.

The selectivity of the masking action of EDTA can be increased slightly, however, by controlling the pH of the solutions. Masking by EDTA is most effective in weakly acidic and alkaline solutions.

Under optimal conditions of acidity, EDTA reacts with most metal ions to form complexes with a cation: ligand molar ratio of 1 : 1. Protonated complexes may be formed in strongly acidic solutions, and mixed hydroxo-complexes may be formed in strongly alkaline solutions. The formation of chelate compounds with molar ratio 1 : 2 is observed only for quadrivalent metals.

Attempts to modify the structure of EDTA in order to improve its coordinating properties have not in general given satisfactory results. Exhaustive data on the results of these studies, which are of undoubted theoretical importance, are given in a review by Dyatlova and Lastovskii[30], so that we shall mention only a few features which are of interest for increasing the efficiency and selectivity of masking. The closure of the alicyclic ring in *trans*-1,2-diaminocyclohexanetetra-acetic acid (DCTA), accompanied by a decrease in the freedom of rotation of the amino-groups in the ligand and the formation of an additional ring in the structure, leads to a marked increase in the stability of the chelate compounds formed with all metals and to a decrease in the rate of chelation; replacement of the cyclohexane ring by cyclopentane or cycloheptane rings gives complexones whose stabilities are respectively greater or less than the stability of DCTA, but greater than the stability of EDTA. Increase in the denticity of the ligand by the introduction of additional iminoacetate groups into the EDTA molecule (diethylenetriaminepenta-acetic, triethylenetetraminehexa-acetic, and tetraethylenepentaminehepta-acetic acids) brings about a selective increase in the stability of the chelate compounds for highly-charged metal ions. Replacement of the hydrogen atoms attached to the carbon atoms of the methylene groups by methyl groups (1,2-diaminopropanetetra-acetic and 2,3-diaminobutanetetra-acetic acids) leads to greater solubility of the complexones and to higher stability in the chelate compounds of various metals. The tetra-acetic acids of amino-ethers (ethyl etherdiaminetetra-acetic and glycol etherdiaminetetra-acetic acids†) combine more readily with the ions of the heavy alkaline earth metals (Ca^{2+}, Sr^{2+}, and Ba^{2+}) than with magnesium ions.

To conclude the list, it can be stated in general that special reconstruction of the complexone molecule by the introduction of hetero-atoms and functional groups, by changing the distance between the iminodiacetate groups or between the nitrogen and the carboxyl group, by replacing the methylcarboxyl groups by hydroxyethyl and methylphosphinic groups, by increasing the rigidity of the entire system, and by breaking down the electron density of individual units, produces chiefly selective reagents, but does not always lead to an increase in the stability of the complexes formed.

Of the known complexones, the most important masking agents are EDTA, DCTA, and nitrilotriacetic acid. These are widely used in qualitative analysis[19-22,25,30], gravimetric analysis[4,5,8,9,12,13,15,19,20,22,26-29], complexometric titration[4-9,12-15,19,20,22-30], photometry[4,5,8,9,15,19,20,22,27-30], polarography[8,9,12,15,19,20,22,27-30], ion-exchange chromatography[12,15,19,20,22,27-30], and a number of other analytical procedures.

Polyamines[12-14], like aminopolycarboxylic acids, contain several donor nitrogen atoms and are multidentate ligands. Thus complex formation with these compounds also involves simple stoichiometry (the chelate compounds formed with metal ions usually have cation: ligand molar ratio equal to 1 : 1) and a chelating effect (leading to the production of chelate compounds with five- or six-membered rings, which are more stable than the complexes with simple ammonia molecules).

The selectivity of polyamines in complex formation with metal ions is greater than that of the complexones, since the strength of the ligand field for amine ligands is greater than that for carboxylic acid ligands. With metal ions which react more readily with donor nitrogen than with oxygen (Cu, Ni, Co, Zn, Cd, and Hg), they form water-soluble chelate compounds with stability constants which differ fairly sharply (Table 6), whereas they undergo almost no reaction with alkaline earth metal ions.

The data in Table 6 first of all illustrate the chelating effect, that is, the effect of combining the donor groups into a single common molecule. For example, comparison of $\lg\beta_1$(Cu-En) (10.55) with $\lg\beta_2$ (Cu-2NH_3) (7.61) shows that the formation of one five-membered chelate ring in the ethylenediamine complex of copper increases the stability of the latter by a factor of ~ 1000 relative to the stability of the copper ammine formed by the coordination of

† Possibly 2,2′-oxybis(ethyliminodiacetic acid) and ethylenedioxybis-(methyliminodiacetic acid) are intended (Ed. of Translation).

two unidentate NH_3 ligands to Cu^{2+}. Table 6 also shows that the increase in the number of chelating rings in the 1 : 1 complexes for a given metal on going from ethylenediamine to penten (that is, with increase in the multidenticity of the ligand) leads to a progressive increase in the stability constants of the chelate compounds and to a gradual decrease in the tendency for the metal ion to combine with a second molecule of the ligand.

Of the above polyamines, tren, trien, tetren, and penten are most widely used as masking agents. A disadvantage of the polyamines as masking agents is their extreme sensitivity to inorganic acids, resulting from their ability to combine with several protons. Moreover, commercial polyamine specimens are always contaminated with lower amines and are difficult to purify, and this hinders their study and practical application.

Hydroxy-acids[12,13,31] have molecules containing chelating hydroxyl and carboxyl groups and act as multidentate ligands which are much weaker than the nitrogen-containing multidentate ligands (aminopolycarboxylic acids and polyamines). Moreover, they have a greater tendency, compared with the polyamines, to react with metal ions by a stepwise mechanism with the formation of chelate compounds with cation : ligand molar ratios of 1 : 1, 1 : 2, etc.; mixed complexes and polynuclear complexes may also be formed.

Table 7. The stability constants of the tartrato- and citrato-complexes of various metals in acid medium (1 : 1 type) (temperature 20°C, ionic strength $I = 0.5$).

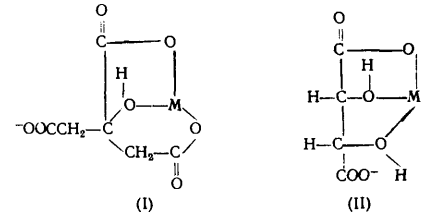
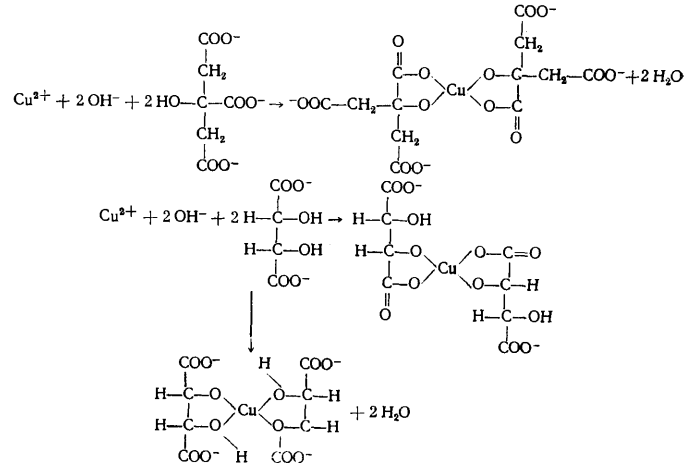
Tartrate $(CHOHCOO)_2^{2-}$	1.5	1.7	2.8	2.1	3.2	1.2	3.8	1.4	2,4
Citrate $C_4H_4OH\,(COO)_3^{3-}$	2.4	3.5	4.0	4.4	6.1	2.8	5.2	2.8	4.5

The properties and stabilities of the chelate compounds formed depend on the number and mutual arrangement of the carboxyl and hydroxyl groups in the hydroxy-acid molecule, and also on the ability of these groups to give up hydrogen ions; this in turn is related to the pH of the solution. Comparison of the stabilities of the citrato- and tartrato-chelates of various metals formed in acid medium (Table 7) shows that the citrato-chelates are more stable than the tartrato-compounds. This is due to the fact that the coordination of the citrate ion to the metal ion leads to the formation of two stable rings including two strongly bonding carboxyl groups and one hydroxyl group (I), whereas the coordination of the tartrate ion is accompanied by the formation of two rings containing two weakly bonding hydroxyl groups and one carboxyl group (II); moreoever, the stabilities of these chelate compounds are also influenced by the magnitude of the charge on the ion (−3 for citrate and −2 for tartrate).



(I) (II)

Because of the comparatively low stability of their chelate compounds, the hydroxy-acids have a low efficiency as masking agents in acid medium, particularly for alkaline earth metal ions. Their masking power increases considerably, however, in alkaline medium (at pH > 10), in which they react with metal ions to form extremely stable chelate compounds, probably with the participation of alkoxy-groups:



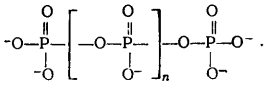
The formation of chelate compounds containing alkoxy-bonds may take place not only in strongly alkaline solutions, in which optimal conditions are created for the formation of alkoxide ions, but also in acidic solutions, if the

metal ion has a sufficiently high polarising power. For example, the Fe^{3+} ion brings about "induced dissociation" of the hydroxyl proton of the hydroxy-acid and forms stable chelate compounds with hydroxy-acids even in acidic solutions.

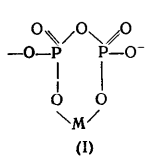
The participation of alkoxide groups in chelate formation probably explains the fact that in alkaline solutions the tartrato-complexes are more stable than the citrato-complexes. It is also of interest to relate the increased stability of the complexes formed by hydroxy-acids in alkaline solutions with the possibility of formation, under these conditions, of mixed dinuclear complexes containing both hydroxide ions and hydroxy-acid anions as ligands[27].

The hydroxy-acids most frequently used as masking agents are tartaric and citric acids, mentioned above, and also malonic, gluconic, and salicylic acids. Tartaric and citric acids are in most instances interchangeable, but there are instances in which the use of one or the other is to be preferred, apparently due to differences in the stabilities of their chelate compounds at different pH values.

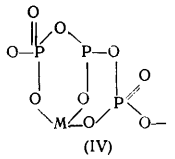
Polyphosphates[12,33], which are used as masking agents, are inorganic linear polymers whose chain structure contains four oxygen atoms arranged tetrahedrally around each phosphorus atom



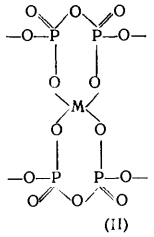
They react with many metal ions, particularly the alkaline earth metal ions, to form water-soluble polymeric complexes with a six-membered chelate structure, in which the metal ion is joined to two or more negatively charged oxygen atoms attached to neighbouring phosphorus atoms (I–III):



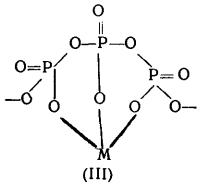
(I)



(IV)



(II)



(III)

Because of the complexity of the structures of the polyphosphates, it is difficult to characterise quantitatively their reactions with metal ions. The published formation constants for the chelates of various polyphosphates (Table 8) indicate, however, that the stabilities of their chelates increase with increase in the length of the polyphosphate chain (that is, with increase in the multidenticity of the ligands).

A serious disadvantage of the polyphosphates as masking agents is their tendency to undergo hydrolysis with the formation of orthophosphate ion, which is able in turn to precipitate the ions of many metals. The rate of hydrolysis depends on many factors (pH, temperature, degree of dehydration of the polyphosphate, etc.), including the length of the polyphosphate chain (the degree of hydrolysis increases rapidly with increase in chain length). The hydrolysis of polyphosphates is catalysed by hydrogen ions, and also by the ions of various metals, the catalytic effect of the latter being directly proportional to their Lewis acid strength ($Cu^{2+} > Mn^{2+} > Mg^{2+} > Ca^{2+}$).

Table 8. Formation constants of chelates for various polyphosphates (temperature 20°C, ionic strength $I = 0.1$).[12]

Polyphosphate	Chain length n	lgβ		
		BaL	CaL	MgL
Sodium pyrophosphate $Na_4P_2O_7$	2	4.5	–	–
Sodium tripolyphosphate $Na_5P_3O_{10}$	3	4.5	–	–
Sodium tetrapolyphosphate $Na_6P_4O_{13}$	4	5.5	–	–
Vitreous sodium polyphosphate	7.5	6.0	–	–
Vitreous sodium polyphosphate	8.5	6.5	–	–
Adenosine monophosphate	0	–	1.41	1.69
Adenosine diphosphate	1	–	2.78	3.11
Adenosine triphosphate	2	–	3.60	4.00

The masking action of polyphosphates with respect to alkaline earth metal ions is widely used in technology for water softening. Organic polyphosphates are of considerable interest in biology; in particular, adenosine triphosphate apparently acts as a universal accumulator and distributor of the chemical energy of nutrients and as the chief energy donor in all fundamental reactions of biosynthesis in the organism, and also in such important physiological processes as muscle contraction and higher nervous activity.

In analysis, the polyphosphates most widely used for masking are sodium pyrophosphate $Na_4P_2O_7$, sodium triphosphate $Na_5P_3O_{10}$, and sodium hexaphosphate $Na_6P_6O_{18}$. Sodium triphosphate in neutral and alkaline media forms water-soluble complexes with the ions of a large number of metals, including Li, Be, Mg, Ca, Sr, Ba, Zn, Cd, Fe^{II}, Fe^{III}, Co, Ni, Mn, Cu, Pb, V, Al, Y, In, La, Ce^{III}, Pr, Nd, Ag, Hg^{I}, Ti, Zr, Bi, Sn^{II}, Sn^{IV}, Th, and U^{VI}.

The following compounds are not precipitated in the presence of $Na_5P_3O_{10}$: the hydroxides, phosphates, carbonates, and borates of all the above elements; calcium fluoride, oxalate, tartrate, and citrate; and lead fluoride, chromate, and sulphate; similarly, iron(III) sulphosalicylate and sulphide are not formed. $Na_5P_3O_{10}$ does not prevent the precipitation of zinc, mercury, lead, and copper sulphides, however.

Of the other known masking agents, extensive use in chemical analysis is made of cyanide, fluoride, and triethanolamine[13]. Cyanide is a very effective masking agent for the elements of Groups IB, IIB, and VIII of the Periodic Table, since extremely stable soluble complexes are formed; cyanide is used chiefly in alkaline or neutral solutions—its use in acid solutions is undesirable because of the formation of toxic hydrogen cyanide. Fluoride forms stable soluble complexes with Be, Al, Fe, Si, Ge, B, Sm, Sb, Ti, Zr, Hf, the rare-earth elements, etc., and is often used to mask these elements. Triethanolamine (2,2,2-nitrilotriethanol) is an effective masking agent for Al, Fe, Mn, and various other highly-charged ions; it prevents the hydrolysis of tervalent and quadrivalent metals at high pH.

VI. CHARACTERISTIC EXAMPLES OF THE PRACTICAL APPLICATION OF MASKING

Any type of chemical reaction—precipitation, oxidation–reduction, complex formation, etc.—can be subjected to masking under various circumstances. Thus masking may be used in all chemical and physicochemical methods of analysis in which a chemical reaction takes part in any form. It can confidently be stated that most papers now published on chemical analysis deal to some extent with the masking of reactions and ions; in a number of instances masking is an essential step in the analytical methods or procedures recommended or described in these papers. It is therefore understandable that a short review cannot give exhaustive data on the practical application of the masking of reactions and ions in chemical analysis. In the present review, therefore, we shall merely refer to published reviews on the use of masking in qualitative analysis [2,3,20-22,25], gravimetric analysis [3,8,9,12,13,20,22,26], complexometric titration [14,20,22,23,27,28], photometry [3,8,9,20,22], polarography [8,9,12,15], and ion-exchange chromatography [12,15,20], and examine some characteristic examples of application of masking.

In most instances the masking of the reaction of a given ion is required when it is necessary to eliminate the interfering influence of this ion when carrying out the analogous reaction of another ion with the same reagent. In equilibrium masking this is achieved by decreasing the concentration of the interfering ion or reagent, and in most instances the mechanism of masking is based on the formation of soluble complexes of the interfering ion or reagent with the masking agent. The necessary decrease in the concentration of the interfering ion naturally depends on the method of analysis employed; in spectrophotometry, for example, the concentration of the interfering ion should be very low, whereas in complexometric titration the conditions of masking are much less severe.

The masked form of the interfering ion must often satisfy additional special requirements in addition to the main requirement of stability, ensuring the necessary decrease in the concentration of the interfering ion. The nature of these additional requirements depends on the analytical method: in gravimetric analysis the masked form should not be coprecipitated with the analytical form, in spectrophotometry the masked and analytical forms should absorb light in different ranges of the spectrum, in redox titrations they should have different redox potentials, in ion exchange they should have different affinities for the ion exchanger, etc.

The satisfactory fulfillment of the main and additional requirements by the masked forms of various ions creates the prerequisite for another widely encountered example of the use of masking, namely for the determination of these ions when present together, or for their separation. The efficiency of the simultaneous determination and separation of ions using masking is particularly high when the abilities of these ions to be masked by given masking agents and to take part in analytical reactions with a given reagent change in the opposite sense.

A large number of examples of the use of masking to eliminate the interfering influence of accompanying ions, to determine various ions when present together, and to separate these ions, that is, examples of the use of masking to increase the selectivity of analysis, are given in the reviews cited above; we shall give only two examples as illustration: (1) the increase in the selectivity of the polarographic analysis of the ions of various metals in the presence of DCTA (Table 9) [34], and (2) the increase in the selectivity of the colour reaction of rare-earth metal ions with Methylthymol Blue in the presence of EDTA (Table 10) [35].

The masking of reactions is often used for the direct detection and determination of ions. In addition to the familiar use of the masking of the formation of the zirconium–Alizarin lake in the presence of F^- for the detection and photometric determination of F^-, mention may also be made of the photometric determination of Te from the decrease in the light absorption of a solution of molybdosilicic acid as a result of the partial masking of the formation of the molybdosilicate in the presence of Te^{4+}. [36]

Lu	19.83	pale pink

Mention may also be made of the mechanism of the masking action of masking agents, in particular F^-. The decolorisation of the zirconium–Alizarin lake in the presence of F^- is usually attributed to the formation of colourless ZrF_6^{2-}, and an analogous explanation was previously put forward for all other examples of the determination of F^- based on the decolorisation of the coloured chelate compounds formed by metals with various dyes. It was found, however, that in a number of instances, for example in the photometric determination of F^- from the decrease in the light absorption of a Zr–Xylenol Orange mixture, the decrease in the light absorption is due to the formation of a colourless Zr–F–Xylenol Orange ternary complex [37], that is, the determination of F^- in this instance cannot be regarded as indirect. These examples deserve careful attention in the theoretical examination of the masking of reactions.

In some instances the masking of reactions provides a very convenient and simple method for establishing the stoichiometric composition and determining the stability constants of complexes in aqueous solutions. Thus the decrease in the light absorption of a solution of molybdosilicic acid as a result of the partial masking of the formation of molybdosilicate in the presence of various complexing agents (oxalate, tartrate, or tellurite) can be used to determine the compositions and stabilities of the complexes formed by molybdenum with these complexing agents [38].

The possibilities provided by the use of the masking of reactions and ions for various purposes are not exhausted by the above examples—the number of examples could be greatly extended. In conclusion, mention must be made of another promising application of masking—for the production of an "ideal" blank specimen. The usual method of preparing a blank specimen suffers from one major disadvantage: because of the need to exclude some component of the analytical reaction from the blank specimen, the chemical composition of the latter is not completely identical with that of the specimen being analysed. Masking makes it possible to eliminate this disadvantage in the preparation of a blank specimen. If an additional reagent (the masking agent) is introduced into a blank specimen containing the substance being analysed and all the necessary reagents in the same quantities as in the specimen being analysed, the analytical reaction is frozen (masked) from the beginning; the additional reagent is added to the specimen being analysed only after the analytical reaction is complete. Thus the blank specimen finally has a chemical composition which is completely identical with that of the specimen being analysed, and differs only in the absence of the analytical effect being measured, that is, it is an ideal blank specimen. The value of this new method of preparing a blank specimen has been illustrated, for example, in the photometric determination of silicon [39] and phosphorus [40] as their molybdenum heteropolycomplexes.

---o0o---

The two types of masking examined at the start of the present paper, namely: (1) equilibrium masking due to a change in the thermodynamic conditions of the reaction being masked, and (2) non-equilibrium masking due to a change in the kinetic conditions of the reaction being masked, cover all examples of the masking of reactions known in practice. The opposite is also true, namely, that almost all chemical reactions can be masked by appropriate means: if a given reaction cannot be masked by influencing its thermodynamic conditions, it can be masked through kinetics and catalysis.

These two forms of masking—equilibrium and non-equilibrium—naturally require different approaches to their theoretical examination. The material given above deals chiefly with the problems of equilibrium masking. This is due to the fact that the techniques of equilibrium masking have been used to a much greater extent up to the present, and the associated problems have undergone corresponding development. Even the few observations and examples which have been published, however, indicate the promising possibilities provided by the use of non-equilibrium (kinetic) masking in addition to equilibrium (thermodynamic) masking.

Non-equilibrium masking is a useful supplement to equilibrium masking, since it is applicable to those systems for which equilibrium masking is unsuitable. An important feature of non-equilibrium masking is the possibility of controlling it by means of the temperature factor.

The kinetics of analytical reactions with particular reference to masking have not been specially studied. It is therefore not yet possible to reach any general conclusions. Recently, however, the importance of a detailed study of the kinetics of analytical reactions, particularly reactions involving complex formation, has been pointed out by a number of authors [5,30,41], particularly Reilley [42], who in addition to other problems discusses the kinetics of the formation and dissociation of metal complexonates, and considers that these problems are the most important at the present stage of the study of complexonates.

Valuable information about chemical structure obtained in the study of infrared spectra of individual compounds produces a natural increase in the interest of chemists in molecular spectroscopy.

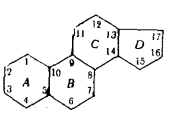
In the Russian literature there are hardly any papers dealing with the infrared spectra of steroids. Furthermore there is not one review on the infrared spectra of the steroids.

This review considers work on the infrared spectra of the steroids during the period from its inception (1939) to 1966.

I. FEATURES OF THE CHEMICAL STRUCTURE OF THE STEROIDS

The main features of the chemical structure of the steroids have now been explained quite definitely. The general principles are reliable, although there are still a greater number of compounds of the steroid series details of whose structure are either unknown or require proof.

The structure of the steroids is based on a complex polycyclic system consisting of three cyclohexane rings and one cyclopentane ring. Such a system is 10,13-dimethylcyclopentanoperhydrophenanthrene, with the accepted numbering of the atoms of the carbon skeleton (I):



(I)

The rings are denoted by the letters A, B, C, and D in accordance with the increasing numbering of the carbon atoms.

There are six asymmetric carbon atoms, so theoretically such a compound can have $2^6 = 64$ stereoisomers but only some of the steroisomeric forms are encountered in natural compounds. From this it follows that the steroid molecules have rigidly fixed spatial conformations, unlike the mobile conformations of cyclohexane.

Sometimes the ring of the steroidal skeleton (ergosterol, 7-dehydrocholesterol, ring B; oestrogen, ring A) contains a C=C double bond. This fixes still more rigidly a definite conformation of the molecule. Despite the non-planar structure of the cyclohexane rings, their combination in a

steroid molecule exhibits a compressed structure—the "thickness" of the plane of the skeleton is ~ 0.8 Å. The cyclohexane rings in the steroidal skeleton have the "chair", not the "boat", conformation.

Free five-membered rings have a non-planar structure thanks to the presence of "Pitzer strain"[1-3]. Clearly, the five-membered ring D in the steroid molecules also has a non-planar conformation, as is shown by certain stereospecific reactions which take place with participation of the functional groups of ring D.

In the sterols and most other steroids side chains of various dimensions are attached to $C_{(17)}$ of the cyclic skeleton.

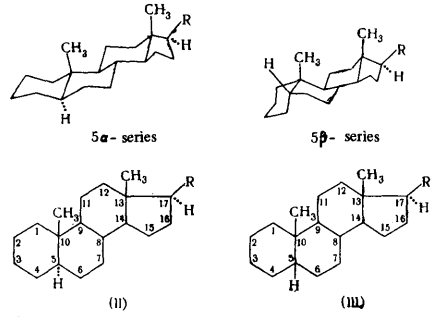
The naming of the steroids depends on the conformation of the cyclic skeleton and the length of the side chain at $C_{(17)}$.

In 1957 the Commission on [the Nomenclature of Organic Chemistry and] the Nomenclature of Biological Chemistry [of the International Union of Pure and Applied Chemistry] issued Definitive Rules for Nomenclature of Steroids.

The conformations of the steroids are distinguished by the type of junction of rings A/B because in all the steroids without exception and their synthetic analogues ring junctions B/C and C/D are the same and are *trans*-fused. Hence there are two steric series of steroids: a series with *trans*-fusion of rings A and B, and a series with *cis*-fusion of rings A and B.

Substituents above the plane of the cyclic system are denoted by the letter β, those beneath the plane by α.

It is easy to see that in the *trans*-fusion of rings A and B the hydrogen atom at $C_{(5)}$ is beneath the plane of the cyclic system, that is, in the α-position (II). With *cis*-fusion at A/B the hydrogen atom at $C_{(5)}$ is in the β-position (III). Therefore the series with A/B *trans*-fusion is termed the 5α-series, and that with A/B *cis*-fusion, the 5β-series.



It has now been shown that in all steroids the side chain at $C_{(17)}$ is in the β position. Unfortunately, investigators working in the field of steroid chemistry have not adhered to unique names for these compounds. Detailed information about the nomenclature of the steroids is given in the Fiesers' monograph[5] and Protiva's paper[6].

A review of the accepted nomenclature of the steroids taking account of the geometrical and optical isomerism has also been given in a special article by Götzky[7] devoted to this question.

II. CORRELATION OF THE INFRARED SPECTRA OF STEROIDS WITH THEIR STRUCTURE

a. C–O Bonds

The C–OH stretching vibrations appear in the infrared spectra of alcohols as an intense band in the 1000–1200 cm^{-1} range. Differences in the position of this band for primary, secondary, and tertiary alcohols were observed by Weniger[8] as long ago as 1910. These researches were continued much later by Tout and Lecomte[9], who also observed a relation between the position of the C–OH band and the structure of the molecule. The more detailed investigations of Zeiss and Tsusui[10] showed the influence of electronic effects and the symmetry of the molecule on the position of this band.

Regular investigations of the infrared spectra of the steroids and particularly the sterols, began about 1946. In one of the first works on the assignment of the bands in the infrared spectra of the sterols, Furchgott and coworkers[11] noted a series of features of the band of the C–OH stretching vibrations. In particular, they showed that the absorption band of the C–O stretching vibrations for the $\rangle$C–OH group is at ~ 1250 cm^{-1}, but when the carbon atom is connected to only single bonds, the absorption takes place in the 1000–1100 cm^{-1} region. They also reported the important fact of the dependence of the position of the C–O band on the mutual arrangement of the substituents at the third and fifth carbon atoms of the steroid skeleton. Thus the 3β-*trans*-5α- and 3α-*trans*-5β-steroids exhibit a band in the 1047–1058 cm^{-1} region, but the 3α-*cis*-5α-steroids have a weaker band with a maximum at 1064 cm^{-1}. Nevertheless a molecule with two OH groups can show only a single C–O bond absorption band (androstan-3β,17α-diol). The same correlation was found by these authors in a subsequent study[12], where they investigated the infrared spectra of the steroids of the pregnane series. Substances of the pregnane series with the 3β-*trans*-5α-configuration are characterised by a band between 1047 and 1058 cm^{-1}. A hydroxyl in the 3β-position and a Δ^5-double bond always produce a band in the 1058–1064 cm^{-1} range and a $C_{(20)}$ hydroxyl, a band at 1079 cm^{-1}. In another paper by the same authors it was noted that a hydroxyl group at $C_{(21)}$ causes an intense band for the C–OH bond between 1073 and 1078 cm^{-1}. Somewhat later (1952) a coauthor of Furchgott's first three papers (Rosenkrantz) and Zabloy[14] made a more detailed examination of the infrared spectra of the steroidal $C_{(3)}/C_{(5)}$ epimers. These investigations refined the results of the first studies. Moreover the range of compounds investigated was extended. Fig. 1 gives their results for the $C_{(3)}/C_{(5)}$ epimers of androstane. Rosenkrantz and coworkers[15] obtained similar results for cholestane, cholest-2-ene, cholest-4-en-3-one, 7-ketocholesterol, and various other compounds. The corresponding infrared frequencies found by the authors[14,15] for various stereoisomeric forms are:

Coprostanol (3β, 5β)	1041 cm^{-1},
Epicoprostanol (3α, 5β)	1062 and 1040 cm^{-1},
Cholestanol (3β, 5α)	1075 and 1041 cm^{-1},
Epicholestanol (3α, 5α)	1038 and 1004 cm^{-1}.

In another study, Rosenknrantz and coworkers[16] investigated the absorption of C–OH bonds in some unsaturated sterols. They assigned the 1053 cm^{-1} band of Vitamin D_2 to the C–OH stretching vibrations and it is evidently characteristic for the opened ring B. However, this correlation cannot be considered to be completely reliable, since in this range of the Vitamin D_2 spectrum there are other bands which are no less intense[17].

At about the same time, two papers by Cole[18] and Cole and coworkers[19] appeared, the latter deserving special attention. It gave proof of the conformational sensitivity of the band of the C–OH stretching vibrations, illustrated by a rather large number of examples. The authors[19] measured the spectra of 72 different steroids and showed conclusively that the band of the C–OH stretching vibrations

is most intense in the 1000–1100 cm^{-1} range and its position is determined by the conformation of the steroid molecule. Table 1 gives the results of Cole and coworkers[19] which charaterise the dependence of the absorption in the 1000–1100 cm^{-1} range on the structural type of the molecule.

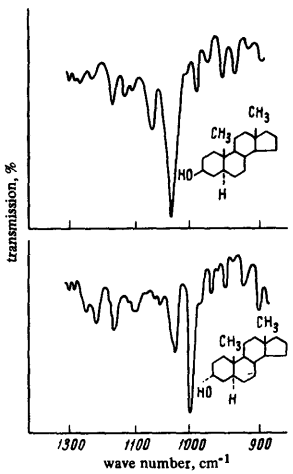


Figure 1. Infrared spectra of $C_{(3)}/C_{(5)}$-epimers of androstane in the 900–1200 cm^{-1} range (see Rosenkrantz and Zabloy[14]).

Table 1. Frequencies of the C–OH stretching vibrations at various orientations of the OH group at $C_{(3)}$ and of the hydrogen atom at $C_{(5)}$ in sterol molecules[19].

Structural type	Absorption of the most intense band in the 1000–1100 cm^{-1} range	Number of examples
	1037—1040	18
	1036—1040	25
	996—1002	9
	1032—1036	6
	1050—1056	14

Fig. 2 gives the spectra of androstan-3β-ol and coprostan-3α-ol. Both compounds have a *trans*-position for the hydroxyl groups and a hydrogen atom at $C_{(5)}$. As Fig. 2 shows, the side-chain at $C_{(17)}$ has no effect on the position of the maximum of the absorption band for the C–OH stretching vibrations (1039 cm^{-1}). In the same paper they showed[19] that the frequency of this band in hydroxy-steroids also depends on the configuration of the C–O bond itself, and not only on the α- or β-positions of the OH groups relative to the plane of the cyclic part of the molecule. The four possible configurations of the C–O bond, taking account of the $\alpha\beta$-epimers, are shown in Fig. 3, and the corresponding infrared frequencies of the sterols in Table 2.

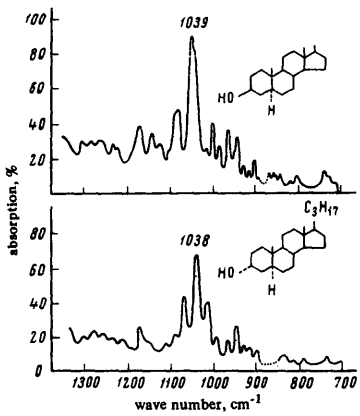

Figure 2. Infrared spectra of androstan-3β-ol and coprostan-3β-ol in the 700–1300 cm^{-1} range (see Cole and coworkers[19]).

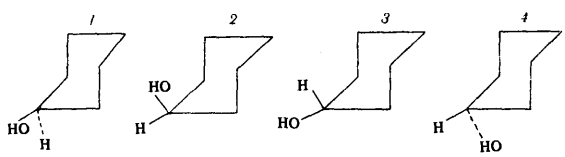

Figure 3. Four possible orientations of the C–O bond in the steroid molecules:
1) β-equatorial; *2*) β-polar; *3*) α-equatorial; *4*) α-polar.

Table 2. Frequencies of the C–OH stretching vibrations for various orientations of the OH group at $C_{(3)}$ and of the hydrogen atom at $C_{(5)}$ and various configurations of the C–O bond in sterol molecules[19].

Type of structure	A/B ring fusion	Configuration		Frequency range, cm^{-1}
		OH	C–O	
	*trans*	3β	equatorial	1037—1040
	*cis*	3α	equatorial	1037—1044
	*trans*	3α	polar	996—1002
	*cis*	3	polar	1032—1036
	Δ^5-double bond	3	equatorial	1050—1056

The frequency of the C–OH stretching vibrations is somewhat greater for the equatorial configuration. This is because an equatorial C–O bond causes some displacement of the $C_{(3)}$ atom along the C–O axis, which produces additional strain and compression of ring A, and this leads to an increase in the frequency of the C–O stretching vibrations. Nothing similar is observed for the polar configuration, since the stretching vibration of the C–O polar bond takes place mainly in the direction normal to the ring. Hence the investigation of the absorption in the range 950–1100 cm^{-1} can provide valuable information about the structure.

True, it must be mentioned that these authors[19] showed that it was possible for bands unconnected with a hydroxyl group to appear in the 1000–1100 cm^{-1} range, but their intensity is always lower. They usually appear for ketosteroids with a C=O group at the $C_{(17)}$, $C_{(7)}$, $C_{(11)}$, $C_{(12)}$, or $C_{(20)}$ carbon atom.

Yet another important work on this problem was published by Rosenkrantz and Scogstrom[20] in 1955. In it they investigated not only the most intense band in the 950–1100 cm^{-1} range but also a series of less intense and closely adjacent bands. Tetrahydrosteroids formed the subject of the investigation. The group of less intense bands situated close to the main band also seemed characteristic for the mutual arrangement of the substituents at $C_{(3)}$ and $C_{(5)}$. The authors[20] give the following results for the absorption of the C–O bond of the tetrahydrosteroids in dependence on the epimeric forms: 3α,5α 1005 cm^{-1}; 3β,5β 1035 cm^{-1}; 3α,5β 1041 cm^{-1}; 3β,5α 1044, 995, 978, and 956 cm^{-1}, depending on the structure of the rest of the molecule. The constant presence of a triplet band in the 3β,5α steroids was associated by the above authors with the possibility of the existence of three spatial orientations of the C–O bond. The possibility of using infrared spectroscopy for determining the spatial arrangement of the C–O bond of sterols was also demonstrated by Heller[21], who illustrated the determination of the polar and equatorial configurations by the example of 22 sterols. Page[22] undertook a similar study of other compounds of the sterol series.

In 1962 Rosenkrantz and coworkers[23] confirmed the earlier correlations by the example of thirteen 19-norsteroids. Unlike the previous studies the spectra of the 19-norsteroids were measured for the solid phase by the technique of the KBr disc. The authors obtained the following values for the infrared frequencies for the various isomeric forms of the 19-norsteroids: 3α,5α 998–1017 cm^{-1}, 3α,5β 1035–1060 cm^{-1}, 3β,5α 1042–1060 cm^{-1}, 3β,5β 1033–1055 cm^{-1}.

The band of the C–OH stretching vibrations is also sensitive to other structural factors. Thus, Meda[24] showed that the epoxide ring has an effect on the free OH group at $C_{(20)}$ but does not affect the absorption of an acetylated OH group in the same position. Jones and Roberts[25] studied the infrared spectrum of various hydroxysteroids. They found the frequencies of the C–O vibrations which characterise the location of the hydroxyl group in the steroid molecule. Jones and Roberts[25] obtained the following frequencies: for OH in the 3β-position and a Δ^5-double bond 1056–1047, 1025–1019, 989–978, 958–953 cm^{-1}; OH in the 17β-position 1059–1046 cm^{-1}; OH in the 20β-position 1100–1090 cm^{-1}; OH in the 20α-position 1016–1008 cm^{-1}. Both 20α,5α- and 20α,5β-steroids have a band in the 957–952 cm^{-1} range, but only the 20α, 5β-epimers are distinguished by a band between 962 and 965 cm^{-1}.

Important successes were achieved in investigating the infrared spectra of the steroidal acetates. Even in an early study of Furchgott[11] it was shown that the >C–O group gives a band for the C–O stretching vibrations close to 1250 cm^{-1}. Subsequently Jones and coworkers[26] studied the dependence of the absorption by the acetate group at $C_{(3)}$ on its *cis*- or *trans*-position in relation to a hydrogen atom at $C_{(5)}$. The decisive role in studying this subject is played by the number of bands of the acetate group (1190–1280 cm^{-1} range). An isolated band in the 1236–1247 cm^{-1} range is observed for all the compounds in which the acetate group at $C_{(3)}$ and the hydrogen at $C_{(5)}$ are in the *trans*-position and also for compounds with a Δ^5-double bond. In every instance when the acetate group occupies a 3β position *cis* to $C_{(5)}$ (3β,5β) there is a triplet band in the range 1200–1250 cm^{-1}. A less expressed triplet band is observed also for the 3α, *cis* to $C_{(5)}$ (3α,5α) configuration[26]. Each of the *trans*- and *cis*-forms has, of course, two stereoisomers, but the latter are readily distinguished by precipitation of the steroid with digitonin, which also determines the configuration at $C_{(3)}$. In another paper, Jones and Herling[27] investigated about 90 spectra of steroidal acetates, which confirmed their previous results. They suggest[26,27] that the reason for the observed differences in the absorption by the C–O bond of the *cis*- and *trans*-compounds is that the *cis*-compounds, which give three bands, can exist as mixtures of rotational isomers produced as a result of the delayed rotation of the acetate group around the C–O bond. As might be expected, when ring A is aromatic, there is a displacement of the band of the C–O stretching vibrations of the acetate group at $C_{(3)}$ to 1205 cm^{-1}.

The characteristic frequencies of the acetate group of steroids was also studied by Fürst and coworkers[28], who confirmed the presence of a triplet band for the 3α-acetoxysteriods. In addition to the 3-acetoxysteroids they investigated[28] the infrared spectra of sterols with acetate groups at $C_{(2)}$ and $C_{(4)}$. It is interesting that in this work[28] the authors ascribe the sterol band in the 1000–1100 cm^{-1} range not to the C–OH stretching vibration but to the deformation vibrations of the O–H bond. Fig. 4 shows the infrared spectra of the sterols and the corresponding acetates.

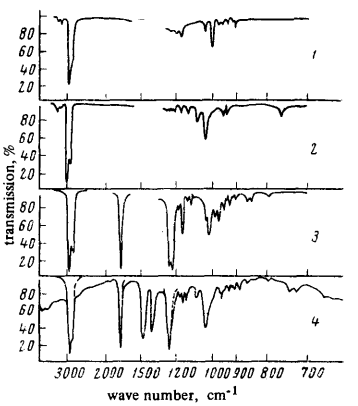

Figure 4. Infrared spectra of 3α-hydroxycholestane (1), 3β-hydroxycholestane (2), 3α-acetoxycholestane (3), and 3β-acetoxycholestane (4) in the 700–4000 cm^{-1} range (see Furst and coworkers[28]).

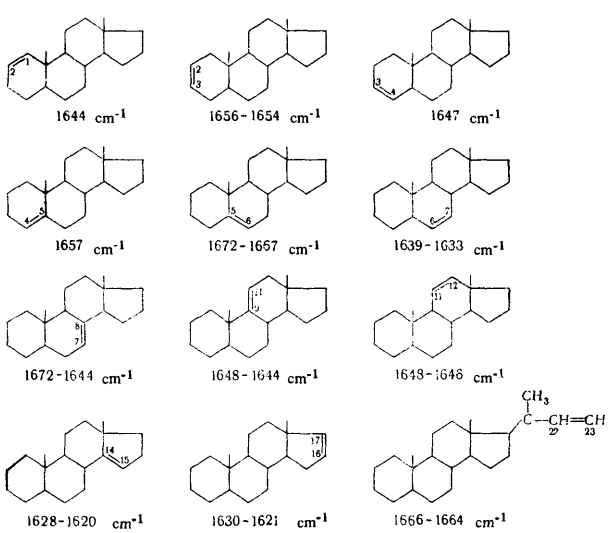
Rosenkrantz[20] obtained similar results, as later did Wotiz and coworkers[29] for 2,3,4-steroidal acetates. The same regularity of absorption was also observed for decanol acetates[30].

b. C=C Bonds

The band for the C=C stretching vibrations in the infrared spectrum is of weak intensity. Its intensity with symmetrical or pseudosymmetrical substitution is especially low. For ethylene and its symmetrical substituted derivatives this band generally does not appear, since it is forbidden by symmetry.

However, in the infrared spectra of such molecules as steroids, which have the lowest symmetry group, the band for the C=C stretching vibrations are sometimes rather sharp and can be suitable for structural conclusions.

Table 3. Frequencies of the C=C stretching vibrations as a function of the position of the C=C bond of the steroid molecule[31].



In the first studies on the infrared spectroscopy of the steroids[11-13] it was shown that the band of the C=C bond lies at 6.0 μm (1667 cm^{-1}) and the conjugation of the double bonds leads to the appearance of a band near 6.2 μm (1613 cm^{-1}). In the same studies[11-13] there were shown to be a difference in the frequencies of absorption by the C=C bond for differences in its position in the steroidal molecule: Δ^5 1671–1667 cm^{-1}, Δ^4 1610 cm^{-1}, Δ^{16} 1597 cm^{-1}, and when the Δ^4 double bond is conjugated with the carbonyl group at $C_{(3)}$ 1616 cm^{-1}.

Somewhat later Jones and coworkers[31] found a similar correlation between the frequency of the stretching vibrations of the C=C bond and its position in the molecule (Table 3).

In another investigation Jones and coworkers[32] confirm the absorption by the Δ^4-double bond of steroids in the 1612–1615 cm^{-1} range when there is a carbonyl group at $C_{(3)}$. The infrared spectra of steroids which contain Δ^5-, Δ^6-, Δ^7-, $\Delta^{5,7}$-, $\Delta^{8(14)}$-, $\Delta^{14(15)}$-double bonds were investigated by Jones and coworkers[33], who found that the compounds with Δ^5- and Δ^7-double bonds give a single weak band at 1600 cm^{-1}. The $\Delta^{5,7}$-sterols, which have two double bonds in conjugation, show two stronger bands at 1607 and 1625 cm^{-1}. Scheer and coworkers[34] found more accurately the characteristic frequencies of $\Delta^{5,7}$ conjugated bonds. They found three bands in the spectra of many steroids: 1575, 1603, and 1629–1624 cm^{-1}.

The dependence of the absorption of the C=C bond on its position in the triterpenoids was studied by Cole and Thornton[35].

The absorption of the Δ^4-double bond in 3,6-diketosteroids[36] lies between 1603 and 1609 cm^{-1}.

The paucity of results on the spectroscopic–structural correlations of the C=C bond is apparently due the the following causes: firstly, the presence and the nature of the double bond is easily found from the ultraviolet absorption spectra; secondly, when there is a hydrogen atom at an aromatic carbon atom the absorption of the stretching and out-of-plane deformation C–H vibrations of the $\rangle$C–H group is more sensitive to a change in structure than the absorption of the C=C bond itself; thirdly, the weak intensity of the band of the C=C stretching vibrations often creates additional difficulties in studying infrared spectra.

In conclusion we note that the band of the C=C stretching vibrations is always active in the Raman spectra. With non-symmetrical substitution the band of the C=C bond is more intense for the *cis*-isomer than the *trans*-isomer.

c. C=O Bonds

The high intensity, the isolated position in the infrared spectrum, and localised nature of the bands of the stretching vibrations of carbonyl groups makes these bands very convenient for spectroscopic investigations of structure. For the same reason the C=O bands are convenient for theoretical investigations of the dependence of the intensity of the bands on the redistribution of the charges in the molecule during the vibration process[37,38].

The keto-steroids have for the most part been studied from the empirical standpoint. The main problem in these investigations was whether a correlation exists between the number and position of the carbonyl groups and the corresponding absorption in the infrared spectrum, on the basis of an analysis of the spectra of keto-steroids with a known structure.

Significant success was attained in this study mainly thanks to the work of Norman Jones, whose investigations into the infrared spectroscopy of steroids can justifiably be considered classical. Earlier investigations of the infrared spectra of the steroids had shown that the frequency of the C=O stretching vibrations depends on the position of the C=O group in the keto-steroid molecule[11-13,39]. The following correlations were established in these studies:

$C_{(3)}$=O of steroids of the pregnane series	1739 cm^{-1},
$C_{(3)}$=O and Δ^4 double bond	1675–1672 cm^{-1},
$C_{(20)}$=O	1704–1712 cm^{-1},
$C_{(20)}$=O and Δ^{16} double bond	1675 cm^{-1}.

(the numbers at the carbon atoms show the numbers of the atoms according to the accepted numbering of carbon atoms in steroids).

Jones and coworkers[32] obtained more detailed information:

Nature of the bond		Frequency of the stretching vibrations, cm^{-1}	Number of examples
Non-conjugated	$C_{(3)}$=O	1717–1719	11
ditto	$C_{(20)}$=O	1706–1710	21
"	$C_{(17)}$=O	1742–1745	14
Conjugated	$C_{(3)}$=O	1674–1677	17
ditto	$C_{(20)}$=O	1666–1670	5

The diketo-steroids mainly have two bands, each of which corresponds to an individual C=O group[32].

In a later investigation Jones and another group of authors[40] completely confirmed the results of the previous work and also investigated some other keto-steroids. The following information was added:

Nature of the bond	Frequency of the stretching vibrations, cm^{-1}	Number of examples
Non-conjugated $C_{(11)}$=O	1710–1716	21
$C_{(7)}$=O	1719*	3
$C_{(12)}$=O	1710	2
Simultaneous presence of $C_{(11)}$=O and $C_{(17)}$=O	1751–1754	5
21-Acetoxy-group and $C_{(20)}$=O	1756–1758	4

* Rosenkrantz[15] obtained the same result later (17121 cm^{-1}).

Finally the generalising work of Jones and coworkers[41] appeared a year later (1950). The results of the previous studies were again confirmed and perhaps only some new results need be stated:

Nature of the bond	Frequency of the stretching vibrations, cm^{-1}	Number of examples
$C_{(16)}$=O	1745	5
$C_{(7)}$=O	1713–1714	7
$C_{(20)}$= and $C_{(21)}$-acetoxy	1756–1758	12
$C_{(6)}$=O	1713–1714	3
$C_{(12)}$=O and $\Delta^{9(11)}$-double bond	1680–1684	4

Approximately the same results were obtained later by Rosenkrantz and coworkers[16,20].

The carbonyl band of an acetate group in the side-chain of a steroid[40] appears at 1742 cm^{-1}, more rarely at 1739 cm^{-1}.

Replacement of a hydrogen atom close to a C=O group by halogen leads to a drop in the frequency of the C=O band[42], by 7 cm^{-1} for 17α-bromo-3β-hydroxy-5α-androstan-16-one, and by 17 cm^{-1} for the corresponding 17β-5α-epimer.

The carbonyl absorption of the steroids of the cholestane series which contain an acetate group was investigated by Fürst and coworkers[28]. Their results[28] suggest that irrespective of the position of the acetate group the carbonyl absorption of this group is strictly localised in the 1734–1740 cm^{-1} range. However, for the 3α- and 3β-acetates of the pregnane series Jones and coworkers[43] found the absorption of C=O between 1735 and 1732 cm^{-1} that is, somewhat lower.

Other results of Jones[44] and of Josien and coworkers[45,46] confirmed the correctness of the assignment of the carbonyl frequencies of the keto-steroids.

Depending on the molecular environment it seemed possible to characterise about 130 types of carbonyl systems of steroids according to their characteristic infrared frequencies. This work was carried out by Jones and Herling[47].

Bellamy and Williams[48], in studying the infrared spectra of keto-sterols noted that the frequencies of the C=O stretching vibrations of these substances are somewhat less (by 6–15 cm^{-1}). The authors[48] explained this by the formation of an intramolecular hydrogen bond C=O....HO. However, directly contradictory results were obtained by Jones and Robertson[49] for the 16,17-ketols of steroidal origin. In this work it was found that in the presence of hydroxy- and acetoxy-groups near to a C=O group there is an increase in the frequency of the C=O stretching vibrations by approximately 10 cm^{-1}. This problem apparently requires further precision.

The number of carbonyl groups could be determined by measurement of the integral intensities. By integral intensity is usually meant the total area bounded by the absorption band. For several monoketo-steroids the integral intensities of the C=O band were found by Jones and coworkers[50]. These results are given in Table 4.

Table 4. Integral intensities of the band of the C=O stretching vibration in the infrared spectra of monoketo-steroids[50].

Type of carbonyl group	Value of the integral intensity for various compounds, 10^4 litre $mole^{-1}$ cm^{12}	Mean value
C_3=O	2.63; 2.41; 2.39; 3.62;	2.55
C_7=O	2.17; 2.15	2.16
C_{12}=O	2.27	2.27
C_{17}=O	2.52; 2.72; 2.81; 2.64; 2.54; 2.91; 2.69	2.69
C_{20}=O	1.75; 1.84	1.80
C_3=O and Δ^4-double bond	2.88; 3.04; 3.67; 4.02; 3.39; 3.51; 3.67; 3.70; 4.11	3.65
Acetate group	3.15; 3.06; 3.14; 3.27; 3.39; 3.41	3.24

Then on starting from the integral intensities of the C=O band of the monoketosteroids, the integral intensities of the C=O absorption of the di- and poly-carbonyl steroids were calculated by an additive scheme. The results of these calculations and the directly observable integral intensities of some polyketosteroids are compared in Table 5.

Dvoryantseva and Sheinker[51] carried out a more concrete study, the aim of which was to determine the number of keto-groups in steroidal ketones.

Table 5. Integral intensities of the bands of the C=O stretching vibrations in the infrared spectra of di- and poly-carbonyl steroids[50].

Number and position of the carbonyl groups of the compounds	Infrared absorption maximum, cm^{-1}	Integral intensity of absorption, 10^4 litre $mole^{-1}$ cm^{-2}	
		calculated from the results in Table 4	observed
C_3=O and C_{17}=O	1719 1745	5.24	5.19
C_3=O and C_{20}=O	1719 1710	4.34	4.45
C_3=O; C_{20}=O and C_{12}=O	1712	6.61	6.93
C_3=O; C_{20}=O and Δ^4-double bond	1708 1677	5.44	5.90
3,20-diacetate	1739	6.48	6.21
3,16,20-triacetate	1739	9.72	9.05

The absorption of the carbonyl groups having various positions in the triterpene skeleton was studied by Cole and Thornton[35]. The effect on the absorption of the conjugation of a double bond with a C=O group was noted. In two papers of Tarpley and Vitiello[52] the influence of the solvent on the position of the bands of the C=O stretching vibrations in the infrared spectra of steroids was studied. The authors[52,53] measured 56 spectra in CS_2, CCl_4, $CHCl_3$, CH_2Br_2, and $CHBr_3$ solutions.

Recently a series of papers has appeared[54–59] on a study of the isotopic shift of the C=O frequency in the infrared

spectra on replacing ^{16}O by ^{18}O. In all instances a drop in frequency by 20–40 cm^{-1} is observed. Simultaneously there is an increase in the intensity of the displaced bands by ~20%.[59] The use of isotopic replacement of oxygen in keto-steroids could give interesting results in the near future.

As regards the other types of vibrations of the C=O bond, evidently they can also appear in the infrared spectrum. Thus Weinmann[60], by measuring the spectra of twenty-three 20-keto-steroids in the 450–800 cm^{-1} range, assigned the band between 588 and 597 cm^{-1} to C=O planar deformation vibrations. For a conjugated keto-group the frequency of this band is increased to 650–655 cm^{-1} and in the presence of an acetoxy-group at $C_{(21)}$ two bands are observed: at 604–600 and 640–648 cm^{-1}. The orientation of an acetoxygroup in steroid acetates was determined from the absorption in this range[61].

d. C–H Bonds

The C–H stretching vibrations appear in the infrared spectra of all organic compounds in the 2750–3100 cm^{-1} range. The bands of the vibrations of the C–H bonds of the methyl, methylene, and ethylene groups differ in frequency and can be differentiated in the infrared spectrum. Furthermore there is a series of different types of vibrations for the same bonds. Such different types of vibrations also differ in frequency. Fox and Martin[62,63] assigned the bands to different forms of C–H vibrations and the assignment was subsequently confirmed by other investigators[64–66].

The following frequencies of the C–H stretching vibrations were found for steroids: 2985, 3080 (for the $\rangle C{=}C{-}H$ structure), 2941 cm^{-1}.[11,12,32,33] The C–H bonds of the aromatic carbon atoms of steroids of the cholestane series give a band for C–H stretching vibrations at 3050 cm^{-1}.[33]

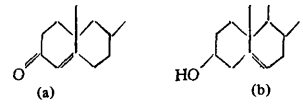
For the $\Delta^{4,6}$-3-keto steroids absorption analogous in nature is found at 3028 cm^{-1}, but for the Δ^{4}-3-keto steriods there is a weak band at 3034 cm^{-1}.

The increase in the frequency of the C–H stretching vibrations is a general phenomenon in the infrared spectra of polycyclic systems. Avram and coworkers[68] investigated this problem in detail, and in 27 polycyclic compounds found an increase in the frequency of the C–H stretching vibrations by 20–100 cm^{-1}. They thought[68] the reason for this is a change in the hybridisation of the electronic orbitals, which is expressed in the fact that the C–C bonds acquire a more and more marked p-character and the C–H bonds acquire an s-character, right up to sp^2 hybridisation.

Despite the fact that there is much information on the infrared spectra of steroids in the range of C–H stretching vibrations, these results do not give particularly valuable information about structure. However, from the absorption in the 2750–3100 cm^{-1} range methyl, methylene, and ethylene groups can be identified and by measuring the integral intensities the number of corresponding groups can be determined.

In studying the infrared spectra of steroids much more attention was and is being paid to the deformation vibrations of C–H bonds.

In even one of the first papers on the infrared spectroscopy of the steroids[7] it was shown that the ranges of the deformation vibrations of the methyl and methylene groups are respectively 1379–1389 and 1429–1481 cm^{-1}. The same investigation showed that steroids with structural formations of types (a) and (b) absorb at 870 and 840 cm^{-1} respectively (the range of the out-of-plane deformation vibrations of the ethylenic C–H bonds).



(a) (b)

Later this correlation was confirmed by other authors[15–16]. Jones and Cole specially considered[69] the problem of the absorption by methyl and methylene groups in steroid spectra. Their results are shown in Fig. 5, where the absorption by the methyl and the methylene groups of androstane are sharply differentiated. Hence their

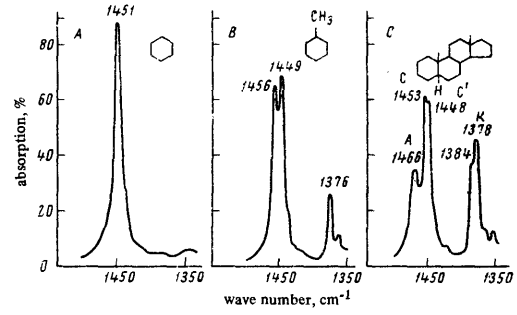


Figure 5. Infrared spectra in the range of the deformation vibrations of the methyl and methylene groups:
A) cyclohexane; *B*) methylcyclohexane; *C*) androstane[65].

results[69] show that the deformation vibrations of methylene groups give a band at ~ 1450 cm^{-1} and the angular methylene groups gives the doublet of bands at 1384 and 1378 cm^{-1} (confirmed by the spectra of many simple steroids which contain two angular methyl groups). However, their spectra of ten steroids which do not have a methyl group at $C_{(10)}$ (19-norsteroids) show a band only in the 1375–1378 cm^{-1} range. This observation allows the bands of the individual methyl groups to be identified:

CH_3 at $C_{(10)}$ 1375–1378 cm^{-1},
CH_3 at $C_{(13)}$ 1384 cm^{-1}.

We will quote some other correlations found by Jones and Cole[69]:

CH_2 group of keto-steroids	1400–1440 cm^{-1},
CH_2 group in a side-chain	1466–1469 cm^{-1},
CH_3 group in a side-chain attached to different atoms	1368 cm^{-1},
CH_3 group in a side-chain attached to a single atom	1380 cm^{-1},
CH_2 group of the cyclic part of the molecule	1448–1456 cm^{-1}.

In addition the authors investigated the region of absorption of an acetate methyl group (doublet band sensitive to the position of the acetate group in the molecule) and the effect of double bonds on the absorption of the methylene groups. Hence individual methyl and methylene groups of steroids could be identified from the infrared spectrum in the 1300–1500 cm^{-1} range. An example in this respect is the spectrum of 19-norpregn-4-en-3,20-dione (Fig. 6) which distinctly shows the absorption by different functional groups and even of the same functional groups found in different atomic environments. These results are confirmed in another paper[43] where the assignment of the bands is checked with the aid of selective deuteration. At about the same time Jones and coworkers[70] undertook the work of

assigning the bands in the infrared spectra of steroidal sapogenins. The range 1408–1435 cm^{-1} was given in a later work of Jones and coworkers[71] for absorption by the methylene group of the $CO-CH_2$ structure of $C_{(19)}$-keto-steroids.

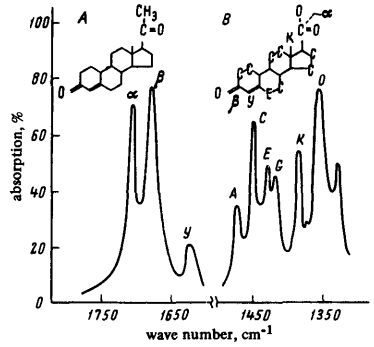

Figure 6. Infrared spectra of 19-norpregn-4-en-3,20-diol in the 1300–1800 cm^{-1} range[69]. *A*) and *C*) methylene groups of the cyclic part of the molecule at $C_{(1)}$, $C_{(7)}$, $C_{(11)}$, $C_{(12)}$ $C_{(14)}$, and $C_{(15)}$; *G*) methylene group at $C_{(2)}$ (influence of $C_{(3)}$=O); *E*) methylene group at $C_{(6)}$ (influence of Δ^4-double bond); *K*) angular methyl group at $C_{(13)}$; *O*) CH_3 at $C_{(21)}$ (characteristic frequency of the structure $H_3C-C=O$); α) and β) $C_{(3)}$=O and $C_{(20)}$=O keto-groups respectively; γ) $C_{(4)}=C_{(5)}$ double bond.

Much attention was paid to the absorption by C–H in unsaturated steroids. The deformation vibrations of the hydrogen atoms connected to aromatic carbon atoms occupy the range 650–1000 cm^{-1}, very sensitive to the molecular structure, in particular, to the location of the double bonds of the molecule. Thus for Δ^{22}-steroids which contain a double bond in the side-chain (ergosterol, vitamin D_2)[17,72], absorption in the 970–974 cm^{-1} range is characteristic. At the same time for steroids which do not have a Δ^{22}-double bond this band is absent (this is evident on comparing the spectra shown in Figs. 7–11).

The difference in the absorption of the C–H deformation vibrations for different positions of the double bond in steroids was found by Furchgott and coworkers[12,13]. Jones and coworkers[33], and then Hirschmann[73] investigated the spectra of steroids with Δ^5-, Δ^7-, or $\Delta^{5,7}$-double bonds in ring B. All the steroids with a Δ^5-double bond are characterised by a 798–803 cm^{-1} band. The $\Delta^{5,7}$-steroids have a characteristic doublet at 800 and 840 cm^{-1}. The Δ^7-steroids show only one band[33], at 835–840 cm^{-1}. Evidently the band at 800 cm^{-1} is from the $C_{(6)}$–H bond and the band at 835–840 cm^{-1} from the $C_{(7)}$–H bond.

Jonson and coworkers[33] also studied the influence on the absorption in this region of the hydroxy- and acetoxy-groups at $C_{(3)}$ and found a characteristic doublet for 3-acetoxy-Δ^4-steroids at 800 and 812–815 cm^{-1}.

The same results in assigning the bands in the infrared spectra of the steroids in the 700–1000 cm^{-1} range were obtained by authors of both earlier[74,75] and later[34,76,77] studies.

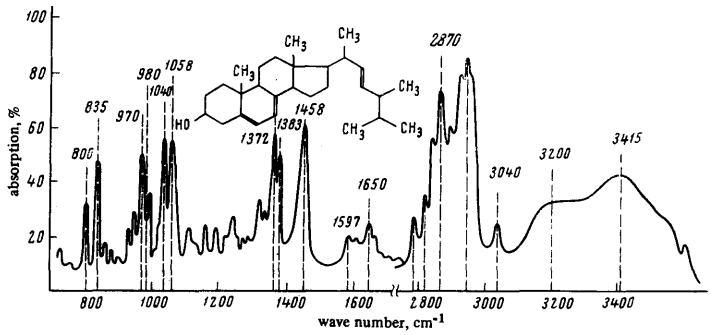

Figure 7. Infrared spectrum of the provitamin D_2 (ergosterol) in the range 700–1400 cm^{-1}.

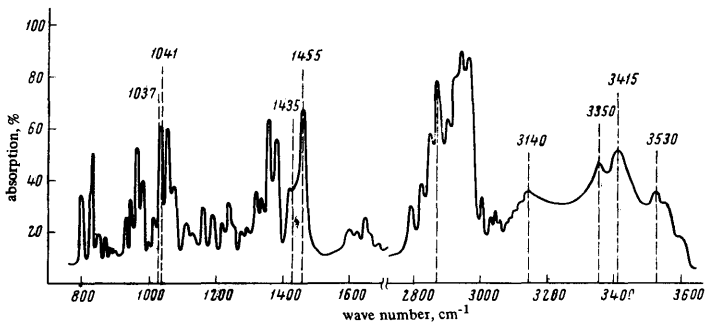

Figure 8. Infrared spectrum of ergosterol in the 700–4000 cm^{-1} range at -183°C.

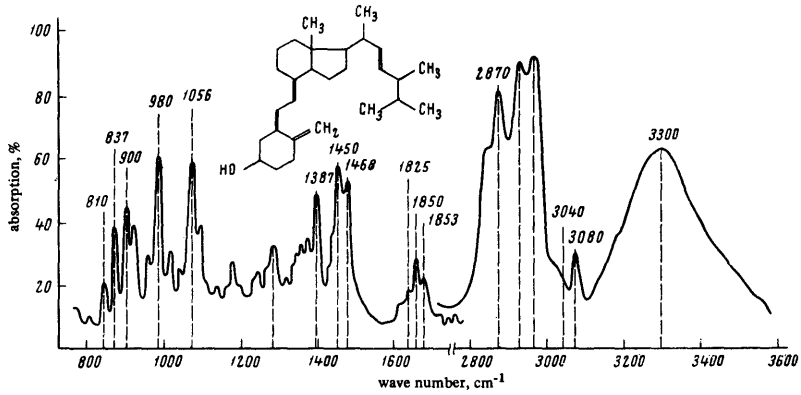

Figure 9. Infrared spectrum of vitamin D_2 in the 700–4000 cm^{-1} range.

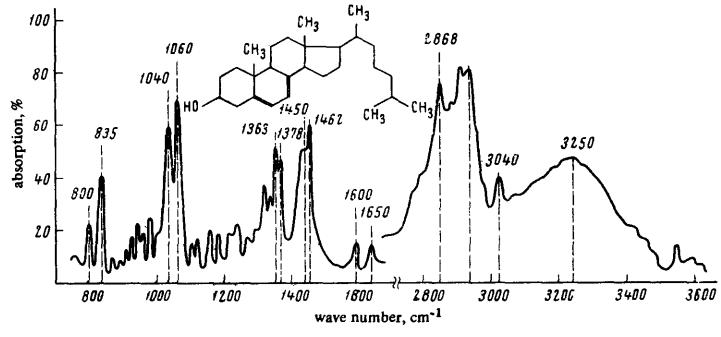

Figure 10. Infrared spectrum of the provitamin D_3 (7-dehydrocholestane) in the 700–4000 cm^{-1} range.

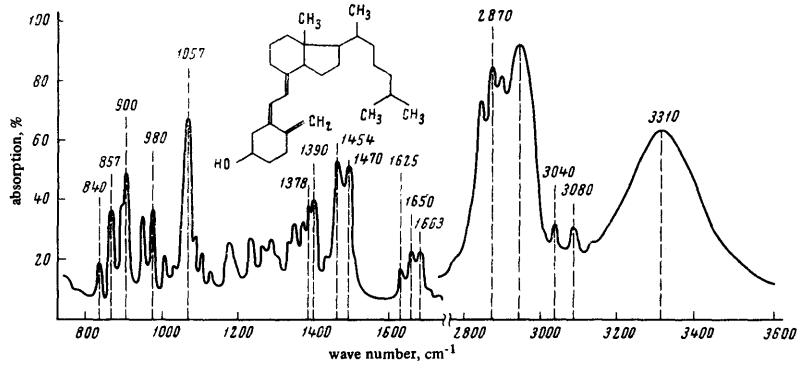

Figure 11. Infrared spectrum of vitamin D_3 in the 700–4000 cm^{-1} range.

When an ethylene bond is conjugated with a carbonyl group, the frequency of the C–H out-of-plane deformation vibrations is raised to the 867–904 cm^{-1} range[78].

Meda and coworkers[79] found a characteristic band in the 860–847 cm^{-1} range for pregn-4-en-16,17epoxy-steroids. This band can be assigned to the out-of-plane deformation vibrations of the $C_{(4)}$–H bond, but Meda and coworkers[79] evidently hold another opinion, since this band is proposed by them for the identification of the epoxy-group.

e. O–H Bonds

Free hydroxyl groups of alcohols in solutions are responsible for the appearance of a narrow absorption band in the 3610–3636 cm^{-1} range. For hydroxy-steroids the region of absorption of the O–H stretching vibrations is rather variable and depends considerably on structure and on the nature of the intermolecular interaction. Furchgott and coworkers[11] found the absorption of the O–H stretching

vibrations at 3597–3344 cm^{-1} for the steroids which they investigated. For the hydroxy-steroids of the pregnane series the same authors give a somewhat different region: 3572–3448 cm^{-1}. Rosenkrantz and Zabloy[14] found a band for O–H stretching vibrations of steroids at 3679 cm^{-1} and showed that a change in solvent can lead to a displacement of the band to 3445 cm^{-1}.

For cholestanol derivatives Jones and coworkers[33] observed the band of the free OH group at 3620 cm^{-1}.

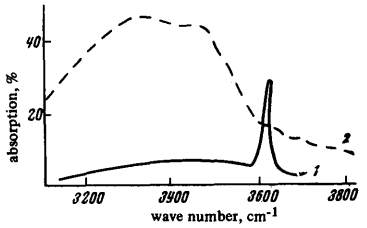

Figure 12. Infrared spectrum of ergosterol in the range of the stretching vibrations of the O–H bond: *1*) solution in CCl_4; *2*) solid phase.

In studying steroids with an aromatic ring A, Pickering and Werbin[77] found that an OH group at $C_{(3)}$ gives a band for O–H stretching vibrations at 3230–3335 cm^{-1}, and on OH group at $C_{(17)}$, one at 3415 cm^{-1}.

Dalton and coworkers[80] observed an increase in the splitting of the absorption bands of the O–H stretching vibrations from a slight shoulder for C_2H_5OH to a well differentiated band of almost equal intensity for 5α-cholestanol. It is suggested[80] that such a splitting occurs thanks to the conformational complexity of the structure of the molecule.

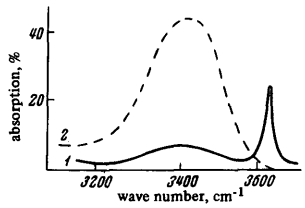

Figure 13. Infrared spectrum of 7-dehydrocholesterol in the range of the O–H stretching vibrations: *1*) solution in CCl_4; *2*) solid phase.

The influence of solvent on the frequency of the O–H stretching vibrations in the infrared spectra of the steroids was studied by Horak and Faikos[81]. The authors of the present review observed that for steroids the band of the free hydroxyl group lies at 3620 cm^{-1}. However, it can only be detected in the spectra for solutions where the molecules of the sterols are in monomeric form. In the spectra of the solid phase this band is absent, but a broad intense band appears between 3100 and 3600 cm^{-1}, due to intermolecular hydrogen bonds (Figs. 12 and 13). Hence the formation of large associates of molecules maintained by hydrogen bonds are inherent for steroids in the crystalline state. In addition to OH groups, the π-electrons of double bonds can participate in the formation of double bonds, for the spectroscopic manifestation of a hydrogen bond in the spectra of crystalline sterols which contain different numbers of C=C bonds is different. The structure of the hydrogen bond band (Fig. 8) is resolved in spectra at low temperature (–183 °C), showing that several types of intermolecular aggregation are realised simultaneously.

f. C–C Bonds and Large Fragments of Molecules

The bands of the stretching vibrations of simple carbon–carbon bonds are of low intensity and lie in the infrared spectrum below 1200 cm^{-1}. The general regularity of the absorption in this region was investigated by Brown and coworkers[82]. The possibility of the use of the band for the C–C stretching vibrations in studies of structure was investigated by McMurry and Thornton[83].

Jones and coworkers[76] found the frequency of the skeletal vibrations which characterise two different structural types of keto-steroids. Josien and coworkers assign the bands at 794 and at 811 cm^{-1} to the vibrations of the cyclopentane ring of 3,5-methylenesteroids.

The band for the deformation vibrations of the C=C bonds lies in the infrared spectrum below 600 cm^{-1} and has not yet found a use in structural spectroscopy.

III. USE OF INFRARED SPECTROSCOPY IN STEROID CHEMISTRY

In most studies of the infrared spectra of steroids carried out up to the 1950's only the nature of the absorption and the known structure of the molecule were connected.

The results on the infrared spectroscopy of steroids have been surveyed in atlases of spectra[85,86], repeatedly checked. The spectroscopic–structural correlations which have been deduced and repeatedly confirmed have enabled molecules of unknown structures to be introduced into the field of the infrared spectroscopy of steroids. Hence since the 1950's infrared spectroscopy has been widely used for revealing the most varied problems of the structure of natural steroids and their synthetic analogues. The examples cited below illustrate the great possibilities and occasionally the necessity of using infrared spectroscopy in investigating the structure and conversions of the steroids.

1. Sterols

The most diverse problems of the steroid chemistry have been solved by analysis of their infrared spectra. Information on the absorption by the hydroxyl groups of sterols has appeared in Soviet[87] and foreign[88] literature.

Specific absorption of the OH groups is observed in the spectra of the cardenolides[89] and glycosides[90]. The infrared spectra of the sterols are used both for identification and for solving structural problems[92]. Thus Fudge and coworkers[93] used the infrared spectra for finding the structure of 5-hydroxy-derivatives of cholestane[93]. The results from molecular spectroscopy were used to determine the orientation of the hydroxyl group itself in molecules of natural sterols[94] and also for investigating the structure of cerebrosterol[95], 20-ketosteroid-3,11-diols[96], lanosterol and its derivatives[97,98], β-spinasterol[99], and derivatives of ergosterol[100].

The hydroxyl groups of steroids are capable of forming both intramolecular and intermolecular hydrogen bonds. From the infrared spectroscopy results the presence of intramolecular hydrogen bonds in 7-hydroxycholesterol was established between the 3-OH and 7-OH hydroxyl groups[101] and in steroidal 3,5-*cis*-diols between the 3-OH and 5-OH hydroxyl groups[102] (there are no hydrogen bonds in the 3,5-*trans*-diols), and in cholesterol and epicholesterol between the OH groups and the π-electrons of the double bonds[103].

Bernstein and coworkers[104] used infrared spectra to study 7α-hydroxysteroids. Infrared spectroscopy has been widely used in the investigation of steroidal diols[105-109] and triols[110-112], and also new sterols[113].

Infrared spectra were used successfully to study the structure and conversions of sterols of un-natural conformation, particularly lumisterol[114-117], which is an important intermediate in the photosynthesis of the vitamins of group D.

2. Unsaturated Steroids

In studying the unsaturated steroids the infrared spectra in the ranges 700–1000 cm^{-1} ($\gtrless$C–H out-of-plane deformation vibrations) and 1550–1650 cm^{-1} (C=C stretching vibrations) are used.

The presence and position of C=C double bonds was shown by infrared spectra for derivatives of allopregn-6-ene[118], Δ^{11}-unsaturated steroids[119], and 1-dehydrosteroids[120]. Levin and coworkers[121] studied the conformation of $\Delta^{5(10)}$-unsaturated steroids. The infrared spectra found application for studying the structure and conversions of steroidal hormones[122-126], derivatives of vitamin D_2,[127] $\Delta^{5,7}$-steroids[128,129], and steroids with an aromatic ring A.[130] Elks[131], and also Henbest and Wilson[132] studied steroidal trienes. Bergman investigated the infrared spectra with the aim of identifying C=C bonds in the side-chain of 22-, 24-, and 25-dehydro-derivatives of cholesterol[133,134]. The results of molecular spectroscopy were used to study the conformation of the D rings in Δ^{14}-unsaturated steroids[135]. Absorption in the 700–1000 cm^{-1} range was used to find certain features of the structure of $\Delta^{3,5}$-steroids[136]. Information has also been obtained about the spectra of synthetic steroidal hormones[137] and their derivatives[138].

3. Steroidal Ketones

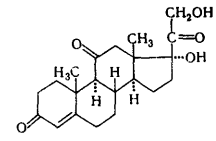
The infrared spectra of steroidal ketones have been widely used both for the identification[139-141] and for elucidating the structure[142-145] of steroids. The principal task of these spectroscopic investigations was naturally to find the presence and position of the carbonyl groups. In the chemistry of steroidal ketones infrared spectra are usually the main test of an investigation of the structure and of the mechanism of chemical reactions in which C=O groups participate.

Infrared spectra are used successfully in studying 3-keto-steroids[146-148], 7-keto-steroids[149], the conversions of 11-keto-steroids[150-152], and 15- and 20-keto-steroids of the pregnane series[153].

The results from infrared spectroscopy allowed the isomerisation of unsaturated ketones to be observed[154] and also the structure and conversions of various steroidal diketones to be investigated[155-161].

On the basis of the results of infrared spectroscopy, Baron and le Boulch[162] studied the structure of intermediate products between cholesterol and the "ketone 250" known in steroid chemistry.

Cortisone (IV) occupies a special place in the chemistry of steroidal ketones—it is the most important of the corticosteroidal hormones. After the discovery of the therapeutic action of this hormone intensive attempts to synthesise cortisone and its analogues were made.

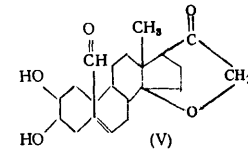


(IV)

In many of these studies the results from infrared spectroscopy of cortisone itself[163] and of its derivatives[164-167] were used fruitfully. With the aid of infrared spectra certain problems in the synthesis of cortisone were solved[168-171], and in particular the problems of the structure of intermediates in the synthesis[172,173].

4. Epoxysteroids and Lactones

In 1953 Gunthard and coworkers[174] proposed a method of distinguishing the stereoisomers of steroidal epoxides by their infrared spectra. Later with the aid of infrared spectroscopy features in the structure of steroids containing a seven-membered lactone ring were established[175]. On the basis of a study of infrared spectra, the structure of digifologenin[176] (V) together with certain other steroids having a five-membered lactone ring as ring D was established.



(V)

Many studies have employed infrared spectra to draw conclusions about the structure of other steroidal lactones[177-182] and epoxysteroids[183-188]. Infrared spectra have also been used to establish the structure of new synthesised lactones[189-191] and epoxysteroids[192]. Henbest and Wrigley[193] studied the reaction of 5,6-epoxysteroids with the complex $BF_3.Et_2O$ on the basis of the results from infrared spectroscopy. A large number of results from infrared spectroscopy was used for solving the problems of the synthesis of an important hormone of adrenal cortices—aldosterone[194-200]. Several studies were also devoted to the infrared spectra of steroidal sapogenins[201-209].

5. Methyl- and Methylene-steroids. Steroidal Acetates

Steroids which contain methyl and methylene groups as angular substituents and substituents in side-chains are conveniently investigated by the methods of molecular spectroscopy thanks to the specific absorption by these functional groups.

Certain structural aspects of this type of absorption were considered in Cole's review[210]. The problems of the structure of 3-methylcholestanol and its photo-derivatives was considered by Barton and coworkers[211]. Several authors give information about the infrared spectra of steroids which contain methyl substituents in the most varied positions in relation to the steroidal skeleton of the molecule: 6,[212,213] 7,[214] 16,[215,216] 20,[217] 9α,[218] 17α,[219,220]

17β,[221] 4α,[222] etc. There are also spectrographic results used in studying dimethyl-[223-225] and methylene-[226,227] steroids.

Since the infrared frequencies of the acetate group are sensitive to its stereochemical location in the molecule, the infrared spectra are often used in studying the structure[228-230], synthesis (acetylated derivatives of cortisone[231-233]), and conversions[234,235] of steroidal acetates and diacetates[236].

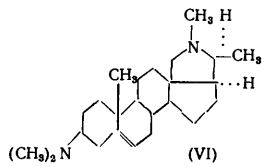
6. Halogenosteroids

The infrared spectra of the bromo-derivatives of steroids have been studied best, those of the iodo-derivatives worst. However, this is not paradoxical, the earliest information concerns iodosteroids; from an analysis of infrared spectra Djerassi and Lenk[237] proved the structure of intermediates in the synthesis of 21-iodo-Δ^{16}-20-ketosteroids. Infrared spectroscopy was used to investigate the bromination of sapogenins[238], bromosteroids of the cholane[239] and androstane[240] series, the configuration of the $C_{(17)}$ substituents in 16-ketoandrostan-6-ol[241]†, the conversion of 17α-acetoxy-16β-bromo-20-ketosteroids[242], the mechanism of bromination of keto-steroids[243-244] and certain other problems[245-247].

The infrared spectra of fluorosteroids have also been fairly well studied[248-253]. Less information is available on the infrared spectroscopy of chloro-steroids[254-256].

7. Nitrogen-Containing Steroids

Nitrogen enters into the composition of the molecule of many natural and modified steroids. It can be found in the steroids both as hetero-atoms in the rings and in the composition of various groups of angular substituents. A good example is conessine (VI), the infrared spectrum and structure of which were investigated by Phillips and Johnson[257].



(VI)

Results from infrared spectroscopy were also used in studying the synthesis of conessimine from conessine[258]. The infrared spectra of nitrogen-containing steroids were characterised by various chromophores, including nitrogen atoms: imine[259] (>C=NH–) 1638 cm^{-1} diazochromophores[260] ($-\overset{+}{N}=N-$) 2080 cm^{-1}, and the cyano- (nitrile-) chromophore[261-263] (–C≡N–) 2237 cm^{-1}.

The molecular spectra of nitrogen-containing steroids have now been reliably interpreted and are used in investigations of aza-steroids[264-267] nitro-steroids[268-270], amino-steroids[271], and hydroxyiminocholane acids[272].

8. Conversions of Steroids

Various changes in the structure of steroids are positively reflected in the infrared spectra. This disclosed the possibility of judging the converions of steroids from the changes in their infrared spectra. The results of this nature are available for steroids modified in the most diverse ways.

Thus Bladon and coworkers[273] observed a change in the infrared spectra of steroids subjected to reduction with sodium amalgam. Several studies are devoted to the infrared spectra of steroids modified by photochemical action[274-277].

Shoppee and coworkers often used infrared spectroscopy in a series of studies they made into the Walden inversion in reactions of compounds of a steroidal nature[278-280]. Infrared spectroscopy has been extensively used in studying the most varied conversions of steroids brought about by micro-organisms[281-291].

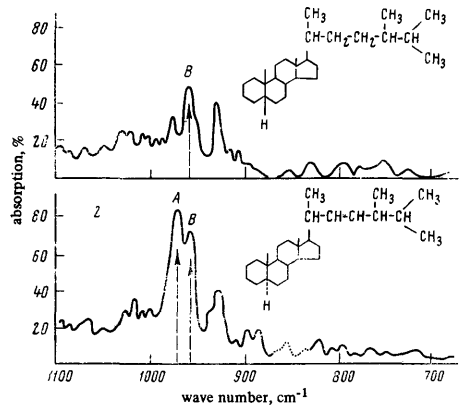


Figure 14. Infrared spectra of ergostane (1) and of ergost-22-ene (2) in the 700–1300 cm^{-1} range[168].

9. Some Particular Structural Problems

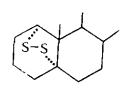
Infrared spectroscopy has been used successfully to solve some particular problems of structure, conversions, and metabolism of steroids.

The first of such studies were made by Jones as long ago as 1950.[72] In it, the absorption in the range 970–974 cm^{-1} showed that for ergost-22-ene the side-chain in $C_{(17)}$ steroids which contain a Δ^{22}-double bond has a *trans*-configuration relative to this bond (Fig. 14). For the *cis*-configuration absorption took place in the 670–800 cm^{-1} range.

Taub and coworkers[292] studied the side chain of corticosteroids from the absorption in the infrared range. Dobriner and coworkers[293] studied the metabolism of previously deuterated steroids from the band of the C–D stretching vibrations in the 2145–2165 cm^{-1}.

On the basis of infrared spectra Mateos and Chao[294] determined the form of ring D in certain steroid molecules.

Tweit and Dobson investigated the spectra of steroids with a trans-annular S–S bridge (VII) in ring A[295]:



(VII)

† This reference (241) does not mention 16-ketoandrostan-6-ol nor infrared spectroscopy! (Ed. of Translation).

Information on absorption in the infrared range of the spectrum was used in studying the structure of the most varied steroids, in particular, digacetinin[296], kitigenin[297], β-anhydrogromphogenin[298], steroidal nucleotides[299], steroidal glucosides[300-302], stereoisomers of prednizolone[303], and steroids with a butenolide ring[304,305]. An atlas of infrared spectra was recently published[306] which contains, in addition to the spectra of coumarins, flavonoids, and anthraquinones, 44 spectra of cardenolides—steroids which exhibit a butenolide ring. The infrared spectra have also found application in studying natural 24-alkyl steroids[307] and steroids isolated from marine products[308,309].

---o0o---

In conclusion it should be noted that the material surveyed in the present review far from exhausts the possibilities of the infrared spectroscopy of steroids. In addition to the structural aspect and identification, infrared spectroscopy can be used for other purposes. However, the space for the present review does not permit consideration of all possible applications of the molecular spectroscopy of steroids.

In recent years the chemistry of steroids has been enriched by physical methods of investigation. Many authors employ in their investigation not only infrared spectroscopy but also the results of ultraviolet spectroscopy, optical rotatory dispersion, and circular dichroism, and electron paramagnetic and nuclear magnetic resonance. However, the value of the infrared spectra of the steroids is not diminished by this, since the combined use of all the above physical methods of studying structure gives, of course, a considerably more detailed information about steroid molecules than any method used in isolation.

I. INTRODUCTION

One of the most surprising peculiarities of the icosahedral system of barene (carborane-10) and neobarene† is the unusual valency state of the two carbon atoms, each of which is bound simultaneously to six other atoms (Fig. 1).

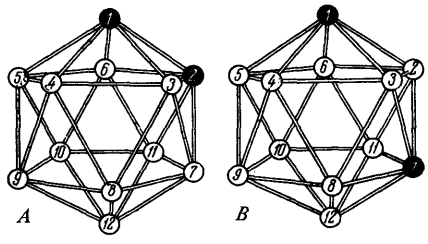

Figure 1. Structure of: *A*) barene; *B*) neobarene.

† The American name for barene is 1,2-dicarbaclovododecaborane-12, carborane-10, or ortho-carborane; neobarene is termed by them neocarborane or meta-carborane. For further details on the nomenclature of the barenes see Ref.1.

This fact, coupled with the strong electron-acceptor properties of the barene cage and the steric hindrance which it creates, makes the study of *C*-functional derivatives of barene extremely interesting. From the point of view of organoelementary chemistry the greatest interest attaches to derivatives containing a direct bond between the element and a cage carbon atom. The investigation of such compounds can obviously give valuable information on the nature and properties of the element–carbon bond in general.

The first papers reporting the discovery of barenes appeared at the end of 1963.[2-5]. A general method for synthesising them consists in the reaction of decaborane with acetylenes in the presence of Lewis bases:

$$B_{10}H_{14} + RC{\equiv}CR' \xrightarrow{L} RC\!-\!CR' + 2H_2$$

(the product is bonded to $B_{10}H_{10}$)

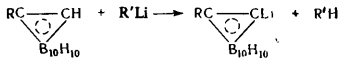
The chemical structure of barene, established theoretically by Lipscomb[6], was confirmed by X-ray[7-10] and electron[11] diffraction, although the first X-ray results subsequently proved to be erroneous[2]. The ten boron atoms and two carbon atoms of barene form an almost regular icosahedron (with interatomic distances C–C = 1.64–1.70 Å, B–C = 1.70–1.71 Å, and B–B = 1.70–1.79 Å), the C–C

bond length having no analogy throughout organic chemistry.

Barenes, in contrast to the original hydroboron, are stable towards oxidising agents, alcohols, strong acids, and bases, and possess phenomenal thermal stability. At 500°C barene isomerises into neobarene, in which the two carbon atoms are in the "meta" position relative to one another[12,13]. The chemical properties of barenes have recently been reviewed by Issleib et al.[14], and therefore we shall henceforward consider only those which are significant for the present paper. The most important of these properties is the "acidic" character of the C–H bonds, as a consequence of which the protons attached to the carbon atoms can be fairly easily replaced by alkali metals when the barenes are treated with the amides or lithium alkyls.

II. MAGNESIUM AND ALKALI-METAL DERIVATIVES; SYNTHESES BASED ON THEM

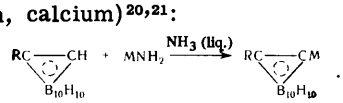
Organolithium derivatives of barenes, which are widely used for the synthesis of various barenyl compounds, are readily obtained by the action of butyl-lithium[15–17] or phenyl-lithium[16–18] both on barene itself and on monoalkyl- and monoaryl-barenes:



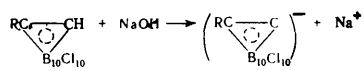
The reaction is usually accomplished by treating the barenes with a benzene solution of butyl-lithium at 60–80°C.[15]

To obtain the monolithium derivative of barene itself, the reaction must be conducted in ether at 0°C, and the solution of n-butyl-lithium or phenyl-lithium added to the barene in such a manner that excess of the latter is present throughout the reaction[16]. In contrast to this, the addition of an ethereal solution of barene to excess of n-butyl-lithium at 0–15°C results in a good yield of dilithiumbarene[16]. This derivative is obtained also by the action of excess of n-butyl-lithium in heptane or pentane on barene in tetrahydrofuran and of phenyl-lithium on barene in ether[17]. Neobarene undergoes methylation under similar conditions[12].

The sodium derivatives of barenes, the possibility of whose synthesis by the action of sodamide on the corresponding barenes was shown by Zakharkin et al.[19], are of great value for preparative purposes. This reaction was subsequently extended to the amides of other metals (lithium, potassium, calcium)[20,21]:

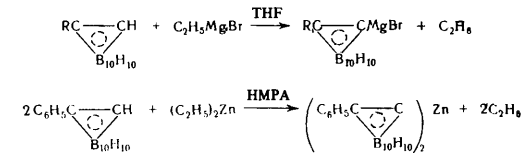


The ease of metallation of barenes by metal amides and lithium alkyls indicates the acidic character of the hydrogen atoms attached to the carbon atoms of the barene cage, this being due to the strong electron-acceptor action of the cage. Replacement by chlorine atoms of the hydrogen atoms attached to boron reinforces the electron-acceptor effect of the barene cage. The acidity of the decachlorobarenes has increased so much that they are now actual proton acids, which should dissolve in weak aqueous solutions of alkalis to give the corresponding sodium derivatives in the completely ionised state[22]:



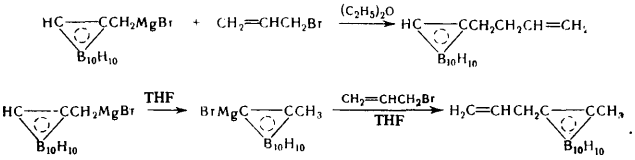
where R = H, C_6H_5.

In contrast to the reactions with lithium alkyls and metal amides, however, the hydrogen atoms attached to the carbon atoms of the barene cage are not replaced by a metal atom on treatment with organomagnesium and organozinc compounds in ethereal medium. The reaction goes only when complexing solvents are used. Thus ethylmagnesium bromide reacts smoothly with barene, methylbarene[17], and neobarene[23] in tetrahydrofuran (THF) medium, and diethylzinc reacts with phenylbarene in hexamethylphosphoramide (HMPA) medium[24]:

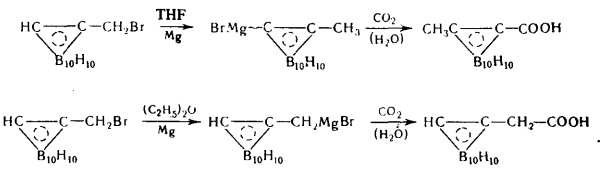


where R = H, CH_3.

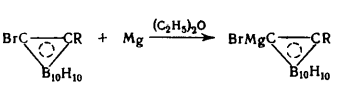
An interesting reaction was discovered by a group of American chemists[17] when preparing a Grignard reagent from bromomethylbarene. It was found that in tetrahydrofuran (unlike ether) the barenylmethylmagnesium bromide underwent isomerisation, and on treatment with allyl bromide gave 1-allyl-2-methylbarene instead of 4-barenylbut-1-ene:



The occurrence of such isomerisation was confirmed by Stanko[25], who showed that carboxylation in tetrahydrofuran of the Grignard reagent obtained from bromomethylbarene yielded methylbarenecarboxylic acid. When the reaction was conducted in ether, barenylacetic acid was formed:



Barenylmagnesium halides were obtained also directly from compounds containing a cage carbon–halogen bond:



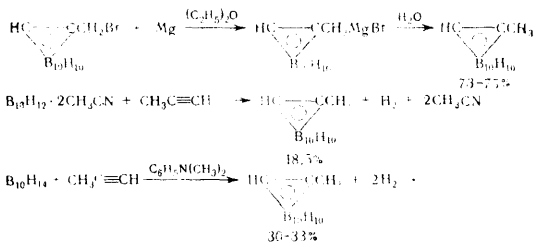
where R = n-C_3H_7, n-C_4H_9. However, these compounds did not react with aldehydes or ketones[16]‡.

The ease with which barenyl derivatives of elements in Groups I and II can be obtained has enabled a large number of diverse barenyl compounds to be synthesised on their basis.

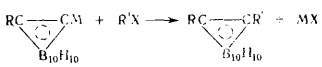
The carboxylation of barenylmethylmagnesium bromide mentioned above provides a more convenient method for preparing barenylacetic acid than synthesis from decaborane and ethyl but-3-ynoate[25]. Formation of methylbarene by the hydrolysis of barenylmethylmagnesium bromide occurs with a far better yield[16,26] than is obtained by the

‡ It has recently been reported[87] that analogous Grignard reagents, containing hydrogen, methyl, vinyl, and phenyl as substituents, react readily with aldehydes and ketones, as well as with alkyl halides[88].

reaction of propyne with decaborane in the presence of a Lewis base[27,28]:

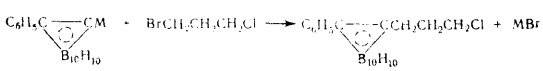


The alkylation of *C*-metal derivatives of barenes was investigated by several American chemists[12,16-18,29,30], and has subsequently been subjected to detailed study by Zakharkin and Kazantsev. They have synthesised a large number of alkyl and aryl derivatives of barene[20,21,31] and neobarene[32] on the basis of the reaction



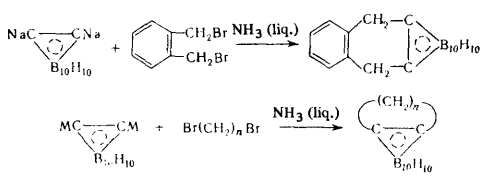
where M = Li, Na, K.

It is more convenient to work with sodium derivatives in liquid ammonia than with lithium derivatives in benzene or ether. Primary alkyl bromides and iodides, alkenyl bromides, $\alpha\omega$-dibromoalkanes (other than 1,2-dibromoethane), chloro-derivatives such as benzyl chloride, and dialkyl sulphates react smoothly. Primary alkyl chlorides react extremely slowly with metal derivatives of the barenes, and this permits the selective alkylation of the *C*-metal derivatives by $\alpha\omega$-bromochloroalkanes with the formation of α-barenyl-ω-chloroalkanes[31]:

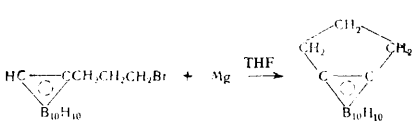


where M = Li, Na.

With secondary and tertiary alkyl bromides practically no alkyl derivatives are formed[31]. Barene derivatives containing two metal atoms react with certain $\alpha\omega$-dihalogeno-derivatives to give five- and six-membered carbocyclic compounds[31,33]:

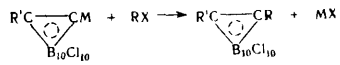


where M = Na, K and n = 3, 4. An analogous five-membered cyclic derivative is formed when an attempt is made to prepare a Grignard reagent from barenylpropyl bromide[34]:

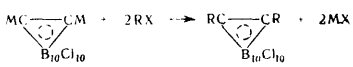


Such cyclisation is explained by metallation by the resulting Grignard reagent of another molecule of the halogenated barene followed by elimination of magnesium bromide.

C-Alkylation of *B*-decachlorobarene goes smoothly by the action of alkyl halides either on lithium salts of decachlorobarene in ethereal or toluene medium[35] or on the analogous sodium derivatives in alcoholic or aqueous-alcoholic medium[36]:



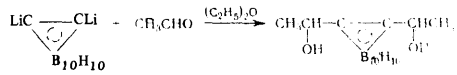
where M = Li, R = CH_3, C_2H_5, R′ = H, X = I;
or M = Na, R = CH_3, R′ = C_2H_5, X = I;
R = C_2H_5, R′ = H, X = I;
R = CH_2 : $CH.CH_2$, R′ = H, X = Br;
R = $C_6H_5.CH_2$, R′ = H, X = Cl;



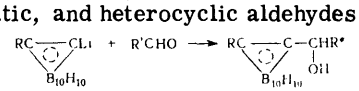
(M = Li, R = CH_3, C_2H_5, X = I or M = Na, R = CH_3, X = I).

The lithium derivatives of barene readily react with various aldehydes, from which alcohols can be obtained containing the hydroxyl in the α-position with respect to a carbon atom of the barene cage[20,21,37,38].

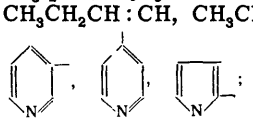
Heying et al.[16], who were the first to accomplish a reaction of this type, used dilithiumbarene, from which the corresponding diol was obtained by reaction with acetaldehyde:



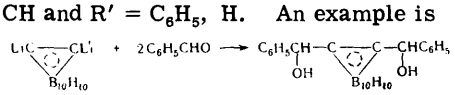
This reaction was subsequently extended to several aliphatic, aromatic, and heterocyclic aldehydes[37,38]:



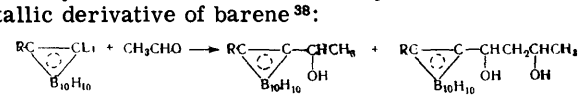
where R = CH_3, $(CH_3)_2CH$, C_6H_5 and R′ = C_6H_5; R = CH_3, C_6H_5 and R′ = H, $CH_3CH_2CH:CH$, $CH_3CH:CH$, *p*-$CH_3OC_6H_4$ *o*-ClC_6H_4,



R = $CH_2:CH$ and R′ = C_6H_5, H. An example is

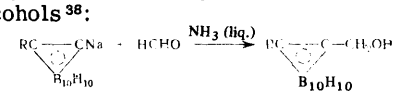


Reaction of lithiumbarenes with acetaldehyde may result not only in the normal reaction product—a secondary alcohol—but also in a diol, a product of the reaction of lithiumbarene with β-hydroxybutyraldehyde, which is probably formed by the action of the secondary alkoxide or a *C*-metallic derivative of barene[38]:

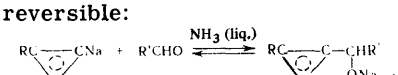


where R = CH_3, C_6H_5.

Sodium derivatives of barenes in liquid ammonia react smoothly only with formaldehyde, to give 92–94% yield of primary alcohols[38]:

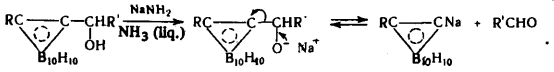


where R = CH_3, C_6H_5. With other aldehydes the yields were substantially lower, mainly because the reaction of sodium derivatives of barenes with aldehydes in liquid ammonia is reversible:

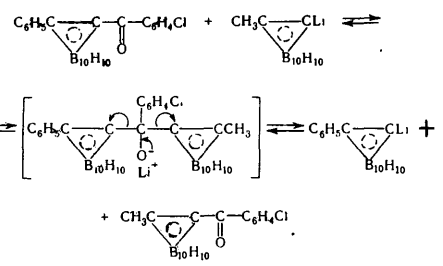


This phenomenon is probably a particular case of the general tendency of the carbon–carbon bond in carbonyl derivatives and alcohols of the barene series to undergo

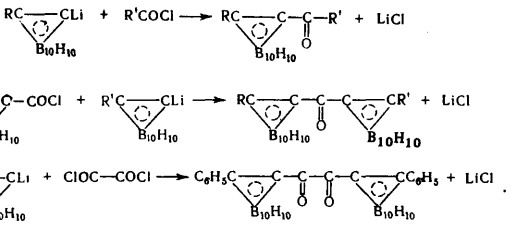
cleavage in the presence of bases[39-41], which is explained by the strong electron-acceptor effect of the barene cage:



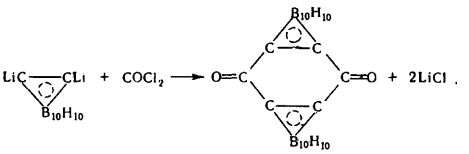
An analogous explanation can be given for the unsuccessful attempts to prepare tertiary alcohols of barenes by the reaction of barenyl-lithium derivatives with barene ketones[42,43]:



For the same reason formation of tertiary alcohols is not observed when lithiumbarenes interact with acid chlorides, the reaction halting at the ketone stage. This has been utilised by Zakharkin and L'vov[42,44] to prepare a large number of ketones of the barene series:



Dilithiumbarene reacts with carbonyl chloride to yield a cyclic diketone[45]:

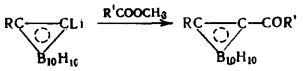


This compound, however, does not react with 1,1-dimethylhydrazine (which would be characteristic of the carbonyl group), owing to the influence of the barenyl cage.

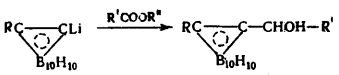
Phenylbarenyl-lithium reacts smoothly with chalcone and with styryl t-butyl ketone in benzene solution to give the corresponding γ-ketones[46]:

where R = C_6H_5, $C(CH_3)_3$.

Esters react with lithium derivatives of barene to form ketones or secondary alcohols, depending on the structure of the ester. Ketones are formed from the methyl esters of aromatic acids and the methyl and ethyl esters of aliphatic acids, whereas alcohols are the main products from ethyl, propyl, and isopropyl esters of aromatic acids[47]:

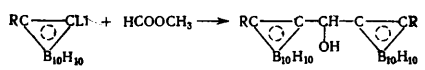


where R = C_6H_5 and R′ = C_6H_5, p-$CH_3C_6H_5$, p-BrC_6H_4; R = CH_3 and R′ = C_6H_5;



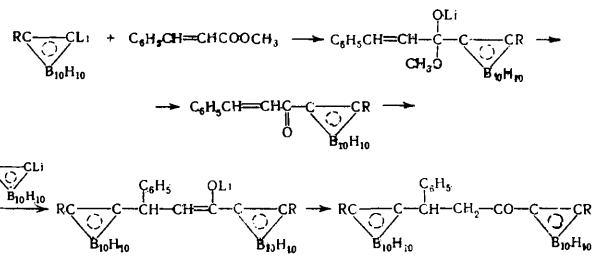
where R = R′ = C_6H_5 and R″ = C_2H_5, C_3H_7; R = CH_3, R′ = C_6H_5, and R″ = C_2H_5.

Lithiumbarenes react with methyl and ethyl formate similarly to Grignard reagents, yielding secondary alcohols containing two barene cages[48]:



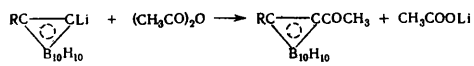
where R = CH_3, C_6H_5.

The reaction between lithium derivatives of barenes and methyl cinnamate takes place in two stages, involving the initial 1,2-addition of the lithiumbarene at the ester carbonyl group to form an $\alpha\beta$-unsaturated barenyl ketone, followed by 1,4-addition of a second lithiumbarene molecule[46]:

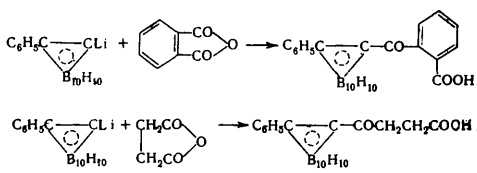


where R = CH_3, C_6H_5.

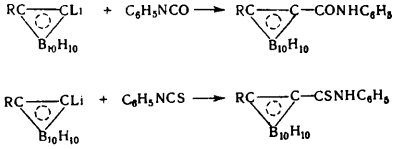
In contrast to the reactions of the usual organolithium compounds, the action of lithiumbarenes on carboxylic anhydrides yields barenyl ketones without the formation of tertiary alcohols[48,49]:



where R = CH_3, C_6H_5. With the anhydrides of dicarboxylic acids lithiumbarenes yield keto-acids of the barene series[48,49]:

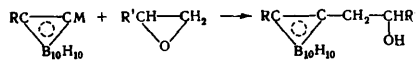


Lithium derivatives of barenes[48] and neobarenes[49] react smoothly with phenyl isocyanate and phenyl isothiocyanate to form the corresponding anilides of the barene- and neobarene-carboxylic and -carbothioic acids:



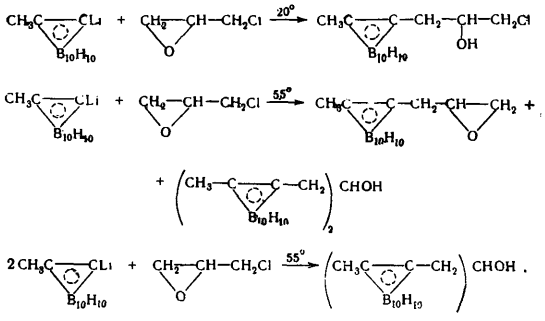
where R = CH_3, C_6H_5.

Lithiumbarenes in ether[16,17] and sodium barenes in liquid ammonia[20,21] react smoothly with α-epoxides to produce high yields of primary and secondary alcohols in which the hydroxyl is in the β-position relative to a carbon atom of the barene cage (the best results are obtained by conducting the reaction with the lithium derivatives in ether)[50]:

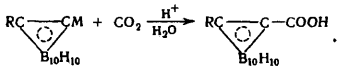


where R = H, CH_3, CH_2:CH, C_6H_5, R′ = H, CH_3, C_6H_5, and

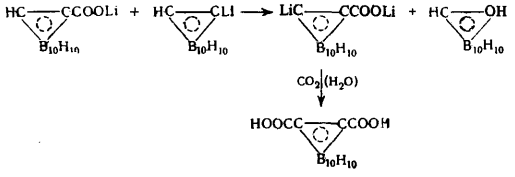
M = Li, Na. In the case of epichlorohydrin in the cold, the oxiran ring is opened without the chlorine atom being affected; when the temperature is raised a mixture of products is formed[50]:



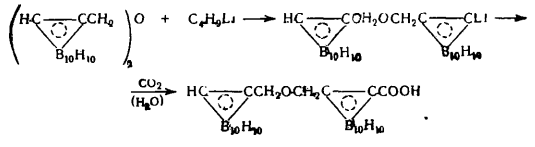
As has already been mentioned (p. 174) magnesium[22,25], lithium[12,15-17], and sodium[19] derivatives of barenes are important starting materials for the preparation of barenecarboxylic acids which are often difficultly accessible:



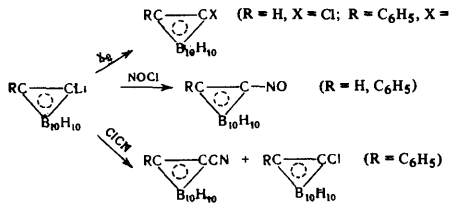
An interesting reaction was observed by Heying et al.[16], who, in attempting to prepare barenecarboxylic acid by treating barene with an equivalent quantity of butyl-lithium and then carboxylating the product, obtained a good yield of barenedicarboxylic acid, as a consequence of the exchange reaction



occurring at the instant of carboxylation. These workers explain the enhanced mobility of the hydrogen atom as a proton in lithium barenecarboxylate by the influence of the carboxy-group. Such a phenomenon is not observed in the absence of a carboxyl or when it is remote from the barene cage. Reaction between bisbarenylmethyl ether and an equivalent quantity of butyl-lithium followed by carboxylation yields only the monocarboxylic acid[51]:

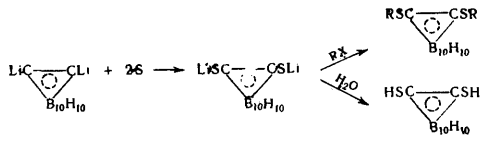


Barenyl-lithium derivatives have been used also for the preparation of halogenobarenes[17,35,44,52], nitrosobarenes[53,54], and cyanobarenes[55]:



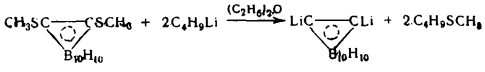
Smith et al.[56], starting from dilithiumbarene and neobarene, obtained compounds containing a barene carbon–sulphur bond:

where R = CH_3, C_2H_5, $C_6H_5CH_2$, C_6H_5, $CH_3C_6H_4$;

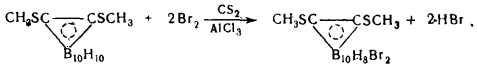


where R = H and X = Cl; R = CH_3 and X = I. Mono-, di-, and tri-*B*-bromobarenes also undergo these reactions. Sulphur dichloride reacts with dilithiumbarene to give polymeric substances of low molecular weight, containing a dithio-bond.

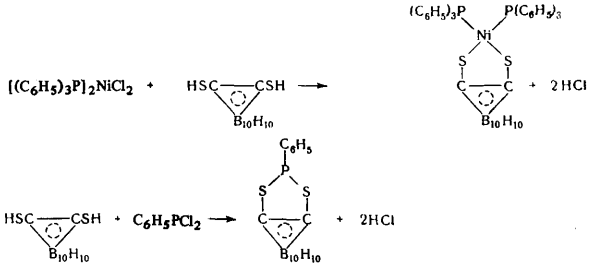
The barene carbon–sulphur bond is cleaved by the action of butyl-lithium. In contrast to dialkyl or mixed alkyl aryl sulphides, this involves nucleophilic attack at the sulphur atom with formation of a carbon–lithium bond[56]:



The electron-acceptor effect of the barene cage on the sulphur atom is shown also in the inability of barenyl sulphides to form sulphonium salts on treatment with bromine in boiling carbon tetrachloride or in carbon disulphide. The addition of aluminium chloride in the latter case merely leads to bromination of the barene cage:

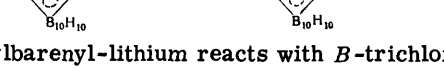


Barenedithiol reacts readily with dichlorobistriphenylphosphinenickel and phenylphosphonous dichloride to form the corresponding five-membered cyclic compounds[56]:

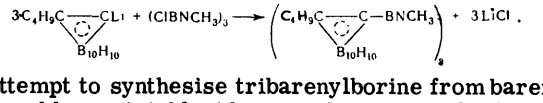


III. BARENYL DERIVATIVES OF BORON

A compound containing a barene carbon–boron bond was first obtained by the action of chlorobisdimethylaminoborine on barenyl-lithium[57]:



n-Butylbarenyl-lithium reacts with *B*-trichloro-*N*-trimethylborazole to give the corresponding barenyl derivative of borazole[57]:

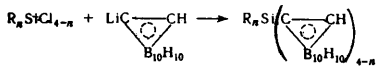


At attempt to synthesise tribarenylborine from barenyllithium and boron trichloride proved unsuccessful[57].

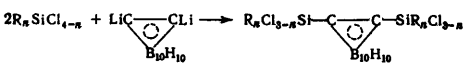
IV. DERIVATIVES OF GROUP IV ELEMENTS

1. Silicon

The specific features of barene compounds permitted the hope that organosilicon polymers containing barenyl radicals would possess unusual properties. This stimulated Papetti, Heying, and their coworkers [58-60] to examine the properties of diverse compounds containing a (barene) carbon–silicon bond, which they synthesised by the action of dilithiumbarenes on various organic and inorganic silicon derivatives containing a silicon–chlorine bond:

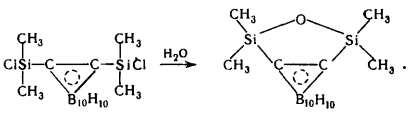


where $n = 2$ and R = CH_3; $n = 3$ and R = CH_3, C_6H_5;

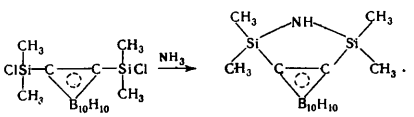


where $n = 0$, 1 and R = CH_3; $n = 2$ and R = CH_3, C_6H_5.

An attempt was made [58] to convert the resulting bis-chlorodimethylsilylbarene into the corresponding silanol, which was necessary for synthesising a polyorganosiloxane. However, this attempt was unsuccessful, owing to the tendency of the diols to undergo cyclisation with formation of a five-membered siloxane ring containing the two carbon atoms of the barene:

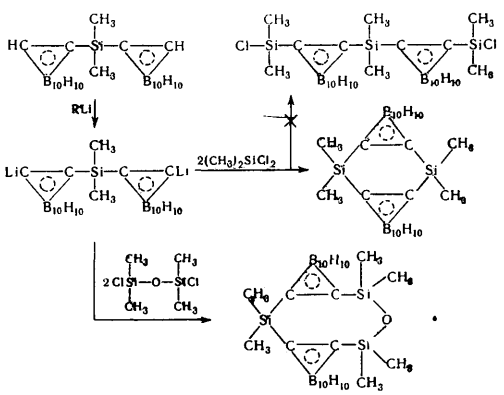


An analogous cyclisation has been observed in the action of ammonia [58]:

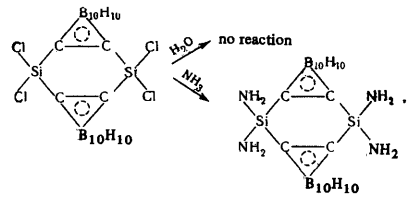


Several workers [16,17,61] have obtained similar compounds containing a ring comprising the two barene carbon atoms together with C–C–C and C–O–C groupings. This ease of formation of five-membered rings is probably due to structural peculiarities in barene (the carbon–carbon distance and the bond angles at a carbon atom).

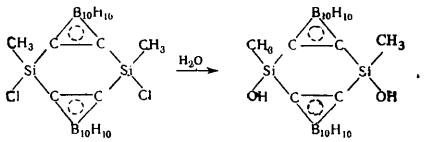
Failure attended also an attempt to obtain an acyclic compound by the action of even excess of dimethyldichlorosilane and tetramethyldichlorosiloxane on the dilithium derivative of dibarenyldimethylsilane [59]:



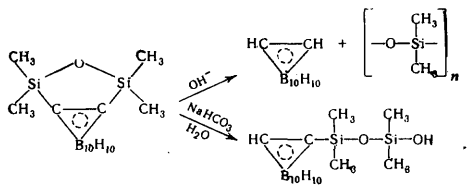
The properties of silicon derivatives of barene are greatly affected also by the strong electron-acceptor action of the barenyl group, as is shown in particular in the stability to hydrolysis of the silicon–chlorine bond in the cyclic tetrachloro-1,4-disilin formed by two barenylidene groups. However ammonia reacts quantitatively with this compound [59]:



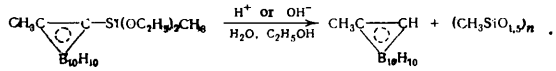
Replacement of one chlorine atom at each silicon atom by a methyl group produces a sharp increase in the ability of the silicon–chlorine bond to be hydrolysed by water, this probably being due to an increase in the ionic character of the bond:



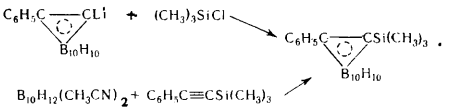
The electron-acceptor influence of the barene cage can explain also the tendency of barenylsilanes to cleavage of the silicon–carbon (barene) bond in the presence of bases [59]:



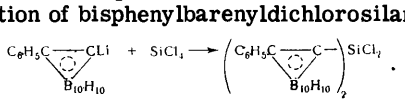
Observations by American chemists [62] indicate that both acids and bases cause rupture of the silicon–carbon bond:



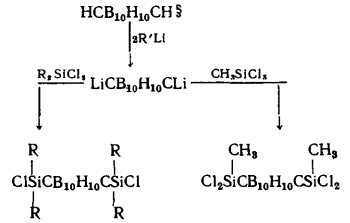
The synthesis of barenylsilanes has been accomplished also by Zakharkin et al. [63] in the case of 1-phenyl-2-trimethylsilylbarene. These workers showed that it was in principle possible to obtain this compound from decaborane–bisacetonitrile and 1-phenyl-2-trimethylsilylacetylene [63]:



Reaction between silicon tetrachloride and phenylbarenyl-lithium (2–4 moles per mole of the halide) results only in the formation of bisphenylbarenyldichlorosilane [64]:

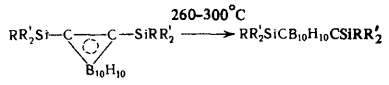


Neobarenylsilanes were obtained [60] in the same way as barenylsilanes:



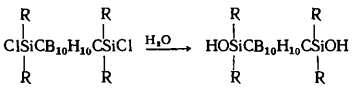
§ Here and subsequently the formula $HCB_{10}H_{10}CH$ will denote neobarene.

where R = CH_3, C_6H_5. It was also noticed[65] that barenylsilanes were able to isomerise into neobarenylsilanes at 260–300°C (barene itself isomerises into neobarene at 500°C [12]):

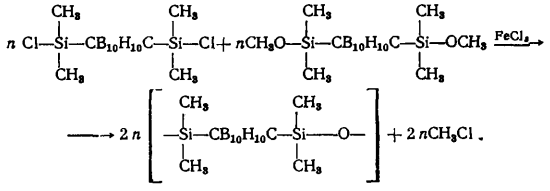


where R = CH_3 and R′ = CH_3, C_6H_5; R = Cl and R′ = C_6H_5; and R = C_6H_5 and R′ = CH_3.

Since the carbon atoms in neobarenes are remote from one another, dihydroxy-derivatives of neobarenylsilanes, unlike their barene analogues, exhibit no tendency to cyclisation[60]:



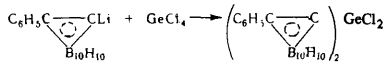
where R = CH_3, C_6H_5. This has enabled neobarenylsilanes to be used in the synthesis of silicon polymers containing the group $-CB_{10}H_{10}C-$ in the polymer chain. However, such polymers could not be synthesised by the hydrolysis of bisdimethylchlorosilylneobarene. The use of various conditions of hydrolysis produced only stable diols[66]. The first polymer of this type was obtained by Papetti et al.[66] by copolymerisation of bisdimethylchlorosilylneobarene with bismethoxydimethylsilylneobarene in the presence of catalytic quantities of iron(III) chloride:



The resulting polysiloxane was a white crystalline substance of molecular weight 16 000. Several polymers containing various combinations of neobarenylene groups and siloxane residues were obtained in the same way.

2. Germanium

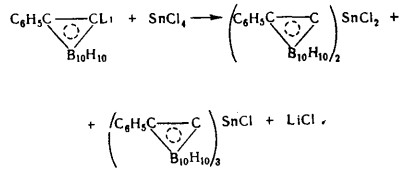
The only barenyl derivative of germanium yet known was obtained by the interaction of phenylbarenyl-lithium and germanium tetrachloride[64]:



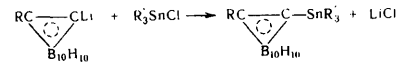
As in the reaction with silicon tetrachloride (see preceding subsection), not more than two chlorine atoms could be replaced owing to steric hindrance due to the bulky barene cage.

3. Tin

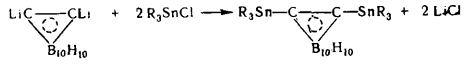
The increase in atomic radius on passing from silicon and germanium to tin makes it possible to obtain a derivative in which tin is attached to three barenyl groups. Thus the reaction between phenylbarenyl-lithium and tin tetrachloride results in a mixture of the corresponding chloride and dichloride[64]:



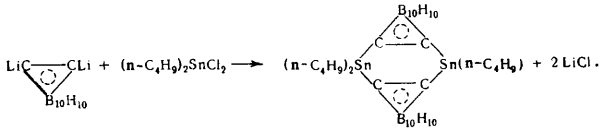
In the absence of steric hindrance, organotin halides are readily alkylated by lithiumbarenes[63,64]:



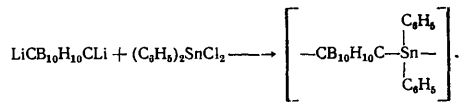
where R = H, C_6H_5, and R′ = n-C_3H_7, C_6H_5. Dilithiumbarene reacts with tri- and di-alkyltin chlorides to give compounds containing two tin atoms in the molecule[64,67]:



where R = n-C_3H_7, C_6H_5; and

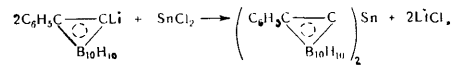


Replacement of dilithiumbarene by dilithiumneobarene in the reaction with dialkyltin dichlorides leads to the formation of—instead of cyclic compounds—polymeric products[68] having molecular weights up to 5750:



A study of the Mössbauer spectra of the organotin compounds obtained has shown[67] that the barenyl group exerts a greater electron-acceptor action on the tin atom than any organic substituent hitherto examined by this method. In its effect on the electronic environment of the tin nucleus it is comparable only with the pentafluorophenyl group. It can be concluded from the Mössbauer spectra that the ionic character of the tin–chlorine and tin–carbon (barene) bonds in trisphenylbarenyltin chloride and bisphenylbarenyltin dichloride is similar to, while the symmetry of the electric field at the tin nucleus is considerably greater than that in the analogous phenyl derivatives, as a consequence of the strong electron-acceptor influence of the barenyl group.

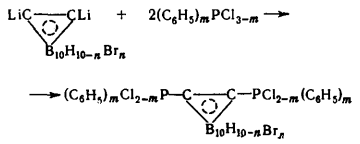
Interaction between phenylbarenyl-lithium and anhydrous tin(II) chloride yields bisphenylbarenyltin, the first derivative of bivalent tin, stable in an inert atmosphere, and showing no tendency to polymerise[67]:



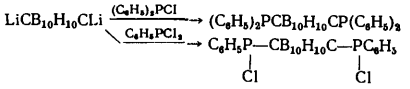
V. DERIVATIVES OF GROUP V ELEMENTS (PHOSPHORUS, ARSENIC, ANTIMONY)

Mixed barenyl(phenyl)phosphines have been obtained by the reaction of phenylchlorophosphines with the dilithium

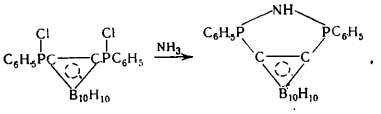
derivatives of barene[69,70], neobarene[71], and *B*-polyhalogenobarenes[30]:



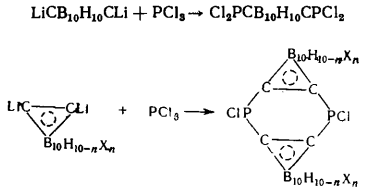
where $n = 0$ and $m = 1, 2$; $n = 1-3$ and $m = 2$; and $n = 2$ and $m = 1$; also



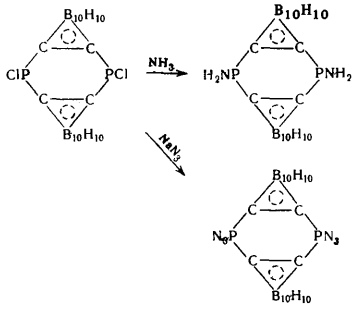
The action of ammonia on *PP'*-dichloro-*PP'*-diphenylbarenylenediphosphine yields a five-membered ring typical of the chemistry of the barenes[69]:



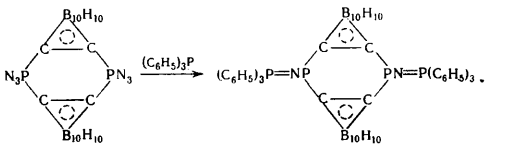
With phosphorus trichloride dilithiumneobarene gives *P*-tetrachloroneobarenylenediphosphine[71], whereas dilithiumbarene gives a six-membered ring containing two phosphorus atoms[30,69,70]:



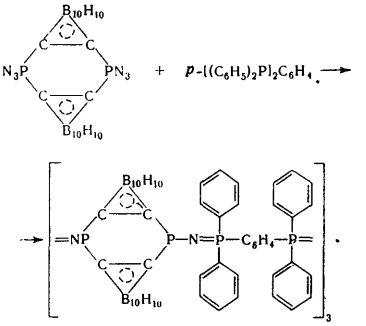
where X = Br, Cl and $n = 0-4$. The chlorine atoms in the resulting compound are readily replaced by the action of ammonia and of sodium azide[69]:



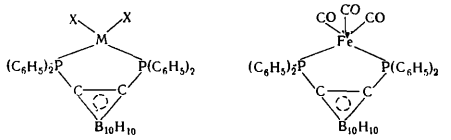
The resulting azido-derivative undergoes two very interesting reactions, the first of which yields a stable phosphine imide derivative[69]:



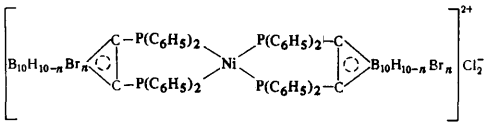
The second reaction[69] gives an oligomer of molecular weight ~ 2500, which has been used as a bonding agent in the manufacture of asbestos materials stable at high temperatures[72]:



Smith[73], and also Zakharkin and Zhigareva[74], discovered that *PP'*-tetraphenylbarenylenediphosphine was able to form stable five-membered chelate complexes with transition metals:

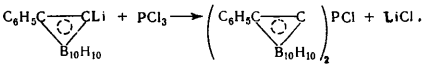


where M = Ni and X = CO, Cl; M = Pd and X = Cl; and also

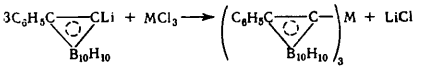


in which $n = 0-3$.

As with barenyl derivatives of Group IV elements, steric hindrance due to the bulky barenyl group is shown in the impossibility of substituting all three chlorine atoms when phenylbarenyl-lithium is treated with phosphorus trichloride[64]:



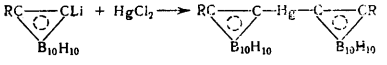
However, the increase in atomic radius on passing to arsenic and antimony compensates for the steric factors, and the halides of these two elements readily form trisubstituted derivatives[64]:



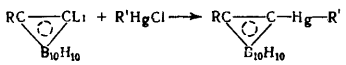
where M = As, Sb.

VI. MERCURY DERIVATIVES

In view of the part played by organomercury compounds in the study of the properties of the metal–carbon bond, the organomercury derivatives of barenes are of great value for an understanding of the peculiarities in the chemical behaviour of the metal–barene carbon bond. They were first obtained by Zakharkin and his coworkers[63,64,75,76] by the action of *C*-lithium derivatives of barenes on mercury(II) chloride or an alkylmercury halide:



where R = H, CH_3, $CH_2:CH$, C_6H_5; or

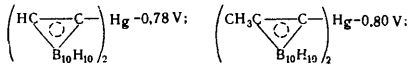


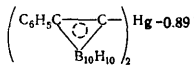
where R = H, CH_3, $CH_2:CH$, C_6H_5 and R′ = CH_3; R = C_6H_5 and R′ = C_6H_5, ferrocenyl.

Symmetrical barenylmercury compounds are distinguished by great stability, remaining unchanged even on prolonged heating at 300–350°C. The unsymmetrical compounds RHgR′ (in which R and R′ are barenyl radicals) do not tend to disproportionate into R_2Hg and R'_2Hg even in the melt (150–200°C) [75].

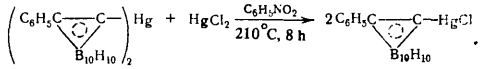
During the action of phenylbarenyl-lithium on mercury(II) chloride the reaction mixture contains no phenylbarenylmercury chloride, which is an unusual feature in the chemistry of organomercury compounds. Bisphenylbarenylmercury is immediately formed, while the excess of mercuric chloride does not react. An analogous phenomenon is observed with vinyl- and methyl-barenyl-lithium. Thus the alkylbarenylmercury chloride is very readily alkylated in comparison with the initial mercury chloride, and this has no analogy in organomercury chemistry.

The strong electron-acceptor effect of the barenyl group towards the mercury atom is confirmed by an examination of barenylmercury compounds by polarographic reduction. Some half-wave potentials obtained (in dimethylformamide) are indicated below [76]



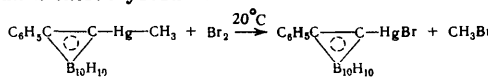


With the mercury derivatives of barenes, especially the symmetrical compounds, cleavage of the carbon–mercury bond under the influence of electrophilic reagents [hydrogen chloride, bromine, mercury(II) chloride], which is so common in the chemistry of ordinary organomercury compounds, goes either with difficulty or not at all. Thus phenylbarenylmercury chloride is not formed by the prolonged boiling of bisphenylbarenylmercury with mercury(II) chloride in alcohol. It was successfully obtained only when the reactants were heated in boiling nitrobenzene (for 8 h) [75,76]:

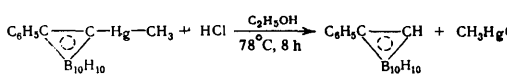


The mercury–carbon bond in symmetrical barenylmercury compounds is not ruptured by the action of bromine in boiling dichloromethane and benzene or on boiling with alcoholic hydrogen chloride solution (for 20 h).

When bromine acts on methyl(phenylbarenyl)mercury in the cold, it is only the mercury–methyl bond which is broken. The mercury–carbon (barene) bond remains unchanged, phenylbarenylmercury bromide being formed in almost quantitative yield [76]:

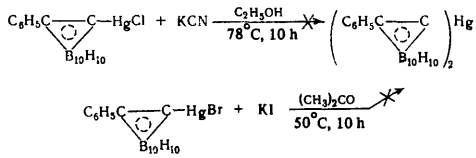


However, the action of alcoholic hydrogen chloride on methyl(phenylbarenyl)mercury produces rupture of the mercury–carbon (barene) bond with formation of phenylbarene [63]:



The above results indicate that cleavage of the mercury–carbon bond proceeds by different mechanisms under the influence of bromine and of proton acids.

Phenylbarenylmercury chloride and bromide were found to be stable to the action of such strong symmetrising agents as potassium cyanide and iodide [76]:

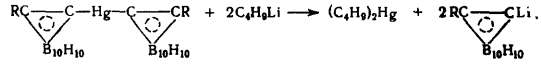


One reason for the anomalous behaviour of barenylmercury compounds in reactions involving electrophilic substitution at a barene carbon atom is probably the unusual valency state of the six-coordinated barene carbon atom, which is unable to form a cyclic transition state, as this would require the unlikely and unprecedented increase in the coordination number of carbon to seven. Furthermore, formation of such a transition complex is prevented also by steric hindrance due to the icosahedral barene cage. It must also be reckoned that the barene cage will exert a strong electron-acceptor influence, preventing localisation of a negative charge on a barene carbon atom.

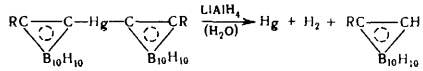
Nothing that has been stated above excludes the possibility, however, of a unimolecular reaction (S_E1), which probably occurs if reaction with the electrophilic reagent does take place [reaction with mercury(II) chloride in boiling nitrobenzene, protolysis].

Under severe conditions (230°C for 9 h) even dimethylmercury reacts with bisphenylbarenylmercury, yielding methyl(phenylbarenyl)mercury [77]:

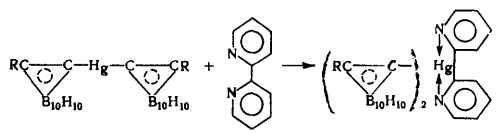
Cleavage of the mercury–carbon (barene) bond occurs far more readily during nucleophilic attack at the mercury atom. Thus symmetrical barenyl derivatives of mercury react with such nucleophilic reagents as butyl-lithium even in the cold, with the formation of products of the exhaustive exchange of radicals [77]:



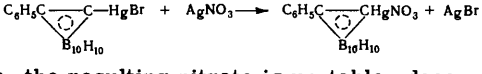
Bismethylbarenyl- and bisphenylbarenyl-mercury are easily reduced by lithium tetrahydroaluminate [77]:



The coordinative unsaturation of a mercury atom attached to two barenyl radicals is so great that even symmetrical barenylmercury compounds readily form complexes with 2,2′-bipyridyl [77]:



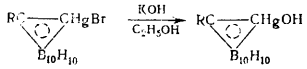
The halogen in barenylmercury halides is replaced by the action of an aqueous–alcoholic solution of silver nitrate [77]:



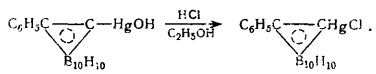
However, the resulting nitrate is unstable, decomposing

even at room temperature with the evolution of oxides of nitrogen.

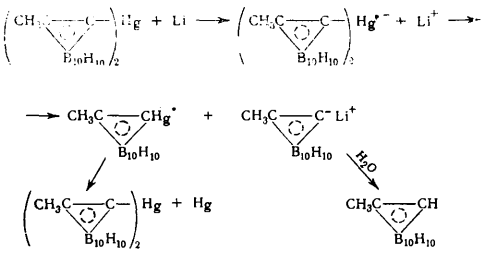
Alcoholic alkali acts on barenylmercury bromides, the bromine being easily replaced by hydroxyl[77]:



where R = CH_3, C_6H_5. The resulting hydroxides are difficultly identifiable substances which are unstable in air. Phenylbarenylmercury hydroxide reacts with hydrochloric acid to give phenylbarenylmercury chloride:

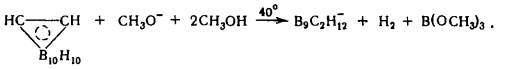


Symmetrical barenyl derivatives of mercury, which are stable towards metals (lithium, aluminium) when heated in an inert medium (xylene), react with lithium in dimethoxyethane even in the cold, as has been shown with bismethylbarenylmercury[77]. The rate of the process is probably determined by electron transfer from the metal to a molecule of the organomercury compound:



VII. ORGANOMETALLIC DERIVATIVES OF DICARBAUNDECABORANE

Treatment of barene with alcoholic alkali results in its partial cleavage with the formation of an anion of dicarbaundecaborane[78]:



By using this anion, Hawthorne and his coworkers were able to synthesise a series of "sandwich" derivatives, which are analogues of the cyclopentadienyl compounds of transition metals (iron, manganese, rhenium, cobalt). The first member of this series was obtained[79] by reaction between iron(II) chloride and the doubly charged anion $B_9C_2H_{11}^{2-}$, formed from $B_9C_2H_{12}^-$ by the action of metallic sodium or of sodium hydride:

Oxidation of the dianion $Fe(B_9C_2H_{11})_2^{2-}$ in the air yields the analogue of the ferricinium cation $Fe(B_9C_2H_{11})_2^-$. Salts of this anion are stable towards acids and bases, and remain unchanged when heated to 300°C.

When a mixture of cyclopentadienylsodium and the disodium salt of the anion $B_9C_2H_{11}^{2-}$ in tetrahydrofuran is boiled with iron(II) chloride, the corresponding mixed derivative π-$C_5H_5Fe(\pi$-$B_9C_2H_{11})^-$ is formed[80]. Study of the crystal structure of this compound showed[81] that the iron atom is approximately at the same distance from the five carbon atoms of the cyclopentadienyl ring (2.07 Å) as from the two carbon atoms (2.04 Å) and the three boron atoms (2.09 Å) of the dicarbaundecaborane. This and several other investigations[79,80,82] have enabled the structure of the above compounds to be established (Fig. 2).

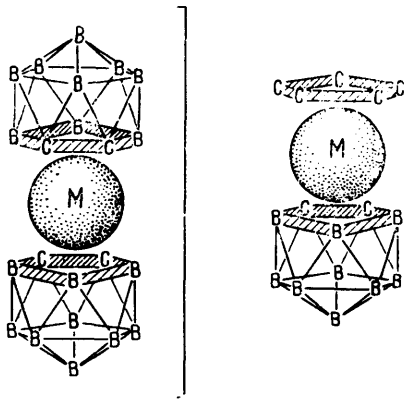


Figure 2. Structure of "sandwich" derivatives of the dicarbaundecaborane anion.

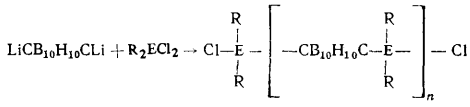
Sandwich derivatives of other metals have also been prepared[83-86]—$(B_9C_2H_{11})Mn(CO)_3^-$, $(B_9C_2H_{11})Re(CO)_3^-$, $(B_9C_2H_{11})_2Co^-$, $(C_5H_5)Co(B_9C_2H_{11})$, and $[\pi$-$(C_6H_5)C_4]Pd$.$[\pi$-$B_9C_2H_{11}]$.

Thus the organoelementary chemistry of these novel non-coplanar aromatic compounds—the barenes—has accumulated within a short time considerable and interesting information. Work on these lines is being vigorously prosecuted.

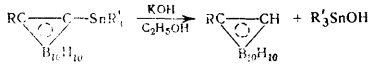
---o0o---

Several interesting researches have recently been done on the barenyl derivatives of Group IV elements. Thus some American chemists[89] have prepared germanium and tin polymers containing a neobarene grouping in the main chain, and having molecular weights up to 9000:

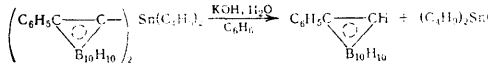


where E = Ge, Sn and R = CH_3, C_6H_5.

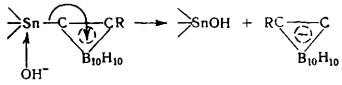
Bregadze and Okhlobystin have shown[90] that the tin–carbon bond in barenyl derivatives of tin is easily cleaved by aqueous and alcoholic solutions of alkalis, with formation of the corresponding barenes and organotin hydroxides:



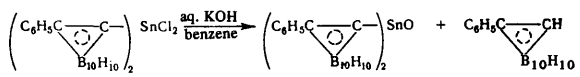
where R = C_6H_5, H and R′ = C_3H_7, C_6H_5; also



The rupture of tin–carbon bonds probably occurs by direct nucleophilic attack on the tin atom, with as a consequence heterolytic dissociation and formation of a barenyl anion:



The lability of the tin–carbon (barene) bond under nucleophilic attack is so great that, when a benzene solution of bisphenylbarenyltin dichloride is treated with aqueous alkali, there is competitive cleavage of tin–carbon and tin–chlorine bonds:



The tin–carbon bonds in the dichloride undergo cleavage even during chromatography on aluminium oxide, which results in the formation of phenylbarene.

IX. Compounds containing a boron atom 194
X. Applications of manganese carbonyl derivatives 194

I. INTRODUCTION

There is now a vast review literature on the chemistry of the carbonyls of chromium, molybdenum, tungsten, iron, cobalt, and nickel[1-4]. However, although more than two hundred papers and patents have been published since 1954 on the chemistry of manganese carbonyl, no review of this subject has appeared. Our paper represents an attempt to fill this gap.

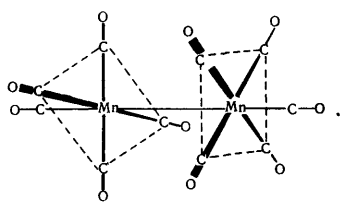
Manganese carbonyl and its derivatives possess several interesting properties, so that they attract wide attention from research workers in various specialised fields.

The present review deals with the structural peculiarities, methods of preparation, chemical properties, and chief fields of practical application of manganese carbonyl and its derivatives other than π-cyclopentadienylmanganese tricarbonyl, the chemistry of which will be discussed in a special paper. The literature published up to the beginning of 1966 is covered in the review.

II. STRUCTURE OF MANGANESE CARBONYL

Decacarbonyldimanganese $Mn_2(CO)_{10}$, like other carbonyls of transition metals, conforms to Sidgwick's rule, according to which the manganese atom must acquire a further eleven electrons. By interacting with five molecules of carbon monoxide the manganese atom gains ten electrons. The electron shell is completed by the formation of a bond between two atoms of the metal.

The decacarbonyldimanganese molecule can be represented by two octahedral groups, the centre of each being occupied by a manganese atom, while five corners are occupied by carbonyl groups, and the sixth by the adjacent metal atom:



A bond is formed between the manganese atom and a carbonyl group by coordination of the free d^2sp^3 orbitals of the manganese atom with the $(s-p_x)^2$ electrons of the carbon atom. It follows from the principle of maximum overlap of atomic orbitals that all the Mn–C–O groups are linear[5-7]. This should not involve any considerable change in the distribution of the electron cloud between the carbon and oxygen atoms, so that, as in free carbon monoxide, the carbon–oxygen bond should be somewhat in the nature of a triple bond. It has in fact been found that the carbon–oxygen distance in the $Mn_2(CO)_{10}$ molecule is 1.16 Å, which is intermediate between the values of 1.128 Å for the triple bond C≡O in carbon monoxide and 1.225 Å for the double bond C=O in formaldehyde.

Electrical neutrality of the manganese atom is probably established by some displacement of its d-electrons towards the carbon atom, as a result of which the manganese–carbon bond is partly double-bonded in character. It has been found experimentally[9] that the length of the manganese–carbon bond is ~ 1.83 Å, which is considerably less than the sum of the covalent radii.

The character of the manganese–manganese bond has not yet been elucidated. Its length in the $Mn_2(CO)_{10}$ molecule is 2.93 Å, whereas the sum of the covalent radii should be only 2.74 Å. The anomalous character of the manganese–manganese bond is confirmed also by the relatively low bond energy of 34 ± 13 kcal mole^{-1}.[10]

It has been found[12-14] that the axial carbonyl group is somewhat more firmly bound to the manganese atom than are the equatorial groups, although the difference in bond energy is not large. This can probably be explained by a breakdown in the symmetry of the electron cloud owing to the presence of different substituents around the manganese atom.

The structure given for the manganese carbonyl molecule agrees well with X-ray data[8].

III. METHODS OF PREPARATION AND PROPERTIES

In contrast to the carbonyls of nickel, chromium, and iron, decacarbonyldimanganese is not formed by the direct interaction of powdered metallic manganese and carbon monoxide. All the methods at present known for its preparation involve reducing a salt or an oxide of manganese to the metal and reaction of the latter *in situ* with carbon monoxide[15].

The existence of a manganese carbonyl was first reported in 1949 by Hurd et al.[16], who obtained mass-spectrometric evidence of its formation during the reduction of manganese iodide by a Grignard reagent in the presence of carbon monoxide. In 1954 Brimm et al.[17,18] obtained a 1% yield of decacarbonyldimanganese by the reaction

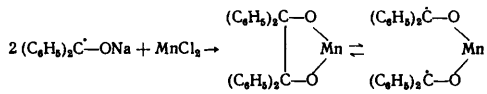
$$2\,MnI_2 + 2\,Mg + 10\,CO \rightarrow Mn_2(CO)_{10} + 2\,MgI_2.$$

The method of preparing manganese carbonyl by means of Grignard reagents has since been considerably improved[19-23].

Metallic sodium[24], sodium hydride, and lithium tetrahydroaluminate[25,26] can be employed as reducing agents. In the last case hydrogen pentacarbonylmanganate is formed, and this then decomposes with the evolution of hydrogen:

$$2\,HMn(CO)_5 \rightarrow Mn_2(CO)_{10} + H_2.$$

It is of interest to obtain manganese carbonyl by means of certain radical-anions, e.g. benzophenone ketyl[27,28]. The manganese salt resulting from the double decomposition



readily decomposes on heating, with the separation of metallic manganese:

$$[(C_6H_5)_2\dot{C}{-}O]_2Mn \rightarrow 2\,(C_6H_5)_2C{=}O + Mn.$$

This reacts with carbon monoxide under pressure, to form manganese carbonyl:

$$2\,Mn + 10\,CO \rightarrow Mn_2(CO)_{10}.$$

A disadvantage of this method is the difficulty of separating the manganese carbonyl from benzophenone. Other radical-anions, e.g. naphthalene–sodium[29], can be used instead of ketyls.

The best yields (up to 54%) of decacarbonyldimanganese are obtained by using as reductants diethylzinc[30], a trialkylaluminium[31,32], or metallic aluminium activated by an organoaluminium compound[33].

Finally, decacarbonyldimanganese can be prepared from derivatives of cyclopentadienylmanganese tricarbonyl by the action of metallic sodium in the presence of diglyme[34,35] or an amine[36].

Decacarbonyldimanganese consists of golden-yellow crystals melting at 154–155°C. It readily sublimes in a vacuum, the heat of sublimation being 15 kcal mole^{-1}.[37] In the air at room temperature it is stable for several months. When heated in air above 110°C it decomposes with the formation of a metallic mirror and carbon monoxide. In an atmosphere of carbon monoxide it is stable up to 250°C.

Manganese carbonyl is soluble in most organic solvents, but is insoluble in water. In air the solutions decompose rapidly at room temperature.

The infrared absorption spectrum of decacarbonyldimanganese is characterised by strong bands at 2063, 2028, and 1997 cm^{-1} which are assigned to the carbonyl groups, and two bands in the region of 640 cm^{-1} attributable to the manganese–carbon bond[11,37]. For the nuclear magnetic resonance (n.m.r.) spectra of manganese carbonyl see Ref. 38.

IV. HYDROGEN CARBONYLMANGANATES AND ALLIED COMPOUNDS

1. Preparation and Properties of Hydrogen Carbonylmanganates

Two hydrogen carbonylmanganates—$HMn(CO)_5$ and $H_2Mn_2(CO)_9$—are formed by the reduction of decacarbonyldimanganese with hydrogen, lithium, tetrahydroaluminate[39], or a hydroborate[40] in an inert solvent. Metals (magnesium, aluminium, amalgams) and other reducing agents can also be used[41].

Hydrogen pentacarbonylmanganate $HMn(CO)_5$ is a colourless liquid (m.p. = −24.6°C, $d^{20} = 1.465$, $n_D^{20} = 1.518$, and dipole moment = 0.70 D), which decomposes at 100°C.[42,43] The infrared absorption spectra of this compound and its deuterio-analogue are characterised by carbonyl bands in the range 2150–1950 cm^{-1}, bands at 1782, 735, 664, 615, and 458 cm^{-1} assigned to the hydrogen–manganese bond, and bands at 1287 and 676 cm^{-1} ascribed to the manganese–deuterium bond[11,44–46].

The $HMn(CO)_5$ molecule has the shape of a distorted octahedron, the length of the hydrogen–manganese bond being 1.5–1.6 Å.[47,48]

The second hydrogen carbonylmanganate $H_2Mn_2(CO)_9$ is unknown in the pure form, but several of its derivatives have been obtained.

Hydrogen carbonylmanganates are weak acids, the dissociation constant of $HMn(CO)_5$ being 0.8×10^{-7}. In aqueous alkalis the hydrogen atom is replaced by an alkali-metal cation[49]:

$$HMn(CO)_5 + KOH \rightarrow KMn(CO)_5 + H_2O.$$

The same salts can be obtained by reducing decacarbonyldimanganese with the alkali metals or their amalgams[50,51].

Hydrogen carbonylmanganates react with Lewis bases to form saltlike complexes[40]. With pyridine, for example, the reaction is

$$6\,HMn(CO)_5 + 12\,C_5H_5N \rightarrow 2\,[Mn(C_5H_5N)_6][Mn(CO)_5]_2 + 10\,CO + 3H_2.$$

Hydrogen carbonylmanganates are strong reducing agents. According to Hieber and Wagner[42], the reduction potential of hydrogen pentacarbonylmanganate in aqueous alkali at 20°C is −0.68 V. In inert solvents this compound reduces halogens:

$$2\,HMn(CO)_5 + I_2 \rightarrow Mn_2(CO)_{10} + 2\,HI.$$

These hydrogen derivatives are able to react also with halogenated hydrocarbons. On ultraviolet irradiation in chloroform or carbon tetrachloride they are converted into the halogenocarbonylmanganese derivatives—$MnCl(CO)_5$ and $[MnCl(CO)_4]_2$.

Hydrogen pentacarbonylmanganate serves as starting material for the preparation of various organic derivatives of manganese carbonyl. With diazomethane, for example, it forms pentacarbonylmethylmanganese[52]:

$$HMn(CO)_5 + CH_2N_2 \rightarrow MnCH_3(CO)_5 + N_2.$$

Hydrogen pentacarbonylmanganate has found an interesting application in the preparation of fluoroalkyl derivatives of manganese carbonyl[43]:

$$HMn(CO)_5 + CF_2{=}CF_2 \rightarrow HCF_2{-}CF_2{-}Mn(CO)_5.$$

2. Ionic Complexes of Manganese Carbonyl

Besides the alkali-metal salts of the hydrogen carbonylmanganates, several compounds are known which are formed by the pentacarbonylmanganate ion with complex cations. In contrast to the analogous complexes of iron and cobalt, they can be obtained only in alkaline solution, owing to the acidic character of hydrogen pentacarbonylmanganate. Hieber and Schropp[53] isolated complex salts formed with the tri-*o*-phenanthroline-nickel(II) and -iron(II), dibenzenechromium(I), and dicyclopentadienylcobalt(I) cations. It is interesting that the dibenzenechromium salt is readily decomposed even at room temperature:

$$2\,[Cr(C_6H_6)_2][Mn(CO)_5] \rightarrow Mn_2^0(CO)_{10} + 2\,Cr^0(C_6H_6)_2$$

whereas the other complexes are considerably more stable. Salts of analogous structure are formed also by the interaction of decacarbonyldimanganese with pyridine[54] and with 1,10-phenanthroline[55].

Complexes are known also in which the carbonylmanganese group is the cation. Such compounds were first obtained by Fischer and his coworkers[56,57] by the reaction

$$ClMn(CO)_5 + AlCl_3 + CO \rightarrow [Mn(CO)_6]^+AlCl_4^-.$$

Instead of a carbon monoxide molecule, an ethylene molecule can be introduced into the cation:

$$ClMn(CO)_5 + AlCl_3 + C_2H_4 \rightarrow [Mn(CO)_5C_2H_4]^+AlCl_4^-.$$

Several complex salts have been obtained by the interaction of such carbonylmanganese cations with various anions[58–61]. All these compounds are usually stable in an inert atmosphere for several days, but they decompose rapidly in air in the presence of moisture.

3. Polymetallic Derivatives

Several compounds are known in which the manganese atom is attached by a covalent bond to atoms of other metals.

Hieber and Schropp[53] obtained mercury derivatives of manganese carbonyl:

$$2KMn(CO)_5 + Hg(CN)_2 \rightarrow [Mn(CO)_5]_2Hg + 2KCN.$$

The same compound was isolated by King[58] from the reaction between sodium pentacarbonylmanganate and sodium amalgam in the presence of 1,4-dibromobutane. Bis-pentacarbonylmanganesemercury readily reacts with mer-

cury halides to form complexes which are practically undissociated:

$$[Mn(CO)_5]_2Hg + HgCl_2 \rightarrow [Mn(CO)_5]_2Hg \cdot HgCl_2 \text{ or } (CO)_5MnHgCl.$$

In the reaction of potassium pentacarbonylmanganate with alkylmercury compounds, the mixed organomercury compounds which are probably formed as intermediates disproportionate with separation of the dialkylmercury:

$$RHgOH + KMn(CO)_5 \rightarrow [RHg—Mn(CO)_5] \rightarrow R_2Hg + [Mn(CO)_5]_2Hg.$$

This reaction may find application for the synthesis of fully organic mercury compounds.

Compounds containing a manganese–metal bond have been obtained by treating sodium pentacarbonylmanganate with chlorine derivatives of various metals[62]:

$$L_nMCl_m + m\,NaMn(CO)_5 \rightarrow L_nM[Mn(CO)_5]_m + m\,NaCl$$

where L = alkyl, aryl, aralkyl, alkaryl, or a radical containing phosphorus, arsenic, or antimony and M = Sn, Si, Ge, Ag, Au, Cu, etc.[64–67]

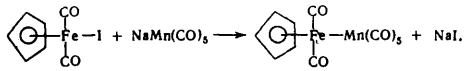
Trichlorogermanylmanganese pentacarbonyl was synthesised by a somewhat different method[63]:

$$Cl_3GeH + ClMn(CO)_5 \rightarrow Cl_3Ge—Mn(CO)_5 + HCl.$$

Stable bispentacarbonylmanganesegermane was prepared by Stone and his coworkers[64] by the reaction of hydrogen pentacarbonylmanganate with germane:

$$GeH_4 + 2HMn(CO)_5 \rightarrow H_2Ge[Mn(CO)_5]_2 + 2H_2.$$

The so called "mixed" carbonyls—i.e. compounds containing carbonyl groups of other metals as well as the pentacarbonylmanganese group—belong to this same type of compounds. The first such compound was cyclopentadienyldicarbonyliron–pentacarbonylmanganese, obtained in 40% yield by King et al.[78] by the reaction



Analogous methods were used to prepare "mixed" carbonyls of manganese and rhenium[79]:

$$(CO)_5ReCl + NaMn(CO)_5 \rightarrow (CO)_5Re—Mn(CO)_5 + NaCl$$

$$(CO)_5ReNa + ClMn(CO)_5 \rightarrow (CO)_5Re—Mn(CO)_5 + NaCl$$

as well as cobalt[80], molybdenum, and tungsten[81].

V. DERIVATIVES OF MANGANESE CARBONYL CONTAINING A CARBON–MANGANESE σ-BOND

1. Alkyl- and Acyl-manganese Pentacarbonyls

Like acids, hydrogen carbonylmanganates are able to react with various alkylating agents to form compounds in which the carbon atom is attached directly to the metal atom. The relatively high stability of these compounds can be explained by the influence of the carbonyl groups on the organic substituents[82].

The simplest organic derivative of manganese carbonyl, pentacarbonylmethylmanganese, can be obtained by the action of diazomethane on hydrogen carbonylmanganate[52,83]:

$$CH_2N_2 + HMn(CO)_5 \rightarrow CH_3Mn(CO)_5 + N_2.$$

Other methylating agents, e.g. dimethyl sulphate[84], can be used besides diazomethane.

Higher alkylmanganese pentacarbonyls can be obtained by the reaction of hydrogen pentacarbonylmanganate with alkenes[85]:

$$CH_2—CH=CH_2 + HMn(CO)_5 \rightarrow CH_3CH_2CH_2—Mn(CO)_5.$$

A method which has found some application for the preparation of alkyl derivatives of manganese carbonyl involves the use of organic derivatives of the alkali metals or of Grignard reagents[52]:

$$C_4H_9Li + BrMn(CO)_5 \rightarrow C_4H_9—Mn(CO)_5 + LiBr.$$

A method based on the reaction of alkali-metal pentacarbonylmanganates with organic halides[83,86]

$$R—X + NaMn(CO)_5 \rightarrow R—Mn(CO)_5 + NaX$$

is most often used. It is possible to obtain only the simplest carbonylalkylmanganese compounds by means of this reaction, since beginning with the isopropyl halides the reaction leads to the formation of halogenopentacarbonylmanganese derivatives, e.g. [50]

$$2\,C_4H_9Br + 2NaMn(CO)_5 \rightarrow 2BrMn(CO)_5 + 2NaBr + C_8H_{18}.$$

However, this method is widely used to obtain alkenyl derivatives of manganese carbonyl[91,92], and also for the synthesis of pentacarbonylacylmanganese derivatives[87]:

$$R—\overset{\overset{O}{\|}}{C}—Cl + NaMn(CO)_5 \rightarrow R—\overset{\overset{O}{\|}}{C}—Mn(CO)_5 + NaCl$$

which when heated to 100–120°C are readily converted into pentacarbonylalkylmanganese compounds:

$$R—CO—Mn(CO)_5 \rightarrow R—Mn(CO)_5 + CO.$$

Numerous alkyl and acyl derivatives of manganese carbonyl have been prepared by all the above methods. Aromatic[93] and heteroaromatic[88,94–96] derivatives can also be obtained by such methods:

$$C_6H_5Cl + NaMn(CO)_5 \rightarrow C_6H_5—Mn(CO)_5 + NaCl$$

as well as compounds containing two pentacarbonylmanganese groups separated by a chain of carbon atoms[89,90]:

$$Cl—(CH_2)_8—Cl + 2NaMn(CO)_5 \rightarrow (CO)_5Mn—(CH_2)_8—Mn(CO)_5 + 2NaCl$$

$$R(COCl)_2 + 2NaMn(CO)_5 \xrightarrow[-2NaCl]{} R—[CO—Mn(CO)_5]_2 \xrightarrow[-2CO]{} R[Mn(CO)_5]_2.$$

Organic derivatives of manganese carbonyl containing a carbon–manganese σ-bond are usually stable towards oxygen and moisture, but on prolonged storage they slowly decompose with the evolution of carbon monoxide. On treatment with halogens the organic radical is replaced by a halogen atom:

$$R—Mn(CO)_5 + Br_2 \rightarrow RBr + BrMn(CO)_5.$$

Concentrated hydrohalic acids act similarly.

Calderazzo and Noack[97] investigated the reaction between lithium iodide and pentacarbonylmethylmanganese, in which one carbonyl group is replaced by an iodine atom, and is then incorporated between the methyl group and the manganese atom:

$$CH_3—Mn(CO)_5 + LiI \rightarrow Li[CH_3CO—Mn(CO)_4I].$$

This reaction is a particular case of the addition to organomanganese pentacarbonyls of ligands which possess a lone pair of electrons, e.g. carbon monoxide, triphenylphosphine,, amines, etc. The ligand displaces one carbonyl group, which is incorporated between the alkyl group and the metal atom:

$$R—Mn(CO)_5 + L \rightarrow RCO—Mn(CO)_4L.$$

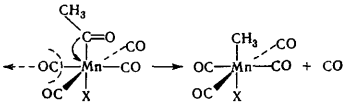
The addition of carbon monoxide (carbonylation) and that of triphenylphosphine have been studied in the greatest detail.

The carbonylation reaction

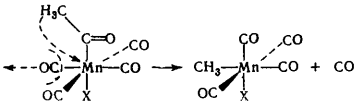
$$R-Mn(CO)_5+CO\rightleftarrows R-CO-Mn(CO)_5,$$

discovered by Coffield et al.[87] in 1957, is reversible: acylmanganese carbonyls when heated to 100°C are converted into the corresponding alkyl derivatives. It was shown with labelled carbon monoxide[98] that in the carbonylation the free carbon monoxide molecule is not immediately incorporated between the alkyl radical and the manganese atom, and in the reverse reaction the liberated carbonyl group also was not initially linked with the alkyl radical.

Mawby et al.[99] point out two alternative mechanisms for the decarbonylation of acyl derivatives of manganese carbonyl—(*a*) carbonyl insertion



or (*b*) migration of the alkyl group



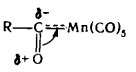
It has not yet proved possible to establish precisely which of these two mechanisms is correct. However, in the carbonylation of complexes of the type $RMn(CO)_4X$, where X is some ligand other than carbonyl, these mechanisms yield different products. If the reaction involves alkyl migration, the product should have a *cis*-configuration; in the contrary case a *trans*-isomer should be formed.

From a study of the decarbonylation of *trans*-tetracarbonyltriphenylphosphineacetylmanganese Mawby et al.[90] concluded that an alkyl migration mechanism (*b*) is to be preferred. Addition to alkylmanganese pentacarbonyls of phosphines and secondary amines[100,101] and other reactions involving incorporation of a carbonyl group between a manganese atom and an alkyl radical probably occur by the same mechanism.

The rate of carbonylation of a pentacarbonylalkylmanganese depends on the nature of the organic radical. Calderazzo and Cotton showed that the rate of carbonylation decreases in the sequence[102]

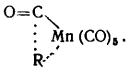
$$n\text{-}C_3H_7\gtrsim C_2H_5>C_6H_5>CH_3\gg C_6H_5CH_2\simeq CF_3.$$

The ease of conversion of alkyl derivatives of manganese carbonyl into the corresponding acyl derivatives and of the reverse reaction indicates that the acyl carbonyl group has a special character. Although the infrared spectra of the acyl derivatives contain an absorption band in the range 1590–1640 cm^{-1}, corresponding to the carbonyl absorption band in aldehydes and ketones, the acyl carbonyl exhibits none of the chemical properties characteristic of a ketonic or an aldehydic carbonyl group. Its specific character is probably due to an increase in electron density on the carbon atom resulting from the positive inductive effect of the pentacarbonylmanganese group. Some levelling out of all the manganese–carbon bonds in the pentacarbonylacylmanganese molecules, owing to the formation of a dative π-bond between the manganese and the acyl carbon atom

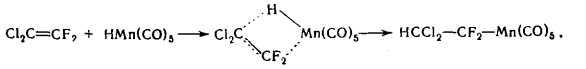


may also be assumed. The presence of strong electron-acceptor groups in the organic radical will prevent an increase in the multiplicity of the Mn=C bond, and thereby tend to strengthen the C–R bond and impede decarbonylation:

It may further be supposed that pentacarbonylacylmanganese molecules will contain a seven-coordinated manganese atom



Complexes of this type have recently been prepared[103]. The hypothesis of seven-coordinated manganese complexes provides an explanation not only for the mechanism of the decarbonylation of acyl derivatives of manganese carbonyl but also for the addition of unsymmetrical halogenated alkenes to hydrogen carbonylmanganate, which under normal conditions involves the formation of only one isomer:



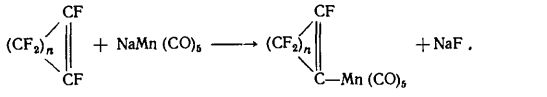
2. Perfluoro-derivatives

A large number of papers have recently been published on perfluoroalkylmanganese pentacarbonyls. The interest taken in these compounds is due to their great stability in comparison with their hydrocarbon analogues, this being an effect of the electronegative fluorine atoms.

Perfluoro-derivatives of manganese carbonyl can be obtained by all the general methods described above for the synthesis of alkyl and aryl derivatives[104]. Methods using organometallic compounds have acquired relatively greater value[105,106]:

$$BrMn(CO)_5+LiC_6F_5\rightarrow C_6F_5-Mn(CO)_5+LiBr$$
$$BrMn(CO)_5+C_6F_5MgBr\rightarrow C_6F_5-Mn(CO)_5+MgBr_2.$$

Certain methods for obtaining perfluoroalkyl derivatives of manganese carbonyl are specific. Thus when perfluorocycloalkenes react with the pentacarbonylmanganate anion, a fluorine atom adjacent to the double bond is replaced by $Mn(CO)_5$ [107,108]:



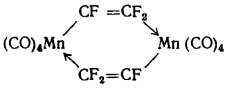
An extremely interesting reaction between perfluoroethylene and compounds containing a tin–manganese bond was accomplished by Clark and Tsai[109]. It involved incorporation of the tetrafluoroethylene molecule in the tin–manganese bond:

$$(CH_3)_3Sn-Mn(CO)_5+CF_2=CF_2\rightarrow(CH_3)_3Sn-CF_2-CF_2-Mn(CO)_5.$$

The resulting compound readily decomposed with the separation of an organomanganese dimer:

$$2[(CH_3)_3Sn-CF_2-CF_2-Mn(CO)_5]\rightarrow 2(CH_3)_3SnF+[CF_2=CF-Mn(CO)_4]_2+2CO$$

which, in the opinion of these workers, had the "bridge" structure



The infrared absorption spectra of these compounds have been studied in great detail[110-114]. There are also data on the ^{19}F n.m.r. spectra of several of these compounds[114-116].

The chemical properties of the perfluoroalkyl and perfluoroacyl derivatives of manganese pentacarbonyl do not in general differ from those of their hydrocarbon analogues[117-121].

VI. HALOGENO-CARBONYLS AND ALLIED COMPOUNDS

1. Halogeno-derivatives of Manganese Carbonyl

Decacarbonyldimanganese reacts with halogens to form halogenomanganese carbonyls[122]:

$$[Mn(CO)_5]_2 + Cl_2 \rightarrow 2ClMn(CO)_5,$$

Other methods for obtaining these compounds are the reactions of alkyl- and acyl-manganese pentacarbonyls with halogens[89]:

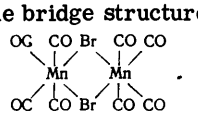
$$Mn(CO)_5R + Br_2 \rightarrow RBr + BrMn(CO)_5$$
$$RCO{-}Mn(CO)_5 + I_2 \rightarrow RCOI + IMn(CO)_5$$

and also heating decacarbonyldimanganese with carbon tetrachloride, chloroform, and other halogenated hydrocarbons under ultraviolet irradiation[42].

Halogenomanganese carbonyls are stable towards moisture and atmospheric oxygen at room temperature. On heating, carbon monoxide is gradually eliminated, with the formation of dimeric halogeno-carbonyls:

$$2Mn(CO)_5X \rightarrow [Mn(CO)_4X]_2 + 2CO.$$

These dimers have the bridge structure[123]



The Mn–Br distance is 2.526 ± 0.005 Å, and the Mn...Mn distance is 3.74 Å, which considerably exceeds the Mn–Mn distance in the decacarbonyldimanganese molecule.

A kinetic study has been made of isotope between exchange halogenomanganese pentacarbonyls and carbon monoxide[40,124]:

$$XMn(CO)_5 + C^*O \rightleftarrows XMn(CO)_4(C^*O) + CO.$$

The rate of exchange of carbon monoxide is found to depend on the atomic radius of the halogen: in the series—chlorine, bromine, iodine—the intensity of exchange diminishes in the proportions 200 : 8 : 1.[40]

The addition of a halogen atom to the pentacarbonylmanganese group makes the carbonyl group somewhat more mobile than in the original decacarbonyldimanganese. Halogenomanganese carbonyls interact with various ligands (L) possessing a lone pair of electrons, with replacement of one or two carbonyl groups:

$$XMn(CO)_5 + L \rightarrow LMn(CO)_4X + CO,$$
$$XMn(CO)_5 + 2L \rightarrow L_2Mn(CO)_3X + 2CO.$$

Besides the carbonyl group the halogen atom may also be replaced[125]:

$$BrMn(CO)_5 + 2KCN \rightarrow K[Mn(CO)_4(CN)_2] + CO + KBr.$$

The infrared spectra of halogenomanganese pentacarbonyls[126-128] support the hypothesis that the axial carbonyl in the pentacarbonylmanganese group is more firmly bound than are the equatorial groups to the manganese atom.

2. Nitrato- and Thiocyanato-compounds

Addison et al.[129,130] prepared stable nitratopentacarbonylmanganese by the reaction of decacarbonyldimanganese with dinitrogen tetroxide:

$$Mn_2(CO)_{10} + N_2O_4 \rightarrow Mn(CO)_5NO_3.$$

This compound consists of pale yellow crystals, and decomposes when heated in a vacuum above 55 °C. It is soluble in polar solvents, but insoluble in carbon disulphide and aliphatic hydrocarbons. It is easily solvated in solution, with the formation of $[Mn(CO)_5Solv]^+NO_3^-$ complexes. The infrared spectrum of this compound confirms the presence of both carbonyl groups (ν_{CO} = 2060 and 2002 cm^{-1}) and a nitrato-group (ν_{NO_3} = 1486, 1284, 1010, and 805 cm^{-1}) attached to the manganese atom.

Farona and Wojcicki[131,132] prepared thiocyanatopentacarbonylmanganese by the reaction of sodium pentacarbonylmanganate with thiocyanogen chloride:

$$NaMn(CO)_5 + ClSCN \rightarrow Mn(CO)_5SCN + NaCl$$

obtaining golden-yellow crystals decomposing at 156 °C and soluble in polar solvents. In air this compound is stable in the dark, but slowly decomposes in the light. It reacts with electron-donor ligands, e.g. triphenylphosphine or pyridine, with replacement of carbonyl groups:

$$Mn(CO)_5SCN + 2C_5H_5N \rightarrow Mn(CO)_3(C_5H_5N)_2SCN + 2CO.$$

It is noteworthy that the reaction between decacarbonyldimanganese and bithiocyanogen $(SCN)_2$ yields a polymeric compound instead of the expected thiocyanatopentacarbonylmanganese.

VII. PRODUCTS RESULTING FROM SUBSTITUTION OF CARBONYL GROUPS

Reactions involving the replacement of carbonyl groups are widespread in the chemistry of metal carbonyls. Carbon monoxide can easily be substituted by various ligands possessing electron-donor properties. Substitution of a carbonyl group in derivatives of manganese pentacarbonyl is not usually accompanied by change in the oxidation state of the metal atom. Complete replacement of all the carbonyl groups is rare, only one or two of them usually being replaced. This is probably due to the increase in stability of the manganese–carbon bond on introduction of an electron-donor ligand, consequent on an increase in the statistical weight of structures of the type[133,134]

$$L{-}M{=}C{=}O \longleftrightarrow L^+{-}M{\equiv}C{-}O^-.$$

1. Isocyanide and Nitrile Complexes

Isocyanides R.N:C are the closest analogues of carbon monoxide, and therefore they should readily displace the latter from metal carbonyls. However, complete replacement of carbonyl groups by alkyl isocyanide groups has been accomplished only with nickel tetracarbonyl[135]. In derivatives of manganese carbonyl only two carbonyl groups can be replaced[125]:

$$BrMn(CO)_5 + 2R{-}N{=}C \rightarrow BrMn(CO)_3(CNR)_2 + 2CO.$$

Further substitution of carbon monoxide is not prevented by instability of the isocyanide complexes, since

ionic isocyanide complexes of manganese are known[136] which do not contain carbonyl groups:

$$MnI_2 + 6R{-}N{=}C \rightarrow [Mn(CNR_6]I.$$

Furthermore, Pauson and Stubbs[137] obtained an isocyanide analogue of tricarbonylcyclopentadienylmanganese:

$$C_5H_5Mn(CO)_3 + 3\,C_6H_5NC \rightarrow C_5H_5Mn(CN{-}C_6H_5)_3 + 3CO$$

this being a stable crystalline substance melting at 97°C. Thus available data suggest that the difficulty of further replacement of carbonyl by isocyanide groups is associated with enhanced stability of the manganese–carbon bonds.

Products have also been obtained in which carbonyl groups in derivatives of manganese carbonyl have been replaced by cyano-groups[125]:

$$BrMn(CO)_5 + KCN \rightarrow K[Mn(CO)_4(CN)_2] + KBr.$$

2. Nitrosyl Derivatives of Manganese Carbonyl

Nitrosyl derivatives of manganese carbonyl can be obtained by the action of nitric oxide on the halogeno-carbonyls[138,139]:

$$Mn(CO)_5I + NO \rightarrow Mn(CO)_4NO + Mn(CO)(NO)_3.$$

Tetracarbonylnitrosylmanganese $Mn(CO)_4NO$ is a pale yellow liquid (m.p. between −1.5° and 0°C), while carbonyltrinitrosylmanganese $MnCO(NO)_3$ is a crystalline substance melting at 27°C. The infrared spectra of these compounds were studied by Beck and Lottes[140].

The carbonyl groups in the mixed carbonyl–nitrosyl complexes of manganese can be further replaced by various ligands:

$$Mn(NO)_3CO + P(C_6H_5)_3 \rightarrow Mn(NO)_3P(C_6H_5)_3 + CO.$$

Another method for obtaining products in which the carbonyl groups have been completely replaced is the action of nitric oxide on substituted derivatives of manganese carbonyl[141–143]:

$$LMn(CO)_4 + NO \rightarrow LMn(NO)_3 + LMn(CO)_3NO$$

where L = $(C_6H_5)_3P$, $(C_6H_5)_3As$, $(C_6H_5)_3Sb$, etc.

A halogen derivative of manganese nitrosyl was obtained[144] by the reaction between iodotetracarbonyl(triphenyl phosphite)manganese and nitric oxide:

$$Mn(CO)_4P(OC_6H_5)_3I + NO \rightarrow Mn(NO)_2[P(OC_6H_5)_3]_2I + MnI_2 + CO.$$

3. Substitution of Carbonyl Groups by Nitrogen Compounds

Besides compounds containing multiple-bonded nitrogen, whose reactions with derivatives of manganese carbonyl have been described above, replacement of carbonyl groups can occur also with compounds in which the nitrogen atom possesses a lone pair of electrons, e.g. amines, pyridine, etc.

Ammonia reacts with bromopentacarbonylmanganese at 70°C and 35 atm to form $Mn(NH_3)_3(CO)_3Br$ (decomposing at ~ 190°C). The corresponding chloride and iodide have been obtained in analogous fashion, as well as the compounds $Mn(NH_3)_2(CO)_4Br$[125]† and $[Mn(NH_3)_3(CO)_3]^+[Mn(CO)_5]^-$.[146]

† This should probably be Ref. 145 (Ed. of Translation).

A similar reaction takes place with various amines[125,147–150]:

$$XMn(CO)_5 + R'NR''_2 \rightarrow Mn(CO)_3(NR'R''_2)_2X + CO.$$

Quaternary ammonium salts react with halogenomanganese pentacarbonyls forming crystalline salts[151]:

$$R_4N^+X^- + XMn(CO)_5 \rightarrow R_4N^+[Mn(CO)_4X_2]^- + CO.$$

The same products are obtained by the action of quaternary ammonium salts on dinuclear halogenomanganese carbonyls:

$$2\,R_4N^+X^- + [Mn(CO)_4X]_2 \rightarrow 2\,R_4N^+[Mn(CO)_4X_2]^-.$$

With decacarbonyldimanganese this reaction yields the complex $(R_4N)_2[MnX(CO)_4]_2$.

Angelici has recently reported[103] the preparation of products of the addition of primary amines to bromopentacarbonylmanganese:

$$3\,RNH_2 + BrMn(CO)_5 \rightarrow Mn(CO)_5(NHR)(NH_2R) + RNH_3^+Br^-$$

(where R = CH_3, iso-C_3H_7, n-C_4H_9, t-C_4H_9, cyclohexyl, or RNH_2 = ethylenediamine). Diamagnetic compounds have been isolated as a result of these reactions. If the structure proposed for the compounds is correct, they constitute the first example of stable complexes of manganese carbonyl having a coordination number of seven, in which the number of electrons around the manganese exceeds the number around the krypton atom.

4. Phosphorus, Arsenic, and Antimony Derivatives

The most thorough study has been made of products obtained by replacing carbonyl groups in derivatives of manganese carbonyl by various alkylated and arylated phosphines, arsines, and stibines. These compounds are readily formed by the direct interaction of decacarbonyldimanganese, or its derivatives, e.g. the halogeno-derivatives, with the ligands[125,152,153]:

$$XMn(CO)_5 + AR_3 \rightarrow Mn(CO)_4X \cdot AR_3 + CO$$

$$XMn(CO)_4X \cdot AR_3 + AR_3 \rightarrow Mn(CO)_3X(AR_3)_2 + CO$$

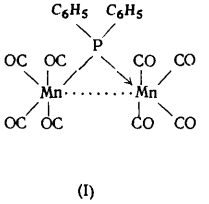
where X = Cl, Br, I; A = P, As, Sb; and R = Alk, Ar.

Angelici and Basolo established[154] the dependence of the rate of substitution of carbonyl groups on the nature of the ligand as $(C_6H_5)_3P > (C_6H_5)_3As \simeq (C_4H_9)_3P \simeq (C_6H_5)_2PCl > (C_6H_5O)_3P \simeq (C_6H_5)_3Sb > C_6H_5PCl_2 \simeq (C_4H_9O)_3P > CH_3C(CH_2O)_3P$.

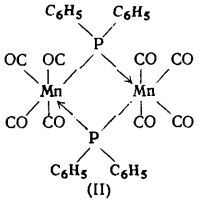
Exposure to ultraviolet radiation during replacement of the carbonyl groups results in the formation of dimeric products[155,156]:

$$Mn_2(CO)_{10} + 2AR_3 \xrightarrow{h\nu} [Mn(CO)_4AR_3]_2 + 2CO.$$

This reaction probably takes place in stages. Green and Moelwyn-Hughes[157] were able to isolate, from the reaction between diphenylphosphinous chloride and sodium pentacarbonylmanganate, two products of the stepwise replacement of carbon monoxide, to which they ascribed the structures

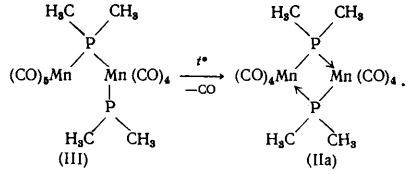


(I)



(II)

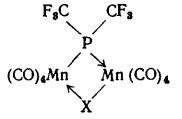
It was shown later[158] that the "doubly bridged" compound (IIa) is formed via the intermediate carbonyl complex (III), which contains only one "bridging" dimethylphosphino-group:



Dinuclear perfluoromethylated phosphine and arsine derivatives of manganese carbonyl have been prepared[159-161] by the reaction

$$[Mn(CO)_5]_2 + (CF_3)_2AX \rightarrow Mn_2(CO)_8A(CF_3)_2X + 2CO$$
(IV)

where A = P, As and X = Cl, Br, I, SCF_3, $SeCF_3$, $(CF_3)_2P$. Complexes of this type probably have the "doubly bridged" structure



In contrast to them, the compound $Mn_2(CO)_9P(CF_3)_2N(CH_3)_2$, obtained by the reaction between decacarbonyldimanganese and dimethylaminobistrifluoromethylphosphine[161], contains no "bridging" phosphine groups. It probably has the linear structure

$$(CO)_5Mn—Mn(CO)_4—P(CF_3)_2—N(CH_3)_2.$$

Decacarbonyldimanganese reacts with *o*-phenylenebis-dimethylarsine at an elevated temperature[162,163] to form the diamagnetic dimeric product

$$\{Mn(CO)_3[(CH_3)_2As—C_6H_4—As(CH_3)_2]\}_2$$

which on further heating passes into a paramagnetic monomer:

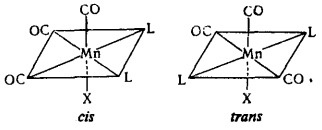
$$\{Mn(CO)_3[diars]\}_2 \rightarrow 2Mn(CO)_3[diars]$$
$$diars = o\text{-}(CH_3)_2AsC_6H_4As(CH_3)_2.$$

The dimeric complex reacts in chloroform with free halogens:

$$\{Mn(CO)_3[diars]\}_2 + Cl_2 \rightarrow 2Mn(CO)_3[diars]Cl.$$

Excess of halogen produces a gradual replacement of carbonyl groups with the formation of $Mn(CO)_2[diars]Cl_2$ and $Mn[diars]Cl_3$. Analogous compounds have been obtained from decacarbonyldimanganese and ethylene-1,2-bisdiphenylphosphine[164-166].

Mononuclear compounds of general formula $Mn(CO)_3L_2X$ can exist in the form of the stereoisomers[167-169]



cis *trans*

The relative proportions of *cis*- and *trans*-isomers formed as a result of the stepwise substitution of carbonyl groups depends on the nature of the added ligand. Thus the replacement of carbonyl groups by triphenylphosphine yields mainly the *trans*-isomer, whereas the pyridine complex exists solely in the *cis*-form[167,168]. The stability of a particular stereoisomer probably depends primarily on steric factors.

The chemical properties of the phosphine-substituted derivatives of manganese carbonyl and their arsine and stibine analogues are fundamentally similar to those of manganese carbonyl itself and its other derivatives[169,170]. These compounds react with sodium amalgam to form the corresponding salts:

$$Mn(CO)_4LX + 2Na \xrightarrow{Hg} NaMn(CO)_4L + NaX$$

$$Mn(CO)_3L_2X + 2Na \xrightarrow{Hg} NaMn(CO)_3L_2 + NaX$$

which can be used to prepare various alkyl and acyl derivatives:

$$NaMn(CO)_3L_2 + (RCO)_2O \rightarrow RCO—Mn(CO)_3L_2 + RCOONa.$$

On being heated, acyl derivatives are also capable of conversion into alkyl derivatives, with the loss of a molecule of carbon monoxide:

$$RCO—Mn(CO)_3L_2 \rightarrow R—Mn(CO)_3L_2 + CO.$$

Hydrolysis of sodium tetracarbonyltriphenylphosphine-manganate yields the corresponding hydrogen compound[170]:

$$NaMn(CO)_4P(C_6H_5O)_3 + H^+ \rightarrow HMn(CO)_4P(C_6H_5O)_3.$$

The sodium salts can be used for the preparation of mercury derivatives of manganese carbonyl:

$$2NaMn(CO)_4PR_3 + Hg(CN)_2 \rightarrow [Mn(CO)_4PR_3]_2Hg + 2NaCN.$$

Analogous mercury derivatives were obtained also from manganese carbonyl compounds containing two ligand molecules:

$$2NaMn(CO)_3[P(C_6H_5)_3]_2 + Hg(CN)_2 \rightarrow \{Mn(CO)_3[P(C_6H_5)_3]_2\}_2Hg + 2NaCN.$$

5. Compounds containing Sulphur and Tellurium

The first derivative of manganese carbonyl containing a manganese–sulphur bond was prepared by Hieber and Schropp[125] by the reaction

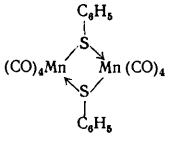
$$ClMn(CO)_5 + C_6H_5SH \rightarrow [Mn(CO)_4—S—C_6H_5]_2.$$

This reaction was subsequently applied to decacarbonyldimanganese[171,172]:

$$R—SH + Mn_2(CO)_{10} \rightarrow 2RS—Mn(CO)_5$$

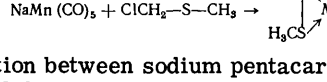
where R = C_2H_5, C_3H_7, C_6H_5, *p*-$CH_3C_6H_4$.

Reaction between manganese carbonyl and compounds containing two sulphur atoms (1,2-diphenylthioethane[164], dithian[173], etc.) has been used to synthesise dinuclear "bridged" compounds



resembling the dinuclear compounds containing phosphine or arsine.

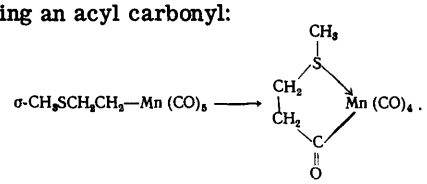
King and Bisnette[174] prepared compounds in which the sulphur atom was attached to the manganese atom by a π-bond:



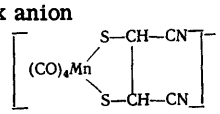
Interaction between sodium pentacarbonylmanganate and alkyl halides containing sulphur initially produces a compound containing a σ-bond:

$$NaMn(CO)_5 + ClCH_2CH_2—S—CH_3 \rightarrow \sigma\text{-}CH_2SCH_2CH_2—Mn(CO)_5 + NaCl$$

and this on ultraviolet irradiation passes into a π-derivative containing an acyl carbonyl:



Finally, the complex anion



in which the manganese atom is attached to two sulphur atoms, has been obtained[175] by the reaction between bromotetracarbonyltriphenylphosphinemanganese and sodium *cis*-1,2-dicyanoethane-1,2-dithiolate.

Derivatives of manganese pentacarbonyl containing the manganese–tellurium[176] and the manganese–selenium bonds can be prepared by similar methods.

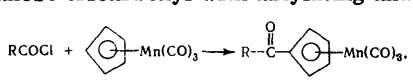
VIII. π-HYDROCARBON MANGANESE CARBONYL DERIVATIVES

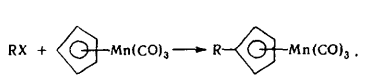
Besides the organic derivatives of manganese carbonyl described in Section V, in which the carbon atom is bound to the metal atom by a σ-bond, several compounds are known in which the π-electrons of carbon atoms effect the link between the manganese atom and a hydrocarbon group. As in other "sandwich" compounds, a π-bond between an organic group and a pentacarbonylmanganese group is possible only when the ligand has a coplanar configuration[177].

The most thoroughly studied π-complex of manganese carbonyl is cyclopentadienylmanganese tricarbonyl $C_5H_5Mn(CO)_3$. Several methods are now known for preparing it, one of the most convenient being the reaction between halogenomanganese pentacarbonyls and cyclopentadienyl-sodium[178] or -thallium[179]:

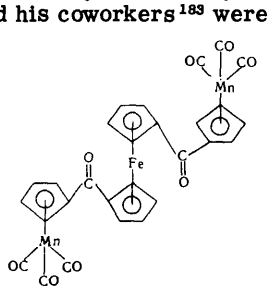
$$C_5H_5Na + BrMn(CO)_5 \rightarrow C_5H_5Mn(CO)_3 + 2CO + NaBr.$$

The chemistry of cyclopentadienylmanganese tricarbonyl and its derivatives has been described in detail[180,181], and therefore we shall mention only certain reactions of this compound. Various substituents can be introduced into the cyclopentadienyl ring by interaction of cyclopentadienylmanganese tricarbonyl with alkylating and acylating agents[182]:





The most diverse compounds containing a tricarbonylmanganese group have been synthesised by this method. For example, Cais and his coworkers[183] were able to obtain the compound



which contains a ferrocene "sandwich" besides tricarbonylmanganese groups.

The cyclopentadienyl ring in the cyclopentadienylmanganese tricarbonyl molecule exhibits all the properties characteristic of aromatic systems. At the same time the presence of carbonyl groups attached to the metal atom enables reactions typical of metal carbonyls to be carried out, e.g. the replacement of carbonyl groups by electron-donor ligands[184]:

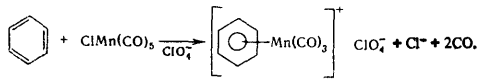
$$C_5H_5Mn(CO)_3 + (CH_3)_2NH \rightarrow C_5H_5Mn(CO)_2NH(CH_3)_2 + CO$$

$$C_5H_5Mn(CO)_3 + P(C_6H_5)_3 \rightarrow C_5H_5Mn(CO)_2P(C_6H_5)_3 + CO.$$

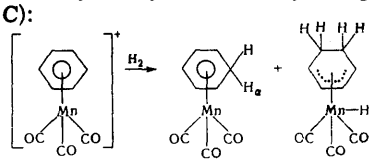
Strohmeier and von Hobe[185] replaced carbon monoxide in cyclopentadienyl tricarbonyl by diphenylacetylene:

$$C_5H_5Mn(CO)_3 + C_6H_5C{\equiv}CC_6H_5 \rightarrow C_5H_5Mn(CO)_2(C_6H_5C{\equiv}CC_6H_5) + CO.$$

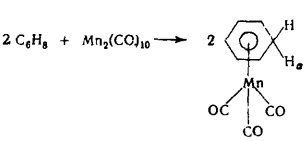
Aromatic systems other than the cyclopentadienyl ring are also able to form π-complexes with manganese carbonyl[185]. Hydrocarbons of the benzene series form either complexes of the type π-Ar–$Mn(CO)_4$ [186] or cations $[\pi\text{-Ar–}Mn(CO)_3]^+$. For example, benzene reacts with chloropentacarbonylmanganese in the presence of Friedel–Crafts catalysts according to the equation



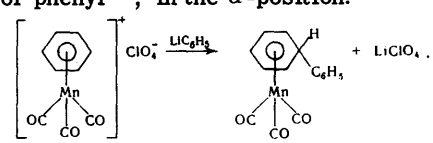
Reduction of this cation with sodium tetrahydroborate[188] or with hydrogen over Raney nickel yields π-cyclohexadienemanganese tricarbonyl (m.p. 78°C) and small amounts of hydrogen tricarbonyl-π-cyclohexadienylmanganate (decomposes at 95°C):



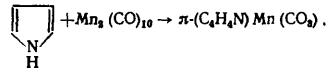
The first of these compounds can also be readily obtained by the interaction of decacarbonyldimanganese with cyclohexadiene[189]:



The benzenetricarbonylmanganese cation can be stabilised also by the addition of various substituents, e.g. methyl[190] or phenyl[191], in the α-position:

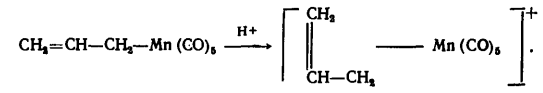


Joshi et al.[192,193] synthesised several derivatives of heterocyclic compounds and manganese carbonyl containing a π-bond:



Not only aromatic systems but also various unsaturated acyclic systems are able to form π-complexes with manganese carbonyl. It is supposed that the pentacarbonylethylenemanganese cation, which has already been discussed (Section IV, 2), formed by the reaction of ethylene with manganese carbonyl[56], and also by detachment of a

proton from ethylmanganese pentacarbonyl by the action of triphenylmethyl tetrafluoroborate[194], is a π-complex. It has been found[195] that an analogous cation is formed by the action of perchloric acid on σ-allylmanganese pentacarbonyl:

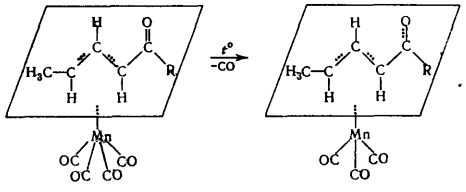


Stable π-allyl complexes of manganese carbonyl have been obtained by heating the corresponding σ-alkyl derivatives $R-Mn(CO)_5$ while exposed to ultraviolet radiation[85,92,196]. This reaction probably involves the intermediate formation of an unstable cation:

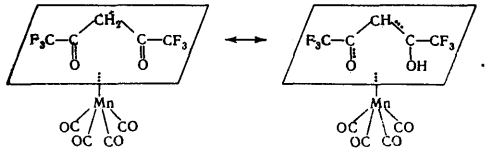
which is then stabilised by eliminating a molecule of carbon monoxide:

Analogous π-complexes have been obtained by interaction between dienes and alkyl or aryl derivatives of manganese pentacarbonyl[197]:

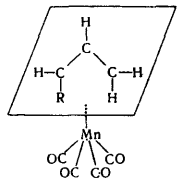
When such a compound (R = C_6H_5) is heated above 110°C, a molecule of carbon monoxide is split off, stabilisation of the resulting tricarbonyl complex probably being due to interaction of the π-orbitals of the ketonic carbonyl with *d*-electrons of the manganese atom:



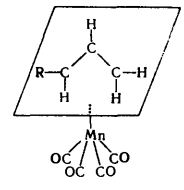
Similar formation of a π-bond by π-electrons of an acyl carbonyl is probably observed also in tetracarbonylhexafluoropentane-2,4-dionemanganese, which was prepared by Kilner and Wojcicki[198]:



π-Allyl compounds of maganese carbonyl are distinguished from the corresponding σ-allyl complexes primarily by the coplanar arrangement of the carbon atoms in the organic portion of the molecule. Some workers postulate[192,193] that the higher homologues of π-allyl derivatives of manganese carbonyl may exist as different stereoisomers



anti-1-alkyl-π-allylmanganese tetracarbonyl



syn-1-alkyl-π-allylmanganese tetracarbonyl

However, such a hypothesis is hardly justified, since such isomers are absent from the "sandwich" compounds, e.g. ferrocene and cyclopentadienylmanganese tricarbonyl, which are allied to the π-allyl complexes of manganese carbonyl[199].

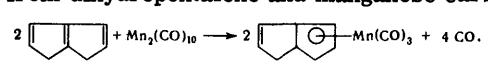
The π-allyl complexes are rather more stable than the corresponding σ-allylmanganese pentacarbonyls. Their boiling (melting) points are usually higher than those of compounds containing a σ-bond. The infrared absorption spectra and the nuclear magnetic resonance spectra indicate that single and double bonds in the organic substituents are levelled out. The accompanying Table gives for comparison some physicochemical characteristics of σ- and π-allylmanganese carbonyls.

Physicochemical properties of σ- and π-allylmanganese carbonyls.

Property	σ-CH_2=$CHCH_2Mn(CO)_5$	π-$(CH_2$=$CHCH_2)$—$Mn(CO)_4$
State	Liquid	Crystals
Melting (boiling) point, °C	25/10^{-3}	55—56
Infrared absorption spectrum, cm^{-1}		
ν C=C	1620	1505
ν C=O	2110, 2079, 2024, 2004	2110, 2060, 2049, 1950
N.m.r. spectrum, τ, p.p.m.	6.14 (sextet) 4.68 (triplet) 1.81 (doublet)	4.80 (sextet) 2.76 (doublet) 1.77 (doublet)

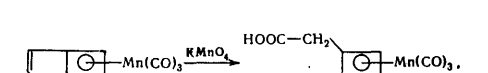
Finally, we must deal with the very peculiar reaction between manganese carbonyl and acetylene[200-202], by means of which the most diverse derivatives of cyclopentadienylmanganese tricarbonyl can be obtained. At 150°C and 40–45 atm acetylene forms with decacarbonyldimanganese or with methylmanganese pentacarbonyl the compound π-dihydropentalenylmanganese tricarbonyl:

The same compound was obtained by Riemschneider[201] directly from dihydropentalene and manganese carbonyl:



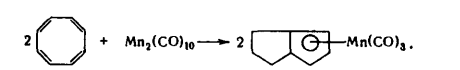
Analogous complexes have been obtained from azulene and indene[203-205].

The oxidation of π-dihydropentalenylmanganese tricarbonyl yields cyclopentadienylmanganese tricarbonyl derivatives:



Reduction over Raney nickel results in a π-tetrahydropentalenyl derivative[206]:

which can be prepared also from manganese carbonyl and cyclo-octatetraene:



IX. COMPOUNDS CONTAINING A BORON ATOM

With most boron compounds manganese carbonyl can react only as a donor of electrons. Thus interaction of the borane–ether complex with sodium pentacarbonylmanganate gave[207] the unstable complex $[(C_2H_5)_4N]^+[H_3B{-}Mn(CO)_5]^-$, which decomposes with the evolution of diborane even at −25°C. A complex in which one carbonyl group had been replaced by triphenylphosphine

$$[H_3B{-}Mn(CO)_4P(C_6H_5)_3]^-[(C_2H_5)_4N]^+$$

was synthesised in an analogous fashion. Nöth and Schmidt[208] isolated several compounds containing a boron–manganese σ-bond, in which the boron atom was attached to a dimethylamino-group or a chlorine or bromine atom.

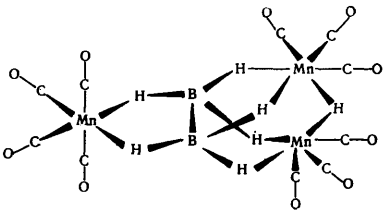
Reaction between diphenyl- or di-n-butyl-boron chloride and sodium pentacarbonylmanganate results in complete elimination of carbonyl groups with the formation of compounds of the type $(R_2B{-}Mn)_2$.

Ionic complexes of manganese carbonyl derivatives have also been obtained containing the tetrafluoroborate anion[194]:

$$C_2H_5Mn(CO)_5 + (C_6H_5)_3C^+BF_4^- \rightarrow [C_2H_4{-}Mn(CO)_5]^+BF_4^-$$

$$[C_2H_4{-}Mn(CO)_5]^+BF_4^- + P(C_6H_5)_3 \rightarrow [(C_6H_5)_3P]_2Mn(CO)_4]^+BF_4^- .$$

An interesting complex of a hydroboron with manganese carbonyl $B_2H_7Mn_3(CO)_{10}$ has recently been synthesised[209]. It is stable only in the absence of air. Electron diffraction has shown that the manganese and boron atoms are linked by hydrogen bonds:



The boron–manganese distances in this compound are 2.30 ± 0.02 Å, the boron–boron bond length is 1.76 ± 0.03 Å, and the manganese atoms are only 2.845 ± 0.003 Å apart. We may recall that the manganese–manganese bond length in the decacarbonyldimanganese molecule is 2.923 ± 0.003 Å.

An organoboron analogue of cyclopentadienylmanganese tricarbonyl has recently been synthesised[210]:

$$B_9C_2H_{11}Cs_2 + BrMn(CO_5) \xrightarrow{\text{rapid}} [B_9C_2H_{11}Mn(CO)_5]^- + 2\,CsBr$$

$$[B_9C_2H_{11}Mn(CO)_5]^- \xrightarrow{\text{slow}} [B_9C_2H_{11}Mn(CO)_3]^- + 2CO .$$

X. APPLICATIONS OF MANGANESE CARBONYL DERIVATIVES

Since manganese carbonyl derivatives have been relatively little studied, it is still early to speak of their widespread application. However, several prospects already exist for making use of these compounds.

During 1956–1957 the first papers appeared[211–214] on the use of methylcyclopentadienylmanganese tricarbonyl and its derivatives as anti-knock compounds. A great deal of work is now being done on the industrial application of cyclopentadienylmanganese tricarbonyl, which is almost twice as effective as tetraethyl-lead, at present widely employed for this purpose; furthermore, it is considerably less toxic[215]. Information is available[216,217] on the use for anti-knock purposes of other derivatives of manganese carbonyl, not containing a cyclopentadienyl ring, including decacarbonyldimanganese itself.

Derivatives of manganese carbonyl find some application as additives to lubricating oils[218].

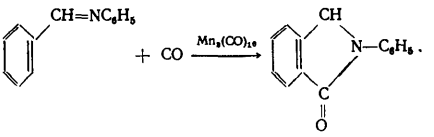
Furthermore, various compounds containing an M–CO bond are gradually finding increasingly wide use as catalysts for various processes. More than fifty types of reactions catalysed by metal carbonyls are known at the present time[199,219], many of them involving manganese carbonyl. The most important of these processes are given below.

(a) Carbonylation of Organic Compounds

Manganese carbonyl and its derivatives can act as a source of carbonyl groups for various processes of carbonylation. For example, dimethylformamide is formed by reaction between decacarbonyldimanganese and excess of dimethylamine[219,220]:

$$22\,(CH_3)_2NH + 3Mn_2(CO)_{10} \rightarrow 2\{Mn[(CH_3)_2NH]_6\}[Mn(CO)_5]_2 + 10HCON(CH_3)_2 .$$

Transfer of carbon monoxide can occur also catalytically in the presence of manganese carbonyl heated to 200–250°C under a high pressure of carbon monoxide. An example of such transfer is the carbonylation of *N*-phenylbenzylideneimine[221]:



Derivatives of metal carbonyls can be used to carbonylate other organic compounds besides amines, e.g. alkyl halides[222,223]:

$$CH_3Cl + NaMn(CO)_5 \rightarrow CH_3{-}Mn(CH)_5 \xrightarrow{CO} CH_3CO{-}Mn(CO)_5 \xrightarrow{Br_2} CH_3COBr + BrMn(CO)_5$$

(b) Hydrogenation

Various organic compounds can be hydrogenated in the presence of a hydrogen carbonylmanganate. With proton-acceptors present, hydrogen pentacarbonylmanganate decomposes forming decacarbonyldimanganese, while the hydrogen atom liberated is transferred to the acceptor:

$$2HMn(CO)_5 \rightarrow 2H^{\cdot} + Mn_2(CO)_{10}$$

$$CH_3COCH_3 + 2H^{\cdot} \rightarrow CH_3{-}\underset{\displaystyle OH}{\underset{|}{CH}}{-}CH_3 .$$

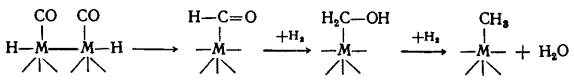
At elevated temperatures the hydrogenation may be autocatalytic[223,224].

(c) Transfer of Carbon Monoxide and Hydrogen (Fischer–Tropsch Synthesis)

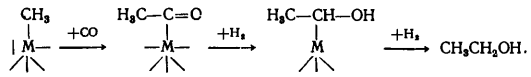
An example of the simultaneous transfer of carbon monoxide and hydrogen is provided by the synthesis of ethanol from methanol, carbon monoxide, and hydrogen in the presence of manganese carbonyl[225,226]:

$$CH_3OH + CO + H_2 \xrightarrow{Mn_2(CO)_{10}} CH_3CH_2OH .$$

The mechanism of this reaction can be represented by a scheme comprising (i) formation of methyl from carbon monoxide and hydrogen



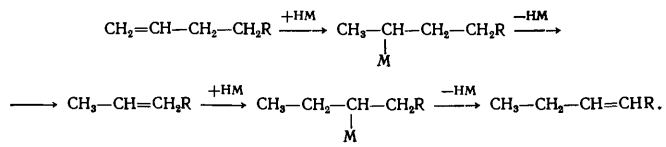
and (ii) chain growth



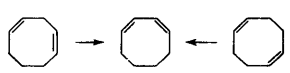
This reaction will probably provide a method of obtaining higher alcohols.

(*d*) Isomerisation of Alkenes

The isomerisation of alkenes involves the intermediate addition of the hydrocarbonylmetal complex (HM) at the double bond in the organic molecule, followed by its elimination according to the scheme



Wittenberg and Seibt[227] accomplished the isomerisation of cyclo-octa-1,4(and 1,5)-diene into cyclo-octa-1,3-diene in the presence of decacarbonyldimanganese:



(*e*) Polymerisation of Alkenes

Little work has yet been done on the possibility of using metal carbonyls as catalysts for the polymerisation of unsaturated compounds. Bamford and his coworkers[228,229] have accomplished the polymerisation of methyl methacrylate in the presence of manganese and rhenium carbonyls in polar solvents, and found them to exert a stereoregulating effect on processes of radical polymerisation.

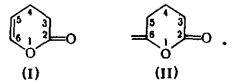
I. INTRODUCTION

Many substances containing unsaturated γ- and δ-lactone rings exhibit physiological activity. It is sufficient to mention the aglycones of cardiac poisons of vegetable and animal origin, various coumarin derivatives, and lactones of the santonin group to have an idea of the importance of compounds of this type.

The varied physiological action of these substances (anthelmintic, effect on heart muscle, ability to arrest the growth of animal tissues and plants), and also the antibiotic activity of the simpler lactones (protoanemonin, parasorbic acid, kawain), are associated with the presence in these compounds of unsaturated lactone rings[1].

These facts are attracting chemists to the study of unsaturated lactones. From the point of view of reactivity, the greatest interest attaches to those in which the double bond is in the vinyl position—either in the ring or outside it—with respect to the heteroatom, this position being responsible for their peculiar chemical behaviour.

Whereas the chemistry of the five-membered unsaturated lactones (but-3(or 4)-en-4-olides) has been developed for many years[2], the principal branches of the chemistry of the six-membered unsaturated lactones (pent-4(or 5)-en-5-olides) have been studied only during the past decade. These investigations have shown wide opportunities for the use of unsaturated δ-lactones in organic synthesis, and have revealed a difference in behaviour between the two types of unsaturated δ-lactones, differing in the position of the double bond—3,4-dihydro-2-pyrones (I) and 6-alkylidenetetrahydro-2-pyrones (II).



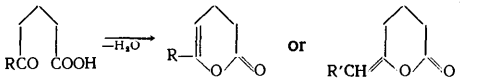
(I) (II)

The present review represents the first attempt to summarise and systematise information on the chemistry of the unsaturated δ-lactones published up to 1966 inclusive.

II. SYNTHESIS OF UNSATURATED δ-LACTONES

1. Dehydration of δ-Keto-acids to Unsaturated δ-Lactones

The chief method of obtaining unsaturated δ-lactones is the cyclodehydration of δ-keto-acids, which can occur in different ways:

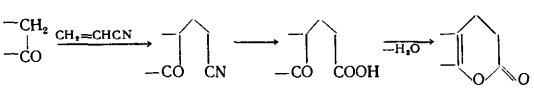


where R = R'CH_2.

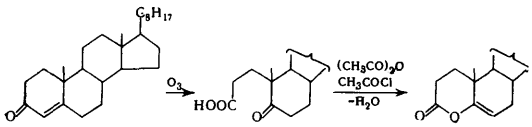
In isolated cases water is eliminated from δ-keto-acids when they are distilled or heated (thermal enol-lactonisation). Since the reaction occurs at a relatively high temperature, this method is used to obtain unsaturated lactones only from keto-acids boiling above 200–250°C.[3-6]

The most important and widely used procedure for the enol-lactonisation of δ-keto-acids† is their dehydration in the presence of acetic anhydride alone[13-23], mixed with acetyl chloride[24,25], or with the addition of catalytic quantities of sodium acetate[26,27], sulphuric acid[6], or perchloric acid[28-30]. This route has been used to prepare δ-lactones having the double bond in the ring (3,4-dihydro-2-pyrones)[30-37] or in the exocyclic position (6-alkylidenetetrahydro-2-pyrones)[4,38,39].

† The possibility of preparing unsaturated δ-lactones in this way is determined mainly by the accessibility of the initial δ-keto-acids, which in turn are synthesised in various ways. Among published general methods of obtaining δ-keto-acids[7-12] the most convenient is the hydrolysis of δ-keto-nitriles[12], which result from the addition of acrylonitrile to ketones. Using this method of synthesising δ-keto-acids, we can pass from ketones to unsaturated δ-lactones in three stages:

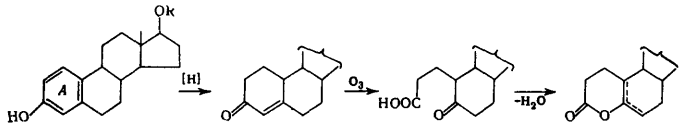


The dehydration of δ-keto-acids is widely used for the preparation of steroid unsaturated δ-lactones. For this purpose the natural steroids are converted by ozonolysis into the δ-keto-acids, which are then lactonised by one of the above methods[25,26]; for example

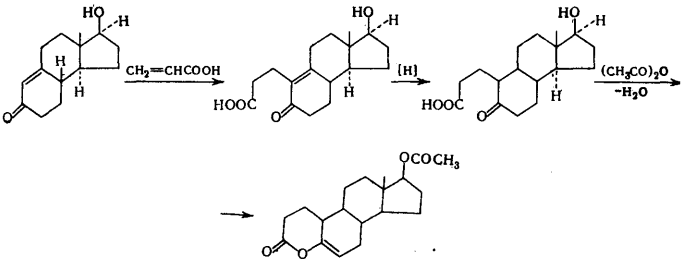


From cholestenone[40-43], testosterone[40,44,45], progesterone[46-49], androsterone and its derivatives[50-52], and cortisone[47,53] have been obtained the corresponding 4-oxasteroids in order to study the physiological action of these lactones, and also to obtain labelled androgens and corticosteroids (see Section III, 3).

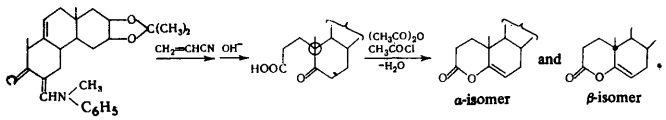
Unsaturated δ-lactones have been obtained also from oestrogens‡, the first stage of the process being in this case reduction of the phenolic ring A to the corresponding unsaturated ketone[54]:



where R = $COCH_3$, COC_6H_5. One of these lactones (with R = $COCH_3$) has been obtained synthetically[55] and then used for the synthesis of 19-nortestosterone:

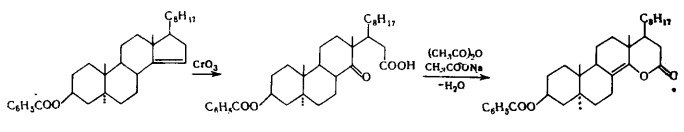


The lactonisation of δ-keto-acids was used by Woodward et al.[26] to prepare tetracyclic unsaturated δ-lactones, which were employed in one of the stages of their total synthesis of steroids:



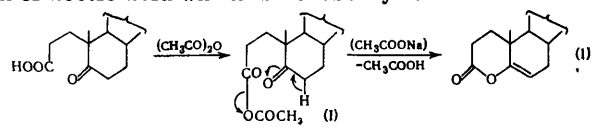
By varying the sequence in which the individual stages in this scheme were accomplished, it then proved possible to obtain predominantly the β-isomer[56-58] (corresponding to the configuration of natural steroids), which, according to Woodward, is obtained in only 13% yield.

In order to obtain a steroid unsaturated δ-lactone in which the D-ring was lactonic, use was made of the δ-keto-acid formed by the oxidation of cholest-14-en-3β-yl benzoate[59]:



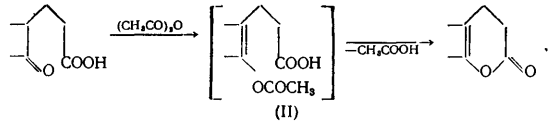
‡ In contrast to the examples given above, the absence of an angular methyl group in position 10 suggests that both isomeric lactones, differing in the position of the double bond, will be formed.

It may be concluded from published data on the mechanism of the action of acetic anhydride in the lactonisation of δ-keto-acids that acylation products are formed initially. But according to Woodward[26] acetic anhydride acylates the carboxyl of the δ-keto-acid to form a mixed anhydride (I)§, from which the unsaturated δ-lactone is obtained by subsequent intramolecular enolacylation of the carbonyl group; the sodium acetate catalyses the elimination of acetic acid which is necessary for this reaction:



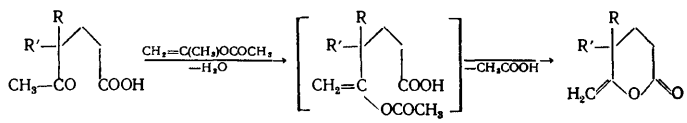
This view of the role of acetic acid is supported by results obtained by Rosenthal et al.[60], who also isolated a mixed anhydride by the action of acetic anhydride on a triterpenoid δ-keto-acid.

However, it may be postulated that the acetic anhydride reacts in a different manner—that it acylates the δ-keto-acid at the carbonyl group with formation of the acetate of the enolic form¶ of the δ-keto-acid (II), subsequent intramolecular reacylation[63,64] of which yields the unsaturated δ-lactone:



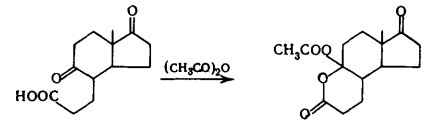
In this case the role of substances of the acidic and basic character of sodium acetate[26], acetyl chloride[25], and sulphuric acid[6], which are used as catalytic additions in enol-lactonisation by means of acetic anhydride, is to facilitate enolisation of the carbonyl group, which is necessary for the reaction to occur in this way. Several authors use scheme (2) to explain the role of acetic anhydride in the lactonisation of δ-keto-acids[65-67].

Scheme (2) also provides an explanation of the anomalous behaviour of γγ-disubstituted δ-keto-acids, which remains unaffected by boiling acetic anhydride[68,69], but are converted into the corresponding unsaturated lactones in 81-99% yield on treatment with isopropenyl acetate:



where R = R′ = CH_3, C_6H_5; R = C_6H_5 and R′ = o-$ClC_6H_4CH_2$. The enolisation of keto-acids containing no γ-hydrogen atom should be difficult, since it can occur only by means of the methyl hydrogen atoms. Therefore the formation of unsaturated acetates of the type (II), which are required

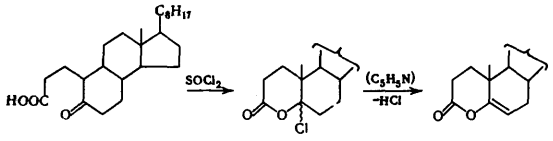
§ On the basis of the infrared spectra Woodward assumed an open-chain structure for the intermediate anhydride (I). More recently, however, it has been shown (from the infrared and nuclear magnetic resonance spectra) that an anhydride of this type obtained from a bicyclic keto-acid has a cyclic structure[27]:



¶ Acetates of the enolic forms of ketones are known to be obtained by the action of acetic anhydride on ketones in the presence of sodium acetate or sulphuric acid[61,62].

for the subsequent production of unsaturated lactones, will take place only in the presence of such a strong acylating reagent as isopropenyl acetate.

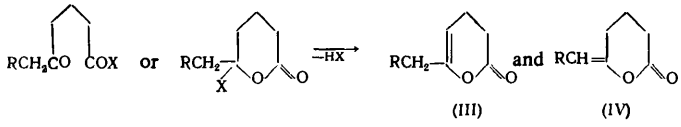
Acid chlorides (acetyl[7,70,71], oxalyl[24], and thionyl[24,72,73]) are widely used for the lactonisation of δ-keto-acids, being more effective than acetic anhydride or phosphorus pentachloride[74]. In this case lactonisation probably involves intermediate formation of the chlorides of the keto-acids, which, as has recently been demonstrated spectroscopically, have (unlike the δ-keto-acids themselves[75]), a cyclic structure[9,76], and readily split off hydrogen chloride[25,45] to form the unsaturated δ-lactones; e.g. [25]



In individual cases these intermediate cyclic acid chlorides have been isolated[9,25,45,54,76-78]. Their properties, which differ from those of ordinary chlorides of carboxylic acids, also confirm their cyclic structure[25,78].

Thus the lactonisation of δ-keto-acids can be accomplished either by their direct dehydration (thermal enol-lactonisation) or by the intermediate conversion of the original acids into acylation products (action of acetic anhydride) or cyclic acid chlorides (action of acid chlorides).

When hydrogen atoms are present in the γ- and ε-positions of δ-keto-acids and their derivatives†, isomeric unsaturated δ-lactones can be obtained, with the double bond either in the ring (III) or in the exocyclic position (IV):



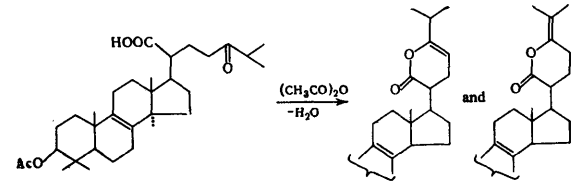
(III) (IV)

where X = Cl, CH_3COO, OH. Which of the isomeric lactones (III) and (IV) is obtained in each individual case is determined either by the direction in which the initial keto-acid undergoes enolisation or by the direction in which HX is eliminated from their cyclic forms[79-83].

Spectral methods have been successfully employed for the investigation of these unsaturated δ-lactones‡. It has been shown that the stretching vibrations of an exocyclic double bond are represented in the infrared spectra of the unsaturated δ-lactones by intense absorption at 1649–1662 cm^{-1},[84,85] whereas the stretching vibrations of an endocyclic double bond in these compounds correspond to extremely weak bands in the range 1695–1710 cm^{-1}.[54,84]

The Raman spectra can also be successfully used to establish the position of the double bond in unsaturated δ-lactones, since they show a difference of the same order as in the infrared spectra for lactones having semicyclic and endocyclic double bonds. However, the intensity of absorption in the region of the carbon–carbon double bond is extremely strong in the Raman spectra for both types of lactones[84].

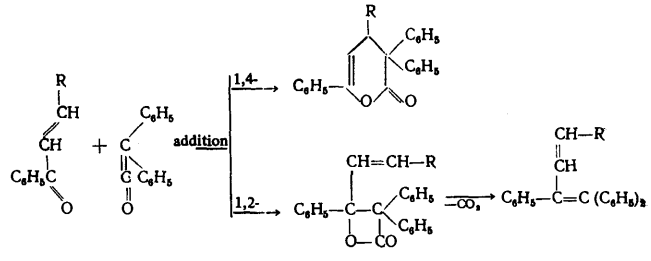
The application of spectral methods of investigation has shown that the simplest δ-keto-acids, whose structure permits the formation from them of both types of unsaturated lactones, are converted predominantly into those containing an endocyclic (more substituted) double bond[84]. Recently, however, examples have been described of the lactonisation of δ-keto-acids of complicated polycyclic structure with the formation of both possible isomers[54,60,91]. Thus the δ-keto-acid obtained by ozonolysis of the triterpenoid eburicoic acid is dehydrated to a mixture of isomeric lactones, the different positions of the double bond in which have been proved by ozonolysis and by the nuclear magnetic resonance spectra[60,91]:



The nuclear magnetic resonance spectra have been used to establish the position of the double bond in other polycyclic unsaturated δ-lactones[5,16,27,60,91,92].

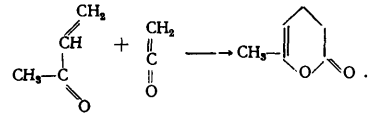
2. Other Syntheses of Unsaturated δ-Lactones

Unsaturated δ-lactones can be synthesised (in 20–30% yield) by Staudinger's method[93]—from ketens and αβ-unsaturated ketones (1,4-addition)—when diene hydrocarbons are also formed, by decarboxylation of the β-lactones produced by 1,2-addition:

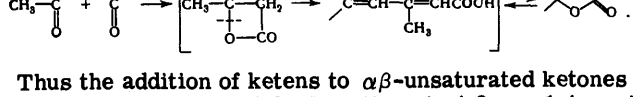


where R = C_6H_5, p-$CH_3OC_6H_4$, p-$(CH_3)_2NC_6H_4$.

The reaction between but-3-en-2-one and keten (the first members of each series) yields only the 1,4-addition product[94]:



Alk-3-en-2-ones react with keten only in the presence of a catalyst (boron trifluoride), forming unsaturated δ-lactones in which the double bond is in the βγ-position. Production of the latter is explained by isomerisation of the β-lactones formed initially by 1,2-addition; e.g.[95]

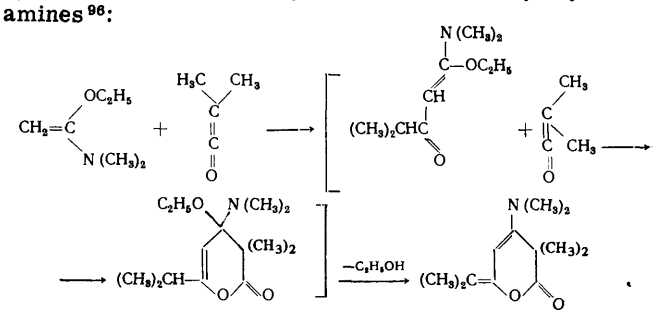


Thus the addition of ketens to αβ-unsaturated ketones takes place in both possible directions in 1,2- or 1,4-positions depending on the structure of both components.

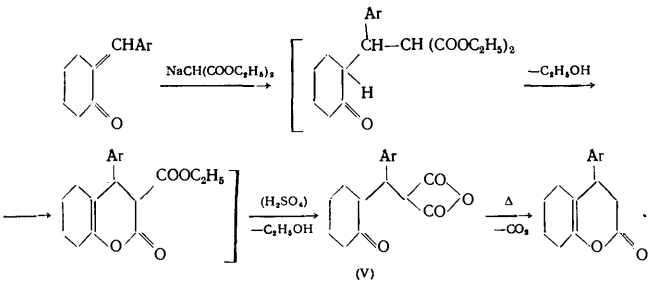
† In contrast to the acid chlorides[25] and anhydrides[27] the δ-keto-acids themselves exist in the open-chain form[75]. However, this fact does not exclude the possibility of their reacting in their cyclic form during lactonisation.

‡ The infrared and Raman spectra of these unsaturated δ-lactones exhibit an intense carbonyl absorption in the range 1750–1780 cm^{-1},[84,85,87,88] which distinguishes them from unsaturated δ-lactones in which the double bond is in the αβ- or βγ-position (carbonyl absorption at 1710–1730 cm^{-1}) and from 2-pyrones (1720–1740 cm^{-1}).[86,89,90]

δ-Lactones containing an exocyclic double bond can be synthesised from dimethylketens§ and 1-alkoxyvinylamines[96]:

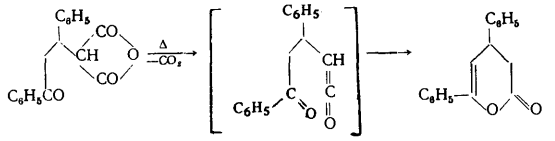


The condensation of benzylidene- and *p*-methoxybenzylidene-cyclohexanone with sodiomalonic ester (the Michael reaction)[98] yielded unsaturated α-ethoxycarbonyl-δ-lactones, which were easily further converted into substituted γ-keto-malonic anhydrides, the latter again being cyclised (on heating) into unsaturated δ-lactones:

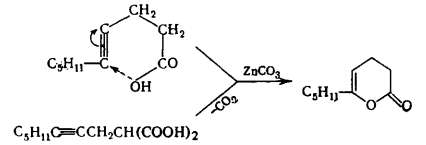


(V)

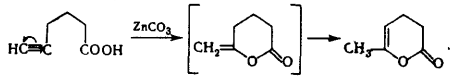
A similar conversion of γ-keto-malonic anhydrides (V)¶ into unsaturated δ-lactones was observed by Mannich and Butz[17], who regarded this reaction as an intramolecular enolacylation of an anhydride keto-group. It may be supposed, however, that under these conditions acylation will be effected by ketens formed as intermediates†, which, according to Staudinger's results[99], are readily obtained from such malonic anhydrides on heating; e.g.



Unsaturated δ-lactones are formed also by the cyclisation of pent-4-ynoic acid or the corresponding prop-2-ynylmalonic acids under the influence of zinc carbonate[100]; e.g.

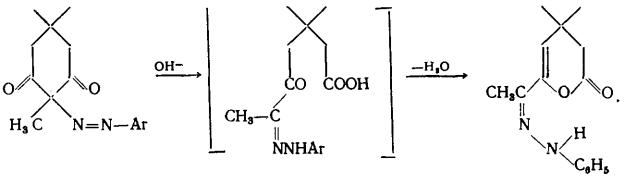


Under these conditions hex-5-ynoic acid could be expected to yield a δ-lactone containing an exocyclic double bond. However, the double bond migrated into the ring, and 3,4-dihydro-6-methyl-2-pyrone was obtained:

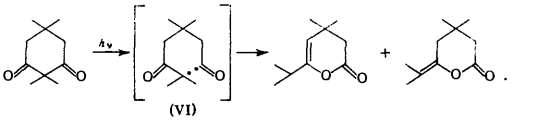


In spite of the comparatively good yields (45–65%) of unsaturated δ-lactones, application of this method is restricted by the relative inaccessibility of the initial alkynoic acids.

Unsaturated δ-lactone rings are formed by the alkaline hydrolysis of azo-derivatives of cyclohexane-1,3-diones (obtained by the Japp–Klingemann method); e.g.[101]



The photoisomerisation has recently been described of 2,2,5,5-tetramethylcyclohexane-1,3-dione (on exposure of a benzene solution) into a mixture of δ-lactones containing an exocyclic or an endocyclic double bond (in 92% and 1.3% yield respectively)[102]:



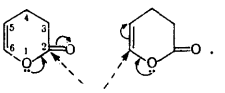
(VI)

This interesting reaction probably involves the intermediate formation of a diradical (VI), which then cyclises into an unsaturated lactone.

III. REACTIONS OF UNSATURATED δ-LACTONES

Unsaturated δ-lactones are highly reactive; in many respects their activity is similar to that of vinyl esters—of which they are cyclic analogues—and of unsaturated γ-lactones[2].

Like these compounds, unsaturated δ-lactones react readily with nucleophilic reagents. Since the distribution of electron density in the unsaturated lactones is such that the ring carbon atoms 2 and 6 are positively charged, it can be expected that attack by nucleophilic reagents will take place at one of these carbon atoms, with subsequent cleavage of the 1–2 or the 1–6 bond and formation of two series of derivatives (as occurs with 2-pyrones)[97]:



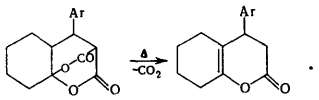
Unsaturated δ-lactones react readily also with electrophilic reagents, forming products of addition at the double bond, which possesses enhanced nucleophilic character in unsaturated lactones (as also in vinyl ethers).

1. Hydrolysis, Alcoholysis, and Ammonolysis

Unsaturated δ-lactones react readily‡ with water, the

§ Use of keten itself in this reaction[97] yields 2-pyrones.

¶ These substances may have the structure of the isomeric dilactones[98], which on decarboxylation also give the corresponding δ-lactones:

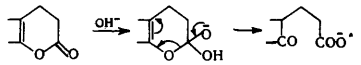


† The formation of these ketens (not the unsaturated lactones) was expected by Mannich and Butz[17], when investigating the behaviour of malonic anhydrides on heating.

‡ Some hydrolysis of unsaturated δ-lactones occurs even under the influence of atmospheric moisture[30,103].

lactone ring being opened and δ-keto-acids being formed.

Alkaline hydrolysis takes place still more easily, and leads (often in the cold) to the formation of quantitative yields of salts of the δ-keto-acids:

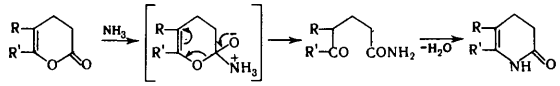


However, the ease of ring opening on alkaline hydrolysis may vary greatly with the nature and position of substituents in the unsaturated δ-lactone and with the strength of the base employed[13,15,17,49,93].

Acid hydrolysis has been described only in the case of one unsaturated lactone, which contained a 4-amino-group[96].

The reaction between unsaturated δ-lactones and alcohols, which results in the formation of esters of δ-keto-acids, also requires the presence of alkaline or acidic catalysts (in the absence of a catalyst the reaction goes very slowly on prolonged heating[17]). The ease of alcoholysis in the presence of acids is, perhaps, explained by protonation of the double bond in the lactone, resembling what occurs in the alcoholysis of vinyl esters[104]. This reaction is used for the preparation of esters of δ-keto-acids[4,31,34,35,68,105].

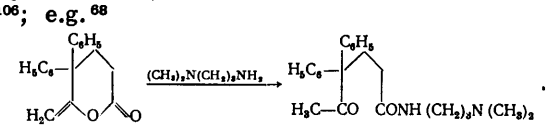
The action of ammonia on unsaturated δ-lactones leads to opening of the ring at the 1–2 bond§ with the formation of δ-keto-amides. Depending on their structure, the latter can be dehydrated with varying ease into the corresponding 5,6-unsaturated lactams (the nitrogen analogues of the δ-lactones)[3,13,17,34,35,38,93,106–108]; e.g.[107]



where R = C_2H_5 and R′ = C_6H_5.

The conversion of steroid unsaturated δ-lactones into the corresponding unsaturated δ-lactams (by the action of ammonia) provided a new method for the synthesis of azasteroids[51,109–111].

With amines unsaturated δ-lactones give high yields (usually in the cold) of substituted δ-keto-amides[13,17,68–74,103,106]; e.g.[68]



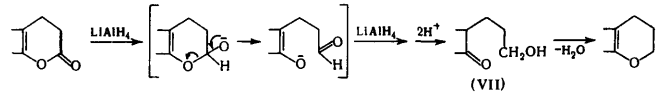
These examples show that unsaturated δ-lactones react with water, alcohols, ammonia, and amines under far milder conditions than do saturated δ-lactones. The reactions of hydrolysis, ammonolysis, and alcoholysis, resulting in the formation of δ-keto-acids and their derivatives, are used for the identification of unsaturated δ-lactones.

2. Reduction with Lithium Tetrahydroaluminate

Recent investigation of the reactions undergone by unsaturated δ-lactones with lithium tetrahydroaluminate has shown that various reduction products are formed depending on the position of the double bond.

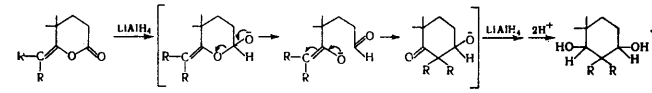
§ Addition at the 1-6 bond should have resulted in the formation of δ-amino-acids, but the latter were not observed in these cases.

Unsaturated δ-lactones containing a cyclic double bond (3,4-dihydro-2-pyrones) are reduced to 5-hydroxyalkanones (VII), which on dehydration readily undergo cyclisation to dihydropyrans[112]:



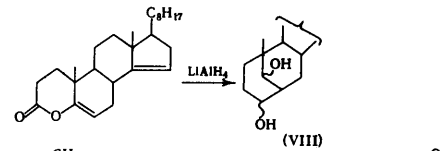
(VII)

Unsaturated δ-lactones containing an exocyclic double bond (6-alkylidenetetrahydro-2-pyrones) are reduced by lithium tetrahydroaluminate to cyclohexane-1,3-diols (in 52–65% yield), with rearrangement[113]:

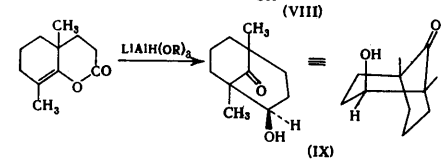


where R = H, CH_3.

The reduction of δ-lactones whose exocyclic double bond forms part of a ring fused with the lactone ring yields bridged compounds. Thus 4-oxacholest-5-en-3-one is converted under the influence of lithium tetrahydroaluminate into the bridged diol (VIII)¶ [114], whereas the action of lithium hydrotri-t-butoxyaluminate on a bicyclic lactone of similar structure yields an incompletely reduced product, the hydroxy-ketone (IX)[115]:



(VIII)



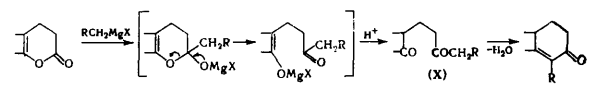
(IX)

Martin et al.[116] have shown that in the last example the reaction goes stereospecifically with formation of the epimer having the hydroxyl in the axial position (IX).

3. Reaction with Organomagnesium Compounds

δ-Lactones which differ in the position of a double bond behave differently with organomagnesium compounds.

3,4-Dihydro-2-pyrones (lactones having the double bond in the ring) add one or two moles of Grignard reagent depending on the conditions. When the reactants are added in the reverse order in the proportions 1 : 1 at −20°C, one mole of the organomagnesium compound is added. The reaction products are 1,5-diketones (X), which are further converted by intramolecular aldol condensation into cyclohex-2-enones[117]:

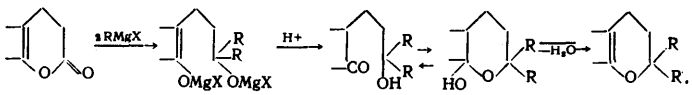


(X)

With excess of the organomagnesium compound at temperatures above 0°C, two moles thereof are added, the

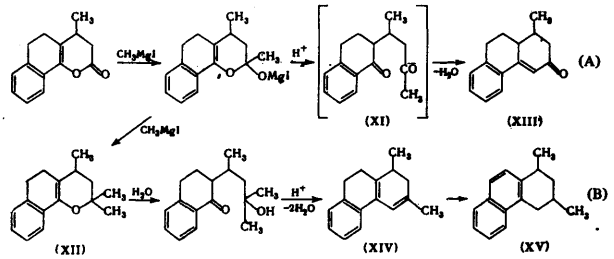
¶ The product of the reduction of this lactone by lithium tetrahydroaluminate had earlier been erroneously attributed the structure 3,5-seco-cholestane-3,5-diol[43].

main reaction products[118] being 3,4-dihydropyrans (yield 47–80%):

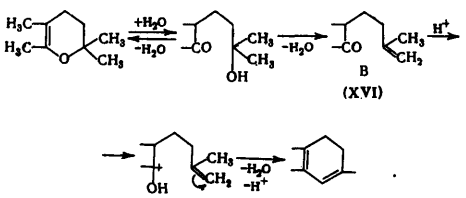


The reaction can be utilised for the preparation of substituted dihydropyrans.

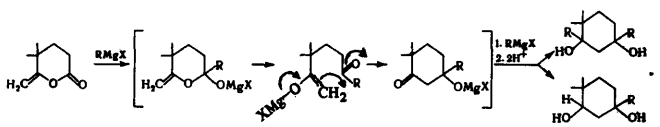
Similar observations were made by Belleau[24]. However, the reaction products formed initially—the diketone (XI) and the dihydropyran (XII)—were converted under the conditions of hydrolysis into respectively the unsaturated ketone (XIII) and the cyclohexadiene hydrocarbon (XIV), the latter of which immediately isomerised into the hydrocarbon (XV). These changes were explained by the scheme



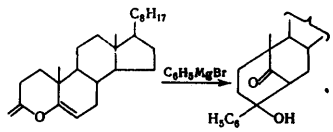
Formation of cyclohexadiene hydrocarbons by the hydrolysis of substituted dihydropyrans has been observed by the present reviewers[119], who showed that, contrary to Belleau's scheme, these hydrocarbons were formed as a consequence of intramolecular cyclisation of δε-unsaturated ketones (XVI) formed from the dihydropyrans; e.g.



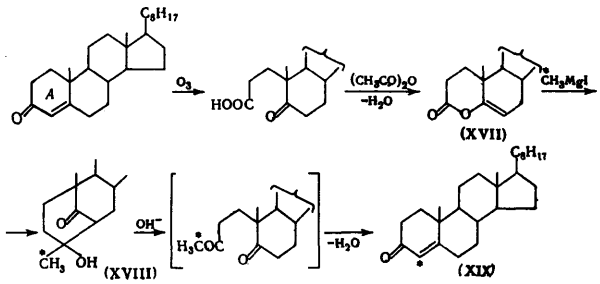
The action of organomagnesium compounds of δ-lactones containing an exocyclic double bond results in the formation of cyclohexane-1,3-diols[120], whose appearance is explained by a rearrangement resembling that described above in the reduction of unsaturated lactones with lithium tetrahydroaluminate; e.g.



Rearrangement accompanies also† the reaction of organomagnesium compounds with steroid δ-lactones containing an exocyclic (with respect to the lactone ring) double bond. In this case the reactions terminate at the stage of formation of bridged hydroxy-ketones[123,124] (reaction products of this type had earlier been regarded erroneously as 1,5-diketones and hemiacetals[40,41]); for example



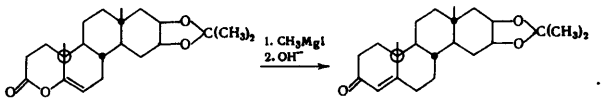
The interaction of organomagnesium compounds with steroid unsaturated lactones has been described in many papers. Thus Fujimoto[40] used this reaction to develop a method for introducing labelled carbon into position 4 in ring A of testosterone and cholestenone. The action of methylmagnesium iodide on the unsaturated lactone (XVII) (obtained from natural cholestenone) produces a bridged hydroxy-ketone (XVIII), which is then converted (by treatment with alkali) into cholestenone (XIX), which is identical with the natural product[40]:



It is obviously possible by means of this series of reactions to break down and recreate ring A of the steroid. In this way, with the use of methylmagnesium iodide containing labelled carbon, the latter can be introduced into position 4 of ring A. This scheme of Fujimoto's served (without isolation of the intermediate hydroxy-ketone of type (XVIII) for the preparation of many ^{14}C-labelled steroids for the study of their metabolism. Cholestenone[41], progesterone[46,47], and 17-hydroxy-17α-methylandrost-4-en-3-one[51] have been obtained in this way.

Fujimoto's scheme can be used also to introduce an alkyl group into the 4-position of the steroid ring system by bringing other alkylmagnesium halides into reaction with steroid unsaturated lactones. Various 4-methylated steroids—4-methylcholestenone[42,125,126], 17-hydroxy-4-methylandrost-4-en-3-one[44,125,126], 17-hydroxy-4-methyl-19-norandrost-4-en-3-one[126], and also 4-ethyl-17-hydroxyandrost-4-en-3-one[126]—have thus been prepared with the aim of studying their androgenic activity. The acetates of 17-hydroxy-4-methyl-19-norandrost-4-en-3-one[54,92] and 4-methylhydrocortisone[127] have been synthesised in a similar manner.

The reaction between unsaturated lactones and organomagnesium compounds was used by Woodward[26] to build up the ring A in his total synthesis of steroids:



The stereospecificity which he observed in the Grignard reaction with lactones differing in configuration at $C_{(10)}$ served for the separation of α- and β-epimers and confirmed their configuration[56,57,128].

Thus the reaction between unsaturated δ-lactones containing an exocyclic (relative to the lactone ring) double bond and organomagnesium compounds has been widely

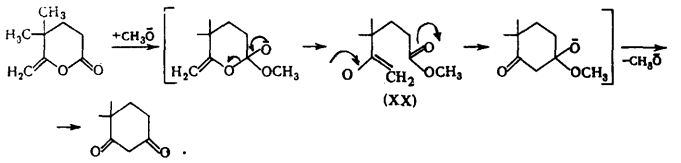
† It was found that rearrangement also accompanied reaction of the linear analogues of unsaturated δ-lactones—vinyl esters—with organomagnesium compounds[121]. The acetate of the enolic form of cyclohexanone, however, reacts normally[122].

used for various synthetic purposes—to prepare cyclohexane-1,3-diols, for the synthesis of 4-methylated steriods containing labelled carbon, and also in the complete synthesis of steroids.

4. Isomerisation of Unsaturated δ-Lactones in the Presence of Sodium Alkoxides

When heated with sodium ethoxide (for 2–10 h), unsaturated δ-lactones isomerise‡ into cyclohexane-1,3-diones[129,130].

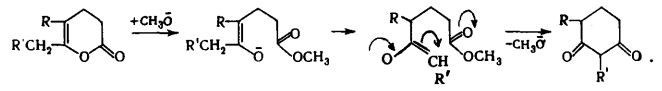
With unsaturated δ-lactones containing an exocyclic double bond (e.g. tetrahydro-5,5-dimethyl-6-methylene-2-pyrone) this transformation is explained by the scheme



(XX)

The anion (XX) is then cyclised by a kind of intramolecular Claisen condensation and is converted into the corresponding cyclohexane-1,3-dione.

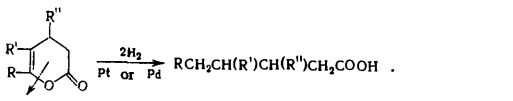
Lactones containing an endocyclic double bond are also converted, when heated with sodium methoxide, into the corresponding cyclohexane-1,3-diones. In this case the double bond probably migrates from the γδ- to the δε-position[130]:



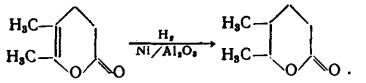
The isomerisation of unsaturated δ-lactones in the presence of sodium methoxide can be utilised for the preparation of cyclohexane-1,3-diones.

5. Catalytic Hydrogenation of Unsaturated δ-Lactones

In the presence of catalysts one or two molecules of hydrogen can be added to unsaturated δ-lactones, with the formation respectively of saturated lactones and saturated acids. Lactones containing a double bond in the ring are hydrogenated in the cold§ over platinum or palladium with the formation solely of carboxylic acids[30,131,132]:

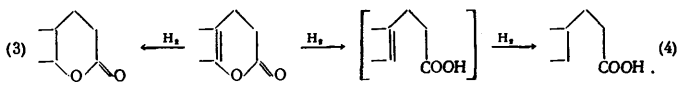


This hydrogenolysis is the only example of the opening of the unsaturated δ-lactone ring at the 1–6 bond. The hydrogenation of lactones of this type over nickel on aluminium oxide in a flow system at 200°C led to the formation of a saturated lactone¶; for example[31]

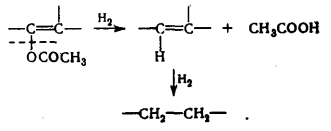


Lactones containing an exocyclic double bond are hydrogenated over a platinum catalyst (in the cold) in both possible ways[25,31].

Thus the hydrogenation of unsaturated δ-lactones can occur simultaneously in two ways—at the double bond with formation of a saturated lactone (3) and at the 1–6 bond of the lactone ring with subsequent hydrogenation of the resulting unsaturated acid (4)—the relative rates of these reactions, determined by the structure of the δ-lactone and the conditions of hydrogenation, governing the formation of the final reaction products:



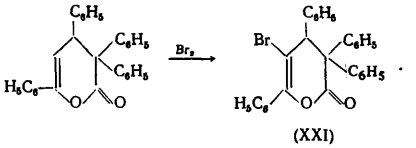
It is interesting that hydrogenation of the linear analogues of the unsaturated lactones—enolic acetates—probably occurs in the second way (hydrogenolysis of the ester bond followed by hydrogenation of the double bond)[137]:



6. Halogenation of Unsaturated δ-Lactones

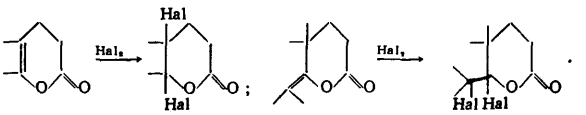
The properties of the double bond in unsaturated δ-lactones, which by analogy with vinyl esters should possess enhanced nucleophilic character, have been studied only with respect to halogenation. The lactone ring is preserved during these reactions.

Staudinger[93] brominated 3,4-dihydro-3,3,4,6-tetraphenyl-2-pyrone, obtaining a monobromo-derivative to which he attributed without proof the structure of a brominated unsaturated lactone (XXI):



(XXI)

A detailed study of the halogenation of unsaturated δ-lactones was made by Levina, Shusherina, and their collaborators[138–141], who showed that in the cold bromine[138,142] or chlorine[141] (by the action of sulphuryl chloride†) is readily added at the double bond to form reactive dihalides:



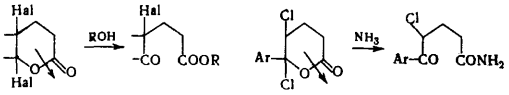
‡ Brief action of sodium ethoxide (in the cold) on unsaturated δ-lactones followed by treatment with water yields esters of δ-keto-acids[53].

§ Unsaturated δ-lactones containing the double bond in the αβ- or βγ-position add hydrogen only at the double bond under the same conditions[95,133]. Endeavours have been made to utilise this difference in behaviour between lactones containing the double bond in different positions to establish the structure of naturally occurring compounds containing an unsaturated lactone ring[134,135].

¶ An attempt to explain the formation of saturated acids by hydrogenolysis of initially formed saturated lactones[131] proved to be untenable[136].

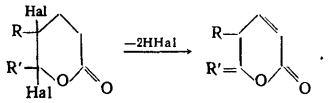
† The action of chlorine on unsaturated δ-lactones involves not only addition at the double bond but also replacement of hydrogen.

The dihalides react with water, alcohols[142-145], and ammonia[146] with opening of the lactone ring and formation of γ- and ϵ-halogenated δ-keto-acids, their esters, and their amides (in 70–100% yield):



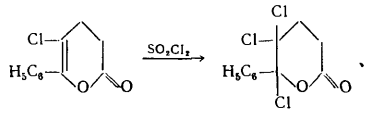
where Hal = Cl, Br and R = H, Alk.

On distillation dihalogenolactones, as well as the trihalogenolactones obtained from them by further halogenation, undergo partial[148] or complete[138,139] dehydrohalogenation, during which the lactone ring is preserved:

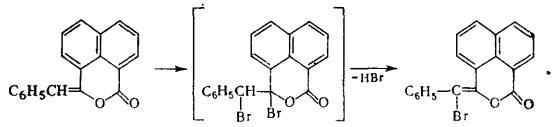


These reactions of the indirect dehydrogenation‡ of unsaturated δ-lactones (involving stages of halogenation and subsequent dehydrohalogenation) provide convenient routes for obtaining difficultly accessible 2-pyrones of various structures[138-141,147-149], including those containing a 5-bromo-substituent or a 6-bromomethyl group.

It is interesting that the nucleophilic character of the double bond is diminished in 5-chloro-3,4-dihydro-2-pyrones. They do not react at all with bromine in the cold, though they add chlorine at the double bond[150]:

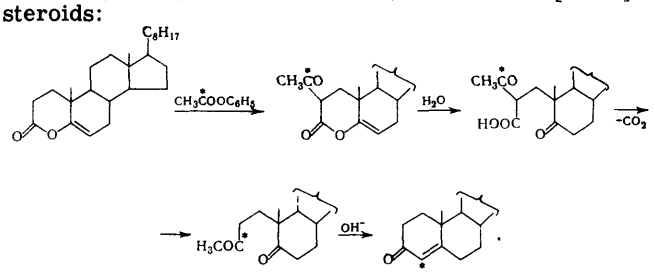


A brominated lactone containing an exocyclic double bond was obtained by the bromination of 3-benzylidenenaphthalide[151]:



7. Reactions of the α-Methylene Group

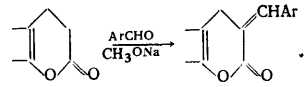
In the presence of sodium hydride the steroid unsaturated δ-lactones obtained from cholestenone and testosterone react as the methylene component in the aldol condensation with phenyl acetate[25]. When labelled phenyl acetate was used, the resulting acylated unsaturated lactones were converted (through the stages of hydrolysis, decarboxylation, and condensation) into labelled [4-^{14}C] steroids:



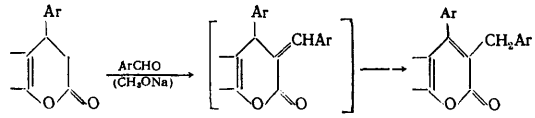
‡ The direct dehydrogenation of unsaturated δ-lactones to 2-pyrones—in boiling cymene over palladium on carbon—has been described only in the case of a triterpenoid unsaturated lactone[60].

This route has been used also to obtain labelled progesterone[49].

Unsaturated δ-lactones condense with aromatic aldehydes in the presence of sodium methoxide[152] to form 3-benzylidene-3,4-dihydro-2-pyrones:

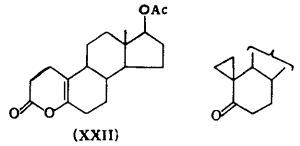


2-Pyrones can be obtained by means of this reaction from unsaturated lactones containing a 4-aryl substituent, since the benzylidene derivatives formed as intermediates immediately isomerise into 3-benzyl-2-pyrones:



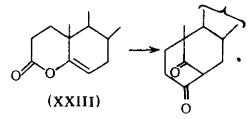
8. Photolysis of Unsaturated δ-Lactones

Interesting results have been obtained by the ultraviolet irradiation of unsaturated δ-lactones. The steroid δ-lactones (XXII) containing an endocyclic double bond was converted under these conditions into the corresponding cyclopropyl ketone in 40% yield[135]:



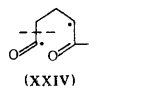
(XXII)

The lactone (XXIII) containing an exocyclic double bond isomerised into a bridged diketone (cf. isomerisation of unsaturated δ-lactones into 1,3-diketones in the presence of sodium methoxide, subsection 4)[153]:



(XXIII)

The most probable mechanism of isomerisation is that the diradical (XXIV), resulting from the lactone (XXII), is then stabilised by the elimination of carbon monoxide with formation of a three-membered ring; the diradical (XXV), formed from the lactone (XXIII), is stabilised as the dicarbonyl compound:



(XXIV) (XXV)

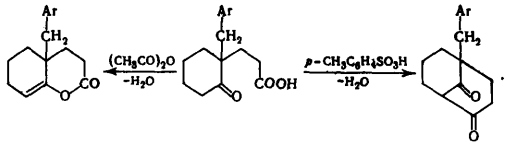
---o0o---

The above survey makes it clear that investigations during recent years have revealed the great reactivity of unsaturated δ-lactones. The two main types of reactions studied (with preservation and with cleavage of the lactone ring) exhibit the peculiarities of the chemical behaviour of these compounds, which are determined by the vinyl position of the double bond relative to the heteroatom.

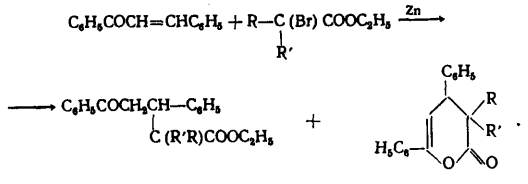
---o0o---

Papers have appeared since this review was submitted for publication which must be considered, if only very briefly, since they are directly concerned with the subject-matter of the present survey.

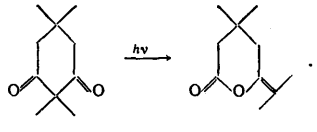
The lactonisation of δ-keto-acids has been described by the action of acetic anhydride[154,155], by the action of this reagent containing added toluene-*p*-sulphonic acid, and also by heating with toluene-*p*-sulphonic acid in tetralin solution[156]. The last method of dehydration, which was applied to β-(1-benzyl-2-oxocyclohexyl)propionic acids, led unexpectedly to the formation of bridged diketones, whereas the action of acetic anhydride on these keto-acids yields the normal dehydration products—unsaturated δ-lactones[157]:



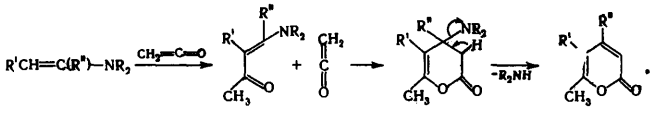
Unsaturated δ-lactones have been obtained from the Reformatsky reagent and αβ-unsaturated ketones, by spontaneous cyclisation of the δ-keto-esters formed directly[158]:



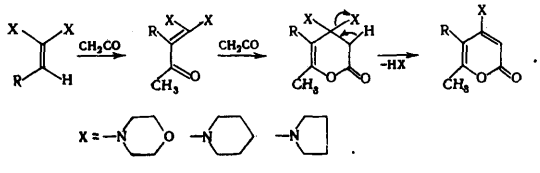
The photochemical conversion has been described of a substituted cyclohexane-1,3-dione into a δ-lactone containing an exocyclic double bond (the reverse reaction to the isomerisation of unsaturated δ-lactones into 1,3-diketones described in Section III, subsections 4 and 8)[159]:



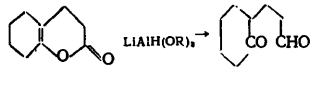
Unsaturated δ-lactones can be obtained by the interaction of acylated enamines with keten, and are easily further converted into 2-pyrones[160]:



Keten reacts similarly with 1,1-diaminoethylenes to form unsaturated 4,4-diamino-lactones[161]:



Martin et al.[116] have shown that 3,4-dihydro-5,6-cyclohexano-2-pyrone is reduced by lithium hydrotri-t-butoxyaluminate to a δ-keto-aldehyde (without rearrangement of the carbon skeleton—cf. Section III, 2):



whereas the isomeric lactone containing an exocyclic (relative to the lactone ring) double bond will give under these conditions a mixture of reduction products obtained with (XXVI) and without (XXVII) rearrangement of the carbon skeleton (cf. Section III, 2):

I. INTRODUCTION

A division of metal complexes into "inert" and "labile" appeared very early in the development of the chemistry of complex compounds. The "inert" complexes included compounds of tervalent cobalt and chromium, the platinum metals, and certain others. These compounds are characterised by the slowness of their formation and breakdown; it was on these that the various types of isomerism and the important reactions of complexes were studied. Research on the kinetics and the mechanism of changes undergone by these compounds has been especially widely developed during recent years[1].

However, the so called "labile" complexes remained outside the scope of contemporary kinetic methods, and all reactions involving them were described as "instantaneous". There are considerably more "labile" than "inert" complexes, and the kinetics of complex formation thus covered a relatively small proportion of known reactions.

During recent years kinetic methods of investigation have appeared which enable reactions to be studied having a half-life period $t_{1/2}$† of 10^{-9} to 10 s,[2,3] i.e. over a considerably wider range (10^{10}) than for reactions occurring at the customary rates (10–10^4 s). With the appearance of these methods the reactions of the "labile" complexes became accessible to investigation. The first results obtained already show the promise of this branch of chemical kinetics.

Quite a large amount of experimental information has now accumulated on the kinetics of fast reactions. Two symposia have been devoted to these matters, the proceedings of which have been published in special issues of journals[4,5].

† The half-life period is the time during which half the initial concentration of a substance, a deficiency of which has been taken, is used up.

Methods of investigating fast reactions in solution and some of the available experimental information have been discussed in two large monographs[6,7]. There are good reviews of individual aspects of the kinetics of fast reactions[8-10] and reactions involving complex formation[11-15]. However, a sufficiently complete critical review of methods and experimental results on the kinetics of fast complexing reactions in solution is lacking. The present paper is intended to fill this gap.

II. EXPERIMENTAL METHODS OF STUDYING FAST COMPLEXING REACTIONS

All existing methods of investigating fast complexing reactions can be divided into a few large groups—flow methods, relaxation methods with step perturbation, relaxation methods with continuous perturbation, nuclear magnetic resonance (n.m.r.) and electron spin resonance (e.s.r.) methods, and electrochemical methods—which are compared in Table 1.

Table 1. Characteristics of methods for studying fast complex-forming reactions.

Methods	Limits of applicability, (time, s)		Soln.vol. for a kinetic curve
	min.	max.	
Classical methods	10	10^5	0.1—10 ml
Flow methods	10^{-4}	10	0.1 ml — 2 litres
Relaxation methods			
(*a*) step methods	10^{-7}	1	0.1—10 ml
(*b*) ultrasonic absorption	10^{-7}	10^{-4}	0.2—100 litres
Nuclear magnetic resonance	10^{-9}	10^{-1}	0.1—1 ml
Electrochemical methods	10^{-6}	1.0	1 ml

Flow methods, which are widely employed in studying reactions having half-life periods from 0.001 to 10 s, are the simplest from the point of view of apparatus, and are the only methods which enable kinetic curves for the processes to be obtained directly.

1. Flow Methods

The characteristic feature of flow methods is that solutions of the reactants are fed continuously to a special mixer, after which the reaction solution, in the form of a homogeneous, constant-velocity stream, enters an observation tube.

The course of the reaction can be followed firstly by using some physicochemical method to measure the reactant concentrations along the observation tube, in which the flow speed of the reactants is constant throughout the time of the measurements. In this case the distance from the mixer to the point at which the variation in reactant concentrations is recorded is proportional to the time which has elapsed from the start of the reaction to the instant of observation. Secondly, by halting the flow abruptly, we can use a suitable transducer and a rapid-acting device to record the variation in reactant concentrations, after the flow has been stopped, at any point in the observation tube. These two methods of measurement are termed the "constant-flow method" and the "stopped-flow method" respectively.

There are also a few methods which possess elements of both constant-flow and stopped-flow methods. Among these we have arbitrarily included accelerated-flow and quenching methods in the first group, and the method of removable partitions in the second.

The most crucial unit in the flow apparatus is the mixer. The design of the mixer determines the time of mixing of the reactant solutions, which determines the lower time limit of the flow apparatus [16,17], since the time of mixing must be much shorter than the half-life period of the reaction.

Among known designs, relatively simple mixers are most often used, with the solutions fed tangentially, these being employed for the study of reactions in which $t_{1/2} \geqslant 10^{-3}$ s. This is probably the limiting time for such mixers [16,18], since they have a special mixing chamber, preceding the observation tube. The presence of this chamber makes it impossible to define the instant of complete mixing. For the study of more rapid reactions, promise is shown by mixers having more than one channel for introduction of the reactant solutions, the minimum time of mixing being 10^{-4} s. [19]

Kletinik [18], by using a special bellows-type mixer, was able to shorten this time to 5×10^{-5} s. The disadvantage of this mixer is that it is made of metal foil, which may affect the kinetics of the reaction under investigation.

The functioning of the mixer can be tested in several ways [7]. The "chemical" method consists in determining the completeness and time of mixing of the reactant solutions in the mixer by means of a very fast chemical reaction, e.g.

$$H^+ + OH^- \rightleftarrows H_2O, \quad (1)$$

$$I_2 + 2S_2O_3^{2-} \rightleftarrows S_4O_6^{2-} + 2I^-. \quad (2)$$

In the "physical" method liquids differing in refractive index are mixed. In both cases the flow of solution should be homogeneous throughout the length of the observation tube following the mixer. A test method which uses a standard reaction is widely used, and is the most reliable of existing methods. The reaction chosen as standard is very often [6,7]

$$H_2CO_3 \rightleftarrows CO_2 + H_2O. \quad (3)$$

(*a*) Constant-flow methods. With constant-flow apparatus the solution, after leaving the mixer, enters the observation tube at a constant rate. The time t_n (in seconds) required for the liquid to reach a plane n crossing the observation tube is then given by the equation [18]

$$t_n = \frac{l_n}{R} \quad (4)$$

where R (mm s^{-1}) is the flow speed, while l_n (mm) is the distance from the plane of mixing to the point of observation, and the time elapsed after mixing is proportional to the length of the observation tube. With a known flow speed R, it is possible to determine the time from the start of the reaction to the instant of observation at the points n. By measuring the reactant concentration at these points by some physical method, we can obtain the kinetic curve for the given reaction.

The minimum time of reaction which can still be recorded on a constant-flow apparatus will depend on the design of the mixer and the rate of flow in the observation tube, but increasing the flow speed above 10 m s^{-1} may result in cavitation [20].

The solutions can be supplied to the mixer either by gravity feed [21], by means of compressed gas [22-24], or by means of syringes [25].

Among physical methods for recording the variation in concentration in the observation tube, spectrophotometric methods are most often employed [26-30].

In the simplest types of apparatus, light filters are used as monochromators, while the sensors are photocells connected to a measuring instrument, usually a galvanometer [26-30]. Such instruments are usually of low sensitivity and small resolution. The variation in light absorption along the observation tube is recorded from the galvanometer readings, which results in diminished accuracy, increased time of measurement, and hence considerable consumption of the reactant solutions. With the use of monochromators of greater dispersion, flow apparatus having spectrophotometric recording is employed for the study of complicated chemical reactions. Thus with a Beckman spectrophotometer as monochromator it was possible to establish that at least six different processes occurred in the oxidation of sulphurous acid by iodine [32,33].

A double-beam apparatus has been described [34]. The most perfect instrument of this type has been described in Ref. 25. Its distinguishing feature is that the absorption spectra of the test solution at definite points in the observation tube are recorded by means of a monochromator and a photomultiplier, the latter connected to an electronic oscillograph, the screen of which can be photographed with a high-speed cine-camera. If spectrophotometric methods are to be applied, of course, the light absorption of the test solutions must change in the course of the reaction. This somewhat restricts the use of such apparatus.

Great versatility is shown by apparatus having thermometric transducers, which are moved inside the observation tube by means of a special device or—what is not as good—are fixed in the tube, when a certain relation must exist between the size of the transducer and the internal diameter of the tube [17]. The sensitivity of instruments in which the thermocouple current is not amplified is very

low, so that only reactions whose heat of reaction exceeds 20 kcal mole^{-1} can be studied with such apparatus. Their sensitivity can be considerably improved by using thermistors [35-39] or d.c. photoelectric amplifiers [40] as transducers. An apparatus of this type described by Perlmutter-Hayman [41] has enhanced sensitivity, is convenient in operation, and requires a relatively small quantity of reactant solutions.

Reactant concentrations in the observation tube can be determined also from conductivity measurements [18,22-24,42], potentiometrically [43-45], and by the n.m.r. method [46,47]. This last method is very promising for the study of complicated chemical reactions, since it permits the unambiguous identification of many intermediate products and changes occurring in the reactant molecules or ions.

The accelerated-flow and quenching methods can be included in the constant-flow method. In the former [48,49] the transducers are fixed at a certain point in the observation tube, whereas the flow speed changes during observation. Both the variation in the flow speed and that of the reactant concentrations with time are recorded oscillographically. The results can be used to plot a kinetic curve for the process. Considerably less solution is required to determine the kinetic curve in the accelerated-flow method than in the other constant-flow methods.

In the quenching method [50-55] the solution of the reactants, after leaving the mixer and flowing through the observation tube, is rapidly mixed with a "stop solution". Ordinary analytical methods are used to determine, in the reaction mixture "frozen" in this way, the change occurring in the reactant concentrations during the time required for the reactant solution to pass from the first to the second mixer, where this solution is mixed with the "stop solution". This time is governed by the dimensions of the tube and by the flow speed.

The apparatus for the quenching method is very simple, while the reactant concentrations can be determined by ordinary analytical methods (gravimetrically or by titration) with great accuracy. The quenching method is widely used for the study of intermediate products, and also in investigating various exchange reactions.

(*b*) Stopped-flow methods. Whereas about a litre of reactant solution is required to plot the kinetic curve when constant-flow apparatus is used, stopped-flow apparatus requires only a few tenths of a millilitre of the reactant solutions for this purpose, and the whole kinetic curve can be obtained from a single experiment. This considerably facilitates working with expensive, rare reagents, but more complicated apparatus is employed in the stopped-flow method.

In such apparatus [56] the rapid flow of reactant solutions is abruptly halted at a certain instant. At the same instant a recording device, connected to a transducer fixed in the observation tube near the mixer, registers the time variation of the reactant concentrations in the halted stream. The reactant solutions are fed to the mixer and the observation tube from syringes, whose pistons are interconnected and are moved by hand, a spring, or an electric motor.

The stream is halted either by abruptly stopping the syringe pistons or by means of special valves following the observation tube [57,58]. The last method is the most reliable, since it excludes entry of solution into the observation tube after the flow has been stopped, e.g. because of possibly play in the mechanical system feeding the solutions.

In all the forms of apparatus described in the literature the kinetic curve is recorded on an oscillograph, triggered either by means of a special photoelectric device [57] or by electromechanical means. The variation in concentration of the reactant solutions is recorded photoelectrically [57-61]. The most perfect apparatus operating by the stopped-flow method with spectrophotometric recording has been described by DeSa and Gibson [62]. Using a double-beam spectrophotometric arrangement with modulated light flux, these workers considerably improved the sensitivity (to 10^{-3} unit of optical density) and lowered the noise level.

The electrical-conductivity [60] and potentiometric [40-42] methods are seldom used in stopped-flow apparatus. Thermometric transducers are not employed here because of their great inertia. However, fine-wire thermocouples [63], having considerably less inertia, can be used in this type of apparatus.

Among these methods can be included the removable partition method, proposed by Connick and his coworkers [64,65] for studying the kinetics of reactions occurring in very dilute solutions, since in this case long cuvettes can be used for observation. As in the stopped-flow method, the solutions are rapidly mixed and the reaction is followed oscillographically, but the removable-partition method differs greatly in the mode of mixing and the construction of the cuvette for observation by the stopped-flow method.

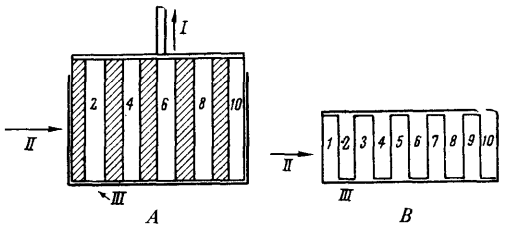

Figure 1. Diagram of cuvette for removable-partition method: *A*) side-view; *B*) plan; *I*) direction of movement of partition by action of spring; *II*) direction of observation; *III*) body of cuvette; *1, 2, 3, 4, ...*) compartments of cuvette.

The cuvette illustrated in Fig. 1 has a movable partition dividing the whole cuvette into a series of compartments (ten in the illustration), with one reactant solution in the even compartments, and the other in the odd compartments. This partition can be removed (upwards in the diagram) by means of a spring, and then the solutions in the isolated compartments will rapidly mix (within 10^{-3} s) and the variation in light absorption of the test solution will be recorded on an oscillograph.

Table 2 gives brief technical characteristics of the types of apparatus designed for the study of fast chemical reactions by flow methods. It is seen that these methods are suitable for reactions having half-reaction times of 10^{-4} to 1 s.

There is little prospect of constructing new mixers and increasing the flow speed to shorten the lower time limit for flow apparatus.

The use of non-aqueous solvents and lowering the temperature of the reactant solutions [66,67] permits the study of reactions which are very fast at 25°C (having rate constants of $\sim 10^6$ M s^{-1}) by existing flow techniques.

A very interesting possibility is the use of magnetic recording instead of photographing oscillograms, which is used to obtain kinetic curves in existing apparatus operating by the stopped-flow method [68].

In the study (by the stopped-flow method) of complicated reactions involving coloured substances, great opportunities are offered by high-speed spectrophotometric instruments, which enable the spectra of substances taking part in processes occurring within 10^{-6} s to be photographed[69].

Table 2. Characteristics of flow methods.

Methods	Limiting time × 10^3, s	Soln. for a kinetic curve, ml	Temp. range, °C	Absorbing layer, mm	Material of mixer	Measurement of concn.
Constant-flow methods	0.1-1		0-50	1-5	glass, plastic, brass	spectrophotometric, conductivity, heat effect
(*a*) Visual readings		500-2000				
(*b*) Automatic recording		6-100				
Accelerated flow	1.0	0.1	10-30	2	plastic	colorimetric
Quenching	10	100	10-50		plastic, glass	any analytical method
Stopped flow	2-5	0.1-1.0	-120 + 40	1-10	glass, plastic	colorimetric, spectrophotometric, potentiometric, conductivity
Removable partitions	15	30	14-30	50	steel	colorimetric

Flow methods (especially the stopped-flow method) are widely used to study the kinetics of fast complexing reactions. Reactions involving the ions of copper[70], iron[71,72], and nickel[73] have been studied in especial detail by these methods.

Among methods for measuring concentrations, the spectrophotometric method has become the most widely used, being the simplest but sufficiently widely applicable and sensitive.

Complex formation is mostly studied in the presence of a large excess of foreign electrolytes, which makes it difficult to use conductivity measurements to determine the reactant concentrations, since existing instruments permit the kinetic curve of a reaction to be recorded only if the change in conductivity occurring during the reaction exceeds 10%. With the use of special amplifiers[74], however, this limit has been lowered to 0.1%, which has enabled the complexing reaction

$$Be^{2+} + HF \rightleftarrows BeF^{+} + H^{+} \qquad (5)$$

to be studied in 0.2 M potassium chloride solution. This opens up wide prospects for the study of various complexing reactions, especially those which are not accompanied by a change in light absorption.

Concluding this survey of flow methods, we must note that these methods can be applied to the study of chemical reactions having $t_{1/2} > 10^{-4}$ s.

Apparatus having a constant flow and electrometric transducers is most simply constructed. For the study of multistage reactions involving coloured substances, more complicated spectrophotometric recording is most often employed, enabling the kinetics of conversion of any of the coloured substances involved in the reaction to be studied directly.

If, however, it is necessary to work with a small consumption of reactants, more complicated apparatus is used, operating by the stopped-flow method, which has the same characteristics as constant-flow instruments, but requires less than 1 ml of reactant solutions for the determination of one kinetic curve.

2. Relaxation Methods

At the present time only relaxation methods permit direct observation of the course of chemical reactions occurring in times less than 10^{-4} s, which considerably facilitates the study of multistage processes of complex formation, such as, for example[75],

$$Co^{2+} + gly \rightleftarrows [Co(gly)]^{+}, \qquad (6)$$

$$[Co(gly)]^{+} + gly^{-} \rightleftarrows [Co(gly)_2], \qquad (7)$$

$$[Co(gly)_2] + gly^{-} \rightleftarrows [Co(gly)_3]^{-}. \qquad (8)$$

(gly = the glycine ion)

A serious limitation of these methods is that they are applicable only to equilibrium processes when the equilibrium has not been displaced too far in the direction of formation of the reaction products.

In relaxation methods a system in a state of dynamic equilibrium is by some means brought out of this equilibrium. After cessation of the disturbing action, a process tending to re-establish the original equilibrium begins in the system. This process is termed relaxation. Relaxation curves are described by the equation

$$I = I_0 e^{-\frac{t}{\tau}}, \qquad (9)$$

where I_0 and I are parameters, which vary linearly with the concentration of an indicator substance, at times t_0 and t respectively, and τ is the relaxation time, which defines the rate of relaxation and is given numerically by the time required for I_0 to change by a factor e. The chemical equilibrium can be disturbed by varying certain physical parameters, such as temperature, pressure, electric field strength, etc.

The relaxation resulting from chemical processes is usually recorded from the variation in the light absorption or the electrical conductivity of the test solution.

With the relaxation time τ known, we can use the mathematical procedure suggested by Eigen[76-79] to calculate the rate constant of the processes under investigation. Thus for a reaction of the type

$$AB \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A + B \qquad (10)$$

for example, the relaxation time is given by the equation

$$\tau^{-1} = (k_1 + 2k_{-1} X_e) \qquad (11)$$

where k_1 and k_{-1} are the rate constants of forward and reverse reactions respectively, and X_e is the equilibrium concentration of the species A and B, provided that [A] = [B].

If the equilibrium constant of (10) is unknown, k_1 and k_{-1} can be determined from the dependence of τ on the concentration of the species AB. When the equilibrium constant

is known, the rate constant k_1 is calculated for the same cases by means of the equation‡

$$k_1 = [\tau([A] + [B] + K]^{-1} . \quad (12)$$

Here [A] and [B] are the equilibrium concentrations of the species A and B, and K is the equilibrium constant corresponding to Eqn. (10). Equation (12) is valid provided that the concentrations [A] and [B] differ at most by a factor of 100. The rate constant k_{-1} for formation of AB is calculated from the equation

$$k_{-1} = \frac{k_1}{K} . \quad (13)$$

Relaxation methods can be divided into two groups—involving step and continuous perturbation—according to the mode of varying the physical parameters disturbing the chemical equilibrium. The first group includes methods involving abrupt changes in electric field strength, pressure, or temperature, as well as the abrupt change of concentration suggested recently[80].

A. Methods Involving Step Perturbation

(*a*) Temperature-jump method. This method is mostly widely used and widely applicable of the relaxation methods described in the literature. It can be employed for equilibrium reactions which are accompanied by a thermal change. The temperature variation of the equilibrium constant K is given by the equation

$$\frac{d \ln K}{dT} = \frac{\Delta H}{RT} \quad (14)$$

where T is the temperature and ΔH the heat of reaction. Relaxation curves are recorded oscillographically from the variation in the light absorption or the electrical conductivity of the solutions.

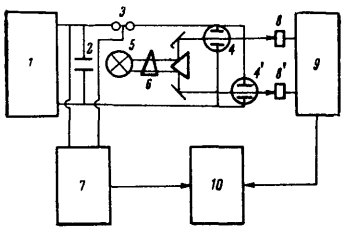

Figure 2. Diagram of apparatus for studying the kinetics of chemical reactions by the temperature-jump method.

For ionic solutions a jump in temperature is achieved by means of a pulse discharge from a capacitor charged to a high voltage[79,81-83]. Fig. 2 shows a simplified diagram of the forms of apparatus used, proposed by Eigen and his collaborators. A high-voltage current source *1* charges the condenser *2* of capacitance 0.1 μF to a voltage at which discharge takes place across the spark gap *3* and through cuvettes containing the test solution *4* and the reference solution *4'*. Platinum electrodes are inserted into the cuvette containing the test solution, of volume 50 ml, in such a way that ~ 1 ml of the test solution lies between them. During the high-voltage discharge, which lasts a few microseconds, the solution between the electrodes is heated by approximately 10 deg. The relaxation curves are recorded by means of a photocolorimetric device consisting of a light source *5*, a monochromator *6*, and photomultipliers *8* and *8'* connected differentially. The amplifier *9* is connected to an electronic oscillograph *10*, triggered by the release device *7*. The rate constant of the processes which occur can be calculated from the variation in optical density of the solution during relaxation[6,7].

It is very important that the duration of the pulses should approximate to the relaxation time. If the duration θ of a pulse differs markedly from the relaxation time of the process under investigation, the error involved in the measurements is considerably increased. The way in which the ratio τ/θ affects the character of the relaxation observed is shown in Fig. 3.

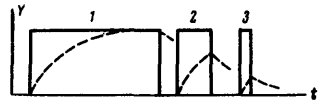

Figure 3. Variation in relaxation signal (broken curve) for periodic pulses (pulse signal represented by full line)—where Y is the magnitude of the signal and t is the time—as a function of the ratio of the duration of the pulse to the relaxation time (θ/τ):
1) 4; *2*) 1; *3*) 0.25.

In apparatus intended for the kinetic study of fast chemical reactions using a temperature jump produced by the discharge of a capacitor (as e.g. in the above apparatus of Eigen's), it is very difficult to vary the duration of the pulse or control its amplitude. An apparatus[84] in which the solution is heated by a powerful high-frequency pulse taken from a magnetron oscillator is free from this defect. This apparatus can be used also to study reactions occurring in non-ionic solutions, where the Eigen method is inapplicable. A periodic temperature-jump apparatus was constructed using repeated high-frequency pulses to heat the test solution[85], which both increased the output of the investigator and improved the reliability of the results, but unfortunately the size of the jump obtainable was small (~ 1 deg).

Equipment combining the flow method with the temperature-jump method is very promising for the study of complicated multistage reactions and also fast irreversible processes[86,87].

(*b*) Electric field-pulse methods. The electrical conductivity of a weak electrolyte increases with increase in the electric field strength. This phenomenon has been termed the Second Wien effect[88]. It is explained by a shift in the equilibrium—weak electrolyte molecule-ion-pairs-free ions—towards formation of free ions.

‡ It would seem that this equation should read

$$k_1 = K\tau^{-1}([A] + [B] + K)^{-1}$$

(Ed. of Translation).

The increase in conductivity is proportional to the applied voltage between 40 and 100 kV cm^{-1}. The total increase may reach 10% of the conductivity in the absence of an electric field. The magnitude of the change is given by the equation[89]

$$\frac{\Delta\lambda}{\lambda_0} \equiv \frac{\lambda_x - \lambda_0}{\lambda_0} = \frac{1-\alpha}{2-\alpha} \cdot b\Delta E \qquad (15)$$

where λ_x and λ_0 are the conductivities of the solution in a field of strength x and in zero field, $\alpha = c_i/c_0$ is the degree of dissociation under the influence of the field, c_i being the concentration of ions formed under the action of the field and c_0 the total concentration of the weak electrolyte, E is the strength of the field, and b is a parameter depending on the mobility of the ions, the absolute dielectric constant, and the temperature.

The electric field–pulse method was first used by Eigen and his coworkers in studying the kinetics of the reaction[76,90-92]

$$H^+ + OH^- \rightleftarrows H_2O. \qquad (16)$$

Relaxation curves are mostly recorded from the variation in conductivity, and the experimental results obtained are processed by the usual methods described previously.

(*c*) Pressure-shock methods. The effect of pressure on the equilibrium constant is represented by the equation[9]

$$\beta = \exp\left[\int_{P_1}^{P_2} (\partial \ln K/\partial P)_s dP\right] = \exp\left[\int_{P_1}^{P_2} \frac{-\Delta V^0 + \Delta H^0 (\partial V/\partial T)_p C_p}{RT} dP\right] \qquad (17)$$

where ΔV^0 and ΔH^0 are the changes in volume and enthalpy, and $\beta = K_2/K_1$, in which K_2 and K_1 are respectively the equilibrium constant at $P = P_2$ and $P = P_1$: a change in pressure thus produces a change in the equilibrium constant, as a consequence of which relaxation processes occur at a rate determined by that of the chemical reactions involved[93-95].

The magnitude of the shift β is 0.004 with $\Delta V^0 = 1$ cm^3 $mole^{-1}$ and a change in pressure from 1 to 100 atm[96]. This shift can be easily recorded by various physicochemical methods.

The types of apparatus used in this method differ both in the way in which the pressure is changed and in the method adopted to measure the reactant concentrations during the relaxation process.

The pressure can be changed by opening a special tap connecting an autoclave to a cylinder containing compressed gas[96]. Since this tap is opened manually, reactions having a half-period exceeding 0.1 s can be studied with such apparatus.

A more modern method of producing a pressure shock[97] consists in rapidly puncturing with a special steel needle a thin steel diaphragm fitted in the system connecting the compressed-gas cylinder with the autoclave containing the test solution. As a result, the pressure in the autoclave drops sharply (within 10^{-5} s). As the workers who have used this method state, reactions can be studied having $t_{1/2} > 10^{-5}$ s.

In all the types of apparatus described, the reactant concentrations are determined either from conductivity measurements or spectrophotometrically.

The great advantage of the pressure shock method is the possibility of studying directly conversions of outer-sphere into inner-sphere complexes and conversely, which is impossible by any other method with the exception of n.m.r.

B. Methods Involving Periodic Perturbation

Fast chemical reactions can be studied not only by pulse methods but also by methods involving a periodic action. Among these, ultrasonic absorption and nuclear magnetic resonance have become the most widely used.

(*a*) Ultrasonic absorption. By means of ultrasonic vibrations it is possible to study chemical reactions whose duration approximates to the period of the sound wave. The frequency dependence of the absorption of sound is influenced by the changes in free energy, entropy, and volume occurring during the reaction, and also by the rates of the chemical reactions taking place in the system[98-101], so that both kinetic and thermodynamic data can be obtained by studying the ultrasonic absorption of the test solution[89,102].

For single-stage reactions the ultrasonic absorption–frequency curve passes through a maximum, the position of which can be used to determine the relaxation time, and from which the reaction rate constant can be calculated by means of Eqns. (11) and (12). With multistage reactions the mathematical processing of the experimental results is considerably more complicated[103,104]. There exists a method of calculation which is applicable only to a two-step process[105,106].

The equipment used in the study of fast chemical reactions by the acoustic method is that usually employed for measuring the velocity and absorption of ultrasound in liquids[60,107,108]. The disadvantages of this method include the relative complexity of the apparatus used, the difficulties of processing the experimental results for complicated reactions, and also the large quantities of solutions necessary for an experiment.

(*b*) Nuclear magnetic resonance. The n.m.r. method is applicable to the kinetic study of chemical reactions occurring at very varied rates. The essence of the method is that, if an atomic nucleus possessing a magnetic moment is placed in a homogeneous magnetic field, its energy levels will be split, and energy quanta may be absorbed or emitted on transition of the nucleus from one split level to another. The magnitude of this splitting will depend on the degree of nuclear screening, which is determined by the nature of the chemical compound formed. Reactions occurring at normal rates can be studied from the time variation in the intensity of the absorption band, while the change in shape of the absorption bands, in particular their broadening, will provide information on the kinetics of reactions which are 50% complete in 10^{-8} s.

Details of the apparatus employed in n.m.r. investigations of fast reactions and of methods of calculating rate constants from experimental results can be found in numerous monographs and reviews on this topic[6,7,104,109-114].

The n.m.r. method has found especially wide use in the study of fast exchange reactions. This requires that the parameters of these n.m.r. absorption bands should be known for the compounds in the absence of exchange. Such data can be obtained, for example, by determining the n.m.r. spectra of the pure compounds. In the case of rapid exchange, the absorption bands of the individual compounds become wider, and at a certain rate they merge into a single broad band, which gradually narrows with increase in the rate of exchange.

The coalescence of absorption bands with rapid exchange can be explained by means of the uncertainty principle,

which in the present case can be written in the form

$$\tau \Delta\nu \approx {}^1/_2\pi , \qquad (18)$$

where $\Delta\nu$ is the distance (in cm^{-1}) between the resonance signals and τ is the shortest time in which these signals still exist separately.

From the shape of the band observed and also its broadening compared with the bands of individual compounds, the rate of exchange can be found [104].

To obtain more accurate data, and also to determine the order of the reactions, the exchange velocity is increased, by altering certain parameters (temperature, catalyst concentration), until the absorption band maxima corresponding to the different chemical shifts coalesce. The rate constant of the reaction is determined from the position and shape of the resulting band, and the order of the reaction is found from the dependence of the broadening $\Delta\nu$ of the band on the variable parameter P. Four cases can be distinguished [115,116] according to the nature of the dependence (Fig. 4).

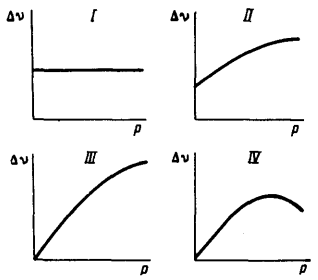

Figure 4. Dependence of $\Delta\nu$ on a parameter P for various types of chemical reactions.

With the type of dependence of $\Delta\nu$ on the parameter P represented by case I (Fig. 4), exchange is very slow. Only "outer-sphere relaxation" occurs, when species in the outer sphere take part in the relaxation process [117]. This type of relationship is observed, for example, with the ethylenediamine complexes of nickel.

In case II the curve obtained does not start from zero, as is possible when first-order and second-order reactions are occurring simultaneously in the system. This relationship can be used to calculate the rate constants of both reactions, as has been done [115] for the glycine complexes of tervalent cobalt and iron.

Case III corresponds to second-order reactions, whereas case IV is observed when variation in the parameter P is accompanied by variation in the concentration of species which make different contributions to the broadening of the absorption band. Case IV is observed with many compounds of bivalent copper [115].

The possibilities of the n.m.r. method in the study of complicated reactions can be considerably extended by using it with flow apparatus [46].

It must be noted that the n.m.r. method is applicable (when the change in shape of absorption bands is used to determine the rate constant) only for the study of very fast reactions of complex formation (having $t_{1/2} < 10^{-4}$ s) in equilibrium systems involving elements whose nuclei have spins differing from zero.

C. Electrochemical Methods

A group of phenomena are known in polarography in which the main electrochemical process of reduction of the depolariser is preceded by chemical reactions occurring in the layer adjacent to the electrode, as a result of which either depolariser is regenerated or it is formed from compounds which are not reduced under the given conditions. As a result of these processes polarographic currents arise which are different in nature from diffusion currents [118], and are termed catalytic or kinetic currents. The magnitude of both catalytic and kinetic currents will depend on many factors, in particular the rate of the chemical reactions associated with the electrochemical process [119,120].

For coupled processes of the type

$$M^{n+} + L \rightleftarrows ML^{n+} , \qquad (19)$$

$$ML^{n+} + me = ML^{(n-m)+} \text{ (on the electrode)} . \qquad (20)$$

Brdička and Wiesner [119] deduced the approximate equation

$$\mu k_1 = \frac{i_{cat}}{nFq10^3 C_M (aC_L - i_{cat})} \qquad (21)$$

linking the strength of the catalytic current with the rate constant k_1 of reaction (19), in which n is the number of electrons involved in the electrochemical process, F is Faraday's constant, q is the mean surface area of the mercury drop, i_{cat} is the maximum catalytic current (in μA), $a = 605nD_L^{1/2}m^{2/3}t^{1/6} \times 10^3$ is the Ilkovič constant, and μ is the thickness of the layer adjacent to the electrode, in which chemical reaction occurs.

For analogous chemical reactions Koutecký [120] linked the rate constant of the chemical reaction with the catalytic (kinetic) current by the more accurate equation

$$\frac{i_{kin}}{i_{diff}} = \frac{0.886\,[(k_1/K)\,t]^{1/2}M}{1+0.886\,[(k_1/K)\,t]^{1/2}M} - \frac{11D^{1/2}m^{-1/2}t^{1/2}(k_1t/K)^{1/4}M^{1/2}}{1+0.14\,(k_1t/K)\,M^2} , \qquad (22)$$

where i_{kin} is the kinetic current, i_{diff} is the diffusion current, $K = k_2/k_1$ is the equilibrium constant of (19), with k_1 the rate constant for formation of the complex ML^{n+} and k_2 the rate constant for dissociation of this complex, m (in mg s^{-1}) is the mercury drop rate, t (s) is the lifetime of a drop,

$$D = (D_M + KD_L)(1 + K) \text{ and } M = (D/D_L)(D_M/D_L)^{1/2}$$

in which D_M and D_L are the diffusion coefficients of the metal ion and the ligand respectively. Equation (22) holds provided that $K \gg 1$ and $(k_1 + k_2)t \gg 1$, i.e. for relatively fast reactions. Tabulated values of the function (22), found by Koutecký and Čižek [121], can be used to calculate the rate constant of reaction (19) from experimental data.

Rate constants of simple chemical reactions of the first and second order can be calculated in a similar manner. If, however, the reaction taking place in the reaction layer is complicated or of order higher than the second, it is difficult to use electrochemical methods to determine the rate constants of fast reactions. Furthermore, the results obtained have poor reproducibility, and require a large excess of the ligand and of foreign substances.

D. Other Methods

Besides the above methods, fast chemical reactions in solution are studied also by concentration relaxation [80],

flash photolysis[122] and radiolysis[123], and pulse conductivity[94]. The rate constants of ultrarapid reactions (having half-conversion periods of 10^{-14}–10^{-11} s) can be calculated from the line broadening in the Raman spectra[124,125]. These methods have not yet become widely used for the study of fast complexing reactions.

III. FAST COMPLEXING REACTIONS

Most cases of complex formation can be regarded as multistage processes, in which the chief part is played by substitution reactions. In aqueous solution all ions are hydrated, so that even with simple electrostatic interaction it is most probable that the formation of complex species involves several stages, for example

$$M^+aq + L^-aq \rightleftarrows [M^+aq][L^-aq] \quad (23)$$

(formation of ionic association complexes),

$$[M^+aq][L^-aq] \rightleftarrows [M^+aqL^-] \quad (24)$$

(formation of ion-pairs),

$$[M^+aqL^-] \rightleftarrows [ML] + aq. \quad (25)$$

It has been shown by various methods that the formation of association (outer-sphere) complexes is controlled by diffusion processes, and has a rate constant of the order of 10^8–10^{10} s^{-1}. In many cases the rate-determining stage is the conversion of outer-sphere complexes into complex compounds containing ligands in the inner sphere (reaction 25); it is more affected than any other stage by the individual characteristics of the interacting species[12].

Substitution reactions involved in the formation of complex compounds can be of two kinds—replacement of one ligand by another or else of one metal ion by another in the complex compound—and in Ingold's proposed classification these types are termed respectively nucleophilic (S_N) and electrophilic (S_E) substitutions. The type of substitution is determined by the starting materials and the final reaction products. Most fast reactions of complex formation which have at present been studied are nucleophilic substitutions (S_N).

1. Rate of Nucleophilic Substitution Reactions

(*a*) Effect of nature of metal ion. The rate of a nucleophilic substitution is influenced by many factors, among the most important of which are the nature of the interacting ligand and the parameters of the central ion—electron configuration, size, and charge.

There is as yet no single reliable method of calculating the rate constants of fast reactions in solution. Existing theories explain only the relative change in rate constant with variation in some parameter. Among such theories those using an electrostatic approach and also the ligand field theory have become most widely known.

The electrostatic approach was first used by Debye[20,126], who applied Stokes' law to ionic reactions of the type

$$H^+ + OH^- \rightleftarrows H_2O$$

and found a relationship between the maximum possible rate constant and the electrostatic characteristics of the reactant species

$$k_{rt} = \frac{4\pi n Z_1 Z_2 e_0^2 (D_1 + D_2)}{10^3 \epsilon k T \left[\exp\left(\frac{Z_1 Z_2 e_0^2}{\epsilon k T \sigma}\right)\right]},$$

where $n = 6.022 \times 10^{23}$ $mole^{-1}$ is Avogadro's number, Z_1 and Z_2 are the charges on the ions (positive and negative integers), $e_0 = 4.80 \times 10^{10}$ $cm^{3/2}$ s^{-1} is the charge of the electron, D_1 and D_2 (in cm^2 s^{-1}) are the diffusion coefficients of the corresponding ions, ϵ is the dielectric constant, $k = 1.38 \times 10^{-16}$ erg deg^{-1} is Boltzmann's constant, T is the temperature on the Kelvin scale, and $\sigma = 7.5 \times 10^{-8}$ cm is the thickness of the reaction layer. This equation holds only for dilute solutions and reactions whose rate is controlled by the diffusion of the reactant ions.

With values of $D_i = 10^{-4}$–10^{-3} cm^2 s^{-1} and $\sigma = 1$–12 Å (i.e. values of these parameters characteristic of ordinary ions) the rate constant of complex formation calculated by means of Eqn. (26) may vary from 10^7 to 10^{10} $mole^{-1}$ s^{-1}. Such rate constants are observed with reactions involving ions of the alkali and alkaline-earth metals as well as certain ions of bivalent metals (Cd^{2+}, Hg^{2+}, Cu^{2+}) (see Tables 7–11, below).

The electrostatic theory can only in certain cases predict the variation in rate constant for a reaction involving ions having a complete electron shell, but it is unable to predict the variation in the rate constant in reactions involving ions of the transition metals. Thus, for example, it cannot explain the great difference in reaction velocities between the ions Fe^{3+} and Cr^{3+}, which have practically the same electrostatic characteristics.

Use of the crystal field and ligand field theory[127–131] for reactions involving transition-metal ions makes it possible in certain cases to calculate the energy characteristics of the initial and a possible transition state. Calculation of these characteristics helps us to foresee qualitative changes in activation energy, and therefore in the rate of complexing reactions involving transition elements.

The energy characteristics of a transition complex are determined mainly by its stereochemistry. To a first approximation the structure of the transition state can be determined from the mechanism of nucleophilic substitution, which may occur either by a unimolecular (S_N1) or by a bimolecular (S_N2) mechanism. In the former case a complex of coordination number 6 is converted into a complex of coordination number 5: i.e. an octahedral configuration passes into a square pyramid or a trigonal bipyramid. In the latter case a complex having the same coordination number is converted into a transition state of coordination number 7, which has the configuration of a pentagonal bipyramid. Which mechanism (S_N1) or (S_N2) is involved in a substitution can be determined from the pressure dependence of the rate constant[1] or from the electrostatic characteristics of the central field.

Table 3. Change in energy (in Dq units) when the initial complex compound passes into the intermediate complex for substitutions involving elements of the first transition period.

Electronic configuration	S_N1 mechanism octahedron → square pyramid		S_N2 mechanism octahedron → pentagonal pyramid		Electronic configuration	S_N1 mechanism octahedron → square pyramid		S_N2 mechanism octahedron → pentagonal pyramid	
	strong field	weak field	strong field	weak field		strong field	weak field	strong field	weak field
d^0	0.00	0.00	0.00	0.00	d^6	4.00	−0.57	8.52	−1.28
d^1	−0.57	−0.57	−1.28	−1.28	d^7	−1.14	1.14	5.34	−2.56
d^2	−1.14	−1.14	−2.56	−2.56	d^8	2.00	2.00	4.26	4.26
d^3	2.00	2.00	4.26	4.26	d^9	−3.14	−3.14	1.07	−1.07
d^4	1.43	3.14	2.98	1.07	d^{10}	0.00	0.00	0.00	0.00
d^5	0.86	−0.57	1.70	0.00					

Table 3, taken from the monograph by Basolo and Pearson[131], gives results of the approximate calculation of the change in energy accompanying the change in configuration

associated with the conversion of an initial complex compound into a transition state. The approximations of the crystal field method were used in the calculation. It is seen that the greatest change in energy is required for ions having d^3, d^6, and d^8 electronic configurations: i.e. reactions involving these ions have a greater activation energy, and should therefore be slower, than reactions involving other ions. This principle is supported by experimental data available in the literature (Table 4).

Table 4. Rate constants for complex formation by elements of the first transition period.

Electronic configuration	Ion	I* k, $M^{-1}\ s^{-1}$	II* k, $M^{-1}\ s^{-1}$	III* k, $M^{-1}\ s^{-1}$
d^0	Ca^{2+}	10^8	$7\cdot10^8$	$2\cdot10^7$
d^5	Mn^{2+}	$2\cdot10^7$	—	10^6
d^6	Fe^{2+}	$3\cdot10^6$	—	$6\cdot10^6$
d^7	Co^{2+}	$33\cdot10^5$	$4\cdot10^4$	10^5
d^8	Ni^{2+}	$3\cdot10^4$	$4\cdot10^3$	10^4
d^9	Cu^{2+}	$3\cdot10^5$	$1\cdot10^6$	10^5
d^{10}	Zn^{2+}	$2\cdot10^5$	$4\cdot10^6$	$3\cdot10^6$

* The reactions are represented by the equations

(I) $[M(H_2\mathring{O})_6] + H_2O \rightleftharpoons [M(H_2O)_6] + H_2\mathring{O}$

(II) $M^{2+} + day \rightleftharpoons [M(day)]^{2+}$

day = 2-*p*-dimethylaminophenylazopyridine

(III) $M^{2+} + SO_4^{2-} \rightleftharpoons MSO_4$.

More detailed consideration of the dependence of reactivity on the electronic structure of the reactant ions from the viewpoint of crystal field theory suggests that the rate of complex formation should decrease in the sequence of ions having the electronic configurations—$d^5 > d^4 > d^3 > d^6$—for both S_N1 and S_N2 mechanisms. Unfortunately, many postulates were made in this calculation, and there are as yet no reliable experimental data supporting this hypothesis.

Qualitative results can be obtained by considering the influence of the Jahn–Teller effect on the reactivity of complex compounds [130-131]. This effect consists in the distortions arising in a symmetrical non-linear polyatomic molecule having a degenerate electronic state, as a consequence of which distortions the symmetry of the molecule is diminished [132]. Thus in the d^9 system (the Cu^{2+} ion), for example, there is one vacant e_g-orbital, whose axes pass through the central ion and opposite ligands. The absence of an electron in one of the e_g-orbitals diminishes the screening of the central ion, with a consequent increase in the strength of interaction between negatively charged ligands and the central ion, so that the distance between them becomes shorter. Either two or four ligands will move towards the central ion; correspondingly either two short and four long—or four short and two long—bonds appear in an octahedron, and the latter is converted into a bipyramid.

Ligands located farther from a central ion are more reactive, since the mobility of ligands increases with increase in the distortion. Hence the rate of substitution should be considerably smaller with highly symmetrical complexes than in less symmetrical complexes.

The dependence of the Jahn–Teller distortion, arising in an octahedral configuration, on the electronic structure of transition-metal ions of the first series is shown in Table 5. It is seen that the greatest distortion appears with the structures d^4 and d^9, so that complexes of Cr^{2+} and Cu^{2+} should possess the greatest reactivity. This principle is supported by available experimental data (Table 4).

Table 5. Distortion of octahedral complexes of transition metals of the first series (Jahn–Teller effect) [132].

Configuration	Symmetry	Expected distortion due to orbital degeneracy	Configuration	Symmetry	Expected distortion due to orbital degeneracy
d^1	T_{2g}	small	d^6	$5\,T_{2g}$	small
d^2	$3\,T_{1g}$	small	d^7	$4\,T_{1g}$	small
d^3	$4\,A_{2g}$	0	d^8	$3\,A_{2g}$	0
d^4	$5\,E_g$	large	d^9	$2\,E_g$	large
d^5	$6\,A_{1g}$	0			

When the mechanism of substitution in a series of neighbouring elements is examined by the molecular orbital method [133], it is found that the decisive role is played by the change in antibonding effects in the formation of the activated complex, since the remaining characteristics of the complex either do not change or vary monotonically. This principle can be most usefully illustrated by substitution reactions in octahedral complexes of the type ML_6.

In a dissociative mechanism, the activated complex has the composition ML_5 and the configuration of a tetragonal pyramid (symmetry C_{4v}) or a trigonal bipyramid (symmetry D_{3h}). The change in symmetry and the arrangement of the orbitals in these two cases are shown in Fig. 5.

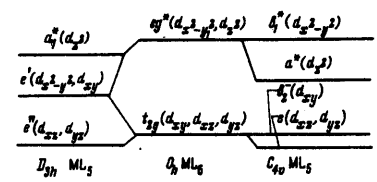

Figure 5. Change in symmetry and arrangement of orbitals for the S_N1 mechanism.

In the formation of ML_5 with the ligands located at the corners of a tetragonal pyramid the non-bonding orbital t_{2g} is converted into the still non-bonding orbitals b_2 and e, while the energy of these orbitals remains fundamentally unchanged. The antibonding orbital e_g is converted into two new antibonding orbitals b_1 and a_1^*, the antibonding effect on the orbitals a_1^* (d_{z^2}) being considerably diminished.

If electrons are present in the e_g^* orbital in a complex, formation of the ML_5 complex should be accompanied by a redistribution of electrons with a gain in energy when they undergo a transition from the orbital e_g^* to the orbital a_1^*. This transition disrupts the monotonic variation in reaction velocity in complexes with metals having d^4, d^5, d^9, and d^{10} configurations (Cr^{2+}, Mn^{2+}, Cu^{2+}, Zn^{2+}, Mn^{3+}, etc. complexes), and as a consequence the activation energy is lower, and the rate of substitution reactions higher, for

compounds of these metals than in the case of neighbouring elements. It is probable that substitution by an S_N1 mechanism is typical of compounds of these elements (of the type ML_6).

Similar conclusions can also be reached if the activated complex ML_5 is regarded as a trigonal bipyramid (symmetry D_{3h}). In contrast to the preceding case, substitution in the ML_6 complex of a metal having the electronic structure d^3 (or d^8) should be characterised here by an especially high activation energy, since in these compounds it is necessary to promote one of the electrons from the non-bonding t_{2g} (d_{xy}) orbital to an antibonding orbital e'.

In an associative mechanism (S_N2) the activated complex has the composition ML_7 and the configuration of a pentagonal bipyramid (symmetry D_{5h}) with the characteristic and rearrangement of orbitals shown in Fig. 6. In this case the monotonic change in activation energy (and reaction velocity) breaks down in the complex compounds of metals having the structure d^3 (or d^8) owing to the promotion of one of the electrons from a non-bonding t_{2g} orbital to an antibonding e_2' (d_{xy}) orbital.

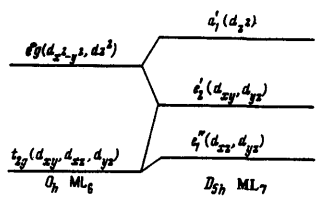

Figure 6. Change in symmetry and arrangement of orbitals for the S_N2 mechanism.

The activation energy is somewhat diminished in the complexes of metals having the configuration $3d^4$ (or $3d^9$), and remains about the same for complexes of metals having the configuration $3d^5$ (or $3d^{10}$) (Table 6).

Table 6. Change in antibonding effect in reactions occurring by S_N1 and S_N2 mechanisms[133].

Electronic structure	σ-Antibonding			π-Antibonding		
	ML_6 (D_{3h})	ML_6 (C_{4v})	ML_7 (D_{5h})	ML_6 (D_{3h})	ML_6 (C_{4v})	ML_7 (D_{5h})

d^3	0.0	0.0	0.0	−1.5	−3.0	+1.5
d^4	0.0	0.0	0.0	−2.0	−4.0	+2.0
d^5	+1.13	0.0	+1.88	−4.0	−4.0	+0.5
d^6	+2.25	0.0	+3.75	−5.5	−4.0	−1.0
d^7	+0.38	−1.0	+2.63	−4.0	−4.0	+1.5
d^8	−1.5	−2.0	+1.5	−4.0	−4.0	+4.0

Experimental results agree well with the variation in rate of substitution by the S_N2 mechanism. Actually, complexes of metals having the electronic configurations d^3 and d^8 react comparatively slowly in substitution reactions, and in this respect differ notably from the complexes of neighbouring metals.

The gradual increase in stability of the complexes with increase in atomic number of the transition metal leads to a gradual increase in the activation energy (decrease in rate) of substitution. This slowing down in the rate becomes especially marked in the complexes of metals having the electronic structures d^3 and d^8 when reactions occur by an S_N2 mechanism, owing to the necessity for promoting one of the electrons to an antibonding orbital. Complexes of metals having d^4, d^5, d^9, and d^{10} configurations, however, are considerably more reactive in an S_N2 and especially in an S_N1 mechanism, because of the transition of one electron from a higher to a lower antibonding orbital.

Unfortunately, none of the available methods enables absolute values to be calculated for the rate constants and activation energies of complex formation. At the best, all existing theories merely explain the relative variation in rate of complex formation in the series of transition elements.

(*b*) Effect of nature of ligand. The rates of many complexing reactions are independent of the nature of the ligands involved. Thus, for example, many doubly charged positive ions (Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}) react at approximately the same rate with various ligands (Table 7).

Table 7. Rate constants (in $M^{-1}\,s^{-1}$) for complex formation by the ions Zn^{2+}, Cd^{2+}, Ni^{2+}, and Co^{2+} with various ligands*.

Ligand	Ions			
	Zn^{2+}	Cd^{2+}	Ni^{2+}	Co^{2+}
Br^-	$5.0\cdot10^5$	$1.4\cdot10^9$	—	—
I^-	$5\cdot10^5$	$5\cdot10^9$	—	—
SO_4^{2-}	$3\cdot10^6$	$1\cdot10^7$	—	—
dye	$4\cdot10^6$	$1\cdot10^7$	—	—
CH_3COO^-		$3\cdot10^8$	—	—
imid	—	—	$5\cdot10^3$	$1.3\cdot10^5$
gly^-	—	—	$1.5\cdot10^4$	$4.6\cdot10^5$
$dgly^-$	—	—	$2.1\cdot10^4$	$4.6\cdot10^5$
dye	—	—	$4\cdot10^3$	$4.0\cdot10^4$
SO_4^{2-}	—	—	$1\cdot10^4$	$1\cdot10^4$

* imid = imidazole; gly = glycine; dgly = glycylglycine; dye = 2-*p*-dimethylaminophenylazopyridine.

This can be explained by an S_N1 mechanism for these reactions, in conformity with the equations[134]

$$[M(H_2O)_n] \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [M(H_2O)_{n-1}] + H_2O, \qquad (27)$$

$$[M(H_2O)_{n-1}] + L \xrightarrow{k_3} [M(H_2O)_{n-1}L]. \qquad (28)$$

Using the steady-state method and assuming that the concentration of $[M(H_2O)_{n-1}]$ is considerably less than the concentration of $[M(H_2O)_n]$, we can write

$$\frac{d[M(H_2O)_{n-1}L]}{dt} = \frac{k_1k_3[M(H_2O)_n][L]}{k_2+k_3[L]}, \qquad (29)$$

when $k_3 \gg k_2$ we obtain

$$\frac{d[M(H_2O)_{n-1}L]}{dt} = k_1[M(H_2O)_n]. \qquad (30)$$

It follows from Eqn. (30) that the rate-determining stage in the formation of complex compounds is reaction (27)—the

elimination of water—the rate of complex formation being completely independent of the nature of the ligand [134-136] (Table 7).

For the same reason the rate of addition of each successive ligand in stepwise complex formation is usually lower than or equal to the rate of addition of the preceding ligand. If, however, substitution of a water molecule involves intermediate formation of an outer-sphere complex, and its stability constant exceeds unity, the reverse effect may be observed [137,138].

The rate of complex formation is sharply diminished in reactions with polydentate ligands involved in the formation of chelate compounds. This is probably associated with the multistage character of ring formation [135,136,139].

2. Rate of Dissociation of Complexes

The influence of various factors on the rate of dissociation of complexes has been examined in detail by Wilkins and his collaborators [70,137,138,140-144], who showed that the rate of dissociation is more dependent than is the rate of complex formation on the nature of the ligand. Thus, for example, the rate constants for dissociation of the complexes of bivalent nickel—

$$[Ni(CNS)]^{+} \xrightarrow{k_1} Ni^{2+} + CNS^{-}, \quad (31)$$

$$[Ni(NH_3)]^{2+} \xrightarrow{k_2} Ni^{2+} + NH_3, \quad (32)$$

$$[Ni\,(en)]^{2+} \xrightarrow{k_3} Ni^{2+} + en, \quad (33)$$

—are respectively (in s^{-1}) $k_1 = 100$, $k_2 = 5.8$, and $k_3 = 0.14$, whereas the corresponding rate constants for formation of these complexes are 10^4, 10^4, and 10^6 M^{-1} s^{-1}. With many of the reactions described in the literature, dissociation rate constants are always smaller than formation rate constants for the same complex compounds.

If the rate-determining stage in complex formation is the elimination of water, the rule [142]

$$\Delta \lg k_d \approx -\Delta \lg K_{st} \quad (34)$$

where k_d is the dissociation rate constant of the complex compound and K_{st} is the stepwise stability constant of the same compound, holds for complex compounds having the same central ion and different ligands, as well as for individual stages in a multistage process of complex formation. This rule has been verified on a series of compounds of bivalent nickel [142].

3. Influence of Stereochemical Factors

Hardly any work has been done on the influence of stereochemical factors on the rate of fast complex-forming reactions. Data are available only on the dependence of reaction velocity on the angle of attack for ions having different electronic configurations [12,144,145].

Hammes and Steinfeld [and Kustin et al.] [75,139] have found that the rate of formation of complex compounds by bivalent cobalt, nickel, and manganese is considerably lower with β-alanine than with α-alanine. The explanation given [139] for this difference in rates is that ring formation in the above compounds is a stepwise process, while with β-alanine, owing to steric hindrance, occupation of a vacant place by a water molecule is more rapid than closure of the ring. This type of substitution has been termed sterically controlled substitution.

IV. REACTIONS HAVING AN S_N MECHANISM

1. Reactions involving Elements of Group I

Study of the kinetics of complex formation involving alkali-metal ions has been begun only recently. Investigation of these reactions has been delayed for at least two reasons: reactions of complex formation involving the alkali-metal ions occur very rapidly, and the resulting complexes are not very stable, so that all investigations must be conducted with high concentrations of the ligand, when the effect of foreign ions is very considerable. Available published data on these reactions are listed in Table 8.

Table 8. Rate constants in the replacement of water by various ligands for alkali-metal ions* ($\mu = 0.5$, pH > 11, $T = 20°C$).

Ion	Ligands			
	$Edta^{4-}$	Nta^{3-}	$Imda^{2-}$	Tmp^{3-}
Li^+	$4.8 \cdot 10^7$	$4.7 \cdot 10^7$	$2.5 \cdot 10^8$	$9 \cdot 10^8$
Na^+	$4.7 \cdot 10^7$	$8.8 \cdot 10^7$	$2.5 \cdot 10^8$	$2 \cdot 10^9$
K^+	$7.5 \cdot 10^7$	$1.5 \cdot 10^8$	—	$5 \cdot 10^9$
Rb^+	$1.4 \cdot 10^8$	$2.3 \cdot 10^8$	—	$5 \cdot 10^9$
Cs^+	$2.1 \cdot 10^8$	$3.5 \cdot 10^8$	—	$5 \cdot 10^9$

* Constants (in s^{-1}) obtained by the ultrasonic method [14]. $Edta^{4-}$ = ethylenediaminetetra-acetate; Nta^{3-} = nitrilotriacetate anion; $Imda^{2-}$ = imidazole anion; Tmp^{3-} = trimetaphosphate anion.

Table 8 shows that in all cases the rate of complex formation increases monotonically from lithium to caesium, and the rate constant of these processes, which is very large, varies linearly with the radius of the reactant ions [14]. This indicates that the rate of complex formation involving alkali-metal ions depends mainly on the purely electrostatic intereaction of the reactant ions and is controlled by diffusion, the rate of elimination of water not being the limiting stage.

Only reactions involving compounds of bivalent copper have been relatively well studied among elements of subgroup IB. It is seen from Table 9 that the rate constants for formation of one-coordinate complex compounds of bivalent copper with various ligands vary within a fairly narrow range (10^6–10^8 M^{-1} s^{-1}). Such a large absolute value of the rate constant for the formation of complexes of bivalent copper, in comparison with the rate constants for complex formation by other transition elements of the first series, is usually explained by strong distortions of the octahedral structure of copper compounds resulting from the Jahn-Teller effect [6,129,131].

The absence of an appreciable effect of the nature of the ligands on the rate constant of complex formation by bivalent copper is probably associated with the fact that these reactions occur by an S_N1 mechanism, the rate-determining stage being the elimination of water [13,14].

The literature contains no data on fast complexing reactions involving compounds of silver, gold, or univalent and tervalent copper.

2. Reactions Involving Elements of Group II

Available published values of the rate constants for the dissociation and the formation of complexes of Group II elements are given in Table 10. The rates of all these reactions, with the exception of those involving beryllium, are determined purely by electrostatic interaction, the elimination of water being the rate-determining stage. It is interesting that the rate of complex formation increases sharply on passing from magnesium to calcium, a fact which has not yet been satisfactorily explained[14].

The relatively small rate constant found with beryllium ions is explained by rapid hydrolysis, as a result of which relatively unreactive species are formed[14,151]. These processes can explain the presence of at least six relaxation times in the relaxation spectrum of beryllium sulphate[151].

Subgroup IIB contains elements whose ions have the configuration d^{10}. In contrast to the alkaline-earth ions, the doubly charged ions of zinc, cadmium, and mercury have an outer d-shell, which may be reflected in their kinetic properties. The comparatively high velocities of reactions involving ions of these elements (Table 11), whose rate constants are approximately equal in magnitude to those of reactions involving elements of the A subgroup, suggest that the mechanism of complex formation is the same in both cases, the rate of the process being determined purely by electrostatic interaction and being limited by diffusion.

3. Reactions Involving Elements of Groups III–VI and Manganese

Preliminary results indicate[14] that complex formation involving V^{2+} ions is abnormally slow, but the ion Cr^{2+} reacts at approximately the same rate as does Cu^{2+}. These data are consistent with the ligand field theory.

Complex formation involving compounds of bivalent manganese is very rapid. Quantitative kinetic data are available for the exchange of water in the inner sphere[111,148] and the formation of sulphate complexes[101] and of complexes with terpyridyl[137] and β-alanine[139]. In most cases the rate constant for the formation of bivalent manganese complexes exceeds $10^6\ M^{-1}\ s^{-1}$.

Fast complexing reactions in which ions of elements in these groups take part in a higher state of oxidation than 3 have not been investigated. Data are available only on the rate of formation of sulphate complexes of aluminium[157] and vanadyl[97] and of dimers of tungsten(VI) and molybdenum(VI).[165]

Few data are available also on reactions involving ions of the rare-earth elements. Eigen[14] assumes that the rate constant for complex formation should be of the order of $10^7\ M^{-1}\ s^{-1}$. This supposition is supported by results for the exchange of ethylenediaminetetra-acetic acid with certain rare-earth ions[166]. For lanthanum this constant is $10^5\ M^{-1}\ s^{-1}$, and it decreases in the sequence—lanthanum, neodymium, dysprosium, ytterbium—in the proportions 7700 : 1200 : 19 : 1.

The temperature-jump method[167] has recently been used to determine the rate constants for the formation and the dissociation of the complexes of lanthanides with murexide,

and the stopped-flow method to find the dissociation rate constants of the complexes formed by Xylenol Orange with the rare-earth elements of the cerium subgroup[168] (see Table 12). It is possible that, in aqueous solutions of compounds of the rare-earth elements, an equilibrium is established between hydrated forms containing different quantities of water in the inner sphere, and that these forms differ in reactivity[167].

4. Reactions Involving Elements of the Ion Group

Data on fast reactions of complex formation involving elements of this group are the most numerous (Table 13). In most cases the rate of complex formation is limited by the rate of elimination of water from the inner sphere, and is therefore independent of the nature of the ligand.

Two groups of reactions occur with Fe^{3+} ions. The first group comprises reactions in which a ligand reacts directly

Table 12. Rate constants for the reaction $M^{3+} + L^n \rightleftharpoons ML^{3-n}$, where M^{3+} is a lanthanide ion and L^n represents murexide or Zylenol Orange.

with the ions according to the equation

$$Fe^{3+} + X^- \xrightarrow{k_1} FeX^{2+} . \qquad (35)$$

Reactions of the second group occur in conformity with the scheme

$$FeOH^{2+} + HX \xrightarrow{k_1} FeX^{2+} + H_2O \qquad (36)$$

As is evident from Eqn. (35), in the former case k is independent of the hydrogen-ion concentration, whereas the rate constant of reaction (36) is substantially influenced by it. As a rule $k_2 \gg k_1$. In many cases the dissociation of complex compounds of tervalent iron is catalysed by Fe^{2+} ions[72].

The Ni^{2+} ion, which has the electronic configuration d^8 and forms highly symmetrical complex compounds, reacts considerably more slowly than the other transition elements of the first series.

The literature contains no data on fast reactions of complex formation by elements of the platinum group.

V. REACTIONS HAVING AN S_E MECHANISM

Substitution of the central ion in complex compounds has so far been studied mainly on slow or moderately rapid[189-191] reactions in which polydentate ligands take part.

The most interesting of the reactions which have been studied is

$$NiTeta^{2+} + CuEdta^{2-} \rightleftarrows CuTeta^{2+} + NiEdta^{2-} , \qquad (37)$$

where Teta represents triethylenetetra-amine and Edta represents ethylenediaminetetra-acetic acid. This reaction—the first non-redox reaction to be studied—has been shown[192] to have a chain mechanism, which can be represented by the reactions

$$NiTeta^{2+} \rightleftarrows Ni^{2+} + Teta , \qquad (38)$$

$$Teta + CuEdta^{2} \rightleftarrows CuTeta^{2+} + Edta^{4-} , \qquad (39)$$

$$Edta^{4-} + NiTeta^{2+} \rightleftarrows NiEdta^{2-} + Teta , \qquad (40)$$

$$Ni^{2+} + Edta^{4-} \rightleftarrows NiEdta^{2-} . \qquad (41)$$

It is interesting that this reaction is catalysed by small amounts (10^{-6} M) of certain ligands (Teta, Edta), and is inhibited by copper and nickel ions at concentrations of

* Dimensions $M^{-1}\,s^{-1}$.

Symbols: en = ethylenediamine; dye = 2-*p*-dimethylaminophenylazopyridine; HT^{3-} = Tiron; gly = glycine; dgly = glycylglycine; imid = imidazole; py = pyridine; bn = butane-2,3-diamine; C_2N_4NH = aziridine; N_2H_4 = hydrazine; α-alan = α-alanine; β-alan = β-alanine; terpy = 2,2′,6′,2″-terpyridyl; Mal = malonate.

** $k = k_1 + k_2/[H^+]$.

Methods: cfl = constant flow; stfl = stopped flow; tj = temperature jump; ps = pressure shock; lt = low-temperature method; n.m.r. = nuclear magnetic resonance method; elch = electrochemical method.

10^{-6} M, which may be utilised for the quantitative determination of these substances.

The above facts are worthy of attention, since many reactions of complex formation occurring by an S_E mechanism are probably chain reactions, as Margerum has shown for several processes analogous to reaction (37). [193,194]

Influence of Intermolecular and Intramolecular Order on the Infrared Absorption Spectra of Polymers

V.N.Nikimin and B.Z.Volchek

In the investigation of the vibrational spectra of macromolecular compounds it has been noticed that, when a polymer passes from the amorphous to the crystalline state, new absorption bands appear in the spectrum, or else splitting occurs in bands present in the spectrum of the amorphous substance. With certain polymers it has been established that several bands increase in intensity on passage from the crystalline to the amorphous state. The former group have been termed "crystalline" bands, and the second group "amorphous" bands. The origin of these absorption bands will become clear from a general theoretical examination of the vibrations described by an individual polymer chain and the crystalline unit cell formed by the chains. The method of theoretical examination of the normal vibrations of the crystalline polymer[1-5] is based on the application of group theory and is analogous to the method employed to investigate the vibrations of molecular crystals[6-8]. In a crystalline polymer the potential field of the crystal acts on the molecule in the same way as in molecular crystals. This should lead to a change in the spectrum of the crystalline polymer as compared with the amorphous material. Certain types of vibrations, which are inactive in an individual polymer molecule, may be active in the unit cell of a three-dimensional or one-dimensional crystal, since the symmetry of a molecule in a crystal field is usually lower than the symmetry of a free molecule. This results in a weakening of the selection rules found for an isolated molecule. It must be noted that, if degenerate vibrations occurred in an isolated molecule, the change in selection rules might result in elimination of the degeneracy. The appearance of "crystalline" bands also may be due to a change in the configuration of the molecular chain in the crystal cell of the polymer compared with its configuration in the amorphous state. Consideration of the vibration of an individual molecule in the crystal field is not complete, since it takes no account of the interactions of vibrations between chains in the crystal cell. This can be done in a theoretical investigation of vibrations in the unit cell of a crystal as a whole.

In the spectra of many polymers, transition from the amorphous to the crystalline state is accompanied not only by weakening of the selection rules but also by splitting of the main vibration frequencies. Physically such splitting occurs as a result of the resonance interaction of analogous vibrations undergone by individual chains in the unit cell. If n molecules are contained in the unit cell, as a result of resonance interaction, there will be n vibrations corresponding to each undegenerate vibration of an isolated molecule. The magnitude of the resonance splitting of frequencies will depend on the intermolecular interaction; it may be so small as to be unobservable experimentally. Furthermore, not all components of the resolved band are active in the infrared absorption spectrum.

Considerable interest attaches to study of the vibrational spectra of polymers having a regular chain structure (isotactic and syndiotactic polymers). In several cases these polymers show resonance splitting of the bands associated with interaction between analogous groups located along the polymer chain. Thus polymers having a helical chain structure, for example, show splitting of certain vibrations into two components polarised respectively parallel to the axis of the helix and perpendicular to the plane of the helix[9], and in this case the magnitude of the splitting depends on the type of interaction between the groups involved in the vibrations. In several cases new bands are found—"amorphous" absorption bands—on passing from the crystalline to the amorphous polymer. The appearance of these absorption bands may be caused either by breakdown in the selection rules operating in the crystal or by the existence in the amorphous phase of rotational isomers which are absent in the crystalline phase. The intensity of the "amorphous" bands is usually low. This is probably

linked with a minute fraction of new isomers appearing when the substance passes between the amorphous and the crystalline states. It must be noted that the theoretical calculation of "crystalline" and "amorphous" frequencies is difficult for several reasons, and in most cases such absorption bands have been discovered experimentally in the polymers. The detection of "crystalline" and "amorphous" absorption bands and their variation with the state of aggregation of the substance are not only of theoretical interest but also of great practical value. Examination of these two types of absorption bands enables the degree of crystallinity of the polymer to be determined, as well as the melting point of the crystals, their degree of orientation, and transitions of one crystalline modification into another. In several cases their study enables conclusions to be drawn on the configuration of the molecular chains in the various states of aggregation of the polymer. The present review presents data on the development, in the infrared spectrum of several polymers, of absorption bands due to intermolecular and intramolecular interaction between the polymer chains, and on the possibility of using these absorption bands to determine physical characteristics of the polymers.

POLY(VINYL ALCOHOL) $[-CH_2-CH(OH)-]_n$

A large number of papers have recently been published, especially by Japanese workers, on investigations of the structure of poly(vinyl alcohol) (p.v.a.). It has been shown[10-13] that the conditions of polymerisation influence the stereospecificity of the resulting polymer. X-Ray results indicate that poly(vinyl alcohol) is a crystalline substance having a repeat distance of 2.52 ± 0.02 Å in the direction of stretching, independently of the conditions of polymerisation[11,14]. Fig. 1 reproduces the infrared absorption spectra of isotactic and syndiotactic poly(vinyl alcohol). The spectrum of the polymer contains bands at

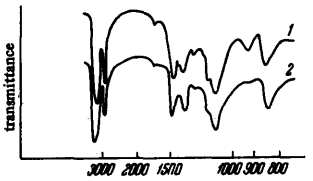

Figure 1. Infrared absorption spectrum of poly(vinyl alcohol):
1) syndiotactic (ordinary) specimen; *2*) isotactic specimen.

1141 and 916 cm^{-1} which are sensitive to intermolecular and intramolecular order. The intensity of the former band increases on heating[5] in parallel with increase in the degree of crystallinity of the polymer, determined by means of X-rays, the sorption of water, and the degree of coloration with iodine. This indicates that the absorption band at 1141 cm^{-1} is "crystalline". The intensity of the band at 916 cm^{-1} decreases[12] on such treatment (Fig. 2). As is evident from Fig. 1, this band is absent from the spectrum of isotactic specimens of the polymer. Transition from the syndiotactic to the isotactic structure is accompanied by a diminution in intensity of the absorption band at 1141 cm^{-1}.

The assignment of the absorption bands at 1141 and 916 cm^{-1} to corresponding modes of vibration is at present uncertain[15-19]. A theoretical calculation has been made[20] of the spectrum of syndiotactic and isotactic poly(vinyl alcohol), and it has been shown that the vibration $\nu(CO)A_1$ should appear in the region of 900 cm^{-1} in the spectrum of

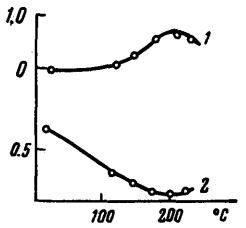

Figure 2. Effect of the temperature of heat-treatment of poly(vinyl alcohol), on relative optical densities in the bands: *1*) 1141 cm^{-1}; *2*) 916 cm^{-1}.

the syndiotactic polymer, and should be absent in that of isotactic specimens. This absorption can be identified with that at 916 cm^{-1} observed in the spectrum of syndiotactic poly(vinyl alcohol). The ratio of the optical densities in the absorption bands at 916 and 850 cm^{-1} (the latter band being taken as internal standard) has been used to determine the degree of stereoregularity of poly(vinyl alcohol) (Fig. 3) as a function of the temperature of polymerisation of the original material, which was poly(vinyl trifluoroacetate). However, it was pointed out that the ratio

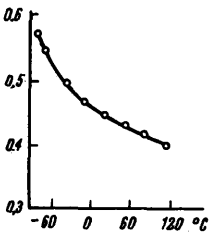

Figure 3. Dependence of ratio of optical densities of the 916/850 cm^{-1} bands on the temperature of polymerisation of poly(vinyl alcohol).

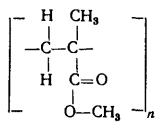
D_{916}/D_{850} itself depends on the optical density of the specimen in the region of 850 cm^{-1}. Measurements independent of the thickness of the specimen can be made when the optical density of the latter for the 850 cm^{-1} band exceeds 0.3. This fact is most probably due to the diffuseness of the reference band at 850 cm^{-1}. Estimation of the degree of syndiotacticity of a specimen from the band at 916 cm^{-1} is uncertain also because the intensity of this band (Fig. 2) depends on the degree of crystallinity of the specimen. However, the crystallinity of a specimen obtained under definite conditions of polymerisation depends on how the specimen had been prepared (humidity, temperature, etc.).

The assignment of the 1141 cm^{-1} band is uncertain. Krimm[18] originally attributed it to a ν(C–O–C) vibration, relating this absorption to the cross-linking of poly(vinyl alcohol) on heat-treatment of the polymer. Subsequently[21] this band was assigned to the vibration ν(CO) of some of the chains having intramolecular hydrogen bonds on one side of the plane of the zigzag of the main chain. It has been shown[11], however, that the isotactic poly(vinyl alcohol) model—rather than the atactic or the syndiotactic polymer—is associated with the formation of intramolecular hydrogen bonds. The 1141 cm^{-1} absorption band has been attributed[11,22] to skeletal vibrations of the atactic or syndiotactic part of the polymer. Irrespective of its assignment, this absorption band can be used to determine the degree of crystallinity of an atactic or a syndiotactic specimen of poly(vinyl alcohol).

POLY(METHYL METHACRYLATE)



Under certain conditions the polymerisation of methyl methacrylate may yield isotactic or syndiotactic poly(methyl methacrylate) or else a mixture of these forms[23–28]. Specimens of the stereoregular polymer can be crystallised, and differ from one another in glass point, melting point of the crystals, and density. X-Ray investigation of isotactic poly(methyl methacrylate) has shown[29,30] that the crystalline conformation of its chains corresponds to a 5_2 or 5_1 helix. The same conformations have been calculated theoretically[31] for the isotactic polymer. Such definite results do not exist for the syndiotactic structure: X-ray photographs of the syndiotactic polymer[29] are identical with those of an isotactic specimen. It has therefore been concluded[29] that the chains of syndiotactic poly(methyl methacrylate) also give a helical conformation. Calculations show[31] that the minimum potential energy for the syndiotactic polymer corresponds to a conformation which is closely similar to a proposed structure[32] or to a *trans*-chain. The infrared absorption spectra of these polymers differ. It has been found[33] that in the amorphous state the syndiotactic polymer is characterised by absorption bands at 1482, 1060, 910, and 822 cm^{-1}, which are very weak in an isotactic sample (Fig. 4). A method has therefore been proposed for the quantitative determination of the percentage syndiotacticity of specimens[33] from the 1060 cm^{-1} absorption band. An empirical method has been suggested[34] for calculating the stereoregularity of poly(methyl methacrylate) from the factor A, where A is a number indicating the character and degree of regularity:

$$A = 179\,(D_{1060})/D_{990} + 27;$$

$$A = 81.4\,(D_{1482})/D_{1390} - 43.$$

The parameter A has the approximate values 100–115 and 25–35 for the completely isotactic and the completely syndiotactic polymer respectively.

Hagai[35] noted an absorption band in the region of 750 cm^{-1} in the infrared spectrum, which had a rather higher frequency for isotactic than for syndiotactic poly(methyl methacrylate), and could be used in principle for quantitative calculations of the degree of stereoregularity of the polymer. Bands in the range 1050–1300 cm^{-1} are also sensitive to the intramolecular order[36]. The infrared spectra of both forms have been studied[37,38] after treatment of the specimens with heptan-4-one, which should result in their crystallisation[24]. On such treatment the infrared absorption spectrum showed the appearance of new bands in the range 1500–1600 cm^{-1}, which varied with the temperature in parallel with the X-ray pattern. It has been shown[39], however, that the appearance of these absorption bands may be due to the presence of an impurity in the specimen. The X-ray pattern observed when poly(methyl methacrylate) is treated with heptan-4-one also may be linked with the presence of this impurity. It is interesting that crystallisation of an isotactic specimen of the polymer has also been observed[34] when it was suspended in water, but no qualitative change in the spectrum was observed.

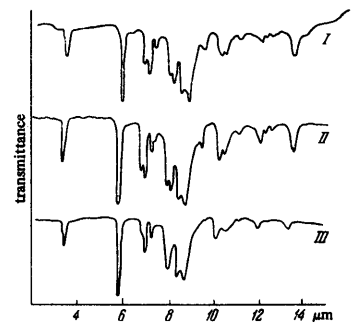


Figure 4. Infrared absorption spectrum of poly(methyl methacrylate):
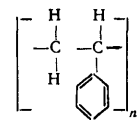
I) syndiotactic; *II*) atactic; *III*) isotactic.

It is evident from the above discussion that, although differences in the stereospecificity of poly(methyl methacrylate) specimens are revealed in the infrared absorption spectrum, the quantitative determination of syndiotactic and isotactic sequences in samples is relative in character. Such determination is less accurate than the nuclear magnetic resonance (n.m.r.) method[40].

POLYSTYRENE



It has been shown[41–46] that the infrared absorption spectrum of atactic polystyrene differs from that of the isotactic polymer in both crystalline and amorphous states. Fig. 5 reproduces the infrared spectra of atactic polystyrene and the spectra of isotactic polystyrene in the melt, in carbon disulphide solution, and in the quenched and crystalline states. Three classes of changes in the infrared spectrum can be distinguished[46] on passing from an atactic to an isotactic specimen of polystyrene.

1. The intensity of several absorption bands increases, or new bands appear, in the spectrum of an isotactic specimen of polystyrene. The bands at 1365, 1297, 1260, and

1187 cm^{-1} can be regarded as of this type. Study of deuteriated derivatives of isotactic polystyrene has shown that these bands are not associated with vibration of the benzene ring.

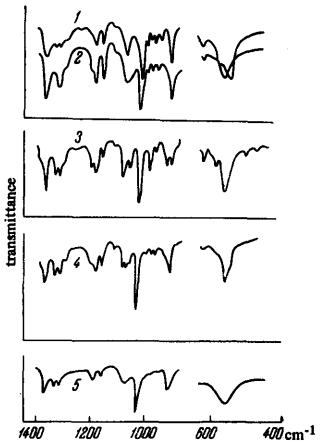


Figure 5. Infrared spectrum of polystyrene in various states of aggregation:
1) atactic; *2*) amorphous isotactic at 20°C; *3*) crystalline isotactic; *4*) isotactic dissolved in CS_2; *5*) molten isotactic.

The bands at 1365 and 1297 cm^{-1} represent deformation vibrations of CH_2 and CH groups, and the bands at 1187 and 1260 cm^{-1} stretching vibrations of the carbon chain. The appearance of absorption bands at 1187 and 1260 cm^{-1} in the spectrum of isotactic polystyrene can be explained by the formation of a helical conformation, which is characteristic of an isotactic sample[47,48]. The change in intensity of the bands at 1365 and 1297 cm^{-1}, however, is linked with some change in mode of the normal vibrations (in the present case deformation vibrations of CH and CH_2 groups) on helication of the carbon chain or on change in the spatial environment, in particular change in the interaction with other modes of vibration.

2. The band at 1070 cm^{-1} and probably that at 1312 cm^{-1} can be included in the second group of absorption bands.

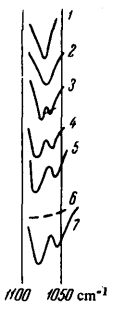

Figure 6. Absorption of polystyrene in the region of 1000 cm^{-1}: *1*) atactic; *2*) molten isotactic; *3*) quenched isotactic; *4*) isotactic dissolved in CS_2; *5*) crystalline isotactic; *6*) isotactic oriented along electric vector $E_\perp$; *7*) isotactic oriented along electric vector $E_\parallel$.

On passing from an atactic to an isotactic specimen these bands are split into two components. This splitting remains in a quenched specimen and in solution, although it is smaller (Fig. 6).

In an oriented specimen in polarised radiation the two components of the resolved bands have the same σ-dichroism. Study of deuteriated specimens has shown that these absorption bands may be due to vibrations of the benzene ring. Since both components of the resolved absorption bands exhibit σ-dichroism, it is difficult to link the splitting with intermolecular or intramolecular ordering of the chains in an isotactic specimen. The reason for splitting of this type is obscure.

3. The bands at 982, 906, 757, and 700 cm^{-1} can be placed in this group. On passing from an atactic to an isotactic specimen they are split into two components close together, which differ in polarisation. Since splitting of the bands is observed only in the crystalline state, it may be regarded as associated with the development of intermolecular order in a crystalline isotactic specimen of polystyrene. Study of deuteriated specimens shows that these absorption bands are due to vibration of the benzene ring.

The absorption range 600–500 cm^{-1} is also of interest in the spectrum of polystyrene. In the crystalline isotactic polymer absorption bands are observed at 567 and 570 cm^{-1} in this range. In solution bands are found at 560 and 544 cm^{-1}, and in the quenched state a broad band occurs at 546 cm^{-1}. The spectrum of atactic polystyrene also contains an absorption band at 546 cm^{-1} and a shoulder at 560 cm^{-1}. Takeda et al.[45] proposed using the ratio of optical densities in the bands at 546 and 560 cm^{-1} to determine the relative degree of "isotacticity" of polystyrene specimens. Pokrovskii and Fedorova[49] have recently suggested a quantitative method for calculating the degree of isotacticity from the ratio of the optical densities in these bands based on the fact that the integral intensity in the range 500–600 cm^{-1} is always constant in a solution of any specimen of polystyrene (isotactic or atactic). Most authors assign these absorption bands to $\nu_4(B_2)$ deformation vibrations of the benzene ring. Variation in the band envelope with the type of stereoregularity of a polystyrene specimen is due to the sensitivity of this vibration to various types of intramolecular order over short sections of the carbon chain. Hence we cannot agree that the integral ratio of the optical densities of the bands[49] 543/560 cm^{-1} does actually determine the absolute degree of stereoregularity in a sample. This is also indicated by the dependence of the envelope of these bands on the state of aggregation of the specimen. Unfortunately, the n.m.r. method, use of which might have given a reference point for subsequent quantitative measurement, by means of the infrared absorption spectra, of the degree of stereoregularity in polystyrene, has not at present been developed for measuring this parameter[50]. The bands at 1260, 1187, or 567 cm^{-1} can be used to determine the relative degree of crystallinity of polystyrene. Takeda[45] proposed the absorption band at 1030 cm^{-1} as internal standard for such measurements.

POLY(VINYL CHLORIDE) $[-CH_2-CHCl-]_n$

The relation between the structure of poly(vinyl chloride) [p.v.c.] and its infrared absorption spectrum over the range 400–1600 cm^{-1} has been investigated by several workers[51-58]. Attention has been directed mainly at the range 400–700 cm^{-1}, in which stretching vibrations of the

C–Cl bonds appear. Fig. 7 reproduces the infrared absorption spectrum of a feebly crystalline specimen of poly (vinyl chloride). The spectrum consists of strongly overlapping absorption bands at 693, 685, 638, and 615 cm^{-1}.

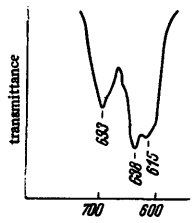

Figure 7. Infrared spectrum of poly(vinyl chloride) in the region of 600 cm^{-1}.

When such a specimen is heat-treated, and also on the polymerisation of poly(vinyl chloride) at −78°C or on channel complexes with urea, the bands at 638 and 683 cm^{-1} diminish in intensity, while fairly sharp bands appear at 603 and 640 cm^{-1} (Fig. 8). These bands disappear when

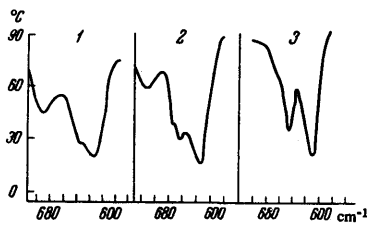

Figure 8. Infrared spectrum of poly(vinyl chloride) obtained under various conditions of polymerisation: *1*) at 50°C; *2*) at -70°C; *3*) on complexes with urea.

the polymer melts or dissolves[58]. Hence most authors[53,54] attribute the bands at 603 and 640 cm^{-1} to intermolecular interaction in the crystalline portion of the polymer. On the assumption that the low-temperature polymerisation of poly(vinyl chloride), like polymerisation on channel complexes with urea, promotes formation of a syndiotactic structure[53,55,59], the 603 and 640 cm^{-1} vibrations are assigned respectively to the B_1 and A_1 types of C–Cl-stretching vibrations. It has been shown[60,61] that the absorption band at 640 cm^{-1} has perpendicular dichroism, while the 603 cm^{-1} band has parallel dichroism, on stretching 2–2½ times; when, however, the specimen is stretched ~ 7 times, the dichroism of the 603 cm^{-1} band becomes perpendicular (Fig. 9). These effects are interpreted as reflecting a change in the intramolecular packing in the crystalline portion of the polymer at different degrees of extension.

Assignment of the absorption bands at 615, 638, 685, and 693 cm^{-1} is difficult; these bands overlap strongly, the degree of overlap depending on their relative intensities. These intensities have been shown to vary appreciably with the conditions of polymerisation of the poly(vinyl chloride) specimens, the heat-treatment of the specimens, their orientation, and finally the way in which the specimen is prepared for exposure (as tablets with potassium bromide, films, etc.). Interpretation of these absorption bands is made difficult also by the fact that no reliable data are yet available on the stereoregularity of specimens obtained under different conditions of polymerisation. X-Ray results[62] indicate that no perfect syndiotactic structure is present even in specimens of the polymer prepared by low-temperature polymerisation. Data on the structure of poly(vinyl chloride) obtained by the n.m.r. method are also as yet fairly indefinite[63,64].

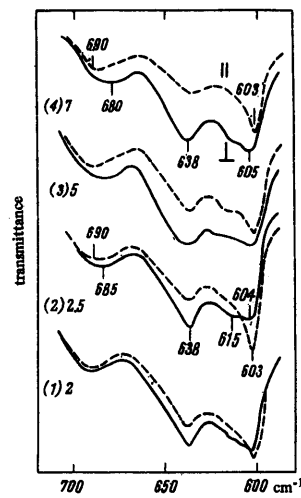

Figure 9. Dependence of dichroism in bands at 603 and 640 cm^{-1} on the stretching of isotactic poly(vinyl chloride).

Owing to the closeness of the absorption frequencies and also the uncertainty in the type of stereoregularity in the specimens, theoretical calculations on the assignment of these frequencies are also in considerable measure approximate[65]. A detailed study of secondary alkyl chlorides[57] has shown that the position of the ν(C–Cl) stretching frequencies is strongly dependent on the nature of the substituent attached to both adjacent C–C bonds located in the *trans*-position relative to the chlorine atom. In view of this, and also the dependence of the ν(C–Cl) vibration frequency on the conformation of the molecular chain, the bands at 615 and 693 cm^{-1} have been assigned to stable and unstable rotational isomers of the syndiotactic part of the polymer, while the absorption bands at 638 and 683 cm^{-1} are correspondingly assigned to unstable and stable isomers in the isotactic part of the poly(vinyl chloride) specimen. On the basis of this assignment of the absorption bands it is possible in principle to calculate several molecular parameters of the polymer: the intensity ratio of the absorption bands 615/638 cm^{-1} provides a measure of the isotactic and syndiotactic configurations present in the stable conformation; the band intensity ratios 615/693 cm^{-1} and 683/638 cm^{-1} define respectively the ratios of stable to unstable conformations in the syndiotactic and isotactic parts of the polymer. However, great caution must be exercised with respect to such measurements. Firstly, owing to the difficulties mentioned above, the assignment

of the absorption bands required for such measurements is not entirely unambiguous. Thus, for example, it is not clear why the absorption bands corresponding to the unstable rotational isomer diminish in intensity when a specimen of the polymer is heated to 180°C, whereas the quantity of unstable rotational isomers usually increases under these conditions. On the other hand, quantitative measurements are inaccurate because of the strong overlapping of the absorption bands. Somewhat better results can be obtained by examining the intensities of these bands in solutions of poly(vinyl chloride).

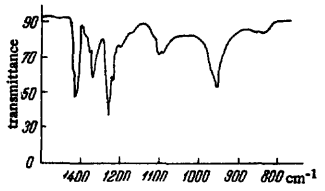

Figure 10. Infrared spectrum of poly(vinyl chloride).

The infrared spectrum of poly(vinyl chloride) in the range 1600–800 cm^{-1} is illustrated[58] in Fig. 10. The variation in absorption coefficients of a series of bands was investigated as a function of the density of the specimen, i.e. its crystallinity. The density of the specimens examined varied from 1.3887 to 1.4022. The ratio of the intensities of the bands at 1428, 1254, 1226, and 963 cm^{-1} to that of the 2920 cm^{-1} band increased linearly with the degree of crystallinity of the sample. A less marked increase occurred in this ratio for the bands at 1434, 1355, and 831 cm^{-1}. At the present time the assignment of these bands by different authors[58,66] is ambiguous. Irrespective of the assignment, these bands are sensitive to the three-dimensional order in the polymer. It is noteworthy that the sign of the dichroism of the 963 and 1254 cm^{-1} bands depends on the degree of stretch of the specimen (just as with the 603 cm^{-1} band).

POLY(VINYLIDENE FLUORIDE) $[-CH_2-CF_2-]_n$

A study has been made[67] of the infrared spectra of poly(vinylidene fluoride) in crystalline and amorphous states. The spectrum of films of this polymer prepared from solution in dimethyl sulphoxide is found to contain absorption bands at 1075, 980, 855, 798, and 762 cm^{-1}. These bands diminish in intensity or disappear when the specimens are heated above 165°C, which corresponds to the melting point of the polymer. Cooling the specimen to room temperature results in the reappearance of these absorption bands. Analogous behaviour is shown by the weak bands in the region of 3700, 3620, and 3380 cm^{-1}. All the above bands can be regarded as "crystalline", since they characterise the intermolecular ordering of the polymer chains. The 740 cm^{-1} band can be regarded as "amorphous", since its intensity increases when the specimen melts.

The infrared spectrum of poly(vinylidene fluoride) has been investigated[68] in greater detail in the range 3000–400 cm^{-1}. In this case films of the polymer were prepared from a solution in boiling acetone. The spectrum of such specimens contains bands at 484, 510, 840, 1073, 1180, and 1235 cm^{-1}, which disappear when the polymer is heated to 220°C. Nor are these bands observed in a spectrum of a solution of the polymer in acetone. For all these reasons the bands can be regarded as "crystalline". The crystalline modification of poly(vinylidene fluoride), whose spectrum is characterised by the above six bands and by a definite X-ray pattern, has been called the α-form. The bands at 600, 740, and 905 cm^{-1}, the intensity of which increases when the polymer melts, are regarded as "amorphous". The content of the amorphous phase in the polymer, determined by means of these bands, is ~ 50%. When a film of the polymer which has been heated to 220°C is cooled to room temperature, new sharp bands appear in the spectrum at 488, 531, 612, 765, 796, 857, 977, 1071, 1152, 1185, 1215, and 1385 cm^{-1}, which are characteristic of the crystalline state of the polymer. The variation in these bands with temperature, together with X-ray investigations, suggest that in this case another crystalline modification of the polymer—the β-form—can exist. Study of the spectra of oriented specimens of poly(vinylidene fluoride) in polarised infrared radiation confirms the existence of α- and β-forms[69]. The different crystalline forms correspond to different conformations of the polymer chain.

Analysis of data obtained from the infrared absorption spectra, together with X-ray structural analysis, shows[70–72] that in the α-conformation the molecular chains have a planar zigzag structure, and in the β-modification they have the TG–TG′ conformation. The existence of a third conformation has been suggested[72], the infrared spectra of which differ from that of the α-conformation in the intensities of certain absorption bands. The most marked differences are observed in the range 250–400 cm^{-1}.

POLYAMIDES

Many authors have been concerned in correlating[73–78] the infrared spectra of polyamides with the intermolecular and intramolecular order in the polymer. It has now been firmly established[79–83] that, depending on the number of methylene groups between the amide groups or on the treatment of the specimens, polyamides can exist in three crystalline modifications—α, β, and γ—or contain these forms together in various proportions. Whereas the α- and β-forms have a monoclinic crystal cell, in which the methylene chain is in the form of a flat zigzag lying in the same plane as the amide group, the γ-configuration has hexagonal packing (the plane containing the amide group is inclined at ~ 30° to the plane of the methylene chain).

Fig. 11 gives the infrared spectra of polycaprolactam in α- and γ-forms and of molten and quenched specimens of the polyamide. It is seen that the monoclinic α-form is characterised by absorption bands at 575, 692, 930, 960, 1201, 1420, 1470, and 1477 cm^{-1} (I). The crystalline γ-form is represented by bands at 625 and 711 cm^{-1} (II). Bands at 976, 1170, 1440, and 1460 cm^{-1} (III) are present in the γ-modification and in the molten polyamide, but are weaker or completely absent in polymers containing only or predominantly the α-modification. The bands at 590, 700, 1240, and 1280 cm^{-1} (IV) increase in intensity on fusion of the specimens. Bands of group I are associated[75,76] with the conformation of the molecular chain in the crystal cell characteristic of the α-form; the bands forming group II are probably linked with the intermolecular order in the γ-form of the crystals; those of group III are associated with the conformation in which the methy-

lene chain is not in the same plane as the amide group; and group IV are associated with the appearance of a coiled conformation of the molecular chains on fusion of the polyamides. A good criterion of the presence of α- and γ-crystalline forms is the position of the amide band[84] V, which in the α-form is located in the range 680–690 cm^{-1}, whereas in the γ-form it lies in the range 711–730 cm^{-1} (Fig. 12).

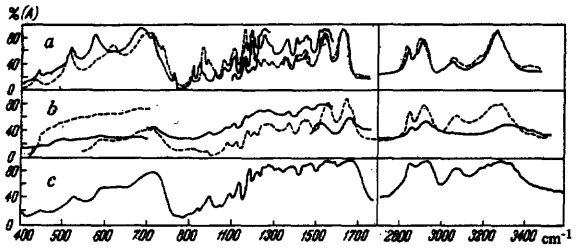

Figure 11. Infrared spectrum (A = absorption, %) of a polyamide: *a*) highly crystalline polymer ($\alpha + \beta$-form), the broken line representing the γ-form; *b*) molten polymer (245°C), the broken line representing the quenched polymer at 110°C; *c*) quenched polyamide at 20°C.

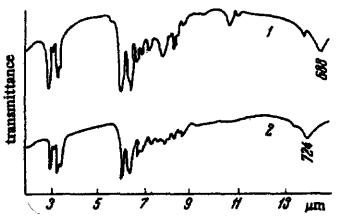

Figure 12. Position of amide V in a polyamide in the modifications:
1) α; *2*) γ.

Since a partly crystalline polyamide at ordinary temperatures exhibits bands characteristic of both α- and γ-forms of the crystal cell, the problem of determining the degree of crystallinity in polyamides is complicated. The 930 cm^{-1} band is most widely used[73,74,86] for this purpose. Such determination is valid provided that the specimen contains only or predominantly the α-form. The intensity of the band is then proportional to the degree of crystallinity of the polymer (Table 1). In all other cases measurement of the crystallinity on the basis of the 930 cm^{-1} band may result in large errors. As already mentioned above, the most convenient method is to determine the degree of crystallinity from "amorphous" absorption bands. However, such bands at 590, 700, 1240, and 1270 cm^{-1} in polyamides overlap other bands, and are unsuitable for quantitative determinations.

Novak et al.[86] have proposed a method for estimating the degree of crystallinity of poly-ϵ-caprolactam from the absorption bands at 930, 1076, and 1118 cm^{-1} (the latter two of which were regarded as "amorphous"). A complicated dependence of crystallinity on orientation was discovered: the orientation of quenched fibres increases the crystallinity, and the orientation of fibres of high crystallinity produces a decrease; finally, with degrees of crystallinity of 18–20% the content of the crystalline phase is unaffected by deformation.

Table 1. Determination of crystallinity in a polyamide as a function of the heat-treatment of the specimen.

POLYPROPYLENE

$$\left[-CH_2-\underset{\displaystyle CH_3}{\overset{|}{C}}H-\right]_n$$

The spectrum of isotactic polypropylene contains several strong and moderately strong absorption bands in the range 1200–800 cm^{-1} (Fig. 13). These bands are interesting because their intensity depends greatly on the degree

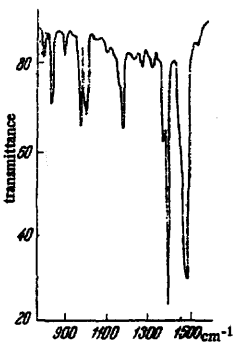

Figure 13. Infrared spectrum of crystalline isotactic polypropylene.

of microtacticity and crystallinity of the specimen, as well as on its state of aggregation. Thus the bands at 841, 997, and 1167 cm^{-1} disappear at 180°C, the melting point of polypropylene[87–90]. The bands at 841, 973, 997, 1153, and 1167 cm^{-1} are absent in specimens of polypropylene which has been prepared on non-stereospecific catalysts[91,92].

In a quenched specimen[93,94] the differential intensity of the bands at 841, 997, and 1167 cm^{-1} is diminished, while those at 973 and 1153 cm^{-1} remain practically unchanged. The 973 cm^{-1} absorption band remains, though diminished in intensity, when polypropylene is dissolved in benzene. X-Ray examination of quenched propylene shows[91] a peak at $2\theta = 22.2°$ besides an amorphous halo: i.e. the intermolecular ordering of molecular chains is partly preserved in a quenched specimen.

Differences in the infrared absorption spectra of different polypropylene fractions, specimens of different degrees of crystallinity, and specimens examined at 20° and 180°C may be associated with variation in both intramolecular and intermolecular order. The behaviour of the bands at 997, 841, and 1167 cm^{-1} on fusion and quenching of the polymer may indicate that these bands are due to the intermolecular order in polypropylene specimens. This order disappears in molten polypropylene, but is partly preserved in a quenched specimen, although X-ray examination indicates such a specimen to be amorphous. This explanation[96,97] is consistent with the fact that the intensity of the 997 cm^{-1} band increases in proportion to the degree of crystallinity of the specimen. The 1153 and 973 cm^{-1} bands may be due to intramolecular order in isotactic polypropylene[93,94]. Natta has shown that the molecular chains in isotactic polypropylene have the configuration of a 3_1 helix.

The Raman spectrum at 20° and 180°C has recently been obtained[98] for specimens of isotactic polypropylene (Fig.14). The changes produced in the Raman spectrum by fusion of the specimen are the same as observed in the infrared absorption spectrum. Since the unit cell of isotactic polypropylene belongs to the symmetry group C_{2h} and has a centre of inversion, this may be expected to lead to mutual exclusion of the frequencies in the Raman and infrared absorption spectra. As these spectra are identical at 20°C, it may be assumed that the spectrum of polypropylene is determined mainly by the chain structure alone.

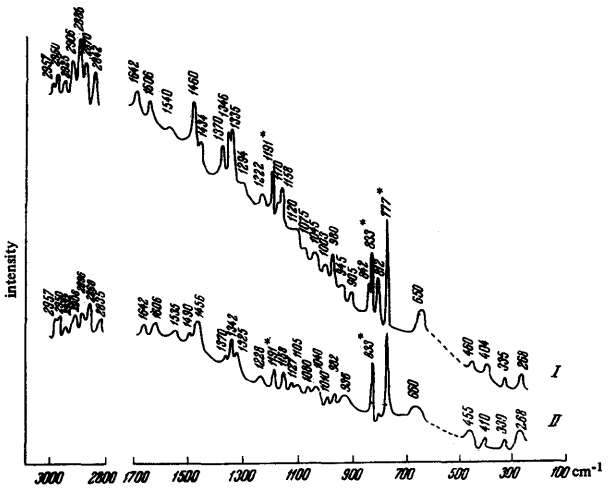

Figure 14. Raman spectrum of isotactic polypropylene: *I*) crystalline; *II*) molten.

Thus the absorption bands at 997, 841, and 1167 cm^{-1} may be associated either with intermolecular ordering of the polypropylene chains or with intramolecular order over large sections of the chains. The 974 and 1153 cm^{-1} bands, however, are probably linked with short-range intramolecular order. It thus becomes possible to measure[93,94,99] the relative "microtacticity" of polypropylene specimens from the intensity of the 974 cm^{-1} band, and the intermolecular ordering of the molecular chains from the 997 cm^{-1} band. A method has been proposed[100] for estimating the degree of isotacticity of polypropylene from the lack of symmetry of the former band. Appropriate fractions of the polymer and mechanical mixtures thereof were used to calibrate the method. The percentage isotacticity determined by this method was shown to agree well with the degree of crystallinity of the same specimen measured by means of the 997 cm^{-1} band at medium values of the isotacticity, and to differ markedly for its extreme values.

Fig. 15 shows the spectrum[101] of isotactic and atactic polypropylene in the range 410–100 cm^{-1}. It is seen from Figs. 15 and 16 that, whereas the spectrum of the isotactic polymer contains well separated absorption bands at 321, 251, 210, 200, 169, and 155 cm^{-1}, the atactic polymer has a diffuse absorption spectrum. There is no exact assignment of these bands to a definite type of vibration. In view of the sign of the dichroism, it is assumed that the bands at 398, 251, 200, and 155 cm^{-1} are due to vibrations of symmetry A, and those at 321, 210, and 169 cm^{-1} to symmetry E ($2\pi/3$) (Fig. 16). It may be supposed that these bands are due to skeletal deformation vibrations or correspond to frequencies of internal rotation in the polymer.

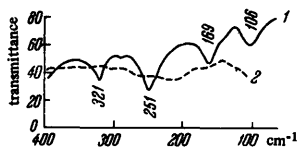

Figure 15. Infrared spectrum of polypropylene: *1*) crystalline isotactic; *2*) atactic.

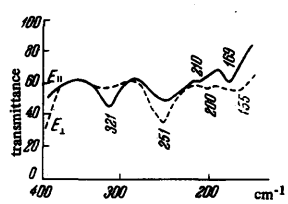

Figure 16. Infrared spectrum of isotactic polypropylene in polarised radiation.

Natta and his coworkers[102,103] synthesised syndiotactic polypropylene at low polymerisation temperatures (−70°C) on homogeneous catalytic systems obtained from a vanadium compound. The resulting polymer had fairly low crystallinity, which probably indicated that it was very inhomogeneous. The infrared spectrum of syndiotactic polypropylene differs somewhat from that of an isotactic specimen[104,105]: several absorption bands, e.g. at 997 and 458 cm^{-1}, are absent from the spectrum of syndiotactic polypropylene, and many bands are either displaced in frequency compared with the spectrum of an isotactic specimen or are characteristic only of this spectrum, e.g. 1005 and 970 cm^{-1}.

Zambelli et al.[104] suggested a method for determining the degree of syndiotacticity of polypropylene specimens using the ratio of the optical densities in the bands at 11.53, 2.32, and 2.35 μm:

$$A = D_{11.53}/^1/_2 (D_{2.32} + D_{2.35})$$

where A is the relative syndiotacticity index. It must be noted that the index is strongly dependent on temperature over the presumed melting range of the specimen[106].

A helical conformation has been suggested for syndiotactic polypropylene. However, a new crystalline modification of syndiotactic polypropylene has been obtained[107]. This modification is formed by the orientation of a quenched specimen of the syndiotactic polymer. The molecular chains then form a planar zigzag. The new modification is characterised by absorption bands at 1005, 1130, 960, and 830 cm^{-1} having parallel polarisation, and bands of lower intensity in the region of 1320 and 820 cm^{-1} having perpendicular polarisation.

The study of deuteriated specimens of polypropylene has enabled several of the above absorption bands to be related to vibrations of certain groups[87,105] (Table 2).

Table 2. Assignment of absorption bands of polypropylene.

Absorption bands, cm^{-1}		Type of vibration
syndiotactic	isotactic

POLYETHYLENE $[-CH_2-CH_2-]_n$

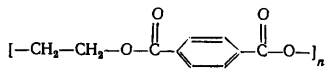
Polyethylene has a simple absorption spectrum, which has been well deciphered[108–110]. The greatest interest is presented by the absorption bands at 720, 730, 1308, 1464, and 1473 cm^{-1}, which are present in the partly crystallised polymer. In the amorphous state the band at 730 cm^{-1} has disappeared from the infrared spectrum, while that at 1303 cm^{-1} has increased in intensity; the doublet 1464–1473 cm^{-1} has been replaced by a single band at 1460 cm^{-1}.

It has been shown theoretically[109,110] that the appearance of the doublets 720–730 and 1464–1473 cm^{-1} is due to resonance interaction of deformation vibrations (rocking and wagging respectively) of methylene groups in the crystal cell, but the polarisation of the resolved components obtained in these papers did not agree with that determined experimentally.

It has since been shown that the type of splitting and the polarisation of the bands can be explained[111] by choosing an appropriate potential taking into account the interaction not only of hydrogen atoms adjacent to the chains but also of more remote hydrogen atoms. The 1303 cm^{-1} band is of especial interest, since it becomes stronger when polyethylene melts, which makes it possible to determine quantitatively the crystalline content[112–114] of the polymer by a method independent of X-ray examination. This band is assumed[112] to be characteristic of the presence of a skew rotational isomer in the amorphous part of the polymer. The presence of rotational isomers in polyethylene[115] has been confirmed also by an investigation of the stretching of the polymer. The 1460/1303 band absorption coefficient ratio increases when polyethylene is stretched by 1000% of its original length, owing to transition of the skew isomer into a *trans*-isomer. The conversion of skew isomers into *trans*-isomers on stretching has since been confirmed by measuring the energy changes accompanying stretching of cross-linked polyethylene[116].

The absorption bands at 1308, 1350, and 1365 cm^{-1} have been used[117,118] to investigate polyethylene single crystals. A method has been suggested[117] which will in principle enable us, by means of the variation in the intensities of these absorption bands, to distinguish the amount of disordered material in the polymer from the amorphous part formed when the polymer is packed into folded crystals.

POLY(ETHYLENE TEREPHTHALATE)



Spectroscopic study of this polymer[119–121] indicates that the changes observed in the spectrum (Fig. 17) on passing from the crystalline to the amorphous state are associated with rotational isomerism. Table 3 lists the absorption band frequencies which are sentitive to a change in crystalline state[119]. It has been shown that these bands do not completely disappear in the above transition.

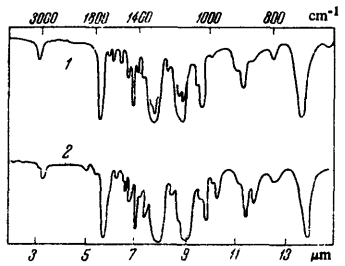


Figure 17. Infrared spectrum of poly(ethylene terephthalate):
1) amorphous; *2*) crystalline.

The absorption spectrum of a model compound (ethylene dibenzoate) in solution contained the same absorption bands as did the molten polymer. It might be supposed that the changes in intensity of the polymer bands indicated in Table 3 were due to intermolecular or intramolecular interaction. Examination of the model compound (ethylene dibenzoate) showed that the intensity remained unchanged on dissolution of the compound in carbon tetrachloride over a wide range of concentrations. In crystalline ethylene dibenzoate, on the other hand, the 1375 and 1100 cm^{-1} bands disappear: they are "frozen out". All this indicates that the bands in Table 3 are not due to intermolecular interaction, but represent different conformations[119] of the polymer.

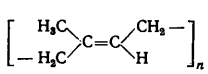
It may thus be supposed that the observed changes in the spectrum of poly(ethylene terephthalate) are associated with the phenomenon of rotational isomerism. When the polymer is stretched, a change is observed[121] in the intensities of the absorption bands in Table 3. It is interesting that the absorption bands which are most sensitive to a change in conformation of the chain are due to normal vibrations including ester and ethylene groups.

Table 3. Absorption bands sensitive to crystalline state.

ν, cm^{-1}	Change in intensity with increasing crystallinity
1475	increases
1375	decreases
1340	increases
1130	increases
1100	decreases
975	increases

An investigation has been made[122] of the dependence on the applied load of the positions of the absorption band maxima associated with vibrations of the main chain and side-chains for poly(ethylene terephthalate), polyethylene, and poly-ϵ-caprolactam. This showed that under load the absorption maxima associated with the main chain move to lower frequencies, while those associated with side-chains are shifted to higher frequencies. These results enable infrared spectroscopy to be used to study the stress in bonds in a polymer subjected to tension, and to compare the mechanical stress produced in the specimen with the true stress acting on a deformed bond.

GUTTA-PERCHA



At 20°C gutta-percha can exist in two crystalline modifications—α and β—melting at 65° and 56°C respectively. α-Gutta-percha is the stable modification, which can be obtained from a solution of the polymer; β-gutta-percha is obtained by rapidly cooling the amorphous polymer which has been heated to 70°C. X-Ray data indicate[123] that the unit cell of β-gutta-percha has the parameters—a = 7.78 Å, b = 11.78 Å, and c = 4.72 Å—and contains four isoprene groups. Data on the parameters of the unit cell of the α-form are more uncertain. α-Gutta-percha has a molecular period of c = 8.9 Å, which is produced by two isoprene groups, not one as with β-gutta-percha, where c = 4.72 Å. The two modifications are obviously rotational isomers.

The infrared spectra of the α- and β-forms of gutta-percha differ markedly in frequency and intensity in the range 1700–400 cm^{-1} (Fig. 18).[124–126] Characteristic absorption bands of α-gutta-percha are located at 1150, 1100, 1055–1035 (doublet), 865, 490, and 470 cm^{-1}. β-Gutta-percha is characterised by absorption bands at 1290–1270 (doublet), 1160, 1108, 760, 603, and 475 cm^{-1}. Table 4 gives the probable assignment of these bands. Comparison of the spectrum of crystalline gutta-percha with the infrared absorption spectrum of a melt of α- and β-forms shows that the bands at 1215, 890, 865, 805, 615, 490, and 470 cm^{-1} are "crystalline" in the spectrum of the α-modification. The absorption bands at 1220, 882, 800, 760, 603, and 475 and the 1290–1270 cm^{-1} doublet are "crystalline" in the spectrum of β-gutta-percha. The difference in the frequencies of the "crystalline" bands due to α- and β-gutta-percha is associated with the difference in structure between their unit cells, which are made up of chains having different configurations. These vibrations most probably arise as a result of intermolecular resonance interaction of corresponding vibrations. This certainly applies to the doublets 1055–1035 and 1290–1270 cm^{-1} in the absorption spectra of α- and β-gutta-percha respectively. With polarised radiation the absorption bands of these doublets show opposite polarisation, and in a melt the doublets are replaced by absorption bands at 1040 and 1260 cm^{-1} respectively.

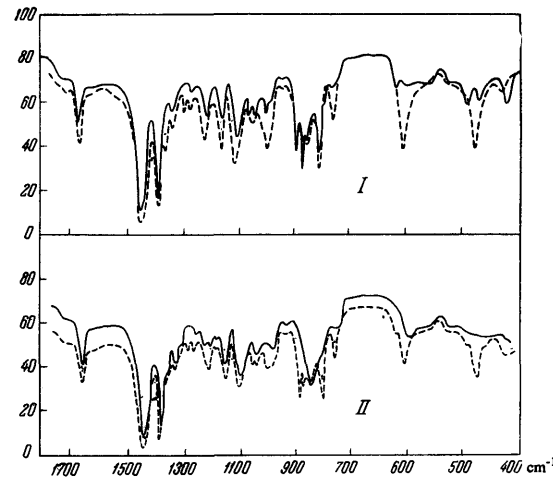


Figure 18. Infrared spectrum of gutta-percha: *I*) α-gutta-percha (full curve) and β-gutta-percha (broken curve); *II*) molten gutta-percha (full curve) and $\alpha + \beta$-gutta-percha (broken curve).

Table 4. Assignment of "crystalline" absorption bands (ν, cm^{-1}) in gutta-percha.

Modification		Assignment
α	β	
	1290	$\gamma_w(CH_2)$, $\gamma_t(CH_2)$
	1270	
1215	1220	
1150	1160	ν (C—C), $\gamma_r(CH_2)$
1100	1108	
1055		
1035		
890	882	
865	760	$\gamma_r(CH_2)$
805	800	
490	603	C—CH_3, C—C—C
475	475	C—C=C deformation
420	425	

In the range 400–700 cm^{-1} the absorption in molten α- and β-gutta-percha and its solution in carbon disulphide is diffuse in character[126]. The appearance of distinct, sharp

absorption bands in this range on crystallisation of the polymer either in α- or β-form, is linked with a change in the selection rules accompanying the transition from amorphous to crystalline gutta-percha. Independently of the reason for the appearance of "crystalline" bands in the α- and β-forms, it is fundamental that these bands characterise, directly or indirectly, the conformation of the chains in the differing crystal cells of α- and β-gutta-percha. This provides a method for studying the crystallinity of the two forms, their melting points, etc. It is also very important that the presence of bands characteristic of α- and β-forms has enabled the rotational-isomerism mechanism of the stretching of polymers to be proved unambiguously[115,126,127]. It has been shown that, when the α-crystalline form of gutta-percha is stretched, it passes into the β-form. This corresponds to conversion of an isomer of shorter chain length (the α-form) into an isomer of longer chain length (the β-form).

The infrared spectra of the α- and β-modifications of gutta-percha differ not only in their "crystalline" bands. The 1108 cm^{-1} band in α-gutta-percha and the 1100 cm^{-1} band in β-gutta-percha are of interest. They are probably due to ν(C–C) vibrations. The 1100 cm^{-1} band characterises the α-conformation of the chain, while the closely situated 1108 cm^{-1} characterises the β-conformation. Fig. 19 shows the infrared spectra in the range 1000–1100 cm^{-1} for the two modifications dissolved in carbon disulphide and for molten gutta-percha. In the spectrum of crystalline α-gutta-percha the main band at 1100 cm^{-1} is accompanied by a weak band at 1108 cm^{-1}, which indicates that the polymer contains, besides chains in the α-conformation, sections of molecular chains in the β-conformation.

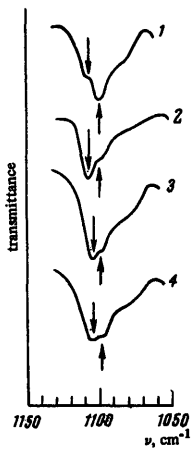

Figure 19. Infrared spectrum of:
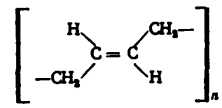
1) α-gutta-percha at 20°C; *2*) β-gutta-percha at 20°C; *3*) gutta-percha dissolved in CS_2; *4*) molten gutta-percha at 70°C.

The spectrum of crystalline β-gutta-percha contains a weak band due to the α-conformation. Two absorption bands, corresponding to the α- and β-conformations of the chain, can also be distinguished in the spectrum of a solution in carbon disulphide and of the melt. The presence in the spectrum of gutta-percha of bands characteristic of both conformations provides a method for determining their contents[126] in crystalline specimens at 20°C. It has been found that crystalline α-gutta-percha contains 60% of chains in the α-conformation and 40% in the β-conformation. Crystalline β-gutta-percha contains 60% of chains in the β-conformation and 40% in the α-conformation.

POLY-*trans*-1,4-BUTADIENE



This polymer can exist in two crystalline modifications[128–130]. Modification I exists up to ~ 50°C. Over the temperature range 50–70°C two modifications are present together. Above 70°C the polymer exists as modification II, which gradually melts with rise in temperature, and at 130°C the polymer is in the amorphous state. The infrared spectrum of this polymer (Fig. 20) is characterised by

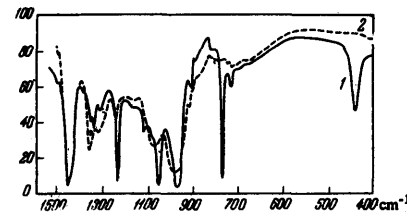


Figure 20. Infrared spectrum of poly-*trans*-1,4-butadiene:
1) crystalline; *2*) amorphous.

"crystalline" absorption bands at 445, 772, 1121, 1235, and 1051 cm^{-1}, the intensity of which decreases with rise in temperature, and "amorphous" bands at 1350 and 1308 cm^{-1}, whose intensity increases with rise in temperature[128]. Fig. 21 shows that the temperature dependence of optical density in "crystalline" and "amorphous" bands[130] is in opposite senses, being associated with transition of modification I into modification II and their fusion. This result is consistent with X-ray investigations[130].

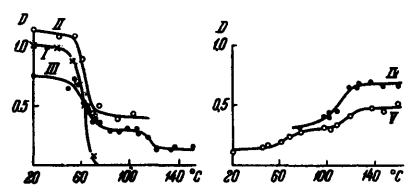

Figure 21. Temperature variation of optical density of poly-*trans*-1,4-butadiene in "crystalline" bands (cm^{-1}):
I) 770; *II*) 1051; *III*) 1235; and in "amorphous" bands at:
IV) 1308; *V*) 1353.

The "crystalline" absorption bands of poly-*trans*-1,4-butadiene can be divided into two groups. The bands at 445, 770, and 1121 cm^{-1} disappear completely on fusion of

the polymer, and their appearance on crystallisation is probably associated with a change in the selection rules. The bands at 1235 and 1051 cm^{-1} become much stronger on crystallisation, but do not disappear completely in the melt. They may be associated with the retention in the melt of a rotational isomer characteristic of the crystalline state of the polymer. The absorption bands at 1308 and 1353 cm^{-1} are especially interesting. Bands at 1353 and 1303 cm^{-1} in polyethylene were assigned to the vibration $\gamma_w(CH_2)$ in the amorphous portion of the polymer[18,113]. In poly-*trans*-1,4-butadiene they can probably be assigned to this type of vibration. These absorption bands have been used for the quantitative determination of the crystalline portion in an unoriented specimen.

The process of orientation of poly-*trans*-1,4-butadiene has been investigated in work[131] on the variation in the intensity and dichroism of the bands at 1308, 1235, 1051, 772, and 445 cm^{-1}. This has shown that the quantity of crystalline material in the polymer increases in the course of orientation, and at degrees of orientation of ~ 45% the crystalline portion is completely oriented along the axis of stretch. Calculation of the angle of orientation between the direction of the dipole moment and the axis of the molecule for the vibration $\delta(CH_2)$ showed that the molecular chains in the crystalline portion of modification I of poly-*trans*-1,4-butadiene do not have a planar *trans*-conformation but are somewhat twisted.

In conclusion we give a published[131] assignment of the "crystalline" and "amorphous" bands in this polymer (Table 5).

Table 5. Assignment of "crystalline" and "amorphous" bands in the spectrum of poly-*trans*-1,4-butadiene.

At 20°C, "crystalline"					At 150°C, "amorphous"	
ν, cm^{-1}	intensity	$R = D_{\parallel}/D_{\perp}$	α, deg	assignment	ν, cm^{-1}	intensity
1350	m.	?	—	(CH_2) amorphous	1354	m.
1340	m.	?	—	(CH_2) crystalline	—	–
1308	w.	?	—	(CH_2) amorphous	1313	m
1235*	s.	10.72	0—23	(CH_2) crystalline	1243	w.
1121	w.	?	—	crystalline	—	–
1051*	s.	3.53	31—37	crystalline	1063	m.
772*	s.	?	—	(CH_2) crystalline	—	–
445*	s.	0.65	62—61	crystalline	—	–

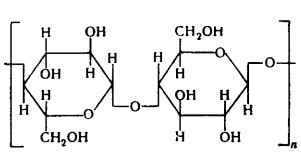
* Band frequencies differ by 2 cm^{-1} with $E_{\parallel}$ *and* $E_{\perp}$.

Intensity: m. = medium; w. = weak; s. = strong.

A question mark (?) indicates that the sign of the polarisation is difficult to determine.

The symbol α denotes the angle between the direction of the dipole moment and the direction of orientation.

CELLULOSE



The view is widely held, based on the results of physical methods of investigation, that the supermolecular structure of cellulose contains highly ordered (crystalline) and less ordered (amorphous) chain segments. Several workers do not accept the presence of strict three-dimensional ordering of chains in this polymer[132]. A more detailed discussion of this matter will be found in a monograph[133].

X-Ray examination shows that cellulose can exist in various crystalline modifications (I–IV). The arrangement of the atoms in the unit cells has not been established definitely, and significant information can therefore be obtained from a study of the disposal of atomic groupings by means of polarised infrared radiation.

The early spectroscopic investigations of cellulose showed that hydroxy-groups in it were hydrogen-bonded[134,135]. This conclusion was based on an examination of the first overtone of the hydroxyl vibration. The nitration of cellulose was shown[135] to be accompanied by the release of hydroxyls from hydrogen-bonding. The shift in the band 2ν(OH) to higher frequencies in the spectrum of cellulose II than in that of cellulose I was explained by the weakening of hydrogen bonds in the former modification. A recent spectroscopic investigation of specimens of methylcellulose of low degrees of substitution indicates that increase in the degree of methylation is accompanied by a diminution in the number of hydroxyls involved in the stronger hydrogen bonds[136].

X-Ray data indicate the existence of various types of hydrogen bonds in the crystallographic unit cell of cellulose. This can be established by examining the hydroxyl bands in the infrared spectra.

The OH band, characteristic of a hydrogen bond, has five peaks[137] in the spectrum of highly crystalline cellulose I (*Valonia ventricosa*). Interesting results have been obtained by investigating deuteriated samples of celluloses. The method of deuterium exchange enables the absorption of associated OH groups, present only in the crystalline portion of a polymer, to be observed, since in the early stages deuteriation does not affect the crystals. It has been established[138] by this method that the crystalline portion of cellulose II exhibits four OH peaks, at 3484, 3444, 3322, and 3163 cm^{-1}, characteristic of a hydrogen bond (Fig. 22). The OH absorption bands in crystalline model compounds—cellotetraose and cellopentose—have been observed at the same frequencies. On deuteriation the frequency of the OH peaks in cellulose II is found[136] to decrease by the same amount. All this suggests that various types of hydrogen bonds are present in the crystalline portion of cellulose II. It must be stressed, however, that great caution must be exercised in establishing a relation between the number of peaks of OH- and NH-stretching vibrations and the number of types of hydrogen bonds, since individual peaks may be caused by other factors[138–140].

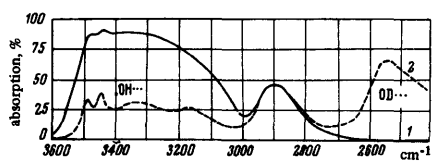


Figure 22. Viscose rayon film:
1) before deuteriation; *2*) after deuteriation for 4 h.

It has been definitely established[140,141] that all hydroxy-groups in the crystalline segments of celluloses I–IV are hydrogen-bonded, since no OH band characteristic of unbonded hydroxyl has been observed in the spectrum.

Replacement of OH by OD in the amorphous portion of cellulose specimens has permitted a detailed investigation of the form of the OH absorption band in the crystalline portion of celluloses I–IV. All four modifications of cellulose were shown[142] to have different spectra (in the range 3100–3600 cm^{-1}). Other workers have concluded[143], however, that all the crystalline forms can be represented by only two types of spectra (in the range 400–3700 cm^{-1}). The difference in the spectra is explained by rotational isomerism of the hydroxymethyl group[143], it being assumed (contrary to Ref. 144) that only two rotational isomers are present in cellulose.

Interesting results have been obtained from a study of oriented deuteriated cellulose specimens in polarised infrared radiation[145,146]. Figs. 23 and 24 show the OH and OD bands observed under these conditions. It is seen that the parallel component is more intense than the perpendicular component. This suggests that in cellulose crystals a large number of OH bonds are arranged parallel—not along the normal—to the chain direction. The hypothesis has been put forward that some of the hydroxyls form part of an intramolecular hydrogen bond between $O_{(3)}$ of one unit and $O_{(6)}$ of another, and between $O_{(5)}$ and $O_{(6)}$, which also belong to different units[146]. The presence in cellulose of intramolecular together with intermolecular hydrogen bonds has been pointed out also by other workers[147].

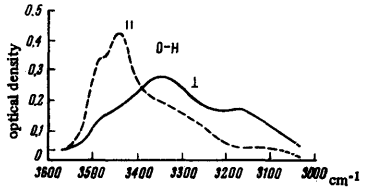

Figure 23. Dichroism of crystalline segments of cellulose II in the region of OH vibrations.

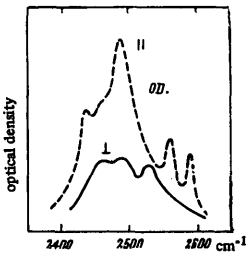

Figure 24. Dichroism of crystalline segments in region of OD vibrations.

The intensities of the bands at 900 and 1430 cm^{-1} are sensitive to structural changes in cellulose[149–151]. Thus they depend on the degree of crystallinity of the specimens[149]. When a sample was ground into powder, the intensity of the latter band diminished, and at the same time that of the 900 cm^{-1} band increased. Hence the 1430 cm^{-1} band was regarded as "crystalline", and the 900 cm^{-1} band as "amorphous". The degree of crystallinity of cellulosic materials is determined from the intensity ratio of the bands at 1430 and 900 cm^{-1}. Other workers have found that these bands change in intensity on passing from cellulose I to cellulose II (on mercerisation), and on this basis have proposed a spectroscopic method for determining this transition[150]. It has been noted also[151] that the intensities of these bands change both with the degree of crystallinity of the specimen and with the extent of conversion of cellulose I into cellulose II. These results show that further study is required of the use of these bands to determine the degree of crystallinity of cellulose and to assess the process of mercerisation. Mention must be made here of work[152] showing that the 900 cm^{-1} band in various specimens of cellulose is composite, consisting of at least two components (Fig. 25). Differences in the position and the intensity of the components in the region of 900 cm^{-1} in different samples of cellulose may be associated with rotational isomerism. A band at 560 cm^{-1} is also sensitive[143] to the transition I → II.

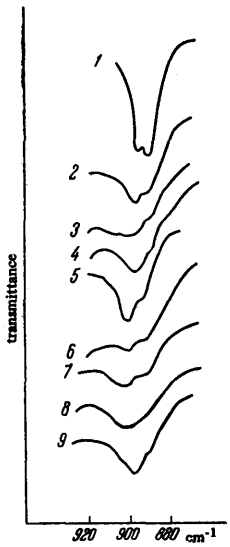

Figure 25. Spectra of:

The method of infrared spectroscopy is used to estimate the crystallinity of cellulose and assess the conversion of cellulose I into cellulose II. As already mentioned, deuterium exchange takes place in the amorphous portion of cellulose, leaving the crystalline portion practically unaffected. This enables the contents of crystalline and amorphous materials in cellulose to be estimated from the relative intensities of the OH and OD bands[148].

The intensity ratio of bands at 1372 and 2900 cm^{-1} has recently been proposed[153] for estimating the crystallinity of celluloses I and II. The former is regarded as the crystallinity band, while that at 2900 cm^{-1} is used as internal standard. This intensity ratio correlates with the crystallinity of the polymer determined from X-ray data, density, and the sorption of moisture. This correlation is

stated to be of the same form for celluloses I and II as for cellulose which has been treated with alkali, which is not the case with the intensity ratio of the bands at 1430 and 900 cm^{-1}.

It must be pointed out that a_{1372}/a_{2900} does not correlate sufficiently well with the crystallinity of cellulose determined by other physical methods[153]. The overlapping of the absorption band at 1372 cm^{-1} with adjacent bands, and also the difficulty of allowing for the background, are the reasons why structural changes in cellulose cannot be assessed with sufficient accuracy from this ratio.

A method has been proposed[154] for measuring the extent of mercerisation of cellulose from the ratio of the optical densities in infrared bands at 1375 and 1325 cm^{-1}. The sensitivity of this ratio to mercerisation has been established by comparing spectroscopic with X-ray data.

The present review has reported work on the structure of cellulose. Information on the spectroscopic investigation of cellulosic materials (the oxidation of cellulose, its ethers, and its esters, the study of substituted celluloses, etc.) can be found in several publications[155-157].

POLYPEPTIDES

The primary reason for interest in this class of polymers is that polypeptides represent one of the closest analogues of proteins. As a consequence, the application of infrared spectroscopy to the study of these compounds is also associated with the modelling of processes occurring in protein molecules under corresponding conditions. In the present review we shall confine ourselves to a brief account of the possibilities of the infrared method for investigating the secondary structure of polypeptides.

The molecular chains in polypeptides exist mainly in one of three conformations—the α-helix, the β-conformation, or a coil[158-160]. X-Ray data indicate that one turn of the α-helix contains 3.6 amino-acid residues. The identity period along the axis of the helix is 27 Å. The height of one turn of the helix is 1.5 Å. An intramolecular hydrogen bond links amino-acid residues 1 and 3. The β-conformation is characterised by an almost completely extended polypeptide chain. Maximum saturation by intermolecular hydrogen bonds occurs when two polypeptide chains are mutually antiparallel. Owing to steric interaction of the β-carbon atoms, the peptide groups emerge from the plane of the carbon chain, and the polypeptide chains form so called folded layers having parallel and antiparallel arrangement of the chains. In the case of a folded layer having the chains parallel the identity period along the chain is 6.5 Å. The interchain period is 4.7 Å. The corresponding periods for a folded layer having antiparallel chains are 7.0 and 10 Å respectively.

The existence of a coiled conformation in polypeptide chains in appropriate solvents has been established from measurements of viscosity and optical rotation. Several polypeptides have been obtained in a coiled conformation in films, e.g. sodium polyglutamate and poly-*S*-carboxymethyl-L-cysteine[161,162]. The methods most widely used for investigating the secondary structure of polypeptide chains are optical rotation, X-ray diffraction, and infrared spectroscopy. Examination of the optical rotation of polypeptides will provide evidence of the presence of a helical conformation of the polypeptide chain in any solvent, but this method gives no information on other ordered conformations of polypeptides without special hypotheses. The X-ray method enables differences in the conformation of a polypeptide chain to be assessed fairly unambiguously, but it is too cumbersome and difficult for everyday use. Infrared spectroscopy began to be used to investigate the structure of polypeptides in the late 1940s and early 1950s. An empirical relationship was used between the conformation of a polypeptide chain and the position and dichroism of bands due to the peptide group

In practically all polypeptides except polyproline[158] the peptide group is in the planar *trans*-conformation[160,163]. This group has the characteristic absorption bands[164-167]—1650 (amide I), 1550 (amide II), 1300–1250 (amide III), 627 (amide IV), 720 (amide V), 600 (amide VI), and 200 (amide VII)—among which amide I and amide II are most often used for structural investigations. Some 80% of the potential energy associated with the amide I band is due to stretching vibrations of C=O groups, 10% is due to CN, and 10% to deformation vibrations of NH groups. Variation in the dipole moment of this oscillation occurs approximately in the direction of the C=O bond. The amide II vibration is 60% associated with deformation vibrations of NH and 40% with vibrations of CN. Variation in the dipole moment of this oscillation is perpendicular to the NH bond. To a first approximation the amide I and amide II vibrations are localised in the amide group, and are thus independent of the chemical structure of the polypeptide[167,168].

The position and polarisation of the amide I and amide II bands, as well as of the NH-stretching band, are given in Table 6 for various conformations of polypeptides[169].

Table 6.

Vibration	α-Helix	Dichroism	β-Form	Dichroism	Coiled
N-H stretching	3290—3330	∥	3280—3300	⊥	3400
Amide I	1650—1660	∥	1630	⊥	1660—1700
Amide II	1540—1550	⊥	1520—1530	∥	<1520?

An explanation has recently been put forward[170,171] for the observed difference in position and polarisation of the amide I and amide II absorption bands depending on the conformation of the polypeptide chain. Calculation of the dichroism and frequency positions of these bands in various conformations took into account the effect of interaction between amide I and amide II vibrations in neighbouring groups along the chain and between chains. Table 7 gives the results of such calculation, the symbols δ and δ' denoting the phase of the vibration in the adjacent amide group along the chain and between chains respectively.

The calculation[170,171] provides a good qualitative explanation of the dependence of the positions of amide I and amide II on the conformation of the polypeptide chain, but the numerical values thus obtained for the frequencies are not always correct. This is due mainly to the choice of unperturbed amide I and amide II vibrations.

Thus Krimm[172,173], unlike other workers[170], considers that the frequency 1520 cm^{-1}—not 1535 cm^{-1}—corresponds to the unperturbed amide II vibration. The value of ν_0 has been shown[174,175] to vary from 1659 to 1653 cm^{-1} for amide I, and from 1540 to 1566 cm^{-1} for amide II, which indicates that factors other than those connected with the conformation of the polypeptide chain influence the position of these frequencies. In this connection it should be noted that the

so-called coiled conformation of polypeptides may contain segments of chains in various states of order. Therefore values of ν_0 calculated from the infrared spectra of polypeptides in a coil are also not altogether correct. In order to determine the conformations of polypeptide chains it is most correct to use the frequency characteristic of the amide I and amide II bands together with measurements of their dichroism. Recently the amide V frequency, relating to out-of-plane vibration of NH, has begun to be used[176-178] to determine the conformation of polypeptide chains. This vibration is situated at 610–620, 700, and 650 cm^{-1} for the α-conformation, the β-conformation, and a coil. However, the degree to which this vibration is localised in the amide group is not altogether clear at the present time, since the positions of amide V for various conformations of the polypeptide chain have been studied on a relatively small class of polypeptides.

Table 7.

Conformation of polypeptide chain	Frequency assignment (δ, δ')	Amide I frequency		Amide II frequency	
		calc.	obs.	calc.	obs.
Coiled	ν_0	1658	1655 1650 s.	1535	1535
Helix	$\nu_{0\parallel}$	1650		1516	1516 w.
	$\nu_\perp$ $(2\pi/n)$	1647	1652 m.	1546	1546 s.
Folded-chain layer with parallel packing of chains	$\nu_\parallel$ (0, 0)	1648	1645 w.	1530	1530 s.
	$\nu_\parallel$ (π, 0)	1632	1630 s.	1550	1550 w.
Folded-chain layer with antiparallel packing of chains	$\nu_\parallel$ (0, 0)	1685	1685 w.	1530	1530 s.
	$\nu_\perp$ (π, 0)	1632	1632 s.	1540	—
	$\nu_\perp$ (π, π)	1668		1550	—

One of the chief perculiarities of polypeptides is the dependence of the conformation of their polypeptide chain on the nature of the solvent. Thus poly(γ-benzyl L-glutamate) has the α-helical conformation in chloroform solution, but passes into the coiled conformation in dichloroacetic or trifluoroacetic acid[179]. Use of the infrared absorption spectra to investigate the conformation of polypeptides in solution is difficult for two reasons: firstly, most solvents themselves absorb in the range investigated, and it is difficult to choose compensating conditions for such solvents as dichloroacetic and trifluoroacetic acids; on the other hand, as has already been noted, the amide I and amide II frequency characteristics do not always fully reflect the conformation of the polypeptide chain, and measurement of their dichroism in solution requires special apparatus[180,181].

At the present time it has not been accurately established what are the factors affecting formation of one or other conformation of polypeptides. Most authors link the conformation either with the molecular weight of the specimens[182-185] or with the type of amino-acid residue[186,187]. It has been shown experimentally and theoretically[188-190] that the α- and β-conformations are energetically close together. In working with polypeptides in the form of films, therefore, it must be borne in mind that the conformation of the polypeptide chain will depend in some cases on the nature of the solvent and also on other conditions of preparation of the specimen[183,184,189].

Measurement of the intensities of the amide I, amide II, and amide V absorption bands provides in principle a method for estimating quantitatively the presence of the α- and β-conformations and the coiled conformation in polypeptides. However, no accurate values are yet available for the absorption coefficients of these three amides in the various conformations. Preliminary results obtained by Blout and his coworkers[191,192] indicate that the absorption coefficients of corresponding amides are the same for the different conformations. The same conclusion has been reached from a study of the orientation of polypeptides[189].

Several polypeptides can exist under certain conditions in an ω-helical[193] conformation, as a 3_{10} helix[194], or as the so-called β-cross conformation[184,195-198]. Only the last of these three conformations has been well defined by means of infrared spectroscopy. A spectroscopic criterion of this conformation is provided by amide I and amide II frequencies characteristic of the β-structure and the dichroism observed in polypeptides present as α-helices. The positions of amide I and amide II in the spectrum of polypeptides in this conformation and their polarisation are explained by peculiarities in the packing of the polypeptide chain. The chains have a β-extended conformation coiled into the shape of bellows, individual units in which are joined by intramolecular hydrogen bonds. This structure recalls that of the polymer chain in a single crystal. The maximum information on the structure and conformation of the polypeptide chain can probably be obtained by investigating amide VII (200 cm^{-1}), but data on its position in the various conformations are not available at the present time, since the manufacture of standard apparatus for this spectral range started only recently.

New Information about Oxygen-containing Compounds of Iodine

M.Dratovský and L.Pačesová

1. INTRODUCTION

The systematic investigation of the oxygen-containing compounds of iodine has been carried out over the last 150 years but their study is far from complete. These compounds differ considerably from the compounds of the other halogens in their composition, nature of the bonding, stability, and other properties. Compared with chlorine and bromine, iodine forms a greater number of compounds, corresponding to the increased stability of the halogen–oxygen bond.

The following stable compounds are known in the solid state: I_2O_4, I_4O_9, I_2O_5, HIO_3, HI_3O_8, IO_3, HIO_4, $H_7I_3O_{14}$, H_5IO_6, and the salts of the acids mentioned. Furthermore, certain polyiodates are also known which have a composition other than that corresponding to tri-iodic acid HI_3O_8. As well as the oxide of composition IO_3 there are also salts which contain iodine(VI) corresponding in composition to the hypothetical acid H_2IO_4 or $H_2I_2O_7$. There have been descriptions of a series of salts which are derivatives of diperiodic acid $H_4I_2O_9$, the existence of which in the free state is disputed, and also salts of the hypothetical mesoperiodic acid H_3IO_5.

Information about the oxygen-containing compounds of iodine(V) and also about lower oxides of iodine is given in a series of well-known reviews and monographs on inorganic chemistry. Compounds of iodine(VI) and iodine(VII) have been less studied. Whilst orthoperiodic H_5IO_6 and metaperiodic HIO_4 acids and periodates of various compositions (derivatives of the acids H_5IO_6, H_3IO_5, HIO_4, and $H_4I_1O_9$) have long been known, the existence of triperiodic acid $H_7I_3O_{14}$, one of the products of the thermal decomposition of orthoperiodic acid, has only been shown recently. The oxide of composition IO_3 was recently isolated as a product of the thermal decomposition of periodic acid in a vacuum. Interesting results were also obtained in studying the thermal decomposition of periodates. These investigations led to the discovery of salts of the triperiodic acid mentioned above and of certain iodine(VI) compounds. The latter compounds, which contain iodine in an uncommon valence state also have the character of salts. Compounds of this type are completely unknown for the lighter homologues of iodine.

Recent investigations of the thermal decomposition of periodic acid and periodates have revealed extremely important information about the chemistry of iodine compounds. A considerable part of this review is devoted to this question.

2. LOWER OXIDES OF IODINE

The oxide of the empirical composition I_2O_4 is formed as a yellow powder on heating iodic acid with concentrated sulphuric acid and decomposing the sulphate first formed $(IO)_2SO_4$ with water[1-3]. This oxide is sparingly soluble in water and in organic solvents. At elevated temperatures with water it disproportionates to iodic acid and iodine. At higher temperatures I_2O_4 decomposes with the formation of iodine pentoxide and elemental iodine[4].

The oxide I_2O_4 is often considered as a compound of iodine of mixed valency (ter- and quinque-valent iodine). It is diamagnetic[5] and therefore it cannot be represented as the monomer IO_2. It must be considered as the dimer I_2O_4, or even as a polymer $(IO_2)_x$. Analysis of the infrared spectra indicate that the structure of this oxide in the solid state is a chain of

–O–I–O–I–O–

groups, with which a lattice of IO_3^- anions is bonded. Ideas[8] about the existence in the crystal lattice of simple iodyl cations and discrete molecules $(IO)^+(IO_3)^-$ seem incorrect.

The iodyl group is present in certain other iodine compounds, particularly salts (especially sulphates, selenates, and nitrates)[9,10].

An oxide of composition I_4O_9 is formed by the action of ozone on iodine (in the gas phase at 50°C or in solution in chloroform or carbon tetrachloride) as a yellow product[3,11-13]. By analogy with other iodine(III) salts this oxide is usually considered[14] as iodine iodate $I(IO_3)_3$.

3. IODINE(V) COMPOUNDS

Iodic acid HIO_3 is the most stable oxygen-containing acid of iodine. Together with iodates and iodine pentoxide it was known as early as the first half of the preceding century (Davy, 1815). Ever since, iodine(V) compounds have formed the subject of investigations by many authors.

The basis of the synthesis of iodic acid is oxidation of iodine by various reagents (for example, nitric acid, chlorine, by electrolysis, etc.) or by displacement of iodic acid from its salts by other acids. Iodates are obtained by neutralisation or even the oxidation of iodine in alkaline medium. Iodine pentoxide I_2O_5 can be made by the direct reaction of the constituent elements at elevated temperature or by dehydration of iodic acid (see below).

As well as simple iodates other derivatives of iodic acid, namely, a series of double salts and also salts with a complex cation, are known. For complexes in which iodate anions act as ligands, the preparation and properties of the acids $H_2[Sn(IO_3)_6]$, $H_2[Sn(OH)_2(IO_3)_4]$, and $H_2[Sn(OH)_4(IO_3)_2]$ and their salts have been investigated[15]. These compounds were obtained by the reaction, and subsequent crystallisation, of tin(IV) chloride (or potassium hexachlorostannate) with iodic acid (or with alkali metal iodates) in acid medium. Compounds of titanium(IV)[16], lead(IV)[17], manganese(IV)[18], and uranium(IV)[19] were isolated in a similar manner and investigated. Compounds of niobium and tantalum, have been described in which the iodine coordination number is 6. These can be represented by the formulae[20]: $Nb_2O_5.2HIO_3.2H_2O$ and $Ta_2O_5.HIO_3.6H_2O$.

Of the compounds which contain a cationic complex, there have been studies of certain iodate salts of hexamminecobalt(II), for example, $[Co(NH_3)_6](IO_3)_2.3H_2O$ [21], and of hexamminecobalt(III), for example, $[Co(NH_3)_6](IO_3)_3.3HIO_3$, also the iodates of hexammineplatinum(IV), of tetrammineplatinum(II), and tetramminepalladium(II).[22,23] The existence of certain simple iodate salts, their hydrates,, and in particular of a series of double compounds was established in a solubility study of multicomponent systems at various temperatures (Table 1).

Iodic acid is known in two modifications: α and β. Both are orthorhombic and differ only in the ratio of the crystallographic axes. Several early papers dealt with the structure of this compound[50-52]. Later only the α modification interested most authors[53-58]. The structure investigated consists of aggregates of molecules mutually connected by hydrogen bridges, which contain IO_3 groups in the form of deformed octahedra. There are 4 HIO_3 molecules in the unit cell. The presence of O–H–O bonds was confirmed also by the neutron diffraction method[59].

Several papers[51-53,60-66] are devoted to the study of the structure of iodates, particularly the alkali metal salts. These are usually compounds for which a perovskite lattice is characteristic, where the iodine has a coordination number of six. The perovskite-type compounds include potassium, rubidium, caesium, and ammonium iodates. It was found that as the atomic number of the cation is increased the edge of the lattice lengthens. The existence of a perovskite-type crystal lattice for these compounds was also established by the NMR method[67]. The structure of sodium iodate remained unexplained. Some authors assume that it has an antiperovskite-type structure[53,61,65]. For several other iodates, particularly those of silver, copper, calcium, barium, radium, and aluminium, the literature mentions only the system in which they are crystallised[51,52,60,68-72]. The structure of cerium(IV) iodate has been studied in greater detail[73,74]. Table 2 lists iodine(V) compounds, the structure of which has been investigated by X-ray diffraction.

$Ba(IO_3)_2 - BaCl_2 - H_2O$	$Ba(IO_3)_2 \cdot BaCl_2 \cdot 2H_2O$	49

The structure of iodic acid and of its salts has been studied by various physical methods (mainly spectroscopic and magnetic) both in the solid state and in solution. The nature of the Raman and infrared spectra agrees with the idea that in the solid state and in highly concentrated solutions there is polymerisation of the HIO_3 molecules[75-90]. The presence of $(HIO_3)_3$ trimers is usually assumed but the possible existence of polymers of the type $H_2I_4O_{11}$ etc. has also been discussed[91]. The degree of polymerisation usually drops with decrease in the concentration of the acid in the solution. In dilute solutions there are simple IO_3^- anions. Fonteyne[92] suggests that molecules of the pseudo-acid $HO-IO_2$ are also present. Study of the spectra of

iodates[81,83,93-107] suggests a symmetrical pyramidal structure for the IO_3^- anions. The molecule of iodine pentoxide I_2O_5 is also constructed symmetrically: two IO_2 groups are connected by an oxygen atom[108]. Magnetic susceptibility measurements also support these ideas on the structure of iodic acid molecule and anion[109-119]. The investigation of other properties of iodic acid and the determination of certain physical constants has mainly given way to a tendency to prove the presence of polymerisation of the molecules in concentrated solutions[120-137].

By thermal decomposition of certain hydrated iodates a series of hydrates with less water, and anhydrous salts, were isolated, and the limits of their stability established[105,106,138-150]. Dehydration of iodic acid at elevated temperature[151,152], forms tri-iodic acid HI_3O_8:

$$3HIO_3 \rightarrow HI_3O_8 + H_2O.$$

This acid can also be obtained by recrystallisation of iodic acid from concentrated nitric acid. Some authors ascribe the formula $3I_2O_5 \cdot H_2O$ to this compound[153-156]. Oxygen bridges were indicated in the HI_3O_8 molecule by infrared spectra[91,157]. The existence of other transitional hydrates, as, for example, $2I_2O_5 \cdot H_2O$, was not confirmed. According to some results the dehydration of iodic acid takes place directly with the formation of iodine pentoxide[158,159]. Some differences have been observed[160] in the dehydration of the α and β modifications of HIO_3.

By heating an equimolar mixture of potassium (or rubidium) iodate and iodine pentoxide in a sealed ampoule at 170°C, and also by the dehydration of salts of the type $M^IH_2(IO_3)_3$, the salts of tri-iodic acid KI_3O_8 and RbI_3O_8 can be obtained[161]. However, the formation of potassium triiodate in the thermal decomposition of $KH(IO_3)_2$ was not observed[152]—here only a mixture of the iodate and iodine pentoxide is formed.

The structure of the acid iodates and the question of the polymerisation of iodic acid and iodates are still unsolved problems. The acid iodates $M^IH(IO_3)_2$ and $M^IH_2(IO_3)_3$ can be obtained by crystallisation from aqueous solution of an equimolar mixture of iodate and iodic acid. According to early ideas they can be considered[162-165] as double compounds of general formula $M^IIO_3 \cdot HIO_3$ or $M^IIO_3 \cdot 2HIO_3$. The existence of such compounds is confirmed by equilibrium diagrams of multicomponent systems (see Table 1). Starting from the behaviour of iodic acid in solution, its dimer

is often considered a dibasic acid and the presence of the anion $I_2O_6^{2-}$ in solution has been suggested[77,92,122,135,166]. In other studies the existence of such an anion has been denied[167,168]. Polyiodates of the type $K_2H_2I_6O_{17}$ and $K_2I_4O_{11} \cdot 2H_2O$ have also been obtained by the thermal decomposition of certain hydrogen iodates. Infrared spectroscopy showed[157] the presence of I—O—I bridges in these polyiodates. Table 3 lists the compounds of iodine(V) the structure of which has been studied by spectroscopic methods.

Iodine dioxide fluoride IO_2F is also an iodine(V) compound. It can be obtained[169] by the action of iodine pentoxide on iodine(V) fluoride or the action of fluorine on iodine pentoxide in anhydrous [hydrogen] fluoride[170]. IO_2F tends to form complexes, for example, the complex arsenate $IO_2[AsF_6]$.

4. THE OXIDE I_2O_7

The existence of the oxide I_2O_7 in the free state cannot be considered as definitely proved. In many attempts to make this substance compounds of another composition were obtained. The following were erroneously taken for the oxide I_2O_7: the product of the reaction of iodine with

oxygen or ozone under the action of a silent discharge[171], the product of the reaction of iodine with chlorine(VII) oxide[172,173], or even the product of the reaction of iodine with iodic acid[174]. Neither could periodic anhydride be obtained by the thermal decomposition of the iodic acid at various temperatures in air or in a vacuum[175]. As a result of the dehydration of orthoperiodic acid by gaseous fluorine[176] only the metaperiodic acid HIO_4, and not periodic anhydride, is formed. Even the metaperiodic acid could not be dehydrated completely by fluorine in anhydrous hydrogen fluoride. As a result of this reaction the iodine(VII) oxide fluoride IO_3F is formed[172]. The most successful was apparently an attempt[177] to dehydrate periodic acid in 65% oleum. The composition of the strongly reactive orange compound obtained differs little from the ultimate analysis of the oxide I_2O_7.

5. PERIODIC ACID

Four solid hydrates of iodine(VII) oxide are known: $I_2O_7.5H_2O$ (H_5IO_6, orthoperiodic acid), $3I_2O_7.7H_2O$ ($H_7I_2O_{14}$, triperiodic acid), $I_2O_7.2H_2O$ ($H_4I_2O_9$, diperiodic acid) and $I_2O_7.H_2O$ (HIO_4 metaperiodic acid).

a. Orthoperiodic acid H_5IO_6 has been known for about 130 years and methods for its preparation and principal chemical properties have been given in well-known monographs. This acid can be prepared by electrolysis[178] or by its displacement from periodates by the action of strong acids (particularly by use of nitric[179] and perchloric[180] acids). Orthoperiodic acid forms the starting point for making all the hydrates of the oxide I_2O_7 poorer in water. As a rule this is done by thermal decomposition of orthoperiodic acid at ordinary pressure or in a vacuum.

Periodic acid can be represented as the ortho-acid H_5IO_6 or as the dihydrate of the meta-acid $HIO_4.2H_2O$. The second formula was proposed on the basis of magnetic measurements[181] according to which the experimental magnetic susceptibility of periodic acid ($\chi = -71.4 \times 10^{-6}$) is close to the value calculated for the dihydrate $HIO_4.2H_2O$ ($\chi = -77.7 \times 10^{-6}$) and slightly different from the value calculated for orthoperiodic acid ($\chi = -55.7 \times 10^{-6}$). Other authors who studied the dehydration of periodic acid in anhydrous pyridine[182] also consider periodic acid to be the dihydrate of the meta-acid. However, the structural measurements show that it is more correct to consider the pentahydrate of the oxide I_2O_7 to be the ortho-acid. The Raman spectrum of periodic acid in the solid state shows the octahedral symmetry of the IO_6 group. In the spectrum of the aqueous solution of periodic acid four lines agree with the frequencies of the metaperiodate anion IO_4^- and three lines correspond with the undissociated H_5IO_6 molecules. It is therefore assumed[183] that in solution the ortho-acid undergoes dehydration:

$$H_5IO_6 \rightleftarrows H^+ + IO_4^- + 2H_2O.$$

In the absorption spectra of periodic acid in the infrared region distinct bands can also be distinguished at 2900 and 2200 cm^{-1}, due to the OH group, and in the 1100–1300 cm^{-1} range there are bands due to the I–OH groups, whereas the bands at 3400 cm^{-1}, typical for water molecules, are absent.

The octahedral structure of the anion IO_6^{5-} also follows from the structure found for orthoperiodic acid[185,186]. This compound is monoclinic with somewhat deformed octahedra of oxygen atoms about the central iodine atoms. Since conclusions based on the direct determination of structure by spectroscopic and X-ray diffraction methods ought to be considered more reliable than those which follow from magnetic measurements and dehydration experiments, it can be assumed that the correct formula for the pentahydrate of I_2O_7 is H_5IO_6, that is, this compound is the ortho-acid.

By heating the orthoperiodic acid in the atmosphere it loses water and is converted into triperiodic and then metaperiodic acid. Above 170°C it undergoes more extensive decomposition into iodine(VII) oxide[187]. The thermal decomposition of this acid in a vacuum is somewhat more complex (see below).

b. Triperiodic acid $H_7I_3O_{14}$ is formed[187] as a primary dehydration product as a result of the thermal decomposition of orthoperiodic acid in the temperature range 121-130°C. This compound was discovered in an attempt to reproduce the diperiodic acid preparation according to Partington and Bahl[188]. The existence of triperiodic acid was proved by thermogravimetric, tensimetric, and X-ray diffraction methods[187]. The decrease in the weight of the specimen observable in the thermogravimetric study of the dehydration of some preparations of orthoperiodic acid (prepared by three different methods) is always less than would correspond with the formation of diperiodic acid. Instead of the expected 1.5 moles water which correspond with the formation of diperiodic acid, the observed loss in weight during the dehydration amounts to 1.33 moles water per 1 mole of the initial acid. Therefore the dehydration can be represented by the equation:

$$3H_5IO_6 = H_7I_3O_{14} + 4H_2O.$$

The formation of triperiodic acid was also confirmed by dehydration in a vacuum on a quartz spiral thermobalance at 60°C. The tensimetric measurements made by Hauptman[187] refute the incorrect conclusions of Partington and Bahl[188] concerning the existence of diperiodic acid $H_4I_2O_9$. The measurements of the latter authors were insufficiently detailed, since they did not record experimental points in the range important for deciding to which composition the break on the tensimetric curve relates ($H_4I_2O_9$ or $H_7I_3O_{14}$).

c. Diperiodic acid $H_4I_2O_9$. The existence of diperiodic acid in the solid state has been noted in only two studies. The first of these is the work of Partington and Bahl already mentioned[188], in which tensimetric measurements were made. As we have already noted, the results obtained by these authors were later refuted by Hauptman[187].

Ripanova and Duca[189] described the isolation of diperiodic acid from aqueous solution. The acid was displaced from barium diperiodate by the action of sulphuric acid of from the silver salt by the action of hydrogen chloride. The acid was separated by crystallisation from the solution obtained. The authors also propose the formation of diperiodic acid in solution, in which orthoperiodic and metaperiodic acids are present in 1 : 1 ratio. From conductometric measurements the authors assume that this acid should be formed on the introduction of carbon dioxide into a solution of orthoperiodic acid. Diperiodic acid should be precipitated, since its solubility is only about one-sixtieth of that of the ortho-acid. However, Hauptman[187] did not succeed in reproducing these extremely unreliable results.

d. Metaperiodic acid HIO_4 was first obtained[190] by dehydrating orthoperiodic acid at reduced pressure at 100°C. Later the formation of this acid was also confirmed by other authors, who investigated the thermal decomposition of the ortho-acid in the air[188,191] in the tem-

perature range 140–170°C and in vacuum[192] at 80°C. Furthermore, it was shown that the sublimate formed as a result of the dehydration of the ortho-acid at reduced pressure is metaperiodic acid. Proof was obtained by the ultimate analysis and by comparison of the X-ray powder patterns of the sublimate and metaperiodic acid[191,193].

Both the well-known hydrates poorer in water, that is, the acids $H_7I_3O_{14}$ and HIO_4, are extremely hygroscopic compounds and therefore they are instantaneously rehydrated to the ortho-acid with atmospheric moisture.

e. The oxide IO_3. In the thermal decomposition of orthoperiodic acid in a vacuum two processes take place in the range 105–117°C: decomposition and simultaneous sublimation. On the colder parts of the apparatus a deposit is formed which according to earlier publications contains only iodine(VII) and is in all probability metaperiodic acid. A yellow substance containing formally sexivalent iodine remains at the bottom of the decomposition tube. According to the ultimate analyses its composition corresponds to the formula IO_3. The X-ray diffraction pattern of the powder also shows the individuality of the compound IO_3. The lines of the powder pattern of the substance were compared with those for HIO_4, I_2O_5, and HI_3O_8. The oxide IO_3 is formed[193] also in the thermal decomposition of the lower hydrates of iodine(VII) oxide ($H_7I_3O_{14}$ and HIO_4) in a vacuum at 115°C. However, the appearance of the sublimate formed by the decomposition of these compounds differs from that of the sublimate obtained in the decomposition of orthoperiodic acid. Because of experimental difficulties (mainly the considerable rehydration of the sublimate under the action of the water liberated) the composition of this product cannot be determined accurately nor is it possible to show whether the decomposition of the lower hydrates of iodine(VII) oxide results in the formation of metaperiodic acid or the anhydrous oxide I_2O_7.[192]

6. SALTS OF PERIODIC ACID

Periodates were discovered[194] in 1833 in the oxidation of a mixture of iodine and sodium carbonate solution with chlorine. Oxidation of various iodine compounds with chlorine in alkaline medium is themain method of preparing alkali metal periodates. Periodates of other metals are obtained from these by double decomposition in aqueous medium (by precipitation). Almost all the known periodates can be divided into four classes according to their composition: the metaperiodates M^IIO_4; mesoperiodates $M^I_3IO_5$ or $M^I_2HIO_5$; the orthoperiodates $M^I_2H_3IO_6$, $M^I_3H_2IO_6$, and $M^I_5IO_6$; and the diperiodates $M^I_4I_2O_9$. In some earlier studies[175,195], periodates of another composition are considered, for example, $M^I_8I_2O_{11}$, etc. Probably the authors isolated basic salts or even mixtures of the metal oxides and the corresponding periodates.

The investigation of the periodates is directed mainly to the preparation of new compounds and the subsequent study of their structure and physical properties. Several papers are also devoted to the investigation of their thermal decomposition.

The preparation of new simple periodates has usually accompanied the detailed study of the metal oxide–iodine(VII) oxide–water ternary system. The formation of new compounds in the ternary systems were established from the solubility curve or from measurements of the pH, etc. With the aid of such a method there has been success in extending considerably the number of known simple and double periodates of lithium[196,197], sodium[198,199], potassium[198,200], beryllium[201], magnesium[202], calcium and barium[203], lead(II)[204], copper(II)[205], silver[206–208], cadmium[209], and iron(III)[210] and observing all the periodates of the corresponding metals which can exist in the range of temperature studied in the presence of water. The systems studied are listed in Table 4.

Table 4. Equilibrium systems of iodine(VII) compounds.

Equilibrium system	Compounds formed in the system	Reference
$Li_2O—I_2O_7—H_2O$	Li_5IO_6, $Li_3H_2IO_6$, $Li_2H_3IO_6$, $LiIO_4 \cdot H_2O$	196

$Cu(ClO_4)_2—NaIO_4—NaOH—H_2O$	$Cu_3HIO_6 \cdot 3\,H_2O$, $Cu_5(IO_6)_2 \cdot 5\,H_2O$ $NaCu_3IO_6$	205
$Ag_2O—I_2O_7—H_2O$	Ag_5IO_6, Ag_3IO_5, Ag_2HIO_6, $Ag_2H_3IO_6$ $AgIO_4$, $AgIO_4 \cdot 2H_2O$	206, 207 208
$Cd_5(IO_5)_2 \cdot 3{,}5\,H_2O—H_5IO_6—H_2O$	$Cd(IO_4)_2 \cdot 8\,H_2O$; $Cd_2I_2O_9 \cdot 13\,H_2O$	209
$Fe_2(SO_4)_3—KIO_4—H_2O$	$Fe_5(IO_6)_3$	210

There is considerable interest in those ammonium and alkali metal periodates which can be obtained[211] from aqueous solutions (primarily by precipitation with methanol or by crystallisation at 0°C). These are mainly mesoperiodates, which apparently contain five-coordinate iodine. They are of low stability and are readily converted into the corresponding orthoperiodates with apparently six-coordinated iodine (Table 5).

However, certain orthoperiodates of the $M^I_5IO_6$ type—for example, Na_5IO_6,[212,213] $Ca_5(IO_6)_2$, and $Ba_5(IO_6)_2$[175,203]—can be prepared only by "dry" methods, since in contact with water they undergo partial hydrolysis with the formation of periodates which have a lower metal : iodine ratio.

In the preparation of new periodates special attention has been paid to the investigation of compounds which contain an anionic complex with a metal atom of higher valency as central atom and periodate anions as ligands Mn^{IV}, Fe^{III}, Co^{III}, Ni^{IV}, Cu^{III}, Ag^{III}, and Ce^{IV} are encountered as central atoms in these compounds (the periodate ions stabilise the higher oxidation state of the metal, which is of low stability). In most instances the sodium, potassium, and barium salts of the following hypothetical acids have been obtained:

$H_{11}Mn(IO_6)_3^{214,215}$, $HMnIO_6^{216}$,
$H_2FeIO_6^{217,218}$, $H_3Fe_4(IO_6)_3$, $H_7Fe(IO_6)_3^{219}$,
$H_3Co_4(IO_6)_3^{220,221}$, $H_7Co(IO_6)_2^{215,222}$.
$HNiIO_6^{223}$,
$H_7Cu(IO_6)_2^{224,225}$,
$H_7Ag(IO_6)_2^{226}$,
$H_6Ce(IO_6)_3^{227}$,

The general method of preparing these compounds[228] consists in the addition of an appropriate oxidant (for example, hypochlorite or peroxodisulphate) to a slightly

acid solution of alkali metal periodate and the corresponding salt of the metal to form the central atom, then making the mixture alkaline. Sometimes the crystallisation of the complexes can be brought about by addition of alcohol. The oxidation state of the central metal atom was found by titration with a suitable reductant or by measuring the magnetic susceptibility. These compounds are usually coloured and readily soluble in water. They are more stable in alkaline medium but some of them retain their stability in acid. For example, the free acid $H_7Co(IO_6)_2$ is stable in aqueous solution and it can be obtained by passing a solution of the sodium salt through a suitable cation-exchange resin.

Other complexes with the character of heteropolyacids are more stable in acid medium. They include chiefly compounds of periodic acid with vanadium[229], niobium, and tantalum[20] pentoxides. In these compounds, which contain an anionic complex, the iodine plays the part of central atom and the ligands are oxygen or oxo-anions of the Group Vb elements.

Periodates with a complex cation, the central atom of which is an atom of a metal with a strongly expressed complex-forming ability (for example, Co^{III},[230-233] Cr^{III},[234,235] Pd^{II}, Pt^{II}, Pt^{IV} [23]), are also well known. The ligands most frequently encountered are NH_3 molecules, molecules of organic compounds, Cl^-, Br^-, and SCN^- ions, etc. Periodate anions usually do not enter the coordination sphere of these compounds.

The structure of periodates has been investigated by X-ray diffraction, especially for alkali metal and silver periodates. Table 6 surveys the published information[236-254]. Clearly, most of the anhydrous periodates are tetragonal. They are isostructural with scheelite and their anions form tetrahedra, whereas in the structure of orthoperiodates the IO_6^{5-} anions are arranged in octahedra. The diperiodate anions are also usually made up of two octahedra with one edge in common (that is, two oxygen atoms).

The structure of the ammonium and alkali metal periodates was also studied with the aid of spectroscopic methods. The infrared spectra led to some unexpected results. It was found, for example, that the structure of certain compounds which were thought earlier to be diperiodates or orthoperiodates corresponds to mesoperiodates[184,211]. Table 7 gives the results of these measurements. The infrared spectra of silver periodates[255] and some transition metal periodates[215] were studied rather more systematically.

The structure of periodates has also been determined on the basis of measurements of magnetic properties, especially, magnetic susceptibility[256-259]. The results of these measurements have sometimes enabled complexes to be distinguished from simple compounds.

Ammonium and silver trihydrogen periodates $(NH_4)_2H_3IO_6$ and $Ag_2H_3IO_6$ exhibit anomalous dielectric constants at low temperatures. This can be explained by a transformation to an antiferroelectric phase at low temperatures[244,260-265].

7. BEHAVIOUR OF PERIODATES AT ELEVATED TEMPERATURE

The thermal decomposition of periodates of various compositions is accompanied by loss of water, oxygen, and iodine (in some instances of only one or two of these components). Depending on the composition of the initial periodates, the products of their thermal decomposition are: partly dehydrated periodates, for example[197]:

$$3\,[LiIO_4\cdot 3H_2O]=Li_3H_4I_3O_{14}+7H_2O\,, \qquad (1)$$

or completely dehydrated periodates[200]:

$$K_4I_2O_9\cdot 9H_2O=K_4I_2O_9+9H_2O\uparrow\,, \qquad (2)$$

periodates of another composition, for example[197]:

$$3\,[(NH_4)_2\,Li_2I_2O_9\cdot 7H_2O]=2Li_3\,(NH_4)_2H_2I_3O_{14}+2NH_3+20\,H_2O\,, \qquad (3)$$

or[269]:

$$5Ba\,(IO_4)_2=Ba_5\,(IO_6)_2+4I_2+14O_2\,, \qquad (4)$$

compounds of iodine(VI), for example[270]

$$Na_2H_3IO_6=Na_2IO_4+\frac{3}{2}\,H_2O+\frac{1}{4}\,O_2\,, \qquad (5)$$

iodates[199]:

$$NaIO_4=NaIO_3+\frac{1}{2}\,O_2\,, \qquad (6)$$

or iodides[199]:

$$NaIO_4=NaI+2O_2\,. \qquad (7)$$

In the thermal decomposition of heavy metal periodates, oxides of the corresponding metal[271] or the metal in an elemental state[266,268] can also be formed.

Whereas the products formed as a result of the thermal decomposition of periodates according to Eqns. (2), (4), (6), and (7) are known substances and their formation during the course of these reactions was established long ago, the products obtained as a result of reactions (1), (3), and (5) were identified only recently. According to Eqn. (1), and also (3), in the thermal decomposition of periodates, periodates are formed which on the basis of their composition could be classified as salts of triperiodic acid $H_7I_3O_{14}$ obtained by Hauptman[187]. The substance produced in the partial dehydration of magnesium periodate[202] may also belong to these polyperiodates:

$$Mg\,(IO_4)_2\cdot 8H_2O=Mg\,(IO_4)_2\cdot 1.66\,H_2O+6.33\,H_2O\,,$$
$$3\,[Mg\,(IO_4)_2\cdot 1.66\,H_2O]=Mg_3\,(H_4I_3O_{14})_2\cdot H_2O\,. \qquad (8)$$

Since the structure of triperiodic acid and its salts has not yet been established, it is impossible to explain why triperiodates are formed as a result of the decomposition of periodates of metals of small ionic radius (Li^+, Mg^{2+}).

It was observed recently that iodine(VI) compounds are formed in the thermal decomposition of periodates at 200°C according to the equations:

		Reference
$Li_2H_3IO_6=Li_2IO_4+\frac{3}{2}\,H_2O+\frac{1}{4}\,O_2\,,$	(9)	272
$Na_2H_3IO_6=Na_2IO_4+\frac{3}{2}\,H_2O+\frac{1}{4}\,O_2\,,$	(10)	270
$Be_3\,(IO_5)_2\cdot 12H_2O=Be_3I_2O_9\cdot 4H_2O+8\,H_2O+\frac{1}{2}\,O_2\,,$	(11)	273
$Mg_2I_2O_9\cdot 2{,}5\,H_2O=2\,[MgIO_4\cdot 0{,}5\,H_2O]+\frac{3}{2}\,H_2O+\frac{1}{2}\,O_2\,,$	(12)	202
$Ca_2I_2O_9\cdot 9\,H_2O=2CaIO_4\cdot H_2O+7H_2O+\frac{1}{2}\,O_2\,,$	(13)	274
$Ba_2I_2O_9\cdot 9\,H_2O=2BaIO_4\cdot H_2O+7H_2O+\frac{1}{2}\,O_2\,,$	(14)	269
$2Al\,(IO_4)_3\cdot 12\,H_2O=Al_2\,(I_2O_7)_3\cdot 2H_2O+22\,H_2O+\frac{3}{2}\,O_2\,,$	(15)	275
$Pb_2I_2O_9\cdot 3H_2O=2PbIO_4+3H_2O+\frac{1}{2}\,O_2\,,$	(16)	271
$2Cd_2I_2O_9=4CdIO_4+O_2\,.$	(17)	209

The products of these reactions, which contain iodine(VI), are white or yellow. Most of them are stable over a wide range of temperatures (see Table 8). These compounds are stable in air in the absence of moisture but they react with water to form a mixture of iodic and periodic acids, iodates and periodates. For example, the compound Na_2IO_4 disproportionates in water to form the soluble iodate and insoluble periodate[270] according to Eqn. (18):

$$2Na_2IO_4+H_2O=NaIO_3+Na_3H_2IO_6\,. \qquad (18)$$

Table 8. Thermal stability of iodine(VI) compounds.

Compound	Temperature of formation, °C	Decomposition temperature, °C

$Al_2(I_2O_7)_3\cdot 2\,H_2O$	+0.17	0.51

† It is impossible to consider as definitely solved the problem whether the dehydration of silver periodate $Ag_4I_2O_9.3H_2O$ (which is usually considered to be the orthoperiodate $Ag_2H_3IO_6$) proceeds by a similar reaction or decomposes more extensively with the liberation of oxygen[266-268].

8. CHARACTERISATION OF IODINE(VI) COMPOUNDS[202-209,269-275]

Although the products of the thermal decomposition of periodates correspond in composition to compounds containing iodine(VI) it could be assumed that they are equimolar mixtures of iodates and periodates or of iodates and peroxides. The latter possibility can be ruled out since the absence of peroxides from these products has been verified by a chemical method and, moreover, it was found that the products react with water to form iodates and periodates. Since peroxide is incapable of oxidising iodate to periodate under any circumstances, the substance which contains the formally sexivalent iodine cannot be a mixture of iodates and peroxides. The problem of whether the thermal decomposition products of periodates are chemical individuals or mixtures of iodates and periodates was solved successfully by magnetic susceptibility measurements. Important results were also obtained by X-ray diffraction studies.

On the basis of the X-ray diffraction results the iodine(VI) compounds obtained by the thermal decomposition of periodates can be roughly classified into three groups:

1. Compounds which do not exhibit X-ray diffraction: $Be_3I_2O_9.4H_2O$, $CaIO_4.H_2O$, $BaIO_4.H_2O$. It has not proved possible to remove the "amorphous to X-rays" nature of these compounds and to being about crystallisation even by prolonged heating at the temperature of their formation.

2. Compounds which exhibit X-ray diffraction analogous to that of the corresponding iodates: Na_2IO_4 and Li_2IO_4 behave analogously to $NaIO_3$ and $LiIO_3$ respectively. These substances are probably also amorphous in the X-ray diffraction sense but under the action of atmospheric moisture they partly decompose into iodate and periodate.

3. Compounds which exhibit a small number of weak lines which are distinguished from the lines of periodates and iodates of the corresponding metal: $MgIO_4.0.5H_2O$, $PbIO_4$, $Al_2(I_2O_7)_3$, $CdIO_4$. Probably the crystal lattice of these compounds is incompletely constructed.

Only the product of the thermal decomposition of silver orthoperiodate and mesoperiodate ($Ag_2H_3IO_6$ and Ag_2HIO_5) of composition Ag_2IO_4 shows X-ray diffraction patterns in which lines coincide with those of the Ag_3IO_5–$AgIO_3$ mixture. Clearly, therefore, the product mentioned is a mixture of mesoperiodate and iodate and cannot be considered chemically distinct[268].

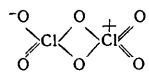
Iodine(VI) compounds are paramagnetic, unlike those of iodates and periodates which are diamagnetic. It has been found that their paramagnetism is not due to impurities but is a property of iodine(VI) compounds. Table 9 gives the values of the mass magnetic susceptibilities of these compounds and the corresponding magnetic moments (calculated from these values).

9. ANALOGUES OF THE COMPOUNDS OF IODINE(VI)

Analogues of the known compounds of iodine(VI) can be found with the lighter homologues of iodine (chlorine and bromine), with its neighbour tellurium, and also its lighter homologue selenium.

As regards chlorine(VI) and bromine(VI), compounds analogous to the iodine (VI) salts of type $M^I_2IO_4$ have not been observed but the oxides Cl_2O_6 (or ClO_3) and Br_2O_6 analogous to the oxide IO_3 are known. These oxides are unstable compounds which are formed as a result of reaction of the corresponding halogen with oxygen or ozone under the action of an electrical discharge[276,277]. An oxide of chlorine(VI) is also formed by the reaction of ozone with the oxide ClO_2 at liquid air temperature[278] or as an intermediate product in the thermal decomposition of perchloric acid[279] and of chlorine(VII) oxide at reduced pressure in the range 100–120°C. It is known[280] also that it is formed as an intermediate product in the reaction of fluorine with potassium iodate at 40–60°C. Chlorine(VI) oxide is a red, oily liquid at ordinary temperature and bromine(VI) oxide a colourless solid.

The presence of a valency of six was demonstrated[281-284] only for chlorine(VI) oxide in the gaseous state: this compound is paramagnetic and consists of ClO_3 molecules. In the liquid state this oxide dimerises. From the Raman spectra the structure of the Cl_2O_6 molecule is analogous to that of the aluminium chloride molecule:



This oxide reacts with water to form chloric and perchloric acids. Therefore some authors suggest[286-288] that it is a compound with the character of a salt $ClO_2^+ClO_4^-$.

For the oxide of bromine(VI) there has been no direct proof of a valency of six for the bromine and there has been no observation of the existence of dimeric molecules Br_2O_6 because of the instability of this compound. Dimerisation can usually be judged only by analogy with the chlorine oxide. However, results were obtained[289,290] which made it possible to rule out the older idea that this oxide is Br_3O_8. With water it gives a solution in which the presence of bromine(V) has been demonstrated. This can be explained by the following reactions:

$$Br_2O_6 + H_2O = HBrO_3 + HBrO_4 ,$$
$$2HBrO_4 = 2HBrO_3 + O_2 .$$

An analogy with the compounds of iodine of higher valency also appears in tellurium compounds. The clearest is the chemical and structural analogy of the compounds of iodine(VII) and tellurium(VI), especially for orthoperiodic and orthotelluric acids. As already noted[183] from the Raman spectra, telluric acid must be considered to be the ortho-acid H_6TeO_6 with an octahedral structure for the anion, as also happens for the periodate anion IO_6^{5-}. The infrared spectra of the two acids are also similar[184,291]. The two acids also form salts analogous in composition—for example, Na_5IO_6, and Na_6TeO_6; or Ag_5IO_6 and Ag_6TeO_6; or $Hg_5(IO_6)_2$ and Hg_3TeO_6, etc.—and in their physical properties (for example, from the solubility of the alkali metal salts). The iodine and tellurium compounds also show an ability to form heteropolyacids of analogous composition (characterised by a ratio of iodine or tellurium to metal atom of 1 : 6), for example, the acids $H_5[I(MoO_4)_6]$, $H_5[I(WO_4)_6]$, and $H_6[Te(MoO_4)_6]$ and $H_6[Te(WO_4)_6]$ respectively.

Analogous composition and properties are shown by certain complexes in which the central metal atom has an unusual valency. A series of salts of diperiodatocopper and diperiodatosilver and respectively ditelluratocopper and ditelluratosilver acids and also periodato- and tellurato-complexes of Co^{III}, Mn^{IV}, Ni^{IV}, Au^{III}, Pd^{IV}, Pt^{IV} has been described[214,217,219,220,224-228,247,253,254,292-295].

In the thermal decomposition of selenium(VI) and tellurium(VI) oxides, telluric acid, and certain tellurates, compounds of selenium(V) and tellurium(V) are formed: Se_2O_5, Te_2O_5, and also the corresponding salts. The tellurium(V) compounds are paramagnetic, like those of iodine(VI).

They are distinguished by this from the diamagnetic tellurates or telluric acid itself. The magnetic properties of the oxide Se_2O_5 have not been measured[296,297].

Siebert has recently published a paper[298] on the chemistry of the periodates.

V. Alicyclic γ-formyl acids 260

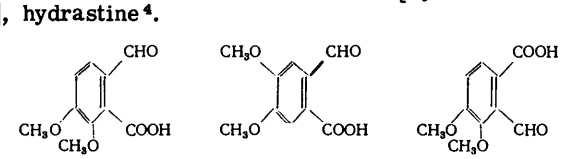
I. INTRODUCTION

The chemistry of γ-formyl acids and especially the problem of their structure has occupied the minds of many eminent investigators for over a century. It is sufficient to mention that Liebig and Wöhler, Gabriel and Libermann, Hans Meyer and Wilslicenus, Alder and Grove worked fruitfully in this field. The Soviet scientists V. M. Rodionov and M. M. Shemyakin also made a significant contribution to the study of the γ -formyl acids. Nevertheless the overwhelming majority of the studies completed up to the present time have been devoted to only an extremely limited number of γ-formyl acids, since the number of known representatives of this class of compound is generally small. They include principally the opianic and 2-formylbenzoic acids and their derivatives, halogenomucic acids, and β-formylpropionic and β-formylacrylic acids. We therefore did not set ourselves the aim of compiling an exhaustive review of all the investigations related to this problem, but have used from them only that part which, in our opinion, allows the contemporary state of the problem to be given with sufficient completeness.

II. METHODS OF PREPARING γ-FORMYL ACIDS

1. Aromatic and Heterocyclic γ-Formyl Acids

The first representative of the class of γ-formyl acids —opianic acid (I) was obtained as long ago as 1842 by Liebig and Wöhler[1-3] in oxidising one of the opium alkaloids—narcotine. Opianic acid (I) is also formed in the oxidation of the alkaloid of Canadian golden seal [*Hydrastis canadensis*], hydrastine[4].



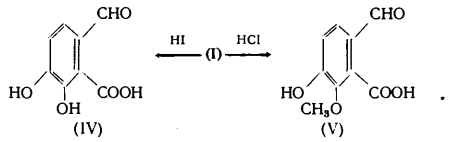
(I) (II) (III)

The structure of opianic acid was established by the work of Matthiessen and his coworkers (for example, see Ref. 5).

As well as opianic acid, γ-formyl acids isomeric with it are known: metaopianic (II)[6-8], which is formed in the

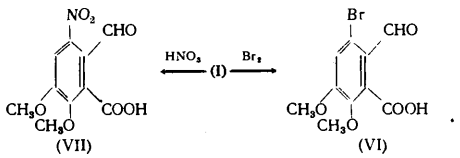
oxidation of the alkaloid cryptopine, and pseudo-opianic acid (III)[9], liberated in the oxidation of berberine.

Noropianic acid (IV)[11] is obtained in the demethylation of opianic acid by hydrogen iodide[10], whereas when hydrochloric acid is used for this purpose a partial demethylation product is formed—methylnoropianic acid (V)[12,13]:



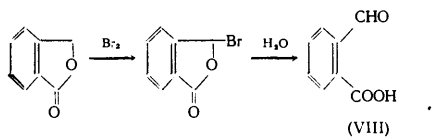
(IV) (V)

Of the derivatives of opianic acid, mention must be made of those obtained from it by the action of bromine or by nitration, the well-known 3-bromo-opianic (VI)[14-16] and 3-nitro-opianic (VII)[14,17,18] acids, and also the reduction products of the latter: 3-nitroso- and 3-amino-opianic acids[19]:



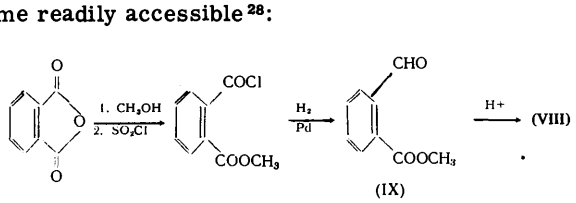
(VII) (VI)

In their chemical and physical properties 2-formylbenzoic acids are very similar to opianic acid. The first method of obtaining 2-formylbenzoic acid itself (VIII), developed in 1886 by Racine[20-22], consists in the bromination of phthalide to bromophthalide and subsequent careful hydrolysis:



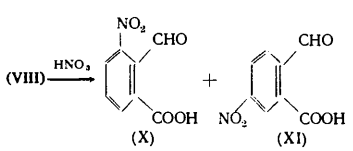
(VIII)

Another method of making 2-formylbenzoic acid which has been well studied is the oxidation of naphthalene with ozone[23,24] or potassium permanganate[25,26]. The best method of making this formyl acid is based on the Rosenmund reaction (yield reaches 60%, calculated on phthalic anhydride)[27]; in this way the normal methyl ester (IX) became readily accessible[28]:



(IX)

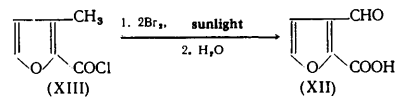
In the direct nitration[29,30] of 2-formylbenzoic acid a mixture of 3- and 5-nitro-2-formylbenzoic acids (X) and (XI) is formed, with the latter preponderating:



(X) (XI)

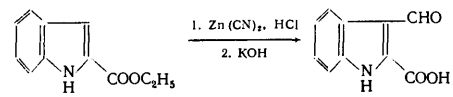
Several substituted 2-formylbenzoic acids were synthesised by Chakravarti and coworkers[31-34].

Several representatives of heterocyclic γ-formyl acids have been described. The first of these chronologically was probably 3-formylfuran-2-carboxylic acid (XII) obtained in 1924 by Japanese investigators[35] on brominating (with subsequent hydrolysis) elsholtzia acid chloride (XIII):



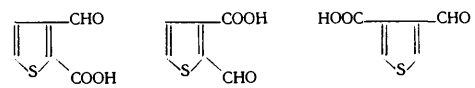
(XIII) (XII)

3-Formylindole-2-carboxylic acid (XIV)[36-38] can serve as an example of a γ-formyl acid of a nitrogen heterocycle:



(XIV)

In 1963 the Swiss scientist Gronowitz and his coworkers[39,40] synthesised three γ-formyl acids of the thiophen series:



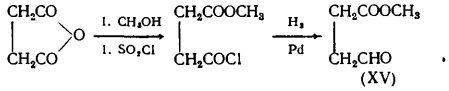
2. β-Formylpropionic Acids

The various β-formylpropionic or formylsuccinic acids which serve as the initial compounds for the synthesis of derivatives of the natural growth substance heteroauxin (β-indolylacetic acid)[41-46] are extremely interesting. In several instances these substances also exhibit antibiotic properties.

The first representatives of this class of compound, β-formylpropionic and β-formyl-α-methylpropionic acids were obtained in 1899 by Perkin Jnr. and Sprankling[47], by the condensation of sodiomalonic ester and, respectively, sodiomethylmalonic ester with bromoacetaldehyde acetal with subsequent hydrolysis and decarboxylation. Later[48,49] a large number of alkyl-substituted β-formylpropionic acids was synthesised by this method. β-Formyl-α-methylpropionic acid was also obtained from ketomethylglutaric acid[50].

Wilslicenus and coworkers[51] effected the synthesis of β-formylpropionic acid by starting from formylsuccinic acid, which they subjected to hydrolysis by heating with water in a sealed ampoule at 120–130°C. The hydrolysis of formylsuccinic ester by an aqueous solution of oxalic acid has also been described[52,53]. β-Formyl-α-phenylpropionic acid was synthesised in a similar manner[54].

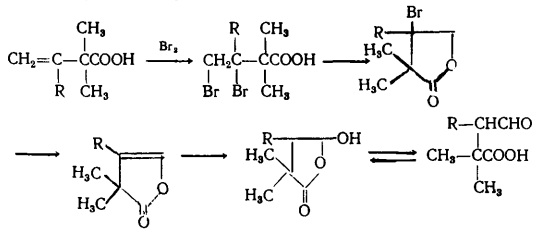
Johnson and coworkers[55] proposed a good method for the synthesis of methyl β-formylpropionate (XV) with the aid of the Rosenmund reaction:



(XV)

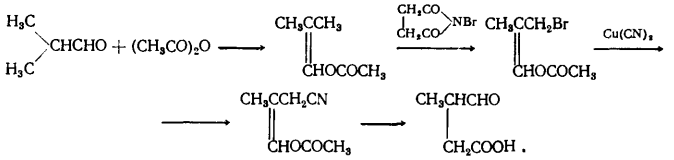
Application of the Rosenmund reaction to monoesters of various dicarboxylic acids is evidently a promising path to a variety of γ-formyl acids and also to γ-formyl acids of another structure.

Blaise and Kourtot[56,57] obtained trisubstituted β-formylpropionic acids from the corresponding trisubstituted βγ-unsaturated acids:

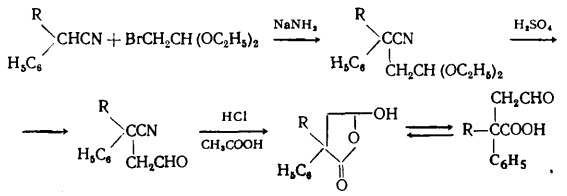


where R = CH_3, C_6H_5.

A new synthesis of β-formylbutyric acid was recently[58] effected according to the following scheme:

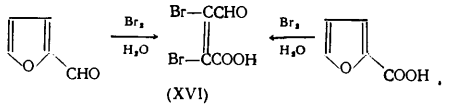


In 1963 Salmon-Legagneur and Paulain[59,60] developed a general method for the preparation of αα-disubstituted β-formylpropionic acids based on the condensation of the nitriles of alkyl aryl carboxylic acids with bromoacetaldehyde acetal in the presence of sodium amide, followed by hydrolysis:



3. β-Formylacrylic and β-Formylcrotonic Acids

Of this type of γ-formyl acid, the halogenomucic and dihalogeno-β-formylacrylic acids have long been known and have been well investigated. These compounds are usually obtained by starting from furan derivatives. For example, in the vigorous bromination of furfural or pyromucic acid in aqueous solutions bromomucic acid (XVI) is obtained in excellent yield[61-63]:



(XVI)

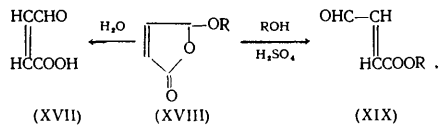
Chloromucic acid was synthesised in an analogous manner[61].

The halogen atoms and the double bond in the halogenomucic acids are distinguished by extremely low reactivity, because of which these compounds have not been used for the synthesis of new representatives of γ-formyl acids to any significant extent. Only the products of the replacement of the bromine atom at the α-carbon atom of bromomucic acid by hydroxy-, phenoxy-, and arylaminogroups[64-66] and also the replacement of the chlorine atom of chloromucic acid by the hydroxyl group[64] are known.

Of great interest for synthetic organic chemistry are the β-formylacrylic and β-formylcrotonic acids which do not contain halogen atoms; they were, for example, used for the synthesis of carotenoids by the Wittig reaction[67].

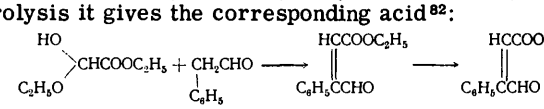
The use of ψ-esters of β-formylacrylic acid as dienophiles in the diene condensation allowed a series of representatives of a previously unknown class of alicyclic γ-formyl acids to be obtained[68-74].

The methods described earlier for obtaining *cis*-β-formylacrylic acid (XVII) were based on the oxidation of pyromucic acid[75,76] or furfural[77] by various oxidants. Later Shenk[78-80] developed a convenient method for obtaining the ψ-esters of *cis*-β-formylacrylic acid (XVIII) by the photochemical oxidation of furan derivatives. Hydrolysis of the ψ-esters with boiling water leads to the corresponding *cis*-acid (XVII)†, whereas on boiling alcoholic solutions of the ψ-esters in the presence of catalytic amounts of sulphuric acid esters of the *trans*-isomer (XIX) are obtained:

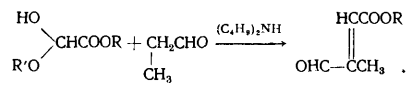


(XVII) (XVIII) (XIX)

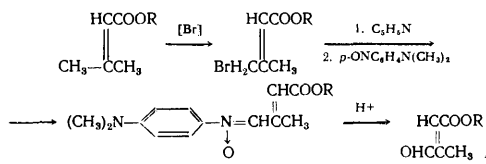
Photochemical oxidation was not used for the synthesis of substituted β-formylacrylic acids, although there are undoubted prospects for its use for such purposes. A few well-known representatives of γ-formyl acids of this type are obtained by other methods. Thus in the condensation of the hemiacetal of ethylglyoxalate with phenylacetaldehyde, ethyl β-formyl-β-phenylacrylate is formed, and on hydrolysis it gives the corresponding acid[82]:



Esters of β-formylcrotonic acids are obtained in good yields in the condensation of the hemiacetals of the esters of glyoxalic acid with crotonaldehyde in the presence of dibutylamine[67]:

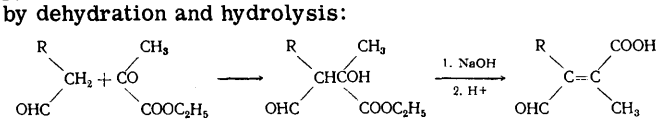


In another method[83] various esters of ββ-dimethylacrylic acid were subjected to bromination by *N*-bromosuccinimide, then the γ-bromo-β-methylcrotonic esters produced were treated (in the form of pyridinium salts) with *NN*-dimethyl-*p*-nitrosoaniline. Careful hydrolysis of the nitrones thus obtained led to the corresponding esters of β-formylcrotonic acid:



Ethyl β-formylcrotonate was also synthesised from β-methylcrotonic ester[84].

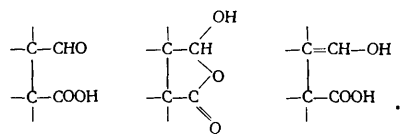
Recently Schreiber and Wermuth described[85] the production of a series of *trans*-β-formyl-β-alkyl-α-methylacrylic acids and their esters by condensation of esters of pyrotartaric acid with various aliphatic aldehydes, followed by dehydration and hydrolysis:



† *cis*-β-Formylacrylic acid is also obtained from 2-acetoxyfuran by bromination and subsequent hydrolysis[81].

III. REACTIONS OF γ-FORMYL ACIDS

The characteristic property of all the γ-formyl acids is their ability to react in two tautomeric forms[86]: the α-form (aldehydic) (XX) and the ψ-form (hydroxy-lactone) (XXI). The aliphatic and alicyclic γ-formyl-acids, although having one unsubstituted hydrogen atom at the β-carbon atom, are capable in some instances of also reacting in a third tautomeric form—enol (XXII)[86]:



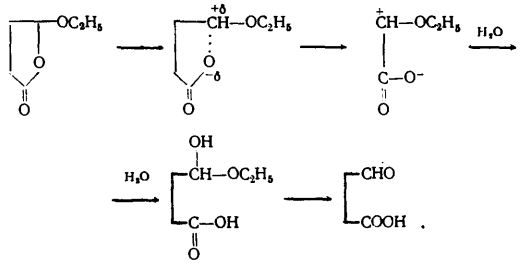
(XX) (XXI) (XXII)

Between these forms there is a mobile chemical equilibrium, therefore the establishment of the structure of γ-formyl acids in the isolated state acquires a special significance. Furthermore, it is very important to investigate the conditions under which displacement of the equilibrium to one of the tautomeric forms takes place, since such a displacement can be determined not only by the influence of the external medium but also by the structure of the γ-formyl acids.

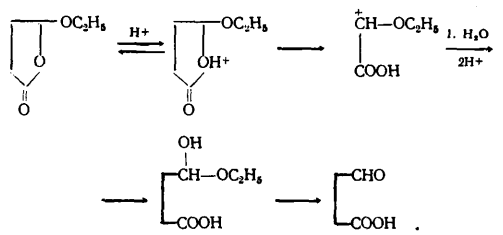
The problem of the structure of isolated γ-formyl acids was presented to chemists immediately after the discovery of the first of their representatives and more than a century later it still remains the subject of lively discussion[87,88]. In order to discriminate in this question it is necessary to first consider in detail the chemical behaviour of γ-formyl acids and to try to understand which factors determine their ability to react in any particular tautomeric form. Above all, it can be assumed as a working hypothesis that in the conditions of a medium which does not facilitate tautomeric transformations aldehydo-acids will react in that form in which they exist in the pure state and form a compound corresponding to this form. Thus it appears that crystalline γ-formyl acids are formed with astonishing ease even when alcoholic solutions of the corresponding ψ-esters, that is, ethers of the hydroxy-lactone form are kept for prolonged periods[89-91]. This conversion takes place more rapidly on heating[7,29,86,92,93] or in the presence of mineral acids[2,86,91,94-96]. A similar reaction has been described for many γ-formyl acids and is evidently a typical feature of those which are incapable of showing tautomerism in alcoholic solution. If the γ-formyl acids exist as a mixture of tautomeric forms then they would be expected to form a mixture of α- and ψ-esters in alcoholic solution. This occurs, for example, with β-formylpropionic, β-formyl-α-methylpropionic, and other α-alkyl-β-formylpropionic acids[47,50,52-58], which are liquids under ordinary conditions. The mercaptans behave like alcohols; they readily react with crystalline γ-formyl acids[97] to form compounds corresponding to their ψ-forms. For a long time examples have been known when either only the ψ-esters or their mixture with the corresponding α-esters are formed in the esterification of γ-formyl acids, depending upon the reaction conditions. Such a phenomenon was, for example, observed on heating 2-formylbenzoic acid with methanol in the presence of sulphuric acid[91]. These facts found explanation in the work of Kirpal and Zieger[98], who showed that normal formyl esters are products of the isomerisation of the ψ-esters formed initially, which takes place under the influence of the mineral acid. A similar isomerism is well known for esters of γ-keto-acids[99,100].

A characteristic property of the ψ-esters of γ-formyl acids is also the exceptional ease of their saponification: many of these are converted into the initial γ-formyl acids even on simple heating with water[29,67,69,86,88]. In the presence of acid catalysts this reaction takes place more rapidly.

On the basis of kinetic investigations of the hydrolysis of the ethyl ψ-ester of β-formylpropionic acid, Fife[101] concluded that a neutral medium is much more favourable for the hydrolysis of such bifunctional compounds of acylal-acetal structure than for ordinary acetals or esters. He proposed the following mechanism for the hydrolysis of a ψ-ester in neutral medium, which is a first-order reaction:

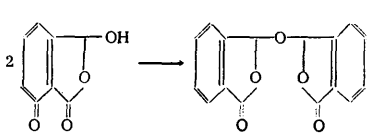


In the presence of mineral acids, in his opinion, the hydrolysis of a ψ-ester takes place by a somewhat different scheme:



On heating γ-formyl acids with acetic anhydride (in some instances in the presence of sodium acetate or sulphuric acid), acetyl derivatives of their hydroxy-lactone form are always produced[21,62,102,103]. The reaction of γ-formyl acids with phosphorus(V) chloride or thionyl chloride also leads to cyclic derivatives[104-108].

When heated above their melting point, aromatic γ-formyl acids are converted into ψ-anhydrides[21,29,103,107,109], for example:



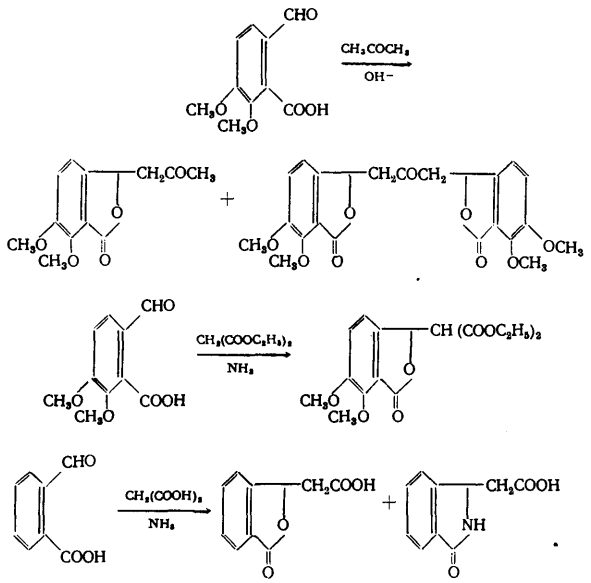
Finally, derivatives of the ψ-form are obtained by the action on γ-formyl acids of such weak bases as aromatic amines[12,110-117].

Since the α-form of the γ-formyl acids exhibits incomparably more reactive functional groups than the hydroxy-lactone form, in all those instances when the α-form arises in a reaction medium, it specifically takes part in the chemical conversion. In this, when the reaction product is insoluble (semicarbazone, and also other analogous derivatives) or is incapable of further conversion under the given conditions (for example, a methyl ester formed under the action of diazomethane), the tautomeric equilibrium is completely shifted to the side of the α-form. When the derivative of the α-form which is produced can undergo secondary transformations, for example, be cyclised into a

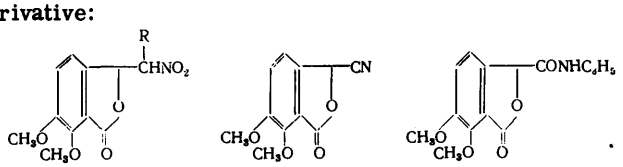
lactone, then the final reaction products are derivatives of the ψ-form of the original γ-formyl acid. Thus, most formyl acids react with Schiff's reagent in alcoholic solutions[86,117] and smoothly form crystalline derivatives with hydroxylamine, hydrazine, and substituted hydrazones[76, 111,112,118-120].

Reactions in which the pure α-form of γ-formyl acids are produced are the reactions of their neutralisation, leading to the corresponding metal salts[1,3,121]. By starting from the potassium opianate it is possible to obtain compounds corresponding to the normal form with yields of ~ 80%; for example, with benzyl chloride it gives the α-benzyl ester, and with chloroacetone, the α-acetonyl ester[121,122].

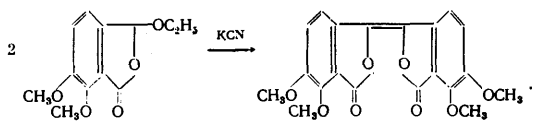
A series of conversions of the γ-formyl acids is known in which the nature of the reagents employed, the conditions of the medium, or the presence of bases would lead us to expect the formation of derivatives of the α-form but nevertheless the final products are derivatives of cyclic structure. Thus, the condensation in the presence of alkali or ammonia of opianic and certain other formyl acids with ketones[123-126], malonic ester, and malonic acid[127-129] leads to compounds corresponding to the ψ-form:



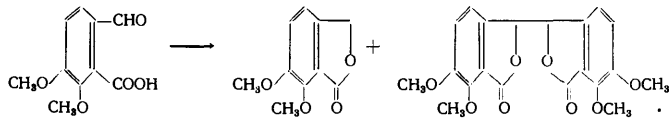
The reaction of γ-formyl acids with nitromethane and other aliphatic nitro-compounds[130-132], potassium cyanide[128,129], or phenyl isocyanide[133] also leads to a cyclic derivative:



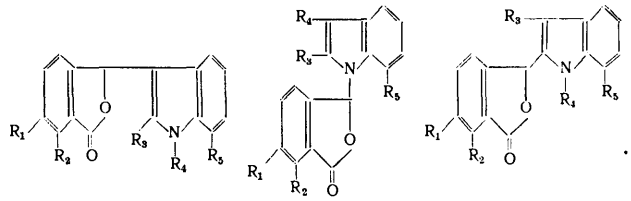
The action of anhydrous potassium cyanide on ethyl ψ-ester of opianic acid in absolute alcohol leads to the formation of meconilidenemeconine[134]:



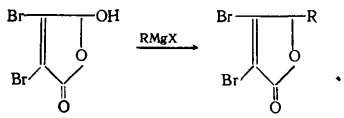
Meconin[5,6-dimethoxyphthalide (Ed. of Translation)] is obtained by the reduction of opianic acid with zinc and sulphuric acid[135] or sodium amalgam[135,136]. Electrolytic reduction of potassium opianate in an apparatus without a diaphragm but with a mercury cathode[136-138] leads to a mixture of meconine and other stereoisomeric dimeconyls (racemic and meso):



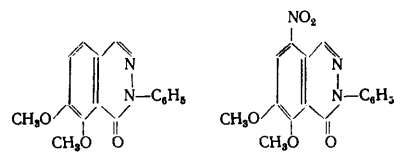
In the condensation of aromatic γ-formyl acids with indole and its derivatives[139-142], various meconylindoles are obtained, the structure of which depends on the position of the substituents in the pyrrole ring:



This reaction was later[142] studied also for chloromucic acid and also extended to other heterocyclic systems: substituted pyrroles, carbazole, indazole, and benzotriazole. For 2-formylbenzoic acid a reaction mechanism was established[141,142] which included the intramolecular catalytic activation of the aldehyde groups by the carboxyl group. The reaction of γ-formyl acids with alkyl (or aryl) magnesium halides leads to compounds which contain a γ-lactone grouping[143-147], for example:



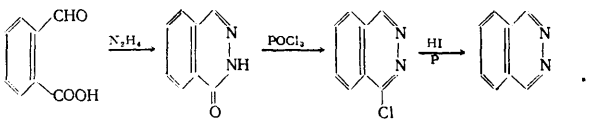
Finally, many reactions of γ-formyl acids are known in which the interaction takes place simultaneously at the aldehyde and carboxyl groups. γ-Formyl acids react in this way with various nitrogen compounds (aromatic o-diamines, hydrazine, substituted hydrazines), leading to derivatives of pyridazine, phthalazine, isocarbostyril, and other heterocyclic systems. Thus as long ago as 1886, in an attempt to obtain phenylhydrazones from opianic and nitro-opianic acids, Liebermann[148] unexpectedly isolated the products of the removal of two water molecules from them. To these compounds, named opiazone (XXIII) and nitro-opiazone (XXIV), Liebermann ascribed the structure of heterocyclic derivatives with two adjacent nitrogen atoms, this being based on the work of Roser[149] who obtained analogous products by the condensation of phenylhydrazine with o-carboxybenzoylacetic acid and related acids:



(XXIII) (XXIV)

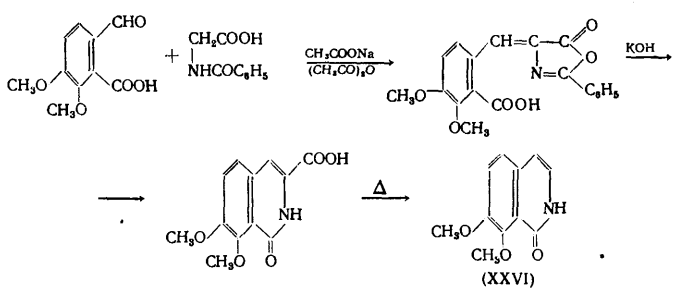
Later the same reaction was studied by the examples of 2-formylbenzoic[21,150], bromo-opianic[119], and bromomucic[151] acids and in every instance analogously constructed heterocyclic compounds were formed.

In 1897 Gabriel and Eschenbach[152] studied the condensation of phthalaldehydric acid with hydrazine itself and developed a method of reduction of the keto-groups formed therein, which preceding workers could not do. In this way a general method of synthesis of the derivatives of a new heterocyclic system, which Liebermann[148] named phthalazine (XXV), was discovered:



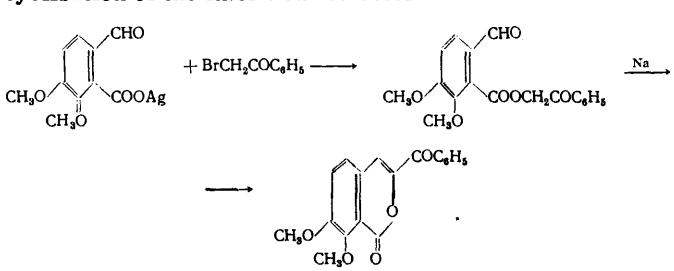
(XXV)

In their classical investigations of the alkaloids of the berberine group, Perkin, Jnr. and his coworkers[153] cleverly used the condensation of opianic acid with hippuric acid to synthesise the 7,8-dimethoxyisocarbostyril (XXVI) which they needed:

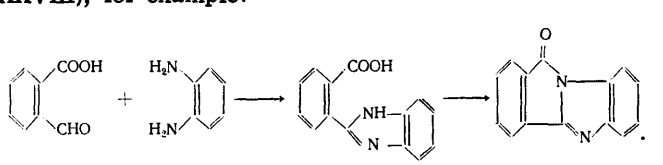


(XXVI)

In an analogous way[153] isocarbostyril itself was obtained from phthalaldehydic acid. 3-Benzoyl-7,8-dimethoxyisocoumarin was synthesised[153] by the reaction of silver opianate with ω-bromoacetophenone and the subsequent cyclisation of the intermediate ester:



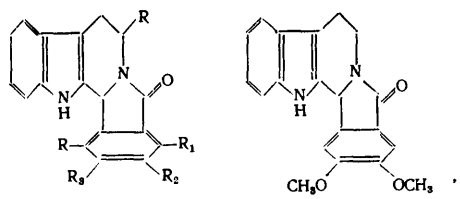
Complex polycyclic nitrogen-containing compounds of alkaloid type can also be obtained on the basis of γ-formyl acids. Even as long ago as the eighteen-nineties Bistrzycki[154,155] showed that 2-formylbenzoic and opianic acids react in the cold with *o*-phenylenediamine and *o*-toluylenediamine, forming cyclic amidines (XXVII), which on boiling with acetic anhydride give the corresponding amidones (XXVIII), for example:



(XXVII) (XXVIII)

Later, Stephenson[156,157] described products of the condensation of phthalaldehydric acid also with other aromatic diamines: with ωω'-diamino-*o*-xylene. 2,2'-diaminobiphenyl, 1,8-diaminonaphthalene, and *o*-aminobenzylamine.

Recently[158], with the aim of synthesising new hypertensive preparations, analogues of reserpine, condensations were effected with the aid of the Pictet–Spengler reaction between 2-formylbenzoic, opianic, metaopianic, and 3,4,5-trimethoxyphthalaldehydric acids and tryptophan and tryptamine. Among the series of pentacyclic compounds thus obtained which contain the β-carboline nucleus, weakly hypertensive activity appeared only in the derivative of metaopianic acid (XXIX):



(XXIX)

IV. INVESTIGATION OF THE STRUCTURE OF γ-FORMYL ACIDS BY PHYSICAL METHODS

Hence, as is evident from the preceding chapters, the study of the chemical behaviour of γ-formyl acids did not provide a conclusive solution for the perennial controversy about their structure‡. A revolutionary role in this sense was played by spectroscopy, the credit for the first use of which for solving the complicated problem of the structure of the γ-formyl acids belongs to Buu-Hoi and his coworkers[163–165]. In 1939–1941 they studied the ultraviolet spectra of 2-formylbenzoic, opianic, 6-bromo-opianic, 6-nitro-opianic acids. It was shown that all these γ-formyl acids in the crystalline state and in chloroform solutions exist in the hydroxy-lactone form. In aqueous solution 2-formylbenzoic and opianic acids have an acyclic form, whereas 6-bromo- and 6-nitro-opianic acids in alcoholic and aqueous–alcoholic solutions exist as equilibrium mixtures of both tautomeric forms. The last two acids, which contain substituents in the *ortho*-position to the aldehydic group, seemed capable of existing in the acyclic form only in strongly alkaline aqueous solutions.

After the ultraviolet spectra, infrared spectra were also used successfully for studying ring–chain tautomerism of γ-formyl acids. Thus with the aid of infrared spectra it was shown that 2-formylbenzoic acid is in a cyclic form in the crystalline state[166]. The extremely thorough work of Wheller and coworkers[167] appeared later. These authors synthesised over fifty derivatives of 2-formylbenzoic acid, the study of the infrared spectra of which in liquid paraffin showed that they exist solely in cyclic form. The absorption spectra of a series of other γ-formyl acids, studied in recent years, also show that these compounds are found exclusively in the cyclic form in the crystalline state, but in solutions they are in the form of equilibrium mixtures of both tautomeric forms, and the position of the equilibrium depends on the dielectric constant of the solvent, its pH, and many other external factors[58,168–174].

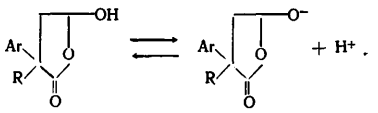
On the other hand, thiophen analogues of 2-formylbenzoic acid (see p. 255) have been shown by Gronowitz and

‡ It must be emphasised that a correct solution of this problem is important not only for the theoretical organic chemistry alone; it also has biological importance, since keto-lactol tautomerism evidently determines the physiological activity of certain antibiotics[159–162].

coworkers[39,40]—on the basis of the NMR spectra in chloroform, dioxan, acetone, and water and also with the aid of ultraviolet and infrared spectra—to exist solely in the acyclic form and it was even found that on esterification in the presence of sulphuric acid 3-formylthiophen-2-carboxylic acid gives a normal ester. The reasons for such a phenomenon are evidently purely geometrical: the incapability of formyl acids of the thiophen series to form lactol tautomers is probably due to differences in the C–C distances and in the values of the valence angles in the benzene and thiophen molecules.

Study of the structure of halogenomucic acids with the aid of NMR showed that they were completely free from an acyclic form, but in the presence of an equivalent quantity of potassium hydroxide halogenomucic acids are converted completely into the acyclic form[170]. According to the ultraviolet and infrared spectra, *cis*-β-formylacrylic acid also has the lactol structure[175].

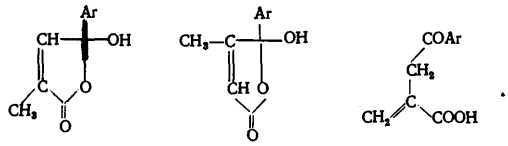
It is interesting to note that for certain substituted β-formylpropionic acids the cyclic form is so stable that it even exhibits a slight acidity, owing to the weak dissociation of the hydrogen of the lactol hydroxyl. These properties are exhibited by αα-disubstituted β-formylpropionic acids which contain not less than one aromatic substituent[176]:



It is necessary to mention here, though briefly, the information about the structure of the nearest relatives of the γ-formyl acids, among which belong above all the γ-keto-acids, with chemical properties very reminiscent of them. The structure of the γ-keto-acids has been extensively studied by spectroscopic methods. Various *o*-benzoylbenzoic acids have been investigated in considerable detail in this respect[177–181]. It was found that most of the methyl-substituted *o*-benzoylbenzoic acids studied exist in the crystalline state and in chloroform or carbon tetrachloride solutions as acyclic tautomers[177–180]. Only acids with a methyl group in the *ortho*-position to carboxyl are an exception, especially 2-benzoyl-3,6-dimethylbenzoic acid, which even in methanol contains only 7% of the keto-acid form[179]. Functional derivatives of *o*-benzoylbenzoic acid (containing halogens, CN, NO_2, and other groups), also have, according to the infrared spectra, an acyclic structure (18 compounds were studied) in the solid state, but form equilibrium mixtures in solutions, with the predominance of the tautomer with an open chain[180]. A well-expressed linear relationship between the free energy and Hammett constant (σ) of the substituents is observed for these compounds.

o-Acetylbenzoic acids have predominantly cyclic structure[178,180]. The increased stability of the tautomers with an open chain in the example of *o*-benzoylbenzoic acid may be connected with the gain in energy due to the formation of a conjugated system.

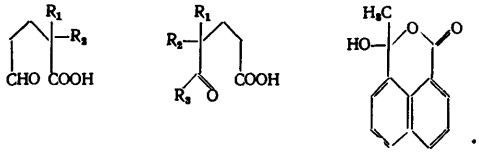
Lutz and coworkers[182] showed with the aid of ultraviolet spectra that various *cis*-β-aroyl-α-methyl- and *cis*-β-aroyl-β-methyl-acrylic acids (XXX) and (XXXI) in alcoholic solutions exist predominantly in the lactol form§. On the other hand, saturated analogues of these compounds—β-aroylbutyric acids, and also β-aroyl-α-methyleneacrylic acids (XXXII) have an open structure:



(XXX) (XXXI) (XXXII)

The structure of the β-acylacrylic acids is closely connected with their stereochemistry. Thus, on the basis of spectroscopic data it was found that β-acetylacrylic acid, with the *trans*-configuration, and also the *trans*-isomer of β-pivaloylacrylic acid are true keto-acids, whereas *cis*-β-acetyl-α-methylacrylic and *cis*-β-pivaloylacrylic acids are lactols[175,184,185]. The solution of the problem of the configuration of the stereoisomeric β-pivaloylacrylic acids on the basis of an examination of their tautomeric structure with the aid of NMR spectra[184] is probably the first example of the use of spectra for such a purpose¶.

Aliphatic mono- and di-substituted δ-formyl acids (XXXIII), recently synthesised by Salmon-Legagneur and coworkers[186,187], are, according to their infrared spectra, tautomers with an open chain. The aliphatic δ-keto-acids (XXXIV) also have an analogous structure[188–190]:

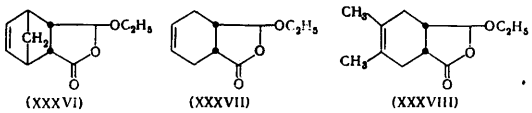


(XXXIII) (XXXIV) (XXXV)

However, 8-acetyl-1-naphthoic acid (XXXV) exists only in the lactol form[191].

V. ALICYCLIC γ-FORMYL ACIDS

γ-Formyl-acids of the cycloaliphatic series remained unknown until very recently, becoming accessible only in 1958, thanks to the work of Alder and Fariña[68], who found that the ethyl ψ-ester of β-formylacrylic acid (XVIII) is capable of undergoing a diene condensation with cyclopentadiene, bivinyl, and 2,3-dimethylbutadiene, forming the corresponding adducts (XXXVI)–(XXXVIII)†:

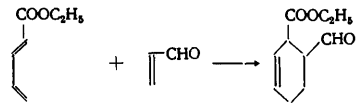


(XXXVI) (XXXVII) (XXXVIII)

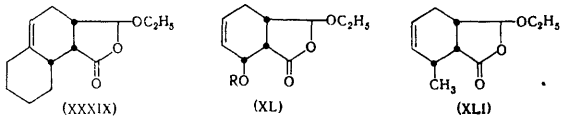
§ For *cis*-β-(4-bromophenyl)-β-methylacrylic acid this was established even earlier by polarograph[183].

¶ See p.262 for the analogous use of infrared spectroscopy in several alicyclic-formyl acids.

† In 1965 the synthesis of an α-ester of an alicyclic γ-formyl acid effected by another path was described[192]:



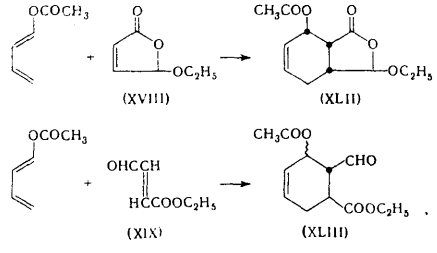
It was found later that an analogous condensation also takes place with 1-vinylcyclohex-1-ene[72], 1-acetoxybutadiene[69], and *trans*-piperylene[74], leading to the adducts (XXXIX)–(XLI):



(XXXIX) (XL) (XLI)

Furan and dienes, like styrene, do not react with the ψ-ester (XVIII)[68]. Instead of the ψ-ester of β-formylacrylic acid the corresponding *cis*-acid (XVII) and also the normal ethyl ester of its *trans*-isomer (XIX) can be used in the diene synthesis[68,69]. The adducts of the diene synthesis obtained with the ψ-ester (XVIII), are readily converted into the corresponding acids or normal esters, which contain a free formyl group and are capable of entering into the Knoevenagel reaction[68,69,73].

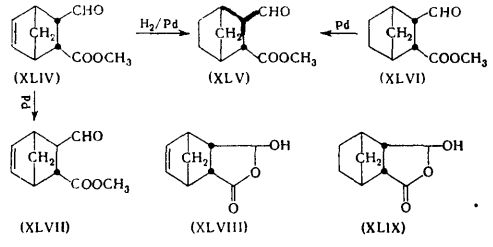
In studying the diene condensation of 1-acetoxybutadiene with the ethyl ψ-ester of β-formylacrylic acid and also 1-acetoxy and 1-methoxy-butadiene with the ethyl α-ester of *trans*-β-formylacrylic acid, Farina and coworkers[69] observed an interesting fact. It appeared that the adducts (XLII) and (XLIII) obtained from the *cis*- and *trans*-dienophiles have not only different configuration but also different structure, which is evidently due to the different orientation abilities in the diene synthesis of the functional groups of the dienophiles:



(XVIII) (XLII)

(XIX) (XLIII)

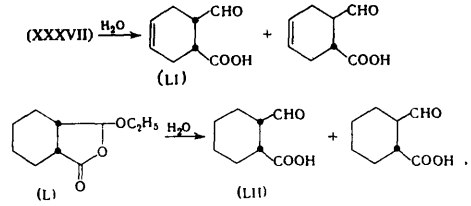
The synthesis and stereochemical conversions of the adducts of the diene condensation of the ethyl ψ-ester of β-formylacrylic acid (XVIII) with cyclopentadiene, 2,3-dimethylbutadiene, and bivinyl were subsequently subjected to a more detailed study[70,71]. Here in particular it was found that the hydrogenation of the unsaturated *cis*-γ-formyl ester (XLIV) is accompanied by the simultaneous isomerisation, leading to the saturated *trans*-γ-formyl ester (XLV), which is obtained also in the simple shaking of the saturated *cis*-formyl ester (XLVI) with reduced palladium catalyst. The unsaturated *cis*-γ-formyl ester (XLIV) is isomerised in an analogous manner, giving the *trans*-isomer (XLVII). Such astonishingly easy isomerisation of the α-esters (XLIV) and (XLVI) and the incapability to isomerisation under the same conditions of the corresponding γ-formyl acids (XLVIII) and (XLIX) are chemical proofs of the lactol structure of the latter[70]:



(XLIV) (XLV) (XLVI)

(XLVII) (XLVIII) (XLIX)

In contrast to Alder and Farina's results[68], it was shown that saponification of the adduct (XXXVII)[71] with boiling water and also saponification of its hydrogenation product (L) (contrary to the behaviour of the analogous derivatives obtained from cyclopentadiene[70]) is accompanied by isomerisation and leads to mixtures of *cis*- and *trans*-γ-formyl acids:



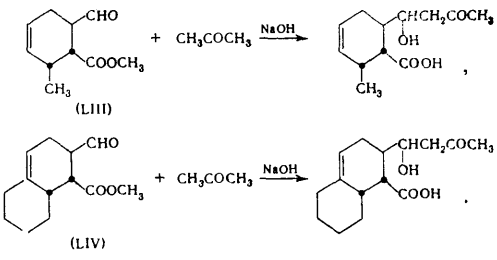
(LI)

(L) (LII)

On this basis it can be suggested that the γ-formyl acids (LI) and (LII) exist in aqueous solution as mixtures of tautomeric forms.

The γ-formyl acids and their derivatives obtainable with the aid of the diene condensation of the ethyl ψ-ester of β-formylacrylic acid (XVIII) with piperylene[74] and 1-vinylcyclohexene are distinguished by a considerable tendency to epimerisation[72,193]. Diene reactions in which these unsymmetrical dienes participate proceed with structural and spatial selectivity, leading mainly to the adducts mentioned above (XXXIX) and (XLI). Hydrolysis of the latter even in neutral conditions is accompanied by partial isomerisation and the *cis*-γ-formyl acids which are formed contain the *trans*-isomers as impurity. Therefore the preparation of the pure γ-formyl acids and their derivatives by these means is practically unattainable. The especially ready isomerisation is observed in the bicyclic series[193]. The catalytic hydrogenation of adducts (XXXIX) and (XLI) takes place readily and in the case of adduct (XXXIX) is stereo-directed—to the side opposite the lactol ring. From the saturated ψ-esters obtained in this manner the corresponding *cis*- and *trans*-formyl acids have been synthesised; these, and also their normal esters, are distinguished by a somewhat smaller tendency to *cis*–*trans*-isomerism than their Δ^4-unsaturated analogues.

The esters of the alicyclic γ-formyl acids of the cyclohex-4-ene series are characterised by considerable inertness in nucleophilic additions at the aldehyde group. Thus, the *cis*-*trans*-formyl ester (LIII) is only saponified, and does not form an acetylenic alcohol under the action of sodium acetylide in liquid ammonia‡[74]. The condensation of the *cis*-*trans*-γ-aldehydo-esters (LIII) and (LIV) with acetone under the influence of dilute sodium hydroxide§ takes place to only 10–15% extent[74,193].



(LIII)

(LIV)

Such behaviour of the formyl group was explained by its participation in an intramolecular interaction with the π-electrons of the double bond (supra-annular effect)[194,195],

‡ The corresponding *cis-cis*-formyl ester in this is isomerised into the *trans*-isomer.

§ Hydrolysis of the ester group takes place simultaneously.

which is confirmed also by diminished reactivity of the double bond in such compounds as was shown by determination of the thiocyanate numbers[74,193].

Interesting regularities were observed in studying the infrared spectra of γ-formyl acids[74,193], derivatives of the adducts of the ψ-esters (XVIII) with 1-vinylcyclohexene and *trans*-piperylene (XXXIX) and (XLI). It was found that unsaturated γ-formyl acids of both the *cis*- and *trans*-series exist in carbon tetrachloride solution as equilibrium mixtures of almost equal amounts of the two tautomeric forms. On the other hand, the corresponding unsaturated γ-formyl acids of *cis*-configuration have under these conditions the structure of lactols, whereas the *trans*-acids are true γ-formyl acids. Evidently infrared spectroscopy is a rapid and reliable method of demonstrating the configuration of stereoisomeric alicyclic γ-formyl acids (especially in the presence of pairs of isomers[85,168].

Progress in the Chemistry of the 1,3-Dioxans

A.V.Bogatskii and N.L.Garkovik

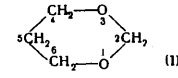
CONTENTS

I. Introduction 264
II. Methods of synthesis of 1,3-dioxans 265
III. Stereochemistry of 1,3-dioxans 267
IV. Chemical changes of the 1,3-dioxans 270
V. Use of the 1,3-dioxans 273

I. INTRODUCTION

In recent years there has been a considerable increase in interest in the 1,3-dioxans. There has been a review of the chemistry of these compounds[1] but it is incomplete and contains references to the literature only up to 1955. The present review fills some of the gaps in this earlier review and surveys the literature for 1955–1965. Furthermore, the present article examines the problem of the stereochemistry of the 1,3-dioxans, which was not considered systematically earlier. In this the authors consider it necessary to express their viewpoint on some of the complicated stereochemical problems relating to works they have carried out.

The first information on 1,3-dioxans appeared in 1865, however, the simplest of them, 1,3-dioxan itself[1], was synthesised only in 1902.[2] Compounds of this type were named 1,3-dioxans (or *meta*-dioxans) only by the external similarity in structure to 1,4-dioxans. However, the latter are simple ethers, whereas 1,3-dioxans are cyclic acetals (ketals).



(I)

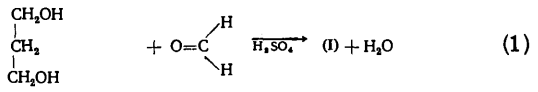
There is no great industrial production of most 1,3-dioxans. However, there are now great possibilities for their rational use. Many substituted derivatives of (I) were found to be good solvents. Some of the compounds of this type are physiologically active and have found application as effective spasmolytic and antihistamine preparations, depressants of the central nervous system, and even antibiotics. A series of 1,3-dioxans seemed an important intermediate product in organic synthesis, particularly in the synthesis of isoprene and other conjugated dienes.

II. METHODS OF SYNTHESIS OF 1,3-DIOXANS

All the preparative methods of synthesis of 1,3-dioxans can be classified in the following main groups.

1. Production of 1,3-Dioxans by the Reaction of Aldehydes and Ketones with Polyhydroxy-Compounds

This method was first proposed by Henry[2] for the synthesis of (I) by the scheme (1):

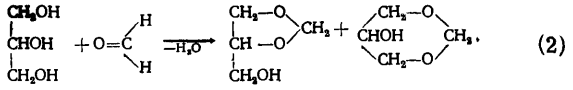


(1)

and was then improved by many authors. Various 1,3-diols and aldehydes were used in the reaction. In addition to sulphuric acid, which several authors have used as catalyst[3-8], other condensing agents have been proposed: hydrochloric acid[9-12], phosphoric acid[13-17], *p*-toluenesulphonic acid[18-26], and ion-exchange resins[27-31]. The use of *p*-toluenesulphonic acid gives good results; when it is employed the resinification and formation of side-products which complicates the condensation catalysed by mineral acids, are not observed. The use of sulphonic cation-exchange resins has still not been extensively studied but there are results which suggest that these are evidently the best catalysts for the reaction considered. In practice, the cation-exchange resins can be used repeatedly, and moreover their use greatly simplifies the purification of the dioxans being synthesised.

An important improvement in the original method of making 1,3-dioxans by the above process was the use of azeotropic distillation of the water formed during the reaction[18,32], which prevented the back reaction of hydrolysis of the dioxans and had special value for obtaining ketals of the type being considered. Besides, in addition to this technique, variations in the method under consideration have been used in which the condensation is effected in an aqueous medium[33].

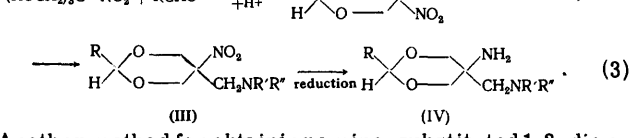
The condensation of polyhydroxy-compounds with aldehydes takes place especially well. The structure of the aldehydes has little influence on the course of the reaction. With ketones the reaction is much more difficult, owing to the greater difficulty in obtaining ketals for stereochemical reasons. It was only in 1938 that Böeseken succeeded in condensing a series of aliphatic, alicyclic, and aromatic ketones with certain glycols in the presence of acid dehydrating catalysts[34]. Before this, only a few examples of the condensation of acetone itself with polyhydroxy-compounds were known[35]. The problem of the production of cyclic ketals of this type was solved by Salmi, by showing that the reason for the lack of success of several authors who had tried to effect the condensation of 1,3-glycols with ketones was because the water is an inhibitor for the reaction. Salmi himself proposed azeotropic distillation of the water formed and by using this method obtained good yields of 1,3-dioxans, effecting the condensation of trimethyleneglycol or 1,3-butyleneglycol with ethyl methyl ketone, pinacolin, cyclopentanone, and acetoacetic ester. The catalyst in Salmi's studies was *p*-toluenesulphonic acid[18]. Many alkyl[36-42], polyalkyl[9,15,21,25,26,43-49], aryl[20,21,50-66], halogenoalkyl[10,21,67-77], hydroxy[78-87], nitro-[88-95], alkoxy-[77,96,97], and alkoxyalkyl[98-100], unsaturated[77,101-104], carbonyl-substituted[105,106], polycyclic[77,107-110], cyano-[77,111], and amino-[48,49,55,56,112] 1,3-dioxans were obtained by this method. Some variants of the method are of interest. Thus, a process has been patented[114] in which a mixture of formaldehyde and 1,3-butyleneglycol is passed continuously over an acid catalyst at high temperature. In this way a mixture of substituted dioxans and dioxolans[115] was obtained from glycerol:



(2)

Still more complex mixtures are obtained from higher alcohols and aldehydes[116,117]. Hill and Carothers[118] obtained tetramethyleneglycol formal and showed that other polyformals are successfully formed in the reaction of glycols of the type $HOCH_2[CH_2]_nCH_2OH$ with formaldehyde in the presence of acid catalysts.

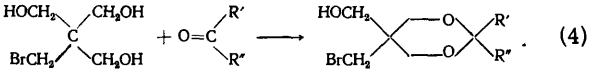
In 1961 Schipper and coworkers[88] proposed an original method for obtaining amino-substituted 1,3-dioxans:



(3)

Another method for obtaining amino-substituted 1,3-dioxans was proposed by Yasnitskii and coworkers in 1963[29-31]. They condensed chloroacetaldehyde with polyhydric alcohols in the presence of cation-exchange resins. The chloromethyl derivatives of 1,3-dioxans thus obtained are comparatively readily converted into alkylaminomethyl derivatives, owing to the rather high lability of the chlorine atom.

Piganiol and coworkers[10,50] obtained interesting, phamacologically active 1,3-dioxans (V) with two functional groups, by condensing pentaerythritol monobromohydrin [2-bromomethyl-2-hydroxymethylpropan-1,3-diol (Ed. of Translation)] with various aldehydes and ketones:



(4)

Of the variants of the method for the production of ketals, note must be made of the work of Kuhn[119], who used unsaturated ketones and esters of laevulinic acid for the production of 1,3-dioxans. By studying a different type of compound containing a ketone group in this reaction, Kuhn succeeded in showing that ketals of the 1,3-dioxan type can be obtained from any α-, β-, or γ-keto-acid except those in which there is a double bond next to the carbonyl group. When that is so ketals are not formed.

2. Production of 1,3-Dioxans by the Reaction of Aldehydes with Unsaturated Compounds

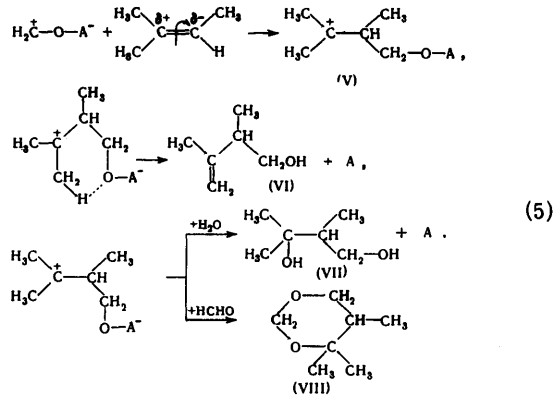
In 1917 Prins first studied the reaction of styrene, pinene, camphene, and anethole with formaldehyde in the presence of sulphuric acid as a catalyst[120]. Since then this reaction, named the "Prins reaction", has obtained wide application. An especially large number of papers devoted to it appeared at the end of the nineteen-thirties[121] after the development of improved procedures for cracking petroleum, which made accessible many unsaturated hydrocarbons. At the same time industrial methods of obtaining aldehydes from hydrocarbons were also developed.

In the condensation of alkenes and some other unsaturated compounds with aldehydes in the presence of aqueous solutions of mineral acids alkyl-1,3-dioxans and butan-1,3-diols are formed. The ratio of the reaction products can be varied by changing the concentration of the catalyst and the temperature of the process.

For a long time the mechanism of the Prins reaction was considered debatable. Several hypotheses were advanced[122-127]. A more or less general standpoint has recently been developed. It is thought that a polarised complex of formaldehyde with the catalyst adds to the alkene according to the Markovnikov rule, Eqn. (5):

$$HCHO + A \rightleftarrows H_2\overset{+}{C}-O-A^-,$$

where A is the catalyst: acid, $SnCl_4$, or other suitable substances.



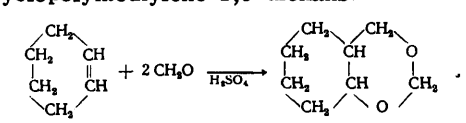
(5)

During this, an intermediate compound (V) is formed, which can then react either as a six-membered ring, or with other components of the reaction mixture. In the first instance an unsaturated alcohol (VI) is formed. In the second, a 1,3-glycol (VII) is formed when the reaction is with water; in the reaction with formaldehyde the 1,3-dioxan (VIII) is formed. Recently there have been many studies of the products of the Prins reaction[128-133]. 1,3-Dioxans can be obtained by this method from both linear and cyclic alkenes. Fitzky[134] and Ritter[135] investigated the preparation of alkyl-1,3-dioxans by the condensation of formaldehyde with propene, 2-methylpropene, trimethylethylene [1,2-dimethylpropene] pent-2-ene, and di-isobutylene [2,2,4-trimethylpentenes (Ed. of Translation)] in the presence of various acid catalysts. The best yields were obtained on using sulphuric acid as catalyst.

Later patents testify to the perfection of the commercial process for the synthesis of 1,3-dioxans[136-143]. A selective method for obtaining 4,4-dimethyl-1,3-dioxan by the reaction of a mixture of hydrocarbons with five or less carbon atoms with formaldehyde in the presence of H_2SO_4 (or H_3PO_4) at 10–85°C and atmospheric or elevated pressure has been patented[144,145]. An interesting variant of this method uses cation-exchange resin[146].

Mottern[147] used the Prins reaction for the selective removal of alkenes having branching at the double bond from fractions obtained as a result of petroleum distillation.

Cyclohexene and other cyclic alkenes also react with formaldehyde at 60–80°C in the presence of sulphuric acid, forming cyclopolymethylene-1,3-dioxans:



(6)

Aldehydes react selectively with ethylenic bonds of arylalkenes (for example, styrene), forming phenyl-1,3-dioxans. Here the catalysts are sulphuric acid[149-151], a solution of sulphuric in acetic acid[152-154], dilute hydrochloric acid[153,155], phosphoric acid[151,156,157], certain salts of hydrochloric acid[158], and other acid catalysts[159-161].

Good methods for obtaining phenyl-1,3-dioxans from arylalkenes and formaldehyde in the presence of sulphuric acid were developed by Shreiner[162], Shortige[163], Emerson[153,164], Beets[149,150,165,166] and their coworkers. Arylalkenes can be replaced by arylalkylcarbinols, but the yields of the dioxans are then reduced to 5–20%.[165-167]

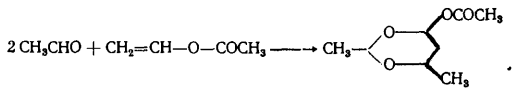
The terpenes (for example, pinene, limonene, camphene, cedrene, allo-ocimene, myrcene) react with formaldehyde in the presence of hydrochloric, sulphuric, and *p*-toluenesulphonic acids to form condensation products and resins, but their nature has not been determined with sufficient precision[152,168,169].

Some substituted alkenes, especially unsaturated halides and ethers, can undergo the Prins reaction, forming various 1,3-dioxans. The condensation of allyl chloride with formaldehyde at 0°C in the presence of concentrated sulphuric acid leads to the production of 4-chloromethyl-1,3-dioxan[170]. Dimethylallyl ethyl ether and formaldehyde readily react in the presence of 25% sulphuric acid at room temperature to form 5-ethoxymethyl-4,4-dimethyl-1,3-dioxan in 73% yield[171].

It must be noted that in the condensation of unsaturated carbonyl compounds (aldehydes, ketones, acids, and their derivatives with formaldehyde) the formation of 1,3-dioxans takes place with some difficulty; unsaturated alcohols and esters react with formaldehyde in the presence of acid catalysts, but the reaction products are difficult to identify, evidently owing to further reaction of the aldehyde with the hydroxyl groups of the molecule.

Recently published patents describe the reaction of branched alkenes, tertiary alcohols, and halogeno-derivatives with aldehydes in the presence of boron trifluoride, which leads to the formation of substituted 1,3-dioxans[172].

In the presence of metallic sodium, acetaldehyde condenses at 0°C with vinyl acetate, as a result of which 6-acetoxy-2,4-dimethyl-1,3-dioxan is obtained[173]:

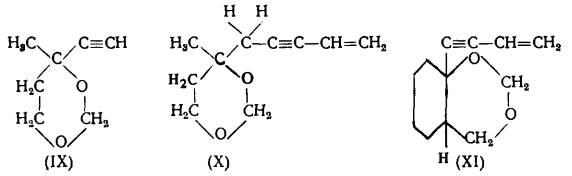


(7)

This reaction is evidently strictly specific both in regard to the reagents and also the conditions used. Cresham and Grigsby[174] studied the condensation of butadiene with formaldehyde in the presence of acid catalysts and hydroquinone (an inhibitor of polymerisation) at 100–120°C. They obtained 4-vinyl-1,3-dioxan in 30% yield. However, according to other results[152] this reaction leads to the formation of a very complex mixture of substances. Evidently the reason for Cresham and Grigsby's success was the use of a polymerisation inhibitor. The Prins reaction with other diene hydrocarbons has not been studied.

Matsoyan and Saakyan's interesting work[175] was published at the end of 1963; it was devoted to the reaction of formaldehyde with enynic and dieneyne hydrocarbons under the conditions for the Prins reaction. It appeared that the latter react selectively at the double bond with the formation of ethynyl- and vinylethynyl-1,3-dioxans. Thus on heating isopropenylacetylene [2-methylbut-1-en-3-yne] with formaldehyde in the presence of 40% sulphuric acid at 60–80°C 4-ethynyl-4-methyl-1,3-dioxan (IX) is formed. Formaldehyde reacts analogously with dienes, the reaction being directed exclusively to the substituted double bond of the divinylacetylene hydrocarbon. The condensation of 5-methylhexa-1,5-diene-3-yne and 5-methylhepta-1,5-diene-3-yne with formaldehyde in the presence of 40% sulphuric acid leads to the formation of 4-methyl-4-vinylethynyl-1,3-dioxan (X; R = H) and 4,5-dimethyl-4-vinylethynyl-1,3-dioxan (X; R = CH_3). Under analogous conditions 1-vi-

nylethynylcyclohexene and formaldehyde gave a bicyclic dioxan (XI):

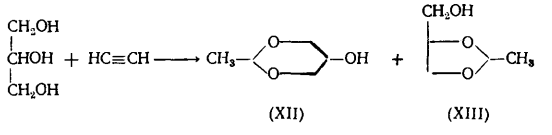


(8)

A quite interesting modification in the Prins reaction was the replacement of mineral acids or their derivatives as catalysts by sulphonic cation-exchange resins[176]. The use of KU-1 cation-exchange resin† for the production of 4-phenyl-1,3-dioxan in the condensation of styrene with formaldehyde greatly facilitates the purification of the reaction product and makes possible the repeated use of the catalyst at the same yield[177] (up to 80%). Similar results have also been obtained for other cation-exchange resins[178,179].

3. Production of 1,3-Dioxans from Acetylene and Polyhydroxy-Compounds

The first information about this method of synthesis was reported in a German patent[180]. As a result of the reaction of a warm solution of glycerol with acetylene in the presence of mercury(II) chloride a mixture of five- and six-membered heterocyclic compounds is obtained, of the *m*-dioxan and dioxolan type. Later, Hill and Hibbert, using the results of Newland on the reaction between acetylene and alcohols in the presence of sulphuric acid and mercury(II) sulphate[181], found that acetylene reacts under these conditions with glycerol to form substituted 1,3-dioxans[182]. The same investigators showed that as a result of this reaction a mixture of five- and six-membered heterocyclic compounds is obtained: 5-hydroxy-2-methyl-1,3-dioxan (XII) and 4-hydroxymethyl-2-methyl-1,3-dioxolan (XIII):



(9)

The details of the cyclisation of this type were found by Hill and Pigeon[183], who showed that in the reaction of acetylene with glycol the vinyl ether

$$CH_2=CH-O-CH_2-CH_2OH,$$

is formed, which in the presence of traces of sulphuric acid is rapidly rearranged into a cyclic ether. Thus under the stated conditions hydroxypropyl vinyl ether is converted into 2-methyl-1,3-dioxan:

(10)

† KU-1 is a difunctional, strongly acid cation-exchange resin with $-SO_3H$ and –OH active groups, prepared by polycondensation of *p*-phenolsulphonic acid with formaldehyde in acid (Ed. of Translation).

4. Production of 1,3-Dioxans by Various Condensations with Formaldehyde

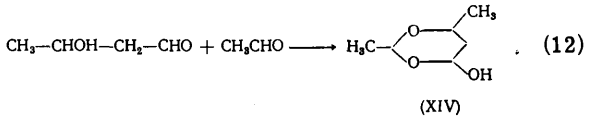
Fuson and coworkers[184] obtained 5-benzoyl-1,3-dioxan by the action of paraform on acetophenone in methanol solution in the presence of potassium carbonate:

(11)

This type of alkaline condensation is unusual, since it is generally accepted that acetals are obtained in the presence of acid catalysts. However, this example is not unique. Thus, Bergman and Miekely[185] isolated cyclic formals produced by the reaction of the simplest primary amines with an excess of an aqueous solution of formaldehyde at low temperature. Finally, alkaline catalysts are used for obtaining cyclic formals from mixtures of aldehydes.

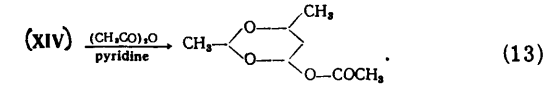
5. Production of 1,3-Dioxans as a Result of the Polymerisation of Aldehydes

In 1935 Shilov[186] reported the formation of 6-hydroxy-2,4-dimethyl-1,3-dioxan in the polymerisation of acetaldehyde in the presence of sodium hydroxide. This problem was developed further in the studies of Späth and Schmid[187], in which the properties of aldol and its derivatives were studied. According to the results of these authors, the monomer of aldol is seldom obtained, except for those instances when the aldol condensation is carried out at high temperature. Evidently, in many instances the aldol reacts as a bimolecular compound. Späth and his coworkers[188] concluded that the presence of the 1,3-dioxan structure in the dimer of aldol is due to intramolecular cyclisation of the hemiacetal formed intermediately. Consequently, simple aldehydes should react with monomeric aldol, forming hemiacetals, which are cyclised into 1,3-dioxans. On heating acetaldehyde with aldol in a sealed tube at 100°C, these authors obtained 6-hydroxy-2,4-dimethyl-1,3-dioxan (XIV):



(12)

Hanschke[189] subsequently produced further proof of the correctness of Späth's hypothesis. The crude product of the polymerisation of acetaldehyde was acetylated with acetic anhydride in pyridine. The acetate isolated seemed identical with the substance obtained by Späth in the acetylation of (XIV):



(13)

Hence in the polymerisation and condensation of aldehydes, beginning with the simplest, a variety of compounds having the 1,3-dioxan structure are formed, including polymerised 1,3-dioxans[190].

III. STEREOCHEMISTRY OF 1,3-DIOXANS

The stereochemistry of 1,3-dioxans has been little studied, nevertheless its development is extremely important for the further perfection of general stereochemical

ideas, in particular for the development of conformational analysis. Being heterocyclic analogues of cyclohexane (the "pseudocyclohexane ring"), 1,3-dioxans have several important peculiarities. Thus, the presence of oxygen atoms in the 1- and 3- positions of the six-membered ring leads to weakening or, in any case, to a change in the character of the non-bonded interactions of the 1–3 type in this ring. This makes the boat configuration more probable and favourable in this series, in comparison with the boat in the cyclohexane series. Although this in itself is extremely interesting and new, it is far from being the only peculiarity of the stereochemistry of the system being studied. The stereochemistry of 1,3-dioxans has made only the first steps but they already merit attention.

Most authors now ascribe to 1,3-dioxan itself (I) the chair conformation (XV). The following is the basis for this. As long ago as 1937 Otto[191], having measured the dipole moment of (I) and having been satisfied that it is small ($\mu = 1.91$ D) suggested that the most probable conformation of (I) should be the chair form. It is easy to see that forms (XV) and (XVI) are identical, which cannot be said about the boat, of the two possible forms of which (XVII) can be called the symmetrical, and (XVIII) the non-symmetrical boat:

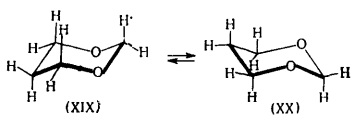
(XV) (XVI) (XVII) (XVIII)

Otto, however, did not make any calculations, but restricted himself to only a qualitative appraisal of these conformations.

Later, Arbuzov[192] pronounced in support of the correctness of Otto's hypothesis. He calculated the dipole moments of the hypothetical planar form (I) ($\mu_{calc} = 1.33$ D), the chair form ($\mu_{calc} = 1.91$ D), and of one of the boat forms ($\mu_{calc} = 2.34$ D).

The information obtained by dipole moment measurements about the conformation of 1,3-dioxan was confirmed by additional results obtained on the basis of an examination of the NMR spectra of this compound[193–195].

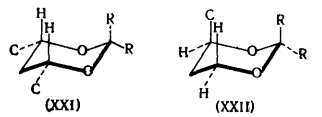
The singlet nature of the peak of the axial and equatorial protons shows the repeated changes of one chair form into the other, (XIX) $\rightleftharpoons$ (XX), hence on average in time the axial and equatorial protons of all the CH_2 groups of the ring become equivalent:



(XIX) (XX)

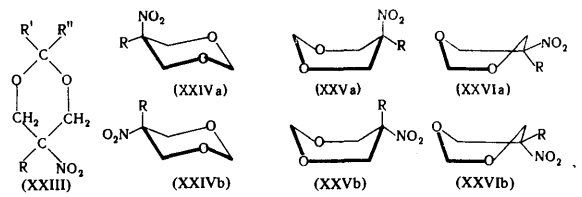
Barbier and coworkers come to the same conclusion in their work, by stating that 1,3-dioxan is present in the chair form and there is a constant chair–chair inversion (XIX) $\rightleftharpoons$ (XX). Consequently Barbier's work confirms completely and independently the interpretation of the spectrum which was given above and was proposed by Samitov.

If the problem of the conformation of (I) can evidently be considered as solved, the problem of the predominant conformations of substituted 1,3-dioxans, the configuration and conformations of the stereoisomeric derivatives of 1,3-dioxan is far from clear and should be decided independently for each separate instance. Thus the chair conformation is evidently favourable for some substituted 1,3-dioxans. This is supported by the theoretical works of Barker and coworkers[196,197], Mills[198], and Klyne[199]. These authors theoretically considered the hypothetical formation of definite types of ring in 1,3-dioxans. All the authors mentioned started from the fact that the most stable conformation of the initial polyhydric alcohol exhibits a zigzag-shaped structure of the carbon skeleton. If this is so then, according to Barker, on closure of the ring the latter can and should be formed by two hydroxyl groups present on the same side of the Fischer projection. This means that as a result of such a reaction the dioxan ring must of necessity be closed with two equatorial substituents in the 4- and 6- positions. This is termed the β-*C*-ring (XXI). The other variant of the ring, the β-*T*-ring (XXII) is more difficult to form, in the opinion of the above authors. All this fits in with the general rules of conformational analysis. However, it should be noted that the authors mentioned[196–199] at once reject the boat form for such molecules without discussing its possible variants:



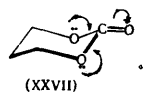
(XXI) (XXII)

Moreover, this is evidently not always true, since a consideration, by the present authors, of this conformation on Stewart–Brigleb models showed that the boat, especially the non-symmetrical boat (XXIII) in the series being considered is incomparably more favourable than in the cyclohexane series. Experimental investigations devoted to this problem are contradictory. There are studies in which the conclusions support the predominance of the chair conformation in substituted 1,3-dioxans. Studies have also been published in which it is stated that substituted 1,3-dioxans exist predominantly in the boat conformation. Of the former, mention must be made above all of the great review paper of Urbanskii[200] at the Butlerov symposium in 1961, in which amongst other data devoted to the study of the stereochemistry of six-membered heterocycles, information was given on the study of the conformation of the 5-nitro-substituted 1,3-dioxans of formula (XXIII). To find the preferable conformations of these substances the dipole moments of all possible conformations of (XXIII) were calculated. These values were then compared with the experimental results.



(XXIII) (XXIVa) (XXIVb) (XXVa) (XXVb) (XXVIa) (XXVIb)

For more complex derivatives of (I) the study of the dipole moments for proof of the conformations becomes difficult[201,202]. Thus dipole moments were calculated for the planar form, and the chair and boat forms of trimethyleneglycol carbonate (XXVII). They were 4.24, 3.56, and 3.28 respectively. The value found is 5.28.[192] Arbuzov[192] explains this anomaly by electronic displacements in the molecule of (XXVII):



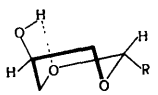
(XXVII)

However, this statement needs additional verification, since it is not confirmed quantitatively.

Most of the information now published shows that the chair conformation is most probable for substituted 1,3-dioxans. Of the studies on which it is maintained that substituted 1,3-dioxans exist in the boat form, mention can be

made of the work of Foster and coworkers [203-206] and that of the authors of the present article [207,208]. These are connected with the use of spectroscopic methods of investigation. Unfortunately, there have been few studies of the 1,3-dioxans by ultraviolet, infrared, Raman, and NMR spectroscopy.

The study of 1,3-dioxans by ultraviolet spectroscopy showed that they absorb in the far vacuum region of the spectrum. However, the number of works devoted to the study of the vacuum ultraviolet spectra of 1,3-dioxans is very small and the conclusions [209-212] do not allow a judgement about the stereochemistry of these substances to be made on their basis. Still fewer papers are devoted to studies of the Raman spectra. There is only one paper [213] on this region and from this it is possible to draw only insignificant information. The study of the infrared spectra of 1,3-dioxans began comparatively recently [214,215]. The first studies confirmed the presence in the infrared spectra of substituted 1,3-dioxans of bands of complex structure but until recently there was no success in finding the number of characteristic bands, without speaking of more far-reaching investigations. However, papers devoted to a more systematic study of this problem have recently appeared [207,208]. Thus, Ledwoch [216] succeeded in finding a set of characteristic bands for the 1,3-dioxan ring (ν = 1025–1035, 1070–1110, 1160–1175, 2745–2795 cm^{-1}), and Foster and coworkers [217-220] found, in a study of the infrared spectra, that some of the *trans*-2-alkyl-5-hydroxy-1,3-dioxans and substituted 5-hydroxy-1,3-dioxans exist in the preferential conformation of the non-symmetrical boat (XXVIII). The reason for the existence of this form was thought by Foster to be that the large group R experiences less non-bonding interactions in this conformation than in the chair. Moreover, the boat (XXVIII) is stabilised due to the formation of a hydrogen bond:



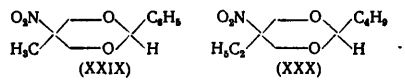
(XXVIII)

Results which show the possibility and permissibility of the boat conformations in a series of 2-substituted 5α-alkoxyethyl-5-alkyl-1,3-dioxans were obtained by the present authors in a study of the NMR spectra of these compounds. These investigations are analysed below.

From all that has been stated it can be concluded that the conformations in the 1,3-dioxan series are somewhat different from the cyclohexane series. Whereas 1,3-dioxan itself evidently exists in the chair form, its derivatives can have not only the most favourable chair conformation, but also the boat conformation, which in the series being considered is more favourable than in the cyclohexane series.

The second important problem of the stereochemistry of the 1,3-dioxans consists in finding the configuration of the geometrical isomers of the 1,3-dioxans. It is easy to see that any (apart from *gem*-substituted) disubstituted 1,3-dioxans, and also tri- and more substituted 1,3-dioxans, should be mixtures of geometric isomers, which often are also diastereomers. This aspect of the stereochemistry of the 1,3-dioxans has been little studied. Very few authors have succeeded in resolving 1,3-dioxans into stereoisomers, and still fewer have firmly established the configuration of these isomers.

In 1928 Hibbert and Carter [221] succeeded in finding experimentally the presence of *cis-trans*-isomers in 2-(-*p*-nitrophenyl)-5-hydroxy-1,3-dioxan and its derivatives (5-methyl, 5-benzoyl, and 5-nitrobenzoyl). In 1942 Verkade and van Roon [84] separated the geometric isomers of 5-hydroxy-2-phenyl-1,3-dioxans. A year later Zenkus [112] synthesised 5-methyl-5-nitro-2-phenyl-1,3-dioxan (XXIX), which was separated into stereoisomers owing to a difference in the solubility of the latter in benzene–cyclohexane mixture. The melting points of these isomers are 118° and 78.4°C respectively. These isomers were then reduced to amino-derivatives, which also seemed stereoisomers and melted at 84° and 48.2°C respectively. A similar operation was also carried out on 2-butyl-5-ethyl-5-nitro-1,3-dioxans (XXX):



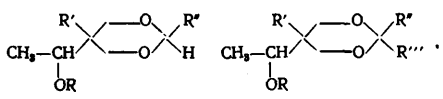
(XXIX) (XXX)

A characteristic for all the older works mentioned was that only the crystalline 1,3-dioxans were separated by fractional crystallisation and the authors refrained from firm statements about the configuration of the substances obtained. In recent years the studies in this field were extended and chromatographic methods were applied to the investigation of stereoisomerism. Thus, Rondestvedt [21] reported on the separation, by use of gas–liquid chromatography, of the geometric isomers of some of the 1,3-dioxans they had synthesised. It is quite interesting that this author applied the method of conformational analysis to the investigation of the systems they synthesised and advanced the hypothesis that the largest substituent should occupy an equatorial position in the molecules of separate isomers. Rondestvedt tried to use infrared spectroscopy for studying these problems. The preparative separation of the isomers, carried out in three instances, was again by fractional crystallisation.

Portoghese and Smissman [222] and later Smissman and coworkers [223], in studying the stereochemistry of the Prins reaction connected the stereoisomerism of 1,3-dioxans with that of the related 1,3-diols. The authors of these works were some of the first to use nuclear magnetic resonance for studying this problem. They succeeded in showing that the Prins reaction is characterised by *cis*-addition in several instances. In studying this process, they found in passing the configuration of some aryl-substituted 1,3-dioxans. Nuclear magnetic resonance was also used by Bagget and coworkers [224] in a work devoted to a proof of the configuration of the stereoisomeric derivatives of 5-hydroxy-1,3-dioxan. In this work hypotheses about the predominant conformations of these stereoisomers were advanced in which it stated that both the *trans*- and the *cis*-isomers have the chair conformation, but whereas the *trans*-isomer does not exhibit the chair–chair type of inversion, the *cis*-isomer does. The latter assumption was made on the grounds that the peak of the protons found in the 4- and 6- positions of the molecule of the *cis*-isomer was a singlet, that is, showed their equivalence. Possibly, however, this statement is not completely correct and the apparent equivalence of the 4- and 6-axial and equatorial protons is due to another reason, as will be discussed below.

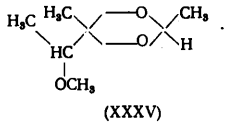
In a series of later studies [216-219] it was suggested that stereoisomers exist in synthesised mixtures of 1,3-dioxans. Quite recently Kaplan [87] succeeded in resolving some 2-alkyl-5-ethyl-5-hydroxymethyl-1,3-dioxans into stereoisomers by gas–liquid chromatography.

In a series of published investigations Bogatskii and coworkers[207,208] examined the problem of the stereochemistry of 2-substituted 5-α-alkoxy-5-alkyl-1,3-dioxans, of the type of (XXXI) and (XXXII):



(XXXI) (XXXII)

During the course of these investigations, initially by gas–liquid chromatography and proton magnetic resonance, the existence of geometrical isomers in substance of type (XXXI) was demonstrated[99,100], after which they were separated into individual isomers by rectification on efficient columns. This was the first example in the literature of the separation of the derivatives of 1,3-dioxans into stereoisomers by rectification. The purity of the isomers obtained was determined chromatographically and was 95 to 99%. To establish the configuration and conformation of the individual isomers, dipole moments and NMR methods were then used. The authors succeeded in showing that the low-boiling isomers of (XXXI) are *trans*-isomers (XXXIII)‡, which exist in the predominant conformation of a chair, and the high-boiling are *cis*-isomers (XXXIV)‡ which exist in the predominant conformation of the non-symmetric boat. The NMR spectra showed that in the specimens examined there was absolutely no sign of inversion of the conformations. A study of the NMR spectra of *cis*- and *trans*-5α-methoxyethyl-2,5-dimethyl-1,3-dioxans raised no doubts on the non-equivalence of the axial and equatorial protons of the methyl groups, which shows the absence of inversion. Comparison of the calculated and measured values of the non-equivalence shows the chair conformation. This conclusion, obtained on the basis of a study of NMR spectra was confirmed by studying the dipole moment. Actually, the dipole moment of the *trans*-isomer (XXXV) was found to be $\mu = 1.15$ D. The value calculated for the chair conformation is $\mu = 1.16$ D.



(XXXV)

A characteristic feature of the spectrum of the *cis*-isomer is the absence of a peak with an anomalously low value of the chemical shift and the singlet nature of the peak of the protons of the $C_{(4)}$ or $C_{(6)}$ CH_2 group. This singlet nature cannot be the result of inversion of conformation, since other regions of the spectrum do not show averaging of the shifts of the axial and equatorial substituents. A comparison of calculated and measured values of non-equivalency shows that such phenomena should take place in the non-symmetrical boat configuration where the calculated non-equivalence of the $C_{(4)}$ protons is $\delta = 0.4$ p.p.m., and that of the $C_{(6)}$ protons $\delta = 0.16$ p.p.m. Conclusions about the configuration *cis*- and the conformation of non-symmetrical boat are in this instance also confirmed by a study of the dipole moments. In *cis*-(XXXV) the dipole moment was found to be $\mu = 2.60$ D and that calculated for the non-symmetrical boat is $\mu = 2.56$ D.

These conclusions about the configuration and conformations of (XXXI) were then confirmed by studying the kinetics of hydrolysis of these isomers, which showed that the low-boiling isomers are hydrolysed much more slowly than the high-boiling ones and the influence of a substituent is greater on the hydrolysis of (XXXIII) than on the hydrolysis of (XXXIV). It is easy to see that this agrees with the results obtained in relation to the configuration and conformation of these stereoisomers.

In the series of stereoisomeric (XXXI) we succeeded in observing a linear relation between the difference in boiling points of the *cis*- and *trans*-isomers (Δt) and the number of carbon atoms in the (XXXI) molecule. Such a relation had been found by Kazanskii and Liberman in the cyclohexane series. This confirms the configurative relationship between the 1,3-dioxan series and the cyclohexane series. However, it is still more interesting that there is also a linear relation between the ratios of the hydrolysis constants of the stereoisomeric (XXXI) and the number of carbon atoms in the same series. Consequently, the dependence of Δt on the number of atoms is not fortuitous but is connected with the extremely intimate configurative features of these compounds.

All the information given above shows that work in this field of study of the stereochemistry of the 1,3-dioxans is developing rapidly and the results obtained up till now show the presence of a trait of similarity and at the same time a series of essential differences between these compounds and cyclohexane. Evidently, 1,3-dioxan systems are a convenient model for studying the problem of the characteristics of the boat conformations.

While this article was being considered by the Editorial Board we were undertaking investigations[338-340] which confirm the conclusions concerning the stability and extensive distribution in this series of the boat conformation and the marked favourability of the $C_{(6)}$ axial position in the 1,3-dioxan ring compared with the cyclohexane rings. It is easily established that the 5-C-axial valency in these systems is unique owing to the considerable weakening of the 1,3-interaction, since there are oxygen atoms in positions 1 and 3 of the pseudocyclohexane ring[339].

The present authors conclude that the ketals of this series are characterised by the presence of a non-symmetric boat conformation, or twist-conformation[338-340]; they have formulated an empirical rule according to which in 1,3-dioxan systems in those instances when inversion of the conformation of the ring is impossible or greatly hindered for steric reasons, the geometric isomers tend to take on the conformation (chair, symmetric or non-symmetric boat, or twist-conformation) with di-equatorial position of the largest substituents or such configuration in which one of the largest substituents occupies a $C_{(6)}$-axial position[339].

It should be noted that interest in the conformational problems in the 1,3-dioxan series is increasing continually, as is shown by the studies[341-345], whose results confirm the above conclusions and the empirical rule given.

IV. CHEMICAL CHANGES OF 1,3-DIOXANS

The chemical changes of 1,3-dioxans are rather varied, but a common feature of them is that, like the reactions of acetals and ketals, they are modified by the presence of a cyclic structure.

1. Hydrolysis and Alcoholysis

The hydrolysis of 1,3-dioxans is effected comparatively readily, although cold water and dilute and cold solutions

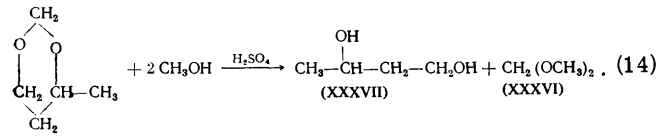
‡ Formulae (XXXIII) and (XXXIV) are not given in the Russian (Ed. of Translation).

of alkalis have little action on 1,3-dioxans[225,226]. However, in an acid medium 1,3-dioxans, like other acetals, are readily hydrolysed in the cold, even extremely dilute solutions of acids being sufficient for this[227-229]. As for all similar reactions of acetals, the hydrolysis of 1,3-dioxans in acid medium is reversible. Therefore it is not profitable to obtain 1,3-diols from 1,3-dioxans since the yield of the latter does not exceed 10–20%.[230,231] True, there are indications that the hydrolysis equilibrium can be shifted to the side of the formation of diols, by bonding the aldehydes formed by chemical means or by carrying out the hydrolysis under pressure[232].

In recent years more and more attention has been paid to the theoretical examination of the hydrolysis of 1,3-dioxans. Dilatometric[233-237], titrimetric[238-240], and spectrophotometric[241-243] methods of studying the kinetics of the hydrolysis of 1,3-dioxans have been developed and employed with success. We stated above the possibility of using a study of the hydrolysis for proving the configuration and conformation of stereoisomeric 1,3-dioxans. Of the studies of the mechanism of this reaction we can single out that of Bender and Silver[244], where the authors succeeded in finding that the rate of hydrolysis of certain substituted 1,3-dioxans in the pH range from 3 to 6 is independent of the hydrogen-ion concentration.

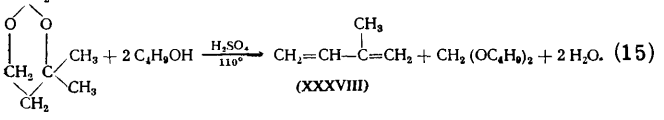
Hydrolysis of the cyclic ketals of the 1,3-dioxan type has been little studied but there are indications that six-membered ketals are less stable than five-membered[245,246], according to conformational considerations. This problem was discussed in the previous section of the present article.

Alcoholysis of 1,3-dioxans leads to the production of diols or alkenes in good yields. Thus on boiling 1,3-dioxans with methanol in the presence of sulphuric acid the splitting of the dioxan takes place very readily, in view of the fact that the methylal formed (XXXVI) is continually removed from the reaction[247,248].



(14)

When the reaction proceeds in methanol as medium its chief products are a glycol (XXXVII), whereas in alcoholysis in the presence of higher alcohols acetals (or formals) of these alcohols are left in the reaction mixture and are, together with diols, the main reaction products. Very often under these conditions the glycols are dehydrated with the formation of conjugated dienes as is shown in Eqn. (15). Consequently, the process considered can serve as a convenient method for obtaining conjugated dienes of type (XXXVIII):[249]

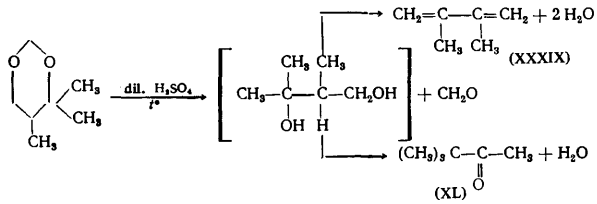


(15)

However, conjugated dienes can be obtained from the 1,3-dioxans without alcohols being present. It has been shown[250] that on boiling substituted 1,3-dioxans with aqueous solutions of mineral acids (1–5%) they are converted directly into dienes. This reaction finds industrial application and many variations of this method have been patented.

It was stated above that dioxans are stable under the action of alkalis in the cold, yet hot alkali solutions can cleave the 1,3-dioxan ring, as also can hot water[252].

An anomaly observed in the course of this reaction merits attention. Thus in the hydrolysis of 4,4,5-trimethyl-1,3-dioxan, in addition to the usual reaction products, a diene (XXXIX) and formaldehyde, ketones of the pinacolin type (XL) are also formed:



(16)

This anomaly can be explained in passing by the occurrence during the course of the reaction of hydrolysis and dehydration with a pinacol rearrangement of the diol formed, Eqn. (16).[253]

2. Thermal and Catalytic Decomposition

This section deals with a wide range of catalytic conversions of 1,3-dioxans connected with cleavage of the ring and in this sense the reactions being considered are close to the previously described hydrolytic cleavage of the 1,3-dioxan systems.

Catalytic pyrolysis of substituted 1,3-dioxans over dehydrating catalysts leads directly to the production in good yields of conjugated diene hydrocarbons. This is the most suitable method industrially for the production of conjugated dienes, in particular isoprene, since the dioxans themselves which are used for these reactions are accessible and cheap, seeing that they are obtained from alkenes by the Prins reaction. There is an extensive literature on this subject, still growing at the present time[254-273], and mainly devoted to the production of isoprene; the different variants of the method mentioned are usually patented.

Several catalysts have been proposed for this reaction. Various authors have at different times proposed as catalysts a mixture of H_3PO_4 or $H_4P_2O_7$ with phosphorus furnace slags, kaolin, or bentonite. The catalyst mass was activated by passing steam at 150–300°C under pressure and was regenerated by passage of an air–nitrogen mixture at 400–600°C.[254-256]

Other authors have used oxide catalysts[256,257], a mixture of boric and phosphoric acids[258], zinc chloride and manganese chloride[259,260], various catalysts based on phosphoric acid[261-264], and several other acid catalysts of the most diverse nature[266].

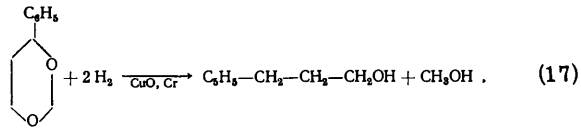
The French authors Coussemant, and Hellin and their coworkers[267-272] have recently made extensive investigations in this field; they studied a series of catalysts based on phosphoric acid and obtained patents on various versions of the industrial production of isoprene from 4,4-dimethyl-1,3-dioxan.

Hamamoto and Mizutani[274] carried out a serious investigation by comparing oxide catalysts, the salts of various metals, and acids, borate catalysts, and catalysts based on phosphoric acid in this reaction[274].

The thermal cleavage of 1,3-dioxans can also take place without catalysts at 200–600°C, but the yields of the cleavage products are lower (not more than 10%). In this reaction the products are usually alkenes, formaldehyde (or other aldehydes), or CO and hydrogen[121].

3. Reduction and Hydrogenolysis of 1,3-Dioxans

The hydrogenolysis of 1,3-dioxans can be used for the synthesis of certain alcohols[275-277]. The hydrogenation of 4-phenyl-1,3-dioxan, leading to the production of 3-phenylpropanol in 85% yield, has been described:



(17)

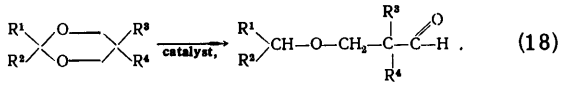
Under analogous conditions 4,4-dimethyl-1,3-dioxan is converted into isopentyl alcohol[278], and the acylated 1,3-dioxans into the corresponding β-monoglycerides[279-282].

1,3-Dioxans arylated in the 4- position are capable of reductive cleavage under the action of sodium in the presence of high-boiling alcohols, for example, di-isobutylmethanol[165-167]. Here also reductive cleavage proceeds selectively leading to the loss of oxygen attached to the $C_{(4)}$ carbon.

Finally, the possibility was recently shown of effecting the hydrogenolysis of 1,3-dioxans under the action of lithium tetrahydroaluminate[283,284] and also their reduction with the aid of organomagnesium compounds[285,286]. These reactions lead to cleavage of the 1,3-dioxan ring and the production of either alkoxy-alcohols[286] or unsaturated alcohols[285], depending on the conditions.

4. Catalytic Isomerisation and Catalytic Changes

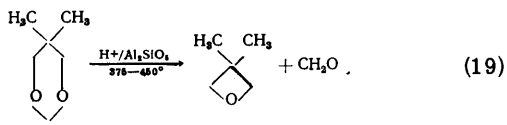
In 1961 Rondestvedt reported the finding of a new type of conversion of 1,3-dioxans—catalytic isomerisation of these substances into β-alkoxyaldehydes according to Eqn.(18)[287-289]:



(18)

This reaction takes place at elevated temperatures in the presence of weakly acid catalysts. For example, on pumice it is effected at 360–450°C and on silica gel at 250–350°C. The ease of rearrangement depends on the nature of the radicals R^1–R^4. For example, the presence of two substituents at position 5 is obligatory, or otherwise further decomposition of the reaction products takes place, into the corresponding alcohol and arylaldehyde. Moreover, it was found that electron-acceptor groups in position 2 hinder the course of the rearrangement, and alkyl and cycloalkyl substituents in the same position facilitate it.

Another interesting reaction was observed by Bartok[290], the conversion of 1,3-dioxans into the oxacyclobutane system:



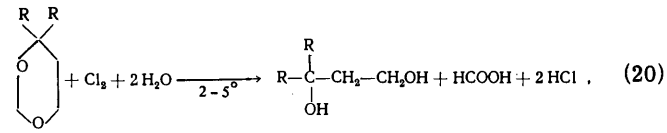
(19)

This conversion is effected on an acid cracking catalyst according to Eqn. (19) at 370–450°C and leads to the production of oxacyclobutane derivatives in 25–30% yield.

5. Halogenations

Of the halogenations of 1,3-dioxans, their chlorination has been studied better than the other reactions.

The chlorination of 4,4-dialkyl-1,3-dioxans in an aqueous medium leads to their hydrolysis with the formation of the corresponding glycols and is not accompanied by the dehydration of the latter. Evidently the unstable 4,4-dialkyl-2-chloro-1,3-dioxan is formed initially, then decomposes in the presence of water to form glycol, and formic and hydrochloric acids[291]:

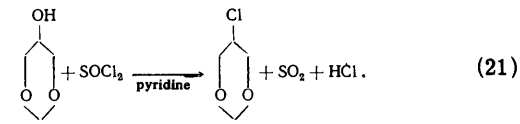


(20)

The chlorination proceeds otherwise in the absence of water. Under these conditions chlorination and bromination lead to the formation of polychloro- and polybromo-derivatives of 1,3-dioxans, which, however, cannot be purified and isolated[292].

There are interesting studies devoted to the action of various halogenating agents—phosphorus(V) chloride, thionyl chloride, etc.[60] Phosphorus(V) chloride breaks the 1,3-dioxan ring, to form trimethylene chloride[293].

Under the action of thionyl chloride on 5-hydroxy-1,3-dioxan, 5-chloro-1,3-dioxan was obtained[68,294]:



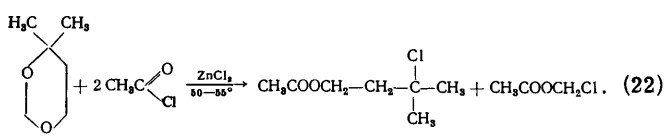
(21)

Halogenation proceeds more easily in the side-chain of substituted 1,3-dioxans. However, here difficulties are encountered since it is constantly necessary to consider the possibility of cleavage of the ring.

6. Action of Anhydrides and Acyl Halides of Organic Acids on 1,3-Dioxans

The action on 1,3-dioxans of anhydrides and acyl halides of organic acids has been little investigated, yet papers have been published which enable the course of the reaction to be predicted. Thus when acetic acid acts on 1,3-dioxan in the presence of concentrated sulphuric acid the ring is broken and the corresponding glycol diacetals are formed. In this way 5-ethyl-5-nitro-1,3-dioxan was converted into 2-ethyl-2-nitropropan-1,3-diol diacetate[295]. It is easy to understand that this reaction is related to the hydrolysis and alcoholysis, with the difference that here attack is by a glycol (not an aldehyde, as in alcoholysis). However, the reaction under consideration does not always proceed so simply. It is known that sometimes it is accompanied by side-reactions and rearrangements. For example, it is known that under the action of acetic anhydride in the presence of sulphuric acid 4-phenyl-1,3-dioxan is converted into 1,5-diacetoxy-2-hydroxy-3-phenylpentanediol[296]. Other authors, for example, Senkus[295], have described similar conversions.

Acyl halides of organic acids react with 1,3-dioxans in a similar manner. When 4,4-dimethyl-1,3-dioxan reacts with acetyl chloride, breaking of the ring and formation of the corresponding chloro-esters is observed[297]. It is interesting that the yields in this reaction are almost quantitative:



(22)

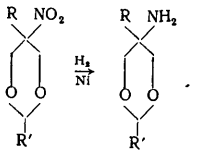
However, here also side-reactions are possible. On boiling alkyl-substituted 1,3-dioxans with small amounts of acyl chlorides in the presence of Friedel–Crafts catalysts, solid resins are obtained[298], probably formed as a result of secondary polycondensation processes.

7. Oxidation

There has been little investigation of the oxidation of 1,3-dioxans. Results have been published which show that in the photo-oxidation of 1,3-dioxan various peroxides can be obtained, depending on the conditions[299]. Oxidation for 100–120 h at 50°C gave a dihydroperoxide, and for 9–10 days at 25°C a hydroperoxide; the latter is then polymerised into a dimer. In 1964 Ikeda and coworkers published an extensive paper[300] devoted to the study of the autoxidation of 1,3-dioxans by atmospheric oxygen and also the oxidation of these substances in the presence of catalysts. The authors of this work obtained five types of oxidation product: peroxides, hydroperoxides, spirocyclic peroxides, $\alpha\beta$-unsaturated ethers, and polymers. The products were obtained in different quantities and proportions, depending on the reaction conditions; without a catalyst, the reaction was directed towards the side of the production of hydroperoxides and spirocyclic peroxides, but in the presence of traces of cobalt(II) derivatives the reaction is directed towards the side of the formation of $\alpha\beta$-unsaturated ethers and polymers, etc. However, the properties of peroxides and hydroperoxides of 1,3-dioxans are still very little investigated.

8. Conversions of Functional Derivatives of 1,3-Dioxans

The patent literature[135] states that in the catalytic reduction of nitro-derivatives of 1,3-dioxans at 110 at pressure and in the presence of Raney nickel in methanol, amino-substituted 1,3-dioxans are obtained exceptionally readily and in good yields:



(23)

Another interesting conversion of substituted 1,3-dioxans is the reaction, studied by Urbanskii and Ekshtein, of 5-nitro- and 5-hydroxymethyl-1,3-dioxans with diazo-compounds, leading to the production of derivatives of 1,3-dioxans[301,302].

In addition to these papers several have been published on the conversions of hydroxy-derivatives of 1,3-dioxans and of halogeno-derivatives[88] and on the production of substances of the 1,3-dioxan type with two keto-groups in positions 4 and 6,[303-305] and several other papers on the synthesis or conversions of functional derivatives[306-315].

---o0o---

In ending the review of the chemical properties of 1,3-dioxans it must be mentioned that at present only those chemical properties of this class of compound which are related to their industrial use are receiving more serious investigation, namely the hydrolysis and catalytic cleavage of 1,3-dioxans to give conjugated dienes. Information about other properties of this group of substances is extremely scanty.

V. USE OF THE 1,3-DIOXANS

Although it is still impossible to speak of the 1,3-dioxans having such a wide industrial use as, for example, 1,4-dioxan or certain other organic compounds, the available published information shows that many of these substances exhibit extremely valuable properties.

The practical uses of 1,3-dioxans can be classified in several groups. The first is the use of 1,3-dioxans as intermediates for synthesis. In this respect the most promising application is their use for making highly pure alkadienes, 1,3-diols, and β-monoglycerides[228,247,254-273,279-282].

These problems are now receiving attention and the greatest number of works is devoted to this direction. They were characterised above in the section devoted to the chemical properties of 1,3-dioxans. According to patents, some of the 1,3-dioxans can serve as components in the synthesis of polymeric materials[316-318]. Thus 5-methyl-5-($\alpha\beta$-dihydroxyethyl)-1,3-dioxan can be used for obtaining non-saturated polyethers[67].

The second direction predicts the use of 1,3-dioxans as solvents, additives, etc.[319] It was shown that 1,3-dioxans are good solvents for resins and lacquers[121,143,320], and can be used as a solvent in the deparaffinisation of oils. Mixtures with 4,4- or 4,5-dimethyl-1,3-dioxans were especially effective[321]. 1,3-Dioxans are good solvents in Grignard reactions[322].

1,3-Dioxans are good antiknock agents to add to motor fuel and increase its octane number[321]. A derivative of spiro-di-1,3-dioxans, which contain sulphur and halogen can be used as intermediates and accelerators for the vulcanisation of rubbers. The addition of 1,3-dioxans to polymers and elastomers improves their properties, increases the elasticity of the adhesives and sealing compositions based on various resins. 1,3-Dioxans are used in the production of lubricants and cements[223,324]. 2,2-dimethyl-1,3-dioxan can be used in the hydrogenation of butadiene rubbers[325,326]. The possibility of using 1,3-dioxans as denaturing agents in alcohol, for the dry cleaning of clothes, and as addition to paints to prevent their skinning during storage[327] has been noted.

The study of the physiological activity of the 1,3-dioxans is extremely promising. The possibility of using 1,3-dioxans as disinfectants has now been shown[319,327]. Blicke and coworkers investigated some pharmacological properties of a considerable number of 2,2-disubstituted 5-methyl-1,3-dioxans and mentioned their spasmolytic and antihistamine activity[48,49,56]. Subsequently, Mel'tser and coworkers synthesised a series of di-substituted 1,3-dioxans in a search for new depressants of the central nervous system[51]. Information has been published about the sedative-hypnotic action of 1,3-dioxans[328].

According to the patent literature, some 1,3-dioxans exhibit antibiotic action[265,276,329], for example, 6-acetoxy-2,4-dimethyl-1,3-dioxan[329] or the products of condensing carboxyl compounds with 1-(p-nitrophenyl)-2-acylaminopropen-1,3-diols[276].

We have obtained results which show the antimicrobial and fungicidal ability of alkoxyalkyl-substituted 1,3-dioxans[330].

Finally, quite interesting information has been obtained about the influence of 1,3-dioxans on plant growth. According to Urbanskii[331] and ourselves[332], 1,3-dioxans stimulate plant growth, especially that of monocotyledons. 1,3-Dioxans have found application in entomology[333-337] and as insect-repellant substances[46,328,337].

Consideration of the progress in the chemistry of the 1,3-dioxans shows that in recent years chemists have paid

increasing attention to these very interesting substances. This is because of the wide possibilities for their use in the synthesis of several important organic substances, the convenience of the system as a model for stereochemical investigations and their high and varied physiological activity. It is evident that in future years we can expect a still more rapid development of the chemistry of the 1,3-dioxans.

VII. Titration of monomeric and polymeric compounds in non-aqueous solutions 288
VIII. Analysis of industrial materials 289

I. INTRODUCTION

With the rapid development of chemistry and chemical technology, it is becoming urgently necessary to improve and develop new and more effective methods for the analysis of inorganic and organic compounds. Among the most extensively applied analytical methods, a unique position is occupied by chemical and physicochemical methods based on the titration of various compounds in a medium of non-aqueous liquid solvents and in liquefied gases[1-25]. As a result, the analytical chemistry of non-aqueous solutions has developed into an important independent branch of chemical science. Reactions in non-aqueous solutions have begun to be used not only in the familiar classical

methods of alkalimetry and acidimetry, oxidation-reduction, precipitation, and complex formation, but also in specific methods of condensation, addition, substitution, oxomercuration, etc. As a result, the range of titrimetric methods has extended and there has been a marked increase in the number of substances whose quantitative determination has been found to be possible by volumetric methods[1,5,15,17,21].

It is sufficient to point out that methods involving the titration of non-aqueous solutions can be now used for the quantitative determination of a large number of individual compounds and that the number of mixtures which can be analysed by these methods is greater than the number of mixtures which analytical chemists have learned to titrate in the 140 years since Gay-Lussac introduced the methods of volumetric analysis in aqueous solutions into analytical practice. Potentiometric, conductometric, high-frequency, spectrophotometric, polarographic, chromatographic, and other physicochemical methods for the analysis of non-aqueous solutions have found the most extensive applications[25-43].

Methods involving the acid–base titration of non-aqueous solutions of various substances exhibiting acidic or basic properties in non-aqueous media are of the greatest practical and theoretical interest. This is due to the specific influence of non-aqueous solvents on many compounds whose aqueous solutions do not exhibit acidic or basic properties. As a result, the method of acid-base titration can be used successfully for the determination of the great majority of compounds, which cannot be titrated in aqueous media. At the present time non-aqueous titrametric methods are not only widely used in scientific research, but are also successfully employed in factory laboratories for chemical analysis.

In the last 4–5 years, since the publication in "Uspekhi Khimii" [Russian Chemical Reviews] of the first review on the application of non-aqueous solvents in analytical chemistry[8], research in this area has been in the following directions: (1) the development of the theoretical principles of the analytical chemistry of non-aqueous solutions—the quantitative estimation of the influence of non-aqueous solvents on the properties of electrolytes, the study of the differentiating action of solvents, etc.; (2) the use of new organic solvents as media for titration and of new reagents for the preparation of titrant solutions; (3) the development of methods for the analysis not only of individual compounds but also of mixtures of substances which exhibit analogous properties, for example mixtures of isomers, members of the same homologous series, etc.; (4) the development of methods for the analysis of compounds which do not exhibit acid-base properties in water, for example neutral salts, unsaturated compounds, ketones, aldehydes, etc.; (5) the extensive introduction of non-aqueous analytical methods for the analytical control of the composition of intermediates and the purity of finished products; and (6) the search for new methods for the determination of the equivalence point in titrations.

II. THEORY OF THE ACID–BASE TITRATION OF NON-AQUEOUS SOLUTIONS

In the theory of the analytical chemistry of non-aqueous solutions, a particularly important position is now held by ideas on the marked influence of the nature and physical properties of the solvent, the concentration of the solution, and the nature of the dissolved substance on the state of the dynamic equilibria between the ions and molecules of the dissolved substance and the solvent. This influence affects the physicochemical properties of the dissolved substance (electrical conductivity, solubility, ability to undergo dissociation, association, complex formation, etc.), and also the direction of ion exchange reactions[44-59].

Izmailov, Shkodin, Kolthoff, Bruckenstein, Hall, and a number of other workers previously carried out detailed studies of the acid–base equilibrium in anhydrous acetic acid. Work has recently been published on acid–base reactions in acetonitrile, ethylenediamine, t-butyl alcohol, dimethyl sulphoxide, and other solvents. The studies were carried out chiefly to estimate the strengths of acids and bases by measuring K_{diss} in non-aqueous solutions.

Acid–base equilibrium in acetonitrile has been studied by Kolthoff and coworkers[60-64]. It was found that in acetonitrile, perchloric acid is completely dissociated, whereas other acids, which are strong in water, are weak electrolytes. Sulphuric, nitric, hydrochloric, and hydrobromic acids dissociate according to the equation:

$$2HAn \rightleftarrows H^+ + AnHAn^-.$$

Picric acid at low concentrations (less than 0.1 M) dissociates to H^+ and Pi^-, but at higher concentrations it dissociates according to the equation

$$3HPi \rightleftarrows H^+ + Pi(HPi)_2^-.$$

Spectrophotometric and conductometric methods have been used to determine the dissociation constants

$$K_{AnHAn^-} = \frac{[AnHAn^-]}{[HAn]\,[An^-]} \text{ and } K_{HAn} = \frac{[H^+]\,[An^-]}{[HAn]}.$$

for the above acids. The acids can be arranged in the following order of decreasing strengths in a medium of acetonitrile: $HClO_4 > HBr > H_2SO_4 > HNO_3 > HCl > HPi$.

The authors cited compare the behaviour of the acids in acetic acid and in acetonitrile, by comparing the difference in the degree of dissociation of the acids with the solvation, dielectric constant, and basic nature of the solvent, with allowance for the formation and dissociation of ion pairs involving hydrogen bonding. The calculated curves for the conductometric titration of the bases in acetonitrile shows good agreement with the experimental curves[62-64]. Acetonitrile is an excellent differentiating solvent, due primarily to its very weak acidic and basic properties.

The behaviour of a number of acids and bases in acetonitrile has also been studied by other workers[65-69]. Measurement of the electrical conductivity of bases in acetonitrile showed that the dissociation of bases such as n-butylamine, diethylamine, triethylamine, 1,3-diphenylguanidine, and others in acetonitrile is less by four orders of magnitude than that in methanol[65]. The authors cited conclude that the low dissociation of the bases in acetonitrile is due chiefly to the very weak acidic properties of the solvent and the weak tendency for solvation to take place. At a concentration greater than 5×10^{-2} M, the dissociation of diphenylguanidine takes place according to the equation:

$$2B + CH_3CN \rightleftarrows (BH : B)^+ + CH_2CN^-;$$

at lower concentrations, the dissociation takes place according to the equation

$$B + CH_3CN \rightleftarrows BH^+ + CH_2CH^-.$$

The other bases are dimerised in acetonitrile and dissociate according to the equation:

$$B_2 + 2CH_3CN \rightleftarrows 2BH^+ + 2CH_2CN^-.$$

The determination of K_{diss} for perchloric acid in acetonitrile and other nitriles gave a value of about 10^{-3}, which does not agree with Kolthoff's data[70].

Schaap and coworkers[71] studied acid–base reactions in ethylenediamine. Because of the low value of the dielectric constant of ethylenediamine (DC = 12.5), none of the acids is completely dissociated in this medium. At a concentration greater than 10^{-3} M, even strong electrolytes are present in this solvent in the form of ion pairs. The association constants for the ion pairs formed by a number of acids which are strong acids in water (HCl, HBr, and HNO_3) have been determined. Values of K_{diss} for a number of derivatives of phenol, benzoic acid, and *p*-toluenesulphonic acid in ethylenediamine have been found by the electrical conductivity method[71]. Ethylenediamine exhibits a levelling action, since for all the acids studied $pK \simeq 4$.

Fritz and Marple[72,73] studied acid–base equilibria in t-butyl alcohol. On the basis of earlier studies in alcohols and other solvents with low dielectric constants, they suggest that the dissociation of acids in t-butyl alcohol takes place with the formation of ion pairs, although this process does not take place very extensively:

$$HAn \rightleftarrows H^+An^-;\ H^+An^- \rightleftarrows H^+ + An^-.$$

Potentiometric and conductometric methods were used to measure K_{diss} for perchloric, picric, and benzoic acids and 2,4-dinitrophenol.

Study of the acid–base properties of dimethyl sulphoxide[74,75] showed that in some respects this solvent behaves like water: perchloric, hydrochloric, and sulphuric acids are completely dissociated in this medium. The order of dissociation of the other acids is different from that in water. Thus picric acid is more extensively dissociated in dimethyl sulphoxide ($\Delta pK = -2.7$) than in water, whereas acetic, benzoic, and salicylic acids ($pK = 11.4$, 10, and 6.9) are less extensively dissociated in this solvent than in water; the dissociation constant of HSO_4^- in dimethyl sulphoxide is less than that in water.

Study of acid–base equilibrium in glycols (HS represents the solvent)[76] showed that the dissociation of acids corresponds to the equation

$$HAn + HS \rightleftarrows H_2S^+ + An^-,$$

and the dissociation of bases to the equation

$$BH^+ + HS \rightleftarrows B + H_2S^+.$$

Shkodin and Sadovnichaya[77–81] measured K_{diss} for various bases by the electrical conductivity method and showed that anhydrous acetic acid increases the strength of all weak bases relative to water; one group of bases, with strengths close to that of the alkali metal acetates ($pK(H_2O) \simeq 4.3$–4.6) are levelled, and the other group of weaker bases ($pK(H_2O) > 5$) are differentiated. The bases are much weaker in propionic acid than in acetic acid. The strengths of bases which are very weak in water are increased in propionic acid, however. The differentiation of bases in propionic acid is much less than that in acetic acid. This confirms that in aliphatic acids the strength of electrolytes is inversely proportional to the magnitude of the dielectric constant.

Electrical conductivity data have been used to calculate p*K* for perchloric (2.85), hydrochloric (5.46), sulphuric (4.5), and hydrobromic (4.10) acids. The behaviour of acids and bases in a medium of acetic acid and its mixtures with other solvents has also been studied by a number of other workers[82–92].

Dulova and coworkers[93–99] studied the differentiating action of alcohols, esters, glycols, and ethylene chloride, and indicator and spectrophotometric methods were used to determine K_{diss} for a number of acids. The authors cited consider that the differentiating action of hydroxyl-containing solvents is related chiefly to the size of the radical and its three-dimensional structure.

A large number of determinations of K_{diss} for acids in methanol and ethanol and their mixtures with water have been made[100–122]. Sano[123,124] determined K_{diss} for a large number of acids in methanol and established that the values of K_{diss} decrease by a factor of approximately 80 000 relative to water. Tabagua[125–128] determined K_{diss} for a number of organic acids in methanol and ethanol and their mixtures with water, and showed that the values of K_{diss} for the acids decrease with increase in the concentration of alcohol in the mixture, and that at low concentrations of the alcohol the strength of the acids depends only on the dielectric constant of the medium. With increase in the alcohol concentration, the influence of the nature of the acids is observed, the changes in K_{diss} for weak acids being less marked than those for strong acids, due to the difference in the solvation energies of the ions and molecules.

Aleksandrov and coworkers[129] determined p*K* for a number of acids in methanol and its mixtures with water and benzene. Izmailov and Spivak[130] determined pK_{rel} for a number of acids in aprotic solvents. Data have been published on the dissociation of electrolytes of the acid–base type in formic acid[131,132], formamide[133–136], dimethylformamide[137], mixtures of dioxan and water[138–145], and other solvents[146–159]. A simple and rapid method for estimating solvent influence on the strengths of acids and bases involves the determination of the relative acidic or basic strength of electrolytes from the half-neutralisation potentials ($E^{1/2}$). When 50% of the weak acid or weak base is neutralised, pH = p*K*, so that $E^{1/2}$ can characterise the relative strength of electrolytes in non-aqueous solutions. Values of $E^{1/2}$ for derivatives of benzoic acid have been determined in pyridine, acetonitrile, methyl isobutyl ketone, 2-nitropropane, *o*-nitrotoluene, nitrobenzene, dimethylformamide, chlorobenzene, and bromobenzene[160]. A linear dependence of $E^{1/2}$ on $pK(H_2O)$ was obtained for all solvents. The solvents studied exhibit a strong differentiating action, and in these solvents it is possible to analyse a mixture of two acids with $\Delta pK(H_2O) = 0.94$. Determination of $E^{1/2}$ for derivatives of phenylurea in n-butylamine showed that the phenyl- and chlorophenyl-derivatives exhibit more strongly acidic properties in n-butylamine than urea and its alkyl derivatives[161].

The dependence of the half-neutralisation potentials on the values of $pK(H_2O)$ for electrolytes gives information on the differentiating action of non-aqueous solvents. The differentiating action of solvents is characterised by the slope of the straight line, which is determined by the number of mV per unit of $pK(H_2O)$. The steeper the straight line, the stronger the differentiating action shown by the solvent with respect to a given group of electrolytes. Comparison of the differentiating properties of nine non-aqueous solvents by measurement of the values of $E^{1/2}$ for the nitro- and halogeno-derivatives of phenol was carried out by Crabb and Critchfield[162]. They arranged the solvents studied in the following order of decreasing differentiating action: t-butyl alcohol > pyridine > tetrahydrofuran > > isopropyl alcohol > dimethyl sulphoxide > acetone > > acetonitrile > ethylene glycol > water. For derivatives of picric acid, the values of $E^{1/2}$, measured in acetone, were found to be linearly dependent on $pK(H_2O)$.[163]

We made a quantitative estimate of the differentiating action of alcohols, ketones, hydrocarbons, and mixed solvents with respect to monobasic aromatic acids, dicarboxy-

lic acids, and organic bases[1]. The observed dependence of $E^{1/2}$ on $pK(H_2O)$ showed that the strongest differentiating action with respect to monobasic aromatic acids is shown by ethyl methyl ketone, with respect to dicarboxylic acids by isopropyl alcohol and ethyl methyl ketone, and with respect to organic bases by mixed solvents: benzene or chloroform with ethyl methyl ketone or acetonitrile.

Measurement of the relative basic strength of phosphines in nitromethane showed that in the phosphine series the strongest electrolytes are tertiary phosphines, whereas in the amine series the strongest electrolytes are primary amines[164]. A linear dependence of $E^{1/2}$ on $pK(H_2O)$ was observed for derivatives of phenothiazine and sympathomimetic amines in acetone, acetonitrile, acetic acid, isopropyl alcohol, and nitromethane[165]. A common linear relationship was observed for all bases in a medium of acetic acid. In acetone, acetonitrile, and nitromethane, which exhibit effective differentiating properties, a characteristic relationship was observed for each group of bases. Isopropyl alcohol has a levelling action on amines. The dependence of $E^{1/2}$ on $pK(H_2O)$ makes it possible to estimate $pK(H_2O)$ for acids and bases for which these values have not previously been determined experimentally[1,89].

An important characteristic of a solvent, determining its scale of acidity in titrations, is the autoprotolysis constant (K_S). A number of authors have determined the values of K_S for acetic acid[166], acetic anhydride[167], ethanol, n-propanol, isopropyl alcohol[168,169], monoethanolamine[170,171], ethylene glycol and propylene glycol[76], dimethylformamide[172], dimethyl sulphoxide[74], and acetonitrile[66].

A number of studies have been devoted to the determination and use of Lewis acids in titrations in non-aqueous solvents[173-186].

Thus a survey of the theory of the analytical chemistry of non-aqueous solutions shows an increase in the number of papers devoted to the study of acid–base reactions in non-aqueous solutions. These studies, however, do not include such solvents as ketones, nitro-derivatives of hydrocarbons, and various mixed solvents, which have found extensive practical application as differentiating solvents. It is necessary to extend studies on the quantitative estimation of the influence of solvents on the dissociation of electrolytes, together with measurements of K_{diss}. Estimation of the relative strengths of electrolytes from half-neutralisation potentials gives extremely valuable information for the development of new methods for the analysis of mixtures of electrolytes. It is also necessary to extend studies on the determination of the autoprotolysis constants of non-aqueous solvents.

III. PRINCIPLES OF THE ACID–BASE TITRATION OF NON-AQUEOUS SOLUTIONS

In the selection of a method for the titration of acids, bases, and salts in non-aqueous solutions, particularly in the selection of a method for the differentiated analysis of mixtures of electrolytes, it is necessary to have a theoretical basis for the selection of the medium for the titration (solvent), the standard solution of the reagent (titrant), and the method for determining the equivalence point. Only a coordinated selection of these titration conditions permits a more rational and effective method for the differentiated determination of the individual compounds in multi-component mixtures[5,187].

1. Solvents used for Acid–Base Titration

In the determination of compounds which exhibit acid–base properties in non-aqueous solutions, various classes of organic solvent can be used as media for the titration: organic acids (formic, acetic, etc.), amines and heterocyclic bases (butylamine, ethylenediamine, pyridine, piperidine, etc.), glycols, alcohols (methaol, ethanol, propanol, isopropyl alcohol, etc.), ketones (acetone, ethyl methyl ketone, methyl isobutyl ketone, etc.), nitriles (acetonitrile), amides (dimethylformamide, formamide, etc.), esters and ethers (diethyl ether, dioxan, esters of acetic acid, etc.), hydrocarbons and their halogeno- and nitro-derivatives (benzene, chloroform, carbon tetrachloride, nitromethane, nitrobenzene, etc.), and various mixtures of these solvents.

In the last 4–5 years, a number of new organic solvents exhibiting valuable properties have been introduced into analytical practice, for example t-butyl alcohol, dimethyl sulphoxide, tetramethylguanidine, and various mixed solvents (mixtures of aprotic solvents with ketones and nitriles). t-Butyl alcohol[162,188-190] has proved to one of the best solvents for the titration of very weak acids; it has a lower acidity than the lower alcohols, and its acid solutions have a high stability. The differentiated titration of mixtures of various inorganic and organic acids can be carried out in t-butyl alcohol.

Dimethyl sulphoxide is an effective solvent for many organic compounds[162,191-194], and unlike a number of solvents it is not toxic and has no odour. The presence of the semipolar bond between sulphur and oxygen in dimethyl sulphoxide gives it protophilic character and leads to an increase in the strength of weak organic acids dissolved in it. This solvent is characterised by a fairly large acidity scale ($pK = 18$) and high dielectric constant (40), and exhibits the same differentiating properties as dimethylformamide, but it does not contain acidic and basic impurities, and therefore does not require preliminary purification. Strong and weak organic acids can be titrated in dimethyl sulphoxide, and the titration of phenols is particularly effective (phenol, guaiacol, eugenol, etc.)[191]. Williams and coworkers[195,196] studied the properties of tetramethylguanidine and suggested its use as solvent without preliminary purification for the potentiometric and visual titration of phenols.

Solvents used for the titration of bases. Compounds which exhibit basic properties in non-aqueous solutions can be determined by titration in protolytic (protogenic and amphiprotic), aprotic, and various mixed solvents.

Among the protogenic solvents for the determination of weak bases, extensive use is still made of anhydrous acetic acid[197-243], first proposed for this purpose by Conant and Hall[8]. In acetic acid, the strengths of bases with $pK(H_2O) = 10-14$ increase, but do not reach the value 4.3, and the bases exhibit their own individual properties. Thus it has been possible to carry out the differentiated titration of two-, three-, and four-component mixtures of bases in acetic acid[244-247].

Bases can be titrated in mixtures of acetic acid and acetic anhydride[248,249], or in pure acetic anhydride[220,250-256]. Acetic anhydride has found application as differentiating solvent for the differentiated titration of amines, sulphoxides, and amides[257]. The improvement in the conditions for the titration of bases in acetic anhydride compared with acetic acid may be attributed to its higher dielectric constant.

Unlike acetic acid, acetic anhydride differentiates bases over the entire scale of acidity[89]. The addition of hydrocarbons, their halogeno-derivatives, dioxan, or ketones to acetic acid or to acetic anhydride makes the end point of the titration sharper, due to a decrease in the ionic product of the medium[205,222,223,249,251,258-261]. The use of mixtures of formic acid with acetic anhydride[262] and propionic acid[263] as media for the titration of bases has also been described.

Of the amphiprotic solvents for the titration of bases, most extensive use has been made of alcohols, ketones, and nitriles. In the titration of bases in alcohols, the end points of the titrations are insufficiently sharp. Alcohols do not exhibit strong differentiating properties with respect to bases[244,264-267]. For the differentiated titration of mixtures of bases, extensive use is made of ketones, particularly acetone[208,233,268-270], ethyl methyl ketone[244,267,271-275], and isobutyl methyl ketone[268,276]. The differentiated titration of two-, three-, and four-component mixtures of strong and weak bases has been carried out in ethyl methyl ketone[267,271,275,277].

Acetonitrile has found extensive application as medium for the titration of bases; this solvent is used for the titration of individual bases[208,224] and for the differentiated titration of their mixtures[233,278]. The end points of the titration of bases in ketones and acetonitrile are sharper than those in protogenic solvents and alcohols, apparently due to the low values of the ionic products of these solvents.

Strong differentiating properties with respect to weak bases are also shown by nitrobenzene and nitromethane. In nitrobenzene it is possible to carry out the differentiated titration of various mixtures of bases whose $pK(H_2O)$ values differ by unity, and in nitromethane it is possible to carry out the differentiated titration of mixtures of components whose pK values differ by 0.3 unit[278]. The conditions of the titration in nitrobenzene are improved considerably when acidic solvents are added[279-281]. Study of the influence of the addition of organic acids on the titration of a mixture of diethylaniline and *m*-nitroaniline in nitrobenzene showed that the addition of 11.1% of a mixture of acetic and formic acids (1 : 3) increases the differentiating properties of the nitrobenzene[279].

Aprotic solvents used for the titration of bases include hydrocarbons (benzene, chlorobenzene, chloroform, dichloroethane, etc.)[268,282-292]. In titrations in aprotic solvents of low dielectric constant values (2–5), alcohols, ketones, and nitriles are added in proportions from 10 : 1 to 4 : 1, to increase the dielectric constant of the solution[267,293-296]. The end point of the titration is less sharp when alcohols are added than when ketones and nitriles are added[267]. Many diamines can be titrated as diacid bases in mixed solvents consisting of mixtures of chloroform or benzene with ethyl methyl ketone or acetonitrile (4 : 1)[267,294-296]. The production of the second inflection in the titration is due to the precipitation of the normal salt of the diamine and perchloric acid, sparingly soluble in aprotic solvents.

Bases can also be titrated in mixed solvents such as *m*-cresol + acetonitrile (1 : 1)[297], dioxan + chloroform[234], and dioxan + acetic acid + nitromethane (75 : 5 : 20)[298]. The titration of compounds with basic properties can also be carried out in acetonitrile[299,300], dimethyl sulphoxide[194], pyridine[301], ethyl acetate[302], and methylcellosolve[303]. New methods have been described for the purification and control of the purity of various non-aqueous solvents[304-309].

Solvents used for the titration of acids. The determination of compounds which exhibit acidic properties in non-aqueous solutions can be carried out by titration in aprotic and protolytic (protophilic, protogenic, and amphiprotic) solvents. The most widely used aprotic solvents are chloroform[310,311] and benzene[312,314]. In aprotic solvents, because of the low dielectric constant, it is possible to titrate not only individual strong, weak, and very weak acids, but also mixtures of acids differentially. Alcohols[190,315,316], ketones[317], and acetonitrile[318,319] in proportions from 3 : 1 to 10 : 1 are often used to increase the dielectric constant of the solution.

Amphiprotic solvents used for the same purpose include various alcohols, ketones, nitriles, esters, and other solvents. Alcohols, as the most readily available and inexpensive solvents, are widely used for the titration of strong and weak acids. Thus methanol[311,320,321], ethanol[311,321-325], propanol and isopropyl alcohol[162,311,326-328], butanol, isobutyl alcohol, and t-butyl alcohol[162,188,189,311], and mixtures of alcohols with one another[329] or with benzene[190,315,316], dioxan[324], pyridine[330], and ketones[331,332] can be used for the titration of higher aliphatic acids, dicarboxylic and inorganic acids, nitrophenols, and other compounds. Co-solvents are used to increase the solvent power of the alcohol and to obtain sharper end points in the titration. Mixtures of inorganic acids are readily titrated in alcohols, particularly lower alcohols (methanol and ethanol)[1]. Mixtures of carboxylic acids with phenols and mixtures of dicarboxylic acids are titrated in less acidic alcohols, such as isopropyl alcohol, isobutyl alcohol, and t-butyl alcohol[188,318,333].

Ketones are the best solvents for the titration of acids. Inorganic and organic acids, phenols, and a number of other substances can be titrated in acetone[193,310,311,332-348], ethyl methyl ketone[310-313,332-334,347,349-354], butyl methyl ketone and isobutyl methyl ketone[193,347] and mixtures of ketones with water[350,355,356], alcohol[331,332], dimethylformamide[350], and acetonitrile[318]. Ketones, because of their amphoteric character, low dielectric constants, and low K_S values, are excellent differentiating solvents. Ketones can be used successfully not only for the titration of two-, three-, and four-component mixtures of various acids, but also for the titration of five- and six-component mixtures of strong, weak, and very weak acids[311,333,353,354]. Nitriles[162,193,310-311,333,347,357] and esters of acetic acid[310,311,333] are effective differentiating solvents. Mineral and organic acids and their mixtures can be readily titrated in these media. High-frequency and potentiometric methods have been used for the titration of acids and their mixtures in dioxan and its mixtures with water[193,358-361].

Protophilic solvents are used as media for the titration of very weak acids. Phenols and weak carboxylic acids can be successfully titrated in ethylenediamine[193,362-366] and butylamine[161,316,363]. The titration of strong, weak, and very weak acids is carried out in pyridine[162,193,314,330,336,337,347,358,363,365,367-369] and piperidine[193,363]. Because of its low dielectric constant (12.5), pyridine is an effective differentiating solvent for the titration of mixtures of strong, weak, and very weak acids. In addition to amines, various amides can be used as media for the titration of acids. Various derivatives of phenols, carboxylic acids, and mineral acids can be effectively titrated in dimethylformamide[172,193,314,332,347,362,363,365,370-374], but the presence of water greatly distorts the results of the titration. Dimethylformamide exhibits weak basic properties, so that it can be used for the differentiated titration of mixtures of acids[347,371,375].

Protogenic solvents used for the titration of mineral acids include anhydrous formic and acetic acids[376-379]. In acetic acid, which has a low dielectric constant, it is possible to titrate differentially mixtures of inorganic acids

with one another and with organic acids[376-378]. Glycol solvents (mixtures of glycols with alcohols, ketones, hydrocarbons, and their halogeno-derivatives)[162,380-382] exhibit weak acidic properties. Mineral and organic acids and their mixtures can be determined in glycol solvents. Tetrahydrofuran[162,193,383], methylene chloride[382,384,386], acetyl chloride[386], and derivatives of aryl amides[387] are used successfully as solvents for the determination of individual carboxylic acids and their mixtures.

2. Titrants used for the Titration of Non-aqueous Solutions

Acidic titrants. The most widely used titrants for the titration of non-aqueous solutions of compounds of basic character are solutions of perchloric acid in acetic acid[198-200, 202-204,225-228,230-234,243-246], dioxan[204,210,241,251,255,257,259,266, 278,286-288,298,388], ethyl methyl ketone[267,273-275,277,294], mixtures of acetic acid and acetic anhydride (1 : 1)[389,390], ethanol[391], methylcellosolve[303], mixtures of acetonitrile and *m*-cresol[297], etc. The differentiated titration of mixtures of diamines, which can be titrated in a medium of benzene or chloroform with acetonitrile (4:1), has been carried out using solutions of $HClO_4$ in the same solvents[267,296]. The use of these titrants gives titration curves with sharper inflections than those obtained when a solution of $HClO_4$ in ethyl methyl ketone is used.

Various workers have used solutions of HCl in isopropyl alcohol[265] and isobutyl methyl ketone[276] for the determination of bases. Bases have been titrated with sulphonic acids, for example *p*-toluene-sulphonic acid in a mixture of ethanol and isopropyl alcohol (1 : 1) or in a mixture of chloroform with 1% ethanol, dioxan, and other solvents[268, 284,285,290,392], and also fluorosulphonic acid[393-396], trifluoromethyl sulphonic acid[397], and chlorosulphonic acid[398]. In a medium of acetic acid, fluorosulphonic acid is stronger than perchloric acid, and the stability of its solutions and the ease of preparation give grounds for considering it a better titrant than perchloric acid[393]. Study of the behaviour of standard methanol, ethanol, and mixed (glycol–methanol, glycol–isopropyl alcohol, and acetone–chloroform) solutions of fluorosulphonic acid[396] has shown that best results are achieved in the titration of bases with a methanol solution of fluorosulphonic acid.

Bases are also titrated with picric acid[399], trichloroacetic acid[392], acetic anhydride perchlorate[400], and an acetic acid solution of sulphur trioxide[401].

Solutions of $HClO_4$ in glacial acetic acid are standardised using tri(hydroxymethyl)methylamine[402]. An advantage of this reagent compared with potassium hydrogen phthalate is that it dissolves in acetic acid without heating, but it is a weaker base than potassium hydrogen phthalate and diphenylguanidine. $HClO_4$ solutions are also standardised using hexamethylenetetramine and pyramidone[241], and *p*-toluenesulphonic acid is standardised using strychnine[284].

Basic titrants. Methanol[320,321,343,345], ethanol[323, 331,335,340,341,375,384], isopropyl alcohol[380], and mixed[403] standard solutions of potassium hydroxide and sodium hydroxide are most widely used as titrants for the titration of compounds of acidic character in non-aqueous media. Extensive use is also made of alcoholic and mixed solutions of alkali metal alkoxides—sodium, potassium, and lithium methoxides[314,316,324,332,337,362,365,371,404] and isopropoxides[326]—and sodium aminoethoxide in ethylenediamine[366]. Organic bases used as titrants include triethanolamine[382], cyclohexylamine[383], diphenylguanidine[360,361], pyridine[377], and piperidine[381].

The strongest basic titrants in organic solvents are the quaternary ammonium hydroxides—tetramethylammonium[322,328], tetraethylammonium[310,312,334,344,347,349-354], and tetrabutylammonium[161,188-190,193,336,352,367,369,387,405,406] hydroxides—and various other derivatives of quaternary ammonium hydroxides, for example hexadecyltrimethylammonium[196], dodecyltrimethylammonium[327], and tributylethylammonium[368] hydroxides. Study of the properties of various derivatives of quaternary ammonium hydroxides, the factors influencing the stability of non-aqueous solutions of quaternary ammonium titrants[407], and the influence of the structure of the quaternary ammonium cation on the titration of various acids[408] by Harlow established that tetramethylammonium, tetrabutylammonium, and tetraethylammonium hydroxides are the most stable titrants, and trimethylbenzylammonium hydroxide the least stable.

In connection with the continuous extension of the range of application of quaternary ammonium bases, several new methods have been proposed for preparing solutions of these compounds. Harlow and Wyld[409] proposed a rapid and convenient method for preparing solutions of quaternary ammonium hydroxides, based on the reaction between potassium hydroxide and the quaternary ammonium chlorides in isopropyl alcohol. Gur'ev[410] used mercuric oxide in place of silver oxide for the preparation of solutions of tetramethylammonium and tetraethylammonium hydroxides. Kreshkov and coworkers[411] developed a very convenient method for preparing solutions of quaternary ammonium hydroxides by ion exchange; the titrants obtained by this method are highly pure.

3. Methods for Determining the Equivalence Point

Visual and physicochemical methods for determining the equivalence point are widely used in titrations in non-aqueous solutions. The potentiometric method[26,412-420] is the most widely used method of titration in non-aqueous solutions. The indicator electrodes used in the potentiometric titration include the hydrogen[413], glass[413,416], graphite[415], platinum[316], platinum oxide[417], antimony[418,421], and silver chloride[419] electrodes. A comparative study has been made of various electrode systems for titrations in acetic acid and dimethylformamide[420]. Comparison of platinum oxide and glass electrodes for acid–base titration in alcohols, ketones, acetonitrile, dimethylformamide, and mixed solvents[417] showed that the inflections observed are greater for the platinum oxide electrode than for the glass electrode.

A method for potentiometric titration at constant current strength[297], a dead-stop method[389], and a chronopotentiometric method which does not involve the use of a burette[422] have been described. Conductometric[25,423], high-frequency[25,27,87,424], and spectrophotometric[245,425] methods are widely used for titrations in non-aqueous media. Chronoconductometric titration in aqueous alcohol[426], thermometric titration in acetonitrile[357], acetic acid[427], and acetone[428], and coulometric[429], luminometric[430], dielectrometric[292], and amperometric[431,432] titrations have also been described. A number of papers have been devoted to the study of acid–base indicators for titrations in non-aqueous solutions[433-444].

IV. TITRATION IN NON-AQUEOUS SOLUTIONS OF BASES

1. Titration of Individual Compounds

Non-aqueous solvents can be used for the determination of the great majority of individual compounds which exhibit basic properties in non-aqueous solutions[1-5]. These compounds include aliphatic, aromatic, and heterocyclic amines[199,206,208,220-222,241,261,281,284,287,290,297,390,445], diamines[233,267,294-296,446], amides[230,250,251], imides[207], amine oxides, phosphine oxides, and aromatic *N*-oxides[255,447], compounds containing the mercapto-group[448], sulphonamides[449], pyrazolones[225,450], vitamins[204], antihistamines[205,223], antibiotics[259], alkaloids[226,228,229,234,249,285,292,293], and other compounds[198,200,224,232,234,240,256,258,286,288,289,451,452].

Shkodin and Karkuzaki[421] titrated very weak bases ($pK(H_2O) > 12$) such as urea, thiourea, caffeine, theobromine, etc. in a medium of absolute anhydrous acetic acid and its mixtures with acetic anhydride. They showed that the titration of these compounds becomes impossible when even small quantities of water are present.

Potentiometric titration at constant current strength in a medium of *m*-cresol–acetonitrile (1 : 1) has been used for the titration of monoacid and diacid aliphatic and aromatic amines and their nitro-derivatives[297], and methods have been described for the micro-titration of weak bases of $pK(H_2O) = 11$ (piperidine, benzidine, diphenylguanidine, pyridine, quinine, strychnine, etc.) in a medium of chloroform[284], dichloromethane, and chlorobenzene[290] with a solution of *p*-toluenesulphonic acid in a chloroform + ethanol medium.

In a 2 M benzene solution of nitrobenzene, modified by means of organic acids such as formic, acetic, or trichloroacetic, bases which are very weak in water (aniline, *p*- and *m*-chloroanilines, diethylaniline, *o*-, *m*-, and *p*-nitroanilines, and diphenylamine) behave as strong, intermediate, or weak bases, depending on the acid added[281].

Study of the possibility of titrating the amides of acids and various other weakly basic compounds (acetanilide and its derivatives) in a medium of acetic anhydride and its mixtures with acetone and chloroform (1 : 1)[251] has shown that the presence of electron-donating groups increases the basic strength and gives a sharper inflection in the titration. Alkaloids can be titrated in a mixture of acetic acid with acetic anhydride and other solvents. Mercuric acetate is added to the solvent to give a sharper inflection in the titration of alkaloids[249]. The conductometric titration of aldehydes and ketones as bases in a medium of H_2SO_4 with tetra(hydrogen sulphato)boric acid is possible[453].

When the compounds to be determined do not exhibit basic properties in non-aqueous solutions, they are treated beforehand with various reagents which convert them into basic compounds[233,237,252]. Thus carbonyl compounds react with various salts of hydroxylamine or hydrazine derivatives to form oximes or phenylhydrazones, which exhibit the properties of weak bases in a medium of acetic anhydride[237,252]. Diamines are oxidised with chloranil, and diimines are reduced with hydroquinone to form basic compounds which can be determined by titration[233]. A method has been described for the determination of acetic anhydride in acetylating mixtures, based on its reaction with aniline, excess of which is titrated in a medium of diethylene glycol[454].

2. Titration of Primary, Secondary, and Tertiary Amines

Mixtures of primary, secondary, and tertiary amines are still analysed by acetylation of the primary and secondary amines with acetic anhydride[201,235,303] and binding of the primary amines with salicylaldehyde[210,264,269,298,455] or phthalic anhydride[202,456].

Strepikheev and coworkers[269] determined primary, secondary, and tertiary amino-groups in polynuclear polyamines in an acetone + acetic acid medium, using salicylaldehyde to bind the primary amines. The authors cited[269] showed that phthalic anhydride combines not only with primary but also with secondary amino-groups. Other workers also established that when solutions of primary and secondary amines with a high concentration of secondary amines are boiled for a prolonged period, the phthalic anhydride reacts to form neutral compounds. In order to hydrolyse the products, the reaction is carried out in 98% acetic acid or in the presence of perchloric acid[202]. Pyromellitic anhydride in a medium of dimethyl sulphoxide has been used to bind primary and secondary amines[194]. The reaction is more rapid when this acetylating reagent is used. A method has been proposed for the determination of primary, secondary, and tertiary amines, based on the difference in the rates of formation of thiourea by the reaction of the amines with isothiocyanates in acetic acid. Samples are removed at measured time intervals and the unreacted amine is titrated[236].

A method has been developed for the determination of tertiary amines in the presence of primary and secondary amines, based on the binding of the primary and secondary amines in the form of thiourea derivatives by the reaction with phenyl isothiocyanate followed by titration of the tertiary amine in isobutyl methyl ketone. This method is not applicable, however, when the secondary amines are N-secondary alkylanilines or ortho-substituted *N*-alkylanilines, where there is steric hindrance to the reaction with phenyl isothiocyanate[276]. In the determination of amine oxides and tertiary amines in the presence of one another, the latter are bound with alkyl halides, which convert them into neutral quaternary ammonium salts[265].

In the quantitative analysis of mixtures of higher aliphatic amines in the products of the hydrogenation of the nitriles of the higher carboxylic acids, the primary amines are bound with acetylacetone and the secondary amines are titrated acidimetrically; the sum of the primary and secondary amines is determined by titration after the amines have been converted into the dithiocarbamic acids[457]. Chloroform and methanol are used as solvents.

To determine piperazine, hydroxyethylpiperazine, and dihydroxyethylpiperazine in the presence of one another, the first two components of the mixture are separated from the dihydroxyethylpiperazine by precipitation with carbon disulphide from a solution of the mixture in chloroform[299], and the dihydroxyethylpiperazine is titrated. The precipitate is dissolved in acetonitrile, and the hydroxyethylpiperazine is determined by titration, after acetylation.

In the titration of amines by a solution of *p*-toluenesulphonic acid using the dielectrometric method, it was found that the titration curves for primary and secondary amines differ from those for tertiary amines[392]. This feature was used for the differentiated titration of a mixture of primary, secondary, and tertiary amines. The determination of tertiary amines in the presence of n-octanol[227] and of primary aliphatic amines in the presence of secondary and tertiary amines by photometric titration with a solution of

2-ethylhexanal[458], and also a method for determining primary and secondary diamines in a medium of ketones[459], have been described.

3. The Differentiated Titration of Mixtures of Bases

Methods which make possible the separate determination of each component in complex mixtures of bases with very similar $pK(H_2O)$ values are of particular interest. Two-, three-, and four-component mixtures of bases have been titrated, for example tetraethylammonium hydroxide + n-butylamine + diethylaniline, piperidine + 1,10-phenanthroline, piperidine + benzimidazole + methylbenzimidazole, etc. in ethyl methyl ketone[271,275-277], quinoline + aniline in acetonitrile, nitrobenzene, and nitromethane[278], diethylaniline + aniline or *m*-nitroaniline in a benzene solution of nitrobenzene, modified with acetic and formic acids[279-281], mixtures of amines, sulphoxides, and amides, and mixtures of pharmaceutical products in acetic anhydride[89,257], and mixtures of diamines in mixed solvents consisting of an aprotic solvent and an amphiprotic solvent[267,294-296]. Mixtures of weak bases are also titrated in acetic acid[233,244-247] and other solvents[260,262].

A method has been developed for the analysis of two-, three-, and four-component mixtures of aliphatic, aromatic, or heterocyclic amines, sulphoxides, and amides of carboxylic acids by titration in a medium of acetic anhydride. In the titration of four-component mixtures the first inflection in the titration corresponds to the neutralisation of the aliphatic amine, the second to the aromatic amine, the third to the sulphoxides, and the fourth to the amides[257]. The differentiated titration of a mixture of weak bases with $pK(H_2O) = 10-14$ (amidopyrine + antipyrine, caffeine + phenacetin, etc.) has been carried out in acetic anhydride[89].

We developed a method for the analysis of two- and three-component mixtures of diamines and of monoamines with diamines in mixed solvents—chloroform or benzene with ethyl methyl ketone or acetonitrile (4 : 1)[267,294-296]. The method can be used to analyse two-component mixtures of the *p*- and *o*- and *p*- and *m*-isomers of phenylenediamine, hexamethylenediamine + *N*-isopropyl-*N'*-phenyl-*p*-phenylenediamine + *p*-phenylenediamine, tyramine + *o*- + *m*-phenylenediamines, and a number of other mixtures.

Kreshkov and Vasil'ev[244,245] developed a method for the spectrophotometric titration of three- and four-component mixtures of weak and very weak bases ($pK(H_2O) > 13.5$) in a medium of acetic acid. Titration of *o*-nitroaniline + 4-methyl-2-nitroaniline + *p*-bromoaniline, *o*-nitroaniline + *m*-nitroaniline + 4-methyl-2-nitroaniline + *p*-nitrosodimethylaniline, and other mixtures showed that the spectrophotometric method can be used to analyse mixtures with a difference in $pK(H_2O)$ values of 0.8–1.5. Mixtures of the isomers of nitro-*o*-toluidine and nitro-*p*-toluidine, nitroaniline and nitro-*o*-anisidine have been titrated in a medium of acetic acid and its mixtures with acetone (1 : 4)[260]. Two-, three-, and four-component mixtures of weak bases with $pK(H_2O) = 10-13.81$ have been titrated in acetic acid by a conductometric method[78,247].

Lorenz and Parks[233] showed that it is possible to analyse mixtures of *NN'*-diaryl-*p*-phenylenediamines and *NN'*-diaryl-*p*-phenylenediimines in a medium of acetic acid. Chloranil was added when the mixture contained an excess of *NN'*-diaryl-*p*-phenylenediamine, and hydroquinone was added when the mixture contained an excess of *NN'*-diaryl-*p*-phenylenediimine. The analysis of mixtures of acylamidines, such as *N*-benzoylbenzamidine, *N*-thiobenzoylbenzamidine, dibenzamide, etc.[460]

V. TITRATION IN NON-AQUEOUS SOLUTIONS OF ACIDS

All organic and inorganic compounds which exhibit acidic properties can be determined in non-aqueous solvents. These compounds include phenols, mono-, di-, and tri-basic aliphatic and aromatic carboxylic acids, and also mono- and di-basic inorganic acids, acid anhydrides and chlorides, enols, imides, amides, and other compounds such as esters and alcohols[1-5].

1. Titration of Compounds Exhibiting Weakly Acidic Properties

Enols and their derivatives are successfully titrated by the potentiometric method in tetramethylguanidine[195,196], dimethyl sulphoxide[74,75,191], t-butyl alcohol[162,188,189,405], and *NN*-dimethylarylamides[387]. A number of papers have been devoted to the titration of phenols in ethylenediamine[362,364], dimethylformamide[172,362,370,372], acetone[347], ethyl methyl ketone[347,349], alcohols[188,328], and other solvents[331,347]. Phenols, cresols, and their derivatives are determined by high-frequency, conductometric[190,339,345,363], and spectrophotometric[329] methods. Polycyclic phenolic compounds are titrated in a medium of pyridine and acetone[337], substituted phenylureas in a medium of butylamine[161], and acylamidines in a medium of pyridine[367]. The differentiated titration of phenol and its nitro-derivatives has been carried out in ethyl methyl ketone[333] and in other solvents[347] by a potentiometric method, and mixtures of isomers of cresol and xylenone[339,345] have been titrated in a medium of acetone by a high-frequency method.

A number of ethers and esters have been titrated in non-aqueous solvents. Pathochornik and coworkers[324] established that in an ethanol + dioxan mixture, esters of *p*-nitrophenol and esters of thiophenol behave as acids and can be titrated with CH_3ONa solution. A method has been developed for the analysis of diethyl malonate and its derivatives, based on enolisation and subsequent titration of the resulting acid in a medium of ethylenediamine, dimethylformamide, or pyridine[365]. The titration of *p*-nitrophenylhydrazones of aldehydes, ketones, and hydrocarbons as acids in a medium of pyridine with tetrabutylammonium hydroxide solution has been studied. The nitrophenylhydrazones of dicarbonyl compounds can be titrated as dibasic acids[369].

Harlow[461] published an interesting study of the influence of potassium ions on the shape of the potentiometric titration curves for weak acids in pyridine. The presence of 10% potassium ions in the solution being titrated decreases considerably the magnitude of the potential jump at the equivalence point.

2. Titration of Monocarboxylic Acids.

Aliphatic and aromatic carboxylic acids and their hydroxo-, halogeno-, nitro-, and other derivatives can be successfully titrated in non-aqueous solvents[366,406,462]. Of particular importance is the titration of the water-insoluble

higher aliphatic acids[315,342,463], benzoic acid and its derivatives, α- and β-naphthalenecarboxylic acids and their derivatives, and a number of other acids[335,352,361]. All carboxylic acids can be titrated with sufficient accuracy in alcohols[342], ketones[193,332,338,342], chloroform[333], ethylenediamine[366], mixtures of dioxan and water[359,360], and a number of other solvents[315].

In differentiating solvents it is possible to titrate mixtures of benzoic and salicylic acids, and also the *o*- and *m*-, and *o*- and *p*-isomers of hydroxybenzoic acid[333]. The differentiated titration of mixtures of naphthalenecarboxylic acids and their hydroxy-derivatives[352] and naphthols[331] can be carried out in a medium of ketones. The differentiated titration of four-component mixtures of carboxylic acids and phenols can be carried out in t-butyl alcohol[188]. Vasil'ev and Tumovkii[212] have titrated two-component mixtures of amphoteric compounds: 1-naphthylamine + 4-nitro-1-naphthylamine, 4-aminophenol + 2-nitro-4-aminophenol, etc., as acids with sodium methoxide in a medium of acetone + methanol (2 : 1) and as bases with perchloric acid in a medium of acetic acid.

3. Titration of Dicarboxylic Acids

In connection with the vast technical importance of dicarboxylic acids, which are widely used in the production of plastics, paints, synthetic fibres, and other macromolecular products, a large number of papers have recently been published on the titration of dicarboxylic acids and their mixtures in non-aqueous solvents[318,335,349,350,464,465]. Non-aqueous solvents can be used as media for the titration of unsaturated dicarboxylic acids (maleic, fumaric, itaconic, and citraconic), saturated dicarboxylic acids (from oxalic to sebacic), and aromatic dicarboxylic acids (the isomers of phthalic acid), and also for various mixtures of dicarboxylic acids, including mixtures of isomers (maleic and fumaric, itaconic and citraconic), and mixtures of acids of the same homologous series (oxalic and succinic, sebacic and adipic). Dicarboxylic acids and their mixtures can be titrated by potentiometric[318] and high-frequency[374,466-468] methods.

The differentiated titration of mixtures of dicarboxylic acids can be carried out in isopropyl alcohol, acetone, ethyl methyl ketone, acetonitrile, and mixtures of aprotic solvents with alcohols, ketones, and acetonitrile[469-472]. For example, a mixture of maleic and phthalic acids can be titrated in ethyl methyl ketone, a mixture of maleic and fumaric acids can be titrated in acetonitrile, and a mixture of sebacic and azelaic acids can be titrated in a chloroform + acetonitrile (4 : 1) mixture.

We developed methods for the quantitative differentiated titration of aromatic dicarboxylic acids, for example mixtures of iso- and terephthalic acids[469], mixtures of phthalic, isophthalic, and terephthalic acids, etc.[470] For the determination of all three isomers, a method was proposed based on two parallel titrations of the mixtures of acids in ethyl methyl ketone, one specimen being titrated with $(C_2H_5)_4NOH$ solution, and the second with KOH solution. The curves obtained were used to calculate the concentration of each isomer in the mixture[351,470]. The method can also be used for the analysis of a three-component mixture of maleic, fumaric, and phthalic acids[318].

Methods have been developed for the titration of mixtures of dicarboxylic acids with one another[335] and with inorganic acids such as hydrochloric[318], nitric, etc.[343] in a medium of ketones.

4. Titration of Inorganic Acids

Non-aqueous solvents can be used as media for the rapid and sufficiently accurate determination of individual inorganic acids, for example phosphoric[377], nitric[188,321,377], sulphuric[188,355,377,382], perchloric[188,377,382], and others[188,377], and also for the differentiated titration of various acid mixtures. Thus mixtures of inorganic acids, for example sulphuric and perchloric[385], can be analysed by potentiometric titration in methylene chloride. Zarinskii and Gur'ev used a high-frequency method for the differentiated titration of mixtures of inorganic acids in acetic acid[378] and in glycol solvents[380]. The differentiated titration of two-component mixtures of inorganic acids, for example sulphuric and phosphoric, nitric and phosphoric, sulphuric and hydrochloric, etc. has been carried out by a conductometric method in ethanol[322] and in acetic acid[376]. Potentiometric titration can be used for the analysis of mixtures of inorganic and organic acids, for example hydrochloric and acetic acids in methylene chloride[384], sulphuric and phenolsulphonic acids in a dioxan + diethylene glycol mixture[381], sulphuric and sulphonic acids[344] and nitric and monochloroacetic acids[346] in acetone, and sulphuric and lactic acids in isopropyl alcohol[326].

Drozdov and Kolchina[473] developed a potentiometric method for the analysis of a three-component mixture of hydrochloric acid, methylphosphonic acid, and isobutyl hydrogen methylphosphonate, and also other mixtures of phosphoric acid derivatives of considerable practical importance.

We developed methods for the titration of two-, three-, four-, five-, and six-component mixtures of strong, weak, and very weak organic and inorganic acids in a medium of ketones and other differentiating solvents[310,353,354]. Methods have been proposed for the determination of mixtures of nitric acid with organic acids (nitrobenzoic acid, nitrophenols, and α-hydroxyisobutyric acid) in ethyl methyl ketone[334], and for the analysis of two- and three-component mixtures of nitric acid with monocarboxylic, dicarboxylic, and hydroxycarboxylic acids (nitric + adipic + oxalic) in methanol[320,321]. A method proposed for the analysis of mixtures of phosphoric and sulphuric acids, and of phosphoric and nitric acids in the presence of trioctylamine[1] is of considerable practical importance in phosphoric acid production.

5. Titration of Acid Anhydrides and Chlorides

A number of papers[313,330,474,475] have been devoted to the determination of the anhydrides and chlorides of carboxylic acids. The chlorides of aliphatic and aromatic carboxylic acids exhibit acidic properties in tetrahydrofuran and can be titrated with cyclohexylamine solution[383]. The method is suitable for the determination of all acid chlorides, including those containing readily hydrolysed groups, and also for the determination of aromatic compounds containing two acid chloride groups. A method has been proposed for the determination of an acid chloride in the presence of pyridine in a medium of dioxan; excess of water is removed with acetic anhydride, and the resulting pyridinium chloride is titrated with perchloric acid solution[358]. A method has been developed for the analysis of the actual concentration of the acid chlorides of carboxylic acids in mixtures with the acid and hydrochloric acid. The method is based on the titration of the acid chloride with sodium hydroxide in ethanol before and after heating, and can be used to

determine the concentrations of hydrochloric and carboxylic acids and the acid chloride[325].

Emelin and Svistunova have proposed a number of methods for the determination of the anhydrides and chlorides of carboxylic acids[341,348,356]. The determination of acetic anhydride in acetylating mixtures is based on the reaction with aniline, excess of which is titrated in diethylene glycol[454], and the determination of the chloride of isophthalic acid is based on the reaction of the chloride with aniline. The differentiated titration of the resulting anilinium chloride and isophthalic acid is carried out potentiometrically in a medium of acetone with alcoholic sodium hydroxide solution.

VI. TITRATION IN NON-AQUEOUS SOLUTIONS OF SALTS

The great majority of salts can be titrated in non-aqueous solvents, since many salts which are neutral substances in aqueous solution exhibit acidic or basic properties in non-aqueous solutions. Titration in non-aqueous solutions not only makes it possible to determine individual salts, but also to analyse multicomponent mixtures and mixtures of salts with acids or with bases[476].

1. Titration of Individual Salts

A number of salts exhibit acidic properties in protophilic and amphiprotic solvents and can be titrated as acids[476]. For example, inorganic salts such as the fluorides of multivalent metals (Mo, Ta, Ti, Nb, and W) can be successfully titrated in a mixed ethyl methyl ketone + benzene (1 : 1) solvent[317]; nitrates, bromides, and chlorides of the rare earth elements can be titrated in a medium of acetone + methanol (1 : 1); and lithium and sodium perchlorates can be titrated in pyridine[368]. Salts of organic acids can be titrated, for example zinc stearate in ethanol[323], and zinc styphnate in ethylenediamine[477]. Jasinski and coworkers titrated salts of organic bases, for example amine picrates in pyridine[403] and aromatic amine hexachlorotellurites in acetonitrile and dimethylformamide[478]. Salts of organic bases and mineral acids are readily titrated in methanol[1].

A number of salts exhibit basic properties in protogenic and amphiprotic solvents and can be titrated as bases[479-483,496-498]. Inorganic salts can be titrated, for example chlorides[484] in dioxan, nitrites in the presence of nitrates in ethyl methyl ketone[476], nitrates[485] and sulphates[486] in an acetic acid + acetic anhydride mixture, ammonium carbonate[487] in acetone, and salts of the rare earth elements in acetic acid, ethyl methyl ketone, and mixtures of glycol with alcohols[488,489].

Most salts of monobasic organic acids (the acetates, formates, benzoates, salicylates, lactates, etc. of lithium, sodium, calcium, zinc, cobalt, manganese, and other alkali and alkaline earth metals) can be successfully titrated in acetic acid and acetic anhydride, alcohols, and ketones[476,490-496]. The salts of polybasic organic acids (oxalic, tartaric, etc.) can be determined by titration in acetic acid[497]. Salts of organic bases[485,499] can also be titrated as bases in acetic acid[500,501], acetic anhydride[499], and acetic acid + acetic anhydride mixtures[485]. A method has been described for the determination of the combined acid in hydrazinium salts, based on the conversion of the hydrazine into the azine by reaction with acetone and titration of the resulting acid with NaOH solution[502].

2. Titration of Salt Mixtures

The use of non-aqueous differentiating solvents makes it possible to analyse salt mixtures[476,503,504]. Mixtures of salts, for example lithium and calcium acetates, potassium and zinc benzoates, sodium adipate and potassium hydrogen phthalate, etc., can be titrated as mixtures of bases with different strengths in ethyl methyl ketone[505] and in a dioxan + water (1 : 1) mixture[359]. Mixtures of salts can also be titrated as mixtures of acids with different strengths in pyridine[368] and methanol[1]. An interesting method has been developed for the analysis of two- and three-component mixtures of nitrates of the rare earth elements with the nitrates of other elements (Ni + La, Al + Eu, Cr + Tu, Fe + Zn + La, and Cr + Co + La) in a methanol + acetone medium[1]. A method has been developed for the analysis of multi-component mixtures of salts of organic acids, based on treatment of the mixture of salts to be analysed with perchloric or sulphuric acid in a medium of ethyl methyl ketone, followed by differentiated titration of the excess of perchloric or sulphuric acid and the acids liberated from the salts[312,506].

3. Titration of Mixtures of Salts with Acids or Bases

Mixtures of salts and acids can be analysed by direct potentiometric titration; for example, two-component mixtures of lithium chlorate and perchloric acid, or of sodium chlorate and benzoic acid, and also three-component mixtures of lithium and ammonium chlorates with perchloric acid can be titrated in pyridine[368], and a mixture of ammonium chloride and hydrochloric acid can be titrated in acetone[510-512].

Kreshkov, Yarovenko, and Milaev[1] developed a method for the analysis of mixtures of the rare earth elements, based on the conversion of the mixture to be analysed into the nitrates, bromides, or chlorides by the action of the corresponding acids followed by differentiated titration of the excess of acid and the mixtures of salts, which in an acetone + methanol medium behave as acids with different strengths (HNO_3 + Lu, HNO_3 + Lu + La, and HNO_3 + Dy + La).

Methods which have been developed for the analysis of salt mixtures, based on the preliminary treatment of the solution to be analysed with a stronger acid, can be used for the analysis of mixtures of salts with acids or bases[340-506-509]. This method can be used in a medium of ethyl methyl ketone for the titration of mixtures of sodium acetate and acetic acid, potassium benzoate and benzoic acid, and sodium acetate and acetic and salicylic acids, etc., and also mixtures of salts and bases, for example potassium benzoate and potassium hydroxide, sodium acetate, potassium salicylate, and sodium hydroxide, and other mixtures[505,508,509]. A method has been proposed for the analysis of mixtures of salts and acids, based on treatment of the mixture to be analysed with HCl solution followed by potentiometric titration of the resulting acids with an ethanolic solution of KOH[340].

A method has been proposed for the differentiated titration of mixtures of salts with hydrochloric, nitric, sulphuric, acetic, and other acids, based on the reaction of the mixture to be analysed with an excess of tetraethylammonium hydroxide solution; the excess of tetraethylammonium hydroxide and the hydroxide of the cation of the salt being analysed are then determined by potentiometric titration with a solution of perchloric acid in ethyl methyl ketone[513]. For the analysis of mixtures of salts of organic bases with

inorganic acids, we proposed a combined method[1], involving ion exchange and potentiometric titration of the mixture to be analysed in a medium of methanol.

4. Determination of Salts Using Ion Exchange

The use of ion exchange in non-aqueous solutions makes it possible to analyse various salt mixtures, and also mixtures of salts with acids or bases [514-521].

Yarovenko, Sayushkina, and Zelenina developed methods for the analysis of salt mixtures, based on the use of ion exchange in non-aqueous solutions. It is possible with H-cation exchange to determine mixtures of salts, whose acids can be determined by differentiated titration in non-aqueous solutions using the potentiometric method, for example, mixtures of the salts of strong inorganic acids such as sulphates + chlorides, sulphates + bromides, or sulphates + nitrates; mixtures of the salts of strong inorganic acids and weak organic acids such as nitrates (chlorides, bromides) + benzoates (salicylates, propionates, valerates, etc.); and mixtures of salts of organic acids such as salicylates + benzoates (propionates, etc.).

It is possible by OH-anion exchange to analyse mixtures of salts, whose bases can be estimated by differentiated titration in non-aqueous solutions. The use of anion exchange with Cl^- or NO_3^- forms can be used to determine mixtures of sulphates, chlorides, and nitrates.

VII. TITRATION OF MONOMERIC AND POLYMERIC COMPOUNDS IN NON-AQUEOUS SOLUTIONS

Titration in non-aqueous solutions has found extensive application for the analysis of monomeric and polymeric compounds.

1. Titration of Organoelemental Compounds

Non-aqueous solutions have found most extensive application in the analysis of organosilicon monomers and polymers. Kreshkov [522] developed the theoretical principles of the analysis of monomeric and polymeric organosilicon compounds in non-aqueous solutions and demonstrated the possibility of their practical application. Non-aqueous solutions can be used for the titration of alkylchlorosilanes [523,524], phosphorus-, boron-, sulphur-, and hydrogen-containing organosilicon compounds [525-535], alkylacetoxysilanes [536-538], silanols, and siloxanes [539]. A conductometric method has been described for the titration of trimethylchlorosilane, dimethyldichlorosilane, and methyltrichlorosilane in a medium of acetonitrile with organic bases containing tertiary nitrogen atoms (pyridine, quinoline, 8-quinolinol, dimethylaminoantipyrine, etc.)[523].

Drozdov and Tarasyants [531] developed a method for the potentiometric titration of alkylthiocyanatosilanes in the presence of alkylacetoxysilanes in a medium of acetonitrile. A method has been described for the analysis of boron-containing organosilicon compounds in the presence of organosilicon compounds containing chlorine and phosphorus [534].

The potentiometric and conductometric titration of alkylsilyl hydrogen phosphates in alcohols, ketones, and acetonitrile have been studied [527,529,530], and it has been established that triethylsilyl hydrogen alkylphosphonates can be determined quantitatively without preliminary separation in the presence of the corresponding triethylsilyl alkylphosphonate esters or alkylchlorosilanes. The behaviour of alkylsilanes, hexaalkyldisiloxanes, and sodium triethylsilanoxide in liquid hydrogen fluoride has been studied by an electrical conductivity method; the conductometric determination of individual alkylsilanols and hexaalkyldisiloxanes and their binary mixtures is possible [539].

Myshlyaeva and coworkers [540,541] developed a new method for the quantitative determination of silicon in organosilicon compounds, based on their decomposition with hydrofluoric acid followed by conductometric titration of the resulting hydrogen fluorosilicate in non-aqueous solvents with a solution of benzidine, tolidine, and other organic amines.

2. Titration of Monomeric Compounds

One method for the determination of unsaturated monomeric compounds is based on oxomercuration:

$$R_1R_2C=CR_3R_4 + Hg(OCOCH_3)_2 + CH_3OH \rightarrow$$
$$\rightarrow R_1R_2(OCH_3)C-CR_3R_4(HgOCOCH_3) + CH_3COOH.$$

Balyatinskaya and Tur'yan [542-544] used this reaction to determine the purity of vinyl derivatives of the pyridine series such as 2-methyl-5-vinylpyridine, styrene, methylstyrene, and 2,4-dimethylstyrene. The acetic acid liberated in the reaction in quantities equivalent to the concentration of the monomer being determined is titrated with a methanolic solution of KOH. The differentiated determination of cis- and trans-isomeric acids (fumaric and maleic, mesaconic and citraconic, and oleic and elaidic is possible [545]. The determination of the *cis*- and *trans*-isomeric forms of the acids involves determination of the total acidity and determination of the concentration of the *cis*-isomer by oxomercuration, followed by potentiometric titration of the unreacted mercury(II) acetate in non-aqueous medium. The rate of reaction of the *trans*-isomer with mercury(II) acetate is smaller by a factor of 20 than the rate of reaction of the *cis*-isomer.

A micro-method has been described for the determination of acetylenic hydrogen, based on the reaction of monosubstituted acetylenes with $AgClO_4$. The $HClO_4$ liberated is titrated with trihydroxymethylaminomethane solution [546].

Non-aqueous titration is finding application for the determination of the concentration of residual monomer in a polymer. Thus a method has been proposed for the determination of methylamine in melamine resins by titration of a specimen of the resin with an acetic acid solution of $HClO_4$ in an acetic acid + acetic anhydride (8 : 2) mixture using Crystal Violet as indicator. An analogous method can be used to determine the concentration of benzoguanamine in benzoguanamine resins. Guretskii and Toryanik [547] determined combined dibasic acids in polyester resins by potentiometric titration, in non-aqueous solutions, of the resin hydrolysis products.

3. Titration of Functional Groups in Organic Compounds

The concentration of carboxyl [371], alkoxy [548-551], hydroxyl [552-554], epoxy [291], dinitrophenyl [555] and other functional groups [556] in organic compounds can be determined in non-aqueous solvents.

Cundiff and Marcunas[549] developed a method for the determination of alkoxy groups, based on their reaction with HI to form the alkyl iodide, which in a medium of pyridine forms the alkylpyridinium halide; the differentiated titration of the latter and the excess of HI can be carried out with tetrabutylammonium hydroxide solution. For the determination of alkoxy groups in higher alcohols, a method has been proposed for the determination of the quantity of alkyl iodide formed, without its distillation[548].

A method has been described for the determination of hydroxyl groups[552] in organic substances in the presence of carbonyl compounds, ethers, amines, alkoxy compounds, and complex hydrocarbon mixtures by direct titration with aluminium and lithium amide in a medium of tetrahydrofuran. Hydroxyl groups can also be determined using 3,5-dinitrobenzoyl chloride[553], which reacts quantitatively with hydroxyl groups to form dinitrobenzoate, which can be titrated as a weak acid in a medium of pyridine.

A method has been proposed for the determination of compounds containing epoxy or ethyleneimine groups by titration in a medium of chloroform with a solution of perchloric acid in the presence of an excess of a quaternary ammonium bromide or iodide[291]. The concentration of acetoxy groups in various substituted acetoxysilanes can be determined by potentiometric titration in ethyl methyl ketone with a methanolic solution of sodium methoxide[536,537].

Titration in non-aqueous solutions is widely used for the determination of terminal functional groups in macromolecular compounds. This method is the most rapid and convenient for the determination of the molecular weights of linear condensation polymers whose molecular weight usually does not exceed 20 000.[557-559] Carboxyl[391,560,561], hydroxyl[562,563], and amino groups[254,391,564] can be determined. Carboxyl groups in polyamides can be determined by titration in a hot 2,6-xylenol + chloroform mixture[560] and in propargyl alcohol[391]. The chief disadvantage of these methods is the necessity to dissolve the polyamides at high temperatures, at which some of them decompose. For the determination of amino groups, the polyamides are dissolved in phenol + ethanol[564] and *m*-cresol + isopropyl alcohol (2 : 1)[391] mixtures. A method has been developed for the analysis of polymeric compounds of the benzimidazole series, based on the determination of the NH-group of the elementary unit of the polymer by titration in an ethyl methyl ketone + formic acid (4 : 1) medium[565]. Primary, secondary, and tertiary amino groups in polynuclear polyamines can be determined in non-aqueous solvents[269,456].

A method has been proposed for the determination of hydroxyl groups in macromolecular alcohols, the products of the addition of ethylene oxide to higher alcohols, and complex mixtures containing alcohols, alkanes, alkenes, esters, acids, and carbonyl compounds, based on acetylation with acetic anhydride in a mixed ethyl acetate + n-hexane solvent with the addition of perchloric acid as catalyst[562]. A similar method has been used to determine hydroxyl groups in polyoxyalkylene ethers[563]. Hydroxyl groups have also been determined in polynuclear phenolic compounds[566].

Guretskii and Rybal'chenko[567] proposed a rapid method for the determination of epoxy-groups in epoxy resins modified by organosilicon compounds. The method is based on the titration of the epoxy resins in a medium of acetic acid saturated with KBr solution, using an acetic acid solution of HBr as titrant. The addition of KBr to the solution makes it possible to increase considerably the rate of hydrobromination of the epoxy groups, Epoxy-groups have also been determined in non-aqueous solvents by other workers[568].

VIII. ANALYSIS OF INDUSTRIAL MATERIALS

Non-aqueous titration is being used successfully for the analysis of raw materials, intermediates, and finished products in the pharmaceutical and food industries, and also in the production of plastics, in the control of the various stages of industrial sulphonation, in the processing of coal, and in other industries. Methods for the titration of pharmaceutical products are particularly widely ployed[198,200,204,206,209,223,225,232,234,242,259,261,266,268,286,288,289,569-577]. Non-aqueous solvents can be used for the titration of not only individual pharmaceutical products with acidic or basic properties, but also their mixtures. Thus Izmailov and coworkers[571] analysed mixed products consisting of mixtures of weak acids (luminal, veronal, and aspirin) with weak bases (pyramidone, caffeine, and codeine). The bases were determined in a mixture of acetic acid and acetic anhydride (1 : 4) and the acids were determined in a mixture of dimethylformamide and benzene (1 : 3).

Titration in non-aqueous solutions is used for the determination of the concentration of antioxidants (*NN'*-disubstituted *p*-phenylenediamines) and polymerisation accelerators (diphenylguanidine) introduced into rubbers and rubber mixtures[233,446,578]. The bases to be determined are first extracted from the rubber mixtures using acetone. The concentration of aliphatic acids in rubbers is determined by a polarographic method[579].

Gribova and Khmel'nitskaya[264] developed a method for the analysis of an industrial mixture of mono-, di-, and tri-ethanolamines. Gribova[338] developed a method for the production control of 2,4-dichlorophenoxyacetic acid and also a method for the analysis of a sulphonation mixture containing sulphuric and sulphonic acids[344]. A method has been described for the analysis of explosive powders in non-aqueous solutions. The specimen is treated with dichloromethane and the concentrations of diphenylamine, 2-nitrodiphenylamine, 2,4-dinitrodiphenylamine, and N-nitrosodiphenylamine in the presence of one another are determined[220].

Emelin and coworkers[580] proposed a method for the determination of pyridine and nitrile nitrogen in the copolymer of acrylonitrile with methylvinylpyridine. Pyridine nitrogen in the form of the amine is determined in nitromethane by titration with perchloric acid solution, and the nitrile nitrogen is determined in dimethylformamide by titration with piperidine solution. The same authors also determined acetic anhydride in acetylating mixtures[454]. Rapid methods have been developed for the analytical control of the quality of crude phthalic anhydride obtained by the catalytic oxidation of naphthalene[581], and for the determination of n-butylamine in a caprolactam melt[270] and of tertiary amines in kerosene solutions[227].

A method has been described for the determination of sulphur in a gas by combustion in an atmosphere of oxygen followed by conductometric titration of the resulting sulphuric acid in aqueous ethanol[582]. Carbon dioxide obtained by the combustion of organic compounds is absorbed in dimethylformamide and titrated with a benzene–methanol solution of CH_3OK[583]. A method has been developed for the determination of traces of carbon in metals, alloys, and ceramics, based on the action of heat on the specimen in a current of oxygen, absorption of the resulting carbon dioxide in acetone, and subsequent titration[584].

The differentiated titration of ammonium nitrogen in ammonium salts and ammonium fertilisers can be carried out by back titration in acetone and other non-aqueous solvents[585-587].

Non-aqueous titrations were also used for the determination of pyridine bases in phenols[238] and of traces of acid in ethyl silicate[588] and surface-active substances[327,340].

Contrast Intensification in the Electron Microscopy of Polymers

E.M.Belavtseva and K.Z.Gumargalieva

CONTENTS

I. Introduction 298
II. Contrast in the electron microscope, and methods of increasing the contrast 298
III. Structural studies of polymers using contrast intensification methods. Effect of contrast materials 303

I. INTRODUCTION

The experience of recent years has shown that the properties of high-molecular-weight materials are determined essentially by their supermolecular structure. Therefore, information on the shape and size of regions of molecular aggregation of chains into bundle-like formations of different kinds is of interest. These structural features of polymeric materials can be investigated, mainly, by electron microscopy.

During the past decades, this method has produced a considerable volume of experimental data which has helped to correlate the properties of polymers with their structure. As a result, real improvements have been made in technological processes, but the problem is far from exhausted. The interlinking of amorphous and crystalline regions in polymers is still poorly understood. The mechanism of a number of transformations in polymeric materials (recrystallisation, polymorphic changes, etc.) has not yet been established. Further progress towards the clarification of these obscure areas of polymer science depends essentially on the development of high-resolution electron microscopy.

Currently available electron microscopes have a resolution of 4.5 Å, which allows crystal lattices with an interplanar spacing of ~ 2 Å to be photographed. However, the high resolving power of the electron microscope cannot always be exploited because of inadequate contrast in the image.

Image contrast in the electron microscope arises mainly from the scattering of electrons at the atoms of the object. Therefore, the contrast† of the electron-microscopic image is determined by properties of the object itself, such as density, thickness, and atomic number. If we fix the parameters of the electron microscope (aperture of the objective lens, accelerating potential) the contrast of the image increases in proportion to these properties of the object.

Organic materials do not meet the requirements for high contrast, because their molecules consist mainly of light atoms and their density usually lies in the range 1–2 g cm^{-3}.

Various methods, based on treating the object with substances containing heavy atoms of high scattering power, have been used to increase the contrast of electron-microscopic images of organic materials. These procedures have advanced most in the study of biological materials. Methods of contrast intensification for the electron microscopy of synthetic polymers are poorly developed, and have found only limited application.

An attempt has therefore been made, in the present article, briefly to review the contrast intensification procedures currently used for synthetic polymers and for biological materials. This is followed by a discussion of work on the morphological structure of polymers involving contrast enhancement by treatment with suitable materials.

Since contrast materials can modify the structure as well as reveal it, we shall consider the influence of contrast materials on the structure of an object being examined in the electron microscope. The review will begin with a short discussion of the dependence of image contrast on the parameters of the electron microscope and on the properties of the specimen.

II. CONTRAST IN THE ELECTRON MICROSCOPE AND METHODS OF INCREASING THE CONTRAST

Depending on the mechanism of image formation, we can distinguish between amplitude contrast and phase contrast in the electron microscope[1–3]. When an electron microscope is operated in the normal way without special attachments, phase contrast is produced by phase shifts arising from: (1) defocussing, and (2) spherical aberration. In addition, diffraction contrast due to the ordered arrangement of the atoms[4–10] can arise, in the study of crystalline materials, as a result of phase shifts.

Although phase shifts can increase the contrast to some extent, they add to the difficulty of a quantitative assessment of the image contrast because of their ambiguity.

At the present time, amplitude contrast plays the most important part in electron microscopy: it provides the basic information on the morphological structure of the object. Electron absorption makes an insignificant contribution and is ignored in practice[11–15].

Electrons which are scattered through angles greater than the aperture are absorbed by the diaphragm of the objective and do not take part in the formation of the image. Only those electrons which pass through the specimen unscattered, or scattered through small angles, contribute to image formation. Hence, the intensity of the electron beam is decreased after passage through the specimen. The intensity at the image of the specimen‡ can be expressed in the form

$$I = I_0 e^{-\frac{N_A}{A}\sigma_a \gamma x}, \qquad (1)$$

where N_A is Avogadro's number, A the atomic weight, γ the specific gravity of the object, x its thickness, I_0 the

† The term refers to the amplitude contrast of the image.

‡ The specimen is assumed to be amorphous.

intensity of the incident beam, and σ_α the effective cross-section of the atom. The contrast K of the electron microscope image is defined as the relative intensity of the electron beams I_1 and I_2 passing through neighbouring areas:

$$K = \frac{I_1 - I_2}{I_1} = 1 - \frac{I_2}{I_1}. \quad (2)$$

By combining Eqns. (1) and (2) we obtain an expression for the contrast K in terms of parameters of the object, in the form

$$K \simeq N_A \left(\frac{\sigma_{\alpha_2}}{A_2} \gamma_2 x_2 - \frac{\sigma_{\alpha_1}}{A_1} \gamma_1 x_1 \right). \quad (3)$$

This equation shows that contrast in the image arises as a result of differences in: (1) the scattering power of the atoms of the object, (2) the thickness, and (3) the density of the object.

The scattering power of an atom is characterised by the effective scattering cross-section σ of the atom. The effective cross-section of interest in electron microscopy is σ_α, which defines the probability of electrons being scattered at that atom by angles greater than the angular aperture α_0.[13,16-19] This is because the image is formed only by those electrons whose scatter angles lie within the angular aperture α_0 of the objective lens.

σ_α is a function of the atomic number Z, of the angular aperture α, and of the accelerating potential U. Since σ_α appears in the equation which defines the contrast, the latter depends on Z, α, and U as well as on γx; in other words, the contrast depends both on the observation conditions in the electron microscope and on the atomic number of the specimen.

It should be noted that the cross-section which appears in the contrast equation is the total cross-section $\sigma_\alpha = \sigma_{e\alpha} + \sigma_{u\alpha}$ (the sum of the effective cross-sections for elastic scattering, $\sigma_{e\alpha}$, and for inelastic scattering, $\sigma_{u\alpha}$, of electrons[20-22]).

1. Variation of Contrast with Accelerating Potential

A decrease of image contrast with increase of accelerating potential is a general feature of electron microscopy.

It has been stated[23,24] that the contrast is inversely proportional to the accelerating potential, or directly proportional to the square of the wavelength λ, since

$$\lambda = \frac{12.225}{\sqrt{U}} \text{ Å}.$$

However, a linear dependence of contrast on accelerating potential is only a special case, and can be realised only under certain observation conditions. In the more general example, the contrast is a power function of U, and therefore of λ^2.[24] The effective scattering cross-section which characterises the contrast is expressed in the form

$$\sigma_\alpha = A(\lambda^2)^l,$$

where A is a coefficient, l is an exponent depending on the particular apparatus, and λ is the wavelength.

Hence, it is desirable to lower the accelerating potential in order to improve the contrast. This problem has been discussed by many workers. Thus, Valentine[25] states that in microscopes with an accelerating potential of 5–6 kV the contrast is higher by a factor of 10 (as compared with 50–60 kV microscopes).

Some low-voltage electron microscopes have already been developed. Nixon[26] reports a considerable improvement in the image contrast by using an accelerating potential of 6 kV. However, the large gain in contrast offered by low-voltage electron microscopes cannot be fully exploited when the image is recorded on conventional photographic materials, because electrons of 6 kV energy cannot penetrate into the bulk of the emulsion, and this causes a loss of contrast in the photographic plate.

The use of electro-photography in low-voltage electron microscopes may enable the possibilities of the technique to be more fully realised. The first experiments in this direction, using electron beams of intermediate energies for electro-photography, have shown that the sensitivity of the method cannot compete with that of the more conventional methods of recording electron microscope images[27,28]. Nevertheless, low-voltage electron microscopes already offer improvements in contrast; these can be achieved by the use of various attachments to the electron microscope. In particular, the brightness intensifier not only allows the range of intensities of illumination of the object to be extended, but it also influences the contrast of the image. Existing methods of contrast intensification in electrophotography may also find application in electron microscopy, by using special photo-recording materials.

When organic materials are examined in a low-voltage electron microscope, allowance must be made for the increased thermal and radiation-chemical effect of the electron beam when the accelerating potential is decreased[29-34]. Thus, it is thought[23,35] that the optimum accelerating potentials for the electron microscopy of organic materials lie in the range 30–40 or 30–60 kV.

2. Variation of Contrast with the Angular Aperture of the Objective Lens

The general rule is that the contrast increases when the angular aperture of the objective lens is decreased. The variation of contrast with α_0 is strongly dependent on the atomic number Z of the material under examination[36-38]. In particular, it has been pointed out that the effective scattering cross-section σ_α (and therefore also the contrast) falls of rapidly with the angular aperture α_0 when Z is small. For large Z the decrease of σ_α with α_0 is more gradual.

For thin layers, and in the range of angular apertures $3 \times 10^{-4} < \alpha_0 < 1.7 \times 10^{-2}$, the relative change in contrast can be expressed in the form

$$\frac{K(\alpha)}{K(0)} = \frac{n_e}{n_e + n_u} \left[\frac{1}{1 + \left(\frac{\alpha_0^2}{\chi_0} \right)} + \frac{n_u}{n_e} \left(0.89 - 0.5 \ln \frac{\alpha_0}{3 \cdot 10^{-4}} \right) \right],$$

where $K(0)$ is the optimum contrast obtainable with $\alpha_0 > 0$; n_e and n_u are the numbers of elastic and inelastic collisions between electrons and the atoms of the object. Also,

$$\chi_0 = 0.84 Z^{1/3} \frac{\sqrt{1-\beta^2}}{\beta} \cdot 10^{-2}.$$

Fig. 1 shows the variation of the relative contrast $K(\alpha)/K(0)$ of the image of thin carbon films ($Z = 6$) with the aperture α_0 of the objective for two values of the accelerating potential, $U = 40$ kV and $U = 100$ kV.[17]

The aperture of the objective, α_0, is determined by the diameter of the aperture diaphragm of the objective lens, by the focal length of the objective, and also by the spherical aberration constant. Valentine has found that the contrast is doubled by changing the diaphragm diameter from

50 to 10 μm. However, extremely small diaphragm orifices rapidly become contaminated, giving rise to astigmatism. For this reason, Valentine recommends the use of diaphragm orifices 25 μm in diameter[23].

In Leisegang's book[17] changes in the accelerating potential and in the aperture of the objective are compared as methods for enhancing the contrast. The author considers it more satisfactory to increase the contrast by lowering the accelerating potential than the angular aperture. For a given object, he shows that the same contrast can be obtained at: (1) $U = 100$ kV, $\alpha_0 = 3 \times 10^{-4}$, and (2) $U = 40$ kV, $\alpha_0 = 10^{-2}$. However, under the former conditions the loss of resolution of the electron microscope is greater than in the latter.

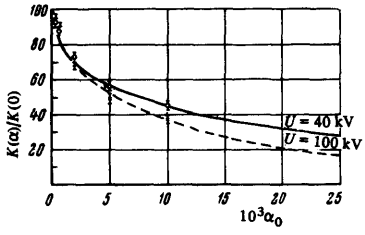

Figure 1. Relative contrast $K(\alpha)/K(0)$ of the image of thin carbon films against the aperture of the objective α_0 for two values of the accelerating potential[17].

Thus, the contrast of the image depends to a great extent on the conditions under which the object is observed. In order to obtain the maximum amount of information on the structure of the object with the help of an electron microscope, the optimum observation conditions should be provided. Pilyankevich has constructed a nomogram[42] which helps to choose the best experimental conditions.

3. Variation of Contrast with Atomic Number

As a general rule, the contrast increases with the atomic number Z[39-42].

The variation of the effective scattering cross-section σ_α with Z can be expressed in the form

$$\sigma_\alpha = AZ^k, \qquad (5)$$

where A and k are constants depending on α_0 and U. On increasing the angular aperture α, the variation of σ with Z tends to a quadratic form[3]. The linear variation of σ with Z is a special case, which applies only for particular values of the microscope parameters[17].

On this general rule is superimposed a periodic variation of the effective scattering cross-section with atomic number Z, which becomes less pronounced as the angular aperture of the objective increases[16,17]. Fig. 2 shows the periodic variation of σ with Z according to Pilyankevich[13]. Hence, not only the atomic number Z but also the position of the element in the periodic curve of σ_α against Z must be considered when calculating the contrast. It follows from Fig. 2 that the greatest contrast can be expected from substances such as iridium, osmium, rhenium, platinum, tungsten, gold, tantalum, chromium, uranium, and palladium, that is, elements for which the effective scattering cross-section lies on the peaks of the curve.

The amount of material needed to produce a standard contrast depends on the atomic number. Thus, the same contrast is obtained with a 50–70 Å layer of chromium, an 8–10 Å layer of gold, or a 3–7 Å layer of platinum or palladium[18].

4. Variation of Contrast with Density and Thickness of the Object

If the object consists of atoms of identical scattering power, image contrast can arise only as a result of differences in mass thickness (the product of thickness and density) of two adjacent areas[43-48]:

$$K = \frac{N_a \sigma_a}{A}(\gamma_2 x_2 - \gamma_1 x_1).$$

The molecules of most synthetic polymers and biological materials consist mainly of light atoms. Since N, C, and O atoms have practically the same scattering power, the

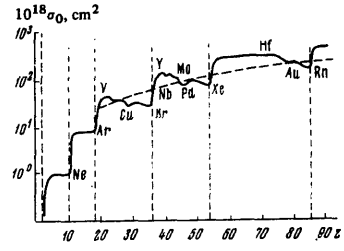

Figure 2. Variation of the effective scattering cross-section σ_0 with the atomic number Z of the elements[13].

image contrast of organic objects is due either to thickness variations or to density variations in the object being examined.

What is the thickness or density difference in an organic object needed to ensure the minimal contrast of the image which can be reliably recorded on photographic materials? (The minimal contrast for photographic materials is $K_{min} = 0.1$.) Valentine and Horne consider that if the product of thickness (in Å) and density (in g cm^{-3}) is greater than 400 the object will be distinctly visible, although a product greater than 100 is sufficient for the object to be detected on the photograph[49]. In the same paper it is shown that a photographic plate will not detect a difference in contrast for two materials of density 1.05 and 1.5 g cm^{-3} respectively: in other words, a density difference of 30% is insufficient to ensure appreciable image contrast.

Since density fluctuations in synthetic polymers and biological objects are usually much lower than this figure, the image contrast is affected almost exclusively by the thickness of the object.

The minimal thickness of an organic object which can be reliably recorded photographically has been discussed by many workers[46,47,50], who find that a thickness of at least 50 Å is necessary for satisfactory recording on a photographic plate. Elsewhere, figures of 100 Å are quoted. These values apply to electron microscopes of intermediate electron energies.

Pilyankevich and Stoyanova[24] investigated the minimal thickness Δd compatible with appreciable contrast as a

function of the accelerating potential of the electron microscope. They found that for $U = 50$ kV the minimal thickness is $\Delta d = 50$ Å (assuming $\rho = 1$ g cm^{-3}), whereas for $U = 200$ kV Δd increases to 500 Å. This means that the higher the accelerating potential, the greater must be the thickness of organic objects to be examined in the electron microscope. However, these results apply to the normal mode of operation of the electron microscope with image formation under bright field conditions. For dark-field images, the variation of the contrast with γ_x follows a different law, discussed in the work of Pilyankevich and Stoyanova. It is found that the dark-field offers a higher contrast than the bright-field method when the specimens are either very thin or very thick [51-54].

Thus, the potential use of electron microscopy in the study of organic materials meets with serious limitations associated with the contrast problem. Minor density changes in synthetic polymers and biological materials are not detected by the electron microscope. Hence, the contrast of organic objects reflects, essentially, only thickness variations in the material under study:

$$K = \frac{N_A \sigma_a}{A\gamma}(x_2 - x_1).$$

Consequently, materials which can be prepared as fine particles (more than 50 Å thick) are the most convenient for the electron microscopy of organic objects without contrast intensification.

In studies of ultra-thin sections having uniform thickness, the image contrast is practically the same in different parts of synthetic polymer or biological sections, giving no information on the morphological structure of these materials unless they are specially treated. Only rarely have differences in contrast of the sections been detected as a result of slight differences in thickness arising from specific features of the method of preparation (for example, in washing the section free from the mounting medium, etc.).

Similar difficulties, due to inadequate contrast, arise also with methods of preparation of organic objects other than the ultra-thin section method.

Various methods of treating the object with substances containing heavy atoms of high scattering power have been used to increase the image contrast of organic materials. The oldest and best developed method of contrast intensification is the shadowing method, which consists in depositing on the object a thin layer of metal, evaporated in a vacuum at a glancing angle to the object. The shadowing method was one of the first contrast intensification procedures, and is still widely used. It was first suggested by Williams and Wickoff [55] in 1944, and is now often applied in electron microscopic practice. However, this method allows one only to reveal the shape of the object and to reproduce the structure of its surface. Furthermore, in high-resolution work the structure of the evaporated layer itself becomes intrusive. The grain size of the evaporated material varies with the nature of the chosen metal and the method of shadowing used. A vast amount of literature has accumulated, both on the shadowing method itself and on its application to organic materials including biological specimens and synthetic polymers. The method is discussed in detail in monographs on electron microscopy [56,57].

Work on the method has been aimed mainly at finding a material and a shadowing technique to give a smaller grain size whilst retaining a high contrast. A relationship between grain size and the identity of the evaporated material has been demonstrated [58,59] in a study of a number of materials for shadowing electron microscopic objects. It is stated that the smallest grain size (down to 15 Å) can be obtained with platinum. The grain size can be brought down also by using special capillaries through which the metal vapour is directed at the object [60]. Noteworthy among these papers is that of Galyanov, who proposed a shadowing technique in which the metal is sputtered in a gas discharge, this allows the grain size to be decreased substantially [61]. Shadowing is used also when the object is examined by the replica method, as in the case of thick samples opaque to electrons. The commonest replica materials are quartz and carbon, both of which have a low scattering power. Hence, in order to increase the contrast, the replicas are shadowed with metals. In this method the quality of the replicas is determined essentially by their resolution. Bradley reports [62] that high-resolution replicas can be obtained by simultaneous evaporation of carbon and platinum. Marikhin obtained good results by evaporating quartz and platinum together [63]. Replica methods are described in detail in special articles and also in books on electron microscopy.

In the present article, however, we shall not dwell on this work, because we are concerned only with problems of contrast in direct examination, that is, in studies of the object itself rather than of its imprint.

Furthermore, we shall be concerned primarily with contrast intensification methods in which the object is impregnated with substances containing heavy atoms of high scattering power. These methods have been developed mainly in studies of biological objects, and have yielded more meaningful information on the morphological structure of these materials than has the shadowing method. In the field of synthetic polymers, the impregnation methods of contrast intensification are less well developed and have not been widely used. We shall therefore devote the major part of this article to those methods. Contrast intensification procedures which have been applied only to biological materials will be briefly mentioned.

Methods of contrast intensification involving impregnation of the object with materials containing heavy atoms were originally termed electronic staining, or simply "staining" methods, because of the obvious analogy with optical microscopy.

The term "staining" is now used mainly in the foreign literature, whereas "contrast intensification" is used in the Soviet literature.

The following methods of contrast intensification (or staining) in the study of organic materials by electron microscopy are known: (1) positive contrast intensification; (2) negative contrast intensification; (3) immunochemical contrast intensification; (4) the autoradiographic method; (5) the development of ordered regions; (6) the silver ion reduction method; and (7) decoration.

Positive contrast intensification or positive staining was one of the first methods for enhancing the contrast of organic objects [64,65]. Originally it was simply called "staining", but when a new method of contrast intensification (termed "negative contrast intensification") was developed, it became known as positive contrast intensification or positive staining. The method consists in impregnating the object with salts of heavy metals, and has been used with biological objects. In multicomponent structures, contrast is generated by the different amounts of metal which penetrate selectively into the structural elements of the object. Thus, osmium gives good contrast with lipoid structures, uranyl acetate with nuclei acids.

Negative contrast intensification (*negative staining* [69]) was first described towards the end

of the 1950's, and quickly became popular[66-70]. The principle of the method is that the particles being examined are surrounded with (or "*embedded*"[62] in) a strongly electron-scattering material, producing a contrast opposite to that obtained by positive staining. The negative staining method has been applied both to synthetic polymers and to biological polymers.

Immunochemical contrast intensification (*immunochemical staining*) is applied exclusively to biological objects[71]. The method depends on the binding of antibodies with antigens. Antigens (for example, virus antigens) become visible in the electron microscope if antibodies specific to the virus particles are previously chemically combined with proteins containing heavy atoms. Ferritin, which contains an iron atom, is frequently used as the protein. When the antibodies become bound to the antigens, the latter develop a higher contrast, which allows their location in the cell to be identified. The sensitivity of this method is extremely high.

The autoradiography method consists in treating the object with radioactive materials, which segregate at specific points[72,73]. A photosensitive layer similar to a photographic emulsion and containing silver atoms is then deposited on an ultra-thin section of the object. After exposure and photographic development of the object, silver particles are deposited on the parts of the cell where radioactive elements are present. The contrast of some of the cell structures is increased, so that they can be seen in the electron microscope. This method, also, is confined to biological objects.

The development of ordered regions is applied to oriented synthetic fibres. The object is impregnated with salts of heavy metals, which concentrate in the disordered regions of the fibre[74,75]. The object is pre-treated with reagents able to loosen the amorphous, disordered regions, thus assisting the penetration of the contrast-producing agent into those regions (but not into the ordered regions).

Contrast intensification by the reduction of silver ions has only recently been proposed. So far, it has been used and investigated only with graft polymers, guanine, poly(acrylic acid)[76], and DNA. The principle of this method is as follows. When the object has been treated with salts of heavy metals (for example, silver), silver crystals are deposited at the active groups of the polymer chain. The process is reminiscent of the formation of silver crystals during physical development. Since the silver nuclei have ~ 50 Å dimensions, we are able to see in the electron microscope the location of the specific groups of the polymer on which a hydrogen ion has been replaced by a silver ion, even though the silver atom itself does not meet the minimal requirements for contrast and is therefore invisible.

The decoration method has been adequately developed for inorganic crystals, in which it allows surface heterogeneities to be made evident[99,100]. The method is relatively simple, and consists in the high-vacuum evaporation under stated conditions, onto the surface of the object, of a metal (such as gold) whose particles can "label" the surface heterogeneities. This method has found practically no application in the study of organic materials. Only very recently has a preliminary report appeared of work by Bassett and coworkers on displaying the defects of the folded surface structure of polyethylene single crystals grown from solution.

Of all these methods, the negative contrast intensification method has attracted most attention in recent years for the electron microscopy of biological objects and synthetic polymers. A great deal of work has been published, particularly in the field of biology, using this method. Many workers have studied the method and have attempted to develop it further. Valentine and Horne[49], and Bradley[77] have reported some interesting studies of the negative contrast intensification method, of the materials used in it, and also of the resolution which can be expected from the method.

Somewhat conflicting views on the resolution of the negative contrast method have been published. Brenner and Horne[69] initially estimated the resolution as 15 Å. However, from recent microphotographic results, Bradley[77] obtains a resolution of 30 Å, reaching 15 Å only in special cases. Valentine and Horne quote figures of 20–30 Å[49]. Kay's book[57] states that details below 20 Å cannot be reliably investigated by negative contrast intensification.

Many workers have discussed the nature of the negative contrast intensification process, but a clear understanding of the interaction between the contrasting agent and the object is still lacking. Brenner, Valentine, Horne, Hall, and Bradley have all made interesting contributions in this area[43,49,50,69]. A paper by Müller and Meyerhoff[78] describes the "anomalous" contrast observed in negative contrast intensification: crystallites of MgO, deposited on a layer of tungstophosphoric acid, produce brighter areas in the image than the layer of contrast material. They ascribe this unusual effect to charges in the object itself. Later, Lippert studied the phenomenon in more detail by measuring the electrons scattered from the object and from the tungstophosphoric acid (TPA) during negative contrast intensification[79]. His experiments disprove Müller and Meyerhoff's hypothesis: Lippert considers that the "anomalous" contrast arises from the relative positions of the object and the TPA rather than from charges in the object. An MgO crystallite deposited on a layer of TPA is drawn into it, and scatters fewer electrons than the surrounding area of TPA. Thus, the "anomalous" contrast disappears, since the density distribution of scattered electrons in the image now varies in the same sense as the mass–thickness product of the object.

Phenomena leading to a loss of contrast also have to be considered in the electron microscopy of organic materials. In particular, a serious obstacle to the study of low-contrast objects is contamination by hydrocarbon vapours deposited on the object from the microscope column, which can lead to the formation of a thin film under the influence of the electron beam. A great deal of work has been done on this problem[80-84], but a discussion of this work would be out of place in the present review. The most recent designs of microscopes already include special attachments for minimising the rate of contamination of the specimen, and this undesirable phenomenon can now be readily overcome.

Thus, the contrast of the image of an organic object can be enhanced either by using the facilities offered by the electron microscope itself or by treating the object with materials of high scattering power. Since the optimum operating conditions in electron microscopic practice are usually chosen for fixed values of the apparatus parameters, most of the published work in this area deals with the problem of contrast intensification in the study of synthetic and biological polymers.

Published studies of biological objects and synthetic polymers by contrast intensification methods show that most of the effort is concentrated on revealing the fine structure of the specimens. The influence of the contrast agent on the specimen is attracting rather less attention, particularly in studies of biological polymers. However, the interaction between the contrast agent and the object is discussed in a number of papers. Therefore, we shall consider in detail not only the structural data obtained by electron microscopic studies of polymers but also the effect of the contrast-producing material on the objects being examined.

III. STRUCTURAL STUDIES OF POLYMERS USING CONTRAST INTENSIFICATION METHODS. EFFECT OF CONTRAST MATERIALS

Synthetic Polymers

The earliest electron microscopic studies of synthetic fibres using contrast intensification methods are due to Hess and his coworkers [74,75,85-89], who tried to detect large network spacings by electron microscopy. Large spacings had previously been observed in most synthetic polymer fibres by low-angle X-ray diffraction. Since the observed large spacings, of the order of 70–200 Å, did not match the length of any of the chemical groupings present in the polymers, it was suggested that superlattices appear in these materials as a result of the periodic alternation of ordered and disordered regions in the polymer. The sum of the lengths of these regions was identified with the observed large spacing. Large spacings were reported in fibres of polyethylene, poly(vinyl alcohol), and in polyamide fibres [89,90]. These materials were therefore investigated in the electron microscope with the aim of displaying the large spacing directly on the photographic plate.

It is well known that the density difference between amorphous and crystalline regions in polymers does not usually exceed 10%, which is not enough to provide the minimal contrast required in the electron microscopic image when working with electrons of intermediate energies, that is, under the normal experimental conditions. Therefore, the polymers were treated with materials containing heavy atoms of high scattering power, before being examined in the electron microscope, in order to enhance the contrast.

Essentially, these workers sought to increase the contrast by virtue of differences in the ability of amorphous and of crystalline regions of the polymers to sorb materials containing heavy atoms, thus producing enhanced contrast between the different regions of the specimen.

In an electron microscopic investigation of poly(vinyl alcohol) fibres, the specimens were treated with iodine after being steeped in formalin [74]. Large spacings of the order of 150 Å were revealed, as well as superspacings of the order of 700 Å. Examination of these fibres by X-ray diffraction confirmed a periodicity of 160 Å, but not the 700 Å superspacing.

Hess and coworkers used tungstophosphoric acid as the contrast enhancing material in their studies of polycaprolactam fibres [87]. The specimens were pretreated with a solution of HCl, which loosened the fibres and assisted the penetration of the contrast intensifier. These workers made a comparative study of the sorption of TPA in synthetic polymers and in collagen fibres. In the latter, the fine structure was developed by the chemical combination of a functional group of the protein molecule with TPA, which remained firmly held during the subsequent washing. In polycaprolactam fibres the TPA was sorbed only under special conditions (after swelling in a 9–10% solution of HCl).

The authors also studied the effect of HCl on the large spacing of polycaprolactam, and showed that the treatment produces a 30% shrinkage of the fibre length. Swelled fibres give more intense X-ray reflections, and their large spacing increases from 70 to 100 Å. After being pretreated with HCl solution, the fibres were dried and washed and treated with a 2% solution of TPA for 48 h. Under these conditions, sorption of TPA and penetration of contrast intensifier into the fibre takes place. The amount of TPA taken up was a function of the concentration of the HCl, that is, of the degree of swelling of the fibre.

High-angle X-ray diffraction studies of the treated fibres showed that the TPA is absorbed only by the disordered regions of the fibre, the crystallites remaining unaffected. The reflections also became stronger, indicating fewer defects in the crystal lattice and a higher degree of order. From the low-angle diffraction observations on treated fibres it was clear that the intensity of the meridian reflections increases with the concentration of the HCl. As the amount of TPA absorbed in the fibre increases, new reflections corresponding to 40–45 Å and 20–25 Å appear (the spacing is 70–90 Å at 9% absorption of TPA, 40–50 Å at 18% absorption).

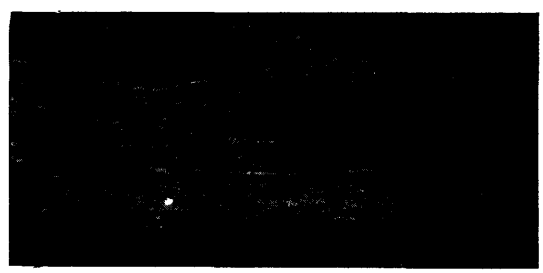

Figure 3. Polycaprolactam fibre stained with TPA [87].

Electron microscopic pictures of the dispersed fibres after treatment with HCl and TPA show that the fibre consists of thin fibrils 50–100 Å wide (Fig. 3). Along the fibrils, spacings of 70–90 Å can be distinguished as an alternation of light and dark bands. The authors point out that the periodicity along the fibre appeared only after treatment with HCl. The large spacing obtained from the X-ray diffraction work coincides with the value given by the electron micrographs.

Comparing the results of the electron microscopy of synthetic and natural fibres, Hess suggested that polycaprolactam is a better model of a protein fibre than poly(vinyl alcohol) or cellulose. This is because the material contains ϵ-aminohexanoic acid, which can react with the contrast intensifier TPA) to produce an electron microscopic image similar to that of collagens.

In 1958, a new method of contrast intensification was introduced into electron microscopy. The method, termed negative contrast intensification, has been widely applied in studies of biological objects. It has also been used by the present writers in studies of synthetic polymers [91-93]. Unlike Hess, who used TPA, we treated our specimens with

the potassium salt of TPA using the procedure suggested by Brenner and Horne[69] for biological objects. No pretreatment of any kind was given to the synthetic fibres. Contrast was achieved with both dispersed and ultra-thin sections of polycaprolactam, Lavsan [Dacron (Ed. of Translation)], and polyethylene fibres.

We had previously investigated the effect of TPA and its potassium salt on the structure of a number of synthetic fibres. The effect of the contrast agent was established by high-angle and low-angle X-ray diffraction, and also from electron microscopic and gravimetric data. From the normal high-angle diffraction patterns, the structure and the orientation of the crystallites in the fibres appeared to be unaffected by treatment with TPA or its potassium salt. Some changes were observed under low-angle diffraction. The intensity distribution curves obtained in an ionisation apparatus for treated and for untreated polycaprolactam fibres were used to calculate the large spacing and the size of the crystallites and of the amorphous regions[94]. The large spacing increased from 92 to 99 Å following treatment with 2 and 20% TPA respectively, the increase being due mainly to an increase in the size of the crystallites. The high-angle diffraction pattern of the fibre was unaffected by treatment in 20% TPA solution. An increase in weight not exceeding 5%, due to absorption of TPA, was observed by weighing the fibres after lengthy treatment in 20% TPA.

Electron micrographs of fibres which had not been washed after being treated with TPA showed extensive absorption of the staining agent, leading to a general increase in the level of intensity but making the structural elements indistinguishable.

Figure 4. Dispersed polyethylene fibre, stained with the potassium salt of TPA[94].

The elements of the fine structure of the fibres were revealed only by treating the dispersed fibres with the potassium salt of TPA. The photomicrographs of a polyethylene fibre (Fig. 4) treated in this way show a system of parallel fibrils, made visible no doubt by the penetration of the TPA salt into the regions between fibrils. The width of the fibrils was constant for different fibres (70–80 Å). A similar system of fibrils was observed in a section of a Lavsan [Dacron] fibre which had been treated with the potassium salt of TPA. It should be noted that the fibrillar picture of the longitudinal section gives an idea of the structure of the compact material of the whole fibre before disintegration by ultrasonic waves. From these results, we were able to conclude that the potassium salt of TPA has no effect on the value of the large spacing, it does not affect the crystallites, and it penetrates only into the interfibrillary spaces and the amorphous regions, in minute amounts. Nevertheless, these amounts of TPA are sufficient to reveal the fine structure of the polymers on the electron micrographs. It is pointed out that TPA (unlike its potassium salt) affects the large spacing, albeit by a small amount. Furthermore, TPA penetrates the fibre extensively, raising the level of the contrast but obscuring the fine structure.

For these reasons, we used the potassium salt of TPA as a contrast intensifier to reveal the large spacing in synthetic polymers. However, we met some difficulties: the minute amounts of contrast material sorbed by the amorphous regions were not always sufficient to provide the minimal contrast needed in the electron microscopic image. Hence, our observations of large spacings did not extend to all parts of the specimen, but were confined to those regions where the concentration of the potassium salt of TPA happened to be high enough, but not so high as to obscure the structure. A large spacing was observed in the micrographs of the following dispersed synthetic fibres: polycaprolactam, Lavsan [Dacron], polyethylene, and pyrolysed polyethylene. The electron microscopic results agreed well with those obtained by X-ray diffraction. TPA was found to be an excellent contrast agent also for single crystals of polyesters. One of our papers[93] describes contrast intensification in polyester single crystals and spherulites. The latter clearly show a fibrillar structure with TPA contrast (Figs. 5*a* and 5*b*).

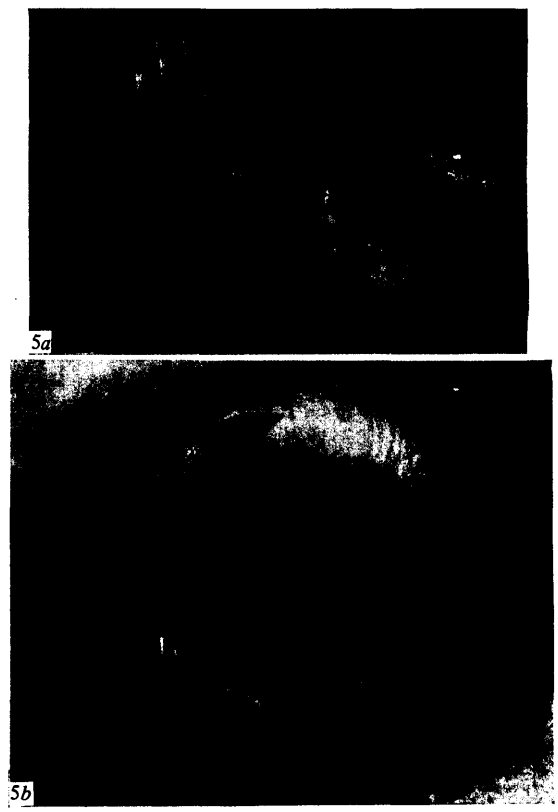

Figure 5. Negative contrast intensification of a polyester preparation[93]:
a) single crystals; *b*) spherulite.

TPA was also used by Spit[95] as a contrast material for thin films of nylon, consisting of spherulitic structures with dark and light bands (revealed by the contrast treatment) of width equal to the known large spacing of the polymer under study.

Osmic acid (OsO_4) is often used as a contrast material in the electron microscopy of biological objects, because it has fixing as well as contrast properties. Marikhin and coworkers[96] investigated the contrast properties of OsO_4 on polymers by the low-angle X-ray diffraction method. They found that the intensity of low-angle reflections does not vary monotonically with the concentration of sorbates (iodine and OsO_4). The high-angle X-ray diffraction pictures show that these sorbates are concentrated in the amorphous regions of the polymers.

When multicomponent polymer systems are examined in the electron microscope, there are difficulties in revealing each individual component in the micrograph, because the polymers consist of light atoms having practically identical scattering powers. The inadequacy of the contrast raises special difficulties in work with ultra-thin sections of multicomponent structures, such as graft polymers. To distinguish between the different types of polymer in a graft fibre, a method of contrast intensification has been proposed for which we suggested the term "contrast intensification by reduction of silver ions"[76,97,98].

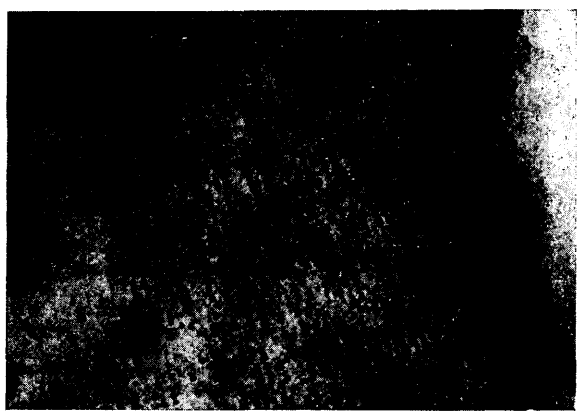

Figure 6. Cross-section of a polycaprolactam fibre treated with $AgNO_3$.[98]

The possibility of producing contrast in these polymers was demonstrated by the present writers by working with polycaprolactam fibres modified with poly(acrylic acid). The fibres were treated with salts of heavy metals: they were boiled for 3 h in saturated solutions of $AgNO_3$ and $HgNO_3$, causing partial replacement of carboxylate ions by heavy metal ions. By virtue of the powerful scattering effect on electrons of the Ag and Hg atoms, the location of the grafted material could be identified. An electron micrograph of the cross-section of a polycaprolactam fibre is reproduced in Fig. 6, where contrasting particles of 50–70 Å dimensions are clearly visible. The number of contrasting particles can be correlated with the percentage of grafted material, and decreases as the polymer being grafted penetrates into the bulk of the host polymer. In a polypropylene fibre with 5% of grafted material the number of particles is quite small. Dark-field observation of these particles showed them to be crystalline[98]. We have shown that the deposition of crystalline silver at the active groups of the polymer chain is not unlike the process of physical development in photography. Obviously, the first nuclei of the silver crystallites are formed at the poly(acrylic acid) sites, and this enables the disposition of the grafted polymer molecules to be seen in the electron micrograph. It was concluded from this work that the mechanism of this method of contrast intensification is similar to the mechanism of oxidation–reduction reactions.

Thus, contrast observation in ultra-thin sections can reveal the morphological structure of the object, but this cannot be done without special treatment of the object. In a few special instances, however, the fibril structure of fibre sections can be observed without artificial contrast thanks to differences in thickness between the different parts of the object, which can be observed after special preparative techniques[101].

Cellulose

The early electron microscopic studies of cellulose were made in the 1940's, before the preparation and staining techniques had been fully developed. The object was prepared by coarse mechanical comminution[102,103], and good preparations, transparent to electrons, were difficult to obtain. The specimens were in no way stained, and the image contrast was determined by differences in thickness only. Because of the low level of the preparative techniques, only a negligible amount of information on the structure of cellulose was gained from the electron microscopic results. The very first studies of cellulose by electron microscopy, reported by Ruska[102], allowed him to observe two layers in the fibre section: a compact outer layer consisting of fibrils, and a porous inner layer. Later work attempted to identify the structural units into which the fibres break down when disintegrated[103]. X-ray diffraction[104,105] was often used in this work to complement electron microscopy; electron diffraction[106–108] was sometimes employed. Fibrillar structures were invariably observed in electron microscopic studies of cellulose, irrespective of the method of preparation. The width of the microfibril, as measured on the electron micrograph, is invariably between 60 and 200 Å, depending on the object and on the method of preparation. Cellulose filaments of 60 Å dimensions have been termed micellar[109]. After the technique of shadowing the object by vacuum evaporation of heavy metals had been proposed, a large number of papers on the electron microscopy of cellulose appeared. The fibrillar structure of the fibres was much more clearly demonstrated in this later work[75,110]. A model of the cellulose fibre was constructed with the help of X-ray diffraction studies.

The model proposed by Hess and Kissig involves alternate ordered and amorphous regions in the fibre. The microfibrils observed in the electron microscope could not be reconciled with this model. Hence, the objective of electron microscopic studies became to identify the structure of the microfibrils—the first structural units of cellulose fibres.

However, problems of contrast arose immediately when the structure of the individual microfibril (20–60 Å thick) was investigated. Since the thickness of the cellulose microfibril is near the lower limit of the condition for minimal contrast, a search for methods of enhancing the

contrast of the object began. Shadowing could not solve the problem, because it can do no more than outline the shape of the object and the relief of its surface, and furthermore it obscures the internal structure. Also, the grain size of the shadowing material varies between 15 and 50 Å, which imposes a further limitation on the development of fine detail. The first attempts to introduce contrast intensification into the electron microscopy of cellulose are due to Hess and coworkers[74,111,112]. Their work on poly(vinyl alcohol) established the possibility of impregnating oriented polymers with iodine. Iodine treatment was applied by Hess also to cellulose. Elongated cellulose fibres were treated with potassium iodide solution, dispersed, and examined in the electron microscope. The principle of this method depends on the unequal absorption

Figure 7. Dispersed cellulose fibres:
a) stained with iodine[74]; *b*) negative contrast obtained with the potassium salt of TPA[113].

of the contrast producing agent by the different portions of the fibre. Contrast was obtained by impregnating the object with iodine and with thallium. The work was aimed mainly at the application of the method to cellulose fibres, that is, at finding the conditions which control the sorption of iodine. Iodine was sorbed by the fibre in amounts corresponding to 12% by weight of the fibre. At this level of absorption, the X-ray diffraction patterns of the iodised fibre were indistinguishable from those of cellulose. The authors showed that, when thallium atoms are used to increase the contrast, the absorption should not exceed 6–8% of the weight of the fibre in order not to disrupt the structure. Thus, Hess's work on the structure of iodine-treated cellulose deals at the same time with the problem of the effect of the contrast material on the object being examined.

The electron micrographs of cellulose fibres treated as above (Fig. 7*a*) show very clearly, along the microfibrils, alternating dark and light transverse bands with repeat distances of 60–200 Å (small spacings) and 500–800 Å (large spacings). The authors examined various types of cellulose (ramie, Fortisan [rayon]) and the pictures were always identical. The ordered regions were invariably unaffected by the sorption of iodine, as shown by high-angle X-ray diffraction.

On the basis of the electron microscopic and X-ray diffraction results, Hess put forward a model of the elementary microfibril of cellulose. Ordered and disordered regions alternate periodically along the cellulose microfibril, and are separated by sharp boundaries, so that the ordered and the disordered regions of all fibrils occur at the same level. The thickness of the microfibril was 200–300 Å, and the micellar filaments (the thinnest of fibrils) were 60 Å wide. The latter value corresponded to the narrowest microfibrils observed after dispersion of the fibres with ultrasonic energy.

The fibrillar structure of cellulose is very clearly revealed in the electron micrographs when the specimen has been treated with the potassium salt of tungstophosphoric acid (TPA). A paper by Belavtseva and Tsvankin[113] describes an investigation of the structure of cellulose treated with TPA and its potassium salt, using high- and low-angle X-ray diffraction as well as electron microscopy. Special attention was paid to the effect of TPA and its salt on the structure of cellulose. The electron microscopic work with dispersed cellulose fibres led to the conclusion that after treatment with a 2% solution of TPA the contrast of the fibre is greatly enhanced, but the individual microfibril cannot be resolved. Treatment of the specimen with the potassium salt of TPA by the negative contrast intensification technique revealed individual microfibrils 70 Å wide and 500–2000 Å in length (Fig. 7*b*). In the photograph, dark regions are visible between fibrils: these are the potassium salt of TPA, which is deposited in the form of a chain of globules. The chain of contrast material had the same width and length as the microfibrils.

The difference between the electron micrographs obtained after treatment with TPA and with its potassium salt respectively, and also the influence of these materials on the structure of cellulose, could be explained by interpreting the X-ray diffraction results.

The high-angle diffraction patterns of the specimens were unaffected by treatment with the potassium salt of TPA, whereas if the specimen had been treated with TPA itself a strong background of the gaseous type appeared on the diffraction patterns. The position and texture of the reflections remained unchanged. These facts suggest that TPA molecules can penetrate into the pores but not into the ordered regions.

As has been previously established, the low-angle scattering of untreated fibres of cellulose arises from diffraction at the elongated pores, oriented along the texture axis[114]. The length of these pores is much greater than their cross-section, and therefore the scattering is concentrated at the equator of the diffraction pattern. Treatment with TPA and its potassium salt yielded different low-angle diffraction patterns. Fibres treated with TPA showed strong equatorial scattering, but after treatment with the potassium salt of TPA the scattering was almost isotropic. Calculations show that the strong scattering in the low-angle diffraction picture after treatment with TPA arises from diffraction at regions having an average cross-section of 30–50 Å, distributed in the form of elongated cylinders 400 Å in length: in other words, the TPA here is lodged in the pores in the form of cylinders. On the other hand, low-angle diffraction from fibres treated with the potassium salt of TPA leads to the conclusion that the TPA is present in the fibre as globules of ellipsoidal shape with axes 60 and 80 Å long. Thus, whereas low-angle scattering in the original fibre was due to density differences between the fibre and the pores, which are minimal, after treatment with TPA the pores are filled with the reagent, giving rise to the observed strong scattering. The authors

showed that when the specimen is treated with TPA (but not with the potassium salt of TPA) the contrast-producing agent—TPA—is absorbed in large quantities. This follows from the electron microscopic and the diffraction results as well as from the gravimetric results. The large amount of TPA filling the pores of the fibre also produces a greatly enhanced contrast in the electron microscopic image of the fibre, but it makes the microfibrils invisible because their scattering power is much less than that of the contrast material. Hence, TPA "stains" the whole of the fibre without revealing its fine structure. The electron microscopic results and those obtained by X-ray diffraction show that when the fibre is washed in distilled water the original state of affairs (before treatment of the fibre) is restored. Only occasionally do crystallites of TPA remain stuck in the pores after washing, and these can easily be seen in electron micrographs obtained under dark-field conditions.

Figure 8. Ultra-thin section of cellulose, treated with silver hydrosol[118].

The ultra-thin section method has been increasingly applied in recent years, as an alternative to the dispersion method, in studies of cellulose fibres. In this method, image contrast is obtained as a result of differences in thickness between different areas of the section, and the fibrillar nature of the fibres has sometimes been revealed in this way[115-117]. Only a few papers have been published on the contrast intensification of ultra-thin cellulose sections. In a paper[117] on the treatment of cellulose fibres with OsO_4 and $AgNO_3$ solutions, it is shown that the dark particles in fibre sections are located on internal surfaces of the fibre.

Salyaev[118] studied sections of plant roots treated with Ag and Pt hydrosols. The electron micrographs of the root sections clearly show, in the thickness of the cell wall, silver particles filling submicroscopic spaces and thus decorating the interfibrillar spaces of the cell walls (Fig. 8).

In the present article we have discussed only the work aimed at contrast intensification in cellulose, and structural problems (as well as other electron microscopic investigations) have been ignored. For information on these topics the reader is referred to a monograph on the electron microscopy of cellulose[119] and to various other publications.

Collagen

Regular striations similar to those found in cellulose and in synthetic fibres have been observed also in a number of biological polymers (for example, collagen). The present review is concerned mainly with synthetic polymers, and therefore we shall deal, briefly, only with the work on collagen, because the electron microscopic results for this material are in keeping with those obtained by X-ray diffraction, and furthermore the electron micrographs show a remarkable similarity to those of oriented synthetic polymers.

The first X-ray diffraction studies of collagen fibres[122,123] revealed the presence of a periodicity of 830, 432, and 838 Å. In this work, attention was devoted to the effect of reprecipitation on the crystal structure of the fibres[121]. Bear[122] observed a periodicity of 640 Å in the low-angle diffraction pattern of air-dried collagen tissue. When these tissues were examined in the electron microscope after mechanical disintegration but without any artificial staining, transverse striations with a periodicity of 500–900 Å were observed. The contrast was evidently due to differences in thickness between the different regions of the fibre. The periodic striations in collagen fibres are easily visible even after shadowing, although they are not discernible in synthetic fibres shadowed with metals.

Figure 9. Collagen treated with TPA[124].

The spacing of 640 Å has been shown, by X-ray diffraction, to be common to all collagen fibres whatever their origin.

By applying contrast intensification to collagen fibres, the periodic striation has been more clearly revealed in the electron micrographs. Furthermore, the application of contrast has led to the discovery in collagen fibres not only of large spacings (Fig. 9), but also of sub-periods within the large period or spacing. As for synthetic and cellulose fibres, OsO_4 and TPA have been used as contrast materials for collagen fibres[124,125]. In that work, dispersed collagen fibres treated with OsO_4 or with a 2% solution of TPA were found in the electron microscope to consist of a thick network of fibrils with clearly developed striations. The repeat distance was approximately 700–1000 Å (large spacing), which was itself made up of a large number of bands

30 Å wide. Collagen fibres can be very effectively "stained" by contrast materials, even the small sub-periods becoming visible, whereas in synthetic fibres it is quite difficult to reveal even the large spacing.

Attempts have been made[126-129] to understand the chemistry of the interaction between TPA and collagen fibres. It has been suggested that polypeptide chains are responsible for the periodicity of the striations in the fibres: the TPA attaches itself to the amino-acid residues and therefore cannot be washed out with water. To confirm this hypothesis, photometric curves of the darkening of collagen fibres after contrast intensification with chromium and with TPA were presented: small bands (sub-periods) are observed only with preparations treated with TPA (not those treated with chromium). The small spacings (or sub-periods) in collagen fibres are thus ascribed to the presence of a chemical repeat distance along the fibre, such as would result from a regular alternation of atoms or groups, whereas no explanation could be put forward regarding the origin of the superperiods.

---o0o---

The tendency of modern, quantitative electron microscopy is to exploit more fully the potentialities of the electron microscopic method. In particular, the image contrast is one of the limiting factors in quantitative electron microscopy. The papers presented at the Symposium on "Quantitative Investigations in Electron Microscopy"[130] discuss the possibilities and prospects in this area.

For this reason, recent publications have been concerned with problems of contrast and contrast intensification. In a number of instances, morphological and structural problems in crystalline polymers have been solved by diffraction methods[131]. However, polymeric materials of low scattering power usually need additional treatment aimed at increasing the contrast. We may conclude, from this review of work on contrast intensification in synthetic polymers, that the problem is still far from solved. Only the following methods for enhancing the contrast of a polymeric specimen are known: shadowing, enhancing the ordered regions, negative contrast intensification, decoration, and contrast intensification by the reduction of silver ions. However, with the exception of shadowing, these procedures have been applied to polymers on a very modest scale as compared with the extensive application of a variety of contrast methods in biology. This is because the scientific applications of electron microscopy have so far been mainly in the field of biology. Furthermore, the specific properties of biological objects are more compatible with the full exploitation of contrast intensification. With synthetic polymers, contrast intensification presents some real difficulties, and in most cases the choice of contrast agent must be made by *ad hoc* methods.

Water as a Semiconductor

V.N.Maslov and Yu.A.Zotov

1. ANALOGY BETWEEN SEMICONDUCTORS AND AQUEOUS SOLUTIONS OF ELECTROLYTES

Over 10 years ago, Reiss and Fuller[1,2] drew attention to the qualitative similarity between electronic semiconductors (such as germanium) and solutions of electrolytes, and suggested a chemical approach to a better understanding of physicochemical phenomena in semiconducting crystals. Later, this concept was successfully applied to the discussion of chemical equilibrium and of impurity and defect interactions in crystalline semiconductors[3,4].

The principle of this analogy is that both water and germanium provide a dielectric medium for the motion and the interaction of charged particles. Water has an electrical conductivity due to its dissociation into H^+ and OH^- ions, the product of the concentrations of these ions remaining constant at a given temperature:

$$[H^+] \cdot [OH^-] = K_w . \quad (1)$$

This relationship is the exact analogue of the expression for the product of the concentrations of holes and electrons in an intrinsic semiconductor:

$$n \cdot p = n_i^2 = K_i . \quad (2)$$

Since both K_w and K_i are equilibrium constants, depending only on the temperature, the dissociation energy at constant pressure can be calculated from the van't Hoff equation

$$\frac{d \ln K}{dT} = \frac{\Delta H^\circ}{RT^2} . \quad (3)$$

This energy amounts to 13.5 kcal mole^{-1} or 0.59 eV per molecule for water, and to ~ 15.7 kcal mole^{-1} or 0.68 eV per bond for germanium. The ionisation energy of germanium or silicon atoms defines the width of the forbidden band in these semiconductors.

The phase transformations which water undergoes, and also other, more complex phenomena, set a limit to the validity of this analogy. In any case, ΔH^0 is slightly dependent on T, leading to departures from linearity. In the case of semiconductors the effect manifests itself as a temperature dependence of the width of the forbidden band.

Expressions (1) and (2) apply not only to the dissociation of the pure materials, but also in the presence of ionised impurities, when the concentrations of charge carriers of opposite signs are no longer equal. Addition of an acid to water raises the concentration of H^+ above the equilibrium value and at the same time lowers the concentration of OH^-, so that the value of K_w remains constant. The corresponding process in semiconductors is a decrease in the concentration of electrons following addition of an acceptor impurity (which raises the concentration of holes). Thus, the terms "n-type" and "p-type" conductivity become the analogues of the terms "basic" and "acidic". We note, in this connection, that the concept of the "Fermi level", of fundamental importance in semiconductor physics, is identical to the electrochemical potential or partial molar free energy of the electron gas per electron[5]. Hence, the height of the Fermi level in the forbidden gap becomes analogous to the pH of an aqueous solution. When the Fermi level is located in the upper half of the forbidden band the system corresponds to a "basic" solution, and when the Fermi level is in the lower half of the borbidden band it corresponds to an "acidic" solution. In this sense, neutralisation of an acid by a base or dissolution in water of the salt of a strong base (e.g. KCl) is analogous to the compensation of an acceptor by a donor impurity.

The ionisation energies of donors and acceptors in semiconductors are comparable to the ionisation energies of weak bases and weak acids.

It has been pointed out[4] that the entropy factor ΔS_i^0 can be negative for weak electrolytes, whereas no entropy change has been reported for current carriers in semiconductors. Nevertheless, the ionisation energies of many weak acids lie in the same range as the ionisation energies of many acceptors in germanium (0.01–0.1 eV).

For example, the ionisation energy (or heat of dissociation for the following equilibria can be determined by means of Eqn. (3):

$$B \rightleftarrows B^- + e^+ \text{ (in the silicon lattice)}$$
$$CH_3COOH \rightleftarrows CH_3COO^- + H^+ \text{ (in aqueous solution)} ,$$

The values obtained are, respectively,

$$\Delta H^0_{CH_3COOH} = 4000 \text{ cal} = 0.17 \text{ eV}$$
$$\Delta H^0_B = 100 \text{ cal} = 0.043 \text{ eV}$$
(at room temperature) .

The fraction of donors or acceptors which are ionised depends on the position of the Fermi level, just as the degree of ionisation of a weak base or a weak acid depends on the pH of the solution.

Multiply ionised solutes, and also amphoteric solutes, are found both in aqueous and in semiconductor solutions. The dissociation of zinc hydroxide can be taken as an example of an amphoteric electrolyte in aqueous solutions.

Zinc hydroxide dissociates as a base when the pH of the medium is low, and as an acid when present in solutions of high pH:[6]

$$Zn(OH)_2 \xrightleftharpoons{\text{acidic medium}} ZnOH^+ + OH^-$$
$$H_2ZnO_2 \xrightleftharpoons{\text{alkaline medium}} H^+ + HZnO_2^- .$$

In a similar way, atoms of gold, say, in germanium and in silicon ionise as acceptors or as donors depending on the position of the Fermi level[7,8].

Many other examples of the similarity between aqueous and semiconductor solutions can be given. The basic concepts of mobility, drift, and diffusion of charge carriers are applicable to electrolytes as well as to semiconductors, although large differences in the numerical values are often found. Thus, the mobility of the H^+ ion in water is approximately 10^6 times lower than the mobility of the electron in germanium. Some properties of germanium and of water are compared in the Table.

As Fuller points out, the analogy between electronic semiconductors and aqueous solutions of electrolytes breaks down when we consider that the ionised atoms of donor and acceptor impurities in semiconductor crystals are immobile, whereas the ions formed by the dissociation of acids and bases are freely mobile throughout the bulk of

the solution. Another difference is the fact that interstitial ions are absent in aqueous solutions[4] whereas they play a major role in the physics of semiconductor crystals.

However, the mobility difference of ionised impurities does not set an absolute limit to the analogy, bearing in mind the appreciable mobility of lithium ions in germanium and silicon at elevated temperatures. In many cases this

Comparison of related parameters in germanium and water*.

Germanium parameters	Germanium properties	Water parameters	Water properties
1. Charge carriers	Electrons, holes, mobile impurity ions (lithium)	1. Charge carriers	Proton, hydroxyl ion, mobile impurity ions
2. Concentration product of intrinsic charge carriers, at 25°C (atoms cm^{-3})^2	5.61×10^{26}	2. Ionic product of water at 25°C (ions cm^{-3})^2	3.6×10^{27}
3. Effective mass of the electron	Density-of-states mass $m_\alpha = 0.22$	3. Effective mass of the proton	1836
4. Mobility of charge carriers at 290°K, $cm^2\ V^{-1}\ s^{-1}$		4. Mobility of charge carriers at 293°K, $cm^2\ V^{-1}\ s^{-1}$	
electrons	3900 ± 100	protons	3.0×10^{-3}
holes	1900 ± 50	hydroxyl ions	1.7×10^{-3}
5. Ionisation energy of donors and acceptors (Groups III and V)	0.01–0.1 eV	5. Heat of dissociation of weak acids and bases	0.01–0.1 eV
6. Resistivity in the intrinsic region, ohm-cm, at 25°C	47	6. Resistivity of pure water, ohm-cm, at 25°C	20×10^6
7. Lifetime of non-equilibrium charge carriers, ms	2000	7. Lifetime of non-equilibrium ions, ms	6.6×10^{-6} 1.3×10^{-5}
8. Diffusion length of extrinsic charge carriers, cm	0.3	8. Diffusion length of extrinsic charge carriers, cm	2×10^{-8}

* This Table was assembled from published data [2,3,4,20,23].

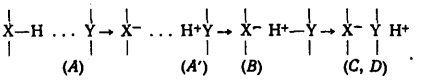
leads to the formation of donor–acceptor ion pairs, corresponding to the Debye–Hückel effect in electrolyte solutions. Furthermore, the acidic and basic residues in aqueous solutions can be spatially fixed in a high-polymer network, as is the case with the functional groups of ion-exchange resins and membranes[9].

2. THEORY OF PROTONIC SEMICONDUCTORS

The analogy between semiconductors and electrolyte solutions presented above is not a purely formal one. Studies of the physicochemical properties of water and of some other hydrogen-bonded substances have revealed that there are good reasons for classifying these materials as amorphous ionic semiconductors with a conductivity of the protonic type[10,11]. Shakhparonov[10,12,13] has introduced the concept of a protonic metallic bond, i.e. of a collective interaction between a proton gas and a system of negatively charged proton defects in whose field the proton gas is forced to move.

Shakhparonov bases his theory on a general proof that localised energy levels are converted into energy bands when charged particles interact in condensed systems[14].

His theory of protonic semiconductors offers a unified approach to the qualitative (and in many cases the quantitative) description of the basic features of dielectric polarisation and conductivity processes in water, alcohols, and many other substances with intermolecular hydrogen bonds. At the same time, the existing fund of experimental data on the temperature and frequency dependence of the dielectric constant can be used to refine the band structure model of protonic semiconductors. The energy spectrum of the states of a proton taking part in hydrogen bonding includes, in order of increasing energy, (a) a valence band, (b) an intermediate band in which states of the H_3O^+ type are formed, (c) levels associated with protonic excitons (exciprotons), (d) a conduction band. The energy band structure is shown schematically in Fig. 1. The change in energy state of a proton on being transferred from atom X to atom Y along the direction of the hydrogen bond (with simultaneous transfer from the valence to the conduction band) can be characterised by the following scheme



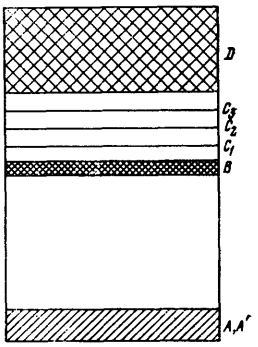


Figure 1. Energy level diagram for protonic semiconductors with intermolecular hydrogen bonds[13]:
A, A' valence band; B intermediate level; C_1, C_2 levels of proton excitons (exciprotons); D conduction band.

According to this scheme, both complex ions (such as H_3O^+) and free ions may be present in substances containing intermolecular hydrogen bonds. Transition from state A to state A' along the line of the hydrogen bond occurs by the tunnel effect with a frequency of the order of 10^{12}–10^{13} s^{-1}. The probabilities of finding a proton in states A and A' are approximately the same. Transition from A to B is accompanied by hydrogen bond breaking. There is evidence that this transition also can occur by the tunnel effect[15] provided the orientation of the molecules is favourable (i.e. when the donor atom is in direct contact with the acceptor atom). The contact may be broken (by thermal motion) at the instant when the proton is located on the acceptor atom, giving rise to the ions H_3O^+ and OH^- in water or ROH_2^+ and RO^- in alcohols, where R is a hydrocarbon radical. Unless the proton is immediately transferred from state B to state C after rupture of the intermolecular hydrogen bond, the ions HY^+ and X^- can readily recombine. Recombination can occur also by the tunnelling of a proton along the line of the intermolecular hydrogen bond. Hence, the lifetime of an H_3O^+ ion is only 10^{-13}–10^{-14} s. Transition from B to C, i.e. to any of the exciproton levels, leads to further expenditure of energy. The mutual repulsion of the protons in the H^+Y ion raises the energy of the proton. Therefore, the difference in potential energy of a proton in positions B and C may not be very large. This transition involves surmounting a potential

barrier whose free enthalpy of activation in the liquid phase usually amounts to 2–5 kcal mole^{-1} (i.e. 0.09–0.2 eV). Transition of a proton from C to D (i.e. to the conduction band) requires a small expenditure of energy of the order of $2kT$ and involves a change in the entropy of the system.

Upon entering the conduction band, protons acquire various properties not unlike the properties of electrons in electronic semiconductors. Protons and proton defects (the ions OH^-, RO^-, etc.) show an anomalously high mobility. The concentration of protons is an exponential function of $1/T$. Protons in the conduction band can be treated as a proton gas [16]. Hence there are grounds for assuming that some of the relationships derived in the band theory may apply also to protonic semiconductors. Since the mass of the proton is 1836 times that of the electron, the degeneracy condition [17] is not fulfilled in aqueous solutions:

$$kT_{deg} \simeq \frac{h^2}{8m^{(N)}} n_{deg}^{2/3} , \qquad (4)$$

where $m^{(N)}$ is the effective density-of-states mass of the charge carriers and n is their concentration. Hence, the proton gas in the conduction band is non-degenerate.

According to Shakhparonov [13], the methods of the band theory, developed for electronic semiconductors, can be used to a first approximation to treat the motion of protons and proton defects in the conduction band. The mobility of protons is found to be

$$\mu = \frac{e}{(m^*)^{1/2}} \left(\frac{m_0}{m_0 + m^*}\right)^{1/2} \frac{1}{2N_0 r_0^2 (2\pi kT)^{1/2} Y(\rho,T)} , \qquad (5)$$

where N_0 is the number of neutral molecules in 1 cm^3, m_0 and r_0 are the mass and the radius of the molecules, m^* is the effective mass of the protons, and $Y(\rho,T)$ is a semi-empirical Enskog function depending on the structure of the material as well as on the density ρ and the temperature T. Since the values of m^* and $Y(\rho,T)$ are not known, a quantitative test of the validity of Eqn. (5) cannot readily be made. However, it is possible to calculate the theoretical ratio of the mobility of hydrogen ions in water to that of deuterium ions in heavy water. The structure of D_2O is practically indistinguishable from the structure of H_2O. At the same temperature, the quantities N_0 and r_0 for H_2O and D_2O are identical. Assuming $m_D^*/m^* = 2$ and $Y_{D_2O} = Y_{H_2O}$ we obtain, from Eqn. (5), $\mu_H/\mu_D = 1.43$, which agrees exactly with the value found experimentally at 18°C.

3. SEMICONDUCTOR DEVICES BASED ON WATER

Various types of electrochemical transducers (or chemotrons) have been used successfully in technology for a number of years as rectifiers, stabilisers, logic cells, relays, d.c. and a.c. amplifiers, etc. [18]. The vast majority of these devices are not true analogues of semiconductor devices. However, many attempts have been made to realise devices of the diode or even the triode type using water as a semiconductor.

Fuller was the first to point out the analogy, in 1956, [2] between a p–n junction in a semiconductor and an electrochemical concentration cell. Fig. 2 shows a schematic comparison of the acid–base cell $H_2|HCl_{aq}|NaOH_{aq}|H_2$ with a semiconductor p–n junction. The ions H^+ and OH^- correspond to electrons and positive holes.

We had previously pointed out [9] that the junction between two ion-exchange membranes of opposite sign offers an even closer analogy to the junction between two semiconductors of opposite conductivity type, because the immobile, ionised, functional groups of the resin give rise to an electric field of the appropriate sign whilst the mobile ions of the electrolyte play the part of charge carriers (see Fig. 2). Independently, Bockris and coworkers [19] showed that the mobility of the counterions can be suppressed not only by using ion-exchange membranes with oppositely charged functional groups but also by separating aqueous solutions of high-molecular polyacids and polybases by a thin semipermeable membrane.

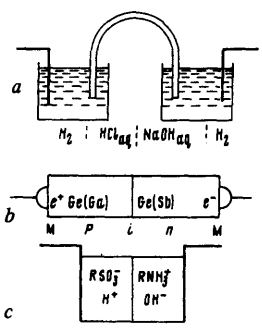

Figure 2. Analogy between (*a*) the acid–base concentration cell, (*b*) the p–n junction, and (*c*) the ion-exchange cell with membranes containing functional groups of opposite signs.

In either case, the application of an external electric field results in asymmetrical electrical conduction in the resin cell, i.e. in the rectification of electric current. Thus, when the cell is connected in the forward direction the mobile H^+ and OH^- ions move towards each other and recombine at the interface between the two membranes. In the blocking direction, the mobile charge carriers are drawn away from the interface, forming a region which is depleted of charge carriers and in which H^+ and OH^- ion pairs can arise only as a result of the termal dissociation of water—a relatively slow process.

A typical, static current–voltage characteristic for an ion-exchange resin rectifying cell, as published by many workers [19–21], is reproduced in Fig. 3. Its shape is reminiscent of a semiconductor diode characteristic, but it shows an additional hysteresis loop. This is ascribed to polarisation of the electrodes, the loop area being significantly decreased by the addition of depolarisers. The nature of the metal electrodes also plays a part [9]. Rectification coefficients do not usually exceed a value of 40. [9,21,22] The change in shape of a 50 Hz sine wave caused by the rectifying action of ion-exchange cells is illustrated in Fig. 4. A strong dependence of the rectification coefficient on frequency was noted in attempts to use cells of this type to rectify alternating current. Most authors [9,19] observed rectification up to frequencies not above 50–60 Hz, but Friedländer [22] reports an appreciable effect even at 6000 Hz. Seno and Yamabe [20] made a special study of this effect, and found that the rectification coefficient falls off rapidly above 1 Hz (Fig. 5), tending to zero above 1000 Hz.

According to the theory developed by Seno and Yamabe, the net current through the membrane cell is satisfactorily described by the expression

$$i = e\left(\frac{D_A n_A}{L_n} - \frac{D_m m_A}{L_m}\right)[\exp(eV/kT) - 1] , \qquad (6)$$

where the subscript n refers to protons and m to hydroxyl ions. L_n and D_n are the diffusion length and the diffusion

coefficient of protons in the region of the anionic resin, L_m and D_m are the corresponding quantities for hydroxyl ions; n_A and m_A are the concentrations of protons and hydroxyl ions in the anionic resin region.

Eqn. (6) is the analogue of Shockley's equation for a p–n junction in a semiconductor [23]. This suggests that the same rectification mechanism is operative in both systems,

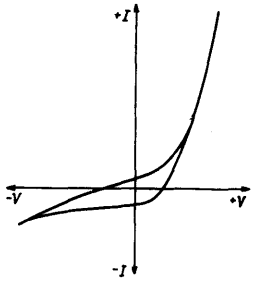

Figure 3. Typical current–voltage curve of an ion-exchange cell [21].

the cationic membrane corresponding to the n-type semiconductor and the anionic to the p-type. Thus, we conclude that a system in which the positive electrode is connected to the cationic exchange resin and the negative electrode is connected to the anion exchange resin will offer a higher resistance to direct current than a system of the opposite polarity.

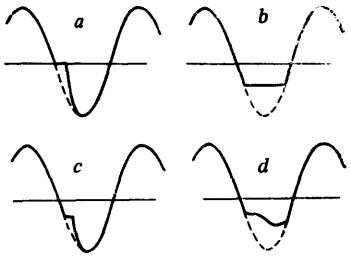

Figure 4. Change in shape of a current sine-wave at 50 Hz frequency resulting from rectification by ion-exchange cells [9]. *a*, *b*, *c*, and *d* are the characteristics of different ion-exchange cells.

Studies of the electrical characteristics of systems based on ion-exchange membranes of different polarities have not been confined to realising the simplest analogue of a semiconductor diode. Bockris and coworkers [19] obtained a rectification efficiency of 85% by connecting several membrane diodes in series.

Later workers [24] showed that the rectification efficiency for homogeneous membranes depends on the ratio of the concentration of fixed charges in the membrane to the concentration of ions in solution. The rectification effect shows a marked increase when this ratio is increased. In addition, the pore size has an important effect in the case of inhomogeneous membranes.

Lovreček and Kunst [25], in some later work on the membrane non-linear element, described an amplifier consisting of two cationic and two anionic membranes, shown diagrammatically in Fig. 6. A current I_i in the input circuit produces an excess current I_e in the main circuit:

$$I_e = I_m - (I_m^0 + I_i), \qquad (7)$$

where I_m is the effective current in the main circuit during the measurement period, I_m^0 is the effective current in the main circuit when this circuit alone is connected, and I_i is the effective current in the input circuit†.

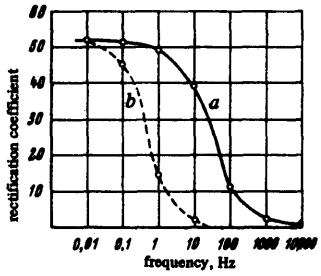

Figure 5. Frequency characteristic of an ion-exchange cell [20]: *a*) characteristic explored from reverse to forward current; *b*) from forward to reverse current.

The current amplification coefficient $P = I_e/I_i$, calculated as the ratio of the excess current to the current in the input circuit, can reach a value of 4. Current amplification is obtained because the current flowing in the input circuit produces injection of mobile ionic charge carriers in whichever diode is biassed in the blocking direction.

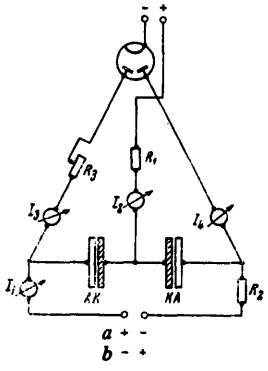

Figure 6. Circuit diagram of a current amplifier based on ion-exchange membranes [25,26].

As a result, the resistance of the diode drops and the current in the main circuit increases.

Lovreček and Kunst investigated also the variation of amplification with frequency and time [26], and they showed

† The currents I_m, I_m^0, and I_i are complex functions of the currents I_1, I_2, I_3, and I_4 shown in the circuit diagram of Fig.6.

that the amplification coefficient is decreased four or five-fold by changing the frequency from 50 to 2000 Hz.

In an attempt to carry the analogy between the membrane cell and the p-n junction a stage further, the Japanese workers Oshida and Yoshida [27,28] constructed a model of a photogalvanic cell. The cation exchange membrance in the H^+ form was saturated with the basic dye thionine in 5×10^{-5} M aqueous solution. The anion exchange membrane was immersed in a 5×10^{-3} M solution of ascorbic acid. (A mixture of thionine and ascorbic acid solutions is known to be bleached by the action of light.) Platinum gauze electrodes were pressed against the assembled membranes with Perspex plates. The cell was illuminated with a 150 W xenon lamp through a filter which absorbed infrared radiation. By measuring the electrical potential of the cell with and without illumination from the lamp, the growth and decay of a photo-e.m.f. was observed against the background of the gradually decreasing membrane potential of the cell. Photocurrents were very small (of the order of a few microamperes): this was ascribed, in particular, to the high internal resistance of the cell (3500 ohm). The power generated by the photogalvanic cell was 10^{-7} W.

4. PROSPECTS OF FURTHER WORK ON SEMICONDUCTOR DEVICES BASED ON WATER

The theory of protonic semiconductors is still in its initial stages of development. We still do not know how far the parallelism between the energy states of charge carriers in electronic semiconductors and in their protonic analogues may be taken. Theoretical studies, in depth, of the band model of protonic semiconductors are needed, because there must be substantial differences between the final expressions of the energy band theory for protonic and for electronic semiconductors respectively, despite the generality of the main starting premises.

The energy band model for protonic semiconductors considered here is only a first approximation. Thus, several intermediate levels or bands can be expected to arise in solutions containing several substances capable of forming hydrogen bonds [10].

Nothing appears to have been published on the band structure of aqueous solutions of electrolytes, which can obviously be considered as impurity protonic semiconductors in contrast to water—a protonic semiconductor with intrinsic conduction. The band theory of protonic semiconductors has not yet been developed to the stage where the parameters of devices based on these materials can be calculated and predicted theoretically.

Nevertheless, the results of the work reviewed here show unambiguously that the semiconductor properties of water can be exploited to realise analogues of a number of familiar devices—in particular, those relaying on the operation of p-n junctions. However, the low mobility of the charge carriers and the occurrence of electrochemical side-reactions at the electrodes introduce serious limitations on the frequency behaviour and other characteristics of devices based on ion-exchange membranes. As a result, these devices are hardly ever in a position to compete with their prototypes, based on electronic semiconductor materials. It should be noted that ion-exchange cells have also a number of favourable properties. For example, these cells can be used to construct models of processes occurring at p-n junctions [9], thanks to the simplicity of assembly and to the lack of critical requirements on size and geometrical shape. Radiation, also, is known to have very little effect on the dissociation and structure of water, and therefore ion-exchange devices can be expected to have a high radiation stability [2]. In principle, ion-exchange devices, like chemotrons, are capable of operation at elevated temperatures, of the order of 500°C and higher, if the electrolyte solutions are replaced by fused salts [18]. In contrast to electronic semiconductors, the difference in chemical nature of the charge carriers and the ability (in principle) to choose systems in which chemical interaction of the components produces both carrier recombination and carrier generation can lead to the realisation of new types of device quite unlike any of the devices based on electronic semiconductors.

We note also that the interest which has been shown in semiconductor devices based on water stems largely from the realisation of the outstanding role played by semiconducting membranes in the operation of the functions of nerve cells (neurons) [17]. Neurophysiological investigations have shown that the propagation of the nerve impulse and the transmission of the impulse from one axon to the next can probably be explained in terms of the rectification which occurs at junctions between cation and anion exchange membranes [21,29,30] present in the cell walls. It follows that the development and study of characteristic active elements based on water may prove to be a path to the realisation of logic cells of the neuristor type and of complex biological models of the "artificial brain" type.

Undoubtedly, the most interesting problem posed by the study and the practical application of the semiconductor properties of water, a problem straddling the boundary of physics, chemistry, semiconductor technology, and biology, will prove to be the object of intensive theoretical and experimental research in the next few years.

Reactions of the Chlorides of Phosphorus Acids with Unsaturated Compounds

N.A.Pudovik and V.K.Khairullin

The review deals with the reactions of the chlorides of acids derived from trivalent and tetravalent phosphorus with unsaturated compounds. Apart from their theoretical importance, these reactions are of great practical interest, since with their aid it is possible to obtain a wide variety of new and interesting types of organophosphorus compounds. In the first part of the review the addition reactions of various halides of trivalent phosphorus acids to ethylene and diene hydrocarbons, $\alpha\beta$-unsaturated aldehydes, ketones, and acids are considered, as well as the oxidative chlorophosphination of unsaturated compounds. The second part of the review is devoted to the reactions of the chlorides of pentavalent phosphorus acids with ethylenic, acetylenic, and diene hydrocarbons and with vinyl ethers and esters and also the addition reactions of dialkoxyphosphinothiolic and dialkoxyphosphinoselenolic chlorides.

CONTENTS

I. Introduction 317
II. Reactions of the chlorides of trivalent and pentavalent phosphorus acids with unsaturated compounds 318
1. Addition of phosphorus trichloride and tribromide to alkenes 318
2. Addition of the chlorides of phosphorus(III) acids to hydrocarbons with conjugated double bonds 318
3. Addition of the chlorides of phosphorus(III) acids to $\alpha\beta$-unsaturated aldehydes and ketones 321
4. Addition of the chlorides of phosphorus(III) acids to $\alpha\beta$-unsaturated carboxylic acids 323
5. Oxidative chlorophosphination of unsaturated compounds 324
III. Reactions of the chlorides of phosphorus(V) acids with unsaturated compounds 325
1. Reactions of the chlorides of phosphorus(V) acids with alkenes 325
2. Reactions of phosphorus pentachloride with hydrocarbons containing a conjugated system of double and triple bonds 326
3. Reactions of the chlorides of phosphorus(V) acids with vinyl ethers 327
4. Reactions of phosphorus pentachloride with enol esters 328
5. Addition of dialkoxyphosphinothiolic and dialkoxyphosphinoselenolic chlorides to unsaturated compounds 329

I. INTRODUCTION

Apart from the widely known substitution reactions of the halides of trivalent and pentavalent phosphorus in which halogen atoms are exchanged for a hydroxy-group, a carbonyl oxygen, or any organic residue, the reactions involving their addition to unsaturated compounds are assuming increasing importance. In addition to their theoretical value these reactions are also of great practical interest, since with their aid it is possible to prepare a wide variety of new and interesting types of organophosphorus compounds. Until recently the range of addition

reactions investigated was fairly narrow and included mainly ethylenic and acetylenic hydrocarbons and unsaturated ketones. These and other addition reactions of phosphorus halides (reactions with epoxides and carbonyl compounds) were reviewed in 1947 by M. I. Kabachnik. During the past two decades the addition reactions of phosphorus halides to unsaturated compounds have been studied very vigorously; apart from the development of earlier studies, a number of new very interesting reactions have been found, such as the addition of phosphorus(III) halides to compounds containing a conjugated system of double bonds and to unsaturated acids, oxidative chlorophosphination, reactions of phosphorus(V) halides with diene hydrocarbons and enol ethers and esters, and the addition reactions of dialkoxyphosphinothiolic and dialkoxyphosphinoselenolic chlorides to unsaturated compounds. The majority of these reactions were discovered and developed by Soviet chemists.

Intensive study of reactions of this type is being continued at the present time and they include both new types of phosphorus halides and of unsaturated compounds. Definite advances have also been made in the study of the mechanism of certain reactions.

We believe it is interesting and timely to compile these extensive and interesting data on the addition reactions of trivalent and pentavalent phosphorus to unsaturated compounds which have accumulated during twenty years. In the review we did not consider the earlier studies which have been summarised by Kabachnik with the exception of those few cases where this was necessary either for the explanation of the systematic development of studies on definite problems or for the examination of the mechanism of certain reactions.

II. REACTIONS OF THE CHLORIDES OF TRIVALENT AND PENTAVALENT PHOSPHORUS ACIDS WITH UNSATURATED COMPOUNDS

1. Addition of phosphorus trichloride and tribromide to alkenes

Under the usual conditions phosphorus trihalides do not add to alkenes. In 1945 Kharasch and coworkers[1,2] described for the first time a process of this kind in the presence of free radicals in the reaction medium. The radicals were generated by the thermal decomposition of acetyl peroxide introduced into the reaction:

$$(CH_3COO)_2 \rightarrow \dot{C}H_3 + CO_2 + CH_3C\dot{O}O,$$
$$\dot{C}H_3 + PCl_3 \rightarrow CH_3Cl + \dot{P}Cl_2,$$
$$RCH{=}CH_2 + \dot{P}Cl_2 \rightarrow R\dot{C}H{-}CH_2PCl_2,$$
$$R\dot{C}H{-}CH_2PCl_2 + PCl_3 \rightarrow RCHCl{-}CH_2PCl_2 + \dot{P}Cl_2 \text{ etc.}$$

The chain reaction results in the formation of chloroalkyldichlorophosphines. The main addition reaction is accompanied by a telomerisation reaction which leads to high-boiling products:

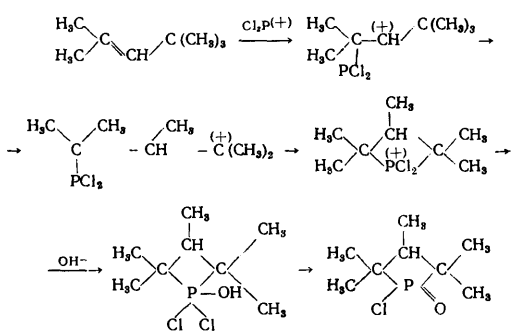
$$R\dot{C}H{-}CH_2PCl_2 + RCH{=}CH_2 \rightarrow R\dot{C}H{-}CH_2{-}CHR{-}CH_2PCl_2,$$
$$R\dot{C}H{-}CH_2{-}CHR{-}CH_2PCl_2 + PCl_3 \rightarrow RCHCl{-}CH_2{-}CHR{-}CH_2PCl_2 + Cl_2\dot{P}.$$

Reactions involving the addition of phosphorus trihalides to a double carbon–carbon bond can be initiated by ultraviolet radiation[3]. When phosphorus tribromide reacts with ethylene under the usual conditions, β-bromoethyldibromophosphine forms in 14% yield; when the reaction temperature is raised to 150°C, the yield increases to 40%. A mixture of isomers is formed with asymmetric olefins, this being confirmed by NMR spectra and gas chromatography. The authors of these investigations suggest that $Br^{\bullet}$ and $Br_2P^{\bullet}$ radicals participate in the reaction:

$$PBr_3 \xrightarrow{h\nu} Br^{\bullet} + Br_2P^{\bullet},$$
$$Br^{\bullet} + CH_3{-}CH{=}CH_2 \rightarrow CH_3{-}\dot{C}H{-}CH_2Br,$$
$$CH_3{-}\dot{C}H{-}CH_2Br + PBr_3 \rightleftarrows CH_3{-}CH(\dot{P}Br_3){-}CH_2Br,$$
$$CH_3{-}CH(\dot{P}Br_3){-}CH_2Br + CH_3CH{=}CH_2 \rightarrow CH_3{-}CH(PBr_2)CH_2Br + CH_3{-}\dot{C}H{-}CH_2Br,$$
$$Br_2\dot{P} + CH_3{-}CH{=}CH_2 \rightarrow CH_3\dot{C}H{-}CH_2PBr_2,$$
$$CH_3\dot{C}H{-}CH_2PBr_2 + PBr_3 \rightarrow CH_3{-}CHBr{-}CH_2PBr_2 + Br_2P^{\bullet}.$$

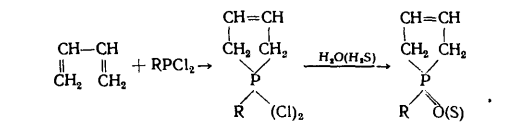
The first type of reaction takes place preferentially. A similar mechanism has been proposed by Little and coworkers[4,5] for reactions involving the addition of phosphorus trichloride to asymmetric olefins under the action of ultraviolet radiation. Trivedi's data[6] concerning the presence of a number of special absorption bands in the spectrum of phosphorus trichloride exposed to ultraviolet radiation confirm this mechanism (involving the participation of $Cl^{\bullet}$ and $Cl_2P^{\bullet}$ radicals).

Phosphorus trichloride adds to olefins in the presence of aluminium trichloride[7–10]. The intermediate complexes are decomposed by methanol and water. According to NMR spectroscopic data the phosphorus-containing acids formed have a cyclic structure. It is suggested (but it has not been confirmed experimentally so far) that reactions of this type involve an ionic mechanism with formation in the first stage of the $Cl_2P^{(+)}$ cation, for example in the case of 2,2,4-trimethylpent-2-ene we have



2. Addition of the Chlorides of Phosphorus(III) Acids to Hydrocarbons with Conjugated Double Bonds

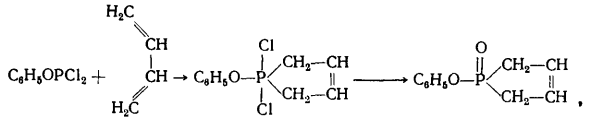
In 1953 McCormack[11,12] found that alkyl-(or aryl-)dichloro-(or dibromo-)phosphines add to diene hydrocarbons with formation of phosphorus-containing cyclic compounds—derivatives of *PP*-dihalogeno-1-phosphacyclopent-3-ene. On their decomposition with water or hydrogen sulphide, 1-oxo- or 1-thiono-phosphacyclopentenes were obtained:



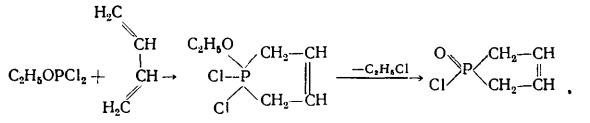
These interesting studies underwent considerable development in subsequent years.

Arbuzov and Shapshińskaya[13,14,15] investigated the addition of aryldichlorophosphines to various diene hydrocarbons. They suggested a reaction mechanism and obtained compounds of the 1-oxo-1-phosphacyclopentene series hitherto not described in the literature. They discovered

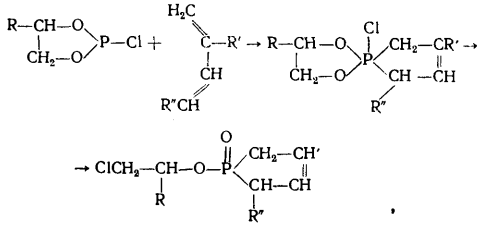
for the first time the reaction of phenyl and ethyl phosphorodichloridites with diene hydrocarbons. Phenyl phosphorodichloridite reacts without the Arbuzov arrangement



while the reaction of ethyl phosphorodichloridite does involve the rearrangement with elimination of alkyl halide:



At the same time Petrov and Razumova[16] studied the reaction of the glycol esters of phosphorochloridous acid with diene hydrocarbons (the final structure of the adducts is not quoted) and obtained the esters of the oxaphospholene oxide series[17]:

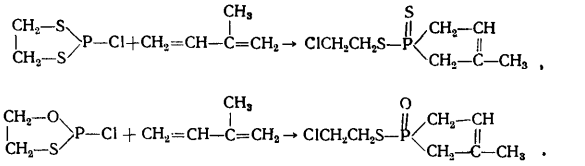


where (1) R = R′ = R″ = H, (2) R = R″ = H and R″ = CH_3, (3) R = CH_3 and R′ = R″ = H, (4) R = R′ = CH_3 and R″ = H, (5) R = R″ = CH_3 and R′ = H, and (6) R = CH_3, R′ = Cl, and R″ = H. They demonstrated the structure of their products by nuclear and proton magnetic resonance and infrared spectroscopy and chemically. A mechanism was suggested for this reaction, involving the Arbuzov rearrangement without the elimination of alkyl halide. When the catechol ester of phosphorochloridous acid is condensed with dienes, the Arbuzov rearrangement does not take place and the reaction terminates at the addition stage, evidently because of the stable bond between the oxygen and the carbon of the aromatic ring[18].

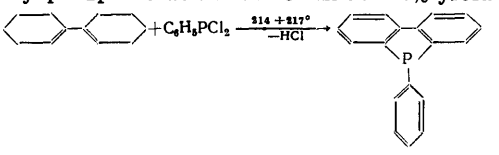
Arbuzov et al.[19,20] showed that cyclic phosphorochloridites add to various dienes with a conjugated system of double bonds by a 1,4-addition mechanism. Since in these reactions the cyclic phosphorochloridites behave as electron-donor components, the ease of the addition is determined by the electron-donor properties of the dienes. The latter become less pronounced in the series cyclopentadiene > anthracene > dicyclohexenyl > diisopropenyl > cyclohexadiene > divinyl > tetracyclone > hexachlorocyclopentadiene. Phosphorochloridites react at the highest rates with dienes at the end of the series and do not react with those pronounced electron-donor properties.

Subsequently Petrov and Razumova[21] showed that cyclic six-membered glycol esters of phosphorochloridous acid react with divinyl, isoprene, and diisopropenyl similarly as the corresponding esters with a five-membered ring. The products are 3-(γ-chloroalkoxy)phospholen 1-oxides. It has been established that in the Arbuzov rearrangement the ester ring is ruptured at the primary carbon atom.

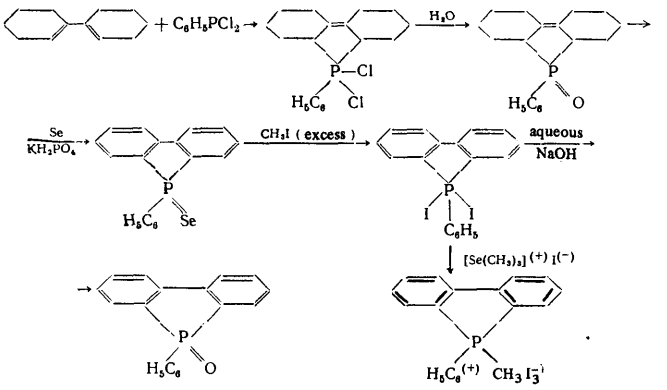
The reactions of the cyclic esters of phosphorochloridothious and phosphorochloridodithious acids with diene hydrocarbons take place similarly as those of their oxygen analogues[22]:



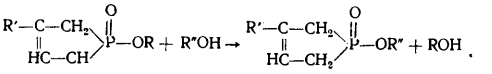
The adducts of dienes with halogen-containing derivatives of trivalent phosphorus can undergo a wide variety of very interesting reactions: for example when the adduct of dicyclohexenyl and phenyldichlorophosphine was heated, the tertiary phosphine was obtained in 50–60% yield[23,24]:



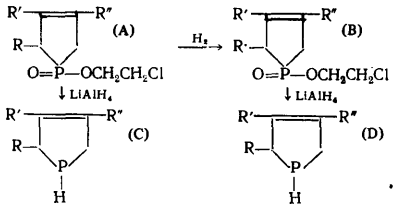
In the presence of selenium and the monopotassium salt of phosphoric acid, cyclic phosphine oxides are dehydrogenated, the oxygen bound to phosphorus being replaced by selenium:



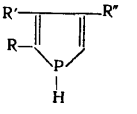
Alkoxyoxophosphacyclopentenes readily undergo transesterification with alcohols in the presence of potassium hydroxide[25]:



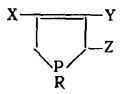
In the catalytic hydrogenation of phosphacyclopentene derivatives (A), compounds with the phospholan ring (B) were obtained[26]. When the esters (A and B) are reduced with lithium aluminium hydride, the phospholenes (C) and (D) are formed:



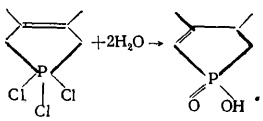
Phospholes can be obtained from these products by halogenation and dehydrohalogenation[27]:



The above syntheses of ring compounds containing phosphorus are simpler and more convenient than those already described in the literature[28]. When the adducts of methyl- or phenyl-dichlorophosphines with various dienes are reduced with magnesium in tetrahydrofuran solution, phospholens are obtained[29]:

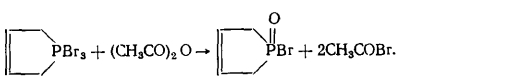


The results of studies on the hydrolysis and alcoholysis of the adducts of phosphorus trihalides with dienes are interesting. In the reaction of phosphorus trichloride and tribromide with divinyl, isoprene, diisopropenyl, dicyclohexene, and 1-phenylbuta-1,3-diene, Hasserodt et al.[30] and Weikamp and Korte[31] obtained the corresponding derivatives of 1,1,1-trihalogenophosphapentene. The authors showed by NMR and infrared spectroscopy that the hydrolysis and alcoholysis of 1,1,1-trichlorophosphapentene takes place with the migration of the double bond in the ring from position 3, 4 to position 2, 3:

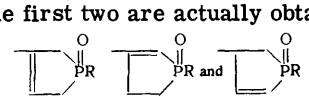


In the study of the reactions of 1,1,1-trichlorophosphapentene[30,31], a wide variety of derivatives of 1-hydroxy-1-oxo-1-phosphapent-2-enes were obtained.

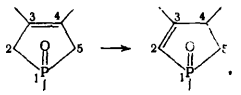
Arbuzov and Vizel'[32,33] isolated 1,1,1-trihalogenocyclopentenes in a pure form. Phosphorus tribromide reacts with diene hydrocarbons more vigorously than phosphorus trichloride. When the adducts of dienes with phosphorus tribromide are treated with acetic anhydride, the bromides of cyclic phosphinic acids are formed:



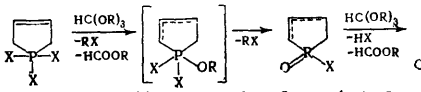
Their hydrolysis yields the acids and their reaction with alcohols the corresponding esters. In these reactions migration of the ring double bond was not observed. In subsequent studies of these investigators[34,35] it was shown that the lability of the double bond, its tendency to prototropic isomerisation, is a specific property of 1,1,1-trichlorophosphacyclopentene only. The migration of the double bond in this compound on hydrolysis, alcoholysis, or treatment with acetic anhydride occurs under very mild conditions. When 1,1,1-trichlorophosphacyclopentene is treated with sulphur dioxide, a mixture of isomeric 1-chloro-1-oxo-1-phosphacyclopentenes is formed. On the other hand, 1,1,1-tribromophosphacyclopentes do not show a tendency towards the migration of the double bond under similar conditions. This makes it possible to synthesise phosphacyclopentene derivatives with a specified position of the double bond in the ring. It has been shown by proton magnetic resonance spectroscopy and double nuclear magnetic resonance[35] that, of the three possible structures of phosphacyclopentene derivatives based on isoprene, only the first two are actually obtained:



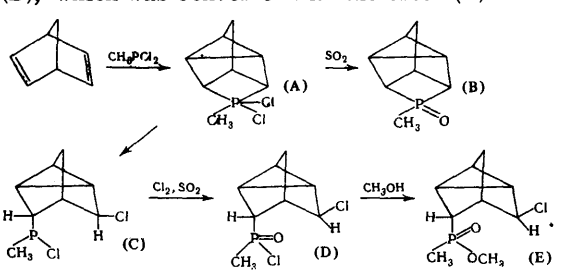
The position of the double bond depends not only on the nature of the halogen and the synthetic pathway but also on the nature of the diene and the symmetry of the distribution of the substituents in the ring. The position of the double bond can be demonstrated by NMR spectra. The application of NMR spectroscopy established that the migration of the double bond from position 3, 4 to position 2, 3 is accompanied by the displacement of one methyl group from the plane of the ring[33]:



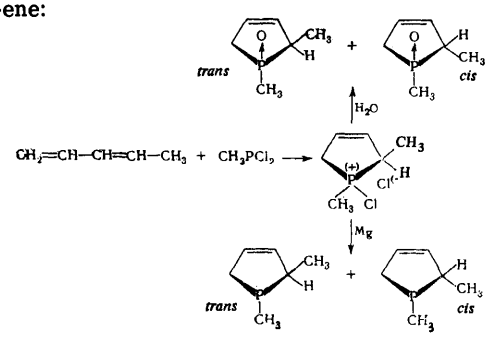
As a result, the phosphorus atom and C_4 become asymmetric. This behaviour is also observed in the reactions of 1,1,1-trihalogenophosphacyclopent-3-ene with orthoesters[36,37]:



When the reactant ratio is equimolar, 1-halogeno-1-oxophosphacyclopentenes are formed. When X = Br, the reaction takes place without migration of the double bond, the final product being 1-alkoxy-1-oxophosphacyclopent-3-ene. With chloro-derivatives, these reactions are accompanied by the migration of the double bond in the ring. Green[38] studied the addition of methyldichlorophosphine to bicyclo[2,2,1]heptadiene, a compound with isolated double bonds. The resulting crystalline adduct (A) yields the phosphine oxide (B) as a result of hydrolysis or under the action of sulphur dioxide. The structure of adduct (A), a substituted nortricyclene, was established by means of chemical conversions and by physical methods. Pyrolysis of the adduct gave the liquid isomer (C); its oxidation with chlorine and sulphur dioxide gave the acid chloride (D), which was converted into the ester (E):



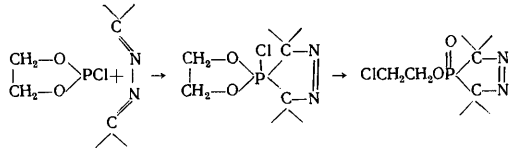
The stereochemistry of phosphacyclopentenes has been inadequately investigated so far. In the reaction of a mixture of the *cis*- and *trans*-forms of piperylene with methyldichlorophosphine followed by hydrolysis of the addition products, Quin and coworkers[39] obtained a mixture of the geometrical isomers of 1,2-dimethyl-1-oxophosphacyclopent-3-ene:



One isomer was isolated in a pure form by means of gas chromatography. The lack of migration of the double bond in the ring during hydrolysis in the suggested reaction mechanism is striking. Probably these reactions

require additional investigation. Reduction of the addition products with magnesium led to two stereoisomeric phosphines. When these are oxidised with hydrogen peroxide, the geometry of the molecules remains unaffected.

Not only hydrocarbons but also compounds with conjugated carbon–nitrogen double bonds can react with phosphorus(III) halides[40,41]. For example the reaction of cyclic phosphorochloridites with acetaldazine takes place by the following mechanism:



The structure of the products was confirmed by infrared and NMR spectroscopy.

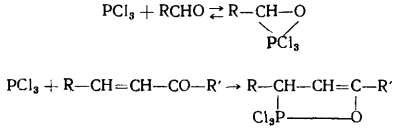
The reactions of phosphorus(III) halides with diene systems open up wide possibilities for the preparation of a great variety of phosphocyclopentene derivatives and other organophosphorus compounds. Compounds of this type are of both theoretical and practical importance. Some of the phosphorus cyclopentene derivatives are recommended as catalysts for the preparation of carbodiimides and carbopolyimides[42,43].

3. Addition of the Chlorides of Phosphorus(III) Acids to αβ-Unsaturated Aldehydes and Ketones

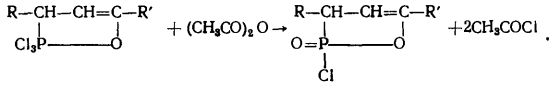
The study of this process was preceded by investigations of analogous reactions with saturated aldehydes and ketones. The results were subsequently used to account for the mechanism of reactions with both saturated and αβ-unsaturated carbonyl compounds; therefore it is useful to consider them briefly in the present review.

The first information about the reactions of aldehydes and ketones with phosphorus trichlorides is to be found in the work of Fossek[44–46] and Michaelis[47–51]. By hydrolysing the addition products, Fossek obtained a series of α-hydroxy-phosphonic acids. In the study of these reactions, Page[52] attempted to isolate the addition of products in a pure form by vacuum distillation, but his attempts failed because of the thermal instability of the products. After hydrolysis of the reaction products, he also isolated α-hydroxy-phosphonic acids. He suggested that the product of the addition of phosphorus trichloride to aldehydes formed initially is an ester of phosphorous acid (A), which subsequently rearranges to compound (B):

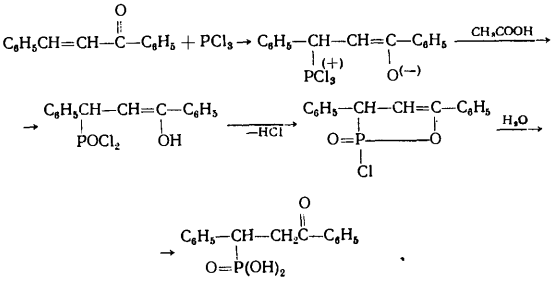
Thorough investigations of the addition of phosphorus trichlorides and certain other phosphorus(III) halides to saturated and unsaturated carbonyl compounds were begun in 1917 by Conant and coworkers[53–64]. In agreement with Michaelis' suggestions, Conant put forward the hypothesis of 1,2-addition of saturated aldehydes and ketones and 1,4-addition of αβ-unsaturated carbonyl compounds with formation of addition products containing three- and five-membered rings respectively:



The products were not isolated in a pure form; their hydrolysis yielded α-hydroxy-phosphonic or γ-oxo-phosphonic acid. Reaction with acetic anhydride gives rise to chlorides of cyclic acids with pentavalent phosphorus:

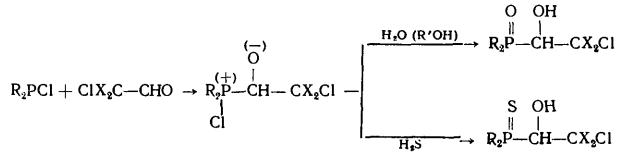


Subsequently, having carried out the reaction in glacial acetic acid, Conant and Wallingford[63] concluded that in the first stage a betaine-like addition product is formed, which is converted into a hydroxy- or oxo-phosphonic acid under the action of acetic acid and in subsequent hydrolysis. For example, for benzylideneacetophenene, these reactions can be described by the following mechanism:



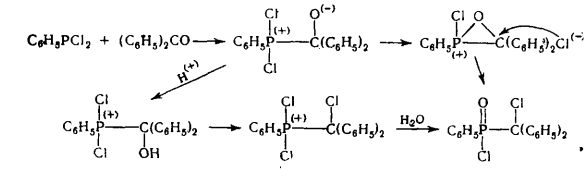
Evidently in this mechanism too the formation of a cyclic product is postulated, but only as a secondary reaction product. Conant's hypothesis concerning the formation in the reactions considered here of betaine-like, dipolar, and cyclic intermediates was widely used in subsequent investigations.

Tsivunin et al.[65], who studied the reactions of dialkyl- and diaryl-chlorophosphines with α-halogeno-aldehydes, suggest that in these reactions there is initial nucleophilic attack on the carbonyl carbon by the phosphorus atom with formation of an adduct in which the phosphorus is sp^3-hybridised. The subsequent decomposition of the complexes with water or alcohols leads to the formation of oxides of dialkyl- or diaryl-α-hydroxyethylphosphines. When the complexes are decomposed with hydrogen sulphide, the corresponding thiones are produced:



where R = C_2H_5 or C_6H_5 and X = H or Cl.

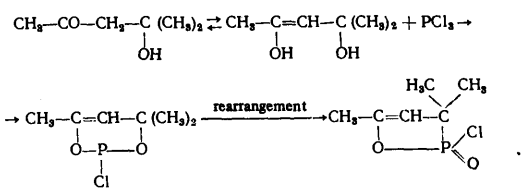
Freeman and Gallagher[66] studied the reaction of phenyldichlorophosphine with benzophenone in the presence of partially hydrated aluminium trichloride. This reaction gave a 65% yield of the chloride of (diphenylchloromethyl)-phenyl phosphinic acid. When the reaction is carried out in the presence of anhydrous aluminium trichloride, the yield of the acid chloride falls. The authors propose the following reaction mechanism:



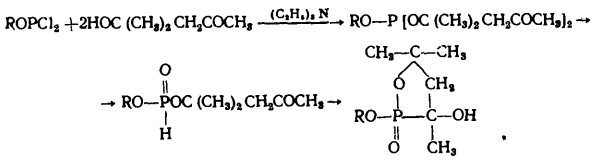
In 1884 Michaelis suggested that a cyclic intermediate, "diacetonephosphorus chloride", forms in the reaction between phosphorus trichloride and acetone in the presence of aluminium trichloride:

In their study of the reaction of phosphorus trichloride with mesityl oxide in the presence of acetic anhydride, Drake and Marvel[67] showed that 4-methylpentan-2-one-4-phosphonic acid forms as a result of the hydrolysis of the reaction product. On this basis, the following formula with a five-membered ring and pentavalent phosphorus was proposed for the "Michaelis chloride" (by analogy with Conant's views):

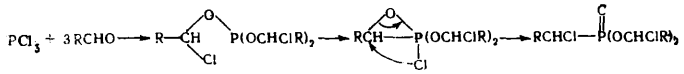
Anschutz et al.[68] and Michaelis[48] believed that diacetone alcohol formed initially and subsequently reacted with phosphorus trichloride to form the "Michaelis chloride":



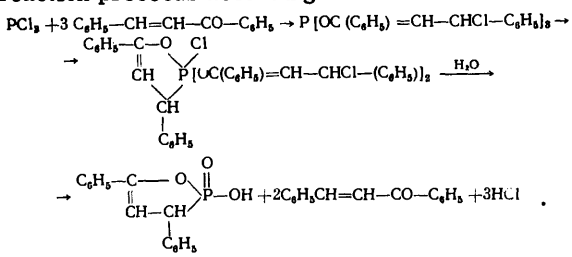
To confirm this mechanism, Anschutz carried out the reaction between phosphorus trichloride and diacetone alcohol. According to his data, the same "Michaelis chloride" is then formed. However, this hypothesis is probably incorrect, since Rizpolozhenskii[69] showed that esters of phosphorous acid are formed in the reaction between diacetone alcohol and monochlorides of phosphorus acids in the presence of a base. The reaction proceeds acccording to the following mechanism:



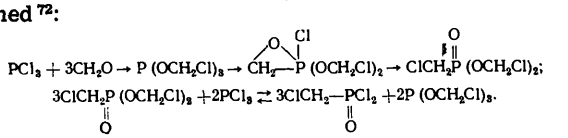
Kabachnik[70,71] believes that the mechanism proposed by Conant for the reaction between phosphorus halides and carbonyl compounds is unlikely because of the difficulty of the first stage, namely alkylation. He thinks that the more probable mechanism, very similar to the mechanism proposed by Page, is one consisting in the formation in the first reaction stage of a tri(α-halogeno-ester) of phosphorous acid, which subsequently undergoes the Arbuzov rearrangement to the ester of α-chloroalkylphosphonic acid:



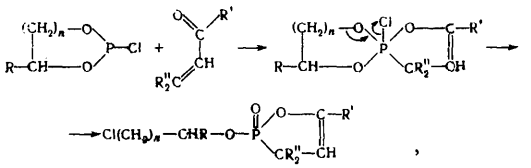
Hydrolysis of the α-chloroalkylphosphonic acid ester of the cyclic intermediate leads to the formation of the α-hydroxyalkylphosphonic acid. With unsaturated ketones, the reaction proceeds according to the mechanism



The validity of these mechanisms was confirmed for a number of examples. Thus in the reaction of phosphorus trichloride with paraformaldehyde in sealed tubes at 250°C, the dichloride of chloromethylphosphonic acid was obtained[72]:

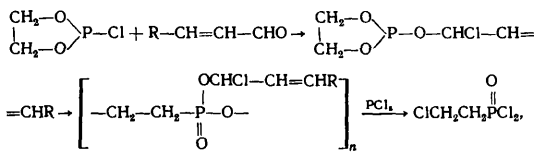


With benzaldehyde, the product was the dichloride of α-chlorobenzylphosphonic acid[73]. Kabachnik and Shepeleva[74] showed that these reactions are common to a wide range of aldehydes. Petrov and coworkers[39,40,75] demonstrated that the reaction of various glycol phosphorochloridites with methyl vinyl ketones or mesityl oxide involve 1,4-addition with subsequent Arbuzov rearrangement of the cyclic intermediate[75]:

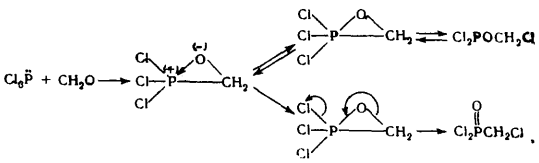


where n = 1 or 2, R = H or CH_3, R′ = CH_3, and R″ = H or CH_3.

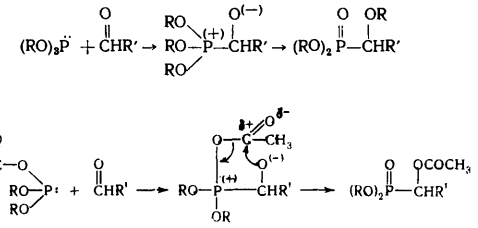
The structure of the final reaction products, isoxaphospholens, was demonstrated by infrared and nuclear and proton magnetic resonance spectroscopy. The reaction of glycol phosphorochloridite with acrolein and crotonic aldehydes leads to oligomeric products[40]. When these oligomers are treated with phosphorus pentachloride, the dichloride of β-chloroethylphosphonic acid is formed:



where R = H or CH_3. Probably the first stage of reactions of this type involves the attack by the nucleophilic phosphorus atom on the electrophilic carbon of the carbonyl group in the saturated aldehyde or the β-carbon atom in the unsaturated ketone. The dipolar ion produced cyclises with simultaneous migration of the P–C and O–C bonds, resulting in ring opening. Depending on the conditions, the rearrangement of the intermediate can lead to the formation of compounds with an ester of phosphorus–carbon bond:



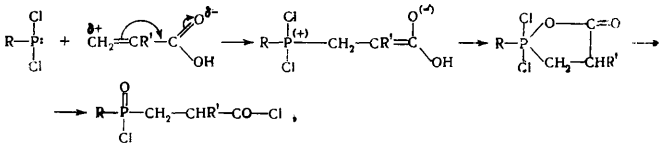
The validity of the suggested first reaction stage, the nucleophilic attack by the three-coordinated phosphorus atom, is confirmed by analogy with numerous reactions between carbonyl compounds and phosphites, which have been investigated in recent years [76]:



In the second reaction R′ can be an alkyl or a chloroalkyl group [77].

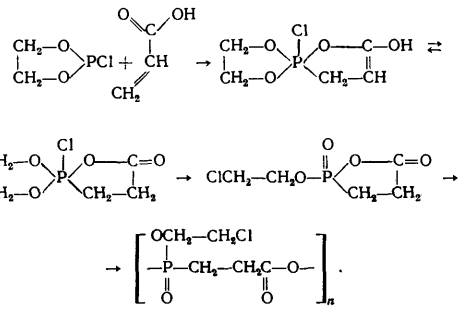
4. Addition of the Chlorides of Phosphorus(III) Acids to αβ-Unsaturated Carboxylic Acids

In 1964 one of the authors of the present review [78] found that, in the reaction between alkyl- or aryl-dichlorophosphines and αβ-unsaturated acids, the chlorides of alkyl- or aryl-(β-chloroformylalkyl)phosphinic acid are formed in good yields:



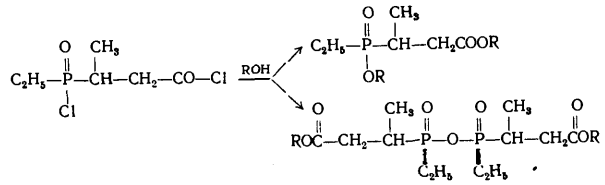
where R = CH_3, C_2H_5, C_6H_5, or C_7H_7 and R′ = H or CH_3.

According to the suggested reaction mechanism, the unshared pair of electrons of the three-coordinated phosphorus atom attacks the most electrophilic β-carbon atom of the αβ-unsaturated acid. The dipolar ion formed is converted into an adduct with a five-coordinated phosphorus atom, which undergoes the Arbuzov rearrangement to form the chloride of alkyl- or aryl-(β-chloroformylalkyl)phosphinic acid [79,80]. In the same year Petrov and coworkers [39] pointed out the possibility of the reaction of glycol phosphorochloridites with acrylic and methacrylic acids. In the reaction between ethylene phosphorochloridite and acrylic acid [40], they obtained an oligomer:

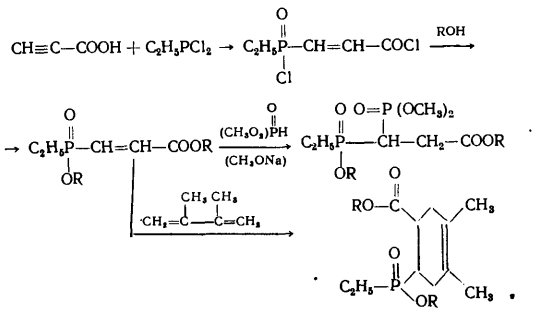


The structure of the oligomer was confirmed by infrared spectroscopy; when it was treated with phosphorus pentachloride, the chloride of dichlorophosphonopropionic acid was obtained.

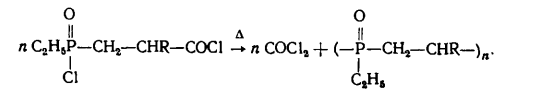
Continuing their investigation of this interesting reaction, the authors of the present review showed that the reaction of ethyldichlorophosphine with crotonic acid leads to the formation of the chloride of ethyl(β-chloroformyl-α-methylethyl)phosphinic acid in 78% yield [81]. When this acid chloride reacts with alcohols, anhydrides of ethyl(β-alkoxycarbonylisopropyl)phosphinic acid are formed together with the esters:



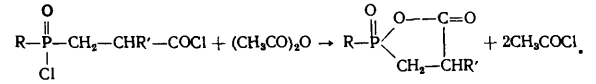
The chloride of ethyl(β-chloroformyl-α-methoxycarbonylethyl)phosphinic acid was obtained by the reaction of ethyldichlorophosphine with the monomethyl ester of maleic acid [82]. On the other hand, under the usual conditions maleic acid itself forms only maleic anhydride; when the reaction mixture is heated in sealed tubes, hydrogen chloride adds to the double bond of maleic anhydride. The reaction of ethyldichlorophosphine with pyromucic and cinnamic acids leads to the formation of considerable amounts of the chlorides of these acids. Evidently in these reactions the β-carbon atom of the acrylic system is blocked by substituents which reduce its positive charge. As a result, the reaction takes place mainly at the carbonyl group. Propiolic acid [83] reacts with ethyldichlorophosphine according to a mechanism similar to that for acrylic acid. The presence of the double bond in the resulting chloride of ethyl(β-chloroformylvinyl)phosphinic acid was confirmed by infrared spectroscopy, by its esterification with subsequent addition to the double bond of dimethyl phosphite esters, and by diene synthesis with 2,3-dimethylbutadiene:



In all cases the yields of the acid chlorides are fairly high when the reaction products are subjected to film distillation in a high vacuum (in the usual vacuum distillation the chlorides are extensively or completely decomposed with the evolution of phosgene and the formation of a polymer):



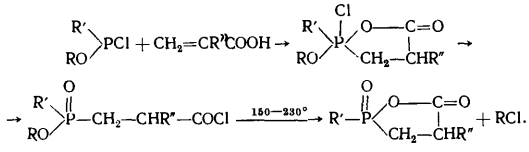
When acetic acid or acetic anhydride react with the chlorides of alkyl- or aryl-(β-chloroformylalkyl)phosphinic acids, cyclic anhydrides are formed:



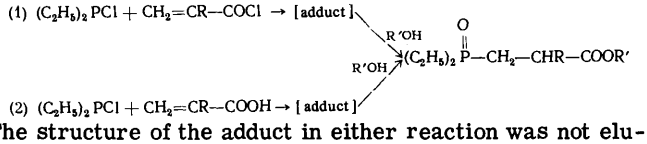
The P–O–C bond in these anhydrides is readily broken under the action of alcohols or amines.

In the reaction with acrylic acid, alkyl phosphorochloridites yield the chlorides of phosphono-carboxylic acids

[RO–P(O)–CH_2CH_2COCl] only when R is a chloro-substituted tertiary alkyl group. Phosphorochloridites with two tertiary chloro-substituted alkyl groups form with acrylic acid the chlorides of dialkylphosphinopropionic acid. Alkyl- or aryl-alkoxychlorophosphines react with $\alpha\beta$-unsaturated acids to form β-phosphono-carboxylic acids, which, on heating to 150–230°C, are converted into cyclic anhydrides with elimination of alkyl chloride:



Tsivunin et al.[85] showed that diethylchlorophosphine reacts with acrylic or methacrylic acid chlorides to form crystalline complexes, which, on treatment with an excess of alcohol, are converted into a dialkylphosphinylcarboxylic acid. The same esters were obtained by treating with alcohol complexes of diethylchlorophosphine with acrylic or methacrylic acids:



The structure of the adduct in either reaction was not elucidated but it is probably (in the second case) the oxide of diethyl(β-chloroformylalkyl)phosphine.

5. Oxidative Chlorophosphination of Unsaturated Compounds

One of the new very interesting and promising methods for the preparation of the dichlorides of alkyl- and chloroalkyl-phosphonic acids is oxidative chlorophosphination of saturated and unsaturated hydrocarbons and their various derivatives. This reaction was described almost simultaneously by Clayton and Jensen[86] in 1948 and by Soborovskii et al.[87] in 1949. (However, in his paper on the oxidative chlorophosphination of hydrocarbons, published in 1952, Graf[88] disputes the priority in the discovery, referring to the patent which he took out in 1942). The oxidative chlorophosphination of unsaturated hydrocarbons was first investigated by Soborovskii and coworkers[87].

The first step in the oxidative chlorophosphination of alkanes and alkenes is the addition of oxygen to phosphorus trichloride with formation of an adduct[88], which may be regarded as the biradical $Cl_3\dot{P}O\dot{O}$ [89,90] or the dipolar ion $Cl_3\overset{(+)}{P}O\overset{(-)}{O}$. In the absence of the hydrocarbon the adduct reacts with a second molecule of phosphorus trichloride, forming phosphorus oxychloride: $Cl_3\dot{P}O\dot{O} + PCl_3 \rightarrow 2POCl_3$. On the other hand, in the presence of the hydrocarbon the dichloride of alkyl- or chloroalkyl-phosphonic acid is formed as the final product:

$$Cl_3\dot{P}O\dot{O} + RH + PCl_3 \rightarrow RP(O)Cl_2 + POCl_3 + HCl,$$

$$Cl_3\dot{P}O\dot{O} + RCH{=}CH_2 + PCl_3 \rightarrow RC_2H_3Cl{-}P(O)Cl_2 + POCl_3.$$

The oxidative chlorophosphination of ethylene, propene, butene, and isobutene has been investigated[87]. When ethylene is used [with the molar ratio $PCl_3 : C_2H_4 = 1 : (3-15)$, at atmospheric pressure, and at a temperature between −140° and −110°C [91-94]], the dichloride of β-chloroethylphosphonic acid forms in yields of up to 80%. In this reaction the solvent may be methyl and ethyl chlorides, methylene chloride, carbon tetrachloride, chloroform, etc. When propene and butene are used in the reactions, a mixture of isomeric dichlorides of chloro-substituted alkylphosphonic acids, differing in the position of the chlorine atom and the $POCl_2$ group, is obtained[95]. There are two reasons for the formation of isomers in these reactions. There is a possibility of different sequences of addition of the chlorine atom and the $POCl_2$ group to the double bond of the olefin, or initially one of the hydrogen atoms of the methylene group is substituted by the $POCl_2$ group with subsequent addition of the resulting hydrogen chloride to the C=C bond. But-2-ene, which does not contain a methylene group, is an exception. Its oxidative chlorophosphination takes place only by the first pathway with formation of the dichloride of 2-chloro-1-methylpropylphosphonic acid. Despite the results of Isbell and Wadworth[96], Zinov'ev and Soborovskii[95] succeeded in isolating in the oxidative chlorophosphination of cyclohexene a mixture of isomeric dichlorides of chlorocyclohexylphosphonic acid. Apart from this mixture, the dichloride of cyclohexenylphosphonic acid formed, as a result of the elimination during distillation of hydrogen chloride from the dichlorides. The oxidative chlorophosphination of cyclohexane and cyclohexane was also studied by American workers[97]. The reactivity of cyclohexane proved to be higher by a factor of 2.3 than the reactivity of cyclohexane. The oxidative chlorophosphination of vinyl chloride, allyl chloride[98,99], 1,2-difluoroethylene, vinyl bromide, vinyl fluoride, 1,2-difluoroethylene, and vinylsulphonyl fluoride[100,101] takes place in most cases with formation of the dichlorides of dihalogeno-substituted alkylphosphonic acids. Their separation presents considerable difficulties but in some cases proved to be possible. Trichloroethylene and tetrachloroethylene do not enter into the oxidative chlorophosphination reaction. In the reaction with vinyl cyanide[102,103] a mixture of isomeric dichlorides of chlorocyanoethylphosphonic acids forms. In view of the impossibility of separating them by fractionation, they were converted into dimethyl esters. One of the esters proved to be liquid and the other crystalline. When oxygen was passed into a mixture of phosphorus trichloride and methyl acrylate[102], the dichloride of β-chloro-α-methoxycarbonylethylphosphonic acid was formed in high yield. In the dehydrochlorination of its esters with the aid of triethylamine, esters of α-alkoxycarbonylvinylphosphonic acid were obtained[104]. The dichloride of (triethylsilyl)chloroethylphosphinic acid was prepared in low yields by the oxidative chlorophosphination of triethylvinylsilane[105]. Acetylenic hydrocarbons react with phosphorus trichloride and oxygen without liberation of free hydrogen chloride[106]. The dichlorides of chloroalkenylphosphonic acids are then formed. The first member of the series (acetylene) reacts with the dichloride β-chlorovinylphosphonic acid to form the tetrachloride of dichloroethylenediphosphonic acid:

$$CH \equiv CH + 2PCl_3 + O_2 \rightarrow CHCl{=}CH{-}P(O)Cl_2 + POCl_3,$$

$$CHCl{=}CH{-}P(O)Cl_2 + 2PCl_3 + O_2 \rightarrow Cl_2\overset{O}{\overset{\|}{P}}{-}CHCl{-}CHCl{-}\overset{O}{\overset{\|}{P}}Cl_2.$$

The yields of the dichlorides, which are low for acetylene, increase for its homologues, hex-1-yne and phenylacetylene, reaching 24%. With vinylacetylene, the reaction takes place only at the triple bond:

$$CH_2{=}CH{-}C \equiv CH + 2PCl_3 + O_2 \rightarrow CH_2{=}CH{-}CCl{=}CH{-}P(O)Cl_2 + POCl_3.$$

Subsequent studies showed that methyl- and ethyl-dichlorophosphines[107,108], phenyldichlorophosphine[109], methyl phosphorodichloridite[110], and diethylaminodichlorophosphine[110] can enter into olefin oxidative chlorophosphination

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

reactions. The reaction products in this case are mixed monochlorides of various acids based on pentavalent phosphorus.

III. REACTIONS OF THE CHLORIDES OF PHOSPHORUS(V) ACIDS WITH UNSATURATED COMPOUNDS

1. Reactions of the Chlorides of Phosphorus(V) Acids with Alkenes

A reaction of phosphorus pentachloride with unsaturated compounds was first described by Marsh and Gardner[111,112] in 1891–1894. They showed that camphene forms a complex compound with phosphorus pentachloride; its hydrolysis leads to camphenylphosphonic acid. In subsequent studies by Harnist[113], Bergman and Bondi[114-117], and other investigators[118-121] this reaction was extended to a large range of ethylenic and acetylenic hydrocarbons; the effect of their structure on the reactivity was established. These investigations were reviewed by Kabachnik[70] in 1947. In subsequent years new data accumulated, the range of application of this reaction was extended, and its mechanism was studied. Woodstock[122,123] and Kosolapoff[184] investigated the mode of addition of phosphorus pentachloride to asymmetric ethylenic hydrocarbons with a terminal double bond. Woodstock treated the complexes formed with phosphorus pentoxide or pentasulphide and obtained the dichlorides of chloroalkylphosphonic or chloroalkylphosphonothionic acids; he assumed that they had the structures $R-CH(POCl_2)CH_2Cl$ and $R-CH(PSCl_2)CH_2Cl$, and accordingly he postulated that the addition of phosphorus pentachloride to asymmetric ethylenes takes place contrary to the Markovnikov rule. Kosolapoff[121,124] showed that Woodstock's conclusions were erroneous. From the complex of phosphorus pentachloride with but-1-ene, he obtained the dichloride which he esterified and converted the product by dehydrochlorination into the ester of an unsaturated phosphonic acid. When this ester was ozonolysed, propionaldehyde was formed. Kosolapoff thus showed that the addition of phosphorus pentachloride to asymmetric olefins takes place in accordance with the Markovnikov rule:

$$RCH{=}CH_2 + 2PCl_5 \rightarrow RCHCl{-}CH_2PCl_4.PCl_5$$

$$\xrightarrow[\text{or } SO_2]{P_2O_5 \text{ or } P_2S_5} \begin{cases} RCH{=}CH{-}PCl_2 \\ \| \\ O \end{cases} \qquad \begin{cases} RCH{=}CH{-}PCl_2 \\ \| \\ S \end{cases}$$

Dibromo- and tribromo-isosafrole[125] and also vinyl and allyl chlorides[126] (at 20°C in benzene) react with phosphorus pentachloride to yield only chlorination products, chlorine adding to the double bond. At 100–110°C under pressure vinyl and allyl chlorides give, together with their double-bond chlorination products, also halogenohydrocarbons with twice as many carbon atoms as the initial olefin.

Kirsanov and coworkers[127,128] made interesting studies on the structure of the complexes formed. Before their investigation, it was assumed (without experimental justification) that the complexes formed from phosphorus pentachloride and olefins are β-chloroalkyltetrachlorophosphoranes $RCHCl-CH_2PCl_4$ or their double salts with phosphorus pentachloride[129-133]. The complexes were not isolated in a pure form. Fedorova and Kirsanov[127,128] were the first to suggest that the reaction of phosphorus pentachloride, which consists in the crystalline state of the tetrahedral cation $P^{(+)}Cl_4$ and the octahedral anion $P^{(-)}Cl_6$, with unsaturated compounds takes place by an ionic mechanism:

$$RCH{=}CH_2 + \overset{(+)}{P}Cl_4 \rightarrow (RCH{-}CH_2PCl_4)^{(+)} \rightarrow HCl + (R{-}CH{=}CH{-}PCl_3)^{(+)} \xrightarrow{\overset{(-)}{PCl_6}} RCH{=}CH{-}\overset{(+)}{P}Cl_3 \cdot \overset{(-)}{P}Cl_6.$$

With styrene as an example, it was shown that the complex formed is $C_6H_5CH{=}CH{-}P^{(+)}Cl_3P^{(-)}Cl_6$. At 70°C its yield was about 70%. The structure of this complex is confirmed by reactions with sulphur dioxide, styrene, and red phosphorus:

$$C_6H_5CH{=}\overset{(+)}{C}HPCl_3 \cdot \overset{(-)}{P}Cl_6{-} \begin{cases} \xrightarrow{2SO_2} POCl_3 + 2SOCl_2 + C_6H_5{-}CH{=}CH{-}P(O)Cl_2 \\ \xrightarrow{C_6H_5CH=CH_2} HCl + 2C_6H_5CH{=}CH{-}PCl_4 \xrightarrow{SO_2} \xrightarrow{P} \\ \xrightarrow{1\frac{1}{3}P} 2\tfrac{1}{3}\,PCl_3 + C_6H_5CH{=}CH{-}PCl_2 \end{cases}$$

Similar complexes were obtained in yields up to 70% when phosphorus pentachloride was allowed to react with the dichlorides of arylphosphonic acids:

$$ArPOCl_2 + 2PCl_5 \rightarrow POCl_3 + \overset{(+)}{ArP}Cl_3 \cdot \overset{(-)}{P}Cl_6.$$

On reduction with red phosphorus, they are converted into aryldichlorophosphines. It was shown, using the reaction of phenyltetrachlorophosphorane with styrene as an example[134], that hydrogen chloride formed in the reaction dissolves in phenylstyryltrichlorophosphorane and can be removed when the latter is reprecipitated from phosphorus oxychloride with petroleum ether or by vacuum distillation:

$$C_6H_5CH{=}CH_2 + C_6H_5\overset{(+)}{P}Cl_3 \rightarrow C_6H_5\overset{(+)}{C}HCH_2(C_6H_5)PCl_3 \xrightarrow{Cl^{(-)}}$$

$$\rightarrow HCl + C_6H_5CH{=}\underset{\displaystyle C_6H_5}{\underset{|}{C}}{-}PCl_3 .$$

Phenylacetylene reacts with phenyltetrachlorophosphorane by a similar mechanism, but the α-carbon atom in the initially formed cation $C_6H_5\overset{(+)}{C}{=}CH{-}P(C_6H_5)Cl_3$ is more firmly bound to the hydrogen, as a result of which the chloride ion adds to the most electropositive β-carbon atom:

$$C_6H_5\overset{(+)}{C}{=}CHP(C_6H_5)Cl_3 \xrightarrow{Cl^{(-)}} C_6H_5CCl{=}CH{-}P(C_6H_5)Cl_3.$$

In the reaction of styryltetrachlorophosphorane with styrene and of β-chlorostyryltetrachlorophosphorane with phenylacetylene[135], distyryltrichlorophosphorane and di-(β-chlorostyryl)trichlorophosphorane were obtained respectively:

$$C_6H_5CH{=}CH{-}PCl_4 + C_6H_5CH{=}CH_2 \rightarrow (C_6H_5CH{=}CH)_2PCl_3 + HCl ,$$

$$C_6H_5CCl{=}CHPCl_4 + C_6H_5C{\equiv}CH \rightarrow (C_6H_5CCl{=}CH)_2PCl_3.$$

The structure of the complexes of phosphorus pentachloride with ethylenic hydrocarbons is consistent with the studies on their reduction. Walsh et al.[136] obtained alkenyldichlorophosphines by reducing complexes of olefins and phosphorus pentachloride with phosphorus in the presence of iodine:

$$3RCH{=}CHPCl_4 + 2P \xrightarrow{I_2} 3RCH{=}CHPCl_2 + 2PCl_3.$$

Kamai et al.[137] also obtained these compounds using antimony:

$$3(CH_3)_2C{=}CH_2 + 6PCl_5 \xrightarrow[-HCl]{} [(CH_3)_2C{=}\overset{(+)}{C}HPCl_3][PCl_6^{(-)}] \xrightarrow{4Sb}$$

$$\rightarrow 4SbCl_3 + 3PCl_3 + 3(CH_3)_2C{=}CHPCl_2.$$

Grechkin and Kalabina regard the reaction between phosphorus pentachloride and olefins as electrophilic substitution of hydrogen, adopting a mechanism[138] very similar to

that proposed by Fedorova and Kirsanov. The authors[138] suggest that a π-complex of the olefin and the cation $P^{(+)}Cl_4$ forms initially and is then converted into a stable complex with elimination of hydrogen chloride: $[RCH{=}CH{-}PCl_3]^+$. The latter reacts with a chloride ion and is converted into an alkenyltetrachlorophosphorane or reacts with the ion $P^{(-)}Cl_6$ to form a saltlike product. It can also form in the reaction between the alkenyltetrachlorophosphorane and phosphorus pentachloride:

$$RCH{=}CH_2 + \overset{(+)}{P}Cl_4 \rightarrow [RCH{-}CH_2PCl_4]^{(+)} \xrightarrow{-HCl} \cdot [RCH{=}CH{-}PCl_3]^{(+)} \xrightleftharpoons{Cl^{(-)}} RCH{=}CH{-}PCl_4$$

$$RCH{=}CH{-}PCl_4 \xrightarrow{PCl_5} \xrightarrow{RCH=CH_2} \xrightarrow{\overset{(-)}{P}Cl_6} [RCH{=}CHPCl_3]^{(+)}[PCl_6]^{(-)}.$$

The reaction between phosphorus pentachloride and acetylenic hydrocarbons has been less investigated. The reaction of phenylacetylene[117,129] with phosphorus pentachloride yields a complex, which, after treatment with sulphur dioxide, gives rise to the dichloride of β-chloro-β-phenylvinylphosphonic acid, while on hydrolysis it is converted into β-chloro-β-phenylvinylphosphonic acid itself:

$$C_6H_5C{\equiv}CH + 2PCl_5 \rightarrow C_6H_5CCl{=}CH{-}\overset{(+)}{P}Cl_3 \cdot \overset{(-)}{P}Cl_6 \xrightarrow{SO_2} C_6H_5CCl{=}CH{-}\overset{O}{\overset{\|}{P}}Cl_2$$

$$\xrightarrow{H_2O} C_6H_5CCl{=}CH{-}\overset{O}{\overset{\|}{P}}(OH)_2$$

p-Nitrophenylacetylene, diphenylacetylene, and phenylethylacetylene do not react with phosphorus pentachloride[117]. However, Bergman and Bondi[117] succeeded in obtaining 2-chloro-3-phenylpropenylphosphonic acid from 1-phenylpropyne and phosphorus pentachloride. They explained this synthesis by postulating that initially 1-phenylpropyne isomerises to 3-phenylpropyne. By analogy with phenylacetylene, it was assumed that the ionic complexes and products obtained from alkynes[105,117] (5-ethoxy- and 5-phenoxy-pent-1-ynes[139]) and phosphorus pentachloride are vinylphosphine derivatives:

$$RC{\equiv}CH + 2PCl_5 \rightarrow RCCl{=}CH\overset{(+)}{P}Cl_3 \cdot \overset{(-)}{P}Cl_6 \xrightarrow{SO_2} RCCl{=}CH{-}\overset{O}{\overset{\|}{P}}Cl_2 .$$

The position of the double bond was not determined. Meisters and Swan[140] observed in the NMR spectrum of the complex of oct-1-yne with phosphorus pentachloride an intense two-proton doublet (δ = 3.8 p.p.m., J = 17 Hz), indicating the presence of a CH_2 group bound to the phosphorus atom. They concluded that the ionic complexes and the substances obtained from them are allylphosphines and not vinylphosphine derivatives as was believed earlier. Not even traces of vinylphosphine derivatives were observed in any of the products even before their purification. The reaction with hexa-1,5-diyne involves only one acetylenic group. The authors assume that a rearrangement takes place after the electrophilic addition of $\overset{(+)}{P}Cl_4$ and then $\overset{(-)}{Cl}$ to the triple bond:

$$RCH_2C{\equiv}CH \xrightarrow{\overset{(+)}{P}Cl_4} \left[RCH_2{-}\overset{(+)}{C}{=}CHPCl_4\right] \xrightarrow{\overset{(-)}{Cl}} RCH_2{-}CCl{=}CHPCl_4 \rightleftarrows$$

$$\rightleftarrows \left[RCH{=}CCl{=}CHPCl_4\right]^{(-)} + H^{(+)} \rightleftarrows RCH{=}CCl{-}CH_2{-}PCl_4 .$$

Alternatively they assume that a rearrangement may occur in the carbonium ion with formation of an intermediate allene derivative. The migration of the chlorine atom from the phosphorus to the positively charged carbon can then complete the reaction:
