According to Baxendale et al.[46], the rate constant is $k = 1.8 \times 10^9 \exp(-10\,000/RT)$ litre mole^{-1} s^{-1}. In the oxidation of benzene with Fenton's reagent the benzene molecule is attacked by hydroxy-radicals. The oxidation products are phenol and biphenyl (in the presence of oxygen, biphenyl does not form). In the first studies on the oxidation of benzene[33,37] the following reaction mechanism was put forward:

$$PhH + HO^{\cdot} \rightarrow Ph^{\cdot} + H_2O,$$
$$Ph^{\cdot} + Fe^{3+} + HO^{-} \rightarrow PhOH + Fe^{2+},$$
$$Ph^{\cdot} + Ph^{\cdot} \rightarrow Ph{-}Ph.$$

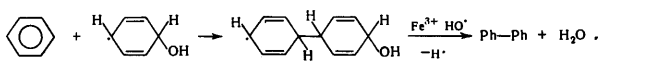
If the oxidation involves the removal of a hydrogen atom from the benzene molecule, an isotope effect should be observed in the oxidation of deuteriated benzene. However, there is no isotope effect in the oxidation of benzene with Fenton's reagent[41]. Dixon and Norman[45] investigated by the ESR method the free radicals formed in the systems H_2O_2–Ti^{3+} and H_2O_2–Ti^{3+}–benzene and established that in the presence of benzene hydroxyl radicals vanish and new radicals appear, to which the following structure is attributed:

i.e. hydroxyl radicals add to benzene. The existence of the above radicals was also demonstrated spectroscopically[47]; the rate constant for the addition of HO$^{\cdot}$ to benzene has been calculated as 4.3×10^9 litre mole^{-1} s^{-1} (at 23°C). The high rate of addition of free hydroxy-radicals to benzene and the absence of an isotope effect are evidence that the oxidation of benzene with Fenton's reagent begins with the addition of OH$^{\cdot}$ to the benzene molecule:

$$C_6H_6 + HO^{\cdot} \rightarrow C_6H_6OH^{\cdot}.$$

The radical $C_6H_6OH^{\cdot}$ is then oxidised to phenol by the reaction with Fe^{3+} and HO$^{\cdot}$. Together with the oxidation to

phenol, this radical probably interacts with benzene and the product of such interaction is oxidised to biphenyl:



In the presence of oxygen the radical $C_6H_7O^{\cdot}$ is oxidised to phenol by the reaction with O_2 and this reaction is probably so fast that it successfully competes with the addition of $C_6H_7O^{\cdot}$ to benzene; this is why biphenyl does not form in the presence of oxygen. However, one cannot exclude the possibility that, as the temperature is raised, the reaction involving the "adhesion" of $HO^{\cdot}$ to benzene begins to be accompanied to a slight extent by the reaction involving the abstraction of a hydrogen atom. This is shown by the increase of the isotope effect: $k_H/k_D = 1.25$ (at 20°) and $k_H/k_D = 1.37$ (at 70°C) in the oxidation of a mixture of ordinary and deuteriated benzene with Fenton's reagent[48].

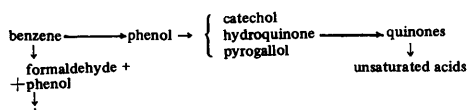
Aromatic compounds can be hydroxylated not only with Fenton's reagent but also with systems such as $Fe^{2+}-O_2$ and $Ti^{3+}-O_2$, but in such systems the hydroxylating agent is not $HO^{\cdot}$ but probably[49] the $HO_2^{\cdot}$ radical. For example, in the hydroxylation of *N*-acetanilide with the reagent hydrogen peroxide–iron(II) complex of EDTA (in this system the reactive species is $HO^{\cdot}$) the following mixture of isomeric *N*-acetamidophenols is obtained: *ortho*-isomer 46.5%, *meta*-isomer 2.5%, and *para*-isomer 51%. On the other hand, hydroxylation of *N*-acetanilide by the system $Fe^{2+}-O_2$ or $Ti^{3+}-O_2$ leads to a mixture of 35% of the *ortho*-isomer, 33% of the *meta*-isomer, and 32% of the *para*-isomer. This is evidence that *N*-acetanilide molecules are not attacked by hydroxy-radicals but by another species (for example $HO_2^{\cdot}$ radicals).

IV. RADIATION-CHEMICAL AND PHOTOCHEMICAL OXIDATION OF BENZENE

Much work has been done on the oxidation of benzene in aqueous solutions initiated by radiation of various kinds[50–71]. When a solution of benzene in water containing Fe^{3+} ions is irradiated with the light of the mercury lamp ($\lambda = 313$ nm), phenol, biphenyl, and Fe^{2+} ions are formed[50]. The addition of Cu^{2+} ions reduces the fraction of biphenyl. A mechanism has been suggested in which the hydroxy-radical removes a hydrogen atom from the benzene molecule. The results of the oxidation of benzene with Fenton's reagent convincingly demonstrate the addition of $HO^{\cdot}$ to benzene. Therefore the following mechanism can be suggested for the oxidation of benzene by Fe^{3+} ions:

$$Fe^{3+}_{aq} + h\nu \rightarrow Fe^{2+} + H^+ + HO^{\cdot},$$
$$HO^{\cdot} + C_6H_6 \rightarrow C_6H_7O^{\cdot},$$
$$C_6H_7O^{\cdot} + Fe^{3+} \rightarrow C_6H_5OH + Fe^{2+} + H^+,$$
$$C_6H_7O^{\cdot} + Cu^{2+} \rightarrow C_6H_5OH + Cu^{1+} + H^+,$$
$$C_6H_7O^{\cdot} + C_6H_6 \rightarrow HOC_6H_6{-}C_6H_6 \xrightarrow{Fe^{3+}} C_6H_5{-}C_6H_5 + H_2O + Fe^{2+} + H^+.$$

The oxidation of benzene in aqueous solution in an ultrasonic field yields phenol, which readily reacts further by the mechanism[52]

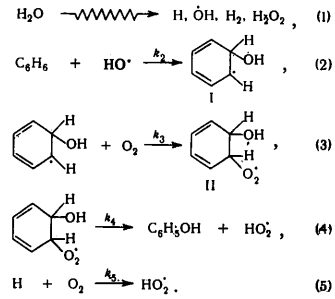


The radiolysis of aqueous benzene solutions under the action of cobalt-60 γ-rays has also been investigated[54–64]. At room temperature in the absence of oxygen oxidation in the two-phase system benzene–water takes place due to the water radiolysis product – H_2O_2, $HO^{\cdot}$, and $HO_2^{\cdot}$. The yields of phenol are slight: 2.64–2.94 m mole litre^{-1} kr^{-1}.[54,55] In the presence of oxygen the radiation-yield of phenol increases and reaches $G = 2$ molecules/100 eV. Proskurin and Barelko[55] established for the first time that the addition of Fe^{2+} or Fe^{3+} ions increases the yield of phenol to $G = 6$ and investigated the oxidation of benzene (under the action of γ-rays at an oxygen pressure of 10 atm) over a wide temperature range, between 20° and 220°C. The main products of the radiolysis of water–benzene mixtures (water : benzene = 32 : 1) under these conditions are phenol and a resin. The maximum yield of phenol at 200°C is 0.035 M with simultaneous formation of 0.025 M resin. The resin contains both phenolic derivatives and polyphenyls. Above 200°C the yield of phenol falls. When irradiation is stopped, the reaction continues with self-acceleration. The authors suggest that at high temperatures the oxidation of benzene is a branched-chain process.

The oxidation of benzene with X-rays yields phenol, biphenyl (in the absence of oxygen), hydrogen peroxide[68], and dialdehydes[69]. In the absence of oxygen the radiation yields G of the main oxidation products are 0.34 for phenol, 0.55 for biphenyl, 0.60 for hydrogen, and more than 0.60 for hydrogen peroxide. In the presence of oxygen or Fe^{2+} and Cu^{2+} ions the yield of phenol increases.

It has been shown[69] that phenol and dialdehydes are formed at the same time and approximately in the same amounts: G(phenol) = 1.8 and G(dialdehydes) = 1.5.

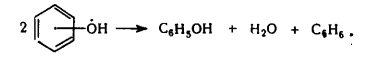
Let us now consider the mechanism of the radiolysis of aqueous benzene solutions[62,69]:



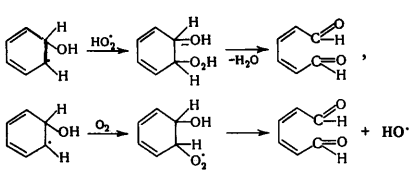
Reaction (2) is faster than reaction (3). Dorfman et al.[62] measured the rate constants k_2 and k_3 at 23°C:

$$k_2 = (4.3 \pm 0.9) \times 10^9 \text{ litre mole}^{-1}\text{ s}^{-1},$$
$$k_3 = (5.0 \pm 0.6) \times 10^9 \text{ litre mole}^{-1}\text{ s}^{-1}.$$

The mechanism shows that phenol forms by the oxidation with oxygen of radicals (I) and that at the same time the radicals disproportionate[41,69]:



It is more logical to assume that reactions (3) and (4) take place in one stage. The formation of dialdehyde together with phenol can take place by the following hypothetical reactions[64,70]:

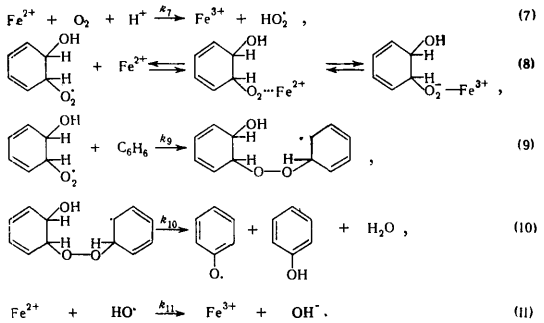


Thus, regardless of the source of radiation, the oxidation of benzene is initiated by the water radiolysis products HO· and $HO_2^·$. The mechanism of the oxidation of benzene is similar to that of the oxidation by Fenton's reagent: an HO· radical adds to benzene and the resulting radical is then oxidised with oxygen to phenol and other products. Some workers believe[71] that the oxidation of benzene under the action of radiation is suitable for the manufacture of phenol, particularly when iron ions are added. However, a considerable disadvantage of the radiation-chemical oxidation is the formation of a large amount of resins by the condensation of phenol and side products. Catechol, hydroquinone, hydroxybenzoic acids, maleic acid, and other compounds are formed in small amounts together with the resins.

As already noted several times, the addition of Fe^{2+}, Fe^{3+}, and Cu^{2+} ions in small amounts (at concentrations between 10^{-4} and 10^{-3} M) in the radiation-induced oxidation of benzene greatly increases the yield of phenol. Quite recently a group of Japanese investigators used the catalytic effect of iron and copper ions for the radiation-catalytic oxidation of benzene[72-79]. Benzene was oxidised in aqueous solutions of $FeSO_4$, $FeCl_2$, $CuCl_2$, and $Fe_2(SO_4)_3$ at concentrations between 10^{-4} and 0.1 M. At an oxygen pressure of 30 atm the reaction mixture was irradiated with cobalt-60 γ-rays for 25 min at different temperatures ranging from 100° to 200°C. When the reaction is carried out in the presence of Fe^{2+} ions, the maximum yield of phenol is 27 mg per ml of benzene, i.e. 2.5%. In the presence of Cu^{2+} ions, 1 ml of benzene yields 40 mg of phenol, i.e. 3.7% relative to the initial benzene. Biphenyl is not formed in the presence of iron and copper ions. It has been established that ferrous sulphate ensures a high yield of phenol both with and without γ-irradiation. In catalysis by Fe^{3+} ions considerable amounts of phenol are formed only on γ-irradiation; without it the yield of phenol is appreciable only at high temperatures (in excess of 180°C). In catalysis by cupric sulphate the yield of phenol is fairly high, both with and without irradiation[74] above 180°C. The catalytic effect of iron and copper chlorides is less than that of the corresponding sulphates[73,74]. The reaction is greatly influenced by the purity of the benzene; impurities such as toluene and thiophen increase the yield of phenol[75]. The addition of SO_4^{2-} ions greatly reduces the amount of phenol formed. When copper filings are introduced into the reaction vessel, the yield of phenol increases. An increase of the concentration of cupric sulphate from 10^{-4} M to 10^{-2} M at 198°C also increases the yield of phenol.

Phenol is the main reaction product but dihydroxybenzenes and also carbon dioxide, acetaldehyde formaldehyde, acetone, acetic acid, formic acid, and maleic acid are formed with it in small amounts (about 10^{-4} M).[77] All these compounds are formed as a result of the oxidation of phenol[76]. This conclusion was arrived at after the investigation of the products of the oxidation of phenol under the same conditions as those in the oxidation of benzene. All the compounds enumerated above were detected in the oxidation of phenol.

The study of the migration of oxygen with the aid of oxygen-18 shows that oxygen is incorporated into phenol both from water[78] and from O_2. In the oxidation of an equimolar mixture of benzene and hexadeuteriobenzene isotope analysis yielded $k_H/k_D = 1.2$. The low isotope effect suggests that a hydrogen atom is removed not from the benzene molecule but from a free radical, for example $\dot{C}_6H_6OH$. On the basis of experimental and literature data, Japanese investigators have suggested a mechanism for the oxidation of benzene under the action of γ-irradiation and in the presence of iron and copper ions. Without reservations, they extend the mechanism of radiation-induced initiation [reactions (1)–(5)], adopted for room temperature, to the high-temperature range:



(7)

(8)

(9)

(10)

(11)

At 25°C and pH 2 $k_{11} = 2.6 \times 10^8$ litre mole^{-1} s^{-1}.[80] It has been stated[81] that at 25°C k_2 is greater by a factor of 3.2 than k_{11}.

$$Fe^{2+} + H_2O_2 \xrightarrow{k_{12}} Fe^{3+} + OH^- + HO· . \quad (12)$$

At 150°C $k_{12} = 6.6 \times 10^{-3}$ litre mole^{-1} s^{-1} and is therefore smaller than k_2.[82] If the catalyst is Fe^{3+} or Cu^{2+} ions, then reaction (13) is the initiating process:

$$Fe^{3+} + H_2O \rightarrow Fe^{2+} + H^+ + HO· . \quad (13)$$

In a number of studies the possibility of this reaction has been demonstrated[83,84]. According to the above mechanism, the role of the Fe^{2+} ion is determined by reaction (7), which leads to the formation of $HO_2^·$ radicals. It is also suggested that Fe^{2+} ions stabilise the peroxy-radicals by reaction (8) and make possible the occurrence of reaction (9). As mentioned above, the reaction of $C_6H_7O·$ radicals with O_2 takes place in one step. Therefore reactions (8)–(10) seem to be extremely unlikely and are superfluous in the mechanism. The inhibiting effect of Cl^- on the oxidation of benzene can be accounted for by the destruction of HO· radicals by the reaction

$$Cl^- + HO· \xrightarrow{k_6} Cl· + OH^- . \quad (6)$$

At 25°C $k_6 = 1.8 \times 10^8$ litre mole^{-1} s^{-1} (at pH 2). In 0.8 N sulphuric acid k_6 is greater by a factor of eight[80], while $k_2 = (4.3 \pm 0.9) \times 10^9$ litre mole^{-1} s^{-1} at 23°C. If the same temperature variation of k_2 and k_6 is assumed, then reactions (1) and (6) may compete at high temperatures.

Japanese investigators believe the oxidation of benzene to be a branched-chain process and on the basis of literature data[85] suggest the following branching mechanism:

$$PhO· + PhH \rightarrow PhOH + Ph· , \quad (14)$$

$$Ph· + O_2 \rightarrow PhO_2^· , \quad (15)$$

$$PhO_2^· + PhH \rightarrow PhO_2H + Ph· , \quad (16)$$

$$PhO_2H + Fe^{3+} \rightarrow PhO_2^· + Fe^{2+} + H^+ , \quad (17)$$

$$PhO_2H + Fe^{2+} \rightarrow PhO· + Fe^{3+} + OH^- , \quad (18)$$

$$PhO_2H = PhO· + HO· . \quad (19)$$

This mechanism is open to a number of significant objections. Reaction (14) cannot occur at an appreciable rate, since PhO· radicals show little activity and the C–H bond in benzene is strong. The reaction is endothermic (–17 kcal mole^{-1}) and cannot compete successfully to any extent with other reactions of phenoxy-radicals, such as

oxidation and addition to benzene. The hydroperoxide PhOOH does not exist as a molecular compound (particularly at a high temperature). Therefore all the reactions involving its participation must be excluded. The mechanism of the acceleration of the oxidation of benzene in the presence of iron and copper ions is discussed in greater detail in the section dealing with the catalytic oxidation of benzene.

V. INITIATED LIQUID-PHASE OXIDATION OF BENZENE

Various methods for the oxidation of benzene in aqueous solutions were discussed above. It has been shown[86,87] that the oxidation of liquid benzene to phenol under pressure below the critical temperature (t_{cr} = 288°C) is possible in principle. The oxidation was carried out in an autoclave at 230–270°C and a pressure of 50 atm. The oxidation results in the formation of phenol and resins.

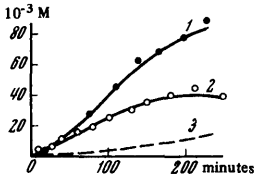


Figure 1. Kinetic curves for the accumulation of phenol at 250°C: *1*) in the experiment with continuous initiation by nitrogen dioxide; *2*) in the experiment with initial 40 min gas-phase initiation; the dashed curve indicates the accumulation of phenol in the experiment without initiation.

Table 2. Initiated oxidation of benzene.

t, °C	Conditions	Rate of formation of phenol, 10^{-3} mole litre min^{-1}	Phenol, mole %	Degree of oxidation, wt. %
250	No additive	0.07	0.16	0.7
230	2% C_6H_{12}	0.18	0.23	6.5
250	1% $C_6H_{10}O$	1.70	0.50	6.0
250	NO_2 continuous	0.49	0.80	5.3
250	NO_2 40 min	0.23	0.33	2.0
250	NO_2 + 1% C_6H_{12}	0.31	0.48	2.7
267	NO_2 continuous	0.88	1.10	4.0

The reaction takes place with self-acceleration, the concentration of phenol tending to a limit during the reaction. In the absence of initiating effects the maximum concentration of phenol at 250°C is 1.8×10^{-3} M and is attained 6 h after the start of the reaction. The oxidation of benzene can be stimulated by the introduction of readily oxidisable substances (cyclohexane, cyclohexanone) and by passing through the system nitrogen dioxide (gaseous initiator) together with air. Fig. 1 presents kinetic curves for the accumulation of phenol in experiments with nitrogen dioxide (2% NO_2 in the 1 : 1 N_2–O_2 mixture). Nitrogen dioxide accelerates the reaction and increases the amount of phenol formed. The results of the experiments are presented in Table 2.

The available data are so far insufficient for the discussion of a concrete mechanism of liquid-phase oxidation of benzene. However, the observed features of the kinetics indicate a free-radical oxidation mechanism (possibly of a chain type). These include the accelerating effect on the oxidation of benzene of the addition of substances readily oxidisable by a chain mechanism such as cyclohexane and cyclohexanone, the powerful effect of nitrogen dioxide which accelerates the oxidation of other hydrocarbons, and the S-shaped kinetic curves for the accumulation of phenol, which is a characteristic of chain auto-oxidation reactions. It should be noted that the oxidation of benzene is a self-inhibiting process, as shown by experiments where the initiation of this reaction by nitrogen dioxide was interrupted (Fig. 1).

VI. CATALYTIC OXIDATION OF BENZENE IN AQUEOUS SOLUTION

The possibility of the oxidation of benzene in aqueous solution at 170–200°C in the presence of iron and copper ions was established by Japanese investigators, who obtained interesting experimental data on this process[72-79,88].

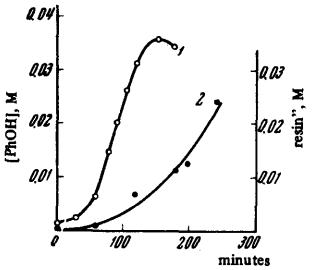

Figure 2. Kinetic curves for the accumulation of phenol (curve *1*) and resins (curve *2*) at 200°C and an air pressure of 35 atm in the presence of 0.012 M Cu^{2+} and 5 ml of benzene; the content of the $C_6H_4O_4$ resins (mole $litre^{-1}$) is plotted.

A detailed study of the kinetics and mechanism of this reaction has been made[89-94]. Benzene dissolved in water (at 185°C the solubility of benzene in water is 0.21 mole $litre^{-1}$) was oxidised with oxygen in an autoclave under pressure. In the presence of iron and copper ions benzene was scarcely oxidised at 185–200°C; Co^{2+}, Mn^{2+}, and Ti^{3+} ions do not catalyse the oxidation of benzene. In the presence of copper and iron ions benzene was oxidised fairly rapidly with formation of phenol. An appreciable quantity of phenolic resin with the elemental composition $C_6H_4O_4$ (Fig. 2) and a small amount of low-molecular products (acetaldehyde, formaldehyde, acetone, acetic acid, and carbon dioxide) were formed together with phenol[92]. The low-molecular products are formed as a result of the oxidation of phenol[76]. The catalytic oxidation of benzene is an autocatalytic reaction[89,92] (Fig. 2). The kinetics of phenol accumulation obey the equation for autocatalysis of the second kind: $dx/dt = k(1 - x)x^2$, where $x = [C_6H_5OH]/[C_6H_5OH]_{max}$. Phenol is an intermediate in this reaction, as can be clearly seen from experiments in which various

amounts of phenol were introduced into the initial benzene (Fig. 3). If the initial concentration of phenol is less than the maximum concentration, phenol accumulates, but if it is greater the concentration of phenol falls. It follows from the kinetic curve for the accumulation of phenol and the resin (Fig. 2), that the latter does in fact form as a result of the oxidation of phenol. Experiments with the introduction of phenol at the beginning of the reaction (Fig. 4) showed that phenol is the main product responsible for the autocatalysis of the reaction[92]. Surprisingly, the accumulation of phenol accelerates the oxidation of the initial benzene (usually in hydrocarbon oxidation reactions phenol behaves as an inhibitor).

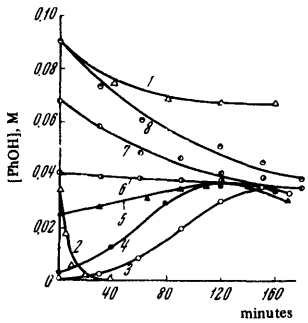

Figure 3. Kinetic curves for the accumulation and consumption of phenol at 200°C and a pressure of 35 atm (50% O_2) in the presence of 0.0125 M $CuSO_4$:
1) oxidation of phenol in benzene; *2*) oxidation of phenol in aqueous cupric sulphate without benzene; *3*)-*8*) kinetic curves for the accumulation and consumption of phenol in aqueous cupric sulphate solution in the presence of benzene (5 ml) in experiments with initial addition of phenol.

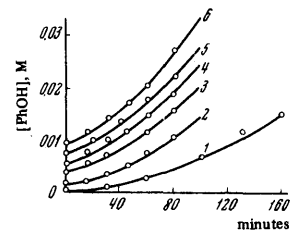

Figure 4. Initial sections of the kinetic curves for the accumulation of phenol at 200°C at pH 1.2 in the presence of 5 ml of benzene and 90 ml of 0.006 M Fe^{3+} solution and different concentrations of added phenol (M):
1) no phenol added; *2*) 0.0018; *3*) 0.0046; *4*) 0.0057; *5*) 0.0074; *6*) 0.0100.

It has been established for iron ions that during the reaction their valence state changes. If trivalent iron is introduced into the initial benzene solution in water, then divalent iron appears and accumulates in the reaction, and conversely. The oxidation in the presence of copper ions is accelerated when a copper plate is introduced into the reactor, metallic copper dissolving during the reaction, i.e. the appearance in the system of copper(I) ions at a certain rate (formed by the reaction $Cu^0 + Cu^{2+} \rightarrow 2Cu^+$) stimulates the oxidation process. There is no doubt that oxidation-reduction reactions with participation of lower- and higher-valence ions play an important role in the catalytic oxidation of benzene.

The kinetics of the oxidation of benzene in the presence of iron and copper ions are very similar[89,90]. As the concentration of benzene increases, the maximum reaction rate w_{max} passes through a maximum, and the maximum concentration of phenol $[PhOH]_{max}$ increases linearly. With increase in the partial pressure of oxygen, both $[PhOH]_{max}$ and w_{max} increase. As the concentration of the catalyst is raised, w_{max} passes through a maximum and $[PhOH]_{max}$ increases in the presence of Cu^{2+} ions. An increase of the concentration of hydrogen ions entails a decrease of the reaction rate. Anions such as F^-, Cl^-, Br^-, CH_3COO^-, and SO_4^{2-} lower both the rate of accumulation of phenol and $[PhOH]_{max}$. Hydrocarbons (cumene, cyclohexene) and alcohols (isopropyl alcohol, cyclohexanol), introduced in an amount of 2% of the initial benzene, retard the oxidation of benzene. The maximum yield of phenol relative to benzene consumed (57%) was obtained in an experiment performed under the following conditions: 200°C, 0.012 M Cu^{2+}, 5 ml of benzene per 100 ml of water, duration 2 h, and P_{O_2} = 17.5 atm. The extent of reaction was 66%.

The mechanism of the oxidation of benzene in this reaction proved to be closely related to the mechanism of the oxidation of phenol and to the valence changes. Therefore a detailed study was made[93] of the oxidation of phenol under conditions similar to those in the oxidation of benzene and also of the oxidation of iron(II) ions. It was found that at 200°C in aqueous solution phenol is oxidised in three different ways: by reaction with molecular oxygen, by reaction with iron(III) ions, and by reaction with free radicals ($HO^\cdot$ and $HO_2^\cdot$).

Molecular phenol and phenoxide ions react with oxygen:

$$PhOH + O_2 \xrightarrow{k_0'} PhO^\cdot + HO_2^\cdot , \qquad (0')$$

$$PhOH + H_2O \rightleftarrows PhO^- + H_3O^+ ,$$

$$PhO^- + O_2 \xrightarrow{k_0''} PhO^\cdot + O_2^{-\cdot} , \qquad (0'')$$

$$O_2^{-\cdot} + H^+ \rightleftarrows HO_2^\cdot ,$$

$$PhOH + HO_2^\cdot \rightarrow PhO^\cdot + H_2O_2 ,$$

$$PhO^\cdot + O_2(HO_2^\cdot) \rightarrow \text{products of further oxidation}$$

(K_0 is the equilibrium constant).

It has been established experimentally that at 200°C $w = 2k[PhOH][O_2]$, $2k = a + b[H^+]^{-1}$, $a = (1.13 \pm 0.17) \times 10^{-5}$ litre mole^{-1} s^{-1}, and $b = (2.9 \pm 0.3) \times 10^{-6}$ s^{-1}. Comparison with the mechanism yields $\frac{1}{2}a = k_{0'}$ and $\frac{1}{2}b = K_0 k_{0''}$.

The reaction between phenol and Fe^{3+} ions was investigated under pressure in an atmosphere of argon. It was established that the reaction rate $w = k[PhOH][Fe^{3+}][H^+]^{-1}$ and $k = (3.5 \pm 0.2) \times 10^{-4}$ s^{-1} at 200°C.

It is suggested that the oxidation takes place according to the reaction

$$PhO^- + Fe^{3+} \rightarrow Fe^{2+} + PhO^\cdot \xrightarrow{Fe^{3+}} \text{molecular products.}$$

At 200°C Fe^{2+} ions (these were introduced in the form of Mohr's salt) are oxidised at the rate

$$w = (4.25 \cdot 10^{-3} + 9.0 \cdot 10^{-5}\,[H^+]^{-1})\,[Fe^{2+}]\,[O_2] \text{ mole litre}^{-1}\,\text{s}^{-1}.$$

According to the literature[95-103], the mechanism of the oxidation of Fe^{2+} ions is as follows

$$Fe^{2+} + O_2 \xrightarrow{k_2'} Fe^{3+} + O_2^- , \qquad (2')$$

$$Fe^{2+}\,aq \rightleftarrows FeOH^+ + H^+ ,$$

$$FeOH^+ + O_2 \xrightarrow{k_2''} FeOH^{2+} + O_2^- , \qquad (2'')$$

$$O_2^- + H^+ \rightleftarrows HO_2^\cdot ,$$

$$Fe^{2+} + HO_2^\cdot \rightarrow Fe^{3+} + HO_2^- ,$$

$$HO_2^- + H^+ \rightleftarrows H_2O_2 ,$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^\cdot + OH^- ,$$

$$Fe^{2+} + HO^\cdot \rightarrow Fe^{3+} + OH^- .$$

Reactions (2′) and (2″) constitute the rate-limiting stage. Subsequent reactions with participation of $HO^\cdot$, HO_2, and H_2O_2 are very rapid and the concentrations of the reacting species (radicals and hydrogen peroxide) correspond to kinetic equilibrium. Since one oxygen molecule oxidises ultimately four Fe^{2+} ions, the rate of oxidation of Fe^{2+} according to the mechanism is $w = 4k_{2'}[Fe^{2+}][O_2] + 4k_{2''}K_2[Fe^{2+}][O_2][H^+]^{-1}$. Comparison with the experimental relations yields (for 200°C) $k_{2'} = 1.06 \times 10^{-3}$ litre mole^{-1} s^{-1} and $k_{2''}K_2 = 2.25 \times 10^{-5}$ s^{-1}. Sulphate ions accelerate the oxidation of Fe^{2+}.

The radicals $HO^\cdot$ and $HO_2^\cdot$, formed in the reactions of O_2 with Fe^{2+} and phenol, react with phenol. Therefore the mechanism for the oxidation of phenol can be represented by the following set of reactions (r$^\cdot$ is a general symbol for an active radical):

$$PhOH + O_2 \xrightarrow{k_0'} PhO^\cdot + HO_2^\cdot ,$$

$$PhO^- + O_2 \xrightarrow{k_0''} PhO + O_2^- ,$$

$$Fe^{2+} + O_2 \xrightarrow{k_2'} Fe^{3+} + r^\cdot ,$$

$$FeOH^+ + O_2 \xrightarrow{k_2''} FeOH^{2+} + r^\cdot ,$$

$$Fe^{2+} + r^\cdot \xrightarrow{k_3} Fe^{3+} + r^- ,$$

$$PhOH + r^\cdot \xrightarrow{k_4} PhO^\cdot + rH .$$

According to this mechanism, the rate of oxidation of phenol is

$$w = (k_0[O_2] + k_1[Fe^{3+}] + k_4[r^\cdot])[PhOH].$$

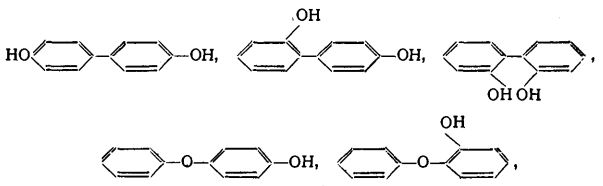
Table 3. Contribution of various reactions to the overall rate of oxidation of phenol at 200°C.

$[O_2]$, M	$[H^+]^{-1}$, litre mole^{-1}	$10^3[Fe^{3+}]$, M	$2 \times 10^5 k_0 \times [O_2]$, s^{-1}	$10^5 k_1 \times [Fe^{3+}]$, s^{-1}	$10^5 k_1 \times [r^\cdot]$, s^{-1}	$\frac{10^5 w}{[PhOH]}$, s^{-1}
0.22	12.6	2.2	1.05	0.97	0.73	2.75
0.22	12.6	1.1	1.05	0.48	0.47	2.00
0.22	12.6	0.5	1.05	0.22	0.03	1.30
0.22	12.0	0.9	0.88	0.38	0.50	1.76
0.44	6.0	17.0	1.20	4.10	5.70	11.00
0.22	52.4	0.2	3.00	0.36	0.81	4.17

Table 3 lists the rates of each of the three phenol consumption reactions for experiments with different initial conditions[93] and shows that the contribution of free-radical reactions ranges from 2 to 50% (in different experiments).

The reaction of hydroxy-radicals with phenol in aqueous solutions has been investigated[62,104-108]. Dixon and Norman[104] obtained hydroxy-radicals by the reaction of Ti^{3+} with hydrogen peroxide; in this system the formation of phenoxy-radicals from phenol was observed by the ESR method. It was reasonable to postulate the following reaction: $HO^\cdot + PhOH \rightarrow H_2O + PhO^\cdot$. However, it has been established by pulse radiolysis[62] that the primary radical product of the reaction of $HO^\cdot$ with phenol is dihydroxycyclohexadienyl, i.e. the hydroxy-radical adds to the phenol molecule: $HO^\cdot + C_6H_5OH \rightarrow HOC_6H_5\dot{O}H$. This contradiction has been resolved by Lamb and coworkers[105,106]. It was established by pulse radiolysis that the hydroxy-radical does indeed add to phenol but the $HOC_6H_5\dot{O}H$ radical formed is unstable and in aqueous solution is rapidly converted into the phenoxy-radical and water. The reaction is catalysed by H^+, OH^-, and $H_2PO_4^-$ ions. In aqueous solutions at pH 6.3 the rate constant for the decomposition of the radical[106] $HOC_6H_5\dot{O}H$ is 4.7×10^3 s^{-1}. This radical also reacts with other free radicals. The rate constant for the addition of $HO^\cdot$ to phenol in aqueous solution at room temperature is 1.06×10^{10} litre mole^{-1} s^{-1} at pH 6–7 [107] and 0.51×10^{10} at pH 9.[108]

In aqueous solutions phenoxy-radicals rapidly recombine with the ultimate formation of dimeric products. The recombination takes place with a rate constant $k = 5.6 \times 10^9$ litre mole^{-1} s^{-1} (determined by flash photolysis[109]). The following compounds have been observed among the products of the reaction of phenol in photolysis both in the presence and absence of oxygen[110]:



as well as dihydric phenols.

Thus kinetic data for the oxidation of phenol and modern ideas on the mechanism of the oxidation of Fe^{2+} show that in the catalytic oxidation of benzene in the presence of Fe^{2+} and Cu^{2+} ions benzene may be attacked by $HO^\cdot$ and $HO_2^\cdot$ radicals. At the initial point of the catalytic oxidation of benzene free radicals are formed by the reactions

$$Fe^{2+}aq + O_2 \rightarrow Fe^{3+}aq + O_2^- , \qquad (2')$$

$$Fe^{3+} + HO^- \rightarrow Fe^{2+} + HO^\cdot . \qquad (2'')$$

Reaction (2′) is much faster than reaction (2″) and therefore, on introduction of Fe^{2+} at the beginning of the reaction, the oxidation develops more rapidly than in the presence of Fe^{3+} ions. For the same reason, a copper surface in the presence of Cu^{2+} ions accelerates the process: the Cu^+ ions formed at a constant rate by the reaction of Cu^{2+} ions with metallic copper are then oxidised by O_2 with formation of O_2^- [by a reaction analogous to reaction (2′)]. Thus Fe^{2+} and Fe^{3+} ions (or Cu^{2+} and Cu^+) constitute the only source of $HO^\cdot$ and $HO_2^\cdot$ radicals at the beginning of the oxidation.

At an advanced stage of the reaction phenol begins to play a significant role in the formation of radicals. In the first place it reacts directly with O_2 forming O_2^-, which is then converted by a series of consecutive reactions into a hydroxyl radical:

$$O_2^- \overset{H^+}{\rightleftarrows} HO_2^\cdot \xrightarrow{Fe^{2+}} HO_2^- \overset{H^+}{\rightleftarrows} H_2O_2 \xrightarrow{Fe^{2+}} HO^\cdot .$$

In the second place, by reducing Fe^{3+} to Fe^{2+}, phenol increases the concentration of the latter and thus increases the rate of formation of radicals by reaction (2′). The increase in the rate of formation of radicals as phenol accumulates is in fact the reason for the autocatalytic course of the reaction.

The oxidation of benzene can be represented schematically by the following reactions:

$$\left.\begin{aligned} PhOH + O_2 &\xrightarrow{k_{0'}} PhO^{\cdot} + HO_2^{\cdot} \\ PhO^- + O_2 &\xrightarrow{k_{0''}} PhO^{\cdot} + O_2^- \\ Fe^{2+} + O_2 &\xrightarrow{k_{2'}} Fe^{3+} + O_2^- \\ FeOH^+ + O_2 &\xrightarrow{k_{2''}} FeOH^{2+} + O_2^- \end{aligned}\right\} \text{formation of free radicals}$$

$$\left.\begin{aligned} PhOH + r^{\cdot} &\xrightarrow{k_4} PhO^{\cdot} + rH \\ PhO^- + Fe^{3+} &\xrightarrow{k_5} PhO^{\cdot} + Fe^{2+} \end{aligned}\right\} \text{consumption of phenol}$$

$$C_6H_6 + r^{\cdot} \xrightarrow{k_6} PhOH \quad \text{formation of phenol.}$$

The present authors calculated[94] kinetic curves for the accumulation of phenol and consumption of benzene by this mechanism. The rate constants for reactions (0), (1), and (2) taken from experiments on the oxidation of phenol were used in the calculations and the ratio k_4/k_5 was evaluated from the ratio of the concentrations of benzene and phenol at the point corresponding to the maximum concentration of the latter, and the concentrations of Fe^{2+} and Fe^{3+} were determined experimentally. Under the experimental conditions (200°C, pH 1.90), the constants have the following values:

$$k_0 = k_{0'} + k_{0''}K_0[H^+]^{-1} = (2.43 \pm 0.30),\ 10^{-4} \text{ litre mole s}^{-1},$$
$$k_1 = (k_{1'}K_0 + k_{1''}K_1)[H^+]^{-1} = (2.80 \pm 0.20),\ 10^{-2} \text{ litre mole s}^{-1},$$
$$k_2 = k_{2'} + k_{2''}K_2[H^+]^{-1} = (2.86 \pm 0.20),\ 10^{-3} \text{ litre mole s}^{-1}.$$

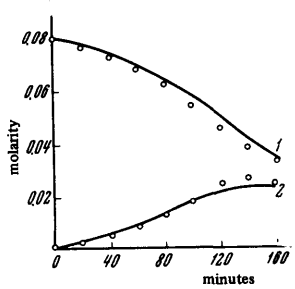


Figure 5. Experimental (circles) and calculated (lines) kinetic curves for the consumption of benzene (curve *1*) and accumulation of phenol (curve *2*).

Fig. 5 shows that the results of the calculations are in good agreement with experiment. The variation of the contribution of each reaction to the overall process of radical formation is plotted in Fig. 6. It is clearly seen that at an advanced stage the main source of radicals in the process is the reaction of phenol with oxygen.

The hydroxylation of benzene in this reaction takes place as a result of the addition of the radical to the benzene molecule. This is indicated by the closeness to unity of the isotope effect in the oxidation of C_6H_6 and C_6D_6 (k_H/k_D = 1.2) [78] and also the fact that the ratio of the rate constants for the reactions of radicals with benzene and phenol is close to unity[94]. Indeed if the free radical ($HO^{\cdot}$ or $HO_2^{\cdot}$) removed a hydrogen atom from benzene, then we should have $k_5 \ll k_4$, since the C–H bond energy in benzene is 102 kcal mole^{-1}, while the O–H bond energy in phenol is 85 kcal mole^{-1}. The available experimental data are so far insufficient for an estimate of the contribution of each radical ($HO^{\cdot}$ and $HO_2^{\cdot}$) to the hydroxylation of benzene.

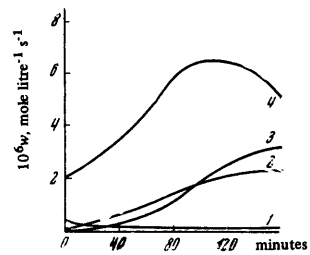

Figure 6. Rates of different reactions at 200°C, pH 1.90, and an oxygen pressure of 35 atm:
1) oxidation of Fe^{2+} ions; *2*) oxidation of phenol by oxygen; *3*) oxidation of phenol by reaction with radicals; *4*) consumption of benzene.

There is no doubt, however, that hydroxy-radicals hydroxylate benzene very vigorously, since it is known that at room temperature $k_{(HO^{\cdot}+C_6H_6)} = 4.3 \times 10^9$ litre mole^{-1} s^{-1},[45] i.e. the rate constant is very high. The question of the activity of the $HO_2^{\cdot}$ radical as a hydroxylating agent still remains obscure. Altogether, it has been shown that the catalytic oxidation of benzene in aqueous solution at 170–220°C is a coupled autocatalytic ion—radical reaction oxidising benzene and phenol by short chains, in which benzene is oxidised by radical addition; this in fact ensures a comparatively high yield of phenol. The chain length under the experimental conditions quoted in Fig. 5 is four units. Chain growth probably takes place by the reactions

$$C_6H_6 + HO^{\cdot} \rightarrow C_6H_7O^{\cdot},$$
$$C_6H_7O^{\cdot} + O_2 \rightarrow C_6H_5OH + HO_2^{\cdot},$$
$$HO_2^{\cdot} \xrightarrow{Fe^{2+}} HO_2^- \xrightarrow{H^+} H_2O_2 \xrightarrow{Fe^{2+}} HO^{\cdot}.$$

The benzene oxidation mechanism described above explains all the kinetic features of this reaction. The inhibiting effect of anions such as Cl^- and Br^- is due to the reactions

$$HO^{\cdot} + Cl^- \rightarrow HO^- + Cl^{\cdot},$$
$$Cl^{\cdot} + C_6H_5OH \rightarrow HCl + C_6H_5O^{\cdot}.$$

which lower the concentration of the hydroxylating agent, while phenol continues to disappear by reactions with $Cl^{\cdot}$ (or $Br^{\cdot}$). The inhibiting effect of certain organic additives[91] is also due to the fact that hydroxy-radicals are consumed in the oxidation of the organic compound and not in the hydroxylation of benzene.

VII. OTHER METHODS FOR THE OXIDATION OF BENZENE

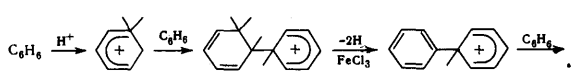
In a number of studies benzene was oxidised under pressure in liquid hydrofluoric acid[111-113]. The reaction at 200°C yields phenol, biphenyl, and carbon black, i.e. under these conditions oxidation is accompanied by dehydrogenation of benzene to carbon. Arsenic and selenium oxides make it possible to lower the oxidation temperature. The mixture hydrogen fluoride–boron trifluoride has also been employed as a catalyst[112], and O_2, ozone, sulphur dioxide, and atomic oxygen have served as oxidants. Phenol is formed in very small amounts.

Benzene can be oxidised to phenol using cupric sulphate as the oxidant by heating a mixture of benzene and aqueous cupric sulphate to 304°C.[114] The maximum yield of phenol (66%) is obtained when sodium phosphate is introduced together with cupric phosphate. Benzene can be oxidised to phenol with cupric acetate and benzoate (210–250°C, water)[115]. At 250°C 0.135 mole of phenol is formed in 5 h per mole of cupric sulphate consumed (benzene : water = 1 : 1). Phenol is obtained in the oxidation of benzene with oxygen at 300°C in the presence of water and the heterogeneous catalyst[116] 6% Cu–17% Mo on alumina. A high yield (75% relative to unreacted benzene) of phenol is obtained when benzene is oxidised with oxygen in benzoic acid in the presence of catalysts such as iron, copper, and silver oxides (260°C, water removed continuously by azeotropic distillation)[117].

The attempt to oxidise benzene in a hydrocarbon medium in the presence of suspended titanium salts and oxides at 25–100°C showed that under these conditions phenol is formed in negligible amounts[118].

Benzene can be polymerised to polyphenyl in the presence of Lewis acids, an oxidant, and water. When benzene is refluxed with anhydrous ferric chloride, a polyphenyl resin is formed[119]. Traces of water accelerate the reaction. Chlorobenzene is produced together with the polymer. Ferric chloride behaves as a catalyst of cationic polymerisation and as an oxidant:

$$H_2O + FeCl_3 \rightleftharpoons H^+ + Fe(OH)Cl_2,$$



A similar mechanism for the formation of polyphenyl from benzene has been suggested for the process in the presence of $MoCl_5$ and water[120] and in the presence of aluminium chloride, cupric chloride, and water. The polymer produced, parapolyphenyl, is thermally stable (up to 525°C) and has a high molecular weight.

Valence Isomers of Benzene

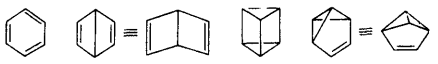
I.G.Bolesov

CONTENTS

I. Introduction 666
II. Methods of preparation of valence isomers of benzene 666
III. Properties of valence isomers of benzene 668

I. INTRODUCTION

Throughout the existence of the theory of the structure of organic compounds, probably no one structure attracted so much attention as that of benzene. As experimental data accumulated, the requirements which had to be met by the formula of benzene were defined. It must reflect (1) the high symmetry of the molecule (sixfold axis), (2) its planar structure, (3) the equivalence of all the hydrogen atoms, and (4) the unsaturated nature of the benzene molecule. One of the first benzene formulae (I) was proposed by Kekulé in 1865. This method of representation came to be generally accepted, although it does not take into account all the experimental data. An enormous variety of structures have been proposed as alternatives to the Kekulé formula (for a detailed discussion of this problem, see Menshutkin[1]). Among these the structures proposed by Dewar (II), Ladenburg (III) (prismane), and Hückel (IV) (benzvalene) should be mentioned.



(I) (II) (III) (IV)

For a long time it was believed that these structures not only cannot describe the properties of benzene but are in fact incapable of existence as non-planar valence isomers of benzene. Recently interest was aroused again in the "non-Kekulé" structures (II)–(IV). This is because in many cases, especially in photochemical reactions, it is difficult to account for the behaviour of aromatic compounds without postulating the intermediate formation of structures of the type (II)–(IV). Furthermore, the advances which have been already achieved in the chemistry of valence isomers of benzene have been attracting an increasing number of investigators.

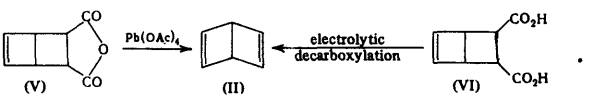
This review presents the main results of studies in the chemistry of this new and unusual field.

The reviews published hitherto on the chemistry of valence isomers of benzene deal with the literature up to the middle of 1965 [2,3] and those on the chemistry of Dewar hexamethylbenzene deal with the literature up to the middle of 1967.[4]

II. METHODS OF PREPARATION OF VALENCE ISOMERS OF BENZENE

1. From Bicyclo[2,2,0]hex-5-ene-2,3-dicarboxylic acid or Its Anhydride

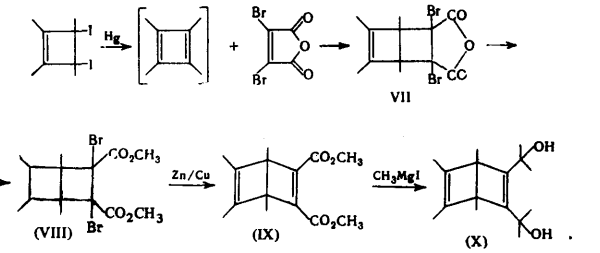
The first valence isomer of benzene, Dewar benzene (II), was obtained in 1963 by oxidising the anhydride (V) with lead tetra-acetate[5]. The yield of compound (II) was about 20%. Later a method of synthesis of compound (II) more convenient for preparative purposes was found—electrolytic decarboxylation of the acid (VI):[6]



(V) (II) (VI)

2. From Cyclobutadiene Generated *in situ*

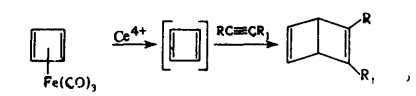
In order to obtain derivatives of Dewar benzene with different functional groups, it is necessary to carry out the condensation of tetramethylcyclobutadiene, obtained from 3,4-di-iodo-1,2,3,4-tetramethylcyclobut-1-ene, with dibromomaleic anhydride. The resulting anhydride (VII) is then further converted into the diester (VIII) and the latter is debrominated to form the "ester of Dewar phthalic acid" (IX):[7,8]



VII (VIII) (IX) (X)

Compound (IX) readily reacts with methylmagnesium iodide, forming a derivative of Dewar benzene (X).[9,10]

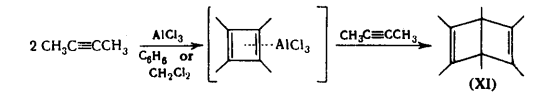
Cyclobutadienyliron tricarbonyl proved to be a convenient source of cyclobutadiene, adding readily to various acetylenes[11,12]:



where R = H and $R_1 = CO_2CH_3$, R = $R_1 = CO_2CH_3$, or R = H and $R_1 = C_6H_5$.

3. Trimerisation of Acetylene Derivatives

Preparatively the most simple synthesis of derivatives of Dewar benzene is that of hexamethylbicyclo[2,2,0]hexa-2,5-diene (XI), which consists in the trimerisation of but-2-yne under the action of aluminium chloride[4,13]:

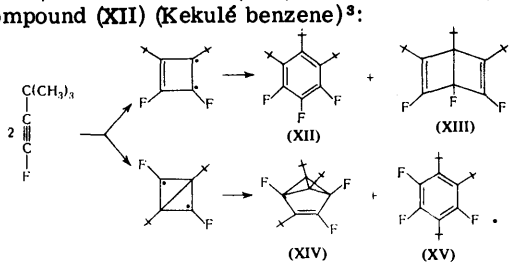


(XI)

Apart from aluminium chloride, aluminium bromide and $RAlCl_2$ (R = C_2H_5, C_3H_7, s-C_4H_9, or n-C_6H_{13}) can be used

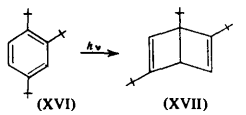
as catalysts. Other Lewis acids ($FeCl_3$, $TiCl_4$, $SnCl_4$, $ZnCl_2$, BF_3) and dialkylaluminium chlorides do not catalyst this reaction.

t-Butylfluoroacetylene forms very readily a mixture of trimers from which derivatives of bicyclo[2,2,0]hexa-2,5-diene (XIII) and benzvalene (XIV) were isolated together with compound (XII) (Kekulé benzene)[3]:

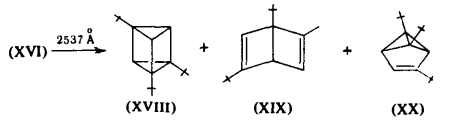


4. Photochemical Reactions of Benzene and Its Derivatives

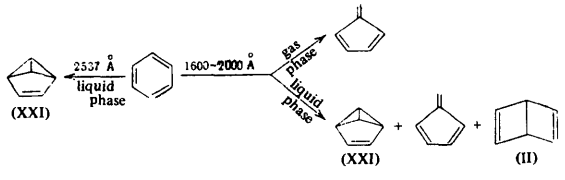
a. Valence isomerisation reactions. In 1962 it was shown that, on irradiation with ultraviolet light, 1,2,3,4-tri-t-butylbenzene (XVI) forms 1,2,5-tri-t-butylbicyclo[2,2,0]hexa-2,5-diene (XVII), a stable substance which can be purified by preparative chromatography on silica gel[14]:



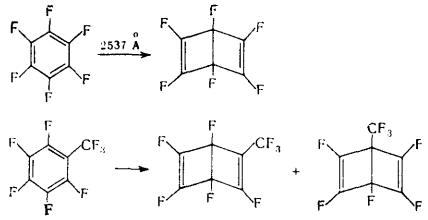
A detailed study of the photoisomerisation of polyalkylbenzenes showed that the observed migrations of alkyl groups are intramolecular processes accompanied by the rearrangement of the aromatic ring into prismane, benzvalene, and bicyclo[2,2,0]hexadiene derivatives, with subsequent rearomatisation[15-18]. Later it was established that, on irradiation with ultraviolet light at a wavelength of 2537 Å, corresponding to the second absorption maximum in the benzene spectrum, 1,2,4- and 1,3,5-tri-t-butylbenzene form a mixture of compounds (XVIII)–(XX), in which the principal component is prismane (XVIII)[18]:



Finally in 1967 it proved possible to synthesize the second (after Dewar benzene) valence isomer of benzene—benzovalene (XXI), characterised by PMR spectra and converted by methanolysis into familiar bicyclohexenyl ethers[19]. This reaction occurred on liquid-phase irradiation of benzene with ultraviolet light at a wavelength of 2537 Å. It is interesting to note that the irradiation of benzene in the gas phase at a wavelength of 1600–2000 Å results mainly in the formation of fulvene[20,21], while liquid-phase photolysis yields benzvalene, fulvene, and Dewar benzene in proportions of 5 : 2 : 1.[22]

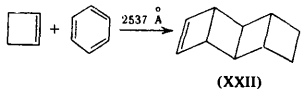


Gas-phase photolysis of hexafluorobenzene or octafluorotoluene results in the formation of the corresponding derivatives of Dewar's benzene,

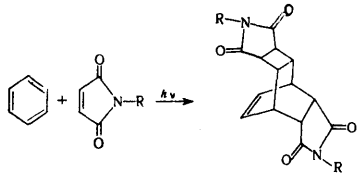


while in liquid-phase photolysis (in cyclohexane, methylcyclohexane, cyclo-octane, and ether) a complex mixture of products is formed[23-25].

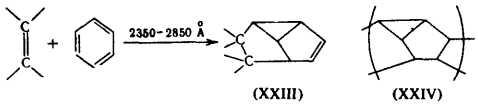
b. Reactions with olefins and dienes. When a 20% solution of cyclobutene in benzene was irradiated, the product isolated was a 1 : 1 adduct to which the structure (XXII) was ascribed[26]:



The imide of maleic acid and its *N*-alkyl, arylalkyl, and *N*-(*o*-tolyl) derivatives form 2 : 1 adducts with benzene, whose structure has been confirmed by synthesis[27]:

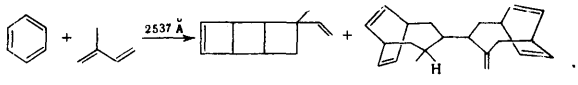


Various olefins (alkenes and cycloalkenes), unconjugated dienes, and ethyl vinyl ether form adducts with benzene as a result of 1,3-cycloaddition[28,29]:

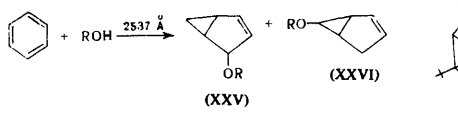


Such addition is accelerated in the presence of β-propiolactone; acetone and benzophenone do not affect the reaction rate[29]. Up to 85% of the adduct (XXIII) is obtained from cyclo-octene. Compounds of type (XXIII), like all other mono-olefins, also add to benzene, which can result in the formation of polymers to which the structure (XXIV) was ascribed (*n* reaches 24).[30]

Isoprene interacts with benzene, toluene, and tetra- and hexafluorobenzene by 1,2- and 1,4-cyclo-addition:[31]



c. Reactions with alcohols and acids. In the presence of methanol, trifluoroethanol, and acetic and phosphoric acids, benzene and 1,3,5-tri-t-butylbenzene form derivatives of bicyclo[3,1,0]hex-2-ene (XXV) and (XXVI):[32-34]



It is interesting to note that compound (XXVII) proves to be the sole product of the reaction of 1,3,5-tri-t-butylbenzene with methanol[34].

The mechanism of the above photoreactions of benzene has not been elucidated, but it has been suggested that these reactions proceed via singlet ($^1B_{2u}$) and triplet ($^3B_{1u}$) states of benzene[35] or via a reactive intermediate (with a Möbius type structure), which differ from the familiar excited states of benzene[36].

III. PROPERTIES OF VALENCE ISOMERS OF BENZENE

The reactivity of valence isomers of benzene has been investigated very little. The only exception in this respect are derivatives of Dewar benzene (especially hexamethylbicyclo[2,2,0]hexa-2,5-diene).

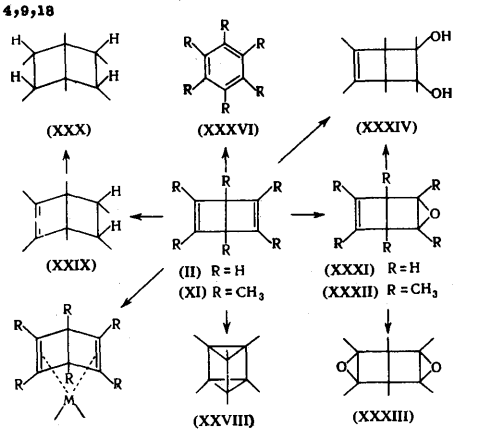
The stability of almost all the valence isomers of benzene examined above is quite sufficient under normal conditions for their isolation and purification.

1. Bicyclo[2,2,0]hexa-2,5-dienes

The PMR spectra of compounds (II) and (XI) show signals due to two types of protons: with $\tau = 3.45$ and 6.16 in the first case[5] and $\tau = 8.45$ and 8.95 in the second[4], the area ratios of the signals being 2 : 1. The first member of the series of Dewar benzenes—bicyclo[2,2,0]hexa-2,5-diene (II)—isomerises to benzene fairly readily even at 20°C (the period required for 50% conversion is about two days) and very rapidly at 90°C, but remains unchanged for a long time at 0°C in pyridine solution[5]. In contrast to bicyclo[2,2,0]hexa-2,5-dienes (II), the hexamethyl derivative (XI) rapidly isomerises to hexamethylbenzene only at about 150°C: the period of its 50% conversion to hexamethylbenzene is 105 h at 120°C, 5.5 h at 140°C, and 2.1 h at 150°C. The hexamethyl derivative of Dewar benzene has the following constants: b.p. 60°C (at 20 mmHg), m.p. 7.5°C, $n_D^{20} = 1.4479$, and $d_4^{20} = 0.8125$.[4]

Other bicyclo[2,2,0]hexadienes also isomerised to benzene derivatives on heating (in some cases only at 200°C)[4,9-12,14,24,37], under the action of Lewis acids[4], and in the presence of rhodium complexes of olefins[37]. Hexafluorobicyclo[2,2,0]hexa-2,5-diene is stable in the crystalline state but can explode in the liquid phase[24].

Under the action of ultraviolet light, bicyclo[2,2,0]-hexa-2,5-dienes are converted into prismane derivatives (XXVIII):[4,9,18]

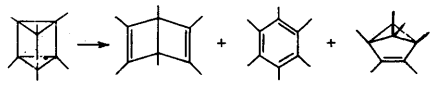


Hexamethylbicyclo[2,2,0]hexa-2,5-diene combines with hydrogen in the presence of catalysts and is reduced with carbodi-imide, forming dihydro-derivatives (XXIX) and tetrahydro-derivatives (XXX)[4,38]. Per-acids oxidise one or both olefinic groups of bicyclo[2,2,0]hexa-2,5-dienes (II) and (XI)[4,6]. Compound (XI) very readily oxidises in air to the diol (XXXIV), which is also obtained in the acid hydrolysis of the epoxide (XXXII)[4]. Treatment of bicyclo-[2,2,0]hexa-2,5-diene (II) with osmium tetroxide yields bicyclo[2,2,0]hexane-2,3,5,6-tetraol[6]. Dewar benzene and its hexamethyl derivatives form complexes with transition metals of type (XXXV)[6,37,39-41]. Other properties which deserve mention are the capacity of bicyclo[2,2,0]-hexa-2,5-dienes to combine with bromine with retention of the bicyclic structure[6,24], to undergo ozonolysis at one or two C=C bonds[4,9], and to exchange fluorine for an alkoxy-residue[24].

2. Prismanes

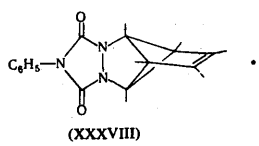
Hexamethylprismane (XXVIII), purified by repeated sublimation, melts at 89–90.5°C; its ultraviolet spectrum shows only terminal absorption characteristic of saturated hydrocarbons and the PMR spectrum has only a sharp singlet with $\delta = 0.97 \times 10^{-6}$.

Like bicyclo[2,2,0]hexa-2,5-dienes, prismanes are unstable at elevated temperatures. Under these conditions, they isomerise into derivatives of Kekulé and Dewar benzene[4,6,18,42]. At 129°C hexamethylprismane is converted to the extent of one third over a period of 30 min into a mixture of compounds (XI) and (XXXVI) in proportions of 2.4 : 1:



Lindlar's catalyst isomerises compound (XXVIII) into compounds (XI) and (XXXVI) and hexamethylbenzvalene (XXXVII). Boron trifluoride-ether causes instant isomerisation of compound (XXVIII) into a mixture of compounds (XI) and (XXXVI)[43]. It has been found that the ratio of compounds (XI) and (XXXVI) varies in the isomerisation of compound (XXVIII) by (a) heat treatment, (b) in the presence of $HF-BF_3$, and (c) in the presence of the rhodium complex of the hexamethyl derivative of Dewar benzene[42]. It has been found that the ratio (XI): (XXXVI) changes markedly under these conditions—from 1 : 30 in case (a) to 1 : 0.05 in case (c).

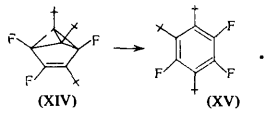
At 20°C hexamethylprismane readily forms adducts with 4-phenyltriazoline-3,5-dione and tetracyanoethylene, the structure (XXXVIII) being adopted for the first adduct[43]:



3. Benzvalenes

Benzvalene (IV), obtained by the liquid-phase photolysis of benzene (at 2537 Å), has a PMR spectrum with three resonance signals of equal intensities: an asymmetric triplet with $\tau = 4.05$, a symmetrical triplet with $\tau = 6.47$, and a quintet with $\tau = 8.16$. When acted upon by a methanol solution of hydrochloric acid, benzvalene (IV) is converted into known bicyclohexenyl ethers[19]. On heating,

1,3,6-tri-t-butyl-tricyclo[3,1,0,$0^{2,6}$]hex-3-ene (XX) isomerises exclusively to 1,2,4-tri-t-butylbenzene[18]. Similarly in the isomerisation of compound (XIV) the sole product is (XV):[3]



(XIV) (XV)

---o0o---

During the preparation of the review for the press, the following new data on the chemistry of valence isomers of benzene were published.

Electrophilic addition of hydrogen halides (HCl and HBr) and methanol to Dewar hexamethylbenzene (XI), readily available from but-2-yne[4,13], leads to 1,2,3,4,5-pentamethyl-5-(α-X-ethyl)cyclopenta-1,3-dienes (X = Cl, Br, or CH_3O), isolated in yields of 45–85%.[44] To account for this course of reaction, a mechanism has been proposed postulating attack by a proton on the double bond with simultaneous or subsequent migration of the central bond, and stabilisation of the homoallyl cation by the nucleophilic agent X^-. The addition of chlorosulphonyl isocyanate to compound (XI) takes place similarly, the intermediate dipolar ion being stabilised intramolecularly with formation of an azasemifulvalene system[45].

When a methylene group is introduced into compound (XI) by treatment with diazomethane in the presence of cuprous bromide, a mixture of substances is formed[46]. The yield of products and the extent of conversion into cyclopropane derivatives strongly depends on the (XI) to CH_2N_2 ratio.

New data have been obtained on the reaction between compound (XI) and $RhCl_3.3H_2O$. The dark red crystalline compound formed has been assigned the structure of the dimer of pentamethylcyclopentadienylrhodium(III) chloride (XXXIX)[47] and not hexamethylbenzenerhodium(III) chloride, as stated earlier[41]. On being acted upon by triphenylphosphine, pyridine, or *p*-toluidine, compound (XXXIX) is converted into the monomeric adducts $[C_5(CH_3)_5]RhCl_2L$ (XL) (where L = triphenylphosphine, pyridine, or *p*-toluidine), while the reaction with cyclo-octa-1,5-diene in the presence of sodium carbonate yields (π-cyclo-octa-1,5-diene)(π-pentamethylcyclopentadienyl)-rhodium(I) (XLI). Elemental analysis, measurements of the molecular weight, and PMR spectra of compound (XXXIX) and the products (XL) and (XLI) obtained from it confirm the suggested structures. The mass spectrum of compound (XLI) contains intense peaks due to the molecular ion (m/e = 346) and the ion $[RhC_5(CH_3)_5]^+$ (m/e = 238).

Three types of reactions of hexafluorobenzene (XLII) with transition metal complexes have been described[48]: (1) like alkoxide ions[24], the anions $[Fe(CO)_2\pi\text{-}C_5H_5]^-$, $[Re(CO)_5]^-$, and $[Mn(CO)_5]^-$ substitute the vinyl fluorine atom; (2) manganese carbonyls with the general formula $RMn(CO)_5$ (R = H, CH_3, or C_6H_5) add to one multiple bond of compound (XLII); (3) tetrakis(triphenylphosphine)platinum forms a stable crystalline compound $Pt(C_6F_6)[P(C_6H_5)_3]_2$ (XLIII), the NMR spectrum of which contains three groups of signals of equal intensity (48.0×10^{-6}, 88.0×10^{-6}, and 99.8×10^{-6}), which have been ascribed to vinyl, Pt–C–F, and bridge fluorine nuclei. The infrared spectrum of compound (XLIII) contains a 1752 cm^{-1} band, but there is no absorption characteristic of a coordinated double bond. In view of this finding, it has been concluded that the molecule of compound (XLIII) contains a threemembered ring with C–Pt σ-bonds.

It has been shown that, in the vapour-phase photolysis (at 2537–2370 Å) of benzene, benzvalene (IV) is formed at very low concentrations[49]. The amount of compound (IV) increases when the photolysis is carried out in the presence of gases, whose efficiency varies in the following sequence: nitrogen < neopentane < *cis*-but-2-ene.

Methods of Preparation and Properties of Compounds with Unsaturated Groups at the Phosphorus Atom

V.K.Promonenkov and S.Z.Ivin

The review deals with problems connected with the synthesis, chemical properties, and applications of organophosphorus compounds with unsaturated groups at the heteroatom. A systematic account is given of the methods of preparation of these substances and the characteristic features and limits of applicability of the synthetic methods, in accordance with the wide variety of structures of the products considered, are noted. The section dealing with the properties of the compounds describes the addition reactions of nucleophilic agents, reactions with substances with a tendency towards homolysis, certain rearrangements, condensations, and other processes. The practical value of compounds with unsaturated groups at the phosphorus atom is noted. The bibliography comprises 344 references.

III. Properties of compounds with unsaturated groups at the phosphorus atom 674

I. INTRODUCTION

The chemistry of organophosphorus compounds has developed considerably in recent years. A large number of substances of practical value have been synthesised and compounds with unsaturated groups at the phosphorus atom are of definite interest in view of the wide variety of their chemical properties. Non-combustible and self-extinguishing polymers, effective preparations with a wide variety of physiological activity, etc. have already been obtained on their basis.

At the present time there are no publications dealing with the main features of such investigations and the present review is an attempt to fill this gap. It deals with two topics, the methods of preparation of alkenylphosphorus compounds and their reactivity, the literature data published up to the middle of 1966 being discussed.

II. PREPARATION OF COMPOUNDS WITH UNSATURATED GROUPS AT THE PHOSPHORUS ATOM

Compounds of this type were synthesised about 50 years ago in the study of the reaction of phosphorus pentachloride with olefins, but the principal methods of their preparation have been developed only in the last 20 years.

1. Interaction of Halogeno-derivatives of Phosphorus with Metal Alkyls

This method of synthesis was quite recently developed and is used mainly for the preparation of phosphorus(III) compounds. In 1959 Kaesz and Stone[1] carried out the vinylation of phosphorus trichloride with divinylmercury[1]:

$$(CH_2{=}CH)_2Hg + PCl_3 \rightarrow CH_2{=}CHPCl_2 + CH_2{=}CHHgCl.$$

The yield of vinyldichlorophosphine was 50%; the compound proved to be very sensitive to air and moisture. Sterlin et al.[2] carried out a similar reaction with perfluorovinyl derivatives:

$$CF_2{=}CFMgX + PCl_3 \rightarrow (CF_2{=}CF)_3P.$$

Related methods have been proposed in Foster's[3,4] and Feder's[5] patents. In 1960 Leavitt and coworkers synthesised cyclic phosphorus compounds from dilithium derivatives and phenyldichlorophosphine[6,7]. Next one may refer to the work of Rabinowitz[8], Maier[9], and Zeiss[10] on further improvement of the method and the investigation of the properties of these compounds.

Kabachnik and Chang Jung-Yü[11,12] and Razumov[13] extended these reactions to dialkyl- and dialkoxy-chlorophosphines.

Double decomposition reactions of alkyl(aryl)magnesium halides with unsaturated phosphines are also possible [14]:

$$C_6H_5CH{=}CHPCl_2 + 2\ RMgHal \rightarrow C_6H_5CH{=}CHPR_2\ .$$

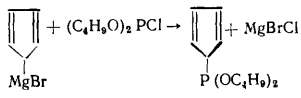
Similar reactions can be performed with metallic derivatives of acetylenes. For example, Chodkiewicz and coworkers studied the following reactions of alkynylmagnesium halides [15,16]:

$$RC{\equiv}CMgX^+ \left| \begin{array}{l} PCl_3 \rightarrow (RC{\equiv}C)_3P, \\ POCl_3 \rightarrow (RC{\equiv}C)_3P{=}O, \\ (C_6H_5)_2PCl \rightarrow (C_6H_5)_2PC{\equiv}CR\ . \end{array} \right.$$

Kabachnik and coworkers carried out similar reactions with dialkyl phosphorochloridites [17] and Maretina and Petrov with dialkylchlorophosphines [18]. The yield of alkyl derivatives was 50–70% [19–23]. Hartmann and coworkers [24,25] and Maler [26] carried out the interesting synthesis of acetylenic diphosphines:

$$2\ (C_6H_5)_2PCl + BrMgC{\equiv}CMgBr \xrightarrow{ether} (C_6H_5)_2PC{\equiv}CP(C_6H_5)_2 + MgCl_2 + MgBr_2\ .$$

Kabachnik and Tsvetkov established that the method can be used for the synthesis of phosphorus compounds with cyclic unsaturated groups, for example, derivatives of cyclopentadiene, indene, and fluorene [27–29]:



Instead of phosphorochloridites, in some cases the alkoxyderivatives can react with organomagnesium compounds [30]:

$$RR'POR'' + CH_2{=}CHMgX \rightarrow RR'PCH{=}CH_2 + MgX(OR)\ .$$

2. Interaction of Metal Derivatives of Phosphorus with Alkyl Halides

The second method of preparation of unsaturated phosphorus compounds is based on the reaction

$$MP^{III(V)} + R{-}Hal \rightarrow MHal + R{-}P^{III(V)}\ ,$$

where M is an alkali metal and Hal a halogen atom. The reactions of metal derivatives of phosphines with halogenoalkenes take place in an inert medium over a wide range of temperatures [31–33]:

$$C_6H_5PHNa + Br(CR')_nC{=}CH_2 \rightarrow C_6H_5PH(CR')_nCR{=}CH_2 + NaBr$$

An interesting process is dealkylation with a secondary phosphide ion, which leads to alkenylphosphines [34]:

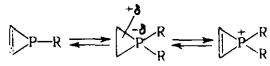
$$(C_6H_5)_2PH + C_4H_9Li \rightarrow (C_6H_5)_2P{-}Li + C_4H_{10}\ ,$$

$$C_6H_5OCH_2CH{=}CH_2 \xrightarrow{(C_6H_5)_2PLi} C_6H_5OLi + (C_6H_5)_2PCH_2CH{=}CH_2\ .$$

Lithium phosphides react with acetylenes [35,36] to form addition products:

$$R_2PLi + CH{\equiv}C{-}CH{=}CH_2 \rightarrow \left\{ \begin{array}{l} CH{\equiv}C{-}CH_2{-}CH_2{-}PR_2, \\ CH_2{=}C{=}CH{-}CH_2{-}PR_2, \\ CH_2{=}CH{-}CH{=}CH{-}PR_2\ . \end{array} \right.$$

Some investigators have discussed the possibility of the existence of three-membered structures with phosphorus as a heteroatom [37,38]:



and also other intermediate alkenyl derivatives of phosphorus [39]. The Michaelis–Bekker reaction is a variant of the above method preparation of organophosphorus compounds with unsaturated groups at the phosphorus atom. Alkenylphosphonates are formed in the reaction of alkenyl halides with alkali metal salts of dialkyl phosphorous aicds [40,41]:

$$R'CH{=}CHCH_2Cl + NaOP(OR)_2 \rightarrow R'CH{=}CHCH_2\overset{\overset{O}{\|}}{P}(OR)_2 + NaCl\ .$$

The Michaelis–Bekker method permits the synthesis of the same substances as the Arbuzov rearrangement, although it is not quite so universal because of the occurrence in many cases of side reactions, for example, the allyl rearrangement [42,43]. The yield of alkenylphosphonate esters in the Michaelis–Bekker reaction is usually lower than in the Arbuzov reaction. Nevertheless a wide variety of alkenylphosphonates have been obtained by this method: allyl- [44], butenyl- [45], butoxypentenyl- [43], cycloalkenyl- [46–48], and others [49–53]. The sodium salt of diethylphosphorothious acid can be used in this reaction instead of sodium diethyl phosphite [43,44]:

$$CH_2{=}CHCH_2Br + (RO_2)P{-}SNa \rightarrow CH_2{=}CHCH_2\overset{\overset{S}{\|}}{P}(OR)_2\ .$$

Diphosphono-derivatives, which are products of the subsequent condensation of dialkyl phosphites with the alkenylphosphonates formed, are almost absent in this case [54,55].

3. The Arbuzov Rearrangement

This most general method of synthesising organophosphorus compounds can be used also for the preparation of compounds with unsaturated groups at the phosphorus atom. The starting materials are either alkenyl halides or polyhalogenoalkanes; in the latter case the products of the rearrangement are dehydrohalogenated [56–59]:

$$CH_2{=}CHCH_2Hal + P(OR)_3 \rightarrow CH_2{=}CHCH_2\overset{\overset{O}{\|}}{P}(OR)_2 + RHal\ ,$$

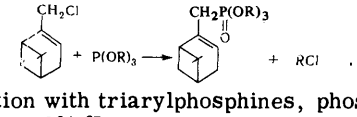
$$CH_3\underset{Br}{CH}{-}\underset{Br}{CH_2} + P(OR)_3 \xrightarrow[-RBr]{} CH_3CH{-}CH_2{-}\overset{\overset{O}{\|}}{P}(OR)_2 \xrightarrow[-HBr]{} CH_3CH{=}CH\overset{\overset{O}{\|}}{P}(OR)_2\ .$$

(Hal = Cl, Br)

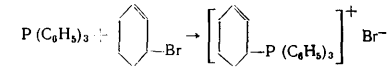
The rate of the process depends on a number of factors—temperature, proportions of the reactants, nature of the alkyl halide, and also the structure of the initial phosphorus(III) compound. Liorber and Razumov found that allylphosphonite esters undergo the Arbuzov rearrangement much more readily than alkyl- and vinyl-phosphonites. Thus, depending on the nature of the group joined to the phosphorus atom, phosphorus(III) compounds can be arranged in the following series [60]:

$$CH_2{=}CHCH_2P(OR)_2 > AlkP(OR)_2 > CH_2{=}CHP(OR)_2\ .$$

Certain more complex alkyl halides readily undergo the Arbuzov reaction [61–63]:

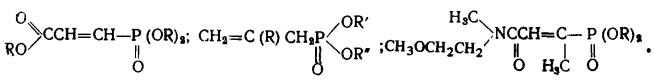


In the reaction with triarylphosphines, phosphonium halides are formed [64–67]:



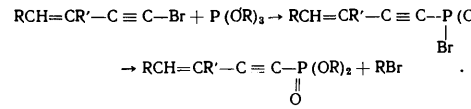
When α-halogeno-ketones are used as the initial alkyl halides, the rearrangement can be more profound [67–69].

At the present time the Arbuzov rearrangement constitutes a widely used method for the synthesis of alkenylphosphonates, whereby it is possible to obtain very complex compounds, for example[70-74]:

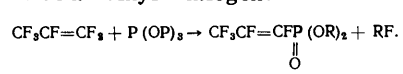


The reaction of trialkyl phosphites with α-halogenoacrylates is very interesting[75]:

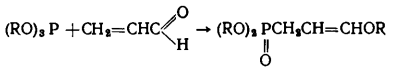
Ionin and Petrov found that halogenoacetylenes can also undergo the Arbuzov rearrangement[76,77]:



Such rearrangements take place particularly readily when the triple bond is conjugated with another multiple bond or a benzene ring[78,79]. Knuyants and coworkers showed that perfluoro-olefins can react with trialkyl phosphites[80-84], this being the first example of the Arbuzov rearrangement of compounds with a "vinyl" halogen:

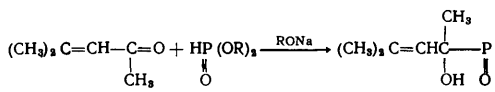


Trialkyl phosphites react by an Arbuzov rearrangement mechanism with $\alpha\beta$-unsaturated carbonyl compounds[85-88], the reaction being extremely specific:



4. Addition Reactions of Dialkyl Phosphites

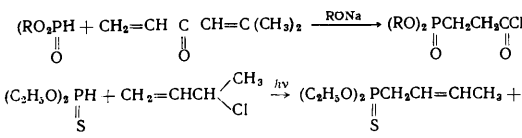
The methods of synthesis of alkenylphosphonates via various reactions of dialkyl phosphites are very unusual and as a rule comparatively simple. Thus Abramov, Pudovik et. al. found that dialkyl phosphites readily react with unsaturated carbonyl compounds forming derivatives of α-hydroxyallylphosphonic acid[89-93]:



Dialkyl phosphorothi-ites react similarly[94]:

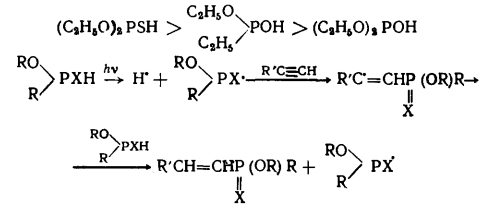
Reactions with ketones yield esters of α-acetoxyvinylphosphonic acid[95-97]:

Pudovik and coworkers found that dialkyl phosphites readily add to certain $\alpha\beta$-unsaturated carbonyl compounds, yielding alkenylphosphonates[98-105]:



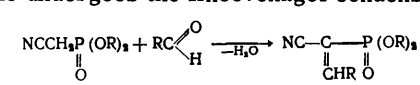
The yield of products is 50–70%. The reaction with propiolic acid derivatives gives β-alkoxycarbonylvinylphosphonates[106]:

Pudovik and coworkers showed that the reaction of dialkyl phosphoric acids with certain acetylenes can involve a radical mechanism. The addition takes place contrary to the Markovnikov rule; the rate of the process decreases in the series[105]:

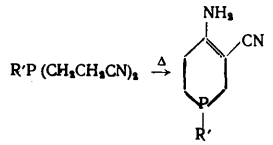


5. Certain Special Methods for the Preparation of Alkenylphosphonates

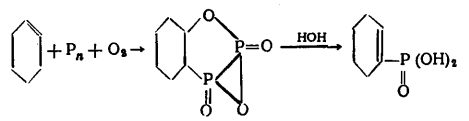
According to the data of Kirillov and Petrov, phosphonoacetonitrile undergoes the Knoevenagel condensation[107]:



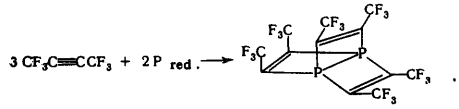
Alkylbis-(β-cyanoethyl)phosphines isomerise to phosphorins in boiling toluene[108-111]:



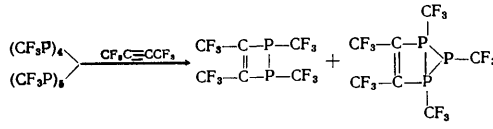
Certain cyclic alkenylphosphines can be obtained from elemental phosphorus[112-114]:



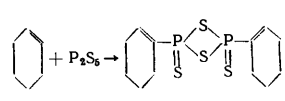
or[115,116]:



Similar polyphosphine heterocycles are formed in high yield when tetra and penta-trifluoromethylphosphines are heated with *sym*-hexafluorobutyne[117]:



Unusual alkenyl structures are produced in the reaction between phosphorus pentasulphide and olefins[118,119]:



6. Reactions Using Phosphorus Trichloride

Much work has been done on the study of the possibility of using phosphorus trichloride to synthesise compounds with a C–P bond, including alkenylphosphonates. Usually the second component is an olefin [120]:

$$PCl_3 + RCH{=}CH_2 \xrightarrow[H_2O]{(CH_3CO)_2O} RCH{=}CHP(O)(OH)_2 \quad .$$

Sometimes ketones are used in the reaction [121-125]:

$$C_6H_5CCH_3 + PCl_3 + CH_3COOH \xrightarrow{HOH;\ HCl} CH_2{=}C(C_6H_5){-}P(O)(OH)_2 \quad .$$

Kinnear, Perren, and other investigators have successfully employed in these processes the complex-forming capacity of aluminium chloride [126,127]:

$$RCl + PCl_3 + AlCl_3 \rightarrow RPCl_4 \cdot AlCl_3 \xrightarrow{HOH} RP(O)Cl_2 + HCl + Al(OH)_3 \quad ,$$

where R = alkenyl.

An extensive series of investigations by Soborovskii, Zinov'ev, and coworkers dealt with the oxidative chlorophosphination of hydrocarbons, including unsaturated hydrocarbons, which makes certain alkenylphosphonates extremely easy to obtain [128-134]:

$$CH_2{=}CHCl + PCl_3 + O_2 \rightarrow CH_2ClCHClP(O)Cl_2 \xrightarrow{ROH}$$

$$\rightarrow CH_2ClCHClP(O)(OR)_2 \xrightarrow{Zn} CH_2{=}CHP(O)(OR)_2 ,$$

$$RC{\equiv}CH + 2\,PCl_3 + O_2 \rightarrow RCCl{=}CHP(O)Cl_2 + POCl_3 \quad .$$

Recently a method has been found, and has been developed successfully, for the synthesis of alkenylphosphonates by the thermal (so called "pseudo-Claisen") rearrangement of various phosphite esters, primarily allyl and propargyl esters [135-140]:

$$(RO)_2P{-}OCH_2CH{=}CHCH_3 \xrightarrow{180^\circ} (RO)_2P(O){-}CHCH{=}CH_2 ,$$

$$(RO)_2P{-}OCH_2C{\equiv}CH \xrightarrow{180^\circ} (RO)_2PCH{=}C{=}CH_2 \rightarrow (RO)_2PC{\equiv}C{-}CH_3 \quad .$$

A possible mechanism of the isomerisation has been put forward [139,140].

7. Reactions of Phosphorus Pentachloride and Its Derivatives with Unsaturated Compounds

The most familiar and most thoroughly developed method for the synthesis of various compounds with alkenyl groups at the phosphorus atom is based on the interaction of phosphorus pentachloride with olefins. As early as 1894, Marsh and Gardner [141,142] stated that camphene reacts with phosphorus pentachloride to form a product which yields camphenylphosphonic acid after hydrolysis. Later, reactions of phosphorus pentachloride with styrene, isobutene, and other unsaturated hydrocarbons were described and it was found that the process takes place best with asymmetric polar systems; the PCl_4 group becomes attached to the most hydrogenated carbon atom and chlorine to the least hydrogenated carbon atom [143,144]. Bergmann and Bondi noted that at least a twofold excess of phosphorus pentachloride is necessary for satisfactory yields [145-147]:

$$RCH{=}CH_2 + 2\,PCl_5 \rightarrow RCHClCH_2PCl_4 \cdot PCl_5 \xrightarrow{HOH} RCH{=}CHP(O)(OH)_2 \quad .$$

It was found that the intermediate complexes can be treated with agents other than water under different conditions [148-150], namely phosphorus pentasulphide [151-152], sulphur [152-155], hydrogen sulphide [156-159], hydrogen selenide [160], and elemental phosphorus [151,158], or they can be heat-treated [151,159]. The yield of the acid chlorides of alkenylphosphonic acids and their analogous thio-derivatives is in the range 60–80%. The method was successfully extended to various styrene derivatives [148,161-163], diene hydrocarbons [164-166], and acetylenes [148,167-172].

It has been established that, depending on the structure of the initial diene and the reaction conditions, phosphorus pentachloride can add both in 1,2- [153,173] and 1,4-positions [174]. Anisimov, Nesmeyanov, Kolobova, and others employed extensively the reaction of phosphorus pentachloride with alkyl vinyl ethers [175-178] and alkyl vinyl sulphides [179,180]:

$$ROCH{=}CH_2 + 2\,PCl_5 \rightarrow ROCHClCH_2PCl_4 \cdot PCl_5 \xrightarrow{SO_2} ROCH{=}CHPCl_2(O) ,$$

$$RSCH{=}CH_2 + 2\,PCl_5 \rightarrow RSCHClCH_2PCl_4 \cdot PCl_5 \xrightarrow{SO_2} RSCH{=}CHPCl_2(O) \quad .$$

As can be seen from the above equations, it was found that the addition takes place in accordance with the Markovnikov rule [178-182]; cycloalkenyl ethers react similarly [183,184].

The treatment of the intermediate complexes with elemental phosphorus is now attracting increasing attention as a convenient method for the preparation of $\alpha\beta$-unsaturated phosphines [185,186]:

$$ROCH{=}CH_2 + 2\,PCl_5 \rightarrow ROCHClCH_2PCl_4 \cdot PCl_5 \xrightarrow{P} ROCH{=}CHPCl_2 \quad .$$

Lutsenko, Kirillov et al. found that the reaction of phosphorus pentachloride with enol esters leads to a wide variety of products. Various substituted alkenylphosphonates can be isolated [187-192]:

$$CH_3C(OCOCH_3){=}CH_2 + PCl_5 \rightarrow CH_3CCl(OCOCH_3)CH_2PCl_4 \xrightarrow{PCl_5,\ CH_3COCl,\ SO_2} CH_3CCl(COCH_3){=}C(O){-}PCl_2 \quad .$$

Apart from phosphorus pentachloride, other phosphorus(V) derivatives, primarily alkyl-and aryl-tetrachlorophosphoranes, can add to olefins [193-196]:

$$C_6H_5PCl_4 + CH_2{=}CHOC_2H_5 \rightarrow C_6H_5PCl_3CH_2CH(Cl)(OC_2H_5) \xrightarrow{SO_2} C_6H_5P(O)(Cl)(CH{=}CHOC_2H_5) \quad .$$

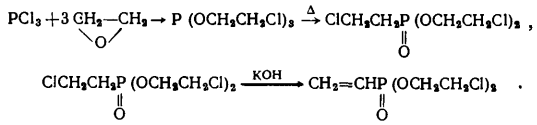
Recently it has been found that certain phosphorus(III) derivatives, mainly phosphorus trichloride [197,198] and tribromide [199-201], alkyl- and aryl-halogenophosphines [202,203], and alkyl and aryl phosphorochloridites [204-212], add readily to dienes, for example:

$$CH_2{=}CH{-}CH{=}CH_2 + ClP(O{-}CH_2{-}CH_2{-}O) \rightarrow \text{bicyclic adduct}(O{=}P{-}OCH_2CH_2Cl) \quad .$$

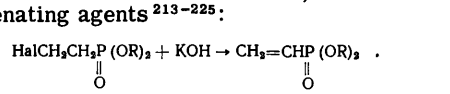
8. Elimination of Water and Acids from Saturated Organophosphorus Compounds

To conclude this review of synthetic methods for compounds with unsaturated groups at the phosphorus atom, we shall consider various methods for the elimination of the elements of water and acids from saturated organophosphorus compounds. Much attention has been devoted to this problem in the literature because various kinds of β-halogenophosphonates are at the present time some of the most widely available organophosphorus compounds and are obtained as a rule by the reaction of phosphorus halides

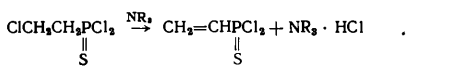
or their derivatives with epoxyalkanes followed by thermal isomerisation[213-218]:



A wide variety of basic substances, especially aqueous or aqueous-alcoholic solutions of alkalis, can be used as dehydrohalogenating agents[213-225]:

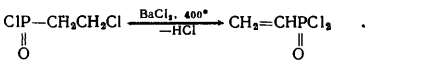


Tertiary amines and in particular triethylamine are dehydrohalogenating agents which come next in order of importance as regards frequency of application. In this case acid halides can also be introduced into the reaction[218,225]:

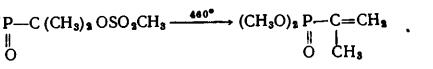


Alkali metal acetates[226-230], sodium carbonate[231], potassium t-butoxide[227], alkali metal hydrides[221], and activated charcoal[232-234] can be used as dehalogenating agents.

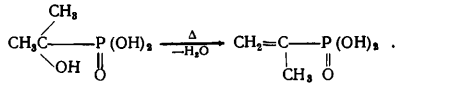
Thermal elimination of hydrogen halides, in the first place hydrogen chloride, is applicable to a comparatively narrow range of substances, but is technologically very promising and is now being effectively developed[235-241]:



The elimination of the elements of acids other than hydrogen halides takes place less completely and is frequently accompanied by side processes[97,242]:



Thermal degradation has been developed to an even lesser extent, although there are certain promising results showing that such a process is in principle possible[243,244]:



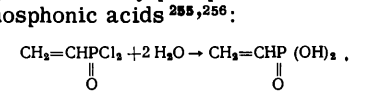
On the whole, the synthesis of organophosphorus structures with unsaturated groups at the heteroatom by the elimination of the elements of acids is at the present time most widely used both in the laboratory and in industrial practice[242,245-254].

III. PROPERTIES OF COMPOUNDS WITH UNSATURATED GROUPS AT THE PHOSPHORUS ATOM

1. Reactions Not Involving the Multiple Bond

a. Synthesis of esters, thioesters, and amides. It is noteworthy that, whereas the methods of preparation of the compounds under consideration have been developed comparatively fully, their chemical properties have been investigated to a much lesser extent. Only the double-decomposition reactions of alkenylphosphonic halides, certain nucleophilic addition reactions, and the tendency towards polymerisation have been investigated. Oxidation and reduction processes and certain specific rearrangements and condensation have been studied to a very limited degree.

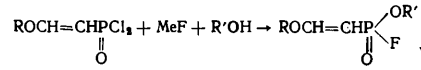
The hydrolysis of alkenylphosphonic halides yields unsaturated phosphonic acids[255,256]:



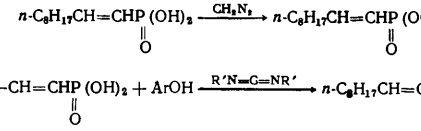
Esters of these acids are usually obtained from their chlorides and alcohols in an inert solvent; various tertiary amines are used as acceptors for hydrogen chloride[257-267]:

where X = H, alkyl, halogen, Sr, etc.

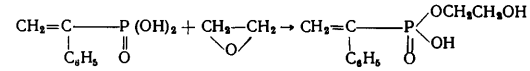
The yields of esters prepared in this way amount to 40-60%. Certain monoester acid fluorides can be obtained by acting upon the dichloride simultaneously with an alcohol and a metal fluoride[268]:



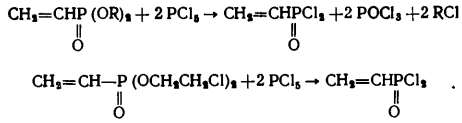
Higher unsaturated phosphonic acids can be esterified with diazomethane and also alcohols and phenols in the presence of carbodi-imide[269]:



Ivin and coworkers showed that certain higher alkenylphosphonic acids react with epoxides to form mono-β-hydroxyalkyl esters[270]:

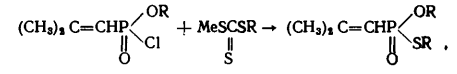


The reverse reaction – the interaction of alkenylphosphonates with phosphorus pentachloride–is possible[256,268]:

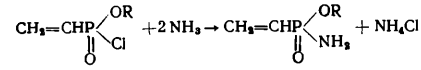


Thioesters of alkenylphosphonic acids [phosphonodithiolates (Translator)] are obtained in good yields when mercaptides react with the acid dichlorides[271-274]:

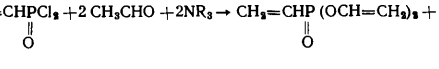
The reaction with salts of alkyltrithiocarbonic acid is similar[274]:



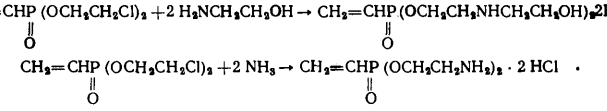
When the acid dichlorides react with ammonia and amines, the amides of alkenylphosphonic acids are formed[275-279]:



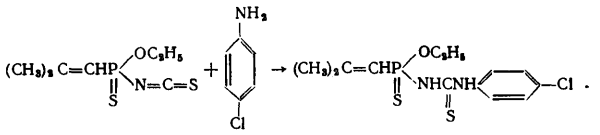
Gefter, Kabachnik, and coworkers extended the general method to alkenylphosphonates for the synthesis of vinyl esters[280,281]:



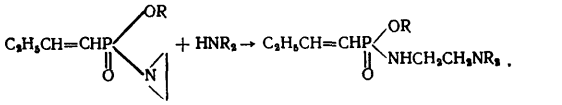
In the presence of halogen atoms in the saturated group, there is a possibility of their exchange for amino-groups, NR_2 groups, etc.[282]:



Alkenylphosphonyl thiocyanates enter into all the reactions characteristic of thiocyanates[283]:

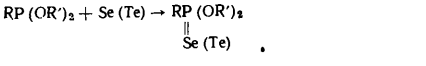


Ethyleneimides are fairly readily cleaved by compounds containing a mobile hydrogen atom[284]:

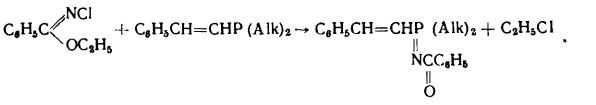


b. Oxidation and reduction reactions. Oxidation and reduction reactions of compounds with unsaturated groups at the phosphorus atom have been very little studied. Whereas the oxidation of various phosphorus(III) structures with oxygen, sulphur, selenium, and tellurium is known if only in principle, there have been almost no studies on reduction. The oxidation of phosphorus(III) compounds with oxygen has been most thoroughly investigated[8-13]. This process, which takes place very readily as a rule, begins sometimes when the substance simply comes into contact with atmospheric oxygen:

Sulphur, selenium, and tellurium add under much more severe conditions[12-16,19-22,285]:

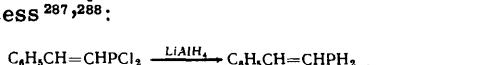


The reaction of tertiary unsaturated phosphines with chloroiminoethers must be classified as an oxidation reaction[286]:

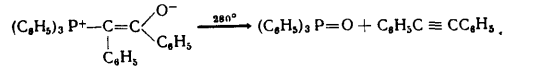


The oxidation of the compounds considered with ozone occupies a special place. As with ordinary olefins, this reaction causes a profound degradation of the molecule, which leads to carbonyl compounds or acids depending on the conditions[96,173].

Lithium aluminium hydride can be used as the reducing agent, since the multiple bond is then unaffected in the reduction process[287,288]:

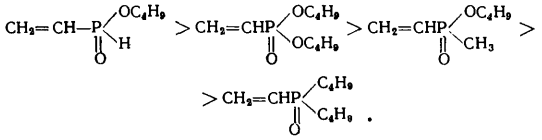


Pyrolysis of certain alkenylphosphonates results in the degradation of the molecule at the C – P bond[289]:



2. Reactions at the Multiple Bond

a. Nucleophilic addition. The specific features of alkenylphosphonates are shown in the study of various reactions involving the multiple bonds. The reviews of Kabachnik[290], Gefter[291], and Pudovik[54] have dealt with certain aspects of these interactions and their systematic description. The general properties of organophosphorus compounds with vinyl groups are described in Kabachnik's review and the problem of the conjugation of the multiple bond with trivalent and pentavalent phosphorus atoms is discussed. The author concludes that, although physicochemical methods such as infrared and ultraviolet spectroscopy and calculations of molar refractions fail to confirm the occurrence of conjugation, ESR data do indicate its existence. This is also shown by a whole series of chemical properties. For example addition reactions of various nucleophilic agents involving the double bond of organophosphorus compounds take place very readily, the proton always adding at the α-position with respect to the P=O group. Unsaturated organophosphorus compounds can be arranged in the following sequence in terms of decreasing capacity for such addition[292-294]:



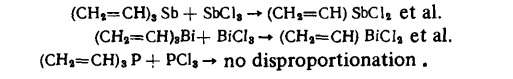
The addition to the first member of the series takes place vigorously with evolution of much heat, while the addition to the last member requires prolonged heating. This is due to the increasing positive inductive effect of the substituents at the phosphorus atom. Therefore the addition of electrophilic agents should follow the opposite sequence—dibutylvinylphosphine oxide should be the most reactive.

The addition of a nucleophilic group to phosphorus(III) compounds of the type $CH_2=CHPR_2$ also takes place at the β-position (although the inductive effect should lead to α-addition. Here evidently the participation of phosphorus d-orbitals in conjugation has an effect, as happens in vinylsilanes[295-297]:

In agreement with the above findings, dialkylamides of vinylphosphonic acid have lost almost completely the capacity to combine with nucleophilic agents, but readily combine with electrophilic agents (chlorine and bromine). If only the inductive effect operated in this case, vinylphosphonic dialkylamides would combine with compounds of the type X–H as readily as tertiary phosphine oxides.

Since vinyl compounds of four-coordinated phosphorus combine with nucleophilic agents and polymerise with greater difficulty than the corresponding carbonyl compounds, the conjugation of the heteroatom with the double bond is weaker in this case. Dipole moment measurements have shown that the conjugation of the phosphorus atom with a triple bond is more pronounced than with a double bond[298].

Of the general properties of compounds with unsaturated groups at the phosphorus atom, their inability to undergo disproportionation reactions, in contrast to the analogous antimony and bismuth compounds, should also be mentioned[299]:



Isomerisation processes of alkenylphosphonic esters in the presence of alkali metal alkoxides on heating merit attention. The phosphonates are then converted into species with maximum conjugation of the multiple bond [300-302]:

$$CH_2{=}CH{-}CH_2{-}P(OC_2H_5)_2 \xrightarrow{C_2H_5ONa} CH_3CH{=}CHP(OC_2H_5)_2,$$

$$CH_3CH{=}CHCH_2P(OR)_2 \xrightarrow{RONa} C_2H_5CH{=}CHP(OR)_2,$$

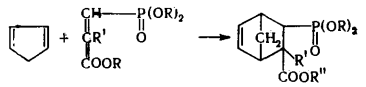
$$H_2C{=}C{=}CH{-}P(OR)_2 \xrightarrow{RONa} CH_3C{\equiv}C{-}P(OR)_2.$$

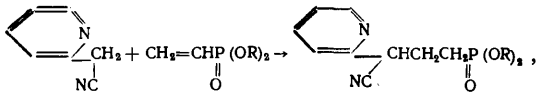
We shall now consider in detail various examples of nucleophilic addition to alkenylphosphonates. Reactions of this type have been investigated most fully for vinylphosphonic acid and have already been treated systematically to some extent [54]. The principal investigations in this field have been carried out by Pudovik, Kabachnik, and their coworkers. Since these reactions have the same mechanism, Pudovik called them "phosphonoethylation" [54], which reflects very correctly the essential features of this type of condensation addition. The reaction takes place readily with alcohol [303-305], hydrogen sulphide, mercaptans and selenium derivatives [17,297,306-311], ammonia and amines [312,313], various phosphorus(III) acids [314-317], thioacetic acid [318], and also thioacetic and malonic esters [309,310,315,319,320]. All the reactions with reagents of the type X – H have the same mechanism and take place as a rule in the presence of alkali metal alkoxides:

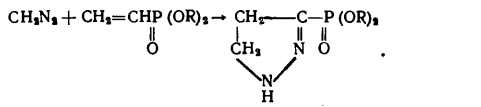
$$X{-}H + CH_2{=}CHP(OR)_2 \xrightarrow{RONa} XCH_2CH_2P(OR)_2,$$

where X = OR, SR, SeAr, NR_2, $P(O)(OR)_2$, $C(NO_2)_3$, etc.

Diene synthesis with vinylphosphonates and also reactions with the nitrile and esters of 2-pyridylacetic acid [321] and diazomethane [322] belong to the same class:







Dienylphosphonates also enter into nucleophilic addition reactions, with preferential 1,4-addition [127,308,323]:

$$CH_2{=}CH{-}C{=}CH{-}P(OR)_2 + X{-}H \xrightarrow{RONa} XCH_2CH{=}CCH_2P(OR)_2,$$

where X = SR, NR_2, or $P(S)(OR)_2$. Diene synthesis with these substances is possible but, in contrast to vinylphosphonates, here they constitute the diene component [324].

Recently the nucleophilic addition reactions have been extended to derivatives of acetoxyvinylphosphonic acid [325], triphenylvinylphosphonium bromide [326,327], alkynylphosphonates [328], vinylphosphonites [11], and perfluoroalkenylphosphonates [78,79,283,329,330].

b. Addition of reagents of the type —Hal. Addition to alkenylphosphonates of compounds with an active X–Hal bond has only just begun to be studied, if one disregards certain earlier investigations of the chlorination and bromination of these compounds [290]. In 1963 Schicke and Schrader took out a patent for the application of the products of the addition of alkanesulphenyl chlorides to vinylphosphonates [331]. At the same time and independently of these investigators similar studies were carried out by Ivin and coworkers [332]. It was found that the addition takes place in accordance with the polarisation of the sulphenyl chloride molecule, which corresponds to the formula RS^+Cl^-:

$$C_2H_5SCl + CH_2{=}CHP(OR)_2 \rightarrow ClCH_2CH(SC_2H_5){-}P(OR)_2,$$

$$C_2H_5SCl + CH_2{=}CHCH_2P(OR)_2 \rightarrow C_2H_5SCH_2CHClCH_2P(OR)_2.$$

The reaction was extended to a wide range of alkenylphosphonates and sulphenyl chlorides. Further development of the reaction showed that sulphur derivatives such as arenesulphenyl chlorides, alkyl dithiochlorides [333] [Ref. 333 refers to reaction of 2-chloroethyldithiochloride with derivatives of vinyl(alkyl)phosphic acid (Ed. of Translation)], sulphur dichloride [334], and acetyl dithiochloride [335] [Ref. 335 refers to acylsulphenyl chlorides (Ed. of Translation)] can enter into it:

$$CH_2{=}CHP(OR)_2 + \begin{cases} ClSCl \rightarrow ClCH_2CH(SCl){-}P(OR)_2 \\ ArSCl \rightarrow ClCH_2CH(SAr){-}P(OR)_2 \\ 2\,CH_3COCl \xrightarrow{-CH_3COCl} ClCH_2CH(SSCOR){-}P(OR)_2 \end{cases}.$$

Similar reactions have been carried out with allylphosphonates. Later it was shown that vinyl- and allyl-phosphonates react with nitryl chloride and hypochlorites [336,337]:

$$CH_2{=}CH(CH_2)_nP(OR)_2 + NO_2Cl \rightarrow O_2NCH_2CH(Cl)(CH_2)_nP(OP)_2,$$

$$CH_2{=}CH(CH_2)_nP(OR)_2 + (CH_3)_3C{-}O{-}Cl \rightarrow (CH_3)_3C{-}O{-}CH_2CH(Cl)(CH_2)_nP(OR)_2,$$

where n = 0 or 1.

The structure of the addition products was proved by their dehydrochlorination and by the ozonolysis of the unsaturated compounds produced.

Addition reactions in the presence of initiators of radical processes are possible with certain alkynylphosphines [19,20]:

$$C_2H_5SH + h\nu \rightarrow C_2H_5S^{\cdot} + H^{\cdot},$$

$$R_2PC{\equiv}CH + C_2H_5S^{\cdot} \rightarrow R_2PC^{\cdot}{=}CHSC_2H_5,$$

$$R_2PC^{\cdot}{=}CHSC_2H_5 + C_2H_5SH \rightarrow R_2PCH{=}CHSC_2H_5 + C_2H_5S^{\cdot}.$$

c. Oxidation and reduction reactions. It has been shown that in the presence of the usual hydrogenation catalysts such as platinum, palladium, and Raney nickel, hydrogen readily adds to double bonds without involving the P=O group [338-340]:

$$\begin{matrix} p\text{-}ClC_6H_4 \\ CH_3OC_6H_4 \end{matrix}\!\!> C{=}CH{-}P(OH)_2 \xrightarrow{H_2;\,Pd} \begin{matrix} p\text{-}ClC_6H_4 \\ CH_3OC_6H_4 \end{matrix}\!\!> CHCH_2P(OH)_2.$$

Rosental and Geyer made a successful attempt to oxidise allylphosphonates by the Bayer–Williger method [341]:

$$CH_2{=}CHCH_2P(OR)_2 + HCOOH + H_2O_2 \rightarrow CH_2{-}CH(OH){-}CH_2{-}P(OR)_2.$$

Pudovik and Gareev found that, in contrast to vinylphosphonates, allylphosphonates react with diazoacetic ester [342]:

$$CH_2{=}CHCH_2P(OR)_2 + N_2CH{-}COOC_2H_5 \rightarrow CH_2{-}CH(CHCOOC_2H_5){-}CH_2{-}P(OR)_2 + N_2.$$

Finally, we may note the capacity of triphenylphosphonium bromide to form cyclic compounds with α-hydroxycarbonyl compounds with simultaneous elimination of triphenylphosphine oxide[343,344]:

Copolymerisation of Cyclic Compounds

T.M.Frunze and V.V.Kurashev

The number of studies dealing with the synthesis of copolymers and the investigation of the copolymerisation of cyclic monomers of a single class is large. The present review is concerned with the polymerisation of cyclic compounds, in which the ring is opened, with monomers of other classes, i.e. of a different chemical type. These processes include the copolymerisation of a number of cyclic compounds with olefins and also the copolymerisation of two cyclic compounds of different classes. The conditions of synthesis, the mechanism of formation, and certain properties of such copolymers are considered. The bibliography comprises 88 references.

I. INTRODUCTION

The study of copolymerisation is of great practical and theoretical importance. Copolymerisation permits the desired modification of the properties of polymers. Sometimes the properties of copolymers differ appreciably from those of the corresponding homopolymers, while in other cases the copolymers combine the properties characteristic of the homopolymers.

The copolymerisation of vinyl monomers has been investigated comparatively thoroughly. Many reviews and monographs describing both the theoretical aspects of the process and the problems of the practical application of various copolymers have been published. The polymerisation and copolymerisation of cyclic compounds has been studied much less adequately. However, the number of papers published in this field increases from year to year.

The polymerisation of cyclic compounds has assumed increasing importance as a general method of synthesis of high-molecular compounds. The principal advances in this field were achieved in the industrial polymerisation of lactams, epoxy-compounds, and certain other cyclic monomers.

In the copolymerisation of cyclic compounds the following principal cases can be distinguished: (1) copolymerisation of cyclic compounds of the same chemical type (for example different lactones or epoxy-compounds); (2) copolymerisation of cyclic compounds with vinyl compounds; (3) copolymerisation of cyclic compounds of different chemical types (for example lactones with epoxy-compounds, etc.). From the theoretical standpoint, the first case is not of fundamental interest, since, in view of the identical chemical type of the monomers, the polymerisation mechanism does not differ from the mechanism of homopolymerisation and the process is determined merely by the kinetic and thermodynamic factors associated with the structure of the monomers. In contrast, the last two cases are extremely interesting from both the theoretical and practical points of view. They give rise to new opportunities for the synthesis of high-molecular compounds both as regards the development of new methods and the synthesis of new copolymers, and they extend the range of monomers suitable for copolymerisation.

The study of the copolymerisation of cyclic compounds has not been as detailed as that of vinyl monomers and the copolymerisation of cyclic compounds with compounds of other chemical types has been studied to an even lesser extent. There is no doubt, however, that such copolymerisation is of great interest and an attempt is made in the present review to give a systematic account of the available literature data on this question.

Polymerisation with ring opening is frequently called polyaddition. It takes place in stages (for example, hydrolytic polymerisation) or is a chain reaction (for example, ionic polymerisation). In the polymerisation of cyclic compounds the products are hetero-chain polymers, which can be obtained also by the polycondensation of certain bifunctional compounds. However, a characteristic feature of the polymerisation of cyclic compounds is that the compositions of the monomer and polymer are the same, i.e. in polymerisation with ring opening chemical bonds of types other than those in the monomer are not produced, the bonds being merely redistributed. Thus the initial monomer and the polymer formed in the polymerisation of cyclic compounds belong to the same chemical class.

Polymerisation has a number of advantages over polycondensation. Thus, in order to obtain polymers with high molecular weight by polycondensation, the proportions of the starting components must be rigorously equimolar and provision must be made for sufficiently effective removal from the reaction sphere of the low-molecular products evolved. In the polymerisation of cyclic compounds this is not necessary and the polymers formed have as a rule a high molecular weight.

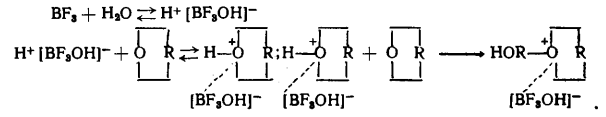
II. COPOLYMERISATION OF CYCLIC COMPOUNDS WITH OLEFINS

The copolymerisation of cyclic compounds with olefins has been investigated relatively little. It usually takes place via an ionic, usually cationic, mechanism, although there are indications that this type of polymerisation occurs also in the presence of radical initiators. Examples of this kind of polymerisation are quoted in Table 1.

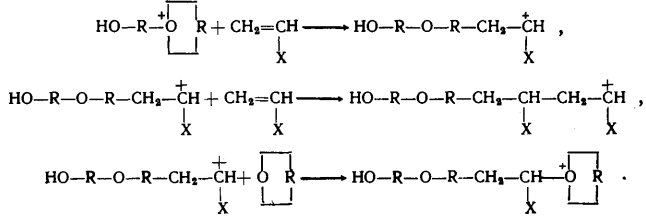
1. Ionic Copolymerisation

a. Cationic copolymerisation. The copolymerisation of cyclic compounds with olefins takes place mainly by a cationic mechanism, which may be because of the particular range of co-monomers investigated at the present time. These are mainly cyclic ethers, lactones, and certain other oxygen-containing compounds.

The initiation of the polymerisation of cyclic ethers in the presence of Lewis acids can be represented as follows:



When this mechanism is extended to the copolymerisation of cyclic ethers with olefins, the formation of copolymers can be represented thus:

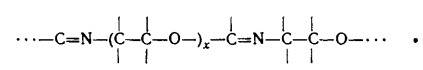


The possibility of the cationic copolymerisation of cyclic ethers and olefins was demonstrated by Merten[1], who achieved the copolymerisation of the following combinations of monomers in the presence of boron trifluoride-ether: styrene–olefin (propene, styrene) oxide, styrene–epichlorohydrin, chloroprene–olefin (propene, styrene) oxide, propene oxide–olefin (isobutene, propene, divinylbenzene), and epichlorohydrin–acrylonitrile. The copolymerisation yielded liquid copolymers. Liquid polyesters with terminal hydroxy-groups are formed in the cationic copolymerisation of epichlorohydrin with styrene in the presence of linear polyacetals and boron trifluoride-ether[2]. In contrast to the previous investigations, Minoura and Minton[3] obtained solid copolymers of epichlorohydrin and styrene by carrying out the reaction in benzene solution in the presence of boron trifluoride-ether. In the first stages of the reaction the copolymer is enriched in epichlorohydrin units. The authors suggest that the first reaction step is the interaction of epichlorohydrin with the catalyst. Gurgiolo[4] described a method for the preparation of solid copolymers

of epoxyalkanes with a number of unsaturated monomers, the copolymers having relatively high softening points (120–190°C) and readily forming very flexible films. The copolymerisation of epoxy-compounds (epichlorohydrin, epoxyethane, epoxypropane) with unsaturated compounds (vinylidene chloride, methyl methacrylate, butadiene) was carried out in the presence of the complex of ferric chloride and the epoxy-compound.

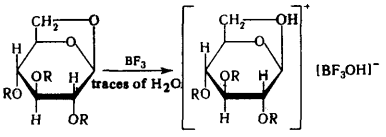
Durgaryan and Beginyan[5] described the copolymerisation of epichlorohydrin with aceto- and benzo-nitriles carried out in the solid phase at 70°C in the presence of 5 mole % $SnCl_4$ as catalyst. It is interesting that, under the conditions chosen, the nitriles taken separately do not polymerise. The formation of copolymers was demonstrated by fractional precipitation. In addition it was shown that the dependence of the composition of the copolymers on that of the initial mixture follows the equation characterising the composition of a copolymer. The copolymerisation constants are $r_1 = 4.2 \pm 0.4$ and $r_2 = 0 \pm 0.02$ for epichlorohydrin and acetonitrile and $r_1 = 2.8 \pm 0.2$ and $r_2 = 0 \pm 0.02$ for epichlorohydrin and benzonitrile.

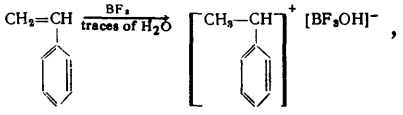
Since in the hydrolysis of copolymers the acids corresponding to the nitrile are formed quantitatively, together with compounds containing amino-groups, it was concluded that the copolymerisation of nitriles with epichlorohydrin does not involve the formation of new carbon–carbon bonds. The following structure was assigned to the copolymer:



Parnikis et al.[6] investigated the copolymerisation of trimethyl-laevoglucosan with styrene under the influence of boron trifluoride-ether. The formation of a copolymer was demonstrated by fractional precipitation, turbidimetric titration, and by thermomechanical compression curves. The following mechanism is proposed for the formation of copolymers.

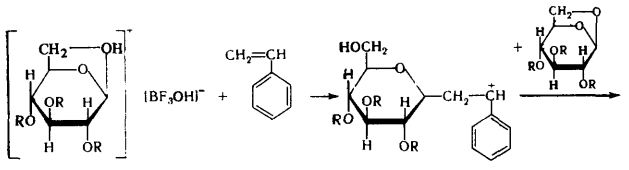
(a) Initiation:

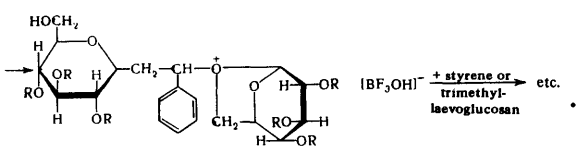




or

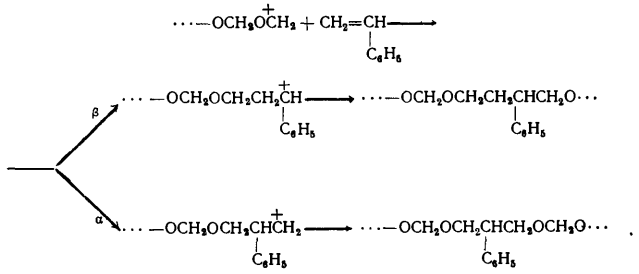
(b) chain growth:



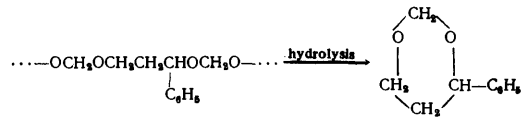


Parnikis et al.[6] believe that, in view of the different reactivities of the oxonium and carbonium ions, initially styrene polymerises preferentially and then trimethyl-laevoglucosan. When styrene or methylmethacrylate is allowed to act on the "live" tetramethyl-laevoglucosan polymer obtained under the influence of boron trifluoride, the corresponding block-copolymers are produced.

Trioxan (a cyclic ether) can also enter into cationic copolymerisation with styrene, vinyl ethers, and acrylonitrile[7]. It is suggested that the copolymerisation of trioxan with styrene takes place under the action of free carbonium cations. The polymeric chain can grow by the addition of a carbonium ion derived from trioxan to the α- or β-carbon atom of the vinyl group in styrene[8]:



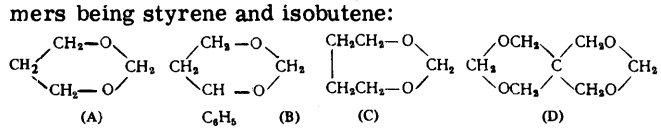
4-Phenyl-1,3-dioxan was isolated after the acid hydrolysis of the copolymer[9]:



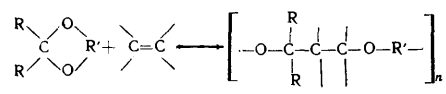
This is evidence of the addition of the carbonium ion to the β-carbon atom of styrene.

There are indications in the literature that the copolymers obtained in the cationic copolymerisation of trioxan with vinyl monomers are thermostable products capable of being worked by pressing (at 190°C and a pressure of 105 atm)[10]. Such copolymers can be used for the manufacture of flexible strips and films[11]. In order to copolymerise dioxan with vinyl monomers, catalysts other than boron triofluoride–ether can be used, for example triethyl or trimethyl hexachloroantimonate, bis(triethyloxonium) hexachlorostannate, trimethyl-, triethyl-, or tri-n-propyloxonium fluoroborate, etc.[11]

Cyclic formals have been polymerised with vinyl compounds[12]. The copolymers thus obtained are low-molecular liquid products with terminal hydroxyls. They are recommended for use in the synthesis of polyurethane rubbers. The cyclic formals used were 1,3-dioxan (A), 4-phenyl-1,3-dioxan (B), tetramethyleneformal (C), and the diformal derived from pentaerythritol (D), the vinyl monomers being styrene and isobutene:

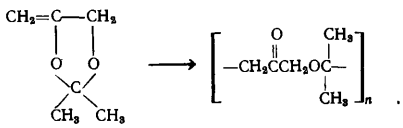


Sulphuric acid or polystyrenesulphonic acid and glycols such as butane-1,4-diol or 1,4-di-(β-hydroxyethoxy)butane were used as catalytic systems. It is suggested that copolymerisation leads to the formation of a copolymer having the following structure:



Okada and coworkers[13] investigated the cationic copolymerisation of 1,3-dioxolan with styrene in toluene solution at 25°C in the presence of boron trifluoride-ether. On the basis of the results obtained after the extraction of the product with hot water and methanol, it is suggested that a true copolymer is formed. The apparent constants for the copolymerisation of 1,3-dioxolan with styrene calculated from the Mayo–Lewis equation are respectively $r_1 = 1.9$ and $r_2 = 0.35$. It has been shown by NMR and by hydrolysing the copolymer that the 1,3-dioxolan ring opens during the reaction at the O_1-C_2 bond.

An interesting example of the formation of polymers involving the opening of the ring and of the multiple bond is the homopolymerisation of 2,2-dimethyl-4-methylene-1,3-dioxolan. Goodman and Abe[14] showed that, in the presence of boron trifluoride-ether, the polymerisation of 2,2-dimethyl-4-methylene-1,3-dioxolan takes place both with participation of the vinyl group and via ring opening and is accompanied by intramolecular rearrangement:



Lactones constitute another type of cyclic compounds capable of undergoing cationic copolymerisation with olefins. The copolymerisation takes place in the presence of stannic chloride or boron trifluoride-ether[15,16]. It has been found that cross propagation takes place with difficulty and under the conditions investigated appreciable amounts of block copolymers are formed. The authors explained this result by the formation in the reaction sphere of a specific complex of the lactone and the catalyst ($SnCl_4$) which catalyses the polymerisation of the lactone but not that of styrene. The authors note that the polymerisation of styrene and its copolymerisation with the β-lactone depend on the content of free catalyst (for example $SnCl_4$) in the reaction mixture, which is determined by the polarity of the solvent in which the copolymerisation is carried out.

In a polar solvent (for example in nitrobenzene) the amount of free stannic chloride increases. The content of lactone units in the copolymer is then reduced.

Although the nature of the complex of the lactone and the catalyst is unknown, the results obtained and also comparison with its catalytic capacity in homopolymerisation (for example of phthalide) show that the formation of the catalyst–cyclic monomer complex is an important factor controlling the copolymerisation of vinyl and cyclic compounds.

b. Anionic Copolymerisation. The anionic copolymerisation of vinyl monomers with cyclic compounds is carried out in the presence of initiators which form either free or co-ordinately bound anions. Under these conditions copolymerisation is rare—usually the homopolymerisation of both the cyclic and the vinyl monomer takes place.

Table 1 lists the known examples of anionic copolymerisation of cyclic compounds, mainly epoxy-compounds, with olefins. Thus Tsuruta and Fujio[17] showed that, in the presence of catalysts such as aluminium alkoxides, methyl vinyl ketone copolymerises with certain epoxy-compounds (epoxypropane or epichlorohydrin). The copolymerisation was carried out in benzene solution at 80°C for three days. The formation of a real copolymer is indicated by the agreement between the results of its investigation by turbidimetric titration and by infrared spectroscopy. Since the infrared spectrum of the copolymer does not contain absorption bands characteristic of the double bond and there are bands corresponding to the carbonyl group, it is suggested that the copolymerisation involves the opening of the ring of the epoxy-compound and of the double bond of the olefin.

Okamura and Hayashi[18] described the copolymerisation of olefins (ethylene, propene) oxides with acrylonitrile under the influence of γ-radiation. Successful copolymerisation depends to a considerable degree on the reaction temperature: at room temperature only the homopolymer of acrylonitrile is formed, while at low temperatures (between −178 and −196°C) copolymers are produced. As the reaction temperature is reduced, the content of olefin oxide units in the copolymer increases. The fact that epoxypropane does not polymerise by a radical mechanism and also the occurrence of the reaction at low temperatures suggest an anionic reaction mechanism in this case, but special studies designed to elucidate the mechanism of copolymerisation were not undertaken.

Lactones are also capable of polymerising with certain unsaturated compounds under the influence of anionic catalysts. Shimosaka et al.[19] carried out the copolymerisation of β-propiolactone with acrylonitrile at room temperature in the presence of various anionic catalysts: $SrZn(C_2H_5)_4$, $Al(C_2H_5)_3$, naphthalenesodium, $C_4H_9Li + Al(C_2H_5)_3$, and $B(C_4H_9)_3 + Cd(C_2H_5)_2$. Copolymerisation results in the formation of polymeric products which can be separated into fractions soluble and insoluble in chloroform. The chloroform-soluble fraction is the homopolymer of β-propiolactone, while the insoluble fraction consists of the homopolymer of acrylonitrile and its copolymer with β-propiolactone.

Shiota et al.[20] achieved the grafting of β-propiolactone onto polyacrylonitrile. Potassium hydroxide, sodium methoxide, and butyl-lithium were used as catalysts of the graft copolymerisation of the β-lactone with polyacrylonitrile.

Apart from the copolymerisation reactions of cyclic compounds with olefins examined above, examples of block-copolymerisation are known. Thus Richards and Szwarc[21] and also Finaz et al.[22] obtained block-copolymers of styrene with epoxyethane. The reaction of "live" polystyrene with epoxyethane results in the formation of terminal ... $CH_2CH_2\bar{O}\dot{N}a$ group, capable of adding epoxyethane with formation of copolymers in which the polystyrene block is included between polyepoxyethane blocks. Such copolymerisation goes almost to completion. When the same reaction is carried out with epoxypropane, only 25% of the epoxy-compound copolymerises. Probably in this case chain transfer to epoxypropane takes place and leads to the formation of a polyepoxypropane homopolymer. Furukawa et al.[23] obtained a block-copolymer of acrylonitrile with epoxyethane, using the alkoxide of polyepoxyethane as the catalyst.

2. Radical Copolymerisation

The radical copolymerisation of olefins with cyclic compounds has been least investigated. Indeed, while the addition of free radicals to atoms attached to a double bond has been known for a long time[24], the process has been inadequately elucidated for various cyclic compounds. In general radicals show a greater tendency to combine with hydrogen or any other reactive atom or group than to effect ring opening. Probably this is why radical copolymerisation of olefins with cyclic compounds is difficult.

Nevertheless cases are known where carbon and other rings open under the influence of free radicals. This has been demonstrated in reactions of low-molecular organic

compounds. For example, in the free-radical chlorination of spiropentanes chloro-derivatives of aliphatic hydrocarbons are formed[25].

Gritter[26] achieved the addition of epoxypropane to oct-1-ene in the presence of t-butyl peroxide; 2-undecanone (a) and 5-hydroxy-2-hexanone (b) were isolated in low yields. By carrying out the reaction at a lower temperature (below 125°C), it proved possible to obtain only the second compound. The authors suggest the following reaction mechanism:

$$(CH_3)_3COOC(CH_3)_3 \longrightarrow 2\,(CH_3)_3CO\cdot ,$$

$$(CH_3)_3CO\cdot + CH_3CH(O)CH_2 \longrightarrow CH_3\dot{C}(O)CH_2 \longrightarrow CH_3C(=O)\dot{C}H_2 ,$$

$$CH_3C(=O)\dot{C}H_2 + CH_2{=}CHC_6H_{13} \longrightarrow CH_3C(=O)CH_2CH_2\dot{C}HC_6H_{13} \xrightarrow{RH} CH_3C(=O)CH_2CH_2CH_2C_6H_{13}, \quad (a)$$

$$CH_3C(=O)\dot{C}H_2 + CH_3CH(O)CH_2 \longrightarrow CH_3C(=O)CH_2CH_2CH(OH)CH_3 . \quad (b)$$

Radicals formed from epoxypropane isomerise to keto-radicals, which are capable of reacting both with the double bond and with the epoxy-ring. Further development of the reaction is difficult due to termination which occurs when the radicals react with hydrogen atoms. The last of the stages enumerated above prevents the formation of a polymeric chain. However, despite the absence of communications on the homopolymerisation of olefin oxides under the action of radical initiators, the possibility of ring opening by a radical mechanism cannot be excluded[25,27]. Nor can one exclude the possibility of the copolymerisation of olefins with cyclic compounds, the occurrence of which has been confirmed in a number of studies quoted below. Examples of the radical copolymerisation of certain cyclic compounds, mainly epoxy-compounds, with olefins are presented in Table 1.

Table 1. Copolymers of cyclic compounds and olefins.

Co-monomers	Type of catalyst: radical	anionic	cationic	Refs.
Epoxyethane-				
-ethylene	benzalazine	–	–	28
-vinylidene chloride	potassium persulphate	–	$FeCl_3$.epoxypropane	30, 4
-chlorotrifluoroethylene	t-butyl peroxide	–	–	34

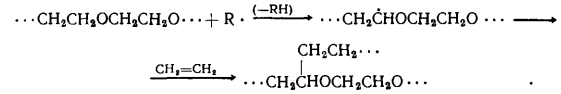
-polyacrylonitrile	–	butyl-lithium, potassium hydroxide, sodium methoxide	–	20

The radical copolymerisation of 1,2-epoxy-compounds with olefins takes place mainly at high temperatures. Coffman[28] described the copolymerisation of ethylene with epoxyethane, which was carried out at 200–250°C under a pressure of 350–1000 atm in the presence of benzalazine as the initiator. The copolymers obtained contained between 5 and 15 mole % of epoxyethane. When the copolymer was treated with hydrobromic acid, most of the epoxyethane units were eliminated in the form of ethyl bromide. This shows that most of these units are arranged consecutively in the copolymer and that the latter is an antistatic agent. Furthermore polyepoxyethane, which can form by a non-radical mechanism, as a result of the presence of ether

links in the main chain, can readily give up hydrogen atoms to radicals. Consequently there is a possibility of the formation of graft copolymers via a chain-transfer reaction:



In 1949 a method for the copolymerisation of dec-1-ene with epoxyethane was patented[29]. The reaction was carried out at 260–370°C for 10 h.

Stanton and Lowry[30] obtained a series of copolymers of vinylidene chloride with the oxides of ethylene, propene, and butadiene. The copolymerisation was carried out in aqueous emulsion using potassium persulphate as the initiator. In contrast to the unmodified poly(vinylidene chloride), the copolymers with epoxyethane had lower softening temperatures (about 135°C) and contained polyepoxyethane, which could not be extracted with water. However, this is not sufficient evidence for postulating the formation of a non-ordered copolymer.

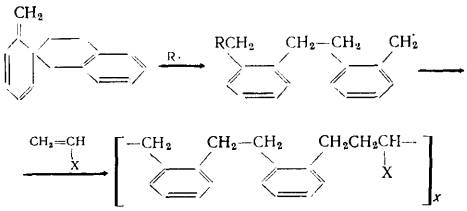
Ponomarev et al.[31] described a study on the copolymerisation of styrene oxide with butadiene in the presence of cumenyl hydroperoxide. It was shown that the polymerisation of styrene oxide and butadiene in aqueous emulsion at 5°C leads to the formation of a copolymer with a high molecular weight.

McCall and Coover[32] described a method for the preparation of copolymers of ethylene and β-propiolactone containing 2.8 wt. % of the lactone. The copolymerisation was performed in the presence of di-t-butyl peroxide.

The copolymerisation of styrene with β-propiolactone in the presence of radical initiators led to the formation of block-copolymers with terminal hydroxy- and carbonyl groups[33].

It is noteworthy that in all the studies enumerated above there are no direct data demonstrating that the addition of cyclic compounds to the growing polymeric molecule takes place via ring opening by a radical mechanism. In general the radical copolymerisation of vinyl monomers with cyclic compounds takes place with difficulty. However, in special cases the process does occur and leads to the formation of copolymers with alternating units of the initial monomer. For example, Hauptschein and Lesser[34] achieved the radical copolymerisation of perfluoropropene with epoxyethane (both with initiation by ultraviolet light and in the presence of di-t-butyl peroxide), the monomer ratio in the initial mixture being varied from 1 : 1 to 2 : 1. In all cases polymeric products were obtained in the form of a thick viscous mass with high stability to the action of chemical reagents. The stability of this copolymer to the action of concentrated sulphuric acid and heating with 47% hydriodic acid for 24 h at 150°C suggests that the reaction product is a copolymer with alternating units of the initial monomers in proportions of 1 : 1, since otherwise it would have decomposed. Probably the chain of this copolymer is constructed on the "head to tail" principle, i.e. $-(C_3F_6-O-CH_2-CH_2-)$. Copolymers of epoxyethane with trifluoroethylene were obtained similarly. Vinylidene fluoride does not form copolymers with epoxyethane but the rate of homopolymerisation of vinylidene fluoride in the presence of epoxyethane is much higher.

Spirodi-*o*-xylylene may be quoted as a specific cyclic monomer, which in the presence of radical initiators is capable of homopolymerisation and copolymerisation with a number of olefins (styrene, acrylates, and methacrylates); its copolymerisation with many olefins yields copolymers with a 1 : 1 ratio of structural units[35]:



A distinct feature of this monomer is the presence of a double bond conjugated with the ring. This double bond evidently makes the monomer sensitive to radical initiators. In this case polymerisation takes place with the opening of the double bond and the conjugated ring, as in the polymerisation of conjugated dienes by 1,4-addition. 1,1-Dichloro-2-vinylcyclopropane[36] and vinylcyclopropane[37] polymerise in the same way, under the action of both cationic and radical catalysts.

III. COPOLYMERISATION OF CYCLIC COMPOUNDS

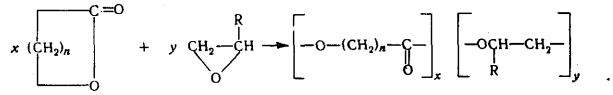
The copolymerisation of cyclic monomers can be used for the preparation of various classes of linear hetero-chain copolymers, which can find a wide variety of applications. Most of the studies which have been made dealt with the copolymerisation of cyclic compounds of the same chemical type, differing from one another only in the number of units in the ring or the presence of various substituents. A number of investigations have been made of the copolymerisation of lactams[41–45] and lactones[46,47]. The copolymerisation of various cyclic ethers has been discussed in detail in the monograph of Furukawa and Saegusa[48].

The present review deals with studies on the polymerisation of cyclic compounds of different chemical types. Copolymers with hetero-bonds in the macromolecular chain derived from both copolymerising monomers can be obtained in such copolymerisation. However, the number of studies on this type of copolymerisation is small and covers a very restricted range of monomers (Table 2).

1. Copolymerisation of Lactones

a. Copolymerisation with oxygen-containing compounds. Lactones can polymerise with cyclic ethers (epoxyalkanes, tetrahydrofuran, oxetans, trioxan), imines, and certain other cyclic compounds. The activity of lactones in the copolymerisation reaction is different and depends on the structure of the lactone, the chemical type and structure of the second co-monomer, and the catalytic system used.

The copolymerisation of lactones with epoxy-compounds should lead to the formation of copolymers containing ether and ester links in the chain:



This process has attracted the attention of many investigators, but satisfactory results cannot be always achieved. Thus Furukawa and coworkers[78] established that, when cadmium, zinc, or aluminium alkyls are used as catalysts

and oxygen, water, or alcohol as co-catalysts (i.e. catalytic systems which are fairly effective for the homopolymerisation of β-propiolactone[78] and epoxypropane[79]) in the copolymerisation of β-propiolactone with epoxypropane, a copolymer does not form. Catalytic systems such as boron trifluoride-ether and triethylaluminium with added water also proved to be ineffective[49]. A copolymer of β-propiolactone and epoxypropane could be obtained only in the presence of aluminium tri-isopropoxide but with a very low (up to 5%) content of epoxypropane units[49]. Cherdron and Ohse[50] also failed when they used organoaluminium compounds and boron trifluoride-ether as catalysts for this copolymerisation. Thus it is evident that the copolymerisation of β-propiolactone with epoxypropane in the presence of the above catalysts either does not take place at all or takes place with great difficulty.

In contrast to epoxypropane, other epoxy-compounds (epichlorohydrin, styrene oxide) undergo copolymerisation with β-propiolactone much more readily. The copolymerisation of β-propiolactone with epichlorohydrin[49,50] and styrene oxide[50] takes place readily in the presence of triethylaluminium, but boron trifluoride-ether and aluminium tri-isopropoxide proved to be ineffective as catalysts of the copolymerisation of epichlorohydrin with β-propiolactone[49].

In contrast to β-propiolactone, δ-valerolactone copolymerises comparatively readily with epoxypropane and styrene oxide in the presence of triethylaluminium or boron trifluoride-ether.

As a rule, the copolymers of lactones with epoxy-compounds are solid crystalline products with a molecular weight of several tens of thousands and with a melting point lower than those of the corresponding lactone-homopolymers. However, the use of polyhydric alcohols or the corresponding alkoxides as polyfunctional co-catalysts in the copolymerisation of lactones with epoxy-compounds leads to the formation of branched-chain liquid copolymers

Table 2. Copolymerisation of cyclic compounds.

Co-monomers	Type of catalyst: anionic	Type of catalyst: cationic	Refs.
β-Propiolactone–			
–epoxypropane	aluminium tri-iso-propoxide	–	49
–epichlorohydrin	triethylaluminium	BF_3-ether	49, 50

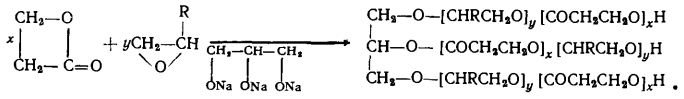
* Without catalyst.

with terminal hydroxyls[50], which gives rise to wide opportunities for the modification of such copolymers by allowing them to react with isocyanates and other compounds:



Cherdron and Ohse[50] also studied the copolymerisation of lactones with epoxy-compounds containing unsaturated bonds. These were butadiene monoxide [epoxybutene ? (Ed. of Translation)], isoprene monoxide, allylglycidyl ether, and vinylcyclohexene monoxide. It was established that unsaturated epoxy-compounds which polymerise with difficulty via ring opening are also difficult to copolymerise with a lactone. The first three epoxy-compounds belong to this class. Vinylcyclohexene monoxide, which itself readily polymerises, is also easy to copolymerise with lactones. It is noteworthy that the choice of catalyst influences to a high degree the composition and properties of the copolymers formed. In the presence of boron trifluoride-ether liquid copolymers of β-propiolactone and vinylcyclohexene monoxide enriched in the second component are produced. On the other hand, in the copolymerisation of the same compounds in the presence of triethylaluminium solid copolymers enriched in β-propiolactone residues are produced. The presence of double bonds in such copolymers gives rise to the possibility of their further modification. For example, when the unsaturated epoxy-compound is copolymerised with a lactone in the presence of triethylaluminium in styrene, which does not polymerise under the influence of triethylaluminium without a co-catalyst, it is possible to achieve two-stage copolymerisation[50]. The first stage involves the formation of the copolymer of the lactone with the unsaturated epoxy-compound, and, after the addition of a radical initiator to the reaction mixture, the copolymerisation of styrene with the copolymer takes place.

Toda et al.[52,53] investigated the copolymerisation of β-propiolactone with 3,3-bis(chloromethyl)oxacyclobutane in the presence of "triethylaluminium–water" and boron trifluoride-ether catalytic systems. In both cases copolymers insoluble in chloroform were obtained. The formation of a copolymer was confirmed by infrared spectroscopy. With increasing content of lactone in the initial mixture, the degree of conversion and the fraction insoluble in chloroform decrease. When the initial mixture contains 75 mole % of 3,3-bis(chloromethyl)oxacyclobutane, only the homopolymer of the latter is formed. The composition of the copolymer depends to a large extent on the type of catalyst used in the copolymerisation. The copolymers obtained in the presence of triethylaluminium and water contain more lactone units than those produced in the presence of boron trifluoride-ether.

Tsuda et al.[54] studied the effect of substituents on the reactivity of lactones in cationic copolymerisation with 3,3-bis(chloromethyl)-oxacyclobutane. The activity of the lactone investigated, found from the composition of the copolymers, decreases in the following sequence: ββ-dimethyl-β-propiolactone ≫ β-methyl-β-propiolactone > β-propiolactone > α-methyl-β-propiolactone > αβ-dimethyl-β-propiolactone. The authors[54] believe that in the polymerisation of β-lactones the C–O bond dissociates on the side of the carbonyl group except in ββ-dimethylpropiolactone where it dissociates on the side of the alkyl groups.

The copolymerisation of lactones with tetrahydrofuran[49] and trioxan[60] is also possible. Copolymers of tetrahydrofuran and β-propiolactone[50] have been obtained in the presence of the "triethylaluminium–water" catalytic system in the form of viscous liquids or resins. Trioxan has been copolymerised with γ-butyrolactam in the presence of boron trifluoride-ether[60].

Table 3 presents the copolymerisation constants of lactones and a series of cyclic ethers. The reactivity of the compounds undergoing copolymerisation, listed in Table 3, depends to some extent on the copolymerisation conditions: the nature of the catalyst, reaction temperature, etc.

Table 3. Constants for the copolymerisation of lactones with certain other cyclic compounds.

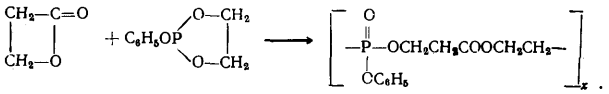
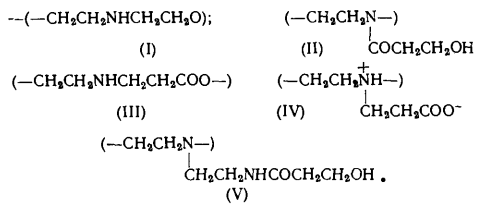
b. Copolymerisation of lactones with other cyclic compounds. Apart from the copolymerisation of lactones with cyclic ethers, cases are known where they were copolymerised with certain other cyclic compounds. The copolymerisation of lactones with cyclic phosphites is interesting[59]:



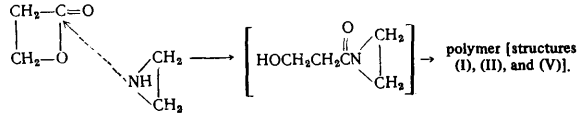
This results in the formation of a solid white polymer melting at 160°C. The reactions take place readily on heating (at or above 150°C) or even at room temperature in the presence of basic catalysts (tertiary amines, amides, alkali metal alkoxides, etc).

A few studies have been made on the copolymerisation of lactones with aziridines[55,56]. The copolymerisation of β-propiolactone, γ-butyrolactone, and ε-caprolactone with aziridine is catalysed by compounds such as boron trifluoride-ether, stannic chloride, triethylamine, sodium cyanide, and mercurous chloride[55]. Polymers with a low molecular weight were obtained in all cases. With increasing dielectric constants of the solvents in which the copolymerisation is carried out, there is an increase in the yield of copolymer. It is interesting to note that aziridine and β-propiolactone activate one another in the copolymerisation reaction and the latter can take place without catalysts[56]. The structure of the copolymer formed depends to a large extent on the dielectric constant of the solvent but is independent of the type of catalyst used[55,56]. On the basic of infrared spectroscopic data, the authors suggest that the formation of several different structures is possible

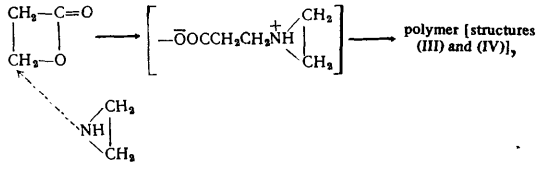
in the synthesis of the copolymer of β-propiolactone and aziridine:



The formation of a particular copolymer structure depends on the site of ring opening, which is in turn determined to a large extent by the polarity of the solvent used in the reaction. The role of the solvent as regards the variation of the site of ring opening is not entirely clear, but it may involve a change in the distribution of electron density of the monomer when the polar solvent adds to the carbonyl carbon of the lactone. In non-polar solvents the carbonyl carbon of the lactone is probably attacked by the nitrogen atom of aziridine:



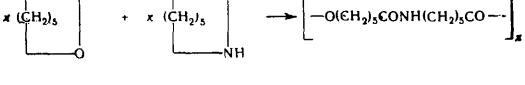
Here too copolymers with structure (I), (II), or (V) are formed. On the other hand, in polar solvents aziridine may attack the β-carbon atom of the lactone:



which results in the formation of copolymers with structures (III) and (IV).

Dermer and Ames[57,58] achieved the copolymerisation of β-propiolactone with the *N*-carboxy-anhydride of DL-valine in a mixture of anisole and benzene in the presence of pyridine and obtained a low-molecular copolymer (mol. wt. about 1150) in the form of a white powder with a softening temperature of 20°C. When the same reactants were copolymerised in the presence of sodium methoxide, it proved possible to increase somewhat both the molecular weight (about 3550) and the softening temperature of the copolymer (85°C).[57]

An interesting method for the preparation of polyamidoethers consists in the copolymerisation of ε-caprolactone with ε-caprolactam in the presence of tri-isobutylaluminium or sodium as catalysts[61]:

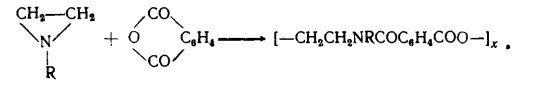


Thus lactones are capable of forming copolymers with a number of cyclic compounds; at the present time the copolymerisation of lactones with cyclic oxygen-containing compounds has been investigated in greatest detail.

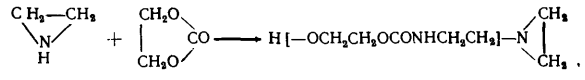
2. Copolymerisation of Aziridines

The copolymerisation of aziridine with lactones was described in the previous section[55,56]. Apart from this, examples of the copolymerisation of aziridines with certain other cyclic compounds are known.

N-Substituted polyamidoethers are formed in the copolymerisation of *N*-substituted aziridines (*N*-butylaziridine, *N*-cyclohexylaziridine) with dibasic acid anhydrides[67]:

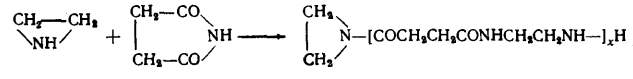


The copolymerisation of aziridines with cyclic carbonates leads to the formation of high-molecular polyurethanes with terminal hydroxy- and alkylimino-groups:



Copolymers with a degree of polymerisation up to 2000 have been obtained in the copolymerisation of aziridine with ethylene carbonate[62]. In both cases described above the copolymerisation was carried out by heating the initial monomers without any catalysts.

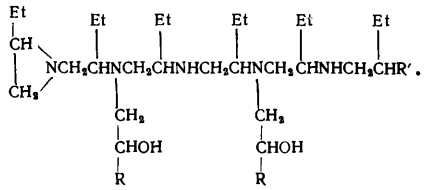
The copolymerisation of aziridines with cyclic imides, which leads to the formation of crystalline polyamides, is an interesting reaction[63]. Thus the copolymerisation of aziridine and succinimide yields a polyamide melting at about 300°C:



This reaction takes place particularly readily with compounds having small rings and constitutes an interesting method for the preparation of polyamides with short methylene chains. Crystalline polyamides have been obtained in the copolymerisation of the following monomer systems: 2-methylaziridine–succinimide, aziridine–glutarimide, and aziridine–phthalimide. The reactivity of imides in copolymerisation with ethyleneimine decreases in the following sequence: maleimide > phthalimide > succinimide > glutarimide > *N*-methylsuccinimide[63]. The copolymerisation of aziridines with imides can be carried out both with and without catalysts by heating the initial monomers. The presence of boron trifluoride-ether as catalyst for the copolymerisation of aziridines with cyclic imides favours the formation of a copolymer enriched in aziridine units, while the addition of triethylamine does not affect the composition of the copolymer[63].

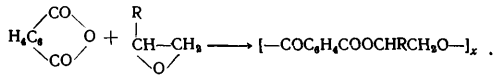
The copolymerisation of aziridines with epoxyalkanes has been described[64,80,81]. However, Overberger and Tobkes[65] have shown that the resulting copolymerisation products have a complex structure. In the copolymerisation of 2-ethylaziridine with 1,2-epoxy-compounds, they used Lewis acids as catalysts. In the presence of the most active catalyst, boron trifluoride-ether, copolymers with a polyimine structure are formed, in which the imino-groups are β-hydroxyalkylated by the 1,2-epoxy-compounds. Under the copolymerisation conditions investigated, the imine is more active than the epoxy-compound. Probably the polyimine chain grows to a considerable length before the epoxyalkane units are incorporated into it. The authors suggest that in the first stages of the copolymerisation, complexes of the catalysts with the imine residues of the

polymer are mainly formed, as a result of which the catalyst is incapable of inducing the polymerisation of the epoxy-compound. The authors attribute the following structure to the copolymer of 2-ethylaziridine and epoxydodecane:



3. Copolymerisation of Anhydrides

The copolymerisation of dicarboxylic acid anhydrides with epoxyalkanes leading to the formation of polyesters has been comparatively well investigated:

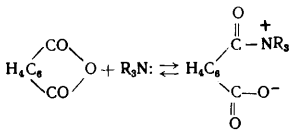


Fish and Hoffman[82-84] established that, in the copolymerisation of epoxy-compounds with anhydrides in the absence of catalysts, the epoxy-compounds are partially homopolymerised. In order to reduce the degree of homopolymerisation and to ensure more complete copolymerisation, the ratio of the anhydride to the epoxy-compound should be 0.85 : 1.[84,85]

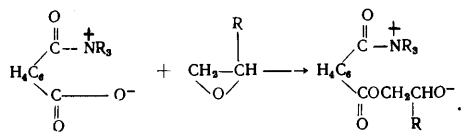
The use of catalysts favours the formation of polyesters. Fisher[69] showed that the polyesterification of dibasic acid anhydrides with epoxy-compounds in the presence of tertiary amines as catalysts takes place to the extent of 98–99% and the molecular weight of the polymers formed reaches about 18 500. The properties of the polyesters depend on the structure of the starting materials. The copolymerisation of epoxyethane with various anhydrides yields highly crystalline polymers which melt in the range 110–165 °C depending on the structure of the anhydride. The copolymerisation of epoxycyclohexane with anhydride yields polyesters melting above 100 °C. Structured polyesters are obtained in the copolymerisation of epoxy-compounds with maleic anhydride[71].

Fisher[69] proposed the following mechanism for the formation of polyesters in the copolymerisation of anhydrides with epoxy-compounds in the presence of amine catalysts.

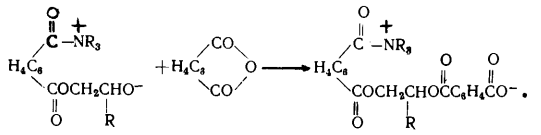
1. Activation of the anhydride by the amine with formation of a carboxylate anion:



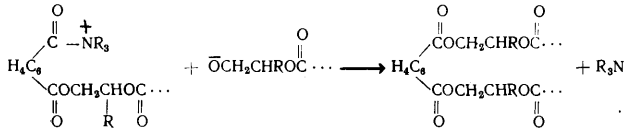
2. Reaction of the carboxylate anion formed with the epoxy-compound to form an alkoxide anion:



3. Reaction of the alkoxide anion with the anhydride:



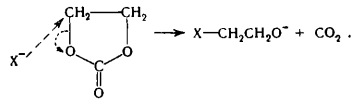
In addition, growth of the polymeric chain is possible also when the amine is replaced by an alkoxide ion:



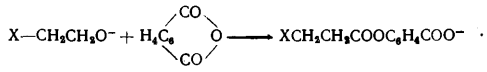
For the preparation of polyesters by the copolymerisation of cyclic compounds, one can use instead of epoxy-compounds the esters of dihydric alcohols and carbonic or sulphurous acids which have a cyclic structure and which are converted at high temperatures into epoxy-compounds with evolution of carbon monoxide or sulphur dioxide[86,87]. In this case polyesters are readily synthesised in the presence of various catalysts (metal oxides, tetraethylammonium bromide, lithium chloride, alkali metal salts of organic and inorganic acids). Schwenk et al.[86] obtained by this method polyesters with molecular weights up to 90 000. The increase of the rate of copolymerisation with the polarity of the reaction medium at various monomer concentrations and also the fact that the initiator anions are incorporated into the polyester macromolecules during copolymerisation, and finally the termination of the growing chain by substances containing active hydrogen ions indicate an anionic copolymerisation mechanism[87]. Schwenk et al.[86] suggest the following mechanism for the formation of polyesters in the copolymerisation of dicarboxylic acid anhydrides with cyclic carbonates in the presence of salts of the type MX.

1. Initiation:

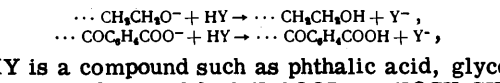
where MX is an alkali metal salt of an organic or inorganic acid;



2. Growth of the polymeric chain:



3. Chain termination:



where HY is a compound such as phthalic acid, glycol, or water and $Y^- = OH^-$, $HOOCC_6H_4COO^-$, or $HOCH_2CH_2O^-$.

Organometallic compounds, for example n-C_4H_9Li, C_2H_5MgBr, $(C_2H_5)_2Mg$, $(C_2H_5)_2Zn$, and $(C_2H_5)_2Cd$ are active catalysts of the reaction of epoxy-compounds with anhydrides[70]. In the presence of diethylzinc the copolymerisation of epoxypropane with anhydrides takes place at relatively low temperatures (about 30 °C). It has been established by infrared spectroscopy and elemental analysis that the copolymer obtained in the copolymerisation of epoxypropane and phthalic anhydride is a polyester with the structural formula $[-CH_2CH(CH_3)OCOC_6H_4COO-]_n$.[70]

Unsaturated polyesters are obtained in the copolymerisation of a mixture of maleic and phthalic anhydrides with epoxypropane in the presence of tetramethyleneammonium bromide or lithium chloride. The polyester formed contains unsaturated bonds and are capable of being modified chemically—for example, it can be copolymerised with styrenes[72].

The copolymerisation of pyromellitic anhydride with the glycidylphenyl ether leads to the formation of a ladder-type polymer in which two polyester chains are linked by bridges consisting of tetrasubstituted benzene rings. The copolymerisation was performed in dioxan in the presence of dimethylbenzylamine, lithium chloride, sodium acetate, sodium phthalate, and triethylaluminium. The first catalyst is the most effective. When the copolymerisation is carried out in dilute solutions, a soluble polyester is formed. Judging from infrared spectroscopic results, the polyester does not contain anhydride groups but its hydrolysis shows that the ratio of the anhydride and epoxy-units is greater than two, i.e. the polymer contains also ester units[73]. The copolymerisation of pyromellitic anhydride with epichlorohydrin and 3,3-bis(chloromethyl)oxetane has also been investigated[73].

The use of an asymmetric catalytic system in the copolymerisation of epoxy-compounds with anhydrides permits the synthesis of active copolymers from inactive monomers. Thus in the copolymerisation of (±)-epoxypropane with the optically inactive 3-phenyl-Δ^4-tetrahydrophthalic anhydride in the presence of the diethylzinc–(+)-borneol system a polyester was obtained which exhibited dextrorotatory optical activity in chloroform (70°).[74]

Branched-chain thermoplastic polyesters are formed in the copolymerisation of dicarboxylic acid anhydrides and epoxy-compounds in the presence of pentaerythritol[88].

4. Other Types of Copolymerisation

Above it was pointed out that epoxy-compounds can undergo copolymerisation with a number of other cyclic monomers (lactones, anhydrides, aziridines), forming copolymers of various types. In addition, there are several patents dealing with the copolymerisation of epoxyalkanes with alkylene sulphides. Alkali metal hydroxides[75] and complexes of $FeCl_2$ and $FeCl_3$ with the monomeric epoxy-compound[77] ($2FeCl_2.C_3H_6O$, $FeCl_3.2C_3H_6O$, and $FeCl_3.3C_3H_6O$) have been suggested as catalysts. In the first case the products are copolymers of low molecular weight (200–1500) which are either mobile liquids or oils. Such copolymers show enhanced stability to oxidation and they are recommended as lubricating oils. In the presence of catalysts of the second type epoxypropane has been copolymerised with phenylethylene sulphide, 1,2-butylene sulphide, and propylene sulphide. Copolymers with a high molecular weight (up to 100 000), capable of forming films stable to the action of light and heat (in the absence of stabilisers) and with a relatively high strength (tensile strength 385 kg cm^{-2}) were obtained.

Tsuruta et al.[77] copolymerised epoxypropane with the *N*-carboxy-anhydride of DL-alanine. Diethylzinc and triethylaluminium are effective catalysts of this copolymerisation. The presence of co-catalysts (water or alcohol) lowers the yield of the copolymer. The main chain of the copolymer obtained probably contains ether, ester, amide, and urethane groups.

---o0o---

At the present time it can be assumed that generally speaking all heterocycles with sufficiently polar bonds or bonds capable of polarisation under particular conditions can undergo polymerisation. Thermodynamic factors play the main role in carbocyclic compounds. However, the polymerisation conditions have been by no means always discovered and not all cyclic compounds could be polymerised.

Even greater difficulties are encountered in copolymerisation. Even among compounds of the same type, the capacity for polymerisation can differ significantly, which makes copolymerisation difficult. On the other hand, for monomers of different types the determination of copolymerisation conditions is frequently very difficult.

Among the problems which arise in the copolymerisation of cyclic compounds, the following are particularly significant at the present time. Very often the molecular weight of the copolymers is lower than that of the corresponding homopolymers. This can be caused by a difference in the reactivity of the copolymerising compounds, as a result of which the chosen conditions are not altogether suitable for both monomers. The reaction conditions can be too mild for the successful polymerisation of one of the components or too severe, so that one monomer decomposes into substances which inhibit polymerisation. Thus the choice of process conditions is very important. In choosing the conditions for copolymerisation, it is necessary to make sure that they differ as little as possible from the polymerisation conditions of the individual monomers. For this reason the problems of catalysis are of primary importance.

Furthermore, considerable difficulties arise in connection with the very proof that copolymers are formed. In contrast to the copolymerisation of vinyl compounds, in the copolymerisation of monomers of different chemical types it is particularly important to prove the formation of copolymers, since under these conditions the homopolymerisation of one or other monomer takes place readily.

The question of the preparation of block copolymers, particularly those of a regular structure, is of great interest in connection with the copolymerisation of cyclic compounds, as for compounds of other types.

Metal Ammonium Phosphates and Their New Applications

L.M.Lapina

The review deals with the methods of preparation and applications of double salts comprising metal and ammonium phosphates. Particular attention has been given to the methods of preparation and properties of divalent metal compounds of composition $MNH_4PO_4.nH_2O$ which are interesting as complex, long-acting fertilizers.
The syntheses and investigations of those trivalent metal compounds which can be formed on interaction between water-soluble phosphorus fertilizers and soils are described extensively. The bibliography comprises 65 references.

I. INTRODUCTION

Metal ammonium phosphates include a wide range of compounds which can be denoted by the common formula $a(NH_4)_2O.bMO.cP_2O_5.nH_2O$, where M is a divalent metal, and $a(NH_4)_2O.M_2O_3.cP_2O_5.nH_2O$, where M is a trivalent metal†.

Many of these compounds were already known in the 19th century. Compounds of the type $MNH_4PO_4.nH_2O$, which have found application in analytical chemistry, have been most thoroughly investigated. For example, the determination of phosphorus and magnesium is based on the isolation of $MgNH_4PO_4.6H_2O$, which is then converted to pyrophosphate by heat treatment, and the isolation of $ZnNH_4PO_4$, $MnNH_4PO_4.H_2O$, and $CdNH_4PO_4.H_2O$ constitutes the basis of the determination of the corresponding metals.

Recently the applications of these compounds have greatly increased. In particular investigators in the field of fertilizers have drawn attention to the fact that certain compounds of the type $MNH_4PO_4.nH_2O$ can be used as complex fertilizers containing three nutrient elements: nitrogen, phosphorus, and the corresponding metal (magnesium, manganese, zinc, copper, etc.). Copper, manganese, and zinc are required by plants in micro-amounts, while magnesium is required in comparatively large quantities.

Technological procedures for the preparation of magnesium, zinc, and iron ammonium phosphates have been developed at the Institute of Fertilizers, Insecticides, and Fungicides (NIUIF).[1] Magnesium ammonium phosphate monohydrate‡ was tested under field conditions on different crops and yielded positive results[2]. Manganese, copper, and zinc ammonium phosphates were subjected to vegetative tests and proved to be fairly effective under many conditions.

American workers showed[3] that the high assimilability of metal ammonium phosphates by plants can be explained by the rapid nitrification of their nitrogen content by soil bacteria, as a result of which the salt molecule breaks down and all the components become available to the plant.

At the beginning of the 1960's Grace and Co. in the USA[4,5] announced the manufacture and application as fertilizers of magnesium ammonium phosphate and certain other similar compounds. This communication was followed by a paper dealing with the study of the properties and tests of these fertilizers[3].

The bright colour of certain of the divalent metal compounds has led to their employment (mainly cobalt ammonium phosphate) as pigments in artists paints[6,7].

Iron ammonium phosphate and manganese ammonium phosphate have been suggested as components of priming paints in anti-corrosion coatings[6,8], since, apart from their other valuable properties, they behave as acceptors of acids and oxygen, whereby they prevent corrosion.

The method of extraction of doubly charged metal cations[9], in particular calcium and magnesium, from sea water to prevent the formation of scale is based on metal ammonium phosphates. In this procedure phosphoric acid and ammonia are added to sea water and the metal ammonium phosphates formed are used as fertilizers.

Salutsky and Dunseth[10] believe it to be more useful to extract cations such as Co^{2+}, Cu^{2+}, Fe^{2+}, Mn^{2+}, Ni^{2+}, Ba^{2+}, and Ca^{2+} from salt solutions of various types, including sea water, by passing them through a layer of $MgNH_4PO_4.H_2O$, where magnesium ions are replaced by the above cations.

† Compounds in which the ammonium ion is replaced by a monovalent metal (sodium, potassium, lithium) are also very widespread but these will be mentioned only incidentally.

‡ $MgNH_4PO_4.6H_2O$ is of no interest as a fertilizer, since it is unstable and contains a smaller percentage of nutrient substances than $MgNH_4PO_4.H_2O$.

Another valuable property of metal ammonium phosphates is the capacity to decompose in the temperature range 200–400°C (the region of cellulose inflammation) with evolution of ammonia and water and the formation of free phosphoric acid, which makes them suitable as fire-resistant agents.

Attempts have been made to impregnate wood with zinc and copper ammonium phosphates in aqueous ammonia in order to make it fire resistant[11]. Soviet workers suggested[1,12] that iron and aluminium ammonium phosphates be used as fire-resistant agents in the manufacture of non-combustible wood-fibre plates and certain other articles. Industrial methods have been devised for their preparation from readily available raw materials[12,13].

Aluminium and iron ammonium phosphates are formed in the reaction of the soluble fertilizer ammonium phosphates with a number of soils and are responsible for the conversion of water-soluble phosphates into an insoluble form. These studies will be described below. Compounds of aluminium and iron(III) of the type $MM'_3H_{14}(PO_4)_8.4H_2O$, where M = Na, K, or NH_4 and M′ = Fe or Al, have been used as baking powders[14].

Since the applications of metal ammonium phosphates are extremely varied, communications concerning them are published in journals dealing with diverse fields. This review presents a wide variety of information about this large class of compounds.

II. PREPARATION OF COMPOUNDS OF THE TYPE $MNH_4PO_4.nH_2O$

At the present time the following compounds of the above type have been isolated and described: $MgNH_4PO_4.nH_2O$ (n = 1 and 6); $ZnNH_4PO_4$; $FeNH_4PO_4.H_2O$; $MnNH_4PO_4.H_2O$; $CuNH_4PO_4.H_2O$; $CoNH_4PO_4.nH_2O$ (n = 1, 6, and 12); $NiNH_4PO_4.nH_2O$ (n = 1 and 6); $CdNH_4PO_4.H_2O$; $CaNH_4PO_4.nH_2O$ (n = 1 and 7); $BaNH_4PO_4.7H_2O$.

Under normal conditions monohydrates are usually precipitated. Exceptions are magnesium, cobalt, and nickel ammonium phosphates which are isolated as hexahydrates, and also zinc ammonium phosphate which is precipitated in the anhydrous state. Lasne[15] isolated calcium ammonium phosphate as the heptahydrate from a solution of calcium oxide in citric acid on introduction of ammonium phosphate into the latter. This salt is unstable, losing water and ammonia on standing in air.

Auger and Ivanoff[16] obtained $BaNH_4PO_4.7H_2O$ and $CaNH_4PO_4.7H_2O$ in the presence of a large amount of ammonium citrate at a low temperature (0–7°C).

Basset and Bedwell[17] described a general method for the preparation of metal ammonium phosphates. It consists in mixing solutions of the given metal chloride and diammonium hydrogen phosphate in a large excess, the mixture being stirred. The resulting mixture of precipitate and mother liquor is kept at room temperature or on a water bath until the precipitate becomes crystalline. It is then filtered off and washed with water, absolute alcohol, and absolute ether. The concentrations of the solutions for different compounds vary, but are in all cases comparatively low. In the individual methods recommended by Basset and Bedwell the amount of ammonium phosphate is reduced by the addition of a large quantity of ammonium chloride. The crystallisation of the hexahydrates required 12 h and that of monohydrates 1 h, except for copper ammonium phosphate which crystallised very slowly. With the ratio P : Cu ≃ 9, the crystallisation of $CuNH_4PO_4.H_2O$ required three months, while with P : Cu ≃ 40, 24 h was sufficient. Basset and Bedwell obtained by the above method all the compounds enumerated above, with the exception of iron, calcium, and barium ammonium phosphates. The hydrates which could not be isolated, for example the hexahydrates of manganese, copper, zinc, and cadmium ammonium phosphates, were obtained in the form of solid solutions in an excess of magnesium ammonium phosphate hexahydrate. The anhydrous compounds of cobalt and magnesium were obtained in the form of solid solutions in zinc ammonium phosphate. Using dipotassium hydrogen phosphate instead of diammonium hydrogen phosphate, the authors obtained a number of metal potassium phosphates by the method adopted for metal ammonium phosphates in particular $KMgPO_4.H_2O$, $KMnPO_4.H_2O$, $KCoPO_4.H_2O$, $KCuPO_4.H_2O$, $KCdPO_4.H_2O$, $KZnPO_4$, and $KMgPO_4.6H_2O$.

Grat-Cabanac[18] obtained the pure salt $CoNH_4PO_4.H_2O$ at 80°C from dilute $CoSO_4$ and $(NH_4)_2HPO_4$ solutions with a large excess of the latter.

Depending on the temperature (15–95°C), mixtures with different amounts of water of crystallisation were obtained. Frazier et al.[19] determined the amount of calcium ammonium phosphate monohydrate in the products of the ammonia treatment of superphosphate. Apart from $CaNH_4PO_4.H_2O$, two dimorphous salts with the composition $Ca(NH_4)_2.(HPO_4)_2.H_2O$ were found. The authors investigated the four-component system $CaO–P_2O_5–NH_3–H_2O$ at room temperature in the pH range 4–9 and established the regions of existence of these salts. The compounds were obtained in a pure form by adding calcium hydroxide or calcium carbonate to concentrated ammonium phosphate solutions with N : P molar ratios between 1 and 3.4 and at pH between 4.0 and 9.9. Their X-ray diffraction patterns and crystal-optical characteristics were determined.

The four-component system $MgO–P_2O_5–NH_3–H_2O$ was investigated by Abashkina[20] at 25°C in the concentration ranges 2.7–60.97% P_2O_5, 0.07–7.67% MgO, and 0.53–12.40% NH_3 and at 75°C in the concentration ranges 0.2–57.08% P_2O_5, 0.09–11.63% MgO, and 0.22–15.22% NH_3. It was established that the region of crystallisation of magnesium ammonium phosphate is located in the most alkaline part of the diagram both at 25° and at 75°C. At 75°C the stable phase is $MgNH_4PO_4.H_2O$, while at 25°C compounds with different degrees of hydration (between 6 and 1 moles of water per mole of salt) were found, depending on the concentration of phosphorus pentoxide in the liquid phase. This finding is inconsistent with the usual hypotheses, according to which the hexahydrate is precipitated at room temperature.

Much work has been done on the technological methods of preparation of metal ammonium phosphates, particularly magnesium ammonium phosphate, in view of their considerable value as fertilizers. Aseev[21] took out a patent for the simultaneous preparation of magnesium bicarbonate and magnesium ammonium phosphate hexahydrate from magnesium minerals, in particular dolomite. Vol'fkovich and Remen[22] developed a method for the preparation of magnesium ammonium phosphate monohydrate from hot concentrated solutions of magnesium chloride and diammonium hydrogen phosphate, which were neutralised with ammonia to pH 8–8.5 after mixing. The proportions of the reactants were close to the stoichiometric values, the time of reaction being 0.5 h. The precipitate was filtered off, washed with hot water, and dried at 106°C. Magnesium ammonium phosphate forms according to the reaction $MgCl_2 + (NH_4)_2HPO_4 + NH_4OH = MgNH_4PO_4.H_2O\downarrow + 2NH_4Cl$. The carbonate was also tested as the raw material; it was stirred in boiling water and allowed to react with the solu-

tion of monoammonium dihydrogen phosphate without additional neutralisation with ammonia. In both cases a product close to the theoretical composition was obtained.

Erskine et al.[8] synthesised $FeNH_4PO_4.H_2O$ for tests as a component of priming paints composed of a ferrous salt and diammonium hydrogen phosphate at pH 8.5. Vol'fkovich and Remen[1] obtained an experimental batch of this product under industrial conditions. The same workers developed a technological method for the synthesis of zinc ammonium phosphate from zinc or zinc oxide, phosphoric acid, and ammonia, on the basis of the reactions

$$ZnO + H_3PO_4 = ZnHPO_4 + H_2O,$$
$$ZnHPO_4 + NH_3 = ZnNH_4PO_4.$$

Salutsky et al.[23] (Grace and Co.) patented a method for the synthesis of metal ammonium phosphates consisting of the following operations: mixing of phosphoric acid with any compound of the corresponding metal soluble in phosphoric acid; (2) treatment of the mixture at 80–105°C for a period ranging from 10 min to 4 h, which results in the formation of a dimetal hydrogen phosphate salt; (3) introduction of ammonia until the attainment of pH 7–9; (4) treatment of the ammonia-pretreated mixture at 25–105°C for a period ranging from 1 h to several days; (5) washing of the precipitate with water; (6) drying at 65–105°C. They obtained by this method magnesium, iron, manganese, nickel, copper, zinc, and cobalt ammonium phosphates. Somewhat later the same firm[24] took out a patent for a continuous method of synthesis of magnesium, nickel, cobalt, and zinc ammonium phosphates, consisting in the continuous supply of a solution of the salt in phosphoric acid and of ammonia at 75–85°C with the pH in the reaction zone about 7.5; the average residence time was 6–9 min.

This method scarcely differs from the procedures developed earlier for the synthesis of magnesium, iron, and zinc ammonium phosphates. The preparation of the salt of the corresponding metal in phosphoric acid is not obligatory: all the compounds can be readily obtained by the simultaneous introduction of the metal salt, phosphoric acid (or ammonium phosphate), and ammonia. The manufacture of iron ammonium phosphate in the USSR is based on this procedure[12]. Apart from magnesium, zinc, and iron ammonium phosphates, manganese and nickel ammonium phosphates can be obtained by this method. Equilibrium in the system $CuO-P_2O_5-NH_3-H_2O$ is established very slowly and therefore a periodic process is more suitable for the synthesis of $CuNH_4PO_4.H_2O$.

In recent years, apart from American studies, communications from other countries have appeared, dealing with the preparation of metal ammonium phosphates, mainly magnesium ammonium phosphate, and their use as fertilizers. Japanese workers[25] have described a method for the synthesis of magnesium ammonium phosphate from magnesium hydroxide, phosphoric acid, and ammonia and investigated the effect of the atomic ratio N : P on the purity of the product.

Hungarian investigators[26] suggested that calcium hydrogen phosphate and ferrous sulphate be used as the starting materials. In this case gypsum is formed as a by-product. The process consists of three stages. The dihydrogen phosphate formed is neutralised with ammonia and the resulting ammonium dihydrogen phosphate is precipitated with the carbonate, oxide, or hydroxide of one of the divalent metals:

$$Ca(H_2PO_4)_2 + MSO_4 = \downarrow CaSO_4 + M(H_2PO_4)_2,$$
$$M(H_2PO_4)_2 + 2NH_3 + nH_2O = \downarrow MNH_4PO_4 \cdot nH_2O + NH_4H_2PO_4,$$
$$NH_4H_2PO_4 + M'CO_3 + nH_2O = H_2CO_3 + M'NH_4PO_4 \cdot nH_2O.$$

By this procedure, it is possible to obtain a mixed fertilizer containing several microelements by introducing into the first reaction the salt of one element and into the last reaction that of another. In the Research Laboratory of the Budapest Chemical Factory[27] a fertilizer containing microelements was obtained, with magnesium ammonium phosphate as the main substance.

There is a Japanese patent[28] for the synthesis of a complex fertilizer containing magnesium ammonium phosphate.

In the above method metal ammonium phosphates are produced in the form of powders. However, American workers believe[3] that, despite their low solubility, metal ammonium phosphates can be obtained in a granulated form, the rate of assimilation of the nutrient substances by the plants being regulated by the size of the granules. The firm Grace and Co. took out two patents for the synthesis of granulated magnesium ammonium phosphate[29,30].

In technological syntheses the formation of metal ammonium phosphates of definite composition is not achieved by means of a large excess of diammonium hydrogen phosphate but by establishing a strongly alkaline medium with the aid of ammonia. Possibly, under manufacturing conditions completely homogeneous products are not obtained, but their purity is quite satisfactory for technical purposes.

For other compounds of the type $a(NH_4)_2O.bMO.cP_2O_5.nH_2O$, there is early information about zinc ammonium phosphates of the composition $(NH_4)_2O.2ZnO.2P_2O_5.5H_2O$ and $4(NH_4)_2O.6ZnO.3P_2O_5$,[31] and also about the iron ammonium phosphate $(NH_4)_2O.FeO.P_2O_5.5H_2O$.[32]

In connection with the expansion of studies on fertilizers and the synthesis of new types of fertilizers, including those containing magnesium and microelements, the number of compounds of this type which have been isolated has greatly increased in recent years.

Lindsay et al.[33] established the presence of the compound $Ca_2(NH_4)_2(HPO_4)_3.2H_2O$ among the products of the interaction of diammonium hydrogen phosphate with soils.

Much work has been done by Frazier et al.[34] on the identification of the compounds formed when the phosphoric acid extract containing magnesium and microelements is treated with ammonia. In the presence of magnesium in the acid, the compounds $Mg_3(NH_4)_2H_4(PO_4)_4.8H_2O$ [empirical formula $(NH_4)_2O.3MgO.2P_2O_5.10H_2O$], corresponding to the mineral hannayite, and $Mg(NH_4)_2H_2(PO_4)_2.4H_2O$ [$(NH_4)_2O.MgO.P_2O_5.5H_2O$] were isolated in addition to $MgNH_4PO_4.6H_2O$ and the corresponding monohydrate. In the presence of aluminium the salt $MgAl(NH_4)_5H_2(PO_4)_4.6H_2O$ was found.

When phosphoric acid containing zinc was treated with ammonia, the salt $ZnNH_4H_3(PO_4)_2.H_2O$ [empirical formula $(NH_4)_2O.2ZnO.2P_2O_5.5H_2O$], mentioned earlier, was obtained in addition to $ZnNH_4PO_4$, and in the presence of potassium the salts $Zn_2KH(PO_4)_2.2H_2O$ and $ZnKPO_4$ were found.

III. PROPERTIES OF COMPOUNDS OF THE TYPE $MNH_4PO_4.nH_2O$.

1. Solubility

The compounds $MNH_4PO_4.nH_2O$ are crystalline salts sparingly soluble in water, which dissolve readily in mineral acids. The solubility of most of these compounds in water and dilute hydrochloric acid was determined by Bridger et al.[3], who estimated the solubility from the amount of phosphate ions passing into solution, assuming that the compounds dissolve congruently. However, Taylor and Frazier[35], who investigated the solubility of $MgNH_4PO_4.6H_2O$ under equilibrium conditions, established that this

compound dissolves incongruently with precipitation of $Mg_3(PO_4)_2$. From the compositions of the solutions in equilibrium with the solid phase at 25°C, they calculated the solubility product of $MgNH_4PO_4.6H_2O$ as 7.1×10^{-14}. The solubility of magnesium ammonium phosphate increases somewhat in the presence of other salts, especially ammonium salts[36] (with the exception of ammonium phosphate). A similar situation was found with $MnNH_4PO_4.H_2O$.[37] Investigations of this kind were not performed on other salts.

It has been established in a number of studies[2,3,5,38,39] that, despite their low solubility in water, many metal ammonium phosphates give rise to a satisfactory agrochemical effect. Lunt et al.[38] and Munk[39] studied the effect of soil conditions on the assimilability of magnesium ammonium phosphate.

2. Thermal Stability

A number of investigations have shown that the hexahydrates are very unstable—they begin to decompose even at room temperature. The monohydrates are much more stable.

Kiehl and Hardt[40] determined the vapour pressure over $MgNH_4PO_4.6H_2O$ and other compounds which might form in its decomposition. They established that below 60°C only water is lost, while above 60°C ammonia begins to appear in the gas phase with simultaneous evolution of the residual water. At 105°C the vapour pressure over $MgNH_4PO_4.6H_2O$ reaches 1 atm. According to the data of these workers, magnesium ammonium phosphate monohydrate begins to decompose at about 150°C, the vapour pressure reaching 1 atm at 250°C. It was established that, when $MgNH_4PO_4.H_2O$ is heated, ammonia is evolved together with water and that $Mg_2P_2O_7$ is formed at a very low temperature, of the order of 200°C, which can be accounted for by the high vapour pressure over $MgHPO_4$.

Auger and Ivanoff[16] found that, on drying $MgNH_4PO_4.6H_2O$ to constant weight at 55°, 70°, and 100°C, 28%, 42%, and 74% of ammonia relative to the initial amount is lost. Water is liberated together with ammonia; at 55°C the loss amounted to 20% and at 70°C to 82% of the total water content. These results show that magnesium ammonium phosphate monohydrate cannot be obtained from the hexahydrate by heating the latter.

Vol'fkovich et al.[41] investigated the stability of magnesium ammonium phosphate hexahydrate and monohydrate in order to determine how these products would behave on storage when used as fertilizers. They established, that when air is passed over a weighed sample of $MgNH_4PO_4.6H_2O$, a small ammonia loss is observed even at room temperature. The heating curves for $MgNH_4PO_4.6H_2O$ and $MgNH_4PO_4.H_2O$ were determined.

French workers made a systematic study of the thermal decomposition of many metal ammonium phosphates[42-44]. It involved the analysis of the intermediate products by X-rays spectroscopy and chromatography. The monohydrates of beryllium, manganese, magnesium, and cobalt ammonium phosphates were investigated. In addition, the thermal decomposition of $CoNH_4PO_4.6H_2O$ and $CoNH_4PO_4$, obtained by heating the monohydrates in a stream of ammonia at 260°C, was studied. $MgNH_4PO_4.H_2O$ was obtained from the hexahydrate by heating the latter in a stream of ammonia at 110°C. The weight loss was determined by means of a thermobalance, with simultaneous analysis of the gas phase for water and ammonia.

The investigation showed that the decomposition of metal ammonium phosphates on heating proceeds via a series of intermediate compounds. In all cases the presence of an amorphous phase was established in the range 220–650°C. The range of existence of the phase is different for different compounds: for $CoNH_4PO_4.H_2O$, the amorphous phase is present between 390 and 415°C, while for $MgNH_4PO_4.H_2O$, the range of its existence is more extensive (225–650°C). Acid phosphates were not detected among the decomposition products, in agreement with the data of Kiehl and Hardt[40].

As a rule, the decomposition of the monohydrates begins at 150–200°C with evolution of water. Sometimes ammonia is liberated together with water. The evolution of water and ammonia takes place in several stages. The final products of the thermal decomposition are pyrophosphates. A simplified decomposition mechanism can be represented thus:

$$MNH_4PO_4 \cdot H_2O \xrightarrow{-NH_3-H_2O} \text{amorph. phase} \xrightarrow{-NH_3-H_2O} M_2P_2O_7 .$$

Ortho-, pyro-, and tri-phosphate ions were detected in the amorphous phase by chromatography. However, none of the intermediates was isolated in a pure form, since several processes superimposed upon one another take place in the decomposition. Traces of orthophosphate were detected even at 580°C, while the more dehydrated form (pyrophosphate) is sometimes observed at a temperature as low as 200°C.

The pyrolysis of $CoNH_4PO_4.6H_2O$ begins at 85°C. It resembles the decomposition of the monohydrates. The decomposition of anhydrous cobalt ammonium phosphate, which was first investigated by Etienne and Boulle[44], begins at 230°C and is also accompanied by the evolution of ammonia and water.

The above investigations show that the decomposition of metal ammonium phosphates is such that it is impossible to distinguish between the evolution of the water of crystallisation and the water of constitution. Hence one may conclude that these compounds have a more complex structure than might be expected from the formula $MNH_4PO_4.nH_2O$ attributed to them.

3. The Structure of Compounds of the Type $MNH_4PO_4.nH_2O$

Structural studies on compounds of the type $MNH_4PO_4.nH_2O$ are not recorded in the literature. Certain hypotheses have been put forward on the basis of their unusual behaviour on heating and the colour changes in the precipitation of coloured salts, mainly cobalt ammonium phosphate.

As early as the 19th century, it was noted that some of these compounds glow on heating. Basset and Bedwell[17] established that the intensity of the glow of the hexahydrates is greater than that of the monohydrates. On this basis, they concluded that the monohydrates are polymeric compounds, while the hexahydrates polymerise during heating and that this process is responsible for the luminescence.

Many investigators drew attention to the fact that the precipitation of $CoNH_4PO_4.H_2O$ is accompanied by a number of colour changes in the precipitate. Initially a pink flaky precipitate is deposited, which then assumes a bright blue colour, and is finally transformed into the violet-red monohydrate. Golynkin[6] and Grat-Cabanac[18] explained this by the initial formation of more hydrated forms, while Basset and Bedwell[17] concluded that the intermediate bright blue compound is anhydrous cobalt ammonium phosphate. Since the hexahydrates have a pure colour (pink for $CoNH_4PO_4.6H_2O$ and green for $NiNH_4PO_4.6H_2O$) corresponding to the colour of the hydrated cation, while the monohydrates assume also another tint, Basset and Bedwell concluded that

in the hexahydrates the metal is present in the cationic form and in the monohydrates partly in the cationic and partly in the anionic forms. Bearing this in mind and also the fact of a higher degree of polymerisation of the monohydrate which they established and the coordination numbers of the metals, they assigned to the hexahydrates the formula

$$NH_4^+ [M(H_2O)_6]^{3+} PO_4^{3-},$$

and to the monohydrates

$$(NH_4^+)_2 [M(H_2O)_4]^{2+} (PO_4MPO_4MPO_4MPO_4)^{6-}.$$

Evidently these formulae too fail to reflect the true structure of compounds of the type $MNH_4PO_4.nH_2O$. According to them, ammonia should be evolved first on heating. They do not explain why water and ammonia are evolved in several stages, suggesting that the bond between the metal and both water and ammonia is the same. More detailed studies in this field were not made and therefore the problem of the structure of these compounds still remains unresolved.

IV. PREPARATION OF COMPOUNDS OF THE TYPE $a(NH_4)_2O.bR_2O_3.cP_2O_5.nH_2O$

Compounds of this type, whose composition corresponds to the formula $(NH_4)_2O.(Al,Fe)_2O_3.2P_2O_5.2H_2O$, were obtained for the first time by Cohen[45] by mixing a concentrated solution of diammonium hydrogen phosphate and a solution of aluminium chloride (or ferric chloride) in hydrochloric acid in the presence of a large excess of phosphate ions ($PO_4 : Al = 23$, $PO_4 : Fe = 7$) and with prolonged heating. Somewhat later an iron salt of this composition was obtained by Weinland and Ensgraber[46] from freshly precipitated ferric hydroxide, phosphoric acid, and ammonia. It differed from Cohen's salt in its colour: Cohen's salt was white and Weinland's salt was pink.

The authors investigated it under the microscope and established that it consists of crystals comprising hexagonal rods narrowing at one end. Both Cohen and Weinland and Ensgraber suggested that this compound can be regarded as the ammonium salt of diphosphatoferric(III) acid, which they called "ammonium diphosphatoferrate", and assigned to it the formula $[Fe(PO_4)_2]H_2NH_4$. Apart from this salt, they obtained other compounds, to which they assigned the formulae $[Fe(PO_4)_2H_3]_3.NH_3.7H_2O$ [empirical formula $(NH_4)_2O.3Fe_2O_3.6P_2O_5.22H_2O$] and $2FePO_4.NH_3.4H_2O$ [empirical formula $(NH_4)_2O.2Fe_2O_3.2P_2O_5.7H_2O$], and also a salt with the ratios $Fe : PO_4 : N = 4 : 9 : 1.5$, which they regarded as the ammonium salt of di- and tri-phosphatoferric(III) acid $H_6Fe(PO_4)_3$. The salts obtained did not dissolve in water but dissolved readily in dilute hydrochloric acid and more slowly in nitric acid. They were decomposed by alkalis with formation of ferric hydroxide and ammonium phosphate. The solubility of $2FePO_4.NH_3.4H_2O$ is lower than that of the remaining salts.

Many investigators[47-49] failed to prepare ammonium aluminophosphate, described by Cohen, using his procedure. Yakimach[47] obtained a salt of this composition but by a procedure differing from that of Cohen: the precipitation was carried out at a higher concentration of phosphate ions and in the absence of hydrochloric acid. In contrast to Cohen's salt, that synthesised by Yakimach did not dissolve in acids. In the author's view this salt had nothing in common with Cohen's salt.

Angelescu and Balanescu[50] studied the composition of the precipitate deposited from solutions containing Fe^{3+} and PO_4^{3-} ions in the presence of different amounts of ammonia. They established that ferric phosphates of definite compositions can be obtained from acid solutions, but in alkaline solutions "adsorption complexes" are formed, whose composition varies with concentration, temperature, etc.

The composition of the insoluble products formed in the synthesis of ammonium phosphates from a phosphate starting material containing aluminium and iron was investigated at the Institute of Fertilizers, Insecticides, and Fungicides (NIUIF). At pH 4.5 and 3.5 for the aluminium salt and at pH 2.5 for the ferric salt in the presence of a large excess of phosphate ions ($PO_4 : Al = 13$; $PO_4 : Fe = 7.5$), Sannikova[51] obtained salts whose compositions were comparatively close to those of Cohen's salts. The salts were precipitated by mixing together at 45°C solutions of the hydroxide in phosphoric acid and of aqueous ammonia followed by prolonged exposure of the resulting precipitate to this temperature. The salts thus prepared were sparingly soluble in water, more so in 2% citric acid, and completely soluble in a solution of ammonium citrate neutralised with ammonia to pH 8 (Peterman's solution). Using a similar procedure, Kheifets[52] obtained at pH 4.8 a yellow-green salt, close in composition to the salt $2FePO_4.NH_3.4H_2O$ described by Weinland and Ensgraber[46], and at pH 1.7 she obtained a lilac-pink preparation similar to the salt $[Fe(PO_4)_2H_3]_3NH_3.7H_2O$. A product approaching the composition of $Fe(PO_4)_2H_2NH_4$, but nevertheless differing from the latter appreciably, was obtained at pH 3.8. The form of the crystals obtained by Kheifets differed as a rule from that of the salts described by Weinland and Ensgraber.

The results of different investigators show that the composition and properties of the precipitates deposited from solutions containing phosphate ions and the corresponding metal and ammonium ions depend to a high degree on the precipitation conditions. This has been confirmed by a study[53] where precipitates of different compositions were obtained by varying the concentration of the solutions, the pH of the medium, or the proportions of the reactants.

Haseman et al.[54] isolated a number of ammonium and potassium phosphato-ferrates(III) and -aluminates from dilute solutions under conditions imitating those obtaining in soils, namely by prolonged storage in a sealed vessel of precipitated aluminium and ferric phosphates with solutions containing potassium and ammonium cations. Solutions of various concentrations, ranging from 0.001 M to 3.5 M, and at various pH between 1.5 and 8 were prepared by adding potassium hydroxide or ammonium hydroxide to standard phosphoric acid solutions. The precipitates were treated at temperatures between 27° and 145°C. The filtered and washed precipitates were dried at room temperature over calcium chloride.

Each specimen obtained was studied under the petrographic microscope and the optical properties of the crystals were determined. Almost all the products were well crystallised. The aluminium phosphates contained as a rule only one mineralogical variety, while certain of the ferric phosphate specimens contained two or more mineral types; in this case a relatively pure specimen was obtained by screening or elutriation. Homogeneous specimens were analysed chemically and their powder diffraction patterns were obtained.

On the basis of the diffraction patterns, crystal-optical properties, and chemical composition, Haseman classified all the specimens into nine groups of minerals, which are listed in Table 1. Each group is characterised by definite chemical composition, diffraction patterns, and crystal-

optical properties. The authors identified compounds of group 1 with the natural mineral taranakite. They also obtained the analogous ammonium compound. Smith and Brown[55], who investigated this compound by X-ray diffraction, concluded that it is more correct to assign to it the formula $3(NH_4)_2O.5Al_2O_3.8P_2O_5.42H_2O$ or, in an expanded form, $H_6(NH_4)_3Al_5(PO_4)_8.18H_2O$.

Table 1. Empirical formulae and the classification of phosphatoferrate and phosphatoaluminate minerals (according to Haseman et al.[54]).

Product	Empirical formula	Classification group
A	$2K_2O\cdot3Al_2O_3\cdot5P_2O_5\cdot26H_2O$	1
B	$2K_2O\cdot3Al_2O_3\cdot5P_2O_5\cdot20H_2O$	1
C	$K_2O\cdot Al_2O_3\cdot2P_2O_5\cdot4H_2O$	2
D	$K_2O\cdot Fe_2O_3\cdot2P_2O_5\cdot4H_2O$	2
E	$K_2O\cdot Fe_2O_3\cdot2P_2O_5\cdot2H_2O$	3
F	$(NH_4)_2O\cdot Fe_2O_3\cdot2P_2O_5\cdot3H_2O$	3
G	$(NH_4)_2O\cdot Al_2O_3\cdot2P_2O_5\cdot3H_2O$	3
H	$K_2O\cdot2Al_2O_3\cdot2P_2O_5\cdot5H_2O$	4
HH	$K_2O\cdot2Al_2O_3\cdot2P_2O_5\cdot5H_2O$	4
I	$K_2O\cdot2Fe_2O_3\cdot2P_2O_5\cdot5H_2O$	4
J	$(NH_4)_2O\cdot2Al_2O_3\cdot2P_2O_5\cdot6H_2O$	4
K	$(NH_4)_2O\cdot3Fe_2O_3\cdot6P_2O_5\cdot20H_2O$	5
L	$K_2O\cdot3Fe_2O_3\cdot6P_2O_5\cdot20H_2O$	5
MM	$Al_2O_3\cdot P_2O_5\cdot4H_2O$	6
O	$0.9Fe_2O_3\cdot0.1Al_2O_3\cdot P_2O_5\cdot4H_2O$	6
P	$Fe_2O_3\cdot P_2O_5\cdot4H_2O$	6
Q	$Al_2O_3\cdot P_2O_5$	7
R	$K_2O\cdot Al_2O_3\cdot P_2O_5\cdot4H_2O$	8
S	$K_2O\cdot Al_2O_3\cdot P_2O_5\cdot2H_2O$	8
T	$K_2O\cdot2Al_2O_3\cdot2P_2O_5\cdot1.6HF\cdot6.2H_2O$	9

Lindsay et al.[33] identified 30 crystalline phosphates (apart from the amorphous precipitates) formed in the reaction between phosphate fertilizers and soils. They investigated the reaction of calcium hydrogen phosphate, ammonium dihydrogen phosphate, potassium dihydrogen phosphate, diammonium hydrogen phosphate, dipotassium hydrogen phosphate, and liquid ammonium-treated superphosphoric acid of type 11-33-0 with sandy and rich calcareous loams. Part of the compounds isolated, relevant to the present review, are listed in Table 2, which shows that the authors obtained ammonium and potassium taranakites and also compounds corresponding to products K, L, P and F in Haseman's classification, but the last product had a somewhat lower water content. The component ratio in the compound $NH_4Al_2(PO_4)_2OH.8H_2O$ corresponds to Haseman's product J but contains a much greater amount of water.

The salts obtained by Cohen and one of Weinland's salts correspond in their chemical composition to compounds or group 3§ (Table 2). However, the ammonium phosphatoferrate(III) described by Weinland consisted of pink crystals comprising hexagonal rods narrowing at one end, while Haseman's product consisted of colourless plates, i.e. the structures of the salts were different.

The present author obtained[53] from concentrated solutions of pH 5 a salt similar in composition to $(NH_4)_2O.Al_2O_3.2P_2O_5.3H_2O$ investigated by Haseman, but their powder diffraction patterns had nothing in common.

Unfortunately the system $(NH_4)_2O-Al_2O_3(Fe_2O_3)-P_2O_5-H_2O$ was not investigated in detail and therefore it is difficult to say whether the various properties of salts of the same composition are due to the fact that some investigators obtained metastable or contaminated compounds or whether it is due to the fact that there exists such a wide variety of compounds in this system at a small change in conditions leads to the formation of a new salt.

Tables 1 and 2 show that a considerable amount of ammonium phosphato-ferrates(III) and -aluminates was also isolated from dilute solutions. Some of these were obtained by many investigators and are well known. For example, there is no doubt that the reaction of ammonium phosphate with many soils results in the formation of a compound whose composition and properties correspond to the mineral taranakite. Such a compound was found by Lindsay[33] in the product of the reaction of calcium hydrogen and ammonium dihydrogen phosphates with sandy and rich calcareous loams. It was also obtained by Tamimi et al.[56] by the reaction of ammonium phosphate at pH 1.0–5.0 with gibbsite $[Al(OH)_3.3H_2O]$ and certain other soils. The same compound was prepared by Haseman in the reaction of aluminium phosphate with dilute solutions (between 0.001 and 1 M) of ammonium phosphate at pH between 1.7 and 5.5. Ammonium and potassium taranakites were also prepared by Taylor and coworkers[57–60], Egan et al.[61], Arlidge et al.[62], and, as already stated, Smith and Brown[55]. Lindsay and Taylor[58] investigated the assimilability of taranakite by plants.

Compounds of group 3 (according to Haseman's classification) were prepared by Lindsay[33] (iron derivatives) and Smith and Brown[55] (aluminium derivatives) and those of group 5 by the same authors and Arlidge et al.[62] However, the compound $NH_4Fe_3H_6(PO_4)_6.6H_2O$ differed in its X-ray diffraction characteristics from the compound described by Haseman.

§ Cohen's compounds contained a lower percentage of water, but this can be attributed to the inaccuracy of the determination, since it was found by difference.

Table 2. Phosphatoaluminates and phosphatoferrates(III) identified in the products of the reaction of phosphate fertilizers with soil[33].

No.	Chemical formula	Empirical formula	Mineral	Form of phosphate fertilizer
1	(K, H) (Fe, Al)$_3$H$_6$(PO$_4$)$_6$·6H$_2$O	$K_2O(H_2O)3Fe_2O_3(Al_2O_3)\cdot6P_2O_5\cdot20H_2O$		$Ca(H_2PO_4)_2$
2	(NH$_4$, H) (Fe, Al)$_3$H$_6$(PO$_4$)$_6$6H$_2$O	$(NH_4)_2O(H_2O)\cdot3Fe_2O_3(Al_2O_3)\cdot6P_2O_5\cdot20H_2O$		ditto
3	Colloidal (Fe, Al)PO$_4$·n H$_2$O			$Ca(H_2PO_4)_2$; $NH_4H_2PO_4$, $(NH_4)_2HPO_4$
4	FePO$_4$·2H$_2$O	$Fe_2O_3P_2O_5\cdot4H_2O$	strengite	Ca $(H_2PO_4)_2$
5	FePO$_4$·2H$_2$O	ditto	metastrengite	ditto
6	K$_3$Al$_3$H$_8$(PO$_4$)$_8$·18H$_2$O	$3K_2O\cdot5Al_2O_3\cdot8P_2O_5\cdot42H_2O$	K-taranakite	$Ca(H_2PO_4)_2$; KH_2PO_4
7	(NH$_4$)$_3$Al$_5$H$_6$(PO$_4$)$_8$·18H$_2$O	$3(NH_4)_2O\cdot5Al_2O_3\cdot8P_2O_5\cdot42H_2O$	NH_4-taranakite	$Ca(H_2PO_4)_2$; $NH_4H_2PO_4$
8	NH$_4$Fe(HPO$_4$)$_2$	$(NH_4)_2O\cdot Fe_2O_3\cdot2P_2O_5\cdot2H_2O$		$NH_4H_2PO_4$
9	NH$_4$Al$_2$(PO$_4$)$_2$OH·8H$_2$O	$(NH_4)_2O\cdot2Al_2O_3\cdot2P_2O_5\cdot17H_2O$		$(NH_4)_2HPO_4$

Tables 1 and 2 do not exhaust the wide variety of compounds which can be prepared from dilute solutions. In the study of the reaction of ammonium phosphate with gibbsite at a pH in excess of 5.4, Taylor et al.[57] found the following compounds which had not been described earlier: $(NH_4)_2AlH(PO_4)_2.4H_2O$ [empirical formula $2(NH_4)_2O.Al_2O_3.2P_2O_5.9H_2O$] and $NH_4AlPO_4(OH).2H_2O$ [or $(NH_4)_2O.Al_2O_3.P_2O_5.5H_2O$]. Somewhat later the presence of the same compound was established in the precipitate deposited in the reaction of wet-process phosphoric acid with ammonia[34]. The above salts were also prepared artificially by Frazier and Taylor[60]. The composition of the salts is close to that of potassium phosphatoaluminate (product of R of group 8), differing from the latter only in a higher water content, which can be attributed either to an error in its determination or to the capacity of these compounds to form numerous hydrates.

Arlidge et al.[62] obtained the ammonium derivatives $NH_4Fe_2(PO_4)_2.(OH).2H_2O$ corresponding to the mineral leucophosphite (product I, group 4).

In future the above list will probably be extended.

V. PROPERTIES OF COMPOUNDS OF THE TYPE $a(NH_4)_2O.bR_2O_3.cP_2O_5.nH_2O$

As already mentioned, Haseman et al.[54] investigated in fair detail the compounds synthesised, including certain metal ammonium phosphates.

In recent years much attention has been devoted to the study of the physicochemical properties of taranakite and certain other products of the reaction of soluble phosphates with soils. Taylor and Gurney[59] determined the solubility of the synthetic taranakites $H_6K_3Al_5(PO_4)_8.18H_2O$ and $H_6(NH_4)_3Al_5(PO_4)_8.18H_2O$. Their solubility products were calculated from the compositions of the solutions in equilibrium with the solid phase. The negative logarithm of the solubility product of ammonium taranakite was found to be 175.5. This value is regarded as approximate, since account was not taken of the possibility of the formation of complex ions in the liquid phase.

It has been established that, in solutions where the activity product $a_{Al}a_{PO_4}$ exceeds 1×10^{-20}, taranakite dissolves incongruently with formation of amorphous aluminium phosphate.

Egan et al.[61] gave the heat capacities, entropies, and enthalpies of taranakite over a wide range of temperatures, between 10° and 310°K. The entropy at 298.16°K, the enthalpy, and the heat of formation from the elements of $H_6(NH_4)_3Al_5(PO_4)_8.18H_2O$ are respectively 339.9 ± 0.6 e.u., 57 170 cal $mole^{-1}$, and −4432 kcal $mole^{-1}$.

Smith and Brown[55] determined by X-ray diffraction analysis the lattice constants and densities of the compounds $(NH_4)_2O.Al_2O_3.2P_2O_5.3H_2O$ (item D, group 3), $(NH_4)_2O.3Fe_2O_3.6P_2O_5.20H_2O$ (product K, group 5), $(NH_4)_2O.3Al_2O_3.6P_2O_5.20H_2O$, and a series of potassium compounds.

Arlidge et al.[62] recorded the powder diffraction patterns and infrared spectra of a large number of synthetic aluminium and iron phosphates corresponding to the natural minerals variscite and metavariscite ($AlPO_4.2H_2O$), strengite and phosphosiderite ($FePO_4.2H_2O$), barrandite (Al, Fe)$PO_4.2H_2O$, leucophosphites (K, NH_4)$Fe_2(PO_4)_2(OH).2H_2O$, and taranakites, and also some of the synthetic phosphates, namely $NH_4Fe_3H_8(PO_4)_6.6H_2O$ [empirical formula $(NH_4)_2O.3Fe_2O_3.6P_2O_5.20H_2O$], and the corresponding potassium compound.

The powder diffraction pattern of the salt $NH_4Fe_3H_8(PO_4)_6.6H_2O$ was also recorded by Haseman, but comparison of the two patterns proves them to be completely different.

The products enumerated above were also analysed thermographically.

Frazier and Taylor[60] made optical, X-ray diffraction, and thermographic studies of the artificial taranakites, and the salts $(NH_4)_2.AlH(PO_4)_2.4H_2O$, $NH_4AlPO_4OH.2H_2O$, and $NH_4AlPO_4.OH.3H_2O$ and measured the infrared spectra. Their differential heating curve for ammonium taranakite differed from those obtained by Arlidge et al. and depended on the conditions of the thermographic experiments (in a stream of air or in a stationary atmosphere) and on the dilution of the specimen; on this basis, the authors concluded that thermal analysis is unsuitable for the identification of ammonium phosphatoaluminates.

The ammonium phosphato-ferrates(III) and -aluminates investigated by the present author[53] behaved on heating similarly to the corresponding divalent metal compounds, namely ammonia and water were evolved from the salts in several stages with formation of a series of intermediate compounds, as shown by the changes in the refractive indices and in the colour of the iron compounds. The intermediate compounds were not identified.

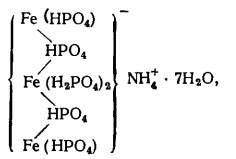
The Structure of Compounds of the Type $a(NH_4)_2O.bR_2O_3.cP_2O_5.nH_2O$

The application of X-ray diffraction and infrared spectroscopy in the study of certain trivalent metal ammonium phosphates isolated in a pure form established the presence of definite groups in these compounds and demonstrated their distribution, and conclusions concerning their structure were arrived at on this basis. As already stated, Smith and Brown[55], having determined by X-ray diffraction the space groups and the density of the compound $2(NH_4)_2O.3Al_2O_3.5P_2O_5.26H_2O$ obtained by Haseman and corresponding to the natural mineral taranakite, found that the formula $(NH_4)_3Al_5H_6(PO_4)_8.18H_2O$ gives a better representation of the properties of this compound.

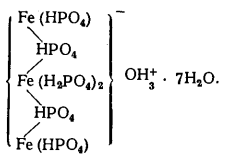
The infrared spectra of taranakite, obtained by Arlidge et al.[62], showed that it contains acid phosphate groups. Arlidge et al. isolated from dilute solutions the compounds $(NH_4, K)_2O.2Fe_2O_3.2P_2O_5.5H_2O$, corresponding to group 4 in Haseman's classification, and found by infrared spectroscopy that they contain the OH and PO_4 groups and water of hydration, which led to their identification with the natural mineral leucophosphite $NH_4Fe_2(PO_4)_2(OH).2H_2O$.

Shishkin and coworkers[63,64], who studied the structure of iron phosphates, established that in some of these part of the water of crystallisation is of the oxonium type. For example, they regard phosphatoferric(III) acid as the oxonium salt $[Fe(HPO_4)_2]^-OH_3^+$, and Weinland's pink salt as an isomorphous compound, and therefore they believe that Weinland's salt is more correctly represented by the formula $[Fe(HPO_4)_2]^-NH_4^+$. They believe that the validity of this formula is confirmed by the fact that two of the hydrogen ions in this salt cannot be substituted by ammonium ions. Furthermore, the compounds $[(Fe(HPO_4)_2]NH_4$ and $[Fe(HPO_4)_2]H_3O$ proved to be very similar in their physical properties (specific gravity, refractive index). It is quite possible that this formula does indeed represent better the structure of the above ammonium phosphatoferrate(III). The possibility of the existence of the complex $[Fe(HPO_4)_2]^-$ in solutions of iron salts in phosphoric acid has been pointed out by Salmon[65].

The second of Weinland's salts, with the empirical formula $(NH_4)_2O.3Fe_2O_3.6P_2O_5.22H_2O$, Shishkin and coworkers represent as follows:



believing it to be isomorphous with the phosphate $3Fe_2O_3.6P_2O_5.25H_2O$ or



The review of the literature data shows that, despite the fact that metal ammonium phosphates are already used in various branches of the national economy, their properties and specially their structure have been investigated quite inadequately.

The structure of certain trivalent metal compounds, formed in the reaction between fertilizers and soils, has been investigated more completely using new research techniques (X-ray diffraction, the crystal-optical method, infrared spectroscopy). These studies were stimulated by the requirements of the technology of fertilizers and agrochemistry: the manufacture of new types of fertilizers and the endeavour to improve their efficacy. As already stated, many of these compounds have been prepared artificially from dilute solutions containing aluminium or ferric phosphates and ammonium phosphate. In this concentration range compounds with the same composition and properties were not always obtained.

The situation is even less clear in the range of high concentrations. Among all the compounds obtained, only the existence of the salt $NH_4Fe(HPO_4)_2$ has been firmly established. The information about all other compounds is contradictory.

On the other hand, the divalent metal compounds are readily precipitated from both dilute and concentrated solutions in the form of crystalline salts having definite composition, but here too very little is so far known about their structure; the available information is insufficient for the solution of a number of problems associated with their properties.

In technological processes involving the synthesis of metal ammonium phosphates it is desirable to carry out the precipitation from concentrated solutions and therefore compounds precipitated in this concentration range are of great practical interest. The synthesis of iron ammonium phosphate has already been achieved in the USSR and the synthesis of a fire-resistent agent based on ammonium phosphato-aluminate and -ferrate(III) is being introduced. The necessity to use in the manufacture of fertilizers low-grade phosphorites containing a considerable amount of iron and aluminium has also stimulated the expansion of studies in this field.

The development of studies on the application of a number of metal ammonium phosphates as slowly hydrolysable complex fertilizers containing both macro- and micro-elements and the development of synthetic methods for these compounds are of considerable interest.

Separation of Rare-earth Elements† by Electrolysis at a Mercury Cathode

G.M.Kolesov and L.N.Pankratova

The review deals with the questions of the mechanism of the reduction of rare-earth elements at a stationary mercury cathode and the conditions of their electrochemical deposition and separation, and of their extraction by alkali metal amalgams, are described and discussed. Examples of the separation of almost all the rare-earth elements at a mercury cathode are quoted. The bibliography incorporates 103 references.

I. INTRODUCTION

Among the methods for the separation of rare-earth elements available at the present time the most widely used are fractionation based on the gradual variation of the solubility or basicity of rare-earth compounds, ion-exchange and partition chromatography, extraction methods, and electrolysis at a mercury cathode. The last makes it possible, in particular, to separate comparatively readily large amounts of one rare earth from very small amounts of other adjacent elements and can be used in most cases where the separation of large amounts of a rare earth by ion-exchange or fractionation methods involves considerable difficulties.

† Lanthanides is the term used at present in Western literature (Ed.of Translation).

At the present time a large amount of data on the separation of rare earth at a stationary mercury cathode has accumulated. However, unfortunately studies on electrolysis with a mercury cathode for the separation of rare-earth elements has not been reviewed so far. Some information is given in the review of Ryabchikov and Terent'eva[1].

II. APPLICATION OF THE MERCURY CATHODE

The method of the electrolytic reduction of rare-earth elements developed as a result of several studies carried out with different aims. In 1906 Matignon[2] isolated samarium(II) sulphate and in 1911 Urbain and Burion[3] isolated for the first time a europium(II) compound. In

1929 Klemm[4] gave a theoretical explanation of the "anomalous" valencies of the rare earths on the basis of Hund's spectroscopic investigations[5] and theories concerning the structure of rare-earth atoms, and demonstrated the existence of divalent ytterbium. At the present time the "anomalous" properties of rare-earth elements have been fairly adequately elucidated in a series of monographs[6-8].

Studies on the electrolysis of aqueous rare-earth solutions have served as a basis for the development of the method of their electrolytic reduction. Krüss[9] showed that in the electrolysis of aqueous rare-earth chloride solutions with platinum electrodes hydrochloric acid decomposes with the evolution of gaseous chlorine at the anode and of hydrogen and rare-earth hydroxides at the cathode. The decrease of the acidity of the solution observed in this process was subsequently used[10-15] for the separation of rare-earth mixtures by the fractional precipitation of their hydroxides or basic salts.

Yntema[16] replaced the platinum cathode by a mercury cathode and, by virtue of the high hydrogen overvoltage of mercury, achieved the reduction of europium and samarium to the divalent state in a mixture of their chlorides and gadolinium chloride. The divalent state of europium was stabilised by its precipitation as the sparingly solubles sulphate by a small amount of sulphuric acid. Ytterbium was isolated similarly[17]. Prandtl[18] suggested that the electrolysis be carried out directly in rare-earth sulphate solutions but the method used to stabilise the divalent ions in all the studies of this period[19-21] was the same. Electrolytic reduction of rare-earths in the presence of SO_4^{2-} ions gives a relatively low yield of the reduced element and cannot be used to obtain pure preparations of samarium and particularly of other rare-earth elements which do not have a stable divalent state.

A new development in studies in this field was begun by the work of Biltz and Mayer[21], who observed that metallic cerium dissolves in mercury with formation of an amalgam. This suggested the possibility of the preparation of other rare earths by electrolysis with a mercury cathode both in aqueous and in alcoholic solutions[22-25]. However, the electrolytic preparation of rare-earth amalgams is prevented by their precipitation as hydroxides (or basic salts) in the electrolysis of neutral or weakly alkaline solutions. This difficulty was overcome by McCoy[26,27], who suggested that the electrolysis be carried out in weakly alkaline solutions of organic acids (citric and tartaric), from which rare-earth hydroxides in the trivalent state are not precipitated. Under these conditions, rare earths from complexes with the acids, which have been thoroughly investigated and are widely used in analytical practice[28-33].

The method of electrolytic preparation of rare-earth amalgams, in contrast to the electrolytic reduction of rare earths in the presence of sulphate ions, excludes the possibility of the entrainment of the electrolyte solution (occlusion and sorption on the surface) and can yield pure preparations in a single operation. Furthermore, it is possible to select the conditions of electrolysis in such a way that almost all the rare earths can be deposited at a mercury cathode. Using Marsh's experimental data[24], Ryabchikov et al.[35] investigated in detail the effect of different factors on the deposition of ytterbium and increased the degree of its isolation to 93–98%, compared with 23% obtained by McCoy[26]. The electrolysis was carried out at 5°C, pH 6, cathodic current density 25 mA cm^{-2}, ytterbium concentration 0.5–1.0%, and molar ratio $Yb^{3+} : Cit^{3-} = 1 : 2$.

Onstott[36,37] succeeded in separating ytterbium quantitatively (99.98%) from solutions of heavy rare earths by increasing the duration of electrolysis to 8 h and by replacing the potassium amalgam by the lithium amalgam.

Europium was isolated under approximately the same conditions[38-43]. Shvedov and Fu I-pei[41-43] paid particular attention to the effect of the ligand and the alkali metal in the electrolyte as well as the pH of the solution on the degree of isolation of europium. They established that the rate of deposition increases in the sequence Trilon B [sodium salt of EDTA (Ed. of Translation)] > citric acid > > tartaric acid > succinic acid at pH 7.0, 6.8, 9.0, and 9.5 respectively. The yield of europium increases also on raising the current density, the temperature (to 30–40°C), and the pH of the solution (from 4.2 to 9.0 for citrate solutions) and on replacing the alkali metal in the sequence sodium < caesium < potassium < lithium.

Much work has been done on the electrolytic isolation of samarium[26,44-50]. The electrolysis was usually carried out[48] in a vessel similar to a separating funnel (Fig. 1) and fitted with a cooling jacket, a two-way tap, and a balancing flask designed to facilitate the renewal of mercury; the volume of solution was 10 ml, the pH was 6, the potential 8–12 V, and the initial current density 50–100 mA cm^{-2}. The electrolyte and mercury were mixed.

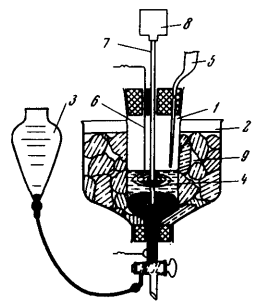

Figure 1. Apparatus for electrolysis with a mercury cathode[48]: *1*) electrolytic cell; *2*) cooling jacket; *3*) balancing flask with mercury serving as the cathode; *4*) initial solution; *5*) tube for the introduction of solution; *6*) platinum anode; *7*) stirrer; *8*) motor; *9*) mixture of dry ice and water.

For example, it was established that the degree of deposition of samarium increases with increasing current density, area of the cathode, the amount of mercury (and its renewal), and duration of electrolysis, and also when potassium ions are replaced by lithium ions; it decreases on raising the concentration of samarium (up to a certain limit) and its content in the amalgam[47-49].

It is interesting to note that the degree of transfer of samarium to mercury at a constant concentration of complex-forming ligand ($Sm^{3+} : CH_3COO^- : Cit^{3-} = 1 : 1 : 2$) is almost constant in the Sm^{3+}-concentration range 6×10^{-3}–6×10^{-2} M, amounting to about 95%. At low concentrations (10^{-4}–10^{-6} M) the degree of its isolation is also high and constant even when the ratio $Sm^{3+} : Cit^{3-}$ is increased by a factor of 5000.

The conditions for the isolation of samarium, europium, and ytterbium in the form of amalgams by the electrolysis of their solutions containing complex-forming ligands (Table 1) were used also for the investigation of the behaviour of other rare earths at the mercury cathodes.

The isolation of promethium was first mentioned by Nauman and Heyne[45] and the conditions for the isolation of this element and other rare earths were investigated in detail in subsequent studies[42,47-53]. The optimum conditions for the isolation of certain rare earths are given in Table 2.

The type of alkali metal amalgam has the main effect on the yield of the rare earth (Table 3). Tables 2 and 3 show that lithium amalgam favours the most complete separation of the rare earth; cerium group elements are more readily isolated than the elements of the yttrium group (see also Fig. 2). The smallest yield is obtained with erbium and lutetium. The effect of the excess of complex-forming ligand and of the concentration of rare earths which do not have a stable divalent state on the degree of their separation is smaller than in the isolation of europium, ytterbium, and samarium. Differences of this kind are used for the enrichment and separation of rare earths,

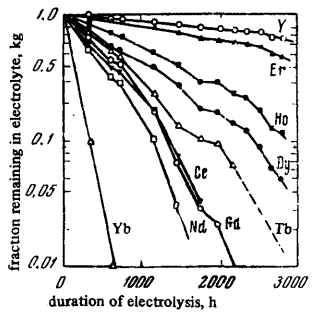

Figure 2. Dependence of the degree of liberation of certain rare-earth elements at a mercury cathode on the duration of electrolysis[46,88].

which can be divided into three groups as regards the relative ease of their electrolytic deposition at a stationary mercury cathode: (1) elements of the cerium group; (2) elements with a stable divalent state under the electrolysis conditions (europium, ytterbium, and samarium); and (3) elements of the yttrium group.

III. MECHANISM OF THE REDUCTION OF RARE-EARTH ELEMENTS

The mechanism of the reduction of rare earths at a mercury cathode was investigated mainly in two ways—in connection with the extraction of rare-earth elements by alkali metal amalgams and polarographically. In the first studies on the conditions of isolation of ytterbium at a mercury cathode[34,35] it was already shown that ytterbium is initially reduced to the divalent state and then to the metal, forming an amalgam with mercury. Somewhat later a similar mechanism was proposed also for the reduction of europium and samarium[38,41,47]. The two-stage reduction of europium, samarium, and ytterbium and also of certain other rare-earth elements is demonstrated by numerous facts, mainly by the presence of two waves in polarograms obtained at a dropping mercury cathode[54-62], corresponding to the consecutive reduction of triply-charged ions to doubly-charged species and then to the metal with formation of an amalgam.

More complex relations indicating a different cathodic process were obtained in other investigations[63-74].

It has been shown[41,47,50] that the transfer of samarium, cerium, and promethium to the mercury cathode is due to electrolytic reduction. However, in the electrolysis of acetate–citrate solutions more complex chemical reactions take place than was believed earlier[35]. The anions Ac^-, H_2Cit^-, $HCit^{2-}$, and Cit^{3-} form ionic complexes of different compositions with rare-earth cations. Their relative concentrations depend on the pH of the solution, the instability constant, and the ratio of the concentrations of the rare earths and the complex-forming ligands. The optimum conditions for electrolysis are thus directly related to the correct choice of ligand[32,33,43]. Apart from the rare earths, the alkali metal and hydrogen cations are reduced at the mercury cathode; the order of their reduction depends on the relative potentials and the pH of the solution. In the presence of complex-forming ligands the reduction potentials of the rare earths, which can be

estimated from the half-wave potentials (Table 4), are displaced towards more negative values and approach under the experimental conditions the reduction potential of alkali metal (Table 5). Consequently the efficiency of the deposition of rare-earth elements is related to the difference between the potentials of the alkali metal and the element being deposited. Thus in the presence of lithium, which has a more negative reduction potential than potassium, caesium, and sodium, the rate and degree of isolation of rare-earth elements are higher.

Table 4. Half-wave potentials of rare-earth elements[54].

Shvedov and Fu I-pei[42,43] give preference to amalgam cathodes. However, it is noteworthy that the deposition of rare-earth elements at a mercury cathode cannot be explained by simple replacement of alkali metal ions in the amalgam; this is confirmed by the data of Shvedov and Fu I-pei[41] concerning the constancy of the concentration of caesium in the solution during the electrolysis of europium. It is most likely that the efficiency of the isolation of rare-earth elements at an amalgam cathode is related, as mentioned above, to the difference between the potentials of the alkali metal and the element being isolated and that the alkali metal in the amalgam behaves as an additional reducing agent.

A large number of rare-earth amalgams obtained in electrolysis with a mercury cathode and by the extraction method have been investigated polarographically and electrochemically. For example, Barrett carried out the extraction of rare-earth elements with about 0.1% alkali metal amalgams from acetate media at pH 4 until the onset of precipitation of the hydroxide[63,64]. Lanthanum, cerium, praseodymium, and neodymium and also samarium, europium, and ytterbium were extracted. The results are presented in Table 6, which shows that the degree of extraction of the elements of the lanthanum–neodymium group decreases in the sequence lithium > sodium > > potassium, while the sequence for europium, samarium, and ytterbium is different: sodium > potassium > lithium, the degree of extraction also decreasing with decrease of the concentration of the alkali metal (Fig. 3). The measured potentials of most of the rare-earth amalgams prove to be lower than those of the corresponding alkali metal amalgams. This evidently accounts for Barrett's[63,64] observation of only single reduction waves at potentials in the range 1.84–2.04 V.

Table 6. Percentage extraction of rare-earth elements by potassium, sodium, and lithium amalgams[63] (c_{Ln} = 0.5 M).

Rare earth	Amalgam*		
	Li	Na	K
La	38	21	17
Ce	—	13	8
Pr	31	13	14
Nd	23	7	5
Sm	45	66	50
Eu	41	50	50
Yb	25	47	37

* 0.04 M amalgam was used.

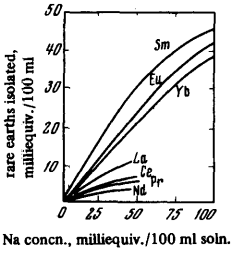

Figure 3. Variation of the degree of extraction of rare-earth elements with the concentration of sodium amalgam[56].

Samarium, europium, and ytterbium are extracted to a higher extent than elements of the lanthanum–neodymium group; the degree of extraction falls with increasing atomic number of the element and does not correspond to the stability of divalent ions in solution. This may be because rare-earth elements form with acetate ions complexes of indefinite composition and low stability, which is independent of the atomic number of the element[76], and also may be associated with hydrolytic phenomena. The size of hydrated rare-earth cations is known to increase with their atomic number[77], which accounts for the increasing tendency of rare earths towards hydrolysis on going from lanthanum to lutetium[78–80]. Biedermann and Giavatta[81] showed that in solution at pH ≥ 6.5 lanthanum is hydrolysed, forming ions of the type $La(OH)^{2+}$ and $La_2(OH)^{5+}$. In this connection, it is logical to expect the formation of

hydrolysed rare-earth species at a lower pH when the atomic number is higher. Thus hydrolysis, which includes also the formation of non-reducible polynuclear ions, can explain the observed tendency of the extraction coefficient to decrease with increasing atomic number. This can also account for the behaviour of non-extractable rare-earth elements:

$$Ln^{3+} + nH_2O + Na \rightleftarrows Ln(OH)^{2+} + Na^+ + H \cdot$$

However, there is no direct proof of the formation of intermediate rare-earth ions in the extraction of elements of the lanthanum–neodymium group[82,83].

The data of Barrett et al.[64] supplement the classification of these elements given above. In extraction by alkali metal amalgams elements of the first group (lanthanum–neodymium) are reduced in one stage[64]. Since the extraction process is the sum of the electrochemical and hydrolytic processes and the tendency towards hydrolysis increases with the atomic number, three-electron reduction becomes impossible for samarium, europium, and ytterbium (second group), which are reduced in two stages. The third group (gadolinium–lutetium) does not have a divalent state and three-electron reduction can be achieved only under very severe conditions in view of the increasing tendency of these elements towards hydrolysis, and for this reason they are hardly reduced by alkali metal amalgams.

The reduction of samarium, europium, and ytterbium takes place in stages, the divalent rare-earth cations formed initially showing some similarity to the alkaline earth elements. In this case the degree of hydrolysis is low, since, for example, europium(II) hydroxide is appreciably soluble in an alkaline solution. Furthermore, divalent rare-earth cations are hydrolysed at higher pH, in contrast to the trivalent cations, which is important in their subsequent reduction to the metal under conditions of a higher hydroxide ion concentration near the cathode than in the bulk phase. This in fact explains why unhydrolysed rare-earth cations are capable of stepwise reduction by alkali metal amalgams in the opposite sequence, i.e. sodium > potassium > lithium.

Treindl[84] made a polarographic and oscillographic study of certain rare earths. On the basis of data showing the high reducing power of the reduction products obtained, the presence of hydroxide ions at the overvoltage potential[85], the dependence of the depth of the minima on the capacity of the anions for deformation and on their concentration, the dependence of the limiting current on the concentration of deformable anions, etc., he suggested that the reduction products are the hydrides and halide hydrides of the corresponding rare earths:

$$xH^+ + 2xe^- = xH^-,$$
$$Ln^{3+} + xH^- + (3-x)X = LnH_xX_{3-x},$$
$$LnH_xX_{3-x} + xH_2O = Ln^{3+} + (3-x)X + xH_2 + xOH^-,$$
$$H^+ + 2e^- + H_2O = H_2 + OH^-,$$

where $x = 1, 2, 3$ and X is a halide ion. The quantitative proportions of the hydrides depend on the electrode potential.

It was established[86,87] that in the presence of 0.1 M lithium chloride at pH 4 all rare-earth elements give rise to a double reduction wave and are reduced irreversibly at a dropping mercury cathode; the diffusion-limited waves observed in some studies[65–74] can be caused by the reduction of hydrogen in the aquo-complexes of these elements:

$$Ln(H_2O)_6^{3+} \rightarrow Ln(H_2O)_{6-x}(OH)_x^{3-x} + xH,$$
$$xH^+ + xe^- \rightarrow x/2\,H_2,$$
$$Ln(H_2O)_6^{3+} + xe^- = Ln(H_2O)_{6-x}(OH)_3 + x/2\,H_2.$$

On the basis of data derived from the electrochemical separation of rare-earth elements at a mercury cathode in the presence of lithium ions and various complex-forming ligands (acetate, perchlorate, tartrate, and citrate ions), Onstott[88] explained the reduction of rare-earth elements (without a stable divalent state) by the formation of hydrides according to the following mechanism:

$$[Ln(H_2O)A_m]^{3+} + e^- \xrightarrow{\text{fast}} [Ln(H)(OH)A_m]^{2+}$$
$$\downarrow e^- \ (\text{slow})$$
$$[Ln(H)(OH)A_m]^+$$
$$[Ln(H)(OH)A_m]^+ + 2e^- \rightleftarrows LnH(Hg) + OH^- + mA.$$

It is noteworthy that the electrolytic reduction of rare-earth elements at a mercury cathode is still insufficiently elucidated. The data of the investigations quoted above make it possible to distinguish the following main types of cathodic processes.

Consecutive reduction to the metal with formation of an amalgam:

$$Ln^{3+} + e^- \rightarrow Ln^{2+},$$
$$Ln^{2+} + 2e^- \rightarrow Ln^0(Hg).$$

Direct reduction of triply charged rare-earth ions to the amalgam:

$$Ln^{3+} + 3e^- \rightarrow Ln^0(Hg).$$

Reduction with formation of hydrides and halides hydrides:

$$Ln^{3+} + xH^+ + 2xe^- + (3-x)X^- = LnHxX_{(3-x)}.$$

Reduction of hydrogen in the aquo-complexes or in the hydrate shells of the rare-earth ions:

$$Ln(H_2O)x^{3+} + 3e^- \rightarrow Ln(OH)_3 + (x-3)H_2O + {}^3/_2\,H_2.$$

For rare-earth elements without a stable divalent state, the last two types, in which the cathodic process is regarded as catalytic reduction of hydrogen ions, are the most likely; the mechanism of the catalysis consists in the formation and decomposition of hydrides[87].

IV. SEPARATION OF RARE-EARTH ELEMENTS

1. Conditions of Electrochemical Separation

The separation of rare-earth elements by electrolysis with a mercury cathode depends on the relative distribution of the rare-earths between mercury and the electrolyte. In other words, any parameter which influences the properties of the rare-earth elements in each phase will influence their relative distribution between the two phases[70]. For example, the formation of rare-earth complexes in the aqueous phase complicates the electrolysis. The degree of complication is greater the more stable are the complexes.

The equilibrium distribution of any trivalent element between the mercury phase and the electrolyte at 25°C can be formulated[46]‡ as follows in accordance with the Nernst equation:

$$E = E^a - 0.02\log(c^a/c^e), \quad (1)$$

where E is the cathode potential, E^a the standard potential of the amalgam, c^a the concentration of the rare earth in the amalgam, and c^e its concentration in the electrolyte.

‡ In the calculations account was not taken of the irreversibility of the cathodic-anodic behaviour of rare-earth elements. Nevertheless, they can be used for practical purposes.

The cathode potential E is the same for the electrode processes of any two rare earths (1 and 2) and therefore the distribution is described by the equation:

$$\Delta E = E_1^a - E_2^a = 0.02 \log (c_1^a \, c_2^e / c_1^e \, c_2^a) . \quad (2)$$

Eqn. (2) shows that the partition coefficient is a constant quantity, which depends only on the difference between the amalgam potentials (ΔE) of any two rare-earth elements. For example, a difference as low as $\Delta E = 20$ mV corresponds to a partition coefficient of 10.

To describe the separation of a mixture of trivalent rare-earth elements, data on standard electrode potentials can also be invoked, particularly if the amalgam potentials have been determined imprecisely. The amalgam potentials of rare-earth elements differ approximately to the same extent as their standard electrode potentials and therefore differences between the potentials of adjacent rare-earths of approximately 20 mV permit satisfactory separation, as stated.

For practical separation of two adjacent rare-earth elements, account must be taken of the purity and the yield of each element. For this purpose, it is necessary to determine the cathode potential from the known values of E_1^a or E_2^a, which can be done with the aid of Eqn. (2). It is also possible to predict whether or not the separation of divalent from trivalent rare-earths is possible. For the description of the reduction of divalent rare-earth elements, Eqn. (1) becomes

$$E_{II} = E_{II}^a - 0.03 \log (c_{II}^a / c_{II}^e) . \quad (3)$$

From Eqns. (1) and (3), we obtain

$$3E - 2E = 3[E^a - 0.02 \log (c^a/c^e)] - 2[E_{II}^a - 0.03 \log (c_{II}^a / c_{II}^e)]$$

and therefore

$$E = 3E^a - 2E_{II}^a - 0.06 \log \alpha , \quad (4)$$

where α is the separation factor, which depends on the cathode potential.

If equilibrium distribution is attained simultaneously for both electrode processes, the variation of E should be represented by a straight line. The time of attainment of a stable cathode potential after optimum equilibrium is reached is determined by the values of E^a and E_{II}^a. In the presence of a complex-forming ligand, Eqn. (2) becomes, from the law of mass action,

$$E_1^a - E_2^a = 0.02 \log \alpha + 0.02 \log \frac{K_{d_2}}{K_{d_1}} , \quad (5)$$

where K_d is the instability constant. If the ligand is a very powerful complex-forming agent, for example EDTA, separation may be difficult because of the high potential necessary to break down the complex.

Complex formation can alter the conditions of the deposition of rare-earth elements and can have a favourable effect on their separation when the complex-forming agent is chosen correctly [33,43].

As already stated, direct deposition of rare-earth elements at a mercury cathode depends on the distribution of their ions between mercury and the electrolyte [46,89] and on the rate of transfer of rare-earth ions through the electrode–electrolyte interface, which is defined by the following equation:

$$-\frac{dc}{dt} = \frac{DA}{V\delta}(c - c^e), \quad (6)$$

where c is the concentration of the diffusing ion in the electrolyte, c^e the concentration of the ion on the surface of the electrode, t the duration of electrolysis, D the diffusion coefficient, A the area of the electrode, V the volume of the electrolyte, and δ the thickness of the diffusion layer.

Integration of Eqns. (6) with $c^e = 0$ yields

$$\ln \frac{c}{c^0} = -\frac{DA}{V\delta} t , \quad (7)$$

where c^0 is the initial concentration of the ions in solution. The plot of $\ln c$ against t is a straight line with slope $DA/V\delta$, which can be regarded as a rate constant (k).

Rare-earth elements present in the electrolyte at low concentrations are hydrolysed at a rate which is mainly determined by diffusion in the region near the electrode [90–92]. The rate of diffusion depends in turn on the concentration at the mercury surface of the ions undergoing electrolysis. When $k = DA/V\delta$, Eqn. (7) is of the form

$$dN/dt = k \, c^s , \quad (8)$$

where N is the number of ions per unit area transferred during time t from the surface of the electrode on which the concentration of ions is c^s. [93] The rate of removal of c^s is determined by the quantity $D(dc/dl)$, where D is the bulk-phase diffusion coefficient of the ions and l the distance from the electrode. In a stirred solution the bulk-phase concentration c^b does not vary significantly with δ, so that

$$dN/dt = D(c^b - c^s)/\delta = k \, c^s . \quad (9)$$

Since c^b depends on time, we obtain

$$-\frac{dc^b}{dt} = \frac{dN}{dt} \times \frac{A}{V} = \frac{\frac{A}{V} \times D k \, c^b}{D + \delta k} . \quad (10)$$

At the extreme values of the parameters δ, D, and k, for example when $\delta k \gg D$, Eqn. (10) acquires the form of Eqn. (6), which reflects Fick's first law applied to electrode reactions [57]. When $\delta k \ll D$, we obtain $-dc^b/dt = (A/V)kc^b$. In this case $c^s \simeq c^b$ and the rate is almost independent of D and δ.

Eqn. (10)can be used to describe the rare-earth separation processes, and one can write

$$-\frac{dc^b}{dt} = \frac{A}{V} \beta \, c^b \quad (11)$$

where $\beta = Dk/(D + \delta k)$.

The ratio of the concentrations of the two rare earths in the electrolyte after a time t can be represented by the relation

$$\frac{c_2^b}{c_1^b} = \frac{c_2^0}{c_1^0} e^{\frac{A}{V}(\beta_1 - \beta_2)t} , \quad (12)$$

where c_1^0 and c_2^0 are the initial concentrations of the rare earths. This ratio is high for high values of t when $\beta_1 \gg \beta_2$.

Since the concentration of any of the two rare earths in the amalgam is defined as $c_i^a = (c_i^0 - c_i^b)V_e/V_a$, where V_e/V_a is the ratio of the volumes of the electrolyte and the amalgam, the ratio of the rare earths transferred to the amalgam is given by the equation

$$\frac{c_1^a}{c_2^a} = \frac{c_1^0 \left(1 - e^{-\frac{A}{V}\beta_1 t}\right)}{c_2^0 \left(1 - e^{-\frac{A}{V}\beta_2 t}\right)} . \quad (13)$$

For low values of t, the ratio $c_1^a/c_2^a \simeq (c_1^0/c_2^0)(\beta_1/\beta_2)$; for high values of t, when the electrolysis of both rare earths is almost complete, $c_1^a/c_2^a \simeq c_1^0 c_2^0$.

Knowing the rate of deposition of any two rare-earth elements at the mercury cathode and their partition coefficients between the two phases, it is possible to predict the efficiency of the separation of the rare earths. The partition coefficient of two rare-earths (1 and 2) deposited simultaneously at a mercury cathode depends on the ratio of their concentrations in the electrolyte (c^e) and in the amalgam (c^a), i.e.[88]

$$\alpha = \frac{c_1^a c_2^e}{c_2^a c_1^e} \quad . \qquad (14)$$

When c_1^a, c_2^a, c_1^e, and c_2^e from Eqns. (12) and (13) are substituted in Eqn. (14), we obtain

$$\alpha = \frac{[1 - e^{-\frac{A}{V}\beta_1 t}]}{[1 - e^{-\frac{A}{V}\beta_2 t}]} \times e^{\frac{A}{V}(\beta_1 - \beta_2)t} \quad . \qquad (15)$$

It follows from Eqn. (15) that, when $\beta_1 = \beta_2$, we have $\alpha = 1$ and there is no separation. For low values of t, $\alpha \simeq \beta_1/\beta_2$; when $t \to \infty$, we have

$$\log \alpha = \frac{At}{V \times 2.303}(\beta_1 - \beta_2) \quad . \qquad (16)$$

Eqn. (16) shows that, when the transfer of both rare earths to mercury is almost quantitative, the ratio of the concentrations of the rare earths remaining in the electrolyte becomes very high. In this case α may be very large compared with the value obtained under conditions of equilibrium separation where α is constant. Fig. 4 shows a plot of α (calculated with the values of β_1/β_2 adopted) for the transfer of rare earth 1 (Ln).

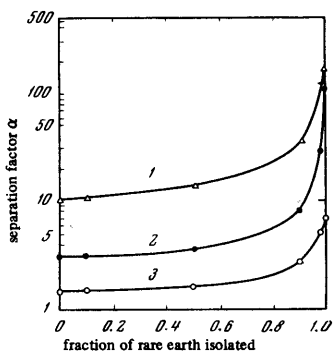

Figure 4. Variation of the separation factor α with the ratio β_1/β_2:[88] *1*) $\beta_1/\beta_2 = 10$; *2*) $\beta_1/\beta_2 = 3$; *3*) $\beta_1/\beta_2 = 1.5$.

In the separation of samarium and europium[8] the results obtained do not meet the requirements of equilibrium separation, but they can be used to obtain a general idea about the rate of the forward reaction. Thus it has been established that 90% of europium is extracted during 55 min of electrolysis of 20.4% of samarium after 230 min; then the ratio $\beta_1/\beta_2 = 42$. It follows from Eqn. (15) that, for 99 and 99.9% of extraction of europium, $\alpha = 856$ and 5570 respectively. These values agree fairly well with the measured α, which is respectively 974 for 99.2% extraction and 2810 for 99.9% extraction of europium[88].

More complete data were obtained in experiments on the separation of europium and samarium where the cathode potential was high and the extraction of europium was almost quantitative[46]; these are presented in Table 7, which shows that α increases rapidly when the degree of extraction of europium is high.

Table 7. Electrolysis of the citrate complexes of europium and samarium at a lithium amalgam cathode in alkaline solutions (cathode potential 2.3–3.0 V, t = 30–39°C)[88].

Extraction, %		α
Eu	Sm	
99.73	18.7	1600
99.83	17.6	2700
99.84	14.6	3700
99.95	26.2	5600
99.96	15.9	13 200

The rate equation for the reaction can be used also to determine the time required for the isolation of the rare earth (europium) at the required concentration[46]. It is noteworthy that better agreement between experimental and calculated data is observed for dilute solutions (Fig. 5, curve *2*).

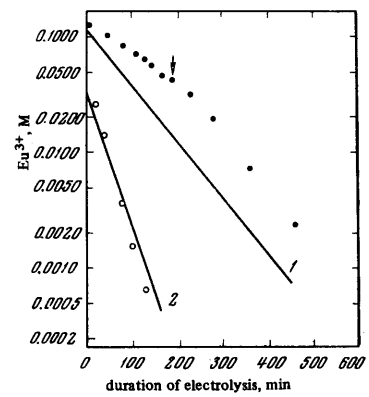

Figure 5. Electrolysis of europium solutions[46]: *1*) volume of electrolyte 498 ml, $c_{Eu^{3+}} = 0.12$ M, $c_{Sm^{3+}} = 0.37$ M; *2*) volume of electrolyte 285 ml, $c_{Eu^{3+}} = 0.039$ M, $c_{Sm^{3+}} = 0.32$ M (current density ~ 14 mA cm^{-2}; amount of mercury 150 ml). Circles—experimental data; straight lines—calculated data; the arrow indicates the renewal of mercury.

It is also possible to calculate α and β for rare earths without a stable divalent state. On the basis of experimental data for the electrolysis of trivalent rare-earth elements presented in Fig. 2, Onstott[88] obtained a series of values of the ratio β_1/β_2 (Table 8). Comparison with the observed and calculated values for a mixture of rare earths at a different concentration shows that β_1/β_2 is

almost the same and independent of the rare-earth concentration ratios in the mixture. The observed variation of β_1/β_2 with the separation factor α is shown in Fig. 4.

2. Examples of the Separation of Certain Rare-Earth Elements

On the basis of the conditions which they developed for the isolation of europium, ytterbium, and samarium, Ryabchikov and coworkers[35,40,44] described the possible ways of separating these elements. Europium can be separated from ytterbium by the electrolysis of their acetate–citrate solutions at high pH and it can be separated from samarium at an $Ln^{3+}:Cit^{3-}$ ratio $> 1:2$. Conditions have also been found for the isolation of ytterbium from a mixture of the elements of the yttrium group[94,95].

Table 8. The ratios β_1/β_2 for a methanol electrolyte containing rare-earth elements.

Rare earth	β_1/β_2 1 (initial mixture)	β_1/β_2 2 (enriched mixture)	Rare earth	β_1/β_2 1 (initial mixture)	β_1/β_2 2 (enriched mixture)
Nd—Gd	1.4	1.9	Dy—Ho	1.5	2.0
Gd—Tb	1.3	1.3	Ho—Er	2.5	2.0
Tb—Dy	1.3	1.5	Er—Y	1.6	1.2

Onstott[37] showed that lithium amalgam is best for the isolation of europium; when potassium citrate is replaced by lithium citrate, the yield of samarium changes only slightly[39]. Onstott notes that samarium, europium, and ytterbium can be separated from other rare earths (whose deposition at a mercury cathode requires more severe conditions) and also from one another if they are present at different concentrations. For example, for an initial ratio of europium and samarium of 1:62 (0.447 M samarium and 7.2×10^{-3} M europium), the concentration of the europium impurity in samarium can be reduced by a thousand-fold by electrolysis.

Shvedov and Antonov[52] investigated the conditions of the separation of samarium from neodymium and praseodymium at different concentrations of the elements (ranging from 0.1 to 1.34 M) in the presence of lithium tartrate at a current density of 15.5 mA cm^{-2}. The proportions of samarium, neodymium, and praseodymium were equimolar, i.e. 1:1:1. It was established that an increase of the concentration of lithium tartrate does not influence the liberation of samarium, and neodymium and praseodymium at tartrate concentrations of 0.4 and 0.7 M respectively do not form amalgams and are not liberated at the mercury cathode. Neodymium and praseodymium can be separated[52] at a current density of 7.7 mA cm^{-2} and a tartrate concentration of 0.34 M. Thus during 60 min electrolysis 47% of praseodymium and 1.5% of neodymium were liberated from 20 ml of solution at a 200 g mercury cathode; the separation factor was 58.

Clusius and Ramirez[96] used the slight differences in the mobilities of neodymium and praseodymium ions for the separation of the elements. Onstott[97] studied the possibility of the separation of the elements by the electrolysis of their chlorides in the presence of lithium citrate. The maximum separation factor in this process was 3.

Lavrukhina and coworkers made a detailed study of the conditions governing the liberation of samarium at a mercury cathode[47–50] and, using the differences in the behaviour of promethium, cerium, and other rare-earth elements, they proposed a method for their separation. In particular, on periodic addition of potassium citrate during electrolysis (the ratio $Ln^{3+}:Cit^{3-}$ decreases) or on renewal of mercury (the electrode potential remains constant and insufficient for the liberation of promethium and cerium), rare-earth elements without a stable divalent state remain in solution. This method was used for the separation of the products of nuclear reactions, the radioisotopes of lanthanum, cerium, praseodymium, neodymium, and promethium, from the main bulk of samarium and europium irradiated by protons having energies between 220 and 660 MeV.[48,49,98,99,100] Radioactive isotopes of the yttrium group elements were separated by the electrolysis of their acetate–citrate solutions from ytterbium irradiated with high-energy protons[101].

Shvedov and Antonov suggested a scheme for the separation of yttrium, ytterbium, and erbium, and lutetium, and also europium and lanthanum[42,43]. They investigated[53] the conditions for the formation of gadolinium, terbium, dysprosium, and holmium amalgams in the electrolysis with a mercury cathode of the acetate–citrate solutions in the presence of lithium ions. It was established that the concentration of lithium ions, the molar ratio $Ln^{3+}:Cit^{3-}$, and the concentration of the rare earths have a considerable influence on the yields of the elements. The optimum molar ratios $Ln^{3+}:Cit^{3-}$ are different for gadolinium, terbium, holmium, and dysprosium, amounting respectively to 12–15, 13, 26, and 17. The following separation factors have been found for binary mixtures of rare-earth elements[53]: 6–8 for gadolinium–terbium, 10–40 for gadolinium–holmium, 5–10 for terbium–dysprosium, 10–30 for terbium–holmium, 20–40 for terbium–erbium, and 30–60 for terbium–thulium. The yield of the rare-earth elements as a rule decreases with their concentration. For example, at a concentration in excess of 0.01 M holmium is not liberated at a mercury cathode; the transfer of dysprosium and terbium to the amalgam becomes negligible when their concentrations in the electrolytes are greater than 2.5×10^{-2} M and 4.0×10^{-2} M. This is associated with the smaller degree of dissociation of the complexes of these rare-earth elements as their concentration is raised.

---o0o---

In the development of a number of new manufacturing processes and the current extensive application of semiconductor materials the problem of the preparation of ultrapure substances and the determination of many elements as impurities at very low concentrations (down to 10^{-10}%) has become particularly urgent[102,103]. In this respect electrolysis with a mercury cathode is one of the promising methods for the concentration of elements with their subsequent determination by different procedures.

Some Electrochemical Properties of Mercury

E.F.Speranskaya and T.G.Pokhvalitova

The first information about the application of mercury as an electrode material dates back to the end of the 19th century[1]. At the same time it was noted that mercury is not an indifferent metal and is capable of reacting with a number of ions in solution. Further extensive application of mercury as an electrode material stimulated systematic investigation of its electrochemical properties: electrocapillary phenomena at the mercury–solution interface, equilibrium and steady-state potentials, kinetics and mechanism of the discharge-ionisation process at the equilibrium and steady-state potentials, and reducing and other properties of mercury. These questions are discussed in the present review. The bibliography comprises 65 references.

I. ELECTROCAPILLARY PHENOMENA AT THE MERCURY–SOLUTION INTERFACE

The electrical double layer arising under equilibrium conditions at the mercury–solution interface is known to consist of anions in the liquid component, the surface of the mercury being positively charged relative to the liquid. The displacement of the potential towards negative values leads to a decrease of the concentration of anions in the double layer. On further displacement of the potential, the charge of the double layer is reversed. The change in potential and the associated charge reversal of the double layer alters the surface tension of mercury.

The first measurement of the surface tension of mercury as a function of the applied potential was made by Lippman[2] with the aid of the capillary electrometer of his design. Paschen[3] and then Gouy[4,5] made systematic studies on the surface tension of mercury as a function of the potential in solutions of different electrolytes (hydrochloric acid, sulphuric acid, nitric acid, potassium hydroxide, etc.) and determined the form of the capillary curve. In all cases the dependence of the surface tension of mercury on the applied potential was represented by a curve passing through a maximum. The maximum surface tension corresponds to the zero charge of the mercury surface. The surface tension and correspondingly the surface energy of the electrode are a maximum at this point.

Adsorption of anions displaces the electrocapillary maximum towards more negative potentials, while adsorption of cations has the opposite effect. Anions can be arranged in the same depolarising effect sequence as that of their effect on the surface tension of mercury. Thus, in the series of anions $NO_3^- < SO_4^{2-} < Cl^- < Br^- < < CN^- < S^{2-}$ their depolarising effect increases from NO_3^- to S^{2-} and the shift of the electrocapillary maximum of mercury towards negative potentials increases in the same direction.

The nature of the anion influences not only the equilibrium or steady-state potential of mercury but also the essential features of the potential-determining process. Members of the Soviet electrochemical school have played

a considerable role in the study of this problem. By deepening and extending their studies in this field, Soviet electrochemists have arrived at important conclusions concerning the nature of these phenomena and their influence on the kinetics of electrode processes.

II. EQUILIBRIUM POTENTIALS OF MERCURY

One of the most important electrochemical characteristics of mercury are the potentials of the equilibrium system comprising mercury and a solution of its ions. The potential jump at the metal–solution interface is known to be established and stabilised by the mutual compensation of two opposed processes:

$$M^0 \rightleftarrows M^{n+} + ne .$$

On the other hand the potential jump can also occur as a result of the adsorption of ions and dipolar molecules. The effect of the last process is shown when the metal ions are absent from the solution. In the presence of the metal ions an equilibrium state is established, characterised by the equality of the rates of two opposed processes. The potential of such an electrode can be calculated from the familiar Nernst formula. The simultaneous occurrence of side reactions brings the electrode to a new state, which can be called the steady state.

The first reliable data on the equilibrium potential of the system $Hg-Hg_2^{2+}$ were obtained by Brodskii[6-8]. From measurements of the e.m.f.'s of the concentration cells $Hg\,|\,Hg_2(NO_3)_2,\ c_n\,|\,KNO_3,$ sat. $|\,Hg_2(NO_3)_2,\ c_1\,|\,Hg$, he determined fairly accurately the activity coefficient of Hg_2^{2+} ions. The normal potential of the system $Hg-Hg_2^{2+}$ was calculated from the formula

$$\varphi^0 = \varphi - \frac{RT}{2F}\ln f c ,$$

where c is the concentration of Hg_2^{2+} ions and f their activity coefficient. According to Brodskii's data, the potential φ^0 of this system at 19.2°C is 0.804 V (relative to the normal hydrogen electrode).

Three potential-determining processes are usually considered for the system mercury–solution:

$$Hg^{2+} + 2e \rightleftarrows Hg^0 ,$$
$$Hg_2^{2+} + 2e \rightleftarrows 2\,Hg^0 ,$$
$$2\,Hg^{2+} + 2e \rightleftarrows Hg_2^{2+} .$$

The potential of the mercury electrode in a solution of a mercurous salt is

$$\varphi_{Hg,\,Hg_2^{2+}} = \varphi^0_{Hg,\,Hg_2^{2+}} + \frac{RT}{2F}\ln a_{Hg_2^{2+}} .$$

Expressing the ionic activity $a_{Hg_2^{2+}}$ in terms of the activity product of, for example, mercurous chloride, and the activity of chloride ions, we obtain the expression

$$\varphi_{Hg,\,Hg_2Cl_2} = \varphi^0_{Hg,\,Hg_2Cl_2} - \frac{RT}{F}\ln a_{Cl^-} ,$$

where φ^0_{Hg,Hg_2Cl_2} is the normal potential of the calomel electrode (corresponding to unit activity of chloride ions).

Thus it has come to be assumed that the system $Hg-Hg_2^{2+}$ is potential-determining for the calomel electrode. However, the equilibrium in solutions of mercurous salts in the presence of certain anions (halide, cyanide, etc. ions) is more complex than is usually assumed[10]. Ogg[11] established that, when a solution of mercuric salt is shaken with metallic mercury, divalent mercury is not quantitatively converted into the monovalent form, but the following equilibrium is set up:

$$Hg_2^{2+} \rightleftarrows Hg^0 + Hg^{2+} .$$

In the presence of a large excess of chloride, the equilibrium is displaced to the right owing to the formation of the weakly dissociated complex $HgCl_4^{2-}$:

$$Hg_2Cl_2 + 2\,Cl^- \rightleftarrows HgCl_4^{2-} .$$

Richard and Archibald[12] showed that the solubility of calomel increases in direct proportion to the square of the concentration of chloride in agreement with the above equation. It follows from this that the potential of the calomel electrode must depend on the activity of mercurous and mercuric ions and is given by the equation[10]:

$$\varphi = \varphi^0_{Hg/Hg_2^{2+},\,Hg^{2+}} + \frac{RT}{2F}\ln\frac{a^2_{Hg^{2+}}}{a_{Hg_2^{2+}}} .$$

In the presence of an excess of chloride ions, the concentrations of mercurous and mercuric ions are low and almost equal to their activities. Then

$$\varphi = \varphi^0_{Hg/Hg_2^{2+},\,Hg^{2+}} + \frac{RT}{2F}\ln\frac{[Hg^{2+}]^2}{[Hg_2^{2+}]}$$

or

$$\varphi = \varphi^{\circ}_{Hg/Hg_2^{2+},\,Hg^{2+}} + \frac{RT}{2F}\ln\frac{[Hg^{2+}]}{[Hg_2^{2+}]} + \frac{RT}{2F}\ln[Hg^{2+}] .$$

The concentration ratio $[Hg^{2+}]/[Hg_2^{2+}]$ is constant[11] and equal to 1/120. Consequently

$$\varphi = \varphi^0 + \frac{RT}{2F}\ln[Hg^{2+}],$$

i.e. the potential of the mercury electrode in a solution of a mercurous or mercuric salt must be determined by the equilibrium concentration of mercuric ions. Accordingly there should exist not three standard potentials but only one, arising in consequence of the following potential-determining process:

$$Hg^{2+} + 2e \rightleftarrows Hg_2^{2+} .$$

This type of equilibrium is also established in the presence of other ligands (Br^-, I^-, CN^-, SCN^-). The potentials of mercury in the presence of a number of complex-forming ions were measured by Tarayan and Ekimyan[13], Burriel-Marti et al.[14], Bagotskaya[15], and others.

In alkali solutions monovalent mercury forms an unstable hydroxide, which decomposes according to the equation

$$Hg_2(OH)_2 \rightleftarrows Hg^0 + HgO + H_2O ,$$
$$HgO + H_2O \rightleftarrows Hg(OH)_2 .$$

Therefore in alkaline solutions in the presence of mercurous ions the mercury electrode behaves as a metal | metal oxide electrode and its potential must be a function of the pH of the solution:

$$\varphi = \varphi^0 + \frac{0.058}{2}\lg K_1[H^+]^2 ,$$

where $K_1 = SP[Hg(OH)_2]/K_w^2$ and SP is the solubility product: $SP[Hg(OH)_2] = 1.4 \times 10^{-26}$ (see Bagotskaya[15]). Therefore

$$\varphi = \varphi_0^1 - 0.058\,pH .$$

Using the above relation, it is possible to calculate φ at different pH. The measurements have been made[10,16] with the aid of a glass electrode. As the pH increases,

the potential is displaced towards more negative values (see Table).

The variation of the potential of the $Hg-Hg^{2+}$ system with the pH is plotted in Fig. 1.[17] In the region of pH 7 in the presence of complex-forming anions (Cl^-, Br^-, I^-, SCN^-), the potential is almost independent of the pH, because these are the anions of strong acids. However, in the presence of the anion of a weak acid (CN^-), the concentration of which decreases as the pH is reduced, the potential of mercury shifts towards more positive values in the acid region, with a corresponding decrease of the reducing activity of mercury.

Variation of the mercury electrode potential* with the pH in 0.01 M mercurous nitrate solution at 20°C.

* Saturated calomel electrode.

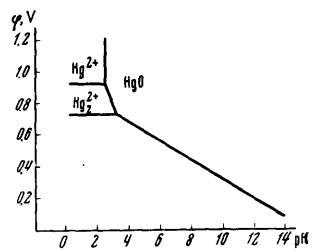

Figure 1. Effect of acidity on the oxidation-reduction potential of mercury.

Thus the equilibrium and steady-state potentials of mercury and hence its reducing properties depend to a high degree on the nature of the anion present in the solution. The effect of the anion is due to its capacity for adsorption, which is closely related to the phenomenon of complex-formation and the formation of sparingly soluble salts. The anion can influence significantly the mechanism of the oxidation of mercury. In particular, when the solution contains readily adsorbable anions (Cl^-, Br^-, I^-, etc.), the process takes place at a higher local concentration of the anions and is described by the equation

$$Hg^0 - 2e \rightleftarrows Hg^{2+}.$$

Data confirming this mechanism were obtained with the aid of non-steady-state techniques (anodic oxidation of mercury in the presence of applied constant and alternating potentials).

It has been noted[18-20] that ions adsorbed directly on the surface of mercury form mercury halides. On the other hand, in the presence of weakly adsorbed anions (NO_3^-, SO_4^{2-}) the process may be different, namely

$$2Hg^0 - 2e \rightleftarrows Hg_2^{2+}.$$

III. KINETICS AND MECHANISM OF THE ELECTROCHEMICAL OXIDATION OF MERCURY

1. Mechanism of the Anodic Oxidation of Mercury

The anodic oxidation of mercury has still been relatively little investigated. Among studies dealing with this problem, those of Ives and coworkers[21-28] and Bewick et al.[29] should first be mentioned.

The anodic oxidation of mercury has been investigated in the following ways[21-23]: (a) by studying the dependence of the potential of the mercury electrode on the amount of electricity passed through the system; (b) by recording $\varphi - t$ curves after switching off the current; (c) by recording micropolarisation curves in the intervals between current pulses in order to establish the degree of reversibility of the process; (d) by recording oscillographic $E-t$ curves with simultaneous application of alternating and constant potentials.

The anodic oxidation of mercury has been carried out[21-23] in acid (hydrochloric acid) and in neutral solutions (potassium chloride, potassium bromide, and potassium iodide) freed from atmospheric oxygen. In the study of acid solutions the polarising current density was 0.25 mA cm^{-2}. The current was interrupted after 5000 μC of electricity had been passed through. After a certain time interval the passage of current was restarted. Following the interruption of current, the variation of the potential with time was observed. Micropolarisation experiments consisted in the measurement of $I-\varphi$ curves at increasing and decreasing current densities.

The degree of reversibility was determined from the hysteresis between the ascending and descending branches of the polarisation curve or from the average slope dI/dt, which should approach infinity for ideally reversible processes.

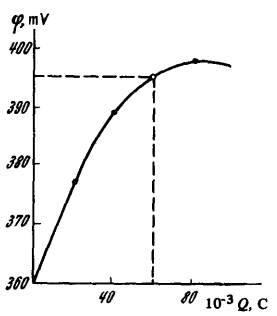

Figure 2. Variation of the mercury potential with the amount of electricity passed through the system.

The study of the dependence of the mercury electrode potential on the total amount of electricity passed through the system is of primary interest. The experimental relation[21-23] (in 0.1 N hydrochloric acid) is represented by the curve shown in Fig. 2. The measurements have shown that 6×10^{-2} C of electricity is required for the attainment of the potential of the calomel electrode (396.8 mV, 0.1 N HCl). However, if calomel were the only anodic reaction, then an incomparably smaller amount of

electricity (about 10^{-12} C) would be sufficient to saturate the entire solution (100 ml) with calomel.

Fig. 2 shows that the variation of the mercury potential with the amount of electricity passed is represented by a curve with a maximum. The potential of the maximum is more positive by 2.2 mV than that of the calomel electrode in 0.1 *N* hydrochloric acid. It has been shown[21-23] that, after the attainment of the maximum, calomel crystals are precipitated. The formation of calomel crystals is accompanied by a decrease of the potential to the value corresponding to the reversible calomel electrode. This led the authors of the above investigations to conclude that the primary product of the anodic reaction is not monovalent but divalent mercury.

The micropolarisation tests and the time variation of the mercury potential after the interruption of current confirm this view[21-23]. The observed hysteresis in the $I-\varphi$ curves disappears after a time, which suggests that the electrode attains a state of equilibrium.

$\varphi-I$ curves have two characteristic features: in the first place the potential falls slowly after the interruption of current, which suggests a slow diffusion of the potential-determining substance from the surface of the electrode; in the second place the potential is displaced towards positive values relative to that of the calomel electrode, passes through a maximum, and then falls to the potential of the calomel electrode. The authors have explained the form of the curve by the occurrence of two consecutive processes: (a) an electrochemical process—anodic generation of Hg^{2+} and (b) a non-electrical (slow but autocatalytic) process—the formation of calomel by the reaction

$$Hg^{2+} + Hg^0 \rightleftarrows Hg_2^{2+}.$$

Thus, according to these data, the product of the anodic reaction at low current densities (0.25 mA cm^{-2}) is divalent mercury; calomel forms as a result of a secondary reaction. After the attainment of equilibrium by the electrode, the reaction takes place according to the equation

$$Hg_2^{2+} + 2e \rightleftarrows 2\,Hg^0.$$

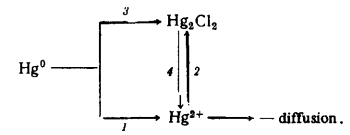
This contradicts the established view[15] concerning the nature of potential-determining processes at the equilibrium potential.

At extremely low current densities the generation of Hg_2^{2+} and Hg^{2+} ions at the equilibrium concentrations is to be expected, since the departure of the electrode from the state of equilibrium is only slight. Hg^{2+} ions arise within the double layer at a high local concentration of chloride ions, with formation of $HgCl_4^{2-}$. As a result of the formation of the complex $HgCl_4^{2-}$, prolonged cathodic polarisation following the anodic polarisation does not restore the electrode to the state of equilibrium.

Oscillographic data for this system confirm the above conclusion[21-23] concerning the mechanism of the anodic oxidation of mercury. $E-t$ curves have two peaks. The first peak is believed to correspond to the formation of Hg^{2+} ions. The rising branch of the peak comes to an end as soon as the calomel film begins to form on the surface of mercury. The horizontal section of the $E-t$ curve corresponds to the gradual coverage of the surface of mercury by the calomel film. When the coverage of the surface by calomel is complete, the discharge of chloride ions begins: the $E-t$ curve shows the corresponding rise. The chlorine liberated oxidises the calomel film, forming $HgCl^+$ ions which diffuse into the bulk of the solution. After a time the film is exhausted and the electrode returns to the non-passive state, this being accompanied by a decrease in the curve.

It has also been stated[24] that an amount of electricity greater by a factor of 10^{10} than the amount required for the saturation of the entire solution (dilute hydrochloric acid) with calomel must be passed through the mercury electrode. Under these conditions (low current density, hydrochloric acid), Hg^{2+} ions are generated. However, at a fairly high current density a small fraction of the above amount of electricity is sufficient for the attainment of equilibrium. Calomel is then generated. Such an electrode is unstable and ceases to be reversible after a short time. This spontaneous decrease of reversibility results from the disproportionation of calomel.

Thus Dibbs et al.[24] conclude that the mercury electrode can attain thermodynamic equilibrium in two different ways according to the scheme



Pathways *1* and *2* operate exclusively at low current densities, becoming superseded by pathways *3* and *4* at high current densities. An increase of the concentration of hydrochloric acid favours reactions *1* and *4*.

The problem of the kinetics and mechanism of the anodic oxidation of mercury was developed further in later investigations[25-28], where solutions containing potassium chloride, potassium bromide, and potassium iodide were studied together with hydrochloric acid. The effect of anions on the kinetics of anodic oxidation of mercury in acid and alkaline solutions has been investigated in detail[15,30,31]. Chloride, bromide, iodide, cyanide, etc. ions displace the steady-state potentials of mercury towards negative values, which must influence the rate of the anodic oxidation of mercury. Bagotskaya[15] notes that the anodic oxidation of mercury is reversible. Accordingly, the polarisation arising under these conditions is of a purely concentration type. Therefore the relation between the anodic mercury dissolution current and the potential must be represented by the equation

$$\varphi = \varphi_0 = \frac{RT}{nF} \ln \frac{I_{Hg}}{(Id)_{Hg}},$$

where φ is the standard potential of the mercury electrode at unit concentration of mercuric ions and Id is the anodic diffusion current of mercury.

Bagotskaya calculated the potential shift in the presence of various anions from the above formula having measured the anodic currents for mercury under these conditions.

The limiting mercury oxidation current depends not only on the nature of the anion but also on its concentration, which serves as a basis for its quantitative determination[32].

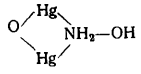
The polarisation phenomena at the dropping mercury electrode have also been investigated by Micka[33].

The kinetics of the anodic oxidation of mercury have been investigated by Elwakkad et al.[34], who demonstrated the validity of the kinetic equation

$$\partial n = AK \times \exp \frac{\alpha \varphi z F}{RT}$$

for low anodic current densities (∂n is the number of mercury atoms dissolving during time t).

The anodic oxidation of mercury in alkaline solutions has also been described[35-38]. The general conclusion that the primary product of the electrode reaction is mercuric oxide was reached. This hypothesis is supported by the finding that the mercury potential found by extrapolating the $E-t$ curves to $t = 0$ is +0.31 V and corresponds to the equilibrium potential of the Hg–HgO system. It is also interesting to note that the potentials of mercury in alkaline solutions containing suspensions of Hg_2O, HgO, and $Hg_2O.NH_2OH$ are similar. This suggests that here the potential-determining system is Hg–HgO. Then mercurous oxide and the amino-compound can be regarded as consisting of mercuric oxide and metallic mercury. Indeed X-ray diffraction analysis of "mercurous oxide" shows that this compound consists of mercuric oxide and finely dispersed metallic mercury. The amino-compounds formed when ammonia reacts with mercuric nitrate and mercurous nitrate do not have the cyclic structure



but are represented by the formula $HgO.Hg.NH_2OH$ and therefore they include mercuric oxide in their composition.

2. Kinetics of Exchange Reactions at the Mercury Electrode at Equilibrium Potentials

Measurements of the rate exchange in the system

$$Hg_2^{2+} + 2e \rightleftarrows 2Hg^0$$

at the equilibrium potential have been made by means of various non-steady-state methods[39-41]. The measurements have shown that the exchange current density for this process is high (0.4 A cm^{-2}). The authors of the investigation disregarded the ψ_1 potential because the measurements were made at a high concentration of an indifferent electrolyte. In the absence of such an electrolyte the ψ_1 potential cannot be neglected. Losev took the ψ_1 potential into account in his investigations[42-44].

According to present views, the electrochemical oxidation of a metal can take place in stages with comparable or different rates in the individual stages. It is believed that the slow stage in the oxidation of metallic mercury is $Hg_2^{2+} - 2e \rightarrow 2Hg^{2+}$, whose rate in fact determines the rate of the entire process.

The exchange currents in the system $Hg–Hg_2^{2+}$ in solutions of mercurous perchlorate, mercurous nitrate, and mercurous fluoride have been measured by the radioactive tracer method[42-44]. The exchange current was found to be 0.1 A cm^{-2}. The linear relation between the exchange current and the concentration of mercury ions in solution is thought to be evidence that the rate of the overall process is limited by diffusion. Therefore the observed exchange currents do not characterise the true rate of the electrochemical stage but the rate of diffusion of mercury ions in solution.

Losev's data are inconsistent with the results of French investigators[45-47]. The latter found that the rate of exchange is almost independent of the concentration of mercurous ions in solution and suggested that the rate of exchange is influenced by the rate of migration of mercury ions through the interface with their subsequent rapid hydration in solution and exchange by the reaction

$$Hg(aq) + Hg^{2+} \rightleftarrows Hg_2^{2+}.$$

It is believed that Hg_2^{2+} ions undergo disproportionation and the exchange takes place between hydrated atoms of metallic mercury and mercuric ions in solution.

IV. REDUCING PROPERTIES OF MERCURY

It has been established in practice that mercury has a reducing effect on a relatively large number of ions. As early as 1842, Schaffhäutel[48] showed that mercury is oxidised in the reaction with iron(III) in hydrochloric acid solution with formation of ferrous chloride and calomel. Later Borar[49] investigated the effect of mercury on certain oxidising agents and observed that their reduction is accelerated with increasing concentration of hydrochloric acid and on heating.

MacCay and Anderson[50] investigated the reduction of iron(II) with mercury and established that the reaction is quantitative. Later they studied the reduction of vanadic acid with mercury. Subsequently MacCay[51,52] discovered the conditions for the quantitative reduction of pentavalent antimony to the trivalent state. Furman and Murray[53] investigated the reduction of oxygen with mercury in hydrochloric acid solution and observed the evolution of hydrogen peroxide in this process. They also studied the reduction of molybdenum(VI) and established that the reaction leads to the formation of tri- or penta-valent molybdenum (depending on the concentration of hydrochloric acid) and calomel. Holtje and Geier[54] confirmed the above data concerning the effect of the concentration of hydrochloric acid on the extent of reduction of molybdenum(VI).

On the basis of these results, Syrokomskii and Klimenko[55] proposed a method for the determination of molybdenum in the presence of vanadium involving the reduction of molybdenum(VI) with metallic mercury.

Burriel-Marti et al.[56] studied the effect of ions forming complexes with mercury on the reducing properties of the latter and established that the presence of such ions leads to an enhancement of the reducing capacity of mercury.

According to Suranova[57], mercury reduces tungsten(VI) quantitatively to the pentavalent state.

Speranskaya and Kozlovskii[58] made a quantitative study of the reduction of a number of ions [copper(II), iron(III), selenium(IV), tellurium(IV), molybdenum(VI) etc.] with metallic mercury in different media. The experiments showed that in non-acidified solutions mercury is capable of reducing persulphate and molybdate. Other ions are reduced only in acid solutions (hydrochloric or sulphuric acid) containing added chloride.

The above data suggest that mercury is reactive with respect to many ions. In this connection, one may expect that ions interact with mercury during their electrochemical reduction at a mercury cathode.

The degree of participation of cathodic mercury in reactions of the above type can be assessed on the basis of kinetic characteristics. However, it should be noted that the kinetics and mechanism of these reactions have not been investigated. Nevertheless, having at their disposal empirical data concerning the possibility of the interaction of metallic mercury with ions undergoing polarography, some investigators have incorrectly interpreted the nature of polarographic waves[59-61]. A correct understanding of these questions requires a detailed study of the kinetics and mechanism of the reactions of metallic mercury with various ions.

The problems of the kinetics of the reactions of mercury with certain ions have been discussed[62-65].

Non-adiabatic Processes of Energy Transfer in Gases

E.E.Nikitin

The present review examines general methods for constructing the adiabatic electronic functions of molecular systems produced by binary collisions of atoms and molecules in gases. Mechanisms of energy transfer accompanying the collision of electronically excited atoms and molecules are discussed on the basis of the selection rules for non-adiabatic interactions and models of non-adiabatic coupling. These mechanisms are classified according to the amounts of electronic energy transferred on collision and according to the distances at which transfer takes place between the electronic states of the colliding species. The quenching of the electronically excited states of the atoms is brought about by close approach of the colliding species, and the probability of transitions and the corresponding cross-section depend in decisive fashion on the characteristics of the electronic functions of the system of two interacting species. Transitions between the components of the fine structure of the atomic terms take place at large distances, and the cross-section can be interpreted in terms of the characteristics of the non-excited functions for the interacting species. Transitions between the vibrational levels of molecules with incomplete electronic sub-levels are determined by vibronic or spin-orbital interaction in a given electronic configuration. The bibliography contains 62 references.

INTRODUCTION

The recent progress in theoretical and experimental studies of elementary processes in the gaseous phase makes possible a detailed interpretation of the mechanisms of molecular collisions leading to energy exchange and to redistribution of the particles. Many processes take place through excited electronic states and their description requires introduction of the theory of non-adiabatic transitions. The present paper examines various processes of energy transfer involving atoms and diatomic molecules under the conditions in which the kinetics of reactions in the gaseous phase are usually studied. These processes are also used to illustrate the achievements of the theory of non-adiabatic processes.

Mention must be made of two characteristic features of molecular collisions under the above conditions. These characteristic features are extremely important, since they make it possible to simplify the overall problem considerably. On the one hand, the energy of the colliding species is so low that in the calculation of the cross-section or rate constant it is possible to consider only a small number of electronic states. On the other hand, the motion of the nuclei can still be treated quasi-classically, and very often an analysis of the classical trajectories is sufficient for the calculation of the redistribution of energy and the probability of transition between closely situated electronic terms.

1. ADIABATIC BASIS

The original approximation in the examination of the process of electronic energy transfer on slow collisions is the adiabatic approximation. There are two ways of constructing the adiabatic electronic basis: one involves the solution of the electronic wave equation for an arbitrary nuclear configuration R, whereas the other involves the solution of the equation for a configuration R_0 fixed in definite fashion[1]. Following Longuet-Higgins[2], we shall call these two possibilities the adiabatic approximation and the simple adiabatic approximation. The construction of the two bases is shown in Table 1. Here $t(r)$ and $T(R)$ denote the electronic and nuclear kinetic energy operators, $V(r, R)$ the electronic–nuclear interaction, H the complete Hamiltonian, and H_{el}, H_{nucl}, H^0_{el}, and H^0_{nucl} the partial Hamiltonians encountered in intermediate stages. Between these two limiting cases there is a whole series of other possibilities corresponding to the partitioning of the potential $V(r, R)$. For example, the usual approximation used in the calculation of the electronic structure of molecules involves making allowance for only the electrostatic contribution $V_{el}(r, R)$ to $V(r, R)$ with complete neglect of the spin-orbital interaction $V_{s.o}$. The corresponding electronic wave functions $\varphi'_n(r, R)$, which can be called the adiabatic functions of the zeroth approximation, depend parametrically on R, but the coupling between them is due not only to the operator $T(R)$ (as in the adiabatic approximation), but also to the interaction $V_{s.o}$ (as in the simple adiabatic approximation).

The exact electronic-nuclear function $\Psi_\epsilon(r, R)$ can be expanded into a series for any set, but the unknown amplitudes $A_{nE}(R)$ and $B_{nE}(R)$ must be found from an infinite system of related equations. Termination of the system, leading to the so called approximation of N-states, will generally speaking give different approximations for the complete function Ψ_ϵ in the adiabatic basis and the simple adiabatic basis. If, however, the main contribution is made only by several electronic states, the partitioning of V into V_0 and δR in appropriate fashion often makes it possible to obtain almost identical results for any basis set. This means that the N functions $\varphi_n(r, R)$ and the N functions $\varphi^0_n(r, R)$ can be regarded to a good approximation as complete sets of functions corresponding to the problem

being considered (the first simplification mentioned in the introduction).

The semi-classical approach to Ψ^a and $\Psi^{0,a}$ is obtained by replacing the nuclear functions by time-dependent exponential terms, where the classical trajectory of the nuclei is introduced $R = R(t)$ (Table 2). The choice of trajectory is a difficult problem, since it should effectively give the motion of the nuclei over several potential surfaces at once (at least in the region of strong coupling). If, however, it is possible to restrict the examination to several closely situated electronic terms, it is possible to formulate a reasonable approximation for $R(t)$ (second simplification mentioned in the introduction).

Table 1. Construction of adiabatic basis.

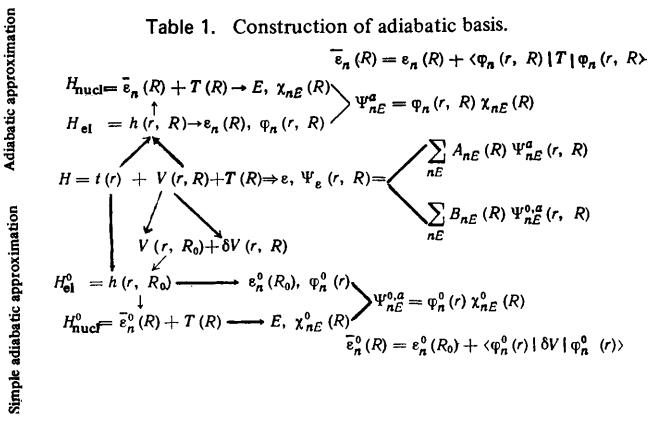

Table 2. Semi-classical approximation and non-adiabatic coupling.

Semi-classical approximation	$\Psi^a_{nE}(r, R) = \varphi_n(r, R)\chi_{nE}(R) \to$ $\to \Psi^a_n(r, R(t)) = \varphi_n(r, R(t)) \times$ $\times \exp\left[-\frac{i}{\hbar}\int^t \bar{\varepsilon}_n(R)\,dt\right]$, $R = R(t)$	$\Psi^{0,a}_{nE}(r, R) = \varphi^0_n(r)\chi^0_{nE}(R) \to$ $\to \Psi^{0,a}_n(r, R(t)) = \varphi^0_n(r) \times$ $\times \exp\left[-\frac{i}{\hbar}\int^t \bar{\varepsilon}^0_n(R)\,dt\right]$ $R = R(t)$
Non-adiabatic coupling	$\hat{C}_a = i\hbar\frac{\partial}{\partial t} = i\hbar v(t)\frac{\partial}{\partial R}$	$\hat{C}^0_a = \delta V[R(t)]$
Non-adiabatic wave function	$\Psi(r, t) = \sum_n A_n(t)\Psi^a_n(r, R(t))$, $i\hbar A_n = \sum\left\langle\varphi_n\left\|i\hbar\frac{\partial}{\partial t}\right\|\varphi_m\right\rangle \times$ $\times \exp\left[-\frac{i}{\hbar}\int[\bar{\varepsilon}_m - \bar{\varepsilon}_n]\,dt\right] A_m$	$\Psi(r, t) = \sum B_n(t)\Psi^{0,a}_n(r, R(t))$, $i\hbar B_n = \sum_n \langle\varphi^0_n|\delta V|\varphi^0_m\rangle \times$ $\times \exp\left[-\frac{i}{\hbar}\int^t[\bar{\varepsilon}^0_m - \bar{\varepsilon}^0_n]\,dt\right] B_m$

We shall not discuss here the problems associated with the calculation of the adiabatic electronic terms, and we shall mention only various useful approximations. If a comparatively large amount of electronic energy is converted into vibrational, rotational, and translational energy, the non-adiabatic coupling is usually localised at small intermolecular distances, and some information from *a priori* calculations of states is necessary. If the energy of the electronic transition is small, the interaction between the electronic terms generally takes place at large distances, and various asymptotic methods for calculating the terms can be used[3-6]. Moreover, a number of semi-empirical methods of estimating potentials, analogous to the methods used in the calculation of the probabilities of vibrational transitions[7], often prove useful.

2. NON-ADIABATIC COUPLING AND THE SELECTION RULES

The semi-classical adiabatic states corresponding to the functions Ψ^a_{nE} and $\Psi^{0,a}_{nE}$ are coupled by an interaction which was omitted in the derivation of H_{nucl} and H^0_{nucl}. The coupling operators and the semi-classical equations for the amplitudes $A_n(t)$ and $B_n(t)$ are given in Table 2. The differential equations should be integrated along the chosen trajectory, so that $\Psi_\varepsilon(r, t)$ gives the time development of the electronic functions along this trajectory. At a distance from the region of non-adiabatic interaction, $A_n(t)$ tend to constant values, and at a distance from the interaction region due to the potential δV the coefficients $B_n(t)$ also tend to constant values. These constant values of the probability amplitudes make it possible to find the system in the electronic states φ_n or φ^0_n.

In the region of non-adiabatic coupling, definite selection rules are obeyed by the electronic quantum numbers n and n'. These can be readily obtained by writing the operator C in terms of the elementary relative displacements and rotations of the axes of the system as a whole. A summary of the selection rules for a system of two colliding atoms is given in Table 3 in terms of the usual symbols[8]. Here Ω is the projection of the total momentum of the electrons on the molecular axis $\Omega = \Lambda + S_z$, and Λ and S_z are the projections of the angular momentum and the spin. The signs + and − for the Σ terms correspond to the sign on reflection of the spatial part of the wave function in a plane containing the molecular axis, and the same signs for the terms of $\Omega = 0$ correspond to the behaviour on reflection of the complete function (spatial and spin parts), whose construction made allowance for spin-orbital interaction. In this classification, for example, the ground state $^3\Sigma^-_g$ of the O_2 molecule can also be written in the form of the doublet $1_g 0^+_g$.

Table 3. Adiabatic quantum numbers and non-adiabatic selection rules for a system of two atoms.

Zeroth adiabatic approximation		Adiabatic approximation	
Perturbation: spin-orbital interaction +		radial and tangential movement of nuclei	
S	$\Delta S = \pm 1$		
S_z	$\Delta S_z = \pm 1$	Ω	$\Delta\Omega = 0\,(z)$
Λ	$\Delta\Lambda = \pm 1$ $\Big\}\ \Delta\Omega = 0$		$\Delta\Omega = \pm 1\ (R_x)$
g, u	conserved	g, u	conserved
Σ^+, Σ^-	$\Sigma^+ \longleftrightarrow \Sigma^-$	$0^+, 0^-$	$0^+ \leftarrow\!\!\!\rightarrow 0^-$

For an arbitrary triatomic system, there is only one obvious adiabatic quantum number—the nature of the reflection of the electronic function in a plane of symmetry. Any motion in the plane leaves it unchanged; this is analogous to the preservation of the sign + or − for the state of a diatomic system, when the fixed plane coincides with a

plane normal to the vector of the relative angular momentum of the nuclei. Rotation of the plane of the triatomic system will induce a change in the sign + or −, leading to mixing of all the states.

For the special case of the collision of an atom with a diatomic molecule with identical nuclear charges, it is possible to introduce a more useful classification of states, if the main contribution to the non-adiabatic coupling is made by the region where the configuration of the nuclei corresponds to C_{2v} symmetry. In this case the symbols of the irreducible representations of this point group serve as adiabatic quantum numbers. The irreducible representations and the corresponding characters are given in Table 4 for the one-dimensional representations (systems with integral spin) and two-dimensional representations (systems with half-integral spin). Here E denotes the identity operator, C_z rotation about the axis of symmetry, σ rotation in the plane of the atoms, and σ' rotation in another plane of symmetry, perpendicular to the first. Q denotes rotation by 2π, which for the two-dimensional representations is regarded as being different from E. The system of coordinates x, y, z is chosen in such a way that the z axis is directed along the axis of symmetry, and the x axis is perpendicular to the plane of the atoms.

Table 4. Adiabatic quantum numbers (irreducible representations and their characters) for a system of three atoms.

Group C_2					Group C_s		
One-dimensional representations	E	C_2	σ_v	σ_v'	One-dimensional representations	E	σ_v
$A_1(z)$	1	1	1	1	$A'(y, z, R_x)$	1	1
$B_2(y, R_x)$	1	−1	1	−1			
$A_2(w = xy, R_z)$	1	1	−1	−1	$A''(x, R_y, R_z)$	1	−1
$B_2(x, R_y)$	1	−1	−1	1			
Two-dimensional representations	E	Q	C_2, C_2Q	σ_v', $\sigma_v'Q$	σ_v', $\sigma_v'Q$	Two-dimensional representations	E	Q	σ_v, σ_v, Q
$E''\begin{pmatrix}\alpha\\ \beta\end{pmatrix}$	2	−2	−0	0	0	$E''\begin{pmatrix}\alpha\\ \beta\end{pmatrix}$	2	−2	0

Table 5. Non-adiabatic selection rules for a system of three atoms.

C_s		A'		A''	
	C_{2v}	A_1	B_1	A_2	B_2
A'	A_1	z	z, y R_x	R_z	R_y
	B_1	z, y R_x	z	R_x	R_z
A''	A_2	R_z	R_x	z	z, y R_x
	B_2	R_y	R_z	z, y R_x	z

It can be seen from Table 4 that there are no special selection rules for systems with half-integral spin. This is related to the fact that, of the two components of the Kramers doublet, one always has the proper symmetry. If the spin-orbital coupling is weak and can be regarded as a perturbation in the adiabatic basis of the zeroth approximation, the classification of states can be carried out in accordance with the one-dimensional representations of the point groups C_{2v} and C_s. The selection rules for the groups C_{2v} and C_s are summarised in Table 5. For C_{2v} symmetry the operation z denotes any movement of the nuclei in the fixed plane, preserving this symmetry, y represents any other movement in the fixed plane, R_z represents rotation about the axis of symmetry, R_x rotation in the fixed plane, and R_y a third rotation, affecting the orientation of the plane of the atoms in space. For C_s symmetry the operations z and y denote any movement in the plane (z and y can be pictured as the radial and tangential relative movement of the interacting species), R_x represents rotation in the fixed plane, and R_z and R_y two rotations of the plane of the atoms. The spin-orbital interaction (if it has not already been taken into account and is regarded as a perturbation) couples all the states.

These selection rules may be used below to discuss the simple elementary processes in which non-adiabatic effects are significant.

3. MODELS OF NON-ADIABATIC COUPLING

After the selection rules have been elucidated and the equations written, the problem reduces to the solution of these equations. The rapid development of electronic computers is simplifying this stage continuously. Simple models which permit an analytical solution are still playing a fundamental part, however, at least in the physical understanding of the non-adiabatic interaction of electrons and nuclei. There are a number of general approaches to the calculation of the probabilities of non-adiabatic transitions. They are all based on the application of perturbation theory either with respect to C or with respect to C^0 (Table 3).[8] If the perturbation is not small, the approximation of strong coupling, that is exact solution of a terminated system of equations, gives best results.

Of the strong coupling approximations, the so called approximation of two states is most widely used. The corresponding models are conveniently classified according to the functional dependence of the expressions adopted for the approximations $\overline{\epsilon}_1^0$ and $\overline{\epsilon}_2^0$, and also of the non-diagonal matrix element δV_{12} in the basis of the two functions φ_1^0 and φ_2^0 of the simple adiabatic approximation.

With this classification we can discuss three main types of model.

a. The linear model, in which the matrix elements in the non-adiabatic region are approximated by linear functions of the nuclear coordinates. This model was first formulated by Landau[9] and Zener[10]. Subsequent studies, published chiefly in the last five years, have extended the range of applicability of this model both for the wave description of the motion of nuclei[11-15] and for the classical description[16-19].

b. The exponential model, in which the matrix elements are approximated by exponential functions of the nuclear coordinates. The most general formulation within the framework of the semi-classical approximation was made in a paper by Nikitin[20], which yielded, in particular, the results obtained by Rosen and Zener[21], who were the first to examine the exponential model. This model was subsequently developed further[22-24].

c. The power model, in which the matrix elements are approximated by power functions of the internuclear distance R^{-n} or R^{n}. This model has been studied comparatively recently[25-27].

Finally, mention must be made of papers[28-34] in which general aspects of the theory of the non-adiabatic coupling of two states are discussed.

All the elementary processes discussed below can be related to the various models, which in turn make it possible to interpret the cross-sections or rate constants of the non-adiabatic characteristics of the interacting species.

4. TRANSFER OF LARGE AMOUNTS OF ELECTRONIC ENERGY

A simple example of the exchange of energy between electronic and translational degrees of freedom is provided by the thermal excitation and deactivation of alkali metal atoms M on collision with atoms of an inert gas X

$$M(^2S) + X(^1S_0) \rightleftarrows M^*(^2P_j) + X(^1S_0) - \Delta\varepsilon \quad . \qquad (1)$$

An early interpretation of the quenching of the fluorescence of sodium by argon[35] was based on a simplified version of the theory and was related to low-temperature experimental data[36]. Recent experiments in shock tubes[37,38] cast doubt on the low-temperature results, although in themselves they are still insufficient for determination of the values of the quenching constant, because of the large experimental errors. Up to the present, only one attempt[39] has been made to calculate the constants k_1 and k_{-1} with allowance for all possible interactions responsible for the change in the electronic state of M.

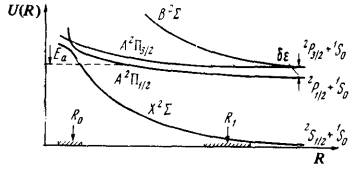

Figure 1. Lower adiabatic terms of the alkali metal atom–inert gas atom system.

As far as the adiabatic terms are concerned, non-empirical calculations have been carried out apparently only for the Li–He system[40,41], which gives the behaviour of the terms for the alkali metal–inert gas general case (Fig. 1). For heavy atoms X, however, the polarisation interaction may be so great that the activation energy E_a of process (1) will be equal to zero. Nevertheless, in order to be specific, we will consider the case for which the qualitative arrangement of the terms corresponds to the picture given in Fig. 1 ($E_a > 0$) and corresponding to a light inert gas.

The change in the electronic state of the colliding pair M and X takes place close to the internuclear distance R_0. In accordance with the usual classification, the ground electronic state of the combined system should be classified as $X^2\Sigma$. At R_0 this term is found to be close to the term of the first excited state $A^2\Pi_\Omega(\Omega = 1/2,\ 3/2)$, which has a fine structure. When $R \to \infty$, this term correlates with the atomic states $^2P_{1/2} + {}^2S$ and $^2P_{3/2} + {}^2S$. Rotation of the colliding pair mixes the states $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$, and this is usually described as a transition from Hund's coupling case a to coupling case b. Each of the two new states in turn is split into two components as a result of non-adiabatic coupling with the close $X^2\Sigma$ state (so called Λ-splitting). Finally, radial movement induces a non-adiabatic transition, since the coupling coefficients are markedly dependent on R. Mathematically, the problem reduces to the solution of three coupled equations for $A_\eta(t)$ within the framework of the linear model first examined by Landau[9] and Zener[10]. A more exact version of the theory[14] takes account of tunneling, which is important for high activation energy or for strong spin-orbital interaction. It has been found that in the semi-classical approximation the probability of a transition can be obtained by simple summation of the fluxes for each electronic term, calculated as if there were independent coupling between each pair of terms at their point of intersection[15]. This denotes the absence of interference between the probability amplitudes for the terms $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$, although the phase difference between the two points of intersection is generally small.

Thus the theory gives extremely general expressions for k_1 and k_{-1}, leaving the theoretical parameters indeterminate. The rate constants can be estimated from familiar expressions[42] with the condition that there are some indications of the magnitude of the activation energy. On the other hand, if the temperature dependence of k_{-1} were measured sufficiently accurately, the theory would make it possible to interpret reaction (1) in terms of the adiabatic characteristics of the pair M and X. This has not yet been done. The only reliable conclusion is that the exchange of electronic and translational energy on atomic collisions has a low probability[43].

Let us now consider the deactivation of excited atoms by diatomic molecules. A number of experiments show that this deactivation takes place extremely effectively[44-48]. This suggests that in these processes there is resonance between an electronic level of the excited atom and the vibrational levels of the molecule. This problem has not been examined theoretically. Apart from the very difficult problem of solving the coupled wave equations (or the corresponding time-dependent equations of the semi-classical approximation), there arises another problem, associated with the possibility that the representative point passes repeatedly through the region where the adiabatic potential surfaces intersect or approach close to one another. Even if all the quantum-mechanical interference effects are neglected, it is very difficult to take account of all the contributions to the probability of a non-adiabatic transition from different points on the two-dimensional or multi-dimensional trajectory.

One of the simplest processes of this kind

$$Na^*(^2P) + N_2(^1\Sigma_g^+,\ v=0) \rightarrow Na(^2S) + N_2(^1\Sigma_g^+,\ v \geqslant 0) \qquad (2)$$

was examined by Bjerre and Nikitin[49], and also by Bauer[50]. These workers first tried to interpret it as a non-adiabatic transition between covalent adiabatic surfaces, produced from the energy states $^2P + {}^1\Sigma_g^+$ and $^2S + {}^1\Sigma_g^+$ of the separated interacting species. These surfaces for a fixed (N–N) distance are represented qualitatively in Fig. 2 in terms of relative coordinates R and Θ (the intermolecular distance and the angle of orientation). The Figure also shows the quantum numbers of the adiabatic states in the zeroth approximation for the symmetries $C_{\infty v}$, C_{2v}, and

C_s. With reasonable assumptions regarding the interactions, however, this attempt proved unsuccessful. Following Laidler[51,52] and Mori[53], the authors supplemented the system of covalent terms with an ionic term. In the zeroth approximation there then arise three potential surfaces: the purely covalent I $[Na(^2P) + N_2(^1\Sigma_g^+)]$, the purely ionic II $\{Na^+ + [N_2(^3\Sigma_u^+)]^-\}$, and the purely covalent III

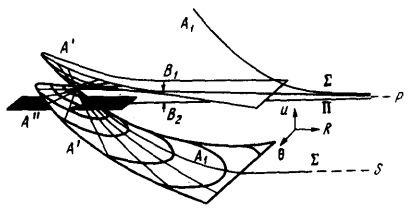

Figure 2. Lower adiabatic terms of the zeroth approximation (the spin-orbital coupling is not taken into account) for the alkali metal atom-nitrogen molecule system. The N–N distance is fixed, and the interaction with the ionic term is not taken into account.

$[Na^g(^2S) + N_2(^1\Sigma_g^+)]$. The ionic surface and the interaction matrix element $\delta V_{nn'}$, corresponding to non-adiabatic coupling between the adiabatic functions of the zeroth approximation, were calculated approximately[49] from experimental data[54] on the resonance scattering of slow electrons by N_2. The general arrangement of the surfaces for linear collision is shown in Fig. 3. Here R denotes the distance between the Na atom and the centre of the N_2 molecule, and r the interatomic distance in the N_2 molecule. The coordinates r_I, r_{II}, and r_{III} correspond to the equilibrium interatomic distances in the N_2 molecule in the corresponding

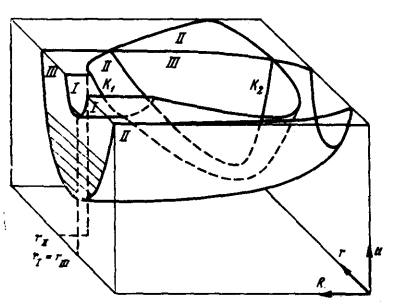

Figure 3. Lower adiabatic terms of the zeroth approximation (the interaction between the ionic term and the covalent terms is not taken into account) for the alkali metal atom-nitrogen molecule system. Linear arrangement of the atoms. Term I—excited covalent state; term II—ionic intermediate state; term III—covalent ground state.

electronic states for an infinitely large distance between the interacting pair ($R \to \infty$). The surfaces I–II and II–III intersect along the lines K_1 and K_2. If the non-diagonal elements of the interaction are taken into account, the intersections are converted into pseudo-intersections. When a certain trajectory L of the representative point reaches the lines K_1 or K_2, there is a certain probability of branching, leading to the appearance of two trajectories. The Landau–Zener formula was used to calculate the probability of the trajectory, and the trajectories were found by computer solution of the classical problem. Analysis of the trajectories made it possible to calculate the partial cross-sections and rate constants for reactions leading to a definite vibrational state v, and also led to the following general conclusions: (1) there is no indication that vibronic resonance is significant in process (2); (2) although the ionic surface shows a fairly deep minimum, the breakdown of $Na^+–N_2^-$ into $Na(^2S) + Na_2(^1\Sigma_g^+, v)$ takes place approximately in the time of one collision. This means that, for effective energy transfer, the formation of a long-lived intermediate complex is not essential, although it is possible that in other instances the formation of a complex facilitates the energy redistribution[55]; (3) the distribution with respect to vibrational levels is very sensitive to the magnitude of the splitting of the electronic terms of the zeroth approximation. Nevertheless, for process (2) a "reasonable" distribution function corresponding to the maximum at $v = 2$ and 3 was found. This conclusion shows qualitative agreement with experiment. An example of the calculated distribution function for the N_2 molecule with respect to the vibrational states is given in Fig. 4.

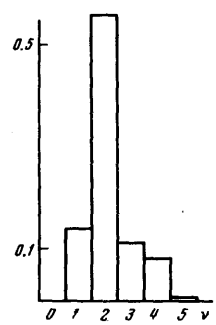

Figure 4. Example of the distribution function with respect to vibrational states for an N_2 molecule excited in the non-adiabatic process (2).

These non-adiabatic transitions take place between electronic terms with the same symmetry. The electronic transition is induced by the movement of the atoms in the plane (coordinates z and y from Table 4) and, to a much smaller extent, by rotation in the plane (R_x) and by spin-orbital interaction.

Another interesting example is provided by the reactions

$$Hg^*(^3P_0) + CO(^1\Sigma^+,\ v=0) \rightarrow Hg(^1S_0) + CO(^1\Sigma^+, v>0), \quad (3a)$$

$$Hg^*(^3P_0) + NO(^2\Pi,\ v=0) \rightarrow Hg(^1S_0) + NO(^2\Pi,\ v>0) \quad (3b)$$

of which the first is less effective than the second[46,47]. In the case of mercury the spin-orbital interaction is so great that it must be included in the electronic Hamiltonian. The initial state in process (3a), produced from $^3P_0 + {}^1\Sigma^+$, should then be classified as the one-dimensional representation A'' of the point group C_s of a system of three atoms. The final state $(^1S_0 + {}^1\Sigma^+)$ corresponds to the symmetry A',

since the transition (3a) is induced by rotation of the complete system by R_z or R_y. For process (3b) the initial and final states correspond to the same symmetry—both belong to the two-dimensional representation E''. This allows the movements in the plane (z and y) to be active in inducing transitions. These two mechanisms provide a qualitative explanation of the difference in the efficiencies of electronic deactivation on collisions with molecules having complete or incomplete electronic sublevels. We shall return to this problem below in connection with the transfer of vibrational energy.

5. TRANSFER OF SMALL AMOUNTS OF ELECTRONIC ENERGY

If an electronic transition takes place between two close energy states as a result of a collision, the cross-section for this process will be large. The probability of a transition depends on the magnitude of the minimal splitting between the adiabatic terms $\Delta\epsilon^{min}$, on the effective dimensions a of the region of the transition, and on the velocity of the nuclei in this range v. The parameter determining chiefly the magnitude of the probability of a transition is the ratio $\xi^{min} = \Delta\epsilon^{min}a/\hbar v$ (the so called Massey parameter), the probability of the transition being exponentially small for $\xi^{min} \gg 1$. Within the framework of the Landau-Zener model, applicable for electronic deactivation, $a \simeq \Delta\epsilon^{min}/\Delta\epsilon\alpha$, where $\Delta\epsilon$ is the energy of the reaction and α the orbital exponent of the outer electron. We thus obtain:

$$\xi^{min} \simeq \frac{(\Delta\varepsilon^{min})^2}{\hbar\alpha v\Delta\varepsilon} = \left(\frac{\Delta\varepsilon^{min}}{\Delta\varepsilon}\right)^2 \xi^{\infty},\ \xi^{\infty} = \frac{\Delta\varepsilon}{\hbar\alpha v}\ , \qquad (4)$$

the linear model being applicable only for the following conditions [35]

$$\xi^{\infty} \simeq \frac{\Delta\varepsilon}{\hbar\alpha v} \gg 1,\ \frac{\xi^{min}}{\xi^{\infty}} \simeq \frac{(\Delta\varepsilon^{min})^2}{\Delta\varepsilon^2} \ll 1\ . \qquad (5)$$

If in a non-adiabatic process one of the inequalities (5) is not fulfilled, the linear model should be replaced by a more general model.

An illustrative example is provided by the reactions

$$M^*(^2P_{1/2}) + X(^1S_0) \rightarrow M^*(^2P_{1/2}) + X(^1S_0) + \delta\varepsilon \qquad (6)$$

in which the collisions induce mixing of the components of the multiplet of the fine structure in the excited atoms of the alkali metal. These processes have been studied experimentally in fairly complete detail, and an extremely marked change in cross-sections was observed in the order M = Na, K, Rb, and Cs.[56] For all processes of this kind, we have $\xi^{\infty} \simeq \xi^{min}$ and under the conditions of the experiment the relationship $\xi^{min} \geq 1$ is satisfied. The mechanism of the change in quantum number is clear from Fig. 1. Mixing takes place at fairly large distances R_1 and, in accordance with Table 3, is brought about by radial movement and rotation, the former making the chief contribution. The theory based on non-linear models[57,58] predicts, in agreement with experiment, a variation in cross-section from the large value of 10^{-14} cm^2 for the Na*–He pair to the extremely small value 10^{-21} cm^2 for the Cs*–He pair. If we make the reasonable estimate $\Delta\epsilon^{min} \simeq \delta\epsilon$, it can be seen that

$$\xi^{min}_{quench} \simeq \left(\frac{\delta\varepsilon}{\Delta\varepsilon}\right)^2 \xi^{min}_{mix}\ . \qquad (7)$$

Thus even if intramultiplet transitions have a low probability ($\xi^{min}_{mixing} \gg 1$), electronic deactivation may be effective, since $\delta\epsilon/\Delta\epsilon \ll 1$. The true efficiency of deactivation of the excited state of course depends on the magnitude of the activation energy (see previous section).

If the inert gas atom is replaced by an inert diatomic molecule $X_2(^1\Sigma_g^+)$, we can expect an increase in the cross-section for the mixing of the components of the multiplet as a result of the contribution of the rotational and vibrational degrees of freedom to the overall process. Under these conditions, an increase in cross-section as a result of vibronic resonance is extremely probable, since resonance leads to a significant change in the selection rules for the vibronic spectrum relative to the selection rules in the independent electronic and vibrational spectra. A reaction of type (6) with replacement of X by X_2 is not very illustrative in this connection, since all the vibronic terms belong to the same two-dimensional representation E'', so that there are no special selection rules.

The following reactions provide a clearer example:

$$Hg^*(^3P_1) + Ar(^1S_0) \rightarrow Hg^*(^3P_0) + Ar(^1S_0) + \delta\varepsilon \qquad (8a)$$

$$Hg^*(^3P_1) + N_2(^1S_0) \rightarrow Hg^*(^3P_0) + N_2(^1\Sigma_g^+,\ v=1) + \delta\varepsilon - \hbar\omega\ . \qquad (8b)$$

The correlation diagrams for the adiabatic terms of the Hg*–Ar pair are given in the right-hand side of Fig. 5. It can be seen from Table 3 that process (8a) is due to rotational (R_x) mixing of the molecular states $\Omega = 0^-(^3P_0)$ and $\Omega = 1(^3P_1)$. The probability of the process is extremely small, since the Massey parameter is large (small exponential factor), and the terms have different symmetries (additional small pre-exponential factor). It is known from experiment that reaction (8a) proceeds very slowly[43]. On the other hand, reaction (8b) proceeds very rapidly, almost in every collision. This fact cannot be attributed simply to a decrease in the Massey parameter, in replacing $\delta\epsilon$ by $\delta\epsilon - \hbar\omega$. The true reason for the increase in efficiency can be seen from the correlation diagram.

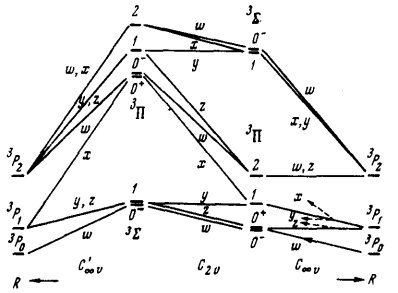

Figure 5. Correlation diagram of adiabatic terms of the system $^2P_j + {}^1S_0$ ($C_{\infty v}$ symmetry) and the system $^3P_j + {}^1\Sigma_g^+$ (C_{2v} and C_s symmetry). The symbols x, y, z, and w correspond to those of Table 4.

For system (8b) with a fixed vibrational quantum number, there are two relative displacements in the plane (z and y). We shall restrict ourselves to a discussion of a specially selected section of the system of two-dimensional adiabatic potentials, by following throughout a path in which the system retains the formal symmetry $C_{\infty v}$ and C_{2v}. Along this path we shall vary the three interaction parameters V_x, V_y, and V_z, which correspond to the three electronic states A_1, B_1, and B_2, produced from the spin-free P state. This section is determined as follows (from right to left in Fig. 5).

1. Free species:

$$V_x = 0,\ V_y = 0,\ V_z = 0.$$

2. $C_{\infty v}$ symmetry:

$$V_x = 0,\ V_y = 0,\ 0 < V_z < V_0.$$

3. C_{2v} symmetry:

$$V_x = 0,\ 0 < V_y < V_0,\ V_z = V_0\ .$$

4. $C_{\infty v}$ symmetry:

$$0 < V_x < V_0,\ V_y = V_0,\ V_z = V_0\ .$$

5. Free species displaced along the energy scale:

$$V_x = V_0,\ V_y = V_0,\ V_z = V_0\ .$$

The broken line shows the splitting of the levels, degenerate for $C_{\infty v}$ symmetry, if the section is defined in a slightly different way (stage 3 replaced by 3a). In this case we have the following situation.

3a. C_{2v} symmetry:

$$V_x = 0,\ 0 < V_y < V_0,\ 0 < V_z < V_0.$$

Decrease in symmetry from C_{2v} to C_S does not lead to further splitting—the only change is in the adiabatic mixing of the states of the same symmetry.

The arrangement of the vibronic terms for states with different quantum numbers v is obtained by superposition of diagrams of this kind with a displacement by $\hbar\omega$. This leads to intersection of the terms. Some of them are converted into pseudo-intersections, after the interaction δV is taken into account. Detailed study[59] shows that reaction (8b) induces combined movement along the coordinates z and y (radial and tangential relative movement of the interacting species), which mixes two states of symmetry A'', correlating with the states $^3P_1 + {}^1\Sigma_g^+$, $v = 0$, and $^3P_0 + {}^1\Sigma_g^+$, $v = 1$ of the interacting pair. The main contribution is made by the configuration close to the configuration of an isosceles triangle. For C_{2v} symmetry, these two states are classified as w (or A_2) and x (or B_2). These two terms have different symmetry and intersect the symmetric configuration; the two vibronic A'' states mentioned above refer to an adiabatic surface in the form of a double cone. It is this feature—the intersection of two terms with the same symmetry in a single point—which provides the fundamental difference between the atom–molecule process (8b) and the atom–atom process (8a). The rotation R_x also makes a contribution to the transition (8b), but its effect is relatively small, whereas for (8a) the rotation R_x is the only perturbation.

6. TRANSFER OF VIBRATIONAL ENERGY

In the previous sections it was shown that the removal of the degeneracy of the electronic state of one of the interacting species plays a large part in the mechanism of the exchange of electronic energy. By analogy, it may be expected that the transfer and exchange of vibrational energy will be different for interacting species with complete or incomplete electronic sublevels. This is in fact the case[60,61]. The physical picture is as follows. The intermolecular interaction leads to splitting (other than the Kramers doublet) of the degenerate electronic term of one of the interacting species, and at a certain distance this splitting becomes equal to the vibrational quantum. As a result of vibronic resonance, there is a high probability of energy exchange between the vibrational and translational movement.

Let us consider first the collision of a diatomic molecule with an inert gas atom, leading to the vibrational transition $v = 1 \rightarrow v = 0$. If the molecule is in a non-degenerate electronic state, both vibronic states correspond to symmetry A' (or A''). In accordance with Table 5, the transitions are then brought about by the perturbations z, y, and R_x. The first two represent relative movement and rotation, and their contribution depends on the corresponding reduced masses. Overall rotation in the plane does not make a significant contribution to the probability of the transition. If, however, the molecule is in, for example, a Π state, states of both types of symmetry A' and A'' are produced on interaction. With allowance for the spin-orbital interaction, the term $^2\Pi$ is split into components $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$, and the possible intersections of the terms $^2A'$ and $^2A''$ are converted into pseudo-intersections. The system of vibronic terms produced in this way is shown in Fig. 6. If the spin-orbital interaction between the vibronic states is small, it can be regarded[59] as the reason for the transition, together with the rotations R_y and R_z.

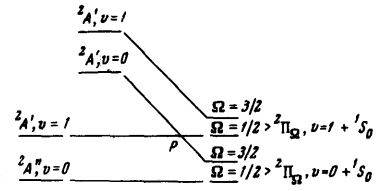

Figure 6. Correlation diagram of vibronic adiabatic terms of the system $^2\Pi_\Omega$; $v + {}^1S_0$ (or $^1\Sigma_g^+$).

Two possible paths of the vibrational transition in the above system are:

the adiabatic path

$$^2\Pi_{1/2}, v = 1 \rightarrow P \rightarrow {}^2A'', v = 1 \rightarrow {}^2A', v = 0 \rightarrow {}^2\Pi_{1/2}, v = 0, \quad (9)$$

the non-adiabatic path

$$^2\Pi_{1/2}, v = 1 \rightarrow P \rightarrow {}^2A'', v = 1 \rightarrow P \rightarrow {}^2\Pi_{1/2}, v = 0 \rightarrow {}^2\Pi_{1/2}, v = 0.$$

For two diatomic molecules, the arrangement of the vibronic states will be more complicated, but the general features are retained. As an illustration, we give here three reactions which have now been fairly well studied:

$$O_2(v = 1) + O_2(v = 0) \rightarrow O_2(v = 0) + O_2(v = 0) + \hbar\omega, O_2(^3\Sigma_g^-), \quad (10a)$$

$$NO(v = 1) + NO(v = 0) \rightarrow NO(v = 0) + NO(v = 0) + \hbar\omega, NO(^2\Pi_\Omega), \quad (10b)$$

$$N_2(v = 1) + N_2(v = 0) \rightarrow N_2(v = 0) + N_2(v = 0) + \hbar\omega, N_2(^1\Sigma_g^+), \quad (10c)$$

Of these processes, only reaction (10b) relates to interacting species with electronic terms quasi-degenerate in space. As a result of the interaction, the states of the system $NO(^2\Pi) + NO(^2\Pi)$ move apart as the interacting species approach. In the system $N_2(^1\Sigma_g^+) + N_2(^1\Sigma_g^+)$ splitting does not take place at all, and in the system $O_2(^3\Sigma_g^-) + O_2(^3\Sigma_g^-)$ electrostatic interaction cannot alter the fine structure of the spatially non-degenerate terms. Detailed examination shows that the main contribution to process (10b) is made as a result of spin-orbital interaction between the lower states $^1A'$ and $^3A''$, correlating with the states $^2\Pi + {}^2\Pi$ of the free species[60]. The Massey parameter for the adiabatic path, as for process (9), is greater than that for the non-adiabatic path, but the interaction is stronger for the adiabatic path (since states with the same symmetry

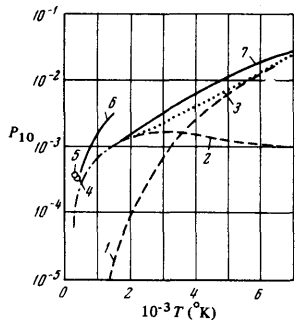

Figure 7. Adiabatic (*1*) and non-adiabatic (*2*) contributions to the total (*3*) probability P_{10} of the vibrational transition $v = 1 \rightarrow v = 0$ for the NO molecule. The points and curves *4–7* correspond to different experimental data[62].

are taking part). Thus these two paths compete, and at low temperature the non-adiabatic process predominates. Thus at room temperature the rates of processes (10a) and (10c) are smaller by three or four orders of magnitude than the rate of process (10b). This competition of the two mechanisms is shown in Fig. 7, taken from Wray's paper[62].

III. "Memory" associated with a disturbance of the electronic equilibrium 726

I. THE "MEMORY" EFFECT UNDER VARIOUS FORMS OF IRRADIATION

This review is concerned exclusively with semiconductors, but all the statements to be made can be generalised to include dielectrics. There is no difference in principle between semiconductors and dielectrics other than the scale used to represent the energy spectrum. By expanding the spectrum we progress from semiconductors to dielectrics, whereas by compressing it we convert dielectrics into semiconductors.

The term irradiation will be used in the widest possible sense. It will refer to electromagnetic radiation, including visible and ultraviolet light, X-rays, and gamma rays. It will refer also to corpuscular radiation, including bombardment with neutrons, electrons, protons, and alpha particles. In every case, the material experiences a flux of energy from outside. Changes induced in solids by these various types of radiation often have a great deal in common.

Radiation is known to affect several of the properties of a semiconductor. First and foremost, it affects the electrical and optical properties of the material: the magnitude, temperature dependence, and sometimes even the type of the conductivity are affected; absorption bands are shifted; the spectrum, the intensity, and the decay rate of the luminescence are altered. The mechanisms underlying changes in all these properties, and involving the formation of radiation defects in the semiconductor, are fairly well understood (at least, qualitatively).

The mechanism of the influence of irradiation on the adsorption and catalytic properties of semiconductors, with which the present article is concerned, is very much less well understood. Irradiation often causes profound changes in the properties of a semiconductor. A semiconductor having little or no catalytic activity often emerges from this operation as an active catalyst. A semiconductor showing negligible adsorption is often converted into a good adsorbent by irradiation. In spite of numerous experimental investigations, the mechanism of these changes remains obscure. Some of the relevant problems will be discussed in this article.

Workers investigating the effect of irradiation on the adsorption and catalytic properties of semiconductors are faced with a two-fold problem. On the one hand, an understanding of the mechanism of the phenomenon is required, and on the other hand we must learn to control the properties of a semiconductor by modifying them to the required extent and in the appropriate direction by means of irradiation.

† Paper presented to the Miller conference on radiation chemistry (Warsaw, September, 1967).

As soon as the problem is formulated in terms of the use of irradiation as a tool for controlling the properties of a semiconductor, one is faced with the problem of the "memory" of the semiconductor: how long will the changes produced by irradiation persist in the semiconductor, or in other words, how long will the semiconductor "remember" the irradiation? The answer to this question varies from case to case. The problem of the memory of a semiconductor is the focal point of the present article.

A semiconductor sometimes forgets the irradiation instantaneously, immediately after the irradiation is removed. This is one extreme case. The opposite extreme is also possible, the "memory" of the irradiation remaining indefinitely in the semiconductor. But we are often faced with the intermediate, and more general, case of a semiconductor which remembers the irradiation for a finite time and gradually forgets it. We shall discuss all three cases.

The first case is encountered when the effect of irradiation is to produce ionisation directly, i.e. to generate non-equilibrium current carriers in the semiconductor. In this case the semiconductor remembers the irradiation only as long as it is exposed to it. The inner photoelectric effect produced by visible or u.v. light, by X-rays, or by gamma rays is a case in point. The irradiation gives rise to a disturbance of the electronic equilibrium in the semiconductor, and when the irradiation is interrupted the semiconductor usually reverts to its original equilibrium state very rapidly and almost instantaneously. Some exceptions to this rule will be discussed below.

The other limiting case (of a semiconductor which, once exposed to irradiation, remembers the event forever) is observed when the irradiation induces a nuclear reaction in the semiconductor. In this case the irradiation has the effect of increasing the impurity content of the semiconductor by converting normal lattice atoms into foreign atoms. This process is irreversible, and is accompanied by a shift in the electronic equilibrium. We note that both limiting cases can occur together when the products of the nuclear reaction are radioactive, and the semiconductor remains exposed to its own radiation.

Lastly, in the more general case, the memory of the irradiation remains in the semiconductor for a certain time and then gradually disappears. This case arises when the radiation, without actually changing the chemical composition of the semiconductor, leads to the appearance of structural defects, i.e. produces additional (radiation-induced) "disorder" in the lattice. This effect results in a shift of the Fermi level, i.e. in a displacement of the electronic equilibrium, which persists under these conditions. This effect is wholly equivalent to the introduction of impurities into the semiconductor, since the terms

"defect" and "impurity" are synonymous in the language of semiconductor physics. All structure-sensitive properties of the semiconductor must immediately find a new level as a result of the effect.

However, the radiation-induced disorder resulting from illumination is gradually re-absorbed when illumination is discontinued. The process can be accelerated by heating. In other words, by heating the semiconductor we compel it to forget the irradiation more quickly. The "impurities" created in the semiconductor by this process eventually disappear: this property distinguishes them from the impurities formed as products of a nuclear reaction.

Thus, by observing the "memory" of a semiconductor, i.e. by noting how quickly the semiconductor forgets its irradiation, we can identify to some extent the events taking place in the semiconductor during irradiation. In general, irradiation produces more or less reversible changes in the semiconductor. Sometimes, when the irradiation produces unfavourable changes in the semiconductor, we shall endeavour to make these changes easily reversible; conversely, when irradiation is applied in order to control the properties of the semiconductor, we shall be concerned with the stability of the changes.

Thus, irradiation affects the semiconductor in two ways. Firstly, it gives rise to structural defects and to chemically foreign impurities in the semiconductor. Secondly, it induces direct ionisation. In the first case we are dealing with a shift in the electronic equilibrium to what can be treated as a new equilibrium situation. In the second case we are dealing with a disturbance of the electronic equilibrium with generation of non-equilibrium carriers. In the first case the semiconductor remembers the irradiation forever, or for more or less extended periods. In the second case it forgets the irradiation almost immediately.

II. "MEMORY" ASSOCIATED WITH A SHIFT IN THE ELECTRONIC EQUILIBRIUM

We shall consider here the case of a shift in the electronic equilibrium as a result of irradiation.

We must stress, first of all, that the adsorption and catalytic properties of a semiconductor, which are our main concern, are usually related to properties of an entirely different kind: to the work function and electrical conductivity of the semiconductor. This statement is based on a large fund of experimental evidence. The adsorption capacity and catalytic activity of a semiconductor (on the one hand), and its work function and electrical conductivity (on the other hand), are linked by well defined correlations in most cases. The origin of this correlation is made clear by the electronic theory of chemisorption and catalysis [1].

A displacement of the electronic equilibrium (or in other words a shift of the Fermi level) results first of all in a change of the work function and carrier concentration of the semiconductor.

According to the electronic theory, an increase in work function (i.e. an increase in the concentration of free holes and a decrease in the concentration of free electrons, or in other words an increase in the contribution of holes and a decrease in the contribution of electrons to electrical conduction) is accompanied by an increase in the adsorption capacity of the surface towards donor molecules and, conversely, by a decrease in the adsorption capacity of the surface towards acceptor molecules.

As regards the catalytic activity, i.e. the rate of catalytic reactions taking place at the surface, all reactions can be divided into two classes from the standpoint of the electronic theory. One class includes the reactions which are accelerated by an increase in the work function. These reactions, called donor reactions, are accelerated by holes and retarded by electrons. Their rate varies in the same sense as the hole conduction, and in the opposite sense to the electronic conduction. The other class (acceptor reactions) includes those reactions whose rate is increased by lowering the work function. These reactions are accelerated by electrons and retarded by holes. In this case the catalytic activity varies in the same sense as the electronic conduction and in the opposite sense to the hole conduction.

Thus, changes in the electrical conductivity of a semiconductor give rise to changes in the adsorption capacity and in the catalytic activity, the changes being in the same sense or in the opposite sense depending on the nature of the semiconductor (p-type or n-type), on the nature of the adsorbed gas (donor or acceptor gas), and on the nature of the reaction (donor or acceptor reaction). The electronic theory is in no way concerned — and this must be stressed — with the cause of the conductivity changes. The correlation applies irrespective of the agency responsible for the shift of the electronic equilibrium. It could be an impurity added to the semiconductor: indeed, we know that changes in conductivity, accompanied by changes in adsorption capacity and in catalytic properties, can be brought about by doping the semiconductor. Alternatively, the agency could be irradiation. Hence, we are able to predict the effect of irradiation on the adsorption capacity and on the catalytic activity from the changes in electrical conductivity caused by the irradiation.

This general conclusion of the electronic theory can be illustrated by considering the decomposition of alcohols, for which two alternative mechanisms are known: dehydrogenation and dehydration. Let us consider first the dehydrogenation reaction. This, in the terminology of the electronic theory (see Section 6b in Ref. 1), is a typical acceptor reaction, accelerated by high concentrations of electrons and by low concentrations of holes in the semiconductor.

Evidence for the acceptor nature of this reaction comes from various sources. Thus, Zhabrova and coworkers [2], in their study of the dehydrogenation of isopropanol on zinc oxide, studied the changes in catalytic activity and in work function resulting from the addition of various impurities (both donors and acceptors) to the catalyst. A distinct correlation was observed: the lower work function, the greater was the activity. In an earlier investigation, Myasnikov and Pshezhetskii [3] examined the same reaction on a zinc oxide surface covered with chemisorbed oxygen, which behaved as a surface impurity in these experiments. Under the influence of oxygen, the electrical conductivity and the catalytic activity were found to decrease together. Since zinc oxide is an n-type semiconductor, conductivity and activity changes occurring in the same sense indicate that the dehydrogenation of an alcohol is an acceptor reaction.

Tsetskhladze and Kalandadze [4] made simultaneous observations of the effect of irradiation on the electrical conductivity and on the catalytic activity. The electrical conductivity of their specimens of cuprous oxide was increased by several orders of magnitude by gamma irradiation. The changes were relatively long-lived, and were probably caused by atomic displacements induced by the irradiation. The same samples were used as catalysts for the dehydrogenation of ethanol. Since cuprous oxide is a typical p-type semiconductor, and the dehydrogenation reaction (as indicated above) is a typical acceptor reaction, the activity could be expected to vary in a sense opposite to

that of the conductivity. This expectation was confirmed: according to the measurements of Tsetskhladze and Kalandadze, the reaction was strongly inhibited by previous irradiation.

Let us now turn to the dehydration reaction. It is usually assumed that this reaction takes place by an acid–base mechanism, which presupposes the presence of mobile hydrogen (Brønsted acid) on the surface. With oxide and hydroxide catalysts the mobile hydrogen is provided by OH groups, and the reaction ceases when these groups are removed from the surface. This mechanism, in every way analogous to the mechanism of homogeneous acid–base catalysis, is believed to exclude any correlation between the catalytic and the electronic properties of the catalyst. Yet, correlations have been observed by many workers and can hardly be dismissed as fortuitous.

Thus, Zhabrova and coworkers (see above[2]) doped their zinc oxide with sodium (donor) and sulphur (acceptor) impurities, and found that the work function was decreased by the former and increased by the latter. At the same time, they measured the catalytic activity towards the dehydration of isopropanol, and found that addition of sodium inhibited the reaction whereas addition of sulphur increased the reaction rate. Since the work function and the catalytic activity vary in the same sense, this reaction is of the donor type from the standpoint of the electronic theory.

Indeed, the dehydration of alcohols can be classified as a donor reaction in the terminology of the electronic theory both in the case of a purely electronic and in the case of an acid–base mechanism (as can be demonstrated). This is because the participation of positive holes is essentially implied in both the purely electronic mechanism (see Section 6b of Ref. 1) and in the acid–base mechanism, in which the catalyst and the reacting molecule exchange a proton with formation of an oxonium ion and subsequently of a carbonium ion as intermediates[5].

Spitsyn and coworkers[6] studied the dehydration of decanol $C_{10}H_{21}OH$ on tungsten disulphide WS_2. The samples had a stoichiometric defect of sulphur; as expected, they were found to be n-type by measurements of thermo-e.m.f. Special preliminary experiments confirmed the absence of hydrogen or hydroxyl groups on the surface. Thus, the acid–base mechanism (in the Brønsted sense) was excluded, and yet dehydration took place at appreciable rates.

The specimen was then placed in a nuclear reactor, where it was irradiated with slow neutrons. Radioactive isotopes of tungsten and sulphur were formed, so that the material remained exposed to internally generated and slowly decaying beta and gamma radiation after the neutron bombardment was stopped. The electrical conductivity of the sample was appreciably lowered by this treatment, and remained lower than the conductivity of the non-irradiated material over the whole of the experimental temperature range (from 20 to 350°). This fact alone is proof that the effect of the radiation in this case cannot be simple ionisation: were it not so, the radiation could only lead to an increase in conductivity.

The catalytic activity was measured at the same time as the electrical conductivity on the same specimens. In view of the donor nature of the reaction, a change in activity in the opposite sense to the change in conductivity could have been predicted (i.e., an increase in activity on irradiation). In fact, the irradiated specimen was found to be more active than the original material over the whole temperature range.

The basic cause of the effect of irradiation on activity is evidently to be found in the correlation between catalytic activity and electrical conductivity established by the electronic theory. Irradiation affects the electrical conductivity of a semiconductor, and changes in activity predictably follow the changes in conductivity as required by the electronic theory. The mechanism by which irradiation influences the electrical conductivity and the mechanism by which it influences the catalytic activity are not two independent problems, but a single problem. Because of the strict correlation between activity and conductivity, we can discount the second problem and concentrate on the first.

In this Section we have considered the case of a change in adsorption and catalytic properties resulting exclusively from a shift in electronic equilibrium brought about by irradiation. The radiation-induced defects which produce this shift do not themselves take part in the adsorption and catalytic acts. The memory associated with radiation-induced defects is retained for considerable times after irradiation is discontinued. As long as these defects persist, the electronic equilibrium remains displaced, the electrical conductivity retains a memory of the irradiation, and so also does the catalytic activity.

III. "MEMORY" ASSOCIATED WITH A DISTURBANCE OF THE ELECTRONIC EQUILIBRIUM

We shall now turn to the case where irradiation disturbs the electronic equilibrium in the semiconductor by generating non-equilibrium carriers without however giving rise to structural defects and impurities. We shall be considering, in other words, the ionising action of radiation. In particular, electromagnetic radiation such as visible and u.v. light, X-radiation, and gamma radiation shows this effect. (Note that gamma radiation can also produce structural disturbances as a secondary effect).

In these cases the semiconductor forgets the irradiation almost as soon as it is removed. This is the general rule. Noteworthy exceptions to this rule, in which the semiconductor retains a memory of the irradiation for an appreciable time even though no radiation defects have been produced, are far from uncommon. This Section is devoted to this anomalous memory, to its manifestations, and to attempts to elucidate its nature.

This memory consists in the following. If the semiconductor is irradiated with u.v. light and adsorption is measured some time after the end of the irradiation period, the dark adsorption capacity is sometimes found to be higher than before irradiation, and conversely the photoadsorption capacity is lower. The surface retains a memory of the irradiation after the irradiation has been removed, even though the production of radiation-induced defects in the sample by u.v. light is, of course, out of the question. This memory disappears very slowly, and can be completely erased only by heating the sample. A memory of this type has been observed by Solonitsyn[7] in his work on the adsorption of O_2 on ZnO.

This memory sometimes manifests itself in the kinetics of photosorption. If radiation is applied after the establishment of adsorption equilibrium, additional adsorption due to the radiation can be observed (photoadsorption). This continues by a kind of inertia for some time after the radiation is interrupted. This memory effect, which could also be termed the delayed action effect or "post-effect", has been observed by Coekelbergs and coworkers[8] during their investigation of the effect of X-radiation on the adsorption of O_2 and CO on Al_2O_3. As in the work of Solonitsyn, there is no possibility of radiation defects having been produced. Again, an increase in temperature tends

to eliminate the effect. At high enough temperatures the "post-effect" disappears completely.

Many experiments on the nature of the adsorption centres produced by irradiation and persisting on the surface for an appreciable time after the end of the irradiation period have been carried out in recent years: these experiments throw some light on the origin of this type of memory. The centres are shown to be non-equilibrium carriers generated by irradiation and captured by intrinsic defects of the surface, i.e. by defects not produced by the radiation.

Thus, the work of Kohn and Taylor[9,10] has shown that gamma irradiation of Al_2O_3 gives rise to adsorption centres for H_2 consisting of holes localised on Al atoms present in stoichiometric excess. Subsequently, Boreskov and coworkers[11] demonstrated that these centres are responsible for the catalytic activity towards the H_2–D_2 exchange reaction. Lunsdorf and Jayne[11,12] showed that u.v. irradiation of MgO produces colouration and an ESR signal due to an electron localised on an anion vacancy. Exposure to CO_2 caused bleaching of the colour and a change in the ESR signal, the new signal corresponding to the CO_2^- radical-ion. The same effect was found in the adsorption of the O_2 molecule, which was converted into the O_2^- radical-ion. Adsorption on *F*-centres produced by previous irradiation was involved also in the work of Bauer and Staude[13] on the adsorption of quinone on coloured AgBr crystals. Colourless crystals had no adsorption capacity at all. A similar effect was found by Rakityanskaya[14] in her work on the adsorption capacity of various alkali metal halide crystals before and after u.v. irradiation.

All these experiments suggest that irradiation can activate a surface by converting its natural structural defects into more or less long lived adsorption centres. Only thus can the memory exhibited by the surface in these systems be explained. We are dealing with adsorption at localised carriers which, from the standpoint of the electronic theory, play the role of localised unsaturated valencies. These centres are formed before adsorption, if irradiation is applied before adsorption, or alternatively they can be formed during the adsorption process if adsorption is taking place during irradiation. The problem of adsorption on a carrier trapped on a defect was treated quantum-mechanically by Bonch-Bruevich[15] in 1953, and later by Hauffe[16] from the point of view of the Boundary Layer Theory (Randschichttheorie), and by Kogan and Sandomirskii[17] and by one of us[1] from the standpoint of the electronic theory.

We have made a theoretical study[18] of the laws of adsorption on centres whose concentration is affected by irradiation. Ionisation followed by localisation of electrons (or holes) on defects leaves the system in a metastable state, i.e. in an excited state such that the system must overcome an activation barrier in order to pass into the stable state. It is because of this barrier that the centres created by the irradiation are relatively stable. As long as the concentration of centres remaining after irradiation has not decayed away, the surface shows an enhanced adsorption capacity. This was observed also by Solonitsyn, who exposed his specimens to preliminary irradiation. Under these conditions, however, the photoadsorption capacity can be shown to be less than before the preliminary irradiation. This is because the additional irradiation can only create a relatively small number of new centres, the bulk of the new centres having been produced during the preliminary irradiation. These phenomena have indeed been observed in practice.

At the same time, some peculiarities are observed in the kinetics of photoadsorption. If the rate of creation of adsorption centres exceeds the rate at which these centres are filled by gas molecules, the centres will continue to be filled by gas molecules even after the irradiation is stopped until an equilibrium between the surface and the gas phase is reached. Under these conditions we would expect to find a "post-effect" — the effect actually observed by Coekelbergs and coworkers but given a different interpretation in the interesting paper already quoted[8].

Having developed a theory of adsorption at a surface with a variable number of adsorption centres, we are led to the conclusion that photoadsorption is irreversible (or, more accurately, slowly reversible), that the activation energy of photoadsorption is negative, and to various other conclusions which are consistent with experimental results.

We have discussed some problems in the radiation chemistry of semiconductor surfaces. The central problem is that of the memory which the semiconductor retains after irradiation. We have considered the case of irradiation causing a shift in the electronic equilibrium, and the case of a disturbance in the electronic equilibrium. These two cases correspond, respectively, to a memory arising from radiation defects produced by the irradiation and lasting for an appreciable time and to a memory arising from the localisation of non-equilibrium carriers on structural defects, also for an appreciable time. Thus we have been concerned with two types of memory, of different origin.

The electronic mechanism of chemisorption and catalysis is particularly relevant to the influence of irradiation on the adsorption and catalytic properties of semiconductors. The electronic theory of chemisorption and catalysis is the key to an understanding of the phenomena observed during irradiation. At the same time, these phenomena are a basis for further development of the electronic theory.

Countercurrent Fractional Crystallisation

Yu.A.Chikin and V.I.Lukhovitskii

Countercurrent fractional crystallisation (CFC) has been attracting increasing attention in recent years. The role of CFC among other methods of separation and purification based on crystallisation is described. Various specific arrangements for applying CFC are given. Different theories of CFC are examined, and the limitations of the process are discussed. 73 references.

I. INTRODUCTION

Effective methods of separation and purification of materials involve repeated application of the elementary processes which constitute the basis of separation. These processes are: evaporation–condensation (in the case of distillation); sorption-desorption (in chromatographic separation); evaporation–crystallisation (in fractional sublimation); fusion–crystallisation (in countercurrent fractional crystallisation), etc. Thermodynamic partition coefficients, calculated from the chemical potentials of the various phases[1], can be defined for each elementary process.

As a rule, partition coefficients for the fusion–crystallisation process are high enough to ensure efficient separation and purification of materials. These high partition coefficients are due to the fact that in most systems of practical importance the impurities form eutectics with the main component. The thermodynamic partition coefficient of a mixture of a eutectic and a pure component tends to infinity. In some systems, however, mixed crystals, peritectics, or intermediate compounds are formed. Even more complicated systems exist, particularly in multicomponent mixtures. These mixtures are characterised by a finite partition coefficient, which makes their separation more difficult. Systems of this type can be used to evaluate the effectiveness of apparatus and to determine the parameters of the separation process. Most convenient for this purpose are the two-component systems which give rise to solid solutions (just as systems giving ideal solutions are used to study fractional distillation).

The present review will examine the theory and practice of only one of the methods of separation and purification based on crystallisation: countercurrent fractional crystallisation.

The theoretical aspects of the crystallisation process have already been adequately discussed in review articles[2,3].

Modern crystallisation methods of separation and purification can be classified into a number of groups, each of which has its own advantages and disadvantages.

The most widely known of these is the zone melting method[4], which gives products of the highest purity and is generally applied in the production of ultrapure metals, semiconductors, etc. However, in spite of later refinements to increase the number of zones per pass, to provide continuous operation, and to raise the efficiency[5], the purification process remains very slow, requiring many days or at least many hours, and its production capacity is therefore low. Furthermore, the separation of large amounts (tens per cent) of impurities is problematic. The same strictures apply to the directional crystallisation method.

The fractional crystallisation method, widely used in the past, is now hardly ever used as it is extremely laborious, and has been replaced by more satisfactory methods. Somewhat improved variants of the fractional crystallisation method are the continuous methods of fractional melting[6] and partial freezing[7], which can be used in laboratory practice but are hardly likely to find industrial applications because of the low efficiency of separation which they afford.

The method called chromatographic crystallisation by Findlay and McKay[8], proposed by Bowman[9] in 1947, consists in the following procedure: a temperature gradient is applied to a column filled with a filtration medium, and the mixture to be separated is applied at the top in the solid form. The mixture is brought into the liquid form by dissolution in a solvent which does not freeze at the separation temperature (or, alternatively, by fusion). The liquid is allowed to flow downwards, simultaneously moving the temperature gradient in the

direction of the flow. The solid phase, consisting of the recrystallised mixture, is retained by the filtration medium. This process is equivalent to a countercurrent of the phases in the temperature gradient. The method gives good results only if a solvent is used. When working with a melt, as described in the original patent[9], we can expect a large amount of melt to be retained in the packing, and this can make the operation of the equipment difficult. Successful separation of paraffins has been achieved by using large volumes of solvent, but in this case the output of the apparatus falls off considerably. The method was later proposed for use in polymer fractionation[10], and is now mainly used for that purpose.

Countercurrent fractional crystallisation (CFC) has become very widely used in recent years, and has reached the stage of industrial application in many countries. The present review is devoted to this method.

II. BASIC PRINCIPLES OF CFC

Any method of separation, to be fully efficient, must meet the following requirements:

1. A multiplicity of elementary separation steps, which in principle should lead to a large number of theoretical plates.
2. Countercurrent motion of the phases, ensuring a large number of elementary steps and a distribution of the component concentrations along the length of the separating equipment.
3. Flow reversal (reflux), which leads to products of maximum purity.

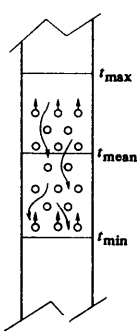

Figure 1. Schematic representation of countercurrent fractional crystallisation.

These factors also characterise the separation of materials by continuous (countercurrent) fractional crystallisation, using separating equipment working on the following principle (Fig. 1). A temperature gradient such that the maximum temperature t_{max} and the minimum temperature t_{min} are respectively higher and lower than the melting point of the mixture and of all its components and eutectics is imposed on the column. The solid phase is continuously moving with respect to the temperature field towards higher temperatures, and melts, and the liquid countercurrent flows between the crystals in the direction of lower temperatures, and freezes. Elementary fusion–crystallisation (or dissolution–crystallisation steps take place over the entire length of the separation layer, leading to a redistribution of the components between the phases. As a result, the less fusible (or less soluble) components migrate towards the hot end of the separation layer, and the more fusible components migrate towards the cold end.

It can be seen from this schematic description of the process that a fairly close analogy exists between CFC from the melt and fractional distillation: this analogy has been pointed out by a number of workers[11,12]. However, there are also a number of essential differences between the two processes. Firstly, because of diffusional limitations in the solid phase[13], the redistribution of components between the phases is achieved mainly by complete fusion of the crystals and formation of crystals of different composition. Secondly, the density difference between crystals and liquid is not usually very large, and countercurrent of the phases is usually achieved by moving one phase relative to the other by some mechanical device. Thirdly, a much greater amount of liquid is entrained in the solid phase by surface tension in its most general sense (occlusion, adsorption, capillarity). As a result, the real partition coefficient is significantly lower than the thermodynamic partition coefficient.

Due allowance for these differences must be made when the formulae and ideas used in fractional distillation are applied to the operation of crystallisation apparatus.

The profound influence of pressure on crystallisation and melting processes must also be stressed[14–16]. Excess pressure can modify the phase diagram of the system and thus affect the separation process: in this context, the application of fluctuating pressure offers the promise of new and improved types of apparatus[17–19] for the separation of materials by CFC (by varying the rates of fusion and crystallisation during each cycle of pressure change).

III. TYPES OF APPARATUS FOR THE SEPARATION AND PURIFICATION OF MATERIALS BY CFC

The equipment described in the literature can be divided into a number of groups, differing in respect of the method used to impart relative motion to the liquid and the solid phase, the extent to which the separator is filled, the method of extracting and supplying heat, and so on.

1. One variant of CFC from solution was described above under the heating "chromatographic crystallisation"[9]. In another similar variant the column is filled with solvent instead of a filtration medium[20]. The cooler is at the top of the column, the heater at the bottom, and the temperature gradient is produced by the moving streams of the phases. Countercurrent motion of crystals and solution is produced by the density difference of the phases, and is assisted by stirring the solution.

2. The use of drums for the separation and purification of materials is described in the patent literature[21,22]. The apparatus consists of a number of stages. Solid phase freezes from the melt on to the surface of the drum, which is cooled from below, and is transferred to the high-temperature region by the rotation of the drum. The drum and its associated equipment for the countercurrent transfer of crystals and melt from stage to stage can be either horizontal or sloping. A heater and a cooler are provided at each stage. The only difference in principle between this process and fractional crystallisation is the absence of filtration. The separation is not induced by a temperature gradient, but by the different rates of melting and crystallisation of the various components. The separation

efficiency is not high, because each stage contributes much less than one theoretical plate to the separation.

3. Graham's rotary crystalliser[23] is an example of the application of pressure to crystallisation processes. The partially crystallised material is passed through rollers, the lower roller being cooled and the upper being heated. The rollers squeeze the mother liquor from the crystals; also, due to the combined effect of the temperature difference on the rollers and of the pressure on the crystals, part of the crystals melts, providing additional scrubbing of the crystals. The purification efficiency is low. Even in the purification of mixtures which form a eutectic the enrichment of the desired component is only from 76 to 90%.

4. Various forms of scraping crystalliser for the separation of materials have been described[24,25]. The crystals, formed on the cold walls of the cooled end of the column, are transferred by scrapers to the hot end. However, these crystallisers have a low separation efficiency and are used only as an auxiliary means of supplying the crystalline paste to the main separating column[8].

5. The apparatus described by Carney[26] is an example of another type of crystalliser for the purification of materials. The layout is shown diagrammatically in Fig. 2: it consists of a column with a cooler *1* at the bottom and a heater *2* at the top. Countercurrent of the crystals and the melt is induced as follows: the crystals are caught in perforated compartments attached to an endless conveyor belt *3*, and move upwards, and the liquid flows under the influence of gravity. Feed material is supplied in the middle of the column (*4*), and the pure product and the near-eutectic mixture are taken off at the top (*5*) and the bottom (*6*) of the column respectively.

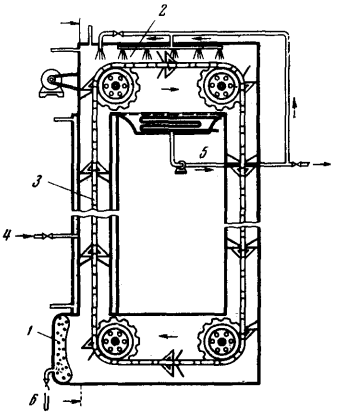

Figure 2. Carney's apparatus.

Using a reflux ratio of 9, dimethylbutane of 99% purity has been produced with a throughput of 3.1 kg h^{-1}.

6. The following types of crystalliser for the purification of materials are disclosed in a number of patents by Weedman and Findlay[27-29]. The crystalline paste is loaded into the column, which can be vertical or horizontal, or alternatively is produced directly in the column. The crystals are moved by a perforated or porous piston towards the heater: they melt, and the resulting liquid flows in the opposite direction towards the piston and filters through it. After one pass of the piston the crystalline residue is taken off as pure product. Although products (such as benzene) of up to 98–99% purity have been obtained in this apparatus, the efficiency of the apparatus must be judged unsatisfactory, since the impurities gave eutectics with the main component.

None of these types of separating equipment has found industrial application, and they are rarely used even in laboratory practice. This is due first and foremost, we believe, to their low efficiency (of the order of 1–2 theoretical plates); furthermore, they are quite complicated when fully engineered and their throughput is low.

7. The use of centrifugation for CFC was proposed by Findlay[30], but the process was first described in full detail by Fleischer[31] in 1962. Essentially, countercurrent of crystals and melt (which must have different densities) is induced in a centrifuge exposed to a temperature gradient such that the minimum temperature (sufficient to cause crystallisation) is near the axis and the maximum temperature (sufficient to cause melting) is near the periphery of the centrifuge. The crystals which have grown to a critical size (determined by the speed of rotation of the centrifuge and by the density difference between crystals and liquid) are impelled in the direction of higher temperatures by the centrifugal field, and the liquid undergoes the opposite flow towards lower temperatures. Supply of feed material and take-off of the separated components are provided on a continuous basis.

The theory of the CFC method in a centrifugal field was developed by Anikin[32] in 1963, but the first purifications[33] (by a batchwise variant) were reported in 1966. Sixteen-fold enrichment of triphenylchlorosilane was achieved in 30 min, but the separation could not be improved by longer operation. Unfortunately, the type of impurity removed is not stated, nor whether the impurity gave rise to mixed crystal or eutectic formation, and therefore the efficiency of the separation cannot be estimated.

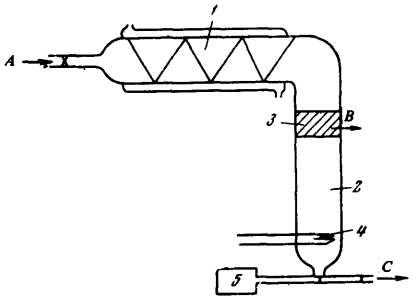

Figure 3. Diagram of the apparatus used by the Phillips company: *A*) input of feed material; *B*) take-off of mother liquor; *C*) take-off of pure product.

8. The variant proposed by Arnold[34,35] and realised by Thomas[36] has proved to be the best for use in industry. The principle of this process has been discussed by McKay and coworkers[8,37,38]. The apparatus (Fig. 3) consists of a preliminary scraping crystalliser *1*, where the crystalline paste is formed, the enrichment section *2* (corresponding to the purification column) with a porous partition *3*, heater *4*, and the pulsatory pump *5*. In a previous form of the apparatus a piston located above the porous partition

was used instead of the pulsatory unit. The piston (or pulsatory unit) operates at 90–350 cycles per minute, and alters the pressure by approximately 1–100 atm during each cycle.

The crystalline paste from the preliminary crystalliser is fed to the enrichment section of the column, the crystal content of the paste being more strictly controlled the higher the required purity of the product. During the period of pulsation corresponding to rarefaction, the paste is drawn downwards and some air is sucked through the porous filter, creating voids in the crystalline paste. During the compression period of the pulsation unit the melt is forced upwards through the crystals, and some of the mother liquor is run off through the porous filter. In the region of the heater the crystals melt: part of the melt is taken off as pure product, and part is displaced upwards by the feed crystals as a reflux. Under these conditions, both scrubbing and recrystallisation of the settling crystals occur in the region between the heater and the porous filter. In this way, a countercurrent of crystals and melt is generated in the column. The temperature gradient in the separating part of the column is generated by the flow of heat carried by the reflux from the heater to the cooler.

A later variant[39] of the same apparatus has the heater in the upper and the cooler in the lower part of the column, so that the directions of motion of the liquid and the solid phase are reversed.

The separation efficiency of the piston version of the apparatus is 3.3 theoretical plates for a column approximately 25 cm in diameter and 2.5 m long operated at a reflux ratio of 95. The capacity of these installations for the separation of eutectic-forming impurities is extremely high. An industrial column operated by the Phillips Company, with pulsation unit, has an output of 60 000 metric tons of *p*-xylene per annum.

9. There is a very large group of assemblies[40–43] in which the countercurrent flow of crystals and melt (or solution) is obtained by moving the crystals from the cooler to the heater by means of a worm-screw or spiral. The melt formed in the vicinity of the heater is displaced by the flow of crystals or flows under the influence of gravity towards the cooler. The most efficient assemblies of this kind are the laboratory crystallisation columns for batchwise or continuous operation developed by Schildknecht and coworkers[44–47].

An apparatus of this type is shown diagrammatically in Fig. 4. It consists of a glass column R_1 with a graded heater winding W and a spiral S, which rotates between the inner (R_2) and the outer tube, impelling the crystals downwards in the temperature gradient (i.e. towards the hotter part of the column). Liquid is displaced upwards by the crystals. Assemblies of this type have been tested for the purification of many organic compounds such as phenanthrene, benzene, cyclohexane, biphenyl, fluorene, azobenzene, β-naphthol, etc. Columns of this type have been used also for the separation of inorganic salts[48]. The results indicate a high operating efficiency, but the data quoted in different papers are somewhat contradictory. Schildknecht et al.[49] published a graph of the melting point of fractions at different heights in the crystallisation column for the purification of phenanthrene. Most of the material (the purer fractions) had a melting point of about 110°C, but after three zone-melting passes the melting point of the purer fractions was raised to 210°C. †

† Although the increase in melting point achieved seems surprising, these data are in fact more or less consistent with the claims advanced in the original paper (Ed. of Translation).

Schildknecht and Vetter[50] have compared the results of the purification of hexadecanol by zone melting and column crystallisation methods. The highest melting point after zone melting (20 passes, velocity of the zone 1 mm h^{-1}) was ~ 50°, and after 2.5 h column crystallisation the melting point was ~ 53°. In both cases, the main bulk of the material had a melting point of ~ 49.5°. Thus, in the purification of phenanthrene the purest product was obtained by zone melting, whereas column crystallisation gave the purest hexadecanol.

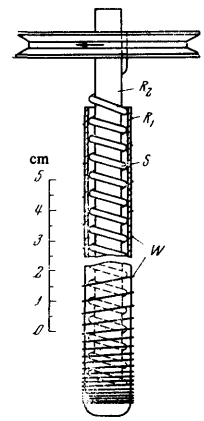

Figure 4. Schildknecht's apparatus.

There are some discrepancies between the published estimates of the efficiency of this method. Thus, Ammon[48] quotes an efficiency of up to 5 theoretical plates for a column length of 25 cm. Schildknecht[51], referring to Rössler's thesis[52], obtained an efficiency of 8–10 theoretical plates in a 20 cm column, corresponding to a value of 2–2.5 cm for the height equivalent to the theoretical plate (HETP). Powers[53] measured the efficiency in terms of the number of unit transfers (NUT) and height for unit transfer (HUT). Using the same data from Rössler, the HUT was 3.3 cm for the azobenzene–stilbene system, which forms mixed crystals, and 12.3 cm for systems giving rise to eutectics. Since the details of Rössler's work are not available in the literature, it is not profitable to discuss the origin of these discrepancies.

To achieve comparable purification (i.e. similar concentration distributions along the column), zone melting requires ~ 10 days as compared with ~ 2.5 h for column crystallisation. The output of crystallisation columns 1–2 cm in diameter and 15–20 cm long is 8–10 g h^{-1}, which makes them fully acceptable for laboratory purposes in spite of some constructional difficulties.

10. The following variant of CFC was proposed[54] in 1964. Column *1* (Fig. 5), with a layer of crystals frozen on its walls to a thickness of not more than 1–2 mm, is moved with respect to the heat exchanger *4*, designed to give a temperature gradient sufficient to keep the upper part of the column above (and the lower part of the column below) the melting points of all the components and eutectics of the mixture to be separated. The liquid flows by countercurrent between the crystals towards the lower-temperature regions under the influence of gravity. Fusion

and recrystallisation processes take place over the entire length of the layer to be separated, and as a result a gradient of component concentrations arises along the column. This process differs from those already described in the following respects: separation takes place in a thin (0.1–0.2 mm) layer which is moving with respect to the heat-conducting column wall, and the heat exchanger imposes a forced temperature gradient (independent of the mixture to be separated). These two special features offer the following advantages: (1) much faster supply of heat to the crystals and removal of heat from the liquid, accompanied by a higher rate of mass exchange, since heat exchange between the phases can occur by heat transfer through the wall as well as by direct contact between the phases; (2) formation of the main bulk of the crystals directly on a heat-conducting surface, which minimises the entrainment or partially melted crystals by more fusible material; (3) the fusion and crystallisation processes and the temperature gradient are practically independent of the mixture to be separated, leading to minimal retention of material by the separation apparatus: in the batchwise variant of the method separation of a mixture into its primary components can be achieved without appreciable formation of intermediate fractions; (4) stable operation of the apparatus, since the liquid moving towards temperatures below the melting point and the crystals moving towards temperatures above the melting point are subjected to ever-increasing temperature differences which tend to arrest their motion; (5) temperature uniformity over the cross-section of the layer to be separated.

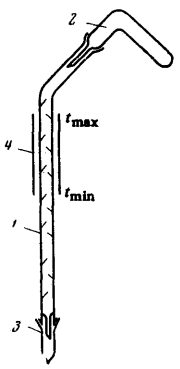

Figure 5. Thin-layer CFC apparatus.

Because of these advantages, the separation apparatus has a very high efficiency. The number of theoretical plates and the number of unit transfers, measured with a standard benzene–thiophen mixture giving mixed crystals [55], are practically equal, and can be as high as 25–30 in the most favourable cases. The HUT and HETP are 2–2.5 cm. The maximum purity of the product (in the absence of eutectic-forming impurities) was 99.9995%. The output of the batchwise laboratory variant of the apparatus is about 10 g h^{-1}. With the continuous variant the output should be at least 1–2 kg h^{-1} from a meter of column perimeter.

The way in which the temperature gradient is moved with respect to the layer to be separated has been shown to be immaterial. It is possible to move the column, the heat exchanger, or even the temperature gradient directly (for example, by passing through the heat exchanger a liquid whose temperature is increased according to a predetermined programme).

Thin-layer operation of CFC is discussed in a number of American papers published in 1965. However, the construction of the apparatus [56,57] is described sketchily, and nothing is said about process parameters or about the operating efficiency of the equipment. The only statement is that the purity of the product can be as high as 99.999–99.9999%.

The high efficiency (8–10 theoretical plates) achieved in devices of the Schildknecht type is probably due to the fact that they operate under conditions approximating to those obtaining in thin-layer separation.

IV. THEORIES OF CFC

A single theory encompassing all methods of CFC is not available at present. Hence, different variants of the theory must be considered, each of which is applicable only to a particular method of separation. The only feature which is common to all these variants is that the CFC process is treated by analogy with fractional distillation, with large or small departures. As in fractional distillation, the efficiency of the separation apparatus is discussed in terms of HETP and N (the height and number of theoretical plates) or of HUT and NUT, of the throughput, and of mass and heat balance.

However, whereas in fractional distillation the partition coefficients are always finite, the thermodynamic partition coefficient for crystallisation with eutectic formation is infinite, and in principle complete separation into one component and the eutectic should be possible with an efficiency of a single theoretical plate. In this case two approaches can be used to calculate the efficiency of separation. In the first the degree of enrichment (and therefore the extent of the approximation to a theoretical plate) is calculated. The second approach requires allowance for the real composition of the phases: the composition of the liquid phase is assumed to remain unchanged, but the composition of the crystalline phase is calculated with allowance (by various means) for the liquid which wets the crystals. Both approaches are found in the literature, and we shall mention them again in the discussion of the various theories. The principles of the calculations for some of the methods described in Sections III.1–III.10 will now be briefly reviewed.

Section III.1 describes a column in which the motion of the crystalline phase in the solvent is caused by density differences. Ciolan [58] has calculated the dependence of the yield on the enthalpies and specific heats of the components starting from the mass and heat balance equations for the enrichment and the exhaustion sections of the column.

Section III.7 describes the operating principle of crystallisation columns in a centrifugal field. The theory developed by Anikin [32] for this system assumes the fullest analogy between CFC and fractional distillation, with the hypothesis that diffusion is fast enough in a solid in a "state of pre-fusion" to produce concentration uniformity in the crystalline phase. The expressions for the time needed to reach steady state and for the ratio of the ultimate concentrations are the same as those obtained by

Cohen[59] for fractional distillation. The fluxes are calculated by combining the centrifugal field and the rate of growth of the crystals.

Devyatykh[60] holds similar views on the overriding role of diffusion in the solid phase during the separation process. By considering the material balance in the column and assuming a steady state he arrives at the following expression for the efficiency under total reflux:

$$\mathrm{HETP} = \omega^2/3D_1\kappa,$$

where L is the flux of solid phase, 2ω is the mean thickness of the platelets of crystalline phase, D_1 is the diffusion coefficient of the minority component in the solid phase, and κ is the fraction of the volume of the column occupied by the solid phase.

It should be noted that most workers consider diffusion in crystals in a state of pre-fusion to be abnormally high but nevertheless 1–2 orders of magnitude lower than in the liquid[13,61]. Using a stage-by-stage treatment of the crystallisation process, Anikin[62] obtained an expression for the number of theoretical plates also analogous to the equations used in distillation and zone melting.

In Section III.8 we have mentioned the efficient separation achieved by the piston column used by the Phillips Company on a pilot-plant scale. The efficiency was determined for the separation of a mixture of cyclohexane and methylcyclopentane, whose phase diagram is quite complicated but can be interpreted as mixed crystal formation in the concentration region between 50 and 100% of cyclohexane. The HETP is 75 cm. Subsequent refinements, including replacement of the piston by a pulsation unit, more precise control of the operating conditions[63,64], on-line computer control[65,66], etc. must obviously have increased the separation efficiency somewhat, but the Phillips columns are still used exclusively for the separation of eutectic-forming impurities. We note that in this case a single theoretical plate is sufficient in principle. Hence, the main interest is not in calculations of efficiency but in the column fluxes and throughputs.

The influence of a number of variables on the purity of the product and on the yield of the column has been discussed[37,38]. Factors such as the crystal content of the paste, the viscosity of the mother liquor, the size of the crystals, the pulsation frequency, etc. have been shown to play an important part. However, the basic factors which determine the operation of the column are: the reverse flow of liquid (reflux), the heat balance, and the degree of recrystallisation in the purification zone. In the words of the authors, recrystallisation is "the key to purification in the column". The degree of recrystallisation can be calculated by carrying out a mass and heat balance for the purification section, making the following assumptions for any cross-section of the column: the occluded liquid is in equilibrium with the crystals; the free liquid rising in the column is at the freezing point and its composition is given by the phase diagram for the system; the ratio of the amounts of solid phase and of occluded liquid is constant; the flow of heat through the column wall is zero.

With these assumptions, the mass and heat balance equations take the form

$$S = W + L - O;$$

$$\Delta H = H_L L - H_O O - H_S S + K(t_L - t_S);$$

$$O = \frac{(1-X_L)[H_S W + \Delta H - K(t_L - t_S) + W(1-X_W)(H_L - H_S)]}{(1-X_O)(H_L - H_S) - (1-X_L)(H_O - H_S)},$$

$$L = \frac{O(1-X_O) - W(1-X_W)}{1-X_L},$$

where S is the flux of solid phase, W is the flux of product, L is the flux of rising liquid, O is the flux of occluded liquid, H is the enthalpy, ΔH is the nett flow of heat in the column, t are temperatures, K is a parameter (including the thermal conductivity of the solid phase, the cross-sectional area of the column, the constant temperature difference between the rising liquid and the falling crystals, and the rate of change of temperature per unit height of the layer), and X is the concentration of the desired component. If the concentration of the crystalline paste entering the column is also known, the degree of recrystallisation can be calculated as the ratio of the amount of newly formed crystals to the amount of crystals entering the column.

McKay and Goard[67] give the following formula for the degree of recrystallisation in the piston column:

$$R = \frac{(T_p - T_c)C_p}{H_f},$$

where R is the degree of recrystallisation, T_p and T_c are the melting points of the pure crystals and of the crystals entering the purification zone, C_p is the mean specific heat of the crystals in the temperature range between T_p and T_c, and H_f is the heat of fusion of the purest component.

In the purification of p-xylene the optimum degree of recrystallisation was ~ 0.2–0.3, and the throughput of the column was as high as 3.23 $m^3\ h^{-1}$ for a cross-sectional area of 1 m^2. It should be noted that the reflux ratio of the liquid must be raised very considerably (to 95 : 1) when the impurities form mixed crystals with the main component: under these conditions the throughput of the column decreases sharply.

A crystallisation column in which the crystalline phase moves with the help of a rotating spiral is described in Section III.9. The CFC variants proposed by Schildknecht and coworkers have been discussed theoretically by Powers[53]. When the system contains mixed crystals, the author makes the following assumptions: phase equilibria are not reached; diffusion in the solid phase is negligibly small; the flux of crystals is constant along the length of the column. Under these conditions the rate of transfer of component A from one phase to the other is defined by the expression

$$\zeta_A = y_A L - x_A C - \rho D A \Phi \frac{dy_A}{dZ}.$$

For equilibrium within an element dZ at a height Z in the column the expression for the rate of transfer takes the form

$$\frac{d(x_A C)}{dZ} = K_t a A (y_A^* - y_A),$$

where x_A is the concentration of component A in the solid phase, y_A is the concentration of A in the liquid, L and C are the fluxes of liquid and of crystals, ρ is the density of the liquid phase, D is the diffusion coefficient in the liquid, A is the total area of the column cross-section, Φ is the volume fraction of the liquid phase, a is the contact area of the phases per unit volume of the column, and K_t is the mass transfer coefficient.

At steady state we can write

$$L = C; \qquad \frac{dX_A}{dZ} = \frac{dy_A}{dZ}.$$

In this case we obtain the following expression for the nett rate of transfer under total reflux:

$$\tau_A = C(y_A^* - x_A) - \left[\frac{C^2}{K_t a A} + \rho D A \Phi\right]\frac{dx_A}{dZ}.$$

Noting that at equilibrium $\tau_A = 0$, and assuming that all factors in square brackets are independent of Z, we can write the equation in an integral form:

$$\frac{Z}{\left[\frac{C}{K_t a A}+\frac{\rho DA\Phi}{C}\right]}=\int_{x_A(0)}^{x_A(Z)}\frac{dx_A}{y_A^*-x_A}\ .$$

The denominator of the left-hand side of this equation contains all the parameters of the column referred to unit length: it may be termed the height for a unit transfer (HUT). The value of the integral depends only on the final compositions and on the equilibrium equation $y_A^* = f(x_A)$. It is a direct measure of the difficulty of separation, and is usually expressed as the number of unit transfers (NUT).

Given the indeterminate but fixed lower limit of the integration, it is possible to evaluate the integral as a function of x_A for any system from the phase diagram. We note that for $x_A = 0$ or $x_A = 1$ the integral tends to infinity. Hence, Powers considers complete separation theoretically impossible. Once the distribution of the concentration x_A along the column is known, the integral can be evaluated as a function of the length Z.

The slope of this linear equation, given by

$$m=\frac{1}{\left[\frac{C}{K_t a A}+\frac{\rho DA\Phi}{C}\right]}=\frac{1}{\mathrm{HUT}}\ ,$$

defines the HUT. The NUT can be calculated from the formula NUT = Z/HUT. Experimental results actually give straight plots, showing that all factors in square brackets are indeed independent of Z.

In his discussion of eutectic systems Powers makes the following assumptions: the system component A–component B is treated as a binary component A–eutectic system in which the eutectic plays the part of a new component B_1; the liquid containing the impurity is in contact with pure crystals of composition A everywhere along the layer to be purified except at the upper end, where the composition of the crystals changes discontinuously to the eutectic composition.

Let the crystals be the pure component A ($x_E = 0$), and let the liquid in contact with them have the composition y'_E and velocity L', in contrast to the composition y_E and velocity L of the main bulk of the liquid. But for these special features, the subsequent discussion is in no way different from the case of mixed crystals. The rate of mass transfer between the adherent liquid and the rising liquid is proportional to the concentration difference:

$$W_E = K_t a (y'_E - y_E)\ .$$

Introducing the balance equations, we arrive at the following expression for the transfer in the total reflux region:

$$\tau_E = Cy'_E - \left[\frac{L'(L'+C)}{K_t a A}+\rho DA\Phi\right]\frac{dy'_E}{dZ}\ .$$

At steady state $\tau_E = 0$, and the integral form is

$$\frac{y'_E}{y'_E(L)}=\exp\left[\frac{C(Z-L)}{\frac{L'(L'+C)}{CK_t a A}+\frac{\rho DA\Phi}{C}}\right]\ ,$$

where $y'_E(L)$ is the concentration of the adherent liquid at the top of the column, L is the total length of the column, and y'_E is the concentration of the adherent liquid at the point Z. When using this expression, we must remember that the model changes as soon as the liquid reaches the eutectic composition. Under these conditions the crystals, the adherent liquid, and the rising liquid all have the eutectic composition.

To test the application of this equation to experimental data, a linear variation of composition with temperature was assumed. In this case we have

$$\frac{y'_E}{y'_E(L)}=\frac{T_B-T(Z)}{T_B-T(L)}\ ,$$

where T_B is the melting point of the pure component, $T(Z)$ is the temperature at point Z, and $T(L)$ is the temperature at the upper end of the column. As stated above, when Rössler's experimental results are examined in the light of this theory, large differences are found between the heights for unit transfer in the case of systems forming mixed crystals or eutectics (3.3 and 12.3 cm respectively).

The separation process described in Section III.10 for binary mixtures forming mixed crystals has been discussed[68] by making the following assumptions: steady state is not achieved; fusion of the crystals is not accompanied by change in composition, because diffusion in the solid phase can be ignored; a change in composition occurs when the liquid crystallises, the composition of the resulting crystals being determined by the liquidus curve.

Hence, using the expressions for material balance and for the rate of transfer of a component from one phase to the other, the following expression was obtained for a given instant:

$$\int_0^Z \pi D\frac{\delta_l \bar{l}}{S}dZ=\int_{y_0}^{y}\frac{dy}{x^*-y}$$

where Z is the length of the layer, δl is the effective thickness of the liquid, $\bar{l}$ is the rate of melting (mole cm^{-3} h^{-1}), S is the flux of solid phase, y and x are the concentrations of one of the components in the crystals and in the liquid, x^* is the concentration of the same component in crystals in equilibrium with x. As was shown from experimental data, replacing y by $\bar{x}$ (where $\bar{x}$ is the mean of the concentrations x and y) and x^* by $\bar{x}^*$ does not introduce significant errors. The integral thus obtained,

$$\int_{\bar{x}_0}^{\bar{x}}\frac{d\bar{x}}{\bar{x}^*-\bar{x}}$$

can be taken as the NUT to a first approximation. The values of HUT and NUT calculated by this method are close to the HETP and N values respectively, calculated from the final concentrations by the Fenske–Underwood formula[69].

Equations have been obtained[68] relating the efficiency of operation of the separating equipment to the following process parameters: h (the length of advance of the column with respect to the temperature gradient), between 12 and 120 cm; v (the rate of advance), between 6 and 480 cm h^{-1}; m (the loading), between 0.5 and 5.3 ml per cm of column periphery. The equations are of the form

$$\mathrm{HUT} = 12\,h^{-0.44}v^{0.2}m^{0.5}\ ,$$

$$\mathrm{NUT} = 1.5 + 3.9\,h^{0.44}v^{-0.2}m^{-0.2} - 0.2\,h^{-0.56}v^{0.8}m^{-0.5}\ .$$

The variation of the separation efficiency with composition of the initial mixture and with temperature gradient has also been determined. All these expressions were obtained from experiments with a standard benzene–thiophen mixture, which gives mixed crystals.

The expression obtained above,

$$\mathrm{NUT}=\int_{y_0}^{y}\frac{dy}{x^*-y}\approx\int_{\bar{x}_0}^{\bar{x}}\frac{d\bar{x}}{\bar{x}^*-\bar{x}}$$

is not accurate enough, because it was derived without

allowance for the wetting (in its most general sense, including occlusion, adsorption, and capillarity) of the crystals by liquids of different composition. Chikin and coworkers[70] have obtained an equation which allows for wetting. If the wetting is not a sensitive function of the height (i.e. composition) of the layer to be separated, the equation has the form

$$\mathrm{NUT}_E = \frac{1}{1-C}\int_{\bar{x}_0}^{\bar{x}} \frac{d\bar{x}}{\bar{x}^* - \bar{x}} \quad ,$$

where C is the wetting coefficient, expressed as the ratio of the mole fraction of the wetting liquid to the sum of the mole fractions of the wetting liquid and of the crystals. At low values of C, corrections for the wettability have a minor effect on the calculated separation efficiencies in systems which form mixed crystals.

In the theoretical discussion of systems giving rise to eutectics the following assumptions have been made: the system consists of two components (the eutectic and one of the pure components); the composition of the liquid along the height of the column (i.e. along the temperature gradient) is determined by the liquidus curve, whereas the composition of the solid is determined by the wettability (in its widest sense) of the crystals of the pure component by a liquid whose composition is determined by the equilibrium curve. For this system, the last formula takes the form

$$\mathrm{NUT}_E = \frac{Z}{\mathrm{HUT}_E} = \frac{1}{1-C}\int_{\bar{x}_0}^{x} \frac{d\bar{x}}{-\bar{x}} = \frac{1}{1-C}\ln\bar{x}\Big|_{\bar{x}}^{\bar{x}_0} \quad ,$$

where Z is the total length of the layer to be separated. Efficiencies calculated by this formula agree almost exactly (except for the region of concentrations close to the eutectic) with the results obtained under the same conditions for the separation of materials forming mixed crystals.

V. FIELD OF APPLICATION OF THE CFC METHOD

Countercurrent fractional crystallisation is most successfully used with materials whose composition changes at their boiling point (by decomposition, polymerisation, etc.). Compounds such as methylvinylpyrrolidone and styrene[71] have been successfully purified; juices, tea, and beer[72] have been concentrated, etc. In some cases the method is economical also for the purification of materials such as *p*-xylene, naphthalene[72], etc. In all these applications the impurities formed eutectics with the main component, and therefore only moderate efficiency (but a high throughput) was required of the separation equipment. Apparatus of this type includes the Phillips columns and also the continuous variant of the centrifugal column.

For laboratory use, and for the preparation of specially costly materials in a high state of purity (drugs, some monomers, etc.), columns of the Schildknecht type or the thin-layer variant of CFC are the most suitable. These types of equipment when operated at a moderate output (tens of grammes per hour) offer extremely high separation efficiencies. The thin-layer variant is simpler to construct and offers somewhat greater efficiency.

In addition to the preparation of super-pure materials, these variants of the separation equipment can be used for the concentration of impurities, for the direct determination of eutectic compositions, etc. Apparatus for the analysis of mixtures can be designed on the basis of these assemblies.

The limitations of the CFC method must be mentioned. Separation is impossible when the composition of materials changes at the melting point or when they are very viscous at the melting point. In these cases a third substance can be added to lower the melting point or the viscosity, but this expedient lowers the output and complicates the separation.

However, in spite of these limitations, the CFC method deserves, on the whole, extensive application both in industry and in the laboratory.

Isotopic Exchange of Hydrogen in Aromatic Complexes of the Transition Metals

V.N.Setkina and D.N.Kursanov

This paper examines and evaluates the data on the isotopic exchange of hydrogen in aromatic complexes of the transition metals. Results of the kinetic investigation of isotopic exchange of a series of metallocenes in acid media are given, and these data are compared with those on hydrogen exchange of benzenoid compounds, permitting the relative reactivity of the sandwich compounds in electrophilic hydrogen exchange to be characterised. The isotopic exchange reactions of hydrogen are used to obtain quantitative data on the influence of electron-donating and electron-withdrawing substituents on the ferrocene system. A deep difference in the nature of the interaction of the substituents with the electron systems of ferrocene and benzene has been established.

The isotopic exchange of hydrogen in alkaline media is used to evaluate the acidic properties of aromatic complexes of the transition metals and as a characteristic of the effect of the nature of the central metal atom on the reactivity of the aromatic ligands.

A combination of hydrogen isotopic exchange and proton magnetic resonance enables the partial rate of exchange of hydrogen atoms at different ligand positions to be determined and hence the quantitative evaluation of their relative reactivity. A levelling of differences in the field of the orientating action of substituents in aromatic ligands π-bonded with the atoms of the transition metals has been established.

There is a bibliography of 87 references.

INTRODUCTION

With the discovery of ferrocene[1] the chemistry of the complexes of the transition metals with organic ligands underwent considerable development. It has now become a large branch of organic chemistry containing enormous factual material and of great theoretical and practical interest[2-9].

The present paper considers the results obtained in the investigation of aromatic complexes of the transition metals by the hydrogen isotopic exchange method.

A series of features of the isotopic exchange of hydrogen allows it to be considered as worthy of separate consideration. Reactions which include the replacement of hydrogen by other atoms or groups, are widely distributed in organic chemistry. Hence the isotopic exchange of hydrogen models this extremely typical and important group of reactions of organic substances. Moreover, an important feature of isotopic exchange reactions is that during the isotopic substitution the electronic structure of the molecule does not change and this allows a more general characteristic of the reactivity of a substance to be obtained than on the basis of the replacement of hydrogen by other atoms or groups.

An investigation of the kinetic isotopic effects due to a difference in the zero-point energies of molecules with C–H, C–D, and C–T bonds, frequently permits significant conclusions about reaction mechanism to be drawn, particularly about the nature of the slowest stage.

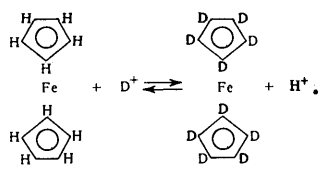
The isotopic exchange of hydrogen is sensitive to the change in the acidity of the medium. Knowledge of this dependence enables the reactivity of substances which differ considerably in their behaviour towards the acidity of the medium to be compared.

A comparison of the methods of proton magnetic resonance and hydrogen exchange allows the partial rates of exchange of various hydrogen atoms in the organic ligands to be determined and hence their relative reactivities to be evaluated quantitatively.

1. ISOTOPIC EXCHANGE OF THE HYDROGEN OF FERROCENE WITH ACIDS

The ability of the hydrogen atoms of aromatic ligands of sandwich compounds to undergo isotopic exchange with acids was first observed with ferrocene[10–12].

Nesmeyanov and coworkers[10] found that all the hydrogen atoms of the cyclopentadiene rings of ferrocene undergo isotopic exchange with acids enriched in deuterium. For example, this reaction occurs with hydrochloric, phosphoric, trichloroacetic, and trifluoroacetic acids enriched in deuterium[10,11]:



Simultaneously with these investigations a reference appeared in the literature[12] to unpublished work by Santer, who observed hydrogen exchange between ferrocene and the complex of boron fluoride and deuterium oxide.

Ferrocene reacts with concentrated deuteriosulphuric acid in a peculiar manner[11]. It was found that in this instance rapid deuterioexchange is accompanied by the oxidation of ferrocene to the ferricinium cation, which, however, is incapable of undergoing isotopic exchange. Both the competing reactions—deuterioexchange and oxidation—take place at different rates, the rate of isotopic exchange the greater, in consequence of which the oxidised form (ferricinium ion) contains a considerable amount of deuterium[11].

Quite recently Pavlik and Šubrt[13] reported that very rapid deuteriation of the cyclopentadienyl rings of ferrocene takes place during its reaction with deuterium chloride in the presence of aluminium chloride.

It was found[14] that the rate of isotopic exchange of the hydrogen of ferrocene depends significantly on the acidity of the medium. There is a linear dependence of the logarithm of the rate constant of the hydrogen exchange $k_{h.e.}$ on a function of the acidity of the medium, that is, Hammett's relation[15]

$$\lg k_{h.e.} + H_0 = \text{const},$$

is observed in the hydrogen exchange of ferrocene with acids.

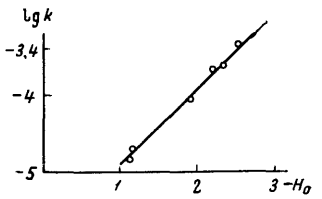


Figure 1. Effect of the acidity of the medium on the rate of isotopic exchange of the hydrogen of ferrocene.

Fig. 1 shows the results[14] which characterise the variation of the hydrogen exchange rate of ferrocene with the acidity of the solutions of trifluoroacetic acid of various concentrations in acetic acid. These results show that for ferrocene, as also for benzene[16], the rate of hydrogen exchange is proportional to the acidity of the medium.

The electrophilic isotopic exchange of hydrogen was used to study the relative reactivity of the compounds of the ferrocene series and other sandwich compounds of the transition metals. Compounds of the benzene series, whose reactivity in reactions with isotopic exchange of hydrogen has been well studied, were used as standards of comparison[17].

A comparison of the kinetic data on the hydrogen isotopic exchange of ferrocene and benzene allowed the relative reactivity of ferrocene to be evaluated. It was found that the relative rate constant for the hydrogen exchange of ferrocene ($k_{rel} = 7.8 \times 10^5$) is almost six orders of magnitude greater than that for benzene[11]. At acidities of the medium differing by six orders of magnitude the rates of hydrogen exchange of benzene and ferrocene are approximately the same.

Later Rosenblum and coworkers[18] compared the rates of acetylation of ferrocene and benzene by a Friedel–Crafts reaction and found that the acetylation of ferrocene ($k_{rel} = 3.3 \times 10^6$) is more rapid by approximately six orders of magnitude.

Hence results on the acetylation of ferrocene and benzene agree well with data on the isotopic exchange of hydrogen and show that in the electrophilic substitutions ferrocene exhibits considerably greater reactivity than benzene.

2. INFLUENCE OF SUBSTITUENTS ON THE ISOTOPIC EXCHANGE OF HYDROGEN OF FERROCENE DERIVATIVES WITH ACIDS

Before the use of the method of isotopic exchange of hydrogen quantitative information on the influence of substituents on electrophilic substitution in the ferrocene series was scarce and related only to alkyl[19], phenyl[20], and acetyl[21] groups. Quantitative data on the effect of substituents of electron-donating and electron-withdrawing character on the ferrocene system were obtained with the aid of the isotopic exchange of hydrogen with acids[22]. With this aim the kinetics of isotopic exchange of hydrogen in acid medium was studied for various monosubstituted and heteroannular disubstituted ferrocenes and the overall rate constants for the isotopic exchange of the hydrogen of these compounds were determined.

If the rate constant for the hydrogen exchange of ferrocene is taken as unity, then the relative rate constants for the exchange of substituted ferrocenes is expressed by $k_{rel} = k_{fc-X}/k_{fc-H}$. Table 1 gives the relative constants for the rate of hydrogen exchange which have been found experimentally.

Table 1. Relative constants k_{rel} of the rate of isotopic exchange of the hydrogen of substituted ferrocenes.

Substituent X	Compound	
	$C_5H_5FeC_5H_4X$	$(C_5H_4X)_2Fe$
—H	1	1
—CH_3	10.7	—
—C_2H_5	10.7	50.8
—OCH_3	6.7	23.3
—C_6H_5	0.6	0.3
—Cl	$2.5 \cdot 10^{-2}$	$7 \cdot 10^{-4}$
—$COOCH_3$	$1 \cdot 10^{-3}$	—

These kinetic results on the influence of substituents on the reactivity of ferrocene derivatives showed[23] that the logarithms of the relative rate constants of the isotopic exchange of hydrogen of the monosubstituted and disubstituted ferrocenes depend linearly on the substituent constants σ_p^0 and that the correlation coefficient r has a high value ($r = 0.992$) (Fig. 2).

Hence the substituent constants σ_p^0 determined from the dissociation constants of phenylacetic acids are a quantitative characteristic of the influence of the substituent on the rate of hydrogen exchange of the ferrocene system. These substituent constants take into account the conjugation of the substituent with the aromatic system but not the conjugation of the substituent with the reaction centre.

From the linear relation between $\lg k_{rel}$ and σ_p^0 it follows that the relation between the inductive effect and the effect of conjugation of the substituent in the electrophilic hydrogen exchange of ferrocene derivatives is approximately the same as in reactions in the side chain of benzene derivatives, that is, the contribution of the conjugation of the substituent is considerably less for the ferrocene compounds than in electrophilic substitution in the benzene series.

This conclusion follows especially clearly from a comparison of the influence of the CH_3– and CH_3O-groups on the ferrocene and benzene systems.

The methyl group, exhibiting a positive inductive effect and a positive conjugation effect (+I, +C effects), increases the rate of hydrogen exchange in cyclopentadienyl rings of ferrocene to a less extent than in benzene[24]:

$$k_{C_6H_5CH_3}/k_{C_6H_6} \simeq 150;$$

$$k_{fe-CH_3}/k_{fe-H} \simeq 10.$$

The methoxy-group, exhibiting a positive conjugation effect and a negative inductive effect (+C, –I) increases the rate of hydrogen exchange in the benzene system 40 000 times[25] but in the ferrocene system by no more than 7 times, that is, the activating influence of the CH_3O group on the benzene ring and on the ferrocene ring differ by almost four orders of magnitude.

$$k_{C_6H_5OCH_3}/k_{C_6H_6} \simeq 4 \times 10^4;$$

$$k_{fe-OCH_3}/k_{fe-H} \simeq 7.$$

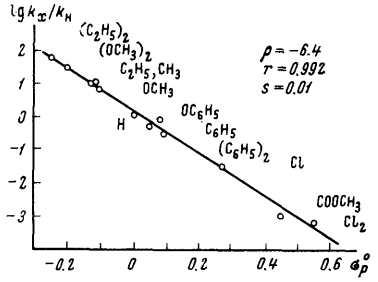

Figure 2. Variation of $\lg k_{rel}$ of hydrogen exchange on σ_p^0.

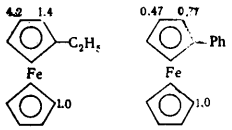
It is significant that the effect of substituents in the ferrocene series on the rate of isotopic exchange of hydrogen seemed identical with the effect of the substituents on the value of the redox potentials of the substituted ferrocenes. A linear relation was found between the logarithms of the equilibrium constants of the redox reactions and σ_p^0 by Nesmeyanov and coworkers[26] for a large number of substituted ferrocenes.

The same type of substituent effect in substitutions (isotopic exchange) and in the oxidation of ferrocene can evidently be explained by the presence in both reactions of a common reaction centre, which it is natural to assume is the iron atom.

3. INFLUENCE OF SUBSTITUENTS ON THE REACTIVITY OF THE 2-, 3-, AND 1′-POSITIONS OF CYCLOPENTADIENYL RINGS OF FERROCENE IN EXCHANGE WITH ACIDS

Quantitative information on substituent effects on the reactivity of the different positions in the cyclopentadienyl rings of monosubstituted ferrocenes is extremely scanty and, as already mentioned, is limited to data characterising the influence of alkyl, phenyl, and acetyl groups[19-21]. From these results it follows that the reaction capability of various positions in cyclopentadienyl rings (2-, 3-, and 1′-positions) is not very different for alkyl- and aryl-substituted ferrocenes. As an example, we give numerical

data on the relative reactivity of the 2-, 3-, and 1'-positions in ethyl- and phenyl-ferrocenes during acetylation[19,20].

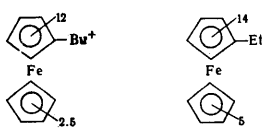


It should be noted that the determination of the reactivity of different positions of the ferrocene substituents in electrophilic substitutions involves great experimental difficulties and in several instances is impossible. For example, the influence of methoxy- and methylthio-groups on the reactivity of the ferrocene system in a Friedel–Crafts acetylation, since methoxy- and methylthio-ferrocenes seemed unstable under these conditions[27].

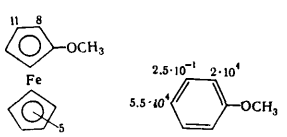
An extremely promising method of studying the reactivity of various positions in the cyclopentadienyl rings of substituted ferrocenes is evidently the method of isotopic exchange of hydrogen in conjunction with the high-resolution proton magnetic resonance (PMR) method.

The proton magnetic resonance spectra of a large number of monosubstituted ferrocenes[28] show that the differences in the chemical shifts of the signals of the protons of the 2-, 3-, and 1'-positions are rather great and consequently the deuterium content in these positions can be determined from the change in the integral intensity of the corresponding PMR signals in the isotopic exchange of hydrogen. Even for alkyl substituents, for which the differences in the chemical shifts of the corresponding protons are relatively small, success was achieved on a spectrometer with working frequency 60 MHz in separating the protons of substituted and unsubstituted rings and hence of evaluating their reactivity[29].

The values determined by this method of partial rate factors for isotopic exchange of the hydrogen of unsubstituted and substituted rings of t-butyl- and ethyl-ferrocenes with deuteriated trifluoroacetic acid have been given by Setkina[30].



The partial rate factors for electrophilic hydrogen exchange with deuteriated trifluoroacetic acid were determined in an analogous manner for the 2-, 3-, and 1'-positions in methoxyferrocene[31]. These values were 8, 11, and 5 for the 2-, 3-, and 1'-positions respectively. It is interesting that the partial rate factors for hydrogen isotopic exchange of the *o*-, *m*-, and *p*-positions of methoxybenzene under analogous conditions are 2×10^4, 2.5×10^{-1}, and 5.5×10^4 respectively[25].



The marked difference in the influence of the methoxy-group on the reactivity of ferrocene and benzene shows the deep difference in the nature of the interaction of this substituent with the electronic systems of both substances†.

4. MECHANISM OF ELECTROPHILIC ISOTOPIC EXCHANGE OF HYDROGEN IN THE FERROCENE SERIES

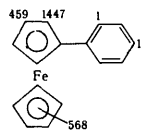
Electrophilic substitutions are characteristic of ferrocene[32]. Such a reaction capability appears clearly also in the isotopic exchange of the hydrogen atoms of ferrocene with acids[10–14]. However, the mechanism of electrophilic substitution in the ferrocene series still cannot be considered established.

In considering the mechanism of electrophilic exchange of the hydrogen of ferrocene it is necessary to settle the following questions: (1) the problem of the position of initial attack of the electrophilic reagent, (2) what are the elementary steps of the process and which of them is rate-determining, and (3) what are the nature and structure of the intermediate species and activated complex.

There is evidence that electrophilic substitution in cyclopentadienyl rings, in particular the isotopic exchange of hydrogen with acids, begins with the addition of the electrophilic reagent to the iron atom.

The formation of an addition product containing an iron–hydrogen bond by the addition of a proton to ferrocene was proved experimentally by Rosenblum and coworkers by the NMR method[12] and also by Pavlik and Šubrt by infrared spectroscopy[13]‡. Having accepted this stage as the initial one, it must be assumed that subsequent stages are the

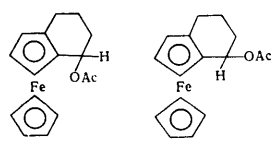
† After the present article had been sent to the press a paper appeared[81] in which values were given for the relative rate constants for the various positions of phenylferrocene in the isotopic exchange of hydrogen with trifluoroacetic acid.



Partial rate factors were determined from the change in the integral intensity of the signals of the corresponding protons in the PMR spectrum. In complete agreement with the data given above[19–21,30,31], the authors[81] concluded that the relative rates of hydrogen exchange in positions 2, 3, and 1' of ferrocene differ very little.

Pauson and coworkers[82–85] came to a similar conclusion after having investigated the aminomethylation of monosubstituted and disubstituted heteroannular derivatives of ferrocene (CH_3-, CH_3O-, and CH_3S-derivatives).

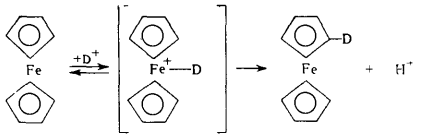
‡ The ability of the iron atom to react with electrophilic reagents agrees with other experimental results. These include, for example, data on the formation of intramolecular hydrogen bonds in ferrocenylcarbinols between the hydrogen of the hydroxyl group and the iron atom[33], between the hydrogen of a protonated carbonyl group and the iron atom in alkylferrocenylketones[34], data on the stabilisation of the carbonium centre in α-ferrocenylcarbonium ions and their conversion into radicals owing to internal single-electron transitions from the iron atom to the α-carbonium centre[35], data on the rates of solvolysis of the *endo*- and *exo*-isomers of the esters of the α-ferrocenylcarbinols A and B[36]:



endo-isomer A *exo*-isomer B

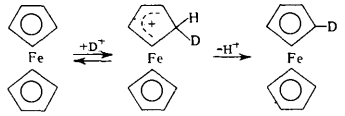
It was found that the rate of solvolysis of isomer B, in which the spatial position of the acetate group does not ensure its interaction with the iron atom (transoidal arrangement of the OAc group), is almost three orders of magnitude greater than the rate of solvolysis of isomer A, but both isomers form only the *exo*-alcohol[37].

migration of the attacking reagent into the cyclopentadienyl ring and the loss of a proton. As a result the final products of the electrophilic substitution are formed. For the isotopic replacement of hydrogen by deuterium in the action of deuterio-acids on ferrocene this final product is deuterioferrocene (scheme 1).



(1)

An alternative mechanism could be one including the immediate addition of a deuteron to the cyclopentadienyl ring (scheme 2) with the formation of a σ-complex similar to that found for aromatic compounds of the benzene series:

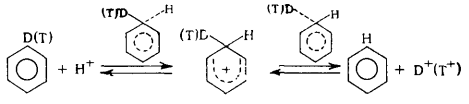


(2)

Recently kinetic isotopic effects (KIE) were used to study the mechanism of this reaction and, in particular, its rate-limiting stage. For this, the kinetics of isotopic exchange at protium of ferrocenes enriched in deuterium and tritium was investigated[38]. The following considerations applied: when the reaction proceeds by a mechanism represented in scheme 1 and its slow stage is the addition of a proton to iron and subsequent stages leading to the final product are fast, then the primary isotopic effect in this reaction should not be observed and the ratio of the rate constants of the exchange of both isotopes should approximate to unity ($k_D/k_T \simeq 1$).

On the other hand, if the reaction proceeds by a mechanism represented by scheme 2, then the kinetic isotopic effect should be observed. Actually, in the isotopic exchange of the hydrogen of benzene aromatic compounds it has been found experimentally by a large number of examples[39-42] that the ratio $k_D/k_T \simeq 2$.

The considerable KIE in the electrophilic isotopic exchange of hydrogen in aromatic compounds of the benzene series is the consequence of the difference in the rate of breaking of the C–H, C–D, and C–T bonds in the intermediate σ-complex in which the hydrogen and deuterium (tritium) atoms occupy equivalent positions (scheme 3).



(3)

However, an investigation of the kinetics of isotopic exchange of ferrocenes containing tritium and deuterium by protium when acids act on them showed that the ratio k_D/k_T here is considerably less and is 1.2[38]§. This result shows that the isotopic exchange of hydrogen in ferrocene does not proceed by mechanism 2. On the contrary, the above result agrees with mechanism 1.

However, as Hammond stated[43], the low value of the KIE can also be due to the free energies of the transition state and the intermediate compound being similar.

At the present time our information about the nature and structure of the activated complex and intermediate substances in the reaction being considered are insufficient and do not allow us to settle this question theoretically. However, in addition to the above results there are several experimental results which also support mechanism 1.

The possibility that the cyclopentadienyl nucleus exerts a specific influence on the KIE is disproved by the data obtained in studying the KIE of azulene[44]. It was shown that the KIE of azulene in electrophilic isotopic exchange of hydrogen has a normal value.

Furthermore it was found that in the protophilic substitution of hydrogen in the cyclopentadienyl rings of ferrocene in liquid ammonia with potassium amide, in which the nucleophilic reagent directly attacks the hydrogen atoms of the cyclopentadienyl rings and consequently mechanism 1 cannot occur, there is actually a significant KIE $k_D/k_T = 2.3$ (see Ref. 38).

The existence of a linear relation between the logarithm of the rate constant of the isotopic exchange of hydrogen of ferrocene and the acidity function of the medium also agrees with the fact that in the rate-determining stage of the hydrogen exchange a protonated form of ferrocene is involved.

Another fact in support of mechanism 1 is that the effect of the substituents on the redox potentials of the ferrocene–ferricinium system and on the kinetics of isotopic exchange of hydrogen in cyclopentadienyl rings is similar. This is shown by the logarithms of the rate constant of the hydrogen exchange and the logarithms of the ratio of equilibrium constants of the redox reaction of the corresponding substituted ferrocenes being linearly correlated with the same substituent constants σ_p^0.

This suggests that both reactions have the same reaction centre, probably the iron atom. Moreover, since the addition of a proton (deuteron) to the iron atom is the rate-determining stage the presence of non-equilibrium positions in the cyclopentadienyl rings will not be reflected in the kinetics of the reaction.

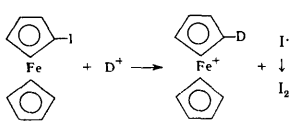
In addition it must be noted that such an explanation of the mechanism of electrophilic isotopic exchange of hydrogen in the ferrocene system encounters certain difficulties. For example, according to X-ray structural analysis the iron atom in the ferrocene compounds is shielded by the cyclopentadienyl rings (distance between the rings 3.32 Å)[45], which should hinder the approach of the attacking reagent towards it.

Quantum-chemical calculations show that the excess of electron density in the ferrocene molecule is concentrated on the cyclopentadienyl rings, and the iron atom has an excess of positive charge and consequently preferential attack of electrophilic reagents on the cyclopentadienyl rings can be expected[46,47].

The explanation of this discrepancy may be that the X-ray structural analysis and the quantum-chemical calculations consider the unexcited ferrocene molecule, present in the ground state and do not take into account the changes which occur to the molecule in the reaction process.

New facts showing the significant part played by the iron atom in the substitution were obtained[48] in studying the reaction of deuteriofluoroacetic acid with iodoferrocene.

It appeared that under these conditions the iodine is replaced by the deuteron of the acid with the simultaneous oxidation of the ferrocene to ferricinium and the detachment of the iodine as atomic iodine (scheme 4):



(4)

§ In a recent paper[86], in which a new point of view about the mechanism of electrophilic substitution in metallocenes was expressed, the value $k_H/k_D = 1.8$ was given for the hydrogen exchange of ferrocene in acid medium. If the ratio $k_H/k_D = (k_D/k_T)^{2.26}$ given by Swain and coworkers[87] is used, then $k_D/k_T = 1.3$ and consequently the values of the KIE given in Refs. 38 and 87 seem similar.

The synchronism of the processes of the replacement of iodine by a deuteron and the oxidation of ferrocene to ferrocinium shows that in the intermediate compound (or transition state) the iron atom plays an active part, with the redistribution of the electrons readily taking place in the system.

5. ISOTOPIC EXCHANGE OF THE HYDROGEN OF METALLOCENES

a. Data on the Relative Nucleophilicity of Some Metallocenes

Over sixty elements are now known to be capable of forming π-cyclopentadienyl compounds[49]. Many metallocenes have been found capable of undergoing electrophilic substitution (compounds of Fe, Mn, Re, Os, Ru, V, Cr, etc.).

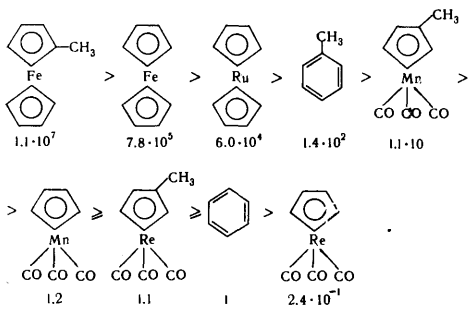
These reactions have been especially widely investigated for ferrocene, whereas other metallocenes have been considerably less studied and for many of them generally nothing is known about substitutions in the cyclopentadienyl ligands.

The failures in attempts to bring about substitution in such metallocenes are not always due to lack of reactivity but are often explained by the instability of the metallocenes under the reaction conditions.

This therefore gives rise to the quite important requirement for a sufficiently general method which will allow the reactivity of the ligands to be characterised both qualitatively and quantitatively. It was shown earlier that the isotopic exchange of hydrogen is extremely suitable for this purpose.

The possibility of changing within wide limits the acidity of the medium, on which the rate of hydrogen exchange depends to a considerable extent, allows systems which differ greatly in reactivity to be compared.

The study of the kinetics of isotopic exchange of hydrogen of certain metallocenes and their methyl derivatives and the comparison of these results with those on the isotopic exchange of benzene compounds led to the following series, in which the rate of hydrogen exchange of benzene is taken as unity and the number characterising the relative rate of hydrogen exchange of the given compound is written under its formula:



It could be expected that in other electrophilic substitutions also these systems will show approximately the same relative reactivity.

Quite recently Fischer and coworkers[50] investigated the reactions of competing Friedel–Crafts acetylation of π-cyclopentadienyl compounds of the transition metals, using the PMR method to determine the composition of the acylation products. On the basis of their results the compounds investigated are arranged in the following order of decreasing reactivity to acetylation:

$$(C_5H_5)_2Fe > CH_3OC_6H_5 > (C_5H_5)_2Ru > C_5H_5Mn(CO)_3 > (C_5H_5)_2Os > C_5H_5Cr(CO)_3NO > C_5H_5V(CO)_4 \approx C_6H_6 > C_5H_5Re(CO)_3.$$

It is essential to note that the Fischer series compiled on the basis of the qualitative data on the competing reactions of acetylation agrees completely with the series constructed on the basis of the kinetic data on the hydrogen exchange rates in acid media.

At the present moment we still do not possess the necessary facts to trace sufficiently broadly the dependence of the reactivity of the ligands on the position of the complex-forming metal in the Periodic System.

However, the results of a study of the kinetics of hydrogen exchange of the π-cyclopentadienyl compounds of the transition metals show that on going from an element of the fourth period (Mn) to an element of the sixth period (Re) in Periodic Group VII the reactivity of the π-cyclopentadienyl ligands in acid media diminishes. A similar picture is observed also for the π-cyclopentadienyl compounds of the Group VIII metals. The cyclopentadienyl derivatives of iron (fourth period) are more reactive than the corresponding ruthenium derivatives (fifth period). More detailed information on the isotopic exchange of hydrogen of some metallocenes is given below.

b. Isotopic Exchange of the Hydrogen of the Metallocenes of the Group VII Transition Metals

π-Cyclopentadienyl compounds are now known for all the transition metals of Group VII—manganese, rhenium, and technetium[51]. The greatest number of papers relate to compounds of manganese, and in particular to cyclopentadienylmanganesetricarbonyl (CMT) and its derivatives.

Electrophilic substitutions are characteristic for the cyclopentadienyl ring π-bonded to the $Mn(CO)_3$ group—alkylation[52], acylation[53], sulphonation[54], phosphorylation[55], mercuration[56], etc.

The reactivity of CMT in electrophilic substitutions was compared with the reactivity of benzene and anisole in competing acylations[57]. It was found that the compounds investigated are arranged in the following series according to their reactivity:

$$CH_3OC_6H_5 > CH_3C_6H_4Mn(CO)_3 > C_6H_5Mn(CO)_3 > C_6H_6.$$

Results which characterise the relative reactivity of CMT quantitatively were obtained in studying the kinetics of isotopic exchange of hydrogen of CMT and benzene with a mixture of deuteriated trifluoroacetic and sulphuric acids in methylene chloride solution[58].

It was found that the rate constant of hydrogen exchange of CMT is 1.3–2 times that for benzene under the same conditions.

Experiments[58] on the competing hydrogen exchange of a mixture of CMT and benzene have been described; they led to the conclusion that there was little difference in the relative reactivity of these substances.

The isotopic exchange of hydrogen with acids was used for studying the influence of alkyl substituents on the reactivity of the CMT system and these results are compared with analogous data for the benzene series (Tables 2 and 3)[59].

It appeared that the influence of electron-donating alkyl groups in CMT is much less than in benzene. The introduction of one methyl group into CMT increases the rate of

isotopic exchange of hydrogen nine times, whereas one methyl group in the benzene ring increases the rate of hydrogen exchange 155 times. Three ethyl groups in the cyclopentadienyl ring of CMT activates the deuterio-exchange less than one methyl group in the benzene ring. The rate constant of the hydrogen exchange of triethylcyclopentadienylmanganese tricarbonyl increases 126 times and the hydrogen exchange of 1,3,5-trimethylbenzene more than 7 orders. It is interesting to note that in the ferrocene series the alkyl groups activate the cyclopentadienyl ring approximately the same as for CMT. Evidently the lesser influence of the alkyl groups in the cyclopentadienyl rings of the metallocenes compared with the compounds of the benzene series has a general character and depends little on the nature of the metal connected with the cyclopentadienyl ring.

Table 2. Isotopic exchange of the hydrogen of derivatives of CMT.

Substance	Relative rate of isotopic exchange of hydrogen
$C_5H_5Mn(CO)_3$	1
$(CH_3)C_5H_4Mn(CO)_3$	9
$(C_2H_5)C_5H_4Mn(CO)_3$	5
$(C_2H_5)_2C_5H_3Mn(CO)_3$	57
$(C_2H_5)_3C_5H_2Mn(CO)_3$	126
$(C_2H_5)_4C_5HMn(CO)_3$	512
$(C_2H_5)_5C_5Mn(CO)_3$	0

Table 3. Isotopic exchange of the hydrogen of alkylbenzenes[60].

Substance	Relative rate of isotopic exchange of hydrogen
Benzene	1
Toluene	155
o-Xylene	850
Mesitylene	$135 \cdot 10^5$

It was shown recently[61] that cyclopentadienylrheniumtricarbonyl (CRT) is capable of electrophilic hydrogen exchange under the same conditions as those under which CMT undergoes this reaction.

The influence of the nature of the metals of the same group, Re and Mn, was compared by the reactivity of the cyclopentadienyl rings π-bonded with them in reactions of electrophilic isotopic exchange. The rate constants of the hydrogen exchange under the same conditions were 0.7×10^{-6} s^{-1} for CRT and 3.9×10^{-6} s^{-1} for CMT. These results show that in the reaction being considered the nucleophilic reactivity of the manganese compound is greater than that of the rhenium compound and therefore it can be expected that the rhenium compounds will also appear less reactive in other electrophilic substitutions.

On the introduction of a methyl group into the cyclopentadienyl ring of CRT the rate of electrophilic hydrogen exchange increases by approximately 5 times and consequently the activating influence of the methyl group in this system is approximately the same as in other metallocenes.

An interesting feature of the cyclopentadienyl derivatives of manganese and rhenium was their ability to undergo isotopic exchange of hydrogen in basic media (protophilic exchange) under comparatively mild conditions with ethanol in the presence of sodium ethoxide[62]. Under these conditions neither benzene nor ferrocene undergoes isotopic exchange.

An investigation of the kinetics of this reaction showed that the rhenium derivative exchanges hydrogen more rapidly than the manganese compound. The rate constant of the hydrogen exchange is 3×10^{-6} s^{-1} for CMT and 80×10^{-6} s^{-1} for CRT. It was found that exchange in alkali media, unlike electrophilic hydrogen exchange is retarded on the introduction of methyl groups into the cyclopentadienyl rings of CMT and CRT.

Hence the investigation of isotopic hydrogen exchange of cyclopentadienyl derivatives of the transition elements of Group VII showed that on going from Mn (fourth period element) to Re (sixth period element) the reactivity of the π-cyclopentadienyl ligands in electrophilic hydrogen exchange is reduced and that in protophilic is increased. The values of the relative constants of the rate of isotopic exchange are as follows:

acid medium

51.0	5.6	5.1	1.0
$CH_3C_5H_4Mn(CO)_3$	$C_5H_5Mn(CO)_3$	$CH_3C_5H_4Re(CO)_3$	$C_5H_5Re(CO)_3$
1.0	1.9	21	50

basic medium

The influence of electron-donating and electron-withdrawing substituents in the protophilic isotopic exchange was investigated in the case of monosubstituted derivatives of cyclopentadienylmanganesetricarbonyl. The overall hydrogen exchange rate constants for cyclopentadienyl ligands, which characterises their relative reactivity, are given in Table 4.[63]

Table 4. Total and relative rate constants for the isotopic exchange of hydrogen of substituted CMT compounds.

Substance	$10^4 k_{h.e.}$, s^{-1}	k_{rel}*
$C_5H_5Mn(CO)_3$	3.1	1
$CH_3C_5H_4Mn(CO)_3$	1.6	0.5
$C_2H_5C_5H_4Mn(CO)_3$	1.2	0.4
$HSO_3C_5H_4Mn(CO)_3$	8.0	2.6
$HCOOC_5H_4Mn(CO)_3$	3.4	1.1

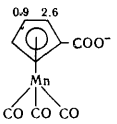
* Rate relative to the rate of exchange of CMT.

From Table 4, the influence of substituents of either donor or acceptor nature appears to be extremely weak in the cyclopentadienylmanganesetricarbonyl system.

The reason for this remarkable feature of the cyclopentadienyl system, π-bonded with a $Mn(CO)_3$ group remains vague and needs further investigation.

Very little is known about the orienting action of the substituents in the cyclopentadienyl nucleus of CMT. The only work in this field is devoted to a study of the orienting action of the carboxyl group in the CMT system in protophilic isotopic exchange[64]. The combined use of the methods of isotopic hydrogen exchange and proton magnetic resonance allowed a difference in the reactivity of the α and β positions of a carboxy-derivative of CMT to be observed. From the change in the integral intensity of the

signals of the α and β protons in the isotopic exchange the partial rate factors for exchange were determined for these positions, which were 2.6 and 0.9 for the α and β sites respectively. The ratio of the factors $f\alpha/f\beta = 2.9$ characterises the difference in reactivity of these sites:



Evidently in protophilic substitution the influence of the electron-withdrawing carboxyl group in the cyclopentadienyl ring π-bonded with the $Mn(CO)_3$ group is due mainly to an inductive effect.

c. Isotopic Exchange of the Hydrogen of Metallocenes of Transition Metals of Group VIII

As already noted, a characteristic reaction for the compounds of the ferrocene series is electrophilic hydrogen exchange, as well as other electrophilic substitutions. However, for the other Group VIII metallocenes—nickelocene and cobalticene, not even one substitution was known.

Unlike ferrocene, cobalticene and nickelocene are unstable in acid media. The rate of oxidation and decomposition of these systems evidently exceeds the rate of the substitution, as a result of which electrophilic hydrogen exchange does not exist for either cobalticene or nickelocene.

However, it was recently found that in protophilic substitution in the presence of bases nickelocene is capable of undergoing isotopic exchange of hydrogen. Thus it appeared that on treating nickelocene with diethylamine containing deuterium at the nitrogen atom, in the presence of lithium diethylamide, isotopic exchange of hydrogen takes place in the cyclopentadienyl rings of nickelocene[65]:

$$(C_5H_5)_2Ni \xrightarrow{Et_2ND,\ Et_2NLi} (C_5D_5)_2Ni\ ,$$

The rate of the hydrogen isotopic exchange of nickelocene depends on the concentration of lithium diethylamide and for example, at a lithium diethylamide concentration of 0.09 N in diethylamine solution (Et_2ND) at 25°C the rate constant of the isotopic exchange is $\sim 6 \times 10^{-5}$ s^{-1}. It is interesting to note that under these conditions neither ferrocene nor cobalticene undergoes hydrogen exchange.

Protophilic isotopic exchange of hydrogen in ferrocene has been brought about only under much more drastic conditions—in liquid ammonia in the presence of potassium amide[38].

The rate constant of the replacement of deuterium in deuterioferrocene by protium in a 0.02 N solution of potassium amide in liquid ammonia at 13°C is 9×10^{-4} s^{-1}. Under the same conditions the rate constant of the exchange of deuterium in benzene is 3×10^{-5} s^{-1}. From these results it follows that in ferrocene and benzene the hydrogen atoms exhibit considerably less acidity than in nickelocene.

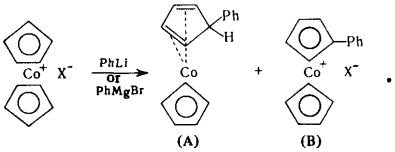
Although the hydrogen isotopic exchange of nickelocene in the presence of bases is so far the only example of substitution in this system, it can be expected that nickelocene is capable of undergoing substitution with catalysis by bases and that these reactions should proceed more readily than in ferrocene and benzene.

The replacement of hydrogen in the presence of bases could also be carried out with the isoelectronic analogue of ferrocene—the cobalticinium ion. It was found that in the reaction of cobalticinium hydroxide with deuteriomethanol in the presence of sodium methoxide cobalticinium hexachloroplatinate, isolated by treatment of the reaction products with hydrogen hexachloroplatinate, contains deuterium in the cyclopentadienyl rings[66].

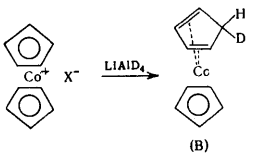
The kinetics of hydrogen isotopic exchange of cobalticinium methoxide with a 10% solution of sodium methoxide in deuteriomethanol (CH_3OD) was studied at 50°C and the rate constant of this reaction is 6.4×10^{-5} s^{-1}:

$$(C_5H_5)_2Co^+X^- \xrightarrow{CH_3OD,\ CH_3ONa} (C_5D_5)_2Co^+X^-\ .$$

An indication of the possibility of substitutions in the cyclopentadienyl rings of the cobalticinium ion was obtained earlier[67], since it was noted that with phenyl-lithium or with phenylmagnesium bromide cobalticinium salts form, as well as addition products (A), a certain proportion of phenyl-containing substitution product (B):



However, in other studies it appeared that compounds of the cobalticinium ion with nucleophilic reagents form only addition products analogous to compound A, and lithium tetradeuterioaluminate, for example, reacts with cobalticinium to form cobaltcyclopentadienylmonodeuteriocyclopentadienide (compound B) and does not form substitution products[68]:



Clearly the available information is insufficient for judging the reactivity of the cyclopentadienyl ligands in the metallocenes of nickel and cobalt, but the above examples of the replacement of hydrogen in these systems provide a basis for assuming that they are capable of undergoing other base-catalysed substitutions.

6. ISOTOPIC EXCHANGE OF HYDROGEN IN THE AROMATIC RINGS OF ARENECHROMIUM TRICARBONYLS

The simplest representative of the arenechromiumtricarbonyls—benzenechromiumtricarbonyl—was obtained by Fischer and Öfele in 1957.[69] A considerable number of representatives of this type of compound have now been listed but their reactions, and especially substitutions in the aromatic ring, have been little studied.

It has been found that electrophilic substitution in arenechromiumtricarbonyl complexes, and particularly Friedel–Crafts acetylation, takes place with much more difficulty than in the corresponding aromatic compounds[70]. However, nucleophilic substitutions take place more readily in these systems than in arenes. For example, the chlorine in chlorobenzenechromiumtricarbonyl is smoothly replaced by the methoxy-group with sodium methoxide in methanol[71]. Quantum-chemical calculations of Brown predict greater ease of nucleophilic replacement in arenechromiumtricarbonyls than in arenes, which agrees with the experimental facts.

One of the cardinal problems of the chemistry of arene complexes of transition metals is the question of how the blocking of the π-electrons of the aromatic ring by the atoms of the transition metals affects the properties of the aromatic system. In particular, it is important to find how the reactivity of an aromatic system π-bonded with a transition metal atom changes and how the electronic effects of the substituents in such systems are passed on.

It is evident that a comparison of the properties of the compounds of the series of benzene and π-arene complexes with the chromiumtricarbonyl group can give valuable information in this respect. Such a type of investigation was made, in particular, by Fischer and coworkers[70]. The Friedel–Crafts acylation of toluenechromiumtricarbonyl and toluene was compared. It was found that the content of the *o*-, *m*-, and *p*-isomers in the acylation products is quite different for toluene and its complex with chromiumtricarbonyl group. Whereas for toluene the proportions of the *o*-, *m*-, and *p*-acetyl substituents were 1.2, 2.0, and 96.8%, for toluenechromiumtricarbonyl they are 43, 17, and 40% respectively.

The much smaller difference in reactivity of the *o*-, *m*-, and *p*-positions of alkyl-substituted arenechromiumtricarbonyls in comparison with the corresponding alkylarenes in the acylation was also noted by Jackson and Jennings[73]. Fritz and Kreiter[74] came to the same conclusion on the basis of studies of the PMR spectra of disubstituted arenechromiumtricarbonyls.

Interesting possibilities for the quantitative study of the transmission of the influence of the substituent in the benzene ring π-bonded with a transition metal atom were presented after it had been observed that the hydrogen atoms in benzenechromiumtricarbonyl are capable of undergoing isotopic exchange with deuterioalcohols or deuterioamines in the presence of bases[75].

It was found that at 100°C in a 10% solution of sodium ethoxide in deuterioethanol the rate constant for isotopic exchange of the hydrogen of benzenechromiumtricarbonyl is $\sim 1.0 \times 10^{-5}$ s^{-1}. It is interesting that benzene itself under such conditions does not undergo isotopic exchange of hydrogen.

Quantitative characterisation of the effect of substituents on the reactivity of the *o*-, *m*-, and *p*-positions of the monosubstituted benzene ring π-bonded with the $Cr(CO)_3$ group were obtained by the combined use of isotopic exchange of hydrogen and proton resonance methods[76,77]. It appeared that in an aromatic ring π-bonded with the $Cr(CO)_3$ group the influence of the substituent in protophilic hydrogen exchange is extremely weak and the difference in the reactivity of the *o*-, *m*-, and *p*-positions of the ring is also very low. Table 5 shows the partial rate factors for isotopic exchange at the various positions of the aromatic ring in toluenechromiumtricarbonyl[76] and anisolechromiumtricarbonyl[77].

For comparison Table 5 also gives partial rate factors for the non-equilibrium positions in toluene and anisole found by Shatenshtein and coworkers[78] in a study of the isotopic exchange of hydrogen of these compounds in liquid ammonia in the presence of potassium amide. These results show that the influence of the methyl, and particularly the methoxyl, group in arenechromiumtricarbonyls is considerably weaker than in the corresponding arene.

Whereas the partial rate factors in anisolechromiumtricarbonyl differ by only a factor of 3, this difference is much greater for anisole.

An investigation of the isotopic exchange of hydrogen of arenechromiumtricarbonyls containing electron-donating (Me_2N–, CH_3–) and electron-withdrawing (CH_3COO–) substituents (Table 6) gave remarkable results: the overall rate constants of hydrogen exchange of arenechromiumtricarbonyls containing substituents with opposite electronic effects do not differ much[77]. Consequently, the influence of different substituents in protophilic hydrogen exchanges in arenechromiumtricarbonyls complexes is weak.

Table 5. Factors of the partial rate of isotopic exchange of the hydrogen of arenechromiumtricarbonyls and arenes.

Compound	Factors of the partial rate of hydrogen exchange			Reaction conditions	Reference
	f_o	f_m	f_p		
$CH_3C_6H_5Cr(CO)_3$	0.3	1.1	1.1	EtOD + 10%	76
$CH_3OC_6H_5Cr(CO)_3$	4.8	1.6	2.5	EtONa 100°	77
$CH_3C_6H_5$	0.2	0.4	0.4	$ND_3 + KND_2$	78
$CH_3OC_6H_5$	500	1	0.5	13°	78

It is interesting to remember that the weak influence of substituents on the reactivity of the cyclopentadienyl rings bound to the $Mn(CO)_3$ group was also noted in studying the reactions of protophilic isotopic exchange in the cyclopentadienylmanganesetricarbonyl system. Despite the fact that quantitative data characterising the reactivity of the arene complexes of chromium are even fewer, nevertheless hydrogen isotopic exchange studies on this system suggest that the electronic effect of the substituents in the benzene ring is much more pronounced than in the system where the benzene ring is π-bound with the $Cr(CO)_3$ group.

Table 6. Total rate constants of isotopic exchange of the hydrogen of arenechromiumtricarbonyls[76,77].

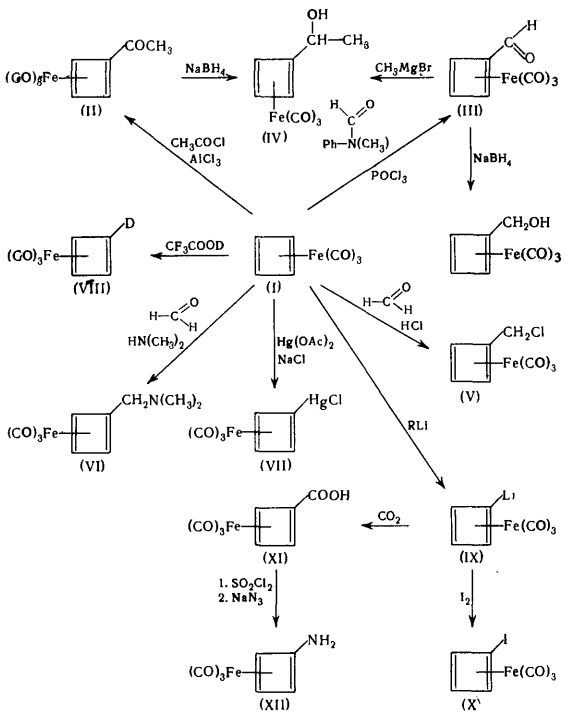
Substance	$10^5 k_{h.e.}$, s^{-1}
$C_6H_6Cr(CO)_3$	1.1
$(CH_3)C_6H_5Cr(CO)_3$	1.4
$(CH_3)_2N{-}C_6H_5Cr(CO)_3$	0.3
$CH_3OC_6H_5Cr(CO)_3$	2.8
$CH_3OCOC_6H_5Cr(CO)_3$	0.8

It is extremely probable that the levelling of the differences in the strength of the orientating action of the substituents in π-bonded aromatic ligands is a common phenomenon.

7. ISOTOPIC EXCHANGE OF HYDROGEN IN CYCLOBUTADIENEIRONTRICARBONYL

In 1965 Pettit and coworkers[79] obtained the first stable complex of cyclobutadiene with irontricarbonyl. It was found that this new complex exhibits aromatic properties and readily undergoes electrophilic substitution[80].

The authors were able to effect most of the usual electrophilic substitutions—acetylation, aminomethylation, chloromethylation, mercuration, etc. (see the scheme, I–XII).



The isotopic exchange of hydrogen with deuterium-enriched trifluoroacetic acid was also studied and it was found that even after a few minutes, in addition to the monodeuterio-derivative, more extensively deuteriated derivatives of cyclobutadieneirontricarbonyl are also formed (see the scheme, VIII).

These investigations led the authors to conclude that the reactivity of cyclobutadieneirontricarbonyl in electrophilic substitutions is very similar to the reactivity of ferrocene, both systems being considerably more reactive than benzene.

Copper and Silver Acetylides in Organic Synthesis

A.M.Sladkov and L.Yu.Ukhin

A review of the reactions of copper, silver, and gold acetylides with halides, aryl halides, unsaturated halogen compounds, diazonium salts, halides of organic acids, and organometallic compounds. Information on the structure of copper and silver acetylides and their physical properties is given. The mechanisms of the reactions of copper acetylides with the above types of compounds and the mechanism of the oxidative condensation of acetylenes are considered. The properties of copper and silver acetylides are compared with the properties of the cyanides of these metals. Bibliography of 127 references.

I. INTRODUCTION

In 1955, Braude, in considering the progress reached in organometallic synthesis, noted two important stages—the discovery of the organomagnesium compounds by Grignard and the development by Ziegler of the chemistry of organolithium compounds. Approximately 25 years after the discovery of the organolithium compounds, Ziegler investigated the organic compounds of aluminium and introduced them into the practice of organometallic synthesis.

And now these three classes of organoelemental compounds are of importance in organometallic synthesis. In addition the unceasing search in the field of reactions of other organoelemental compounds is evidence that the use of organic compounds of other elements is necessary to solve many particular and some general problems of synthetic organic chemistry.

Even as long ago as 1959 at the VIIIth Mendeleev Conference on General and Applied Chemistry, A. N. Nesmeyanov noted that the intensive investigations of the last decade had allowed almost all the known types of organoelemental compounds to be introduced into the practice of organic synthesis; organoelemental chemistry, which had been separated as an independent branch of organic chemistry was reunited with it again on another, more modern, level.

The impression is created that there is now an accumulation of experimental material and of its generalisation in the field of the reactions and properties of many organoelemental compounds. It must be expected that the development of the chemistry of certain of these compounds will lead to the emergence of a new stage in the development of organometallic synthesis.

Of such compounds the organic compounds of copper merit attention. An investigation of the aryl and alkyl compounds of copper showed the possibility of their use in organic synthesis. However, the ethynyl compounds of copper were of the most interest, owing to their relative stability and promise of application. Copper acetylides have already come to be regarded as common reagents in organic synthesis. Oxidative condensation of acetylenes was recently examined in several extensive reviews. Information published recently about certain reactions of the copper acetylides reflects the great interest in these compounds. Evidently the acetylides of the bisacetylene derivatives present a unique possibility for the synthesis of individual poly-ynes and of polymers, the chain of which consists of conjugated carbon–carbon groupings with triple bonds.

Because of this we thought it timely to review the information on the synthesis, structure, and reactions of the copper and silver acetylides.

II. ACETYLIDES OF ACETYLENE

The first information on copper acetylides was published by Böttger[1] in 1859. On passing illuminating gas through an ammoniacal solution of copper(I) chloride he observed the formation of a cinnabar-red precipitate, explosive when dry. Some of the reactions of copper acetylide led the author to suggest that he had obtained a substance containing copper, carbon, and very little hydrogen. In particular it was found that under the action of potassium cyanide and hydrochloric acid the precipitate is decomposed with evolution of a gaseous hydrocarbon burning with a very smoky flame. Analogous compounds were obtained with salts of silver(I) and gold(I). A year later Berthelot[2] purified the hydrocarbon obtained from the copper acetylide, investigated it, and named it acetylene.

From the moment of discovery of the acetylides their intensive investigation began. Finding the composition and structure of the acetylides became the theme of a series of investigations, but immediately a large number of contradictions arose, both in the results of the experiments and also in their treatment. A detailed review of the work at the end of the XIXth century and the beginning of the XXth century was given in a monograph[3]. It seems desirable in the present review to pay attention mainly to the latest studies in this field, referring to the older studies mainly as illustrative material.

The most widespread of the methods for obtaining the copper acetylides, including also those for analytical purposes, was developed by Ilosvay[4]. He proposed reagents which stored well, prepared by the reduction with hydroxylammonium chloride of ammoniacal solutions of copper(II) chloride, sulphate, or nitrate. Keiser[5] showed that copper acetylides, unlike the silver acetylides, always contain a certain amount of elemental carbon and explained its formation by the oxidising action of atmospheric oxygen. He obtained the purest specimen of copper acetylide in the reaction of acetylene with copper hydroxide (CuOH)

suspended in water. The analyses were in complete agreement with the formula Cu_2C_2 for copper acetylide and Ag_2C_2 for silver acetylide.

Klement and Ködermann-Gros[6], who obtained copper acetylide in the absence of oxygen, consider that ammoniacal solution first deposits a non-explosive red acetylide of composition $Cu_2C_2.H_2O$, which in air is partly oxidised and loses water, being converted into a black, extremely explosive acetylide. Brameld and coworkers[7] obtained acetylides from various copper(I) salts in alkali and acid media in an atmosphere of nitrogen. The acetylides obtained in an ammoniacal medium from Cu_2Cl_2 and dried in a vacuum over H_2SO_4 and P_2O_5 had a C/Cu ratio in the range 0.94–1.2, depending on the alkalinity of the ammoniacal solution.

In Easterbrook and Erskine's comprehensive review[8] it was noted that slight variations in the method of preparation are reflected in the composition of the acetylide. The time of passing (or the flow rate) of the acetylene and the possibility of oxidation had a considerable effect. Even the dry acetylide is slowly changed on storage in the air with normal humidity, $Cu(OH)_2$ and a carbonaceous substance being formed. The authors[8] found that the copper acetylide obtained by passing acetylene into an ammoniacal solution of copper(I) salt contains on average 91–93% of an acetylide of the empirical formula $(Cu_2C_2)_2.H_2O$, 4–6% $Cu(OH)_2$, and 3–5% of a carbonaceous substance. On raising the acetylene flow rate the proportion of the carbonaceous substance is raised to 5–6%, but that of $Cu(OH)_2$ falls.

The above investigations were carried out with acetylides obtained in alkaline solutions. This is a comparatively simple example, where in the main the process is always the replacement of the acetylenic hydrogen by the metal. The reactions of acetylene with copper and silver salts in neutral or acid media are much more complicated.

The first indications of the formation of insoluble acetylenic compounds in dilute neutral aqueous solutions of Cu_2Cl_2 is in Bertholet's work[9]. Chevastelon[10] obtained the acetylide $C_2Ag_2.AgNO_3$ from neutral silver nitrate solution. The passage of acetylene into an acidified aqueous or alcoholic solution of copper(I) chloride led to the formation of colourless crystals, the composition of which was close to the formula $C_2H_2.Cu_2Cl_2$.[11] Chevastelon also isolated more complex compounds: white $C_2H_2.2Cu_2Cl_2.KCl$ and yellow $C_2H_2.4Cu_2Cl_2.2KCl$.[12]

Manchot and coworkers[13,14] found that on treatment of a hydrochloric acid solution of copper(I) chloride with acetylene a transparent solution of an addition product is formed initially, which is then converted into a violet precipitate of composition $Cu_2C_2.CuCl.H_2O$, with liberation of acetylene.

Various authors have described a large number of compounds isolated from neutral and acid solutions of silver salts but the formulae proposed for some of them (for example, $4Ag_2S_2O_3.Na_2S_2O_3.8Ag_2C_2.13C_2H_2$ [15]) raise doubts as to the individuality of the products.

The variety, and often the contradiction, in the results on the composition and structure of the acetylides reflects the complexity of the work with these substances. The explosive tendency and low solubility often do not permit the usual methods of purification to be used. At the same time the voluminous precipitates which are formed can absorb and retain firmly various impurities on the surface. The sensitivity of the acetylides to the action of oxidants and also the possibility of the conversion of the compounds formed in the presence of an excess of one of the reagents creates additional difficulties for investigators. All this evidently led in a series of instances to mixtures being described as pure substances and the adsorbed impurities being included in the composition of the acetylides.

In this connection a series of studies by Vestin and coworkers[16-24], in which the authors examine the acetylene compounds of silver and copper as analogues of sparingly soluble inorganic salts and determine the conditions of formation and existence of various compounds by measurement of equilibria, is of interest. This was usually possible. For example, by starting from the equation for the formation of silver acetylide

$$C_2H_2 + 2\,Ag^+ \rightleftarrows C_2Ag_2\,(solid) + 2\,H^+ \quad K_1 \qquad (1)$$

an expression can be written for the equilibrium constant:

$$K_1 = \frac{[H^+]^2}{[C_2H_2]\cdot[Ag^+]}.$$

When Eqn. (1) is written in the form

$$H^+ + {}^1/_2\,C_2Ag_2\,(solid) \rightleftarrows {}^1/_2\,C_2H_2 + Ag^+ \qquad (2)$$

then

$$K = \frac{[Ag]\cdot[C_2H_2]}{[H^+]} = \frac{1}{K_1}.$$

Hence

$$\lg K = \lg[Ag^+] + {}^1/_2\,\lg[C_2H_2] - \lg[H^+]$$

$$pK = -\lg K = -\lg[Ag^+] - {}^1/_2\,\lg[C_2H_2] - \lg[H^+],$$

or

$$pK = (pAg - pH) + {}^1/_2\,pP_A,$$

where P_A is the partial pressure of acetylene in the gas mixture and (pAg – pH) the difference in potentials between silver and glass electrodes. All these three quantities can be measured directly. As a result of the investigations it was shown that in ammoniacal aqueous solutions of silver salts Ag_2C_2 is precipitated but usually complexes are not formed. It is suggested that the yellow and white silver acetylides are modifications distinguished by size of the colloidal particles. Ag_2C_2 was also obtained by the reaction between dry silver acetate and acetylene:

$$2\,CH_3COOAg + HC{\equiv}CH \rightarrow 2\,CH_3COOH + AgC{\equiv}CAg.$$

Of the complex silver acetylides described earlier the individuality of the following were confirmed: $C_2Ag_2.AgNO_3$, $C_2Ag_2(AgNO_3)_6$, $C_2Ag_2.AgCl$, $C_2Ag_2.Ag_2SO_4$, and another two were obtained $C_2Ag_2.HPO_4$ and $C_2Ag_2.(AgClO_4.H_2O)_2$. All the compounds are colourless and crystallise well. The perchlorate and nitrate (1 : 1) detonate with considerable force, the others weakly.

Some authors[16-24] suggested the existence of soluble acetylene compounds of silver $(C_2Ag_2)_n.(Ag^+)_m$. The dissolution of a certain amount of acetylene in concentrated solutions of silver salts without the formation of a precipitate was noted, whereas an increase in the pH suggested the chemical bonding of acetylene. It was noted[25] that not a single silver complex is known in which the acetylene would retain both hydrogen atoms. Neither could a non-symmetrical silver acetylide be obtained[16,24]; it was shown[16] that information about the existence of complexes containing such an acetylide is unreliable. Any asymmetric copper compound of the type $HC{\equiv}CCu$ has also not been identified. The red copper acetylide obtained from ammoniacal solutions of copper salts or from dilute solutions of CuCl in an aqueous solution of alkali metal chloride

was found to have the composition Cu_2C_2 and reports of the existence of the hydrate $Cu_2C_2.H_2O$ were considered erroneous by these authors.

The complexity and variety of the compounds formed in neutral and acid media is shown by the example of the C_2H_2–CuCl–KCl–H_2O system from which no less than six solid and four dissolved compounds of acetylene can be prepared. Österlöf's[25] results on the existence of the colourless crystalline compounds $C_2H_2(CuCl)_3$ and $C_2H_2(CuCl)_2$ were confirmed.

An investigation of the violet complex, to which Chevastelon ascribed the formula $C_2H_2.Cu_2Cl_2.Cu_2O$ but Manchot and coworkers[14] $C_2Cu_2.CuCl.H_2O$, showed that this complex contains Cu_2C_2, and the ratio Cu_2C_2 : CuCl equals unity, which supports the Manchot formula. The existence of several compounds of the type $(C_2Cu_2).(CuCl)_m$ was suggested.

It was found that in a neutral concentrated solution of KCl (or NH_4Cl) and CuCl acetylene forms a yellow crystalline precipitate for which the formula $M_2[C_2(CuCl)_8]$, where $M^+ = K^+$, NH_4^+, was proposed[19]. There are grounds for considering that the violet and yellow complexes are in equilibrium:

$$Cu_2C_2 \cdot CuCl\ (solid) + 5\ CuCl + 2\ KCl \rightleftarrows K_2[C_2(CuCl)_8]\ (solid).$$

It was found subsequently that both in solution and in the solid phase compounds of two types can be formed—acetylides (bright yellow) and molecular (colourless)[20], the first in alkaline solutions, the second in neutral and acid. The results obtained suggest that in the HCl–CuCl–H_2O and HCl–$HClO_4$–CuCl–H_2O systems there are soluble complexes $CH_2.CuCl$, $C_2H_2.CuCl_2$, and $C_2H_2Cu^+$. In aqueous solutions CuCl–MCl (M = alkali metal) which contain an insignificant amount of the base, a small quantity of acetylene brings about an intense yellow coloration. The concentration of the yellow product is determined by the equilibrium, which can be written in the form:

$$C_2H_2 + n\,CuCl \rightleftarrows C_2(CuCl)_n^{-2} + 2\,H^+$$

where n lies in the range 6–8.

These results are correlated with the existence of solid complexes $M_2[C_2(CuCl)_8]$, which are readily soluble for Na^+ and Li^+, and poorly soluble for K^+ and NH_4^+.

In connection with the nature of the acetylene–metal bond it was shown[21] that copper molecular compounds of acetylene are probably close to the corresponding alkenic compounds, that is, they are π-complexes. As for the acetylenic complexes, there is only the general view that they should contain a special type of C–M bond.

The first report of the synthesis of a copper(II) acetylide belongs to Söderbaum[26]. By passing acetylene into ammoniacal solutions of various copper(II) salts he obtained a black explosive substance with the approximate molar ratio C : Cu = 2. The formulae proposed on the basis of the analytical results—the approximate $nC_6Cu_3.H_2O$ and the more accurate $nC_{17}Cu_8H_4O_3$, make it extremely doubtful that the substance is an individual and the fact that only a little acetylene is liberated under the action of hydrochloric acid, most of the carbon being converted into a humus-like substance—suggest that the product obtained is not a copper(II) acetylide.

Easterbrook and Erskine showed[8] that the precipitate obtained on passing acetylene into an ammoniacal solution of $CuCl_2$ does not contain copper(II) but is a mixture of Cu(I) acetylides and poly-ynes.

Nast and Pfab[27] obtained copper(II) acetylide in liquid ammonia by the reaction:

$$[Cu(NH_3)_4](NO_3)_2 + 2\,KC_2H \rightarrow CuC_2 + C_2H_2 + 2\,KNO_3 + 4\,NH_3.$$

The authors consider that they had isolated the compound described earlier by Söderbaum. With acid a carbonaceous residue is also formed. The only analysis for copper, made a day after obtaining the precipitate, gave a 2.7% difference from theory. We think that the results given are completely insufficient for drawing a definite conclusion about the nature of the product obtained.

By the reaction of acetylene with aqueous solutions of copper(II) salts Brameld and coworkers[7] obtained a precipitate whose composition and appearance varied with the anion, the pH of the medium, and the nature of the alkali. For products formed in ammoniacal solutions the C : Cu ratio was 2.7–2.8, for those formed in NaOH solutions, 1.99–2.07. Silvery grey, extremely explosive plates with ratio C : Cu = 2.18 separated from concentrated ammoniacal and acetic acid solutions of copper(II) acetate.

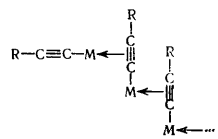
However, not one of the compounds described corresponds to the formula CuC_2—the discrepancy between the analyses and theory is always < 20%, hence here also there is also either a mixture or a compound of more complicated structure containing other components as well as C and Cu.

Feitknecht and Hugi-Carmes[28] made a detailed study of the conditions for the formation of red and black copper acetylides and even attempted to investigate the structure of these products by an X-ray diffraction method. The authors found that the acetylide precipitates obtained by Brameld and coworkers[7] from ammoniacal solutions of copper(II) sulphate and acetate, give identical X-ray diagrams, irrespective of their appearance. They did not observe bivalent copper in the acetylides obtained from solutions of copper(II) salts.

III. STRUCTURE OF ACETYLIDES

Favorskii[29] first made a cryoscopic determination of the molecular weight of copper t-butylacetylide and found that it is an octamer in benzene. The same result was obtained by ebullioscopy[30].

Calvin and coworkers[31,32] suggested that copper(I), silver(I), and gold(I) acetylides are coordination polymers in which each metal atom is π-bound with at least two acetylenic groupings. The electrons are drawn from the π_u-bonding acetylenic orbitals to the metal and from the filled d-orbitals of the metal to the unoccupied π_g-antibonding orbitals of the acetylene:



where $M^+ = Cu^+$, Ag^+, Au^+.

Both these effects should decrease the order of the C≡C bond and lead to a decrease in its frequency. Coates and Parkin[30,33] investigated the infrared spectra of copper and silver acetylides. It is known that disubstituted acetylenes absorb light in the range 2190–2260 cm^{-1}, owing to the stretching vibrations of the C≡C bond[34].

The characteristic frequency of the triple bond in the π-complex of di-t-butylacetylene with platinum is decreased[35] by 200 cm^{-1} and analogous effects are noted in transition metal complexes with alkenes[36]. In confirmation of the fact that copper acetylides are coordination polymers it was found[30,33] that these compounds absorb light in the range 1920–1960 cm^{-1}, that is, the frequency of the C≡C stretching vibrations lies 270–300 cm^{-1} lower

than in disubstituted acetylenes. The depression of the frequency is somewhat less appreciable in silver and gold acetylides (by 150–200 cm^{-1}).

The X-ray diffraction investigation of the acetylides of acetylene showed that they were crystalline but the smallness of the particles prevented any decisions concerning structure. Thus, according to the X-ray powder diagram Ag_2C_2 is a distinctly crystalline substance consisting of agglomerates of particles with a size of $> 0.1\ \mu$.[24] X-Ray diffraction data for the acetylides have also been published elsewhere[28,33].

Copper(I) and silver acetylides and cyanides have much in common. The electrons which form the coordinate bond in acetylides are the π-electrons of the acetylene groups, and in cyanides, the free pair of p-electrons of the nitrogen atom. Unfortunately, there is no information about the value of the characteristic frequency of the stretching vibrations $\nu_{C\equiv N}$ for the complexes of copper cyanide with electron-donating ligands, for which evidently an effect opposite to that observable in the infrared spectra of acetylide complexes can be expected.

Terenin and coworkers[37] showed that $\nu_{C\equiv N}$ in nitriles is increased in the formation of complexes with Lewis acids ($SnCl_4$, $AlCl_3$, etc.), copper in the cyanide can be regarded as a Lewis acid in relation to the nitrogen of the other molecule; if such an analogy is correct the release of the pair on the nitrogen should lead to a decrease in $\nu_{C\equiv N}$.

Brune and Zeil[38] consider that in nitriles the carbon of the C≡N bond group is in an sp-hybrid state, as in the acetylenes, but the nitrogen is not hybridised. In confirmation of the pair on the nitrogen having an s-character and not participating in the hybridisation as in amines the authors refer to the low basicity of the nitriles and the absence of $n \rightarrow \pi^*$ transitions in their ultraviolet spectra. Hence the σ-bond in the C≡N group will be formed by the sp-hybrid orbital of the carbon and one p-orbital of the nitrogen, but the π-bond from the C π-electrons and the N p-electrons. During coordination sp-hybridisation also appears at the nitrogen.

From quantum-chemical considerations the sp–sp bond is more stable than the sp–p bond. This is due to an increase in the strength of the bond inside the C≡N group on going from free nitrile to coordination-bound, and to the increase in $\nu_{C\equiv N}$.

However, the difference in the structure of the copper(I) acetylides and cyanide has more effect on the reactivity than on the nature of the processes which take place—copper cyanide is usually more active than acetylides in the various reactions.

IV. CHEMICAL PROPERTIES OF ACETYLIDES

1. Reactions with Formation of Acetylide Ions

The investigation of the chemical properties of the acetylides was begun by Böttger[1], who found that on treating copper acetylide with potassium cyanide a hydrocarbon is liberated, which burns with a very smoky flame. The reaction is:

$$Cu_2C_2 + 2\,KCN + 2\,H_2O \rightarrow 2\,CuCN + HC\equiv CH + 2\,KOH\,. \qquad (3)$$

In this reaction copper acetylide behaves as a sparingly soluble salt which is characterised by a definite solubility product. The bonding of the copper ions by the cyanide ions leads to a shift of the equilibrium to the right but the hydrolysis of the acetylide ion makes this process irreversible. Since the solubility product of the acetylide is scarcely greater (and usually much less) than of copper cyanide (10^{-14})[39] the occurrence of the reaction is evidently due to the formation of complex cyanides of copper $[Cu(CN)_3]^{2-}$ and $[Cu(CN)_4]^{3-}$. The instability constants of these ions are each[40] 5×10^{-28}. An approximate calculation shows that the copper ion concentration thus created in 1 M solutions is approximately seven orders of magnitude below the Cu^+ concentration in saturated CuCN solutions. Hence, Eqn. (3) is the overall process for the following reactions:

$$Cu_2C_2 \rightleftarrows 2\,Cu^+ + C_2^{2-}, \qquad (a)$$

$$2\,Cu^+ + 6\,CN^- \rightleftarrows 2\,[Cu\,(CN)_3]^{2-}, \qquad (b)$$

$$C_2^{2-} + K^+ + H_2O \rightleftarrows C_2H_2 + 2\,KOH\,. \qquad (c)$$

Like copper cyanide, acetylides are capable of the formation of ionic complexes with acetylenic groups as ligands. Nast and coworkers obtained several such compounds by the action of alkali metal acetylides on the acetylides of copper(I),[27] silver(I),[41] and gold(I),[42] in liquid ammonia:

$$M_2\,[Cu\,(C\equiv CR)_3] \text{ and } M\,[Cu\,(C\equiv CR)_2]\,,$$

where M = Na, K; R = H, CH_3, C_6H_5;

$$K\,[Ag\,(C\equiv CH)_2] \text{ and } K\,[Ag\,(C\equiv CR)_2]\,,$$

where R = CH_3, C_6H_5; and

$$K\,[Au\,(C\equiv CH)_2],\ K\,[Au\,(C\equiv CPh)_2]\,.$$

The bifunctionality of acetylene imparts a singularity to this class of acetylide complexes, making possible the existence of μ-complexes, unknown for cyanides:

$$K_2\,[HC\equiv C—Au—C\equiv C—Au—C\equiv CH]\,.$$

An interesting complex acetylide of Cu^0 was obtained[43] by the reduction of $K_2[Cu(C\equiv CPh)_3]$ with metallic lithium in liquid ammonia and precipitation with $Ba(CNS)_2$. The infrared spectrum and diamagnetism of this compound $Ba_3[Cu(C\equiv CPh)_3]_2$ allowed its anion to be ascribed the dinuclear structure:

$$[(PhC\equiv C)_3\,Cu—Cu\,(C\equiv CPh)_3]^{6-}.$$

Whereas cyanide ions stabilise copper(II) cyanide, by forming the anionic complexes $[Cu(CN)_4]^{2-}$ the complex acetylides of copper(II) are evidently even less stable than its simple acetylenic compounds. Attempts to obtain complex acetylides of copper(II) ended in failure. In the reaction of $[Cu(NH_3)_4].(NO_3)_2$ with KC≡CH in liquid ammonia instead of the expected complex acetylide a black, very explosive precipitate is formed, which the authors consider[27] to be copper(II) acetylide, CuC_2:

$$[Cu\,(NH_3)_4]\cdot(NO_3)_2 + KC\equiv CH \rightarrow 2\,CuC_2 + C_2H_2 + 2\,KNO_3 + 4\,NH_3\,.$$

Quantitative reduction of Cu^{II} to Cu^{I} takes place with potassium methylacetylide and phenylacetylide:

$$2\,[Cu\,(NH_3)_4]^{2+} + 4\,(C\equiv C—CH_3)^- \rightarrow 2\,CuC\equiv C—CH_3 + H_3C—C\equiv C—C\equiv C—CH_3\,.$$

The reaction takes place in stages. A mixed salt of copper(I) and copper(II) is formed as an intermediate:

$$3\,[Cu\,(NH_3)_4]^{2+} + 6\,(C\equiv CPh)^- + NH_3 \rightarrow [(Cu\,(NH_3)_4]\cdot[Cu\,(C\equiv CPh)_2]_2\cdot x\,NH_3 + \\ + PhC\equiv C—C\equiv C—Ph + 8\,NH_3$$

which decomposes on distilling off the solvent, with reduction of the copper(II) and dimerisation of the acetylene radicals:

$$[Cu\,(NH_3)_4]\cdot[Cu\,(C\equiv CPh)_2]_2\cdot x\,NH_3 \rightarrow \\ \rightarrow 3\,CuC\equiv CPh + (x+4)\,NH_3 + {}^1/_2\,Ph—C\equiv C—C\equiv C—Ph\,.$$

All the complex acetylides of Cu copper(I), unlike the cyanide complexes, are extremely sensitive to moisture, which is due to the acidic properties of the alkynes being much weaker than those of even such a weak acid as HCN ($K = 4.8 \times 10^{-10}$).

2. Complexes with Electron-Donating Molecules

Like most of the compounds of copper(I), the acetylides tend to form complexes with molecules which are donors of a free pair of electrons. However, these complexes are usually considerably less stable than the corresponding derivatives of inorganic copper(I) compounds.

In liquid ammonia many acetylides form colourless insoluble ammines, stable only at low temperatures. Thus, copper phenylacetylide[27] forms the compound $C_6H_5C{\equiv}CCu.NH_3$. The analogous compound of copper cyanide, $CuC{\equiv}N.NH_3$, on being dried in a vacuum, is completely stable in dry air under ordinary conditions[44]. Copper phenylacetylide can be slowly extracted with isopropylamine[33].

Silver phenylacetylide dissolves in various amines and with isopropylamine it forms the complex $Pr^iNH_2.AgC{\equiv}C-Ph$, which rapidly loses the amine in air[31].

Gold acetylides form much more stable ammines. In the reaction of a solution of AuI in liquid ammonia—polymeric $(AuI)_n$ dissolves in liquid ammonia to form $AuI.6NH_3$—with potassium acetylide a yellow-white explosive ammine complex $Au_2C_2.xNH_3$ is precipitated, which after 4 h in a vacuum at room temperature is converted into a black-brown $Au_2C_2.xNH_3$, insensitive to moisture but extremely explosive[42]. With phenylacetylene, an aqueous ammoniacal solution of $Na_3[Au(S_2O_3)_2].2H_2O$ forms white, diamagnetic, light-sensitive $AuC{\equiv}C-C_6H_5.NH_3$, sparingly soluble only in liquid NH_3.[44]

It has been noted[27] that a suspension of dry Cu_2C_2 in liquid NH_3 is indifferent to CO. On passing dry, pure carbon monoxide into a suspension of copper methylacetylide or phenylacetylide in liquid ammonia a colourless solution of an adduct of the acetylide with CO is formed. The vaporisation of ammonia leads to the decomposition of the compound into the acetylide and carbon monoxide[45].

The copper(I) carbonyl cyanide is also unstable. With the similarly obtainable carbonyl acetylides at −79°C it decomposes with liberation of CO, even at the boiling point of liquid ammonia. Carbon monoxide is displaced from it even on blowing nitrogen through the solution[44].

A suspension of gold phenylacetylide in liquid ammonia, unlike copper phenylacetylide, does not react with CO, that is, it behaves analogously to copper acetylide[42].

On adding *p*-toluisonitrile to an ether–pyridine suspension of copper phenylacetylide at −10°C a colourless crystalline complex

$$(CH_3C_6H_4{-}N{\equiv}C)_3{\cdot}Cu{-}C{\equiv}C{-}C_6H_5$$

is formed rapidly[46]. The compound is extremely labile, is decomposed by water and organic solvents, whereas it is completely stable thermally (it decomposes at ~ 100°C). Keeping in air leads to a decomposition of the complex in a few hours. The loss of isonitrile molecules takes place even under the action of dry ether at room temperature. In aqueous pyridine at 0°C the complex dissolves with liberation of CO, since hydration of the isonitrile molecule takes place simultaneously with the decomposition:

$$C_7H_7{-}N{\equiv}C \xrightarrow{H_2O} CO + C_7H_7{-}NH_2 \xrightarrow{C_7H_7N{\equiv}C} C_7H_7{-}NH{-}CH{=}N{-}C_7H_7 .$$

It is especially interesting that there is an analogy between the other complexes of the acetylides, the reaction of the isonitrile complex of the phenylacetylide with chloroform, dissolution in which is accompanied by rapid replacement of the phenylacetylene residue by chlorine:

$$(Ar{-}N{\equiv}C)_3\,Cu{-}C{\equiv}C{-}C_6H_5 \xrightarrow{CHCl_3} (Ar{-}N{\equiv}C)_3 \cdot CuCl .$$

Copper, silver, and gold acetylides form stable complexes with tertiary phosphines, arsines, and stilbines. Coates and coworkers[30,31,33,47] synthesised and studied a large number of such complexes. The stability of these complexes, which is sharply contrasted with the instability of the ammine and amine complexes, was attributed by the authors to the ability of phosphorus and its analogues to back coordination owing to the vacant *d*-orbitals. Depending on the ratio of the components, compounds with a different number of ligands belonging to one metal atom can be obtained. The maximal number is three but the only complex of this composition:

$$PhC{\equiv}C{-}Cu\cdot(PMe_3)_3$$

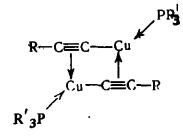
was unstable in solution, which did not allow its molecular weight to be determined. As the cryoscopic investigations showed, complexes with two ligands,

$$Bu^t{-}C{\equiv}CCu\cdot(PMe_3)_2 \text{ and } Ph{-}C{\equiv}C{-}Cu\cdot(PMe_3)_2$$

are monomeric in benzene, but the monophosphinic complexes:

$$Bu^t{-}C{\equiv}CCu\cdot PMe_3,\ Ph{-}C{\equiv}CCu\cdot PMe_3,\ Ph{-}C{\equiv}CCu\cdot PEt_3 \text{ etc.}$$

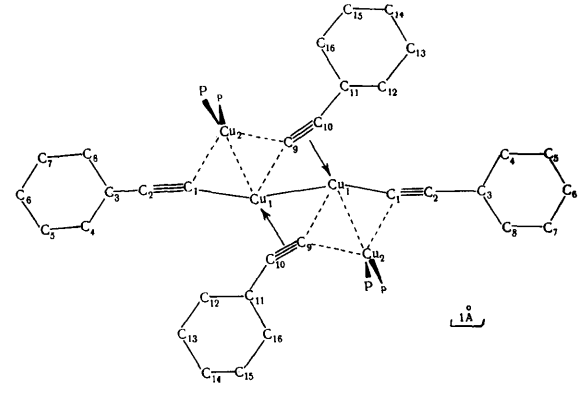
are dimeric in nitrobenzene. The authors suggest that the dimeric complexes are constructed in the following manner:



Coates and Parkin[30] give the results of an X-ray structural investigation of the complex

$$(PhC{\equiv}C{-}Cu\cdot CuPMe_3)_4.$$

Each tetrameric cell contains a zig-zag of four copper atoms. With the exception of phosphinic groups lying above and below the plane of the diagram, the structure of the tetramer is almost planar. Atoms $C_{(4)}$ and $C_{(5)}$ remain 0.2 Å from the *X*–*Y* plane of the diagram, but $C_{(7)}$, $C_{(8)}$, $C_{(15)}$, and $C_{(16)}$, 0.3 Å. The departure of all the other atoms along the *Z*-coordinate averages 0.06 Å. The benzene ring is only slightly inclined to the *X*–*Y* plane. The Cu–Cu distance ($Cu_{(1)}$–$Cu_{(1)}$ = 2.7 Å, $Cu_{(1)}$–$Cu_{(2)}$ = 2.45 Å) is almost the same as in metallic copper.



The monophosphinic complexes of silver acetylides are also not monomeric. For example, Rh–C≡CAg.PEt_3 is dimeric in nitrobenzene, and for it a structure analogous to that given above is proposed. Unlike the compounds of copper and silver the monophosphinic derivatives of gold acetylides are monomeric, which is explained by the relatively low tendency of Au^+ to an increase in the coordination number above 2. The degree of association of the phosphinic complexes can be varied within wide limits, depending on the composition of the complex, its concentration, and the nature of the solvent. Thus Ph–C≡CCu.PEt_3 is trimeric in nitrobenzene and has a degree of association from 3.3 to 3.8 (depending on the concentration) in benzene.

Unexpected properties destroying the concept of the monophosphinic complexes as coordination unsaturated compounds and therefore associated in solutions, were displayed by p-$O_2NC_6H_4$–C≡CCuPPh_3. It was monomeric in nitrobenzene. In the solid state it could be obtained in two different forms—bright red and orange, having identical composition. In benzene it is dimeric, that is, behaves similarly to many other complexes of similar structure. Monomeric diphosphinic complexes are usually coloured more than weakly associated compounds. For example, the octamer Bu^t–C≡C–Cu is orange-red[29], the dimeric Bu^t–C≡CCu.PMe_3 is yellow-green[30], but the monomeric Bu^t–C–CCu.$(PMe_3)_2$ is colourless[30]. The phosphinic complexes of copper acetylides are completely stable thermally (most of them melt without decomposition at temperatures up to 150°C) but gradually decompose on storage in air. The complexes of the diacetylenes seemed unexpectedly stable in this respect. Whereas Ph–C≡CCu.PEt_3 is converted into yellow amorphous Ph–C≡CCu after standing in air for 1–2 days, Ph–C≡C–C≡CCu.PEt_3 remains unchanged after a week.

The complexes of silver acetylides with phosphines decompose more rapidly on access of air and also in the light.

3. Reactions with Halogens and Halogenoacetylenes

Even Böttger[1] in studying the chemical properties of copper acetylide found that the reaction with chlorine is explosive, $CuCl_2$, HCl, and carbon being formed. In reacting with Br_2, or on grinding with I_2, copper acetylide ignites and carbon is liberated. On reacting silver acetylide with iodine in ether, Berend[48] obtained di-iodoacetylene. Bayer[49] found that a mixture of di-iodoacetylene and di-iododiacetylene is obtained from copper acetylide under these conditions. By the reaction of an aqueous suspension of copper acetylide of propargyl alcohol with iodine, Lespieau[50] obtained iodopropargylic alcohol:

$$HO{-}CH_2{-}C{\equiv}C{-}Cu + I_2 \rightarrow HO{-}CH_2{-}C{\equiv}CI + CuI\,.$$

It is interesting to compare the reaction of halides with acetylenic derivatives of various metals and the reaction of halides with copper acetylides. It is known that during the action of halides on the acetylenic derivatives of various metals the metal is replaced by halogen[48,51–57]:

$$BrMgC{\equiv}CMgBr + 2\,X_2 \rightarrow XC{\equiv}CX + 2\,MgBrX,(X{=}I,\ Br),$$
$$RC{\equiv}CMgBr + X_2 \rightarrow RC{\equiv}CX + MgBrX,(X{=}I,\ Br),$$
$$(RC{\equiv}C)_2Hg + 2\,Br_2 \rightarrow 2\,RC{\equiv}CBr + HgBr_2,$$
$$AgC{\equiv}CAg + 2\,I_2 \rightarrow IC{\equiv}CI + 2\,AgI,$$
$$RC{\equiv}CNa\ (K,\ Li) + Cl_2 \rightarrow RC{\equiv}CCl + NaCl\ (KCl,\ LiCl).$$

In all these instances the interaction proceeds as a competition of the halogen with the metal for the redistribution of electrons of the existing metal–carbon bond since the metals (excluding silver) are found in their highest oxidation states.

For copper acetylides, in addition to the analogous process:

$$R{-}C{\equiv}C{-}Cu + X_2 \rightarrow R{-}C{\equiv}C{-}X + CuX$$

there is another possibility—oxidation of Cu^+ to Cu^{2+}. Unlike univalent copper, bivalent copper is a typical transition metal. It could be expected that the Cu–C σ-bond in the compounds being formed, as in most compounds of metals with an incomplete d-level, will be weak and easily broken with formation of a new compound of Cu^+ or Cu^{2+} and an acetylenic radical:

$$RC{\equiv}CCu \longrightarrow [RC{\equiv}C\overset{\cdot}{)}Cu^{+}\ X^{\cdot -}] \longrightarrow RC{\equiv}C^{\cdot} + CuX + X^{\cdot},\ (\text{or } CuX_2)$$

$$2RC{\equiv}C^{\cdot} \longrightarrow RC{\equiv}C{-}C{\equiv}CR\,.$$

The weakness of such σ-bonds is explained by the similarity in energy of the electrons of the bond and the d-electrons of the metal[58]. The ease of interaction here must depend on the properties of the acetylide as a base and the halogen as a Lewis acid. The strengths of the halogens as Lewis acids change in the order

$$F_2 > Cl_2 > Br_2 > I_2.$$

This is well illustrated by the relative rates of addition of the halogens and interhalogen compounds at a double bond[59]:

I–I	1	I–Br	3000	I–Cl 100 000
		Br–Br	10 000	Br–Cl 4 000 000 .

In the molecule of the acetylide the electron-accepting groupings at the C≡C bond should hinder the removal of the d-electron of copper and electron-donating ones facilitate it.

Actually it was found[60,61] that in the reaction of copper acetylide with iodine—a weak Lewis acid, at room temperature only iodoacetylenes are formed. The reactions evidently proceed through a four-centre state of the type:

$$R{-}C{\equiv}C{-}Cu \cdots \overset{\delta+}{X} \cdots \overset{\delta-}{X}\,.$$

The simplicity of the experiment, the possibility of using acetylides with different functional groups and the high yields of iodoacetylenes allow this reaction to be regarded as a convenient preparative method for making iodoacetylenes.

By introducing iodine monobromide into the reaction it was shown that the final product is determined by the initial polarisation of the reacting molecules:

$$C_6H_5{-}\overset{\delta-}{C}{\equiv}\overset{\delta+}{C}{-}Cu + \overset{\delta+}{I}\,\overset{\delta-}{Br} \rightarrow C_6H_5C{\equiv}C{-}I + CuBr\,.$$

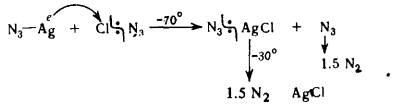
Actually, iodophenylacetylene acetylene was obtained in 60% yield.

Even at low temperatures, bromine oxidises more than half copper phenylacetylide to diphenylbutadiyne—the yield of bromophenylacetylene is $\gtrsim$ 40%. Copper p-nitrophenylacetylide gives under these conditions ~ 70% p-nitrobromophenylacetylene and only traces of di-(4-nitrophenyl)-butadiyne[61–63]. Hence acetylides with electron-withdrawing substituents at the triple bond can give bromoacetylenes in high yields.

The yield of chlorophenylacetylene from the action of a carbon tetrachloride solution of chlorine on copper phenylacetylide does not exceed 20%.

The possibility of an oxidation is also not ruled out for silver acetylides. It is known, for example, that silver

azide reacts with chlorine azide at −70°C with the formation of silver(II) azide chloride, which decomposes when the temperature is raised to −30°C to give silver chloride and molecular nitrogen[64]. The reaction is interesting in that with an obvious analogy with the oxidising action of halogens on copper acetylides an intermediate compound of the bivalent metal is fixed:



However, the bivalent state is not very characteristic for silver and is achieved only in the reaction of its compounds with very strong oxidants.

Since the ethynyl group exhibits a strong *I*-effect, the appearance of quasi-halide properties can be expected from the halogenoacetylenes, in particular the ability to play the part of strong electrophilic reagents. The dipole moments of the monohalogenoacetylenes[65] show that the electron-withdrawing properties of ethynyl and the halogens in these compounds are of the same order of magnitude:

$$HC{\equiv}CF \quad 0.75\ D\ ,$$
$$HC{\equiv}CCl \quad 0.44\ D\ ,$$
$$HC{\equiv}CBr \quad 0.00\ D\ .$$

The result of the electrophilic substitution, as for the halogens and interhalogen compounds, will be determined by the initial polarisation of the halogen derivative, for example[66,67]:

$$2\,R{-}C{\equiv}C{-}MgX + \overset{\delta+}{I}C{\equiv}C\overset{\delta-}{I} \rightarrow 2\,R{-}C{\equiv}C{-}I + XMgC{\equiv}CMgX\,,$$
$$R{-}C{\equiv}C{-}MgX + \overset{\delta-}{Cl}C{\equiv}C\overset{\delta+}{Cl} \rightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}Cl + MgXCl\,.$$

Actually, it was found[68] that di-iodoacetylene reacts with copper acetylides in the same way as with organomagnesium compounds:

$$2\,R{-}C{\equiv}C{-}Cu + IC{\equiv}CI \rightarrow 2\,R{-}C{\equiv}C{-}I + CuC{\equiv}CCu\,.$$

It was also shown[68] that the copper is replaced by iodine in reactions of the acetylides with di-iodoacetylene and iodonitroform $IC(NO_2)_3$.

The reaction of bromoacetylenes with acetylenes in the presence of catalytic amounts of CuCl, dissolved in the primary amine, and of a small quantity of reductant ($NH_2OH.HCl$) was proposed by Chodkiewicz and Cadiot[69] as a method for the synthesis of non-symmetrical diacetylenic compounds. Although the overall process is expressed by the equation:

$$R{-}C{\equiv}CH + BrC{\equiv}CR' \rightarrow R(C{\equiv}C)_2R' + HBr$$

the reaction actually proceeds between bromoacetylene and the acetylide[70]:

$$R{-}C{\equiv}CH + Cu^{+} \rightarrow R{-}C{\equiv}C{-}Cu + H^{+}\,, \qquad (4)$$
$$R{-}C{\equiv}C{-}Cu + Br{-}C{\equiv}C{-}R' \rightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}R' + CuBr\,. \qquad (5)$$

There is also the side-process of condensation of the bromoacetylene under the action of Cu^{+} ions:

$$2\,R'{-}C{\equiv}C{-}Br + 2\,Cu^{+} \rightarrow R'{-}C{\equiv}C{-}C{\equiv}C{-}R' + 2\,Br^{-} + 2\,Cu^{2+} \qquad (6)$$

which is thought to proceed through the following two stages:

$$R'{-}C{\equiv}C{-}Br + 3\,Cu^{+} \rightarrow R'{-}C{\equiv}C{-}Cu + Br^{-} + 2\,Cu^{2+}\ (\text{slow})\,, \qquad (7)$$

$$R{-}C{\equiv}C{-}Cu + Br{-}C{\equiv}C{-}R' \rightarrow R'{-}C{\equiv}C{-}C{\equiv}C{-}R' + Cu^{+} + Br^{-}\ (\text{fast})\,. \qquad (8)$$

The formation of the dimer ($R'{-}C{\equiv}C{-}C{\equiv}C{-}R'$) from the acetylide can be explained by the oxidising action of the Cu^{2+} ions which are produced in reaction (6), or by the replacement of the copper in the acetylide by halogen under the action of the halogenoacetylene. The halogenoacetylene obtained can undergo condensation (6) just like the initial one. It is possible for both these processes to proceed simultaneously. A thorough survey of the Cadiot–Chodkiewicz condensation and also extensive data on its practical application have been given in a review[70].

It was found[68] that in the reaction of bromoacetylenes and iodoacetylenes ($R{-}C{\equiv}C{-}X$) with copper acetylides ($R'{-}C{\equiv}C{-}Cu$), introduced in stoichiometric amounts, a mixture of three diynes is formed:

$$R{-}C{\equiv}C{-}C{\equiv}C{-}R',\quad R{-}C{\equiv}C{-}C{\equiv}C{-}R \quad \text{и} \quad R'{-}C{\equiv}C{-}C{\equiv}C{-}R'.$$

For example, from a reaction mixture of bromophenylacetylene with copper *p*-bromophenylacetylide in dimethylformamide the products diphenylbutadiyne, 1-*p*-bromophenyl-4-phenylbutadiyne, and di-(*p*-bromophenyl)butadiyne were isolated.

The similarity in the chemical properties of copper cyanide and acetylides is observed in the reaction of CuCN with iodo- and bromo-phenylacetylenes. It was shown[62] that this results in the formation of phenylpropiolonitrile in ~40% yield. When the iodophenylacetylene was used, diphenylbutadiyne was also isolated from the reaction mass. The formation of diphenylbutadiyne during the synthesis of phenylpropiolonitrile from iodophenylacetylene and copper cyanide could be the result not only of condensation under the action of Cu^{+}, but also of the exchange of copper and halogen between the initial components.

4. Reactions with Aromatic and Unsaturated Halogen Derivatives

Friedman and Schlechter[71] found that aryl chlorides and bromides in boiling dimethylformamide react with copper(I) cyanide to form nitriles in yields from 80% to quantitative:

$$ArX + 2\,CuCN \rightarrow (ArCN)_2{\cdot}CuX + CuX\,,$$
$$(ArCN)_2\,CuX \xrightarrow{H^{+}} 2\,ArCN + CuX\,.$$

The similarity between the copper acetylides and cyanide led the authors of the present review to investigate the possibility of the introduction of acetylenic groups into the aromatic nuclei in an analogous way. It was found[60] that when aryl iodides are boiled with copper acetylides in dimethylformamide for 8–16 h disubstituted acetylenes are formed in 30–70% yield:

$$ArC{\equiv}C{-}Cu + Ar'I \rightarrow Ar{-}C{\equiv}C{-}Ar' + CuI\,.$$

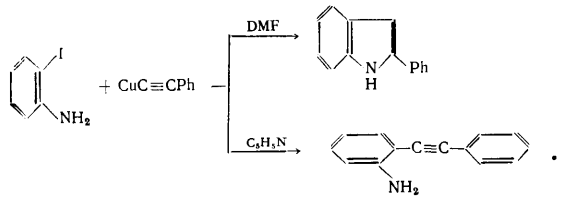
Aryl iodides with various functional groupings (nitro-, amino-, hydroxy-, etc.) can be used in the synthesis. In di-iodoaryl compounds one or both of the iodine atoms can be replaced by acetylenic radicals. Boiling a suspension of copper *p*-iodophenylacetylide in dimethylformamide leads to its autocondensation into the acetylide of 4-iodo-4-ethynyltolane.

This reaction was described simultaneously and independently by Castro and Stephens[72,73], who synthesised several tolanes in yields of 70–90% by the reaction of *para*- and *ortho*-substituted derivatives of iodobenzene with copper phenylacetylide in boiling pyridine:

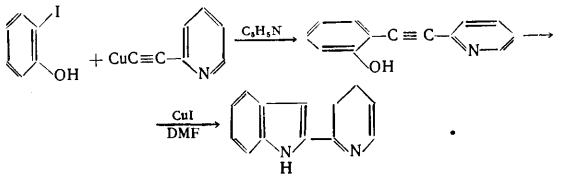
$$ArI + CuC{\equiv}CPh \rightarrow Ar{-}C{\equiv}C{-}Ph + CuI\,.$$

Heterocyclic compounds were obtained from some of the *ortho*-substituted derivatives in the same high yields. Further investigations[74] showed that this reaction is a general method for the synthesis of tolanes, indoles,

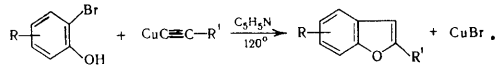
benzofurans, and phthalides. For the *ortho*-amino-derivatives the direction of the reaction is determined by the solvent: in dimethylformamide an indole is formed; in pyridine, either only an *o*-aminotolane, or a mixture of both products, depending on the acetylide:



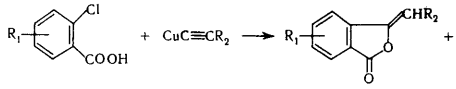
The reaction proceeds in two stages: substitution and cyclisation. The second stage takes place only in the presence of copper salts:



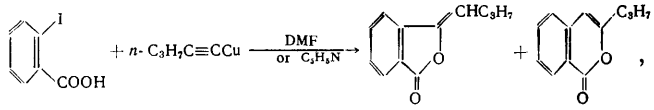
The synthesis of benzofurans proceeds easily in pyridine. Halogenophenols react more vigorously than the corresponding anilines. This allows the more stable *o*-bromophenols to be used as starting compounds:



Halogenobenzoic acids are a group of most reactive substances. Here the use of even chloro-derivatives is possible and the formation of phthalides occurs even at room temperature both in dimethylformamide and in pyridine:

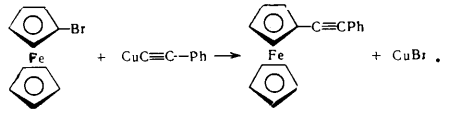


Only in one instance was the formation of isocoumarin noted as well as the phthalide:



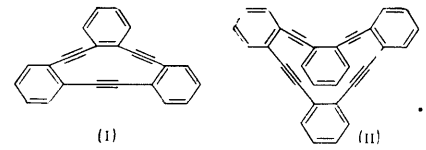
The simplicity of the behaviour and the high yields of the final products made this reaction a convenient preparative method for obtaining various acetylenic derivatives with aromatic substituents.

Nesmeyanov and coworkers[75] extended it to halogen derivatives of ferrocene. Whereas aryl bromides do not react with copper acetylides, on boiling bromoferrocene for three hours with copper phenylacetylide in a medium of dimethylformamide, ethynylphenylferrocene was formed in 48% yield:



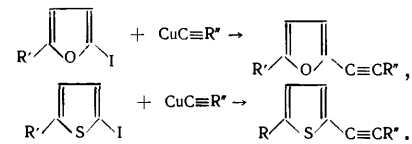
By starting from iodoferrocene, Rausch and coworkers[76] obtained the same product in 84% yield.

Campbell and coworkers[77] isolated cyclic condensation products from the pyridine solution after heating copper *o*-iodophenylacetylide—mainly the trimer (I) and a little tetramer (II):

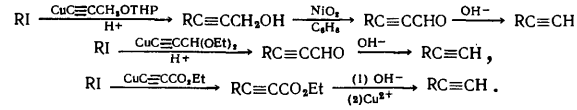


(I) (II)

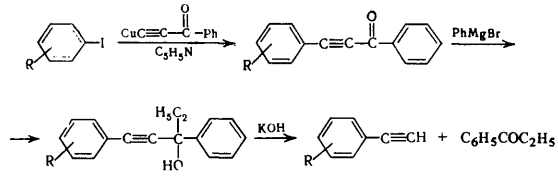
The work of Atkinson and coworkers[78,79] was devoted to the production of the acetylene derivatives of furan and thiophen:



Monosubstituted arylacetylenes were also synthesised. The authors used the tetrahydropyranyl group (THP) for the protection of the hydroxyl group in the acetylides of propargyl alcohol:

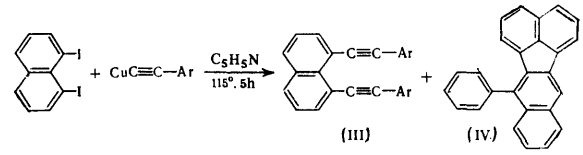


Shvartsberg and coworkers[80] developed another way of obtaining the monosubstituted arylacetylenes:



Filler and Heffern[81] carried out the reaction with pentafluoroiodoacetylene:

By studying the intramolecular reaction of closely situated triple bonds, Ipaktschi and Staab[82] synthesised a series of 1,8-substituted naphthalenes from 1,8-di-iodonaphthalene and copper acetylides:



(III) (IV)

Here in addition to the colourless product (III) its yellow isomer (IV) was formed. The yield of (IV) from the copper phenylacetylide was 19.5% and rose to almost quantitative on continuing boiling.

Colonge and Falcotet[83] obtained acetylenic and ethylenic alcohols by the reaction of allyl chloride and bromide or propargyl chloride (and their alkylated derivatives) with acetylides of propargyl alcohol or methylbutynol. The reaction was carried out in an aqueous solution of ammonium chloride:

where R = CH_2OH.

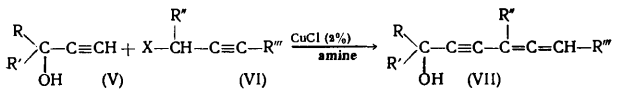
Somewhat later Kurtz[84] reproduced the same reaction but in an aqueous alcoholic solution of sodium chloride:

$$H_2C{=}CR{-}CH_2Cl + HC{\equiv}C{-}R' \xrightarrow[NaCl]{Cu+,\ H_2O} H_2C{=}CR{-}CH_2{-}C{\equiv}CR' + HCl$$

a	*b*	*c*	*d*
R=H	R=CH_3	R=H	R=CH_3
R'=CH_3	R'=C_2H_5	R'=H	R'=H

Hepta-5-en-2-yn-1-ol and 5-methylhepta-6-en-2-yn-1-ol were obtained from the acetylide of propargyl alcohol. The yields were from 29 to 90% at 70–80°C and a reaction time of 7–8 h.

On using amines as a medium for the same reaction and ethynyl carbinols as the acetylenic component, Sevin[85] employed catalytic quantities of CuCl, and observed the isomerisation of the propargyl group into allenyl:



(X = Cl or Br)

(V)	*a*	*b*	*c*	(VI)	*a*	*b*	*c*
R	H	CH_3	CH_3	R''	H	CH_3	H
R'	H	H	CH_3	R'''	H	H	CH_3

The activity of amines in reactions for the condensation of propargyl halides with ethynylcarbinols in the presence of copper(I) chloride falls in the order NH_3 > primary > > secondary > tertiary. The author suggests that the reaction proceeds by a six-centre cyclic mechanism.

Allyl halides also react with copper acetylides in boiling dimethylformamide, forming a substitution product with yields of up to 40% on the acetylide taken[60].

$$CH_2{=}CH{-}CH_2X + Cu{-}C{\equiv}C{-}R \rightarrow CH_2{=}CH{-}CH_2{-}C{\equiv}C{-}R + CuX\,.$$

For the acetylide to react completely, a large excess (up to 100%) of the allyl halide is necessary. In the presence of a catalytic amount of copper powder the reaction takes 5–15 min. The reaction proceeds readily with high yields in liquid ammonia at −33°C.

Propargyl chloride reacts no less vigorously with copper acetylide[68] on heating in dimethylformamide above 70°C. However, the products formed under these conditions are polymerised and low-molecular-weight individual substances cannot be isolated. The use of liquid ammonia instead of dimethylformamide in the reaction of copper phenylacetylide with propargyl chloride allowed a little of a hydrocarbon of composition $C_{11}H_8$ to be obtained in subsequent high vacuum distillation. On the basis of the infrared spectra it was ascribed the cumulene structure $C_6H_5{-}CH{=}C{=}C{=}CH_2$.

The ability of halogen as an isolated double bond to react with copper acetylides was studied by the example of *trans*-di-iodoethylene[86]. Copper acetylides react with di-iodoethylene more readily than with aryl iodides. Depending on the ratio of the reagents and the duration of the reaction, mono- or di-substituted products can be isolated in yields up to 65%.

$$R{-}C{\equiv}C{-}Cu + ICH{=}CHI \rightarrow RC{\equiv}C{-}CH{=}CHI + CuI\,,$$
$$2\,R{-}C{\equiv}C{-}Cu + ICH{=}CHI \rightarrow R{-}C{\equiv}C{-}CH{=}CH{-}C{\equiv}C{-}R + 2\,CuI\,.$$

The reaction takes place without change in the configuration of the *trans*-di-iodoethylene. To replace the first iodine atom it is sufficient to boil the reagents for 10–15 min. About 2 h is needed to replace the second atom.

Copper(I) cyanide also reacts analogously to the acetylides with di-iodoethylene, forming fumarodinitrile.

Burdon and coworkers[87] also reacted dihalogenoethylenes with copper acetylides in dimethylformamide or pyridine and obtained enyne and endiyne compounds in yields of up to 90%:

$$R{-}C{\equiv}C{-}Cu \xrightarrow[1\text{–}12\ h;]{40\text{–}100^\circ} \begin{cases} \xrightarrow{ICH{=}CHCl} R{-}C{\equiv}C{-}CH{=}CHCl \\ \xrightarrow{ICH{=}CHI} R{-}C{\equiv}C{-}CH{=}CH{-}C{\equiv}C{-}R\,. \end{cases}$$

The activity of the halogen at an sp^2-carbon atom increases in the order I > Br > Cl; fluorine does not react.

It can be assumed that the reaction of copper acetylides with iodoaryl and halogen derivatives containing multiple bonds takes place through an intermediate complex. The bond with the metal in this complex can be effected by the π-electrons of the halogen derivative molecules. The absence of an interaction between alkyl halides and copper acetylides supports this assumption.

The reactivity of a halogen derivative can be determined by its basicity in relation to the copper atom of the acetylide. Only indirect data can be produced to explain the results from this viewpoint.

It is known that alkylalkenes exhibit in relation to a proton much more basic properties than aromatic hydrocarbons or conjugated alkenes[88]. If this dependence is also valid for the complex formation of halogeno-derivatives with a transition metal the drop in reactivity in the sequence

$$ICH{=}CHI > ICH{=}CH{-}C{\equiv}C{-}R > ArI$$

is completely regular.

The polarisability of the halogen atom can also play a significant part in reactions of this type. From the Table it is clear that the least reactive allyl halides, aryl chlorides and bromides have the highest dipole moments, that is, they are more difficult to polarise.

The possibility of a change in the valency of copper during the interaction also cannot be excluded. Silver phenylacetylide, for which a change in the valency of the metal under these conditions is improbable, dissolves when heated in pyridine with di-iodoethylene, but does not react.

5. Reaction with Acid Chlorides

Nef[89] reported that on dissolving silver phenylacetylide in benzoyl chloride and boiling the resulting solution, phenylpropiolophenone is formed. The reaction cannot be performed with large quantities of materials since it can take place very violently.

Davis and Scheiber[90] observed that some silver alkylacetylides dissolve in CCl_4, $CHCl_3$ or benzene. By the interaction of such acetylides with various acid chlorides in carbon tetrachloride they obtained the corresponding ketones in yields of up to 72%. It appeared that these reactions are catalysed by Lewis acids. For example, silver n-butylacetylide does not react with benzoyl chloride without a catalyst, but in the presence of $AlCl_3$ n-butylpropiolophenone is formed in 72% yield:

$$n\text{-}C_4H_9{-}C{\equiv}C{-}Ag + Cl{-}\overset{O}{\overset{\|}{C}}{-}C_6H_5 \xrightarrow[CCl_4]{AlCl_3} n\text{-}C_4H_9{-}C{\equiv}C{-}\overset{O}{\overset{\|}{C}}{-}C_6H_5 + AgCl\,.$$

Crombie and Griffin[91] used this method for obtaining intermediates in the synthesis of certain derivatives of

unsaturated acids. The reaction was carried out with the acid chlorides of the partial esters of dicarboxylic acids:

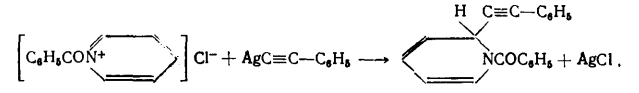
$$R{-}C{\equiv}C{-}Ag + ClCO[CH_2]_n COOMe \rightarrow R{-}C{\equiv}C{-}\overset{\overset{O}{\|}}{C}[CH_2]_n COOMe + AgCl.$$

The yields of the ketones were 30–35%.

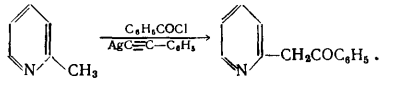
Additional moments of halogen derivatives.

X	Dipole moment, D		
	CH_3CH_2X	$CH_2{=}CHX$	C_6H_5X
Cl	2.05	1.44	1.73
Br	2.02	1.41	1.71
-	1.90	1.26	1.50

Interesting work by Agawa and Miller [92] disclosed new synthetic possibilities of reaction of silver acetylides with acid chlorides. These authors found that pyridine introduced into the reaction medium (CCl_4) becomes, in the form of an acylpyridinium salt, the main object of the nucleophilic attack of the silver acetylide. As a result of the reaction α-ethynyl derivatives of *N*-acyl-1,2-dihydropyridines are formed in yields of up to 70%:



Analogous products were also obtained with quinoline. The acetylenic ketones present as impurity did not exceed 15%. Reaction between 2-picoline, benzoyl chloride, and silver phenylacetylide takes place with the formation of 2-phenacylpyridine, AgCl, and probably phenylacetylene:



The first report of the synthesis of α-ethynylketones from acid chlorides and copper arylacetylides was published recently [93]; the yields were 40–60%:

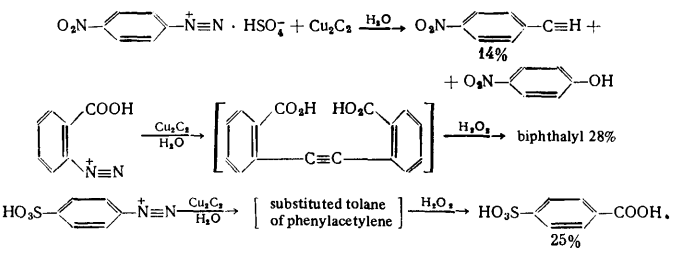
$$R{-}COCl + Cu{-}C{\equiv}C{-}C_6H_5 \rightarrow R{-}\overset{\overset{O}{\|}}{C}{-}C{\equiv}C{-}C_6H_5 + CuCl$$

where R = C_6H_5, *p*-BrC_6H_4, *p*-$O_2NC_6H_4$, *m*-$O_2NC_6H_4$, mesityl.

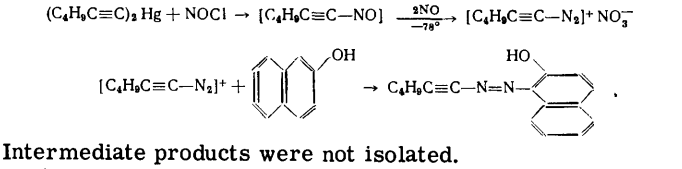
Bifunctional acid chlorides (terephthalyl chloride and isophthalyl chloride) react analogously. The reaction was carried out with the successive action of triethylamine, and then pyridine in a medium of dioxan, dichloroethane, or benzene. In the presence of only triethylamine, or only pyridine, and also in a medium of pyridine or dimethylformamide the formation of acetylenic ketones was not observed.

6. Reactions with Diazonium Salts

Sandmeyer [94] studied the reaction of copper acetylide with phenyldiazonium chloride and found that chlorobenzene is formed and acetylene does not take part in the reaction. Sharvina and Plakhuta [95] isolated tetraphenylethane from the products of the reaction of copper acetylide with phenyldiazonium sulphate, showing in this way that acetylene takes part in the reaction to an insignificant extent. Sokol'skii and Nikolenko [96] found that the presence of an electron-withdrawing substituent at the *para*- and especially the *ortho*-positions of the diazonium salt facilitates the entry of the acetylenic radical into the aromatic nucleus:



Robson and Tedder [97,98] first reported the production of compounds containing an azoethynyl grouping. The reaction proceeded thus:



Intermediate products were not isolated.

A new method for the synthesis of azoethynyl compounds by the reaction of aqueous solutions of aryldiazonium chlorides with silver acetylides [99,100] was developed:

$$Ar\overset{+}{N}_2Cl + AgC{\equiv}C{-}Ar' \rightarrow Ar{-}N{=}N{-}C{\equiv}C{-}Ar' + AgCl.$$

All the compounds except one were obtained from diazonium salts containing electron-withdrawing groupings in the *para*- or *ortho*-positions. The simplest compound of this series with two unsaturated phenyl radicals could not be synthesised. 4-Hydroxyazobenzene and bisphenylazophenol were isolated from the products of the reaction of phenyldiazonium chloride with silver phenylacetylide. The competitive formation of phenol with subsequent azocoupling makes the part of the substituents in the nucleus of the diazonium salt understandable.

It is known that the decomposition of diazonium compounds is unimolecular. There are many facts supporting an S_N1 mechanism [101,102]:

$$(Ar{-}\overset{+}{N}{\equiv}N{:})\,\bar{X} \xrightarrow{\text{slow}} Ar^+ + {:}N{\equiv}N{:} + X^-,$$

$$Ar^+ + H_2O \xrightarrow{\text{fast}} Ar{-}\overset{+}{O}H_2 \rightleftarrows ArOH + H^+.$$

$-M$- and $-I$-groupings in the *ortho*- and *para*-positions should hinder the removal of nitrogen (by impeding the displacement of the electrons $Ar{-}\overset{\curvearrowright}{N}{}^+{=}N$) but $+M$- and $+I$-groups should facilitate it. At the azo-coupling stage the substituent will exert an opposite influence on the components.

In the diazonium ion substituents which increase the positive charge on account of an inductive or mesomeric effect will increase its reactivity in relation to aromatic compounds, but $+I$- and $+M$-substituents will decrease it [59]. In the phenol being formed, on the other hand, $-I$- and $-M$-groups, by withdrawing electrons from the aromatic ring, reduce its basicity, and consequently its capability for azo-coupling. Hence the rate of decomposition of the diazonium salts with electron-withdrawing substituents and the tendency to coupling with the phenols being formed will be reduced. At the same time the rate of electrophilic replacement of silver should increase with increase in the electrophilic nature of the diazonium ion. Azoethynyl

compounds can also be obtained from diazonium salts with electron-donating substituents in the nucleus. However, as the example of tolyldiazonium chloride showed, the yields here are very small.

The known similarity of copper and silver acetylides with sparingly soluble salts suggests the possibility of their existing in aqueous medium in equilibrium with the solid a definite concentration of acetylide ions and metal ions:

$$L = [R{-}C{\equiv}C^-][Ag^+]$$

where L is the solubility product. Reaction with diazonium salts could then proceed as a simple exchange:

$$Ag^+ + R{-}C{\equiv}C^- + R'{-}\overset{+}{N}_2 \rightleftarrows R{-}C{\equiv}C{-}N{=}N{-}R' + Ag^+ .$$

The factor displacing the equilibrium to the right is the formation of the C–N covalent bond.

One of the significant objections against this mechanism is the weakness of the acid properties of acetylene and its homologues. The acetylide ions would be completely hydrolysed under the reaction conditions (weakly acid medium):

$$R{-}C{\equiv}C^- + H^+ \rightarrow R{-}C{\equiv}CH .$$

Interaction would lead to a combination of the diazonium salt with acetylene, which, as shown by the example of phenylacetylene[103], proceeds as follows:

$$C_6H_5{-}C{\equiv}CH + Ar\overset{+}{N}_2 \rightarrow (C_6H_5{-}\overset{+}{C}{=}CH{-}N{=}N{-}Ar) \xrightarrow{H_2O}$$

$$C_6H_5{-}\underset{\underset{O}{\|}}{C}{-}CH{=}N{-}NH{-}Ar \rightleftarrows C_6H_5{-}\underset{\underset{OH}{|}}{C}{=}CH{-}N{=}N{-}Ar .$$

It is also difficult to explain the dependence of the results of the reaction for a single acetylide on the electrophilic nature of the diazonium ion.

The reaction of silver acetylides with diazonium salts can evidently be regarded as an electrophilic substitution similar to the reactions of diazonium fluoroborate with organozinc and organomagnesium compounds[104,105]:

$$R{-}ZnCl + \overset{+}{N}_2{-}Ar \rightarrow R{-}N{=}N{-}Ar + Zn^{2+} + Cl^- .$$

The presence in the reacting molecule of an acetylenic group does not rule out the possibility of yet another reaction mechanism—two-stage addition–splitting. The carbonium ion produced would differ from that obtained from phenylacetylene by the presence of a =C–Ag bond of comparatively low stability. The elimination of the Ag^+ ion in this instance would also lead to an azoethynyl compound.

$$R{-}C{\equiv}CAg + N{\equiv}\overset{+}{N}{-}R \rightarrow [R{-}\underset{\underset{Ag}{|}}{\overset{+}{C}}{=}C{-}N{=}N{-}R'] \xrightarrow{-Ag^+} R{-}C{\equiv}C{-}N{=}N{-}R'$$

However, such a mechanism seems to us much more probable for the following reasons.

It is known[106] that styrylsilver $Ag{-}CH{=}CH{-}C_6H_5$ is insoluble, brightly coloured, and—unlike the alkylethynyl derivatives of silver, for example, $Ag{-}CH{=}C(CH_3)_2$ [107]—is a rather stable compound, stable in air at room temperature for several hours. A comparatively high stability could also be expected from the product of the addition of a diazonium salt to silver phenylacetylide, similar in structure to styrylsilver. Furthermore, in all the examples investigated[106,108] compounds with an Ag–C bond decompose homolytically with liberation of metallic silver.

7. Interaction of Copper Acetylides with Inorganic Compounds

The interaction of $HgCl_2$, $HgBr_2$, and $Hg(OOCCH_3)_2$ with various acetylides has been studied in tetrahydrofuran, dioxan, alcohol, and water[109]. The formation of insoluble compounds was always observed. With an aqueous solution of ammonia the compound decomposes with separation of bisacetylene derivatives of mercury.

An investigation of the product of the reaction of two moles of copper phenylacetylide with one mole of mercury(II) bromide showed that it has the composition $HgBr_2 \cdot 2C_6H_5C{\equiv}CCu$. The complex is insoluble in ordinary organic solvents, soluble in pyridine but in dissolving it decomposes (as under the action of ammonia) into bis-(phenylethynyl)mercury and copper halide. An aqueous alcoholic solution of potassium iodide also decomposes the complex on heating, with liberation of the initial copper acetylide:

$$K_2(HgX_2I_2) + 2\,CuC{\equiv}CR \xleftarrow{2KI} HgX_2 \cdot 2\,CuC{\equiv}CR \xrightarrow{NH_3} Hg(C{\equiv}CR)_2 + 2[Cu(NH_3)_n] + 2\,X^- .$$

It is extremely probable that the reaction of HgX_2 with $R{-}C{\equiv}CCu$ takes place in the coordination sphere of the metals in the solid phase, however, it is also possible to postulate the existence of a double equilibrium between the solid and the solution:

$$HgX_2 + 2\,CuC{\equiv}CR \rightleftarrows HgX_2 \cdot 2\,CuC{\equiv}CR \rightleftarrows Hg(C{\equiv}CR)_2 + 2\,CuX .$$

Potassium iodide can shift the equilibrium only to the side of the formation of the acetylide. Both directions are possible for ammonia in principle, and the result will be determined by the ratio of the reaction rates.

In the infrared spectrum of the complex there are two bands in the range of the stretching vibrations of the triple bond: a weak one at 2000 cm^{-1} and a medium at 2040 cm^{-1}, which evidently shows the presence in the complex of triple bonds of different type. The decrease in the frequencies of the triple bonds compared with the monomeric bis-(phenylethynyl)mercury ($\nu_{C{\equiv}C}$ = 2143 cm^{-1}) suggests their interaction with the copper atoms, but less strongly than in copper phenylacetylide ($\nu_{C{\equiv}C}$ = 1930 cm^{-1}). The position of the bands of the stretching vibrations of the triple bonds and their relative intensities are reminiscent of the same parameters of the infrared spectra described by Coates and Parkin[30] for the tetrameric complex of copper phenylacetylide with trimethylphosphine.

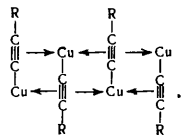
The absence of interaction between bis-(*C*-methylbarenyl)mercury and copper phenylacetylide[109] suggests that a significant part in the formation of such complexes is played by the difference in electronegativity associated with the mercury halide and the ethynyl group of the acetylide. The capability of the more electronegative ethynyl group to withdraw part of the electron density of the readily polarisable mercury atom can lead to the formation of a four-centre structure with bridging halogen atom:

$$\begin{array}{l} Br{-}Hg{-}Br \\ \quad\vdots\quad\vdots \\ R{-}C{\equiv}C{-}Cu \end{array} .$$

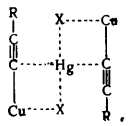
With bis-(*C*-methylbarenyl)mercury the formation of such a cyclic structure is also impossible because of the (already unusually high) coordination saturation of the barene carbon atom, which here should increase the coordination number from six to seven.

The formation of the complex $HgBr_2 \cdot 2CuC{\equiv}CR$, even in the presence of 100% excess of a mercury salt, can be explained by first assuming that oligomeric fragments of

acetylene are constructed from molecules oriented "head to tail":



On p. 1760 a structure was given for the complex $[CuC{\equiv}C\text{-}Ph.PMe_3]_4$, in which the phenyl rings of the acetylide were directed to opposite sides. The same orientation is proposed for the dimeric complexes of the copper[30] and silver[31] acetylides. It has also been suggested[31] that in the copper acetylides every metal atom is π-bonded with not less than two acetylene groupings, resulting in the coordination saturation of these compounds. Hence the structure given above for the mercury complex (not necessarily planar)—is one of the possible variants corresponding to these ideas. In this orientation in the blocks of the acetylide each molecule of the mercury halide can be inserted in the ready "matrix" of two molecules of acetylide:



If the complex is constructed from such fragments linked to one another by the coordination of the π-electrons of the triple bonds with the copper atoms, then even for the dimer an explanation is found for the two bands of the stretching vibrations of the triple bond in its infrared spectrum.

Like mercury, thallium forms two extremely stable covalent bonds with organic radicals. Grignard reagents alkylate thallium(III) chloride to stable and sparingly soluble dialkylthallium chlorides[110]:

$$TlCl_3 + 2\,RMgX \rightarrow R_2TlCl + 2\,MgXCl.$$

The significant difference of the Tl^{3+} salts from the Hg^{2+} salts is the tendency to the formation of ions with an electron cloud containing an "inert pair" determining the strong oxidising properties of the thallium(III) compounds. From the value of the oxidation potential of Tl^{3+} in the reaction $Tl^{3+} + 2e \rightarrow Tl^{+}$ (1.25 $E°$, V), clearly the Tl^{3+} ion occupies a position intermediate between bromine and chlorine (+1.066 and 1.358 $E°$, V respectively).

This feature of the thallium(III) salts was also determining in the reaction between $TlCl_3.4H_2O$ and copper phenylacetylide. The reaction can be represented by the following equation:

$$TlCl_3 \cdot 4\,H_2O + 2\,CuC{\equiv}C{-}C_6H_5 \rightarrow TlCl + 2\,CuCl + C_6H_5C{\equiv}C{-}C{\equiv}C{-}C_6H_5 + 4\,H_2O.$$

Dry copper phenylacetylide in a medium of phosphorus trichloride forms a colourless insoluble complex. An aqueous solution of ammonia or pyridine destroys the complex with the liberation of tri(phenylethynyl)phosphine $(C_6H_5C{\equiv}C)_3P$.

The same course for the reaction is evidently determined by the structure of the reactants, which permits intermediate coordination of one molecule of phosphorus trichloride with three molecules of the acetylide. The zig-zag arrangement of the copper atoms in the oligomeric blocks of the acetylide should facilitate such interaction, bearing in mind the pyramidal structure of the PCl_3 molecule.

It is also known that in many instances an increase in the polarity of the element–halogen bond hinders alkynylation[111]. As the phenylethynyl group is a stronger acceptor of electrons than chlorine its introduction into the molecule should decrease the polarity of the remaining P–Cl bonds and facilitate the subsequent stage of alkylation.

8. Oxidative Condensation of Copper Acetylides

The reactions most widely employed in synthetic organic chemistry are those connected with the oxidation of acetylenic derivatives of copper(I), and above all there is the oxidative condensation of copper acetylides into diacetylene derivatives, discovered by Glaser[112]:

$$2\,R{-}C{\equiv}CCu \xrightarrow{\text{oxidant}} R{-}C{\equiv}C{-}C{\equiv}C{-}R.$$

The extensive reviews of the reactions for oxidative condensation of acetylides which have recently appeared[70, 113-115] allow the present discussion to be restricted to only a brief statement of the main stages in the development of this branch of synthesis.

Perhaps the most important changes introduced into the method since the time of the discovery of the reactions was its conversion from heterogeneous to homogeneous. The choice of the conditions under which all the components of the reaction mixture are present in the dissolved state allowed the yields to be greatly increased, the temperature to be decreased, the reaction time to be curtailed and the range of acetylenes employed in the condensation to be greatly extended. Various macrocyclic compounds with diacetylene groupings were obtained from bisacetylenes in extremely dilute solutions for the first time. Methods of oxidative condensation in a homogeneous medium proposed by Hay[116] and Eglinton[117,118] were used most extensively. In Hay's method the reaction is carried out in pyridine with a catalytic amount of copper(I) chloride, using oxygen as the oxidant. In Eglinton's method the solvent is a mixture of pyridine and methanol, and the oxidant copper(II) acetate.

Another significant contribution in the study of the oxidation reactions was Zal'kind and Fundyler's discovery[119,120] of the possibility of carrying out oxidative condensation of acetylenes in an acid medium.

The development of the ideas about the mechanism of the oxidative condensation of acetylenes received detailed discussion in reviews[70,115], which allows the consideration in the present review to be restricted to only the most interesting studies of the principal aspects of these concepts.

The first ideas about the mechanism of oxidative condensation were purely hypothetical. Thus Zal'kind and Fundyler[119,120] suggested that the process starts with the decomposition of acetylenic compound into radicals, which recombine to form a diacetylene derivative:

$$R{-}C{\equiv}CH \rightarrow R{-}C{\equiv}C^{\cdot} + H^{\cdot},$$
$$2\,R{-}C{\equiv}C^{\cdot} \rightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}R.$$

The authors advanced the hypothesis that the formation of derivatives of diacetylene is facilitated by an increase in the positive induction effect of the group or atom situated close to the triple bond. The hydrogen liberated is either used up in the hydrogenation of part of the acetylene or is oxidised by atmospheric oxygen to water. The part played by the copper salts and oxygen remains unexplained in Zal'kind's scheme.

Westcott and Baxendale[121] showed that Cu^{2+} ions are oxidants. Thus with a stoichiometric amount of $CuSO_4$ in

an aqueous buffer solution (pH 6) dimethylethynylcarbinol rapidly forms a diyne in 50% yield. The other half of the ethynyl compound is precipitated as copper(I) acetylide:

$$4\,RC{\equiv}CH + Cu^{2+} \rightarrow R[C{\equiv}C]_2R + 2\,RC{\equiv}CCu + 4H^+ .$$

Klebanskii and coworkers[122] proposed a three-stage mechanism for the formation of the diyne in aqueous solution:

$$\text{(I)}\ RC{\equiv}CH \rightleftarrows RC{\equiv}C^- + H^+ \ \text{(slow)},$$
$$\text{(II)}\ RC{\equiv}C^- + Cu^{2+} \rightarrow RC{\equiv}C^{\cdot} + Cu^+ \ \text{(rapid)},$$
$$\text{(III)}\ 2\,RC{\equiv}C^{\cdot} \rightarrow RC{\equiv}C{-}C{\equiv}CR \ \text{(rapid)}.$$

The authors consider that in an alkaline medium the acetylene slowly dissociates with formation of the acetylide ion, which is then oxidised by the Cu^{2+} ion into a radical. The Cu^+ ions do not affect the process. An analogous mechanism is also proposed for condensation in an acid medium but it is suggested that ionisation (1) takes place through the formation of an intermediate complex of type

$$RC{\equiv}C\cdot CuCl\cdot NH_4Cl,$$

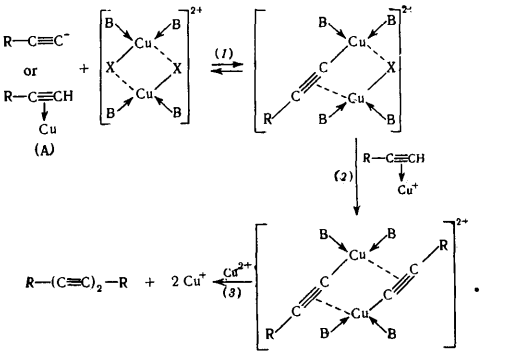
since on introducing an acetylenic compound into weakly acid (pH 4) solution of $CuCl_2$ and NH_4Cl the pH of the medium rapidly drops to pH 1.

Bohlmann and coworkers[123] found that the Klebanskii scheme does not correspond with the experimental results. Were the dissociation determining the rate of reaction to take place by Eqn. (1) the reaction rate would be first order. However, the reaction was always second order. To investigate the kinetics of the reaction, Bohlmann used a solution of the complex of copper(I) chloride with ethanolammonium chloride in 80% aqueous methanol. All the acetylenic compounds and copper(II) chloride are sufficiently soluble in this medium. The Cu^+ and Cu^{2+} are used in large excess. It was shown, by more than ten examples, that the reaction is second order. At pH 3 the reaction rate decreases with increase in the number of conjugated triple bonds. Thus the dimersiation time for half the initial quantity of phenylacetylene is 260 min, for phenyldiacetylene 6900 min, and for phenyltriacetylene 30 000 min. It is remarkable that in alkaline medium the reverse relation is observed (phenylacetylene 35 000 min, phenyldiacetylene 65 min). In pyridine solution the reaction rate increases with increase in the mobility of the acetylenic hydrogen; in acid medium the reverse is observed. In alkaline media the accelerating effect of Cu^+ ions is strongly expressed. The dependence of the reaction rate on the Cu^+ ion concentration is especially evident in the reactions of alkynes with increased mobility of the hydrogen. Thus on varying the concentration of Cu^+ ions from 0 to 100 the rate of dimerisation of the phenylacetylene increases 700 times and that of methyldiacetylene by about twice. The only probable explanation for the action of Cu^+ ions is the formation of π-complexes of the copper with the triple bond. This reaction can be regarded as a quasi-electrophilic addition. In this instance it is clear that with increase in the number of conjugated triple bonds the ability to form π-complexes should fall. The precise structure of these complexes is unknown but it can be assumed that the formation of a π-complex will be facilitated by an increase in the mobility of the acetylenic hydrogen to such an extent that even in acid media the dissociation:

$$R{-}C{\equiv}C{-}H \rightleftarrows R{-}C{\equiv}C^- + H^+$$
$$\downarrow\ Cu \qquad\qquad \downarrow\ Cu^+$$

can proceed.

Cu^{2+} ions take part in Bohlmann's scheme as an oxidant. Since a second-order reaction is observed at a large excess of Cu^{2+} ions the author suggests that the complex is formed from two molecules of the acetylenic compound. The general scheme of reaction can then be expressed in the following way:



In an acid medium copper(I) acetylide can be formed only as a π-complex (A), which then reacts according to (*1*). Thanks to the increase in the acidity of complex (A) and also the increase in the Cu^{2+} concentration, the reaction will be shifted to the right, to the side of the formation of a diacetylenic derivative.

If the reaction is carried out with compounds which contain two terminal acetylenic groups separated by a flexible chain, sufficiently long for ring closure, then the reaction is first order, since stage (*1*) is then an intramolecular reaction. Subsequent confirmation of Bohlmann's scheme was provided by the formation of products of mixed oxidative dimerisation. On assuming the radical nature of the process, the acetylenic radical formed initially should react with the second acetylenic radical selectively. However, it appeared that in the reaction of phenylacetylene with pentenynol in pyridine solution only 0.3% of the mixed dimerisation product is formed, which corresponds with a significantly greater reactivity of the phenylacetylene by the proposed mechanism. The yield of unsymmetrical products of the dimerisation is greater from acetylenic compounds with comparable reactivity.

The oxidative dimerisation mechanism proposed by Bohlmann reflects most completely the reaction process. However, much remains uncertain in this scheme. Thus, no explanation has been found for the reaction rate in alkaline media depending considerably on the amine concentration. The problem of the necessity for the reaction of a Cu^{2+} complex with an amine of definite composition remains open, since the complex is formed only when there is a large excess of amine. The nature of the amine plays a large part in the formation of the complex. Hay[116] showed that a high rate of reaction could be secured by using a total of 5–10 parts tetramethylenediamine per part of Cu^{2+} instead of a large excess of pyridine (as medium). The rate of dimerisation of phenylacetylene under strictly equal conditions varied in the ratio 40 : 7 : 1 on going from pyridine to 2-picoline to 2,6-lutidine.

Interesting results are given in a review[70] with reference to the private communication of Brandt, who found that the reaction of copper ions with acetylene can take place according to the scheme:

$$RC{\equiv}CH + Cu^+ \rightarrow RC{\equiv}CCu + H^+ \ \text{(fast)},$$
$$RC{\equiv}CCu + Cu^{2+} \rightarrow RC{\equiv}CCu^+ + Cu^+ \ \text{(slow)},$$
$$RC{\equiv}CCu^+ \rightarrow RC{\equiv}C^{\cdot} + Cu^+ \ \text{(fast)}.$$

An analysis of the results on the oxidative condensation of acetylenic compounds creates an impression of the possible existence of three different mechanisms for dimerisation in an alkaline medium, leading to a similar result: the oxidation of the acetylide ion, the oxidation of copper(I) acetylide, and finally the formation of an unstable acetylide derivative of copper(II), which decomposes into the acetylene radical and a copper(I) salt.

An example of the realisation of the first mechanism in a pure form is the oxidation of sodium phenylacetylide by permanganate in liquid ammonia[70]; diphenylbutadiene was obtained in 67% yield.

The possibility of the second path scarcely needs proof, since the lengthy time of the Glaser reaction carried out both oxidation of the copper acetylides previously liberated. Copper(II) can also be used as a strong oxidant:

$$R{-}C{\equiv}C{-}Cu + Cu^{2+} \rightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}R + Cu^{+}.$$

Evidently the part of copper(II) here differs significantly from its role in the scheme proposed by Bohlmann, who suggests the formation of an intermediate acetylene complex of Cu^{2+} directly from a copper(II) compound. In the last stage (*3*) of the Bohlmann scheme copper(II) is introduced as an oxidant but this is evidently not necessary since the complex which is formed decomposes spontaneously with homolytic breaking of the transition metal (Cu^{2+})–carbon bond, owing to the instability of this bond.

The work of Coates and coworkers[30-33] also suggests that the copper(I) acetylides themselves already have a structure convenient for dimerisation. It is not difficult to see, for example, that the oxidation of the metal in the phosphinic complex of the acetylide (see p. 1759) leads to a compound analogous to the complex (B) in Bohlmann's scheme.

---o0o---

On comparing the available information on the stability of the organic compounds of copper and silver with the acetylides of these metals, the following series can be compiled:

$$R{-}M \ll Ar{-}M < Ar{-}\overset{R}{\overset{|}{C}}{=}CH{-}M < R{-}C{\equiv}C{-}M < Ar{-}C{\equiv}C{-}M,$$

where R = alkyl, Ar = aryl, M = Cu or Ag.

Evidently the increase in the stability of the C–M bond in this series is explained, on the one hand, by the stability of the organic radical connected to the metal, and on the other, with the possibility of the formation of polymeric π-complexes. It is well known[124], for example, that phenylcopper is an insoluble polymeric substance. It can be suggested that the relative stabilisation of the C–Cu bond is attained here owing to the formation of Cu–Ph acceptor–donor bonds. In styryl (vinyl) compounds of Cu and Ag the possibility of complex formation is increased owing to the presence of mobile π-electrons of the double bond. Naturally the maximal stability is observed in acetylides.

On comparing the chemical reactivity of aryl derivatives and copper acetylides, clearly the Ar–Cu bond is considerably more active. Thus phenylcopper reacts with benzaldehyde[125], and acetophenone was obtained (54% yield) with acetyl chloride[125]. Information about such reactions with copper acetylides is not available. It should be noted that in addition to ketones a considerable amount of biphenyl is always formed in this reaction. Biphenyl was obtained exclusively in an attempt to condense carbon monoxide with phenylcopper[126].

Phenylcopper reacts with allyl bromide[125], forming allylbenzene in 31% yield. Copper acetylides undergo similar reactions but the yields are then usually higher.

The similarity of the copper acetylides to the organic compounds of copper also appears in the ability of the latter to form complexes with phosphines[127]. Thus, σ-cyclopentadienylcopper forms a stable complex with triethylphosphine $C_5H_5Cu.P(C_2H_5)_3$.

From the above examples it is evidently sufficiently clear that the acetylides of the metals of Group 1b, although exhibiting specific properties, also are closely connected with the organic compounds of these elements.

Dipole Moments and the Structure of π-Complexes of Metals

A.D.Garnovskii, O.S.Osipov, and V.I.Minkin

Information on the dipole moments of π-complexes of metals is surveyed and systematised in this article: cyclopentadienyl, arene, alkene, carbonyl, and polymetallic complexes. The possibility of using the dipole moments method for finding the geometric structure of the π-complex molecules, the spatial position of the ligands, and the nature and polarity of the bonds which arise in complex formation has been shown. The results obtained in measurements of dipole moments are compared with data from infrared and NMR spectra, X-ray diffraction, and the chemical properties of the π-complexes. There is a bibliography of 298 references.

I. INTRODUCTION

There is now an ever-increasing interest in the study of the structure of coordination compounds, in which the bond of the metal with the ligand is delocalised and brought about by interaction of the molecular π-orbitals of the ligand with the corresponding orbitals of the metal.

A series of monographs[1-4] and reviews[5-12] have generalised and systematised the information on the properties and structure of the π-complexes; these publications consider the results obtained by the methods of vibrational and NMR spectra, magnetochemistry, X-ray diffraction, and electron diffraction.

However, in none of these, nor in any of the other monographs[13-15] of a more general nature, is sufficient attention paid to the results of investigations of the polar properties of the π-complex molecules. Nevertheless a considerable number of papers has now been published[16-17] on the study of the structure and properties of coordination compounds by the dipole moment method, which gives valuable information on the geometrical structure of the molecules of the complexes, the spatial position of the ligands, the nature and polarity of the bonds arising in complex formation.

Interpretation of the values of the dipole moments does not require complicated mathematical equipment needed for dealing with the results from several other methods. However, it should be noted that the dipole moments method and vector calculations cannot always give an unambiguous characterisation of the structure of a complex molecule containing several polar groups. Because of this a knowledge of the value of the dipole moment is especially convenient when it is necessary to find which of several probable structures (*cis*- or *trans*-, centrosymmetric or otherwise) truly corresponds with the physical and chemical properties of the complex. The results obtainable on measuring the dipole moments are of special interest and cannot be replaced by X-ray structural investigations, since unlike the latter they characterise the structure of individual molecules in solution and not in a condensed phase.

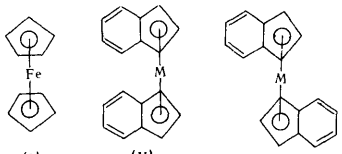
The present review surveys material (up to 1968) on the study of polar properties and the structure of coordination compounds of the transition metals and the halides of the elements of Groups III–V with unsaturated and aromatic and nitrosyl complexes. We usually compare the conclusions nitrosyl complexes. We usually compare the conclusions drawn from the values of the dipole moments with the results of other methods of investigation (infrared and NMR spectroscopy, X-ray diffraction, etc.) and also from certain data on the chemistry of the π-complexes.

The methods of determining dipole moments and the problem of estimating and calculating atomic polarisation are not examined in this review as these problems were discussed earlier[16,18-24].

II. CYCLOPENTADIENYL, ARENE, AND CYCLOALKENE COMPLEXES OF THE TRANSITION METALS

1. Cyclopentadienyls and Cyclopentadienides

Even in the first paper[25] devoted to the study of the structure of biscyclopentadienyliron, synthesised by Kealy and Pauson[26], on the basis of the zero value of the dipole moment and the results of other methods of investigation the now generally accepted structure (I) was proposed for ferrocene†:



M = Fe, Ru.

(I) (II) (III)

The zero value of the dipole moment was subsequently used as an unambiguous criterion of the high symmetry and sandwich structure of various cyclopentadienyl complexes of transition metals (Table 1).

Of the data given in Table 1,[25,28-42] attention may be paid to the different values of the atomic polarisation (P_A) at which the values of the dipole moments of the complexes reach zero. Taking into account that the ratio $(P_A + P_E)/P_E$ ‡ is a unique criterion of the "ionicity" of the bonds in the complexes[43], conclusions can be drawn about the largest ionicity of the cyclopentadienyl derivative of magnesium. This conclusion is also confirmed by the results of an investigation of magnesium biscyclopentadienide by mass spectroscopic and X-ray diffraction methods[6].

The different nature of the bond in cyclopentadienyl complexes can be observed not only from the values of P_A, but also from the changes in the values of the dipole moments of the complexes in different solvents[32]. Whereas in *cyclopentadienyls* with a pure covalent bond and low values of P_A (ferrocene, nickelocene, etc.) the dipole moment hardly changes on going from heptane to dioxan, for the "ionic" magnesium and manganese cyclopentadienyls it increases by 1.9 and 2.3 D respectively[32].

In addition to the *dipole-free* cyclopentadienyl complexes there is a group of compounds with a dipole moment different from zero: these are the derivatives of beryllium, tin, bismuth, lead[29,31], manganese[32], mercury[34], and also tantalum, niobium[38], molybdenum[39], and lutetium[36]. The explanations for the polarity of these derivatives are contradictory. Whereas in the early studies[29] suggestions are advanced concerning the organometallic nature of these complexes with an angled position for the σ-bound rings, it was subsequently shown that the $Pb(C_5H_5)_2$ and $Sn(C_5H_5)_2$ molecules are "sandwich" with non-parallel cyclopentadienyl rings[6,31,34,42,44]. An investigation of the structure of the metal biscyclopentadienyls using gas electron diffraction leads to the same conclusion[8,11].

Nevertheless, on the basis of the infrared and NMR spectra Fritz[44,45] does not rule out the possibility of σ-bonding of one of the five-membered rings in $Pb(C_5H_5)_2$ and $Pb(C_5H_4CH_3)_2$.

We see[46] that the cyclopentadienyl rings are also non-parallel in the $Zn(C_5H_5)_2$ molecule. Moreover, an angular arrangement of the σ-bound nuclei has been demonstrated[47] for $Hg(C_5H_5)_2$ with dipole moment 1 D.[34]

† The electronic structure of ferrocene has been discussed by Shustorovich and Dyatkina[27] and also by several other foreign authors[4].

‡ P_E is the electron polarisation.

The dipole moment (~ 2.5 D) of $Be(C_5H_5)_2$ was at first attributed to the presence in its molecule of π- and σ-bound cyclopentadienyl rings[31,34,35]. However, an investigation of the structure of biscyclopentadienylberyllium in the gas phase by electron diffraction shows the free motion of the Be ion in the cell formed by the five-membered rings, and explains the value given above for the moment by the possibility of the metal's being situated at a different distance from the π-cyclopentadienyl nuclei[8,48]. The last feature leads to the polar C_{5v} symmetry[48]. An examination of its infrared spectrum shows that $Be(C_5H_5)_2$ also has an asymmetric sandwich structure[49].

Table 1. Dipole moments of the cyclopentadienyl complexes of metals.

Compound	Name *	Solvent **	P_A, % of P_E	Dipole moment μ, D	Reference
$[\pi\text{-}C_5H_5]_2Fe$	bis-(π-cyclopentadienyl)iron(II) (ferrocene)	B	6	0	25, 28

* Given by Wilkinson and Cotton[6].

** B = benzene, D = dioxan, C = cyclohexane, H = heptane.

Similar considerations explain[41] the polarity (μ = 0.8 D)[40,41] of cycloheptatrienyl(cyclopentadienyl)chromium $C_5H_5Cr^0C_7H_7$. Clearly the complex $C_5H_5V^0C_7H_7$,[50] in which according to X-ray diffraction data the metal is found at a different distance from the planes of the cyclopentadienyl (1.9 Å) and cycloheptatrienyl (1.5 Å) rings[51], should also be polar.

The polarity of tetrakis(cyclopentadienyl)tantalum[38] and tetrakis(cyclopentadienyl)molybdenum[39] is explained by the participation in the formation of their molecules of σ- and π-bonded cyclopentadienyl rings, and that of manganese cyclopentadienide by the high "ionicity" of the bonds in this complex[32].

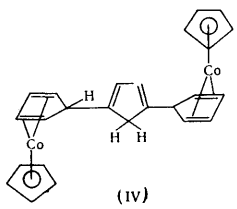
In connection with what has been stated it must be borne in mind that the values of the dipole moments cannot be an unambiguous criterion allowing the π-cyclopentadienyls to be distinguished from the usual organometallic compounds: the zero value of the moment shows the high symmetry of the molecule, but the appearance of polarity is not necessarily due to a change in the nature of the bonding. Therefore the conclusions concerning the type of bonds in the cyclopentadienyl complexes of metals drawn solely on the basis of values of dipole moments must be approached with caution.

The values of the dipole moments have been used to determine the possibility of free rotation of the cyclopentadienyl rings of disubstituted ferrocenes. Richmond and Freiser[52], who determined the dipole moments of the monoacetyl- (3.02 D) and diacetyl- (4.23 D) ferrocenes, concluded there was free rotation of the acetylcyclopentadienyl rings around an axis perpendicular to these nuclei[52]. However, these quantities can also be consistent with a restrained configuration[5].

A similar conclusion is also valid for *p*-chlorophenylferrocene[53]: the value found for its dipole moment (3.12 D) agrees best with those calculated for the 1,1'-prismatic (3.12 D) or antiprismatic (2.97 D) models. The value of the dipole moment calculated assuming free rotation of the *p*-chlorophenylcyclopentadienyl rings is 2.2 D.[53,54]

It is now assumed that whereas for ferrocene itself free rotation is only slightly restricted[3,4,6,55], bulky substituents can significantly inhibit it[54,56,57].

The bis(indenyl) derivatives of iron[31] and ruthenium[29] can be considered to belong to this class of compounds. These are extremely interesting as compounds having different structures in the crystalline state and in solution. The X-ray diffraction results show the asymmetric *cis*-position of the indenyl rings (II) in relation to the metal[58] and the zero value of the dipole moment gives a basis for attributing to the bis(indenyl) compounds the symmetric structure (III) with *trans*-arrangement of the ligands[31]. A study of the NMR spectra of indenyl complexes leads to the same conclusion[59]. The determination of the dipole moments of derivatives of ferrocene[60] and biferrocenyl[61], for which X-ray diffraction studies have been made[62-64] is of considerable interest in this connection.



(IV)

An interesting cyclopentadienyl derivative of a metal is the dinuclear complex $Co_2C_{25}H_{24}$. The structure first proposed for this compound, pentakis-(π-cyclopentadienyl)-dicobalt $(C_5H_5)Co_2$ in which each cobalt atom forms a trigonal prism surrounded by three cyclopentadienyl rings[29], was subsequently disproved[65-69]. It has now been found[69] that the molecule of this complex, which is 2,4-bis-(π-cyclopentadienylcobaltcyclopentadien)ylcyclopenta-2,4-diene, is constructed from two sandwich fragments connected through a planar cyclopentadiene bridging ring (IV). This structure agrees with the low polarity of complex (IV).[29]

2. Arene Complexes

The absence of a dipole moment was an important argument in support of a highly symmetric sandwich structure for bis(benzene)chromium[70] and several of its derivatives[29,31,71]. Just as for ferrocene, the atomic polarisation for the arene complexes of chromium is not more than 5–10% of the electronic polarisation; this has been shown not only by calculation[29] but also by the infrared spectra: P_A for bis(benzene)chromium is 3.3 ± 1 cm³ and that for bis(mesitylene)chromium[72] is 3.2 ± 0.7 cm³. In relation to these compounds the high dipole moments of bis(hexamethylbenzene)cobalt $Co[C_6(CH_3)_6]_2$, 1.78 D[73]—and the analogous chromium derivative (1 D)[74] seem extremely strange. The values given for the moments refute a centrosymmetric structure[73] but the reason for the polarity of these complexes is still not clear§.

This type of compound also includes the arenechromiumcyclopentadienyls[31], which do not have a dipole moment.

Determination of the dipole moment makes it possible to find certain details in the structure of heteroangularly substituted bis(benzene)chromium complexes. Thus the absence of dipole moments shows the *trans*-position of the substituents in the arene nuclei of bis(toluene)- and bis-(xylene)-chromium[31].

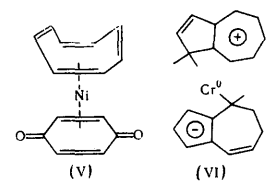
3. Cycloalkene Complexes

A large number of π-complexes of the transition metals with cycloalkenes[76-78], *p*-quinones[79,80], and acyclic alkenes[10,81] is now known.

Unlike the cyclopentadienyl and arene compounds, the cycloalkene complexes of metals are usually polar. Cycloheptatriene(cyclopentadienyl)chromium(0) $C_7H_8CrC_5H_5$ has a dipole moment of 1.1 D,[77] 1,3,5-cyclo-octatriene(cyclopentadienyl)chromium(0) 1.4 D.[77] The low dipole moment of (1.2 D) of π-cycloheptadienyl(cyclopentadienyl)nickel $C_5H_5NiC_5H_7$, which was initially given the structure of bis(cyclopentadienylnickel)[76] in error, agrees well with its unsymmetrical structure.

For the same reason allyl(cyclopentadienyl)palladium (μ = 1.5 D)[82] is polar. Nevertheless among similar complexes compounds with zero dipole moments are encountered, for example, benzene(cyclohexa-1,3-diene)-iron(0).[78]

π-Complexes of nickel with duroquinone and cyclooctatetraene (V), bicyclo[2,2,1]hepta-2,5-diene, bicyclopentadiene, and cyclo-octa-1,5-diene exhibit high dipole moments (3.5–4.3 D), due, evidently, to the high contribution of the polar structures[79,80].



(V) (VI)

It has been found that the value of the dipole moment depends on the polarity of the π-alkene bond and varies symbathically with the donor strength of the alkene ligand[80].

Of the cycloalkene π-complexes the bis(azulene) derivatives of chromium (VI) and iron[83,84] are of considerable

§ Nicholson and Longuet-Higgins[75] explain this anomaly by the Jahn-Teller effect.

interest. The slight polarity (1.18 D) of the chromium complex can scarcely serve as a basis for the structure proposed for it (VI). Here the polar properties are possibly connected with a difference in the distance of the metals from the planes of the azulene rings[8].

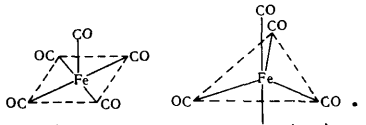
III. CARBONYLS AND NITROSYLS OF METALS

A series of detailed reviews[3,6,10,85,86] have dealt with the nature of the bonds, the methods of preparation, and properties of the carbonyls and the related nitrosyl, isonitrile, and cyano-complexes, but have not, however, considered the polar properties of these compounds.

1. Mononuclear Carbonyls and Nitrosyls

The absence of a dipole moment[87,88] shows the symmetrical nature of the tetracarbonylnickel molecule and can be consistent with planar, square, or tetrahedral configurations. This conclusion is not contradicted by the data obtained in investigating $Ni(CO)_4$ by other physical methods: study of the Raman spectra shows a planar configuration[89], but the infrared spectra[89,91] and electron diffraction[92] allow this complex to be assigned a tetrahedral structure.

The dipole moment for pentacarbonyliron $Fe(CO)_5$, determined by various authors, varies within the range 0–0.8 D. On the basis of the values first obtained for the moment (0.64 [92] and 0.81 D [93]) a square-pyramidal structure (VII) was proposed for $Fe(CO)_5$ and the non-polar configuration of a trigonal pyramid (VIII) was rejected. The non-zero values of the dipole moments were contradicted, however, by the results of an investigation of $Fe(CO)_5$ by vibrational spectroscopy[13,91,94] and by electron diffraction[95], according to which a trigonal bipyramidal structure was proposed for this complex:



(VII) (VIII)

Later investigations made by Weiss[96] showed that on taking account of the atomic polarisation (20% of the electronic) the value of the dipole moment is close to zero. A definitive solution of the problem in support of structure (VIII) gives a zero value to the dipole moment of $Fe(CO)_5$ obtained by a microwave method[97]. This conclusion is confirmed by the similarity in the values found experimentally for the entropy[98] and those calculated from spectroscopic data, and also by the X-ray diffraction results[99,100].

Carbonyls in which CO groups have been replaced by nitrosyl ligands have dipole moments extremely close to zero. Tricarbonylnitrosylcobalt $Co(CO)_3(NO)$ exhibits a moment of 0.4 D ($P_A = 20\% P_E$) and that of dicarbonyldinitrosyliron $Fe(CO)_2(NO)_2$ is 0.7 D.[96]

The low polarity of the carbonylnitrosyls[96], hydrogen pentacarbonylmanganate[101], and alkyl and aryl pentacarbonylmanganates (at an atomic polarisation equal to 20% of the electronic their dipole moment is 0–0.5 D[102,103]) gives a value of 0.5–0.8 D for the moment of the M–Co bond[96,104,105]. Measurements of the dipole moments of the cyclopentadienylcarbonyl complexes lead to the same value¶.

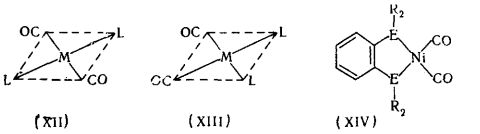
¶ For more details about these complexes, see below.

The introduction of polar groups into the complexes leads to a sharp rise in their dipole moments. The moment of $Fe(CO)_4(CNCH_3)$ is 5.07 D.[96] This value cannot be explained by the polarity of the isocyanide with dipole moment 2.5 D [106] and is connected with the high polarisation of the donor–acceptor bond (structure IX).

(IX) (X) (XI)

Analogous polar structures are proposed to explain the dipole moments of the complexes $CF_3Mn(CO)_5$ (X) 3.6 D and $RCOMn(CO)_5$ (R = Alk, 2.3 D; CF_3, 3.5 D; Ar, 2.3 D) and also of acrylic acid derivatives (XI) 2.4 D.[103] Similar dipole moments are possessed by the rhenium carbonyls $CH_3CORe(CO)_5$ 2.5 D and $C_6H_5CORe(CO)_5$ 2.6 D [103] and also the nickel complexes[105,107] $Ni(CO)_3PAr_3$ 3.84 D and $Ni(CO)_3AsAr_3$ 3.59 D.

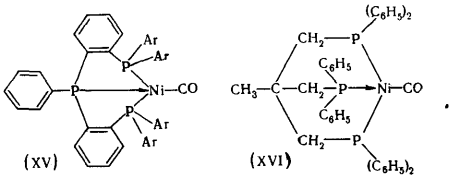
The values of the dipole moments of the planar dicarbonyl complexes of the type $L_2M(CO)_2$ are determined by their stereochemistry: the *trans*-isomers (XII) should not have dipole moments but the *cis*- (XIII) should exhibit considerable polarity:



(XII) (XIII) (XIV)

where E = As or P.

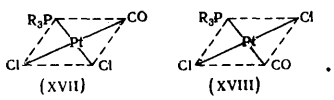
The moment of bis(chlorocarbonyl)platinum is 3.65 D [104] and therefore the complex is ascribed the *cis*-structure (XIII; M = Pt, L = Cl). $Ni(CO)_2(AsAr_3)_2$ with dipole moment 3.34 D and $Ni(CO)_2(PAr_3)_2$ with 3.82 D have the *cis*-configuration[105]†. The *cis*-structure seems the only possibility for complexes (XIV): their dipole moments lie in the range 5–5.5 D.[105,107] Taking into account that the Ni–C–O group is of low polarity (0.5 D) the authors estimate the moments of the Ni–P and Ni–As bonds to be 3.4 and 3.2 D respectively[105]. The same value for the Ni–P bond is also obtained from the value of the dipole moments for the monocarbonylphosphinic complexes (XV, $\mu = 5.18$ D) and (XVI, $\mu = 4.95$ D):[109]



(XV) (XVI)

For the same reason the Fe–P bond should also exhibit considerable polarity, since the dipole moment of $Fe(NO)_2[P(C_6H_5)_3]_2$ is 4.99 D.[110]

Chatt and coworkers investigated the polar properties of monocarbonylphosphinic complexes of platinum(II) chloride[111]. On the basis of the high values of the dipole moments (~ 10 D) and the infrared spectra the *cis*-structure (XVII) is ascribed to these complexes: the *trans*-isomers (XVIII) should have lower moments[111]:



(XVII) (XVIII)

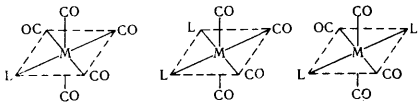
† For $Ni(CO_2)(PEt_3)_2$ of the same structure $\mu = 4.4$ D.[108]

The polar properties of the metal carbonyls and nitrosyls $M(CO)_5L$, $M(CO)_4L_2$, $M(CO)_4L$, $M(CO)_3(NO)L$, $M(CO)_2(NO)L$, and $M(CO)_2L$, where L is a p-electron donor, and M the metal, depend on both the geometry of the molecule and the polarity of the M–L bond.

The high value of the dipole moment is characteristic for the halogenopentacarbonyls of manganese $Mn(CO)_5L$ (for the bromo-derivative μ = 3.2 D [103] or 3.99 D, [112] for the iodo-derivative 3.25 D [103]) and for the derivatives of chromium, molybdenum, and tungsten with nitrogenous bases (L = pyridine, quinoline, piperidine, and aniline 6–7 D [113]). For all these complexes structure (XIX) is assumed and the formula

$$\mu_{M-L} = \mu_{expt} - \mu_{M-Co} - \mu_L$$

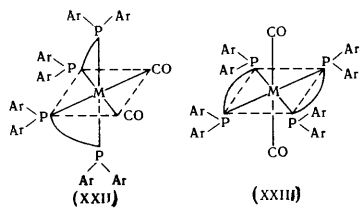
can be used to determine the partial dipole moment of the M–C bond [113]. For $Cr(CO)_5L$ and $Mo(CO)_5L$ the latter lies within the limits 3.6–4.1 D; for $W(CO)_5L$ it is higher by 0.7 D and only depends slightly on the nature of the donor [113]. It is somewhat lower (2.5–3.3 D) only for complexes with acetonitrile, benzonitrile, and aniline [113].



(XIX) (XX) (XXI)

For complexes of the $M(CO)_4L_2$ type *cis*- (XX) and *trans*- (XXI) configurations are possible and the values of the dipole moments can vary from 10 (XX) to 0 (XXI) D. The values of the dipole moments of the *cis*-phosphinic derivatives of the tetracarbonyls of chromium, molybdenum, and tungsten lie within the limits 7–8 D. [114] $Mo(CO)_4$. .2Py has a moment of 9.3 D, the analogous tungsten complex 10.3 D, [113] and $Cr(CO)_4[P(C_6H_5)_3]_2$ and $Cr(CO)_4$.2(cyclohexylnitrile), which have been assigned the *trans*-structure, do not possess dipole moments [115].

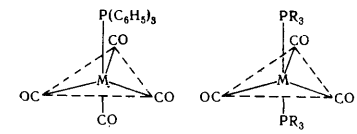
The calculated dipole moment for the *trans*-structure is zero, and that for the *cis*- can be calculated by the formula $\mu_{cis} = \mu_{mono}\sqrt{2}$ (for a regular octahedron), where μ_{mono} is the moment of the complex $M(CO)_5L$ with the same donor, and agrees satisfactorily with the values obtained experimentally [113]. It should be noted that only the *cis*-isomers of the above Mo and W complexes have been isolated, whereas both configurations are known for the chromium compounds [114]. Similar regularities are also observed for the dicarbonyl complexes of the Group VI metals with bidentate phosphines [114]. For $[Cr(CO)_2\{C_2H_4(PAr_2)_2\}_2]$ both the *cis*- (XXII; μ = 6.2 D) and the *trans*- (XXIII; μ = 6.95 D) isomers are known but the similar molybdenum and tungsten complexes with dipole moments 6.15 and 6.7 D respectively, have only the *cis*-octahedral structure (XXII). [114]



(XXII) (XXIII)

The dipole moment of *cis*-$Fe(CO)_4.(HgCH_3)_2$ is extremely low—2.1 D. [116] There may be an equilibrium of the *cis*- and *trans*-isomers in solution here.

The reasons for the considerable differences in the values of the dipole moments of triphenylphosphineirontetracarbonyl $Fe(CO)_4.P(C_6H_5)_3$, 5.1 D [110] and of the analogous manganese derivative $Mn(CO)_4.P(C_6H_5)_3$‡, 1.1 D [117] and mononitrosyltriphenylphosphinemanganesetricarbonyl $Mn(NO)(CO)_3P(C_6H_5)_3$, 4.9 D, [110] to which is assigned a trigonal bipyramidal structure (XXIV): [110,117,118]

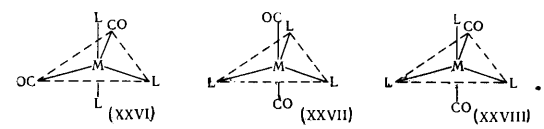


(XXIV) (XXV)

are not understood.

Attempts to explain these differences by the large contribution of the polar form $\bar{M} \leftarrow \overset{+}{P}(C_6H_5)_3$ do not appear to be very convincing in relation to the nitrosyl complex $Mn(NO)(CO)_3.P(C_6H_5)_3$. [110] The anion $[Mn(CO)_4(PAr_3)]^-$ is assigned a trigonal bypyramidal structure on the basis of the identical values of the dipole moments (5.1 D) of $HMn(CO)_4PAr_3$ and $Fe(CO)_4PAr_3$. [119] However, such a comparison can scarcely be considered an unambiguous criterion in the solution of structural problems particularly as the octahedral complex $CH_3Mn(CO)_4PAr_3$ has a moment (4.9 D), extremely close to that given above [119]. Dipole moments close to zero suggest for the complexes $Fe(CO)_3[P(C_6H_5)_3]_2$, [120] $Mn(CO)_2(NO)[P(C_6H_5)_3]_2$, and $Mn(CO)_2(NO)[P(C_6H_{11})_3]_2$ [110] the trigonal bipyramidal model (XXV) with *trans*-PR_3 groups. As Hieber and Tengler [110] consider, the tetragonal pyramidal and trigonal bipyramidal structures with *cis*-arrangement of the PR_3 ligands which are formally possible here should have a dipole moment of ~ 5 D. [110] In this instance it is not clear what structure is characteristic for $Fe(CO)_3[P(OC_6H_5)_3]_2$ with a moment 2.31 D. [121]

The high value of the dipole moment (4.97 D) allows tris(triphenylphosphine)irondicarbonyl to be assigned the structure of a trigonal bipyramid with CO groups lying at the vertices of the triangular base (XXVI). [121] The possible structure (XXVII), is rejected on the basis of the infrared spectra, and (XXVIII) should have a dipole moment of ~ 7 D: [121]



(XXVI) (XXVII) (XXVIII)

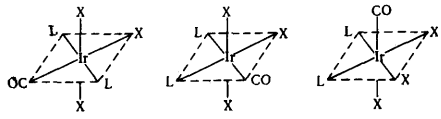
A structure analogous to (XXVI) is proposed starting from the values of the dipole moments and the results of studies of the infrared spectra, for the phosphine derivative of the dicarbonyl halides of cobalt(II) [122] and also for $IMn(NO)_2[P(C_6H_5)_3]_2$ with moment 3.19 D. [123]

For the triphenylphosphinedinitrosyliron halides, $Fe(NO)_2P(C_6H_5)_3X$, it was noted [124] that there is an increase in the dipole moment with increase in the atomic weight of the halogen (X = Cl, μ = 6.78 D; Br, μ = 7.02 D; I, μ = 7.21 D). The same regularity was observed earlier for the analogous complexes of cobalt [125]. However, the increase in the moment in the last instance is insignificant (Cl 6.79 D, Br 6.83 D, I 6.89 D [125]), as it is for the halogen derivatives of pentacarbonylmanganese [103]. More significant changes in the values of μ are characteristic

‡ According to Sidgwick's rule this compound should be a dimer and consequently diamagnetic. However, published data [117] show it to be paramagnetic (1.86 μ_B) and monomeric (M_{exp} = 420; M_{calc} = 429.2).

for the complexes being considered on replacing the phosphorus by other elements of Group V: whereas the dipole moment of $Co(NO)_2P(C_6H_5)_3Br$ is 6.83 D, that for the analogous manganese derivative is 6.4 D and that for antimony 5.26 D.[125] The phosphine-substituted complexes $Co(NO)(PAr_3)_3$ and $Co(NO)(CO)_2PAr_3$ should have similar dipole moments for a tetrahedral configuration. Actually, if the atomic polarisation is not taken into account, then for $Ar = C_6H_5$ the moments of these complexes amount to 4.27 and 4.56 D respectively, and for $Ar = OC_6H_5$ 2.38 and 2.27 D.[125] However, at $P_A = 20\% P_E$ the values of the dipole moments in the first instance differ by 1.2 D, but in the second, by 0.5 D.[125] The reasons for these differences are, in the opinion of these authors[125], connected with the distortion of the valence angle of the tetrahedron under the influence of the bulky PAr_3 groups.

On the basis of dipole moments the configuration of the isomeric carbonyl complexes of the type $IrX_3(CO)(ER_3)_2$, where X = Cl, Br; E = P, As, Sb, and R = Alk, Ar, and of the iridium carbonyl hydride $IrHCl_2(CO)[P(C_2H_5)_2C_6H_5]_2$ was established[126]. For these complexes with X = Cl, E = P, and R = C_2H_5, two, (XXIX) and (XXX), of the three possible isomers, (XXIX)–(XXXI), were isolated and all three of the analogous butyl derivatives: (XXIX) 2.35 D, (XXX) 9.55 D, (XXXI) 12.35 D.[126]



(XXIX) (XXX) (XXXI)

Two isomers, (XXIX) and (XXX), are observed for the phosphinic complex $IrCl_3CO[P(C_2H_5)_2(C_6H_5)]_2$ with dipole moments 3.3 and 9.65 D, for the analogous arsenic derivatives 2.95 and 9.8 D, and also the carbonyl hydrides $IrHCl_2(CO)[P(C_2H_5)_2(C_6H_5)]_2$ 1.2 and 5.1 D.[126] The complexes $IrBr_3(CO)[P(C_2H_5)_2(C_6H_5)]_2$ and $IrCl_3(CO)[Sb(C_3H_7)_3]_2$ are assigned the configuration (XXIX) (their dipole moments are 3.4 and 2.4 D respectively), but $IrCl_3(CO)[As(C_2H_5)_3]_2$ with moment 9.65 D and the bromo-derivative of the above carbonyl hydride (5.35 D) the configuration (XXX).[126]

From the dipole moments (2.5–3.5 D) the *trans*-structure can be assigned to complexes of the general formula $Rh[(XC_6H_4)_3M]_2(CO)Cl$, where M = P, As, and X = H, CH_3, Cl, OCH_3.[127]

Analogous results were obtained for the carbonyl-phosphinic derivatives of rhenium and manganese[120,128]. For $Re(CO)_3[P(C_6H_5)_3]_2I$ *cis*- and *trans*-isomers were observed[128] with dipole moments of 7.6 and 3.0 D respectively but for $Re(CO_3)[P(OC_6H_5)_3]_2I$ only the *cis*-isomer (5.7 D). The carbonyl hydride derivatives of manganese $HMn(CO)_3[[(C_6H_5)_3]_2$ with dipole moment 0.58 D and $HMn(CO)_3.[P(OC_6H_5)_3]_2$ with 2.09 D[120] analogous to the rhenium complex $HRe(CO)_3.[P(C_6H_5)_3]_2$ with 2.5 D,[128] and also carbethoxybis(triphenylphosphine)tricarbonylmanganese (1.7 D),[129] have the *trans*-structure. In this connection the dipole moment of the recently synthesised[130] *cis*-isomer $HMn(CO)_3.[P(OC_6H_5)_3]_2$ is of definite interest.

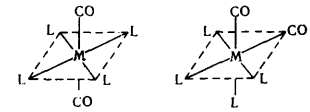
The dipole moment values allow the isomers of halogenophosphinic derivatives of manganese carbonyls to be distinguished[112]. The complex $Mn(CO)_3[P(OC_6H_5)_3]_2Br$ with dipole moment 4.78 D is ascribed the *cis*- and the compound with $\mu = 3.52$ D the *trans*-structure[112].

$$Re(CO)_3[(C_6H_5)_3PO]_2X$$

(X = Cl, Br, I; μ = 8–10 D) has the *cis*-structure[131].

Similar conclusions concerning the structure of complexes of the $L_3MN(CO)_3X$ type follow from their infrared spectra[130,131].

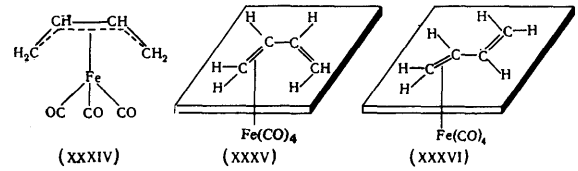
Structural problems similar to those described above also arise in solving problems of the configuration of complexes of type $M(CO)_2L_4$.[132] Here, in addition to an isomer without a dipole moment (XXXII) with *trans*-arrangement of the CO groups (D_{4d} symmetry), a polar *cis*-form should exist (XXXIII, C_{2v}).



(XXXII) (XXXIII)

2. Diene- and Polyene-carbonyls

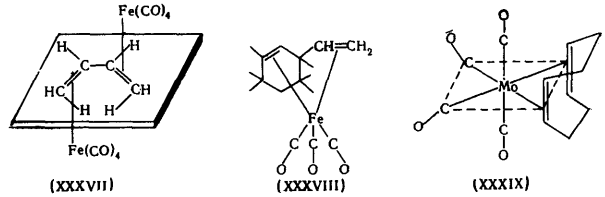
The simplest complexes of this type are the butadieneirontri- and tetracarbonyls[133–136]. Undoubtedly these compounds are of the π-complex type[10,136]. Hallam and Pauson[134] proposed structure (XXXIV) for butadieneirontricarbonyl, and this was confirmed[10,137] by X-ray structural data[138] and chemical properties. The infrared spectrum of butadieneiron tetracarbonyl shows that complex formation takes place through only one π-bond[135].



(XXXIV) (XXXV) (XXXVI)

It seems probable that there are two structures with *cis*- (XXXV) or *trans*- (XXXVI) arrangement of the butadiene fragment (analogous structures can also be postulated for butadieneirontetracarbonyl). The dipole moment method was used to distinguish these structures[135]. However, the values of the dipole moments 2.15 D (for butadieneirontetracarbonyl) and 1.94 D (for the tricarbonyl analogue) did not permit *cis–trans* isomers to be distinguished[135].

More definite information was obtained for butadienylironoctacarbonyl, which on the basis of its low polarity ($\mu \simeq 0.9$ D) was assigned structure (XXXVII) with $Fe(CO)_4$ groups arranged on both sides of the plane of the butadiene ring[135].



(XXXVII) (XXXVIII) (XXXIX)

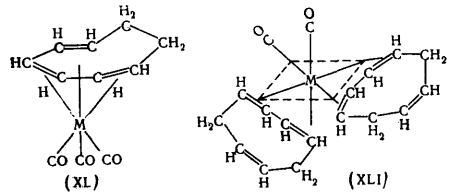
Complexes (XXXV)–(XXXVIII) are evidently the only exceptions among the carbonyl–alkenes where the diene occupies one coordination site: in all the other instances the diene acts as a bidentate ligand.

In the 3-vinylcyclohexeneirontricarbonyl complex the alkene is coordinated by both π-bonds with the formation of the complex (XXXVIII) with $\mu = 2.94$ D.[1]

On the basis of the dipole moment (4.9 D),[139] and the infrared[139] and NMR[140] spectra the (cyclo-octa-1,5-diene) metaltetracarbonyls are assigned the structure (XXXIX) with a boat conformation of the cycloalkene.

Clearly, an analogous structure can be assumed for cyclo-octa-1,5-dieneirontricarbonyl with dipole moment 3.1 D,[139] the infrared spectra[141] being consistent with this structure.

The comparatively high value of the dipole moment of cyclo-octatrienemolybdenumtricarbonyl $C_8H_{10}Mo(CO)_3$, 4.1 D, shows the coordination of the cycloalkene as 1,3,5-cyclo-octatriene (XL) and the displacement of the electron density from the cyclo-octatriene ring to the metal and further towards the carbonyl groups[142]. The lower moment for bis(cyclo-octatriene)molybdenumdicarbonyl $(C_8H_{10})_2Mo(CO)_2$, 1.96 D, can be explained by the participation of the 1,3,6-isomer in the complex formation[142]. Fischer and coworkers assume that the *trans*-arrangement of the 1,3-diene system is improbable. However, because of its comparatively low dipole moment (~ 2 D) the compound has been assigned the structure (XLI):[142]



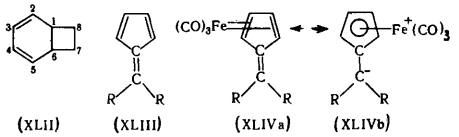
(XL) (XLI)

where M = Mo or W.

Two alkene carbonyl complexes of iron were also obtained by the reaction of a mixture of cyclo-octatriene isomers with $Fe(CO)_4$: a yellow liquid and red crystals[142]. By analogy with the molybdenum complexes the liquid product (dipole moment 2.37 D) was assigned the structure of a 1,3,6-cyclo-octatriene complex.

The solid, with a higher dipole moment (3.66 D) was assigned a structure with 1,3,5-configuration of the cyclo-octatriene ligand[142]. Later investigation of the chemical properties[143,144] and the infrared[144] and NMR[145] spectra showed that any isomerisation of cyclo-octatriene with iron carbonyls leads to bicyclo[4,2,0]octa-2,4-diene (XLII) of which the complexes under consideration are derivatives[143].

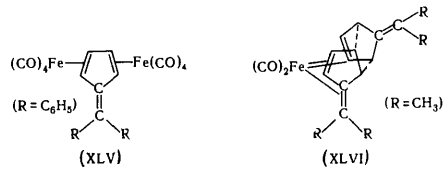
The π-system of the cyclopentadiene ring of the diphenylfulvenes was found to be convenient for the formation of alkene(carbonyl) complexes[146].



(XLII) (XLIII) (XLIVa) (XLIVb)

The values of the dipole moments of the diphenylfulveneirondi- and tricarbonyls reach 2.5–3.5 D[146] whereas diphenylfulvene itself (XLIII; R = C_6H_5) has a moment of 1.34 D[147] and its *p*-chlorophenyl derivative (XLIII, R = *p*-ClC_6H_4) 0.68 D.[18] These values of the dipole moments are connected with the contribution of the polar structures (XLIVb), which is especially significant for the *p*-chlorophenyl derivatives[146]. Weiss and Hübel[146] consider that the realisation of structure (XLIVb) is confirmed by the marked rise in dipole moment (XLIVa, R = *p*-ClC_6H_4) in comparison with the initial fulvene and complex (XLIVa, R = C_6H_5), whereas electron-withdrawing substituents in the phenyl nuclei of the ligand decrease the moment[146].

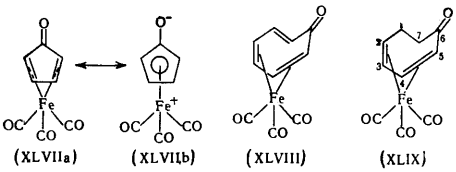
Diphenylfulvenedi-ironoctacarbonyl $C_{18}H_{14}Fe_2(CO)_8$ has moment 1.73 D, not greatly above that of free diphenylfulvene (1.34 D). Therefore the complex under consideration is assigned the structure (XLV) with symmetrically arranged $Fe(CO)_4$ groups, each of which is coordinated with one double bond of the diene ligand.



(XLV) (XLVI)

A quite unusual structure (XLVI) in which the exocyclic double bond of fulvene is utilised, is assigned to bis(dimethylfulvene)irondicarbonyl $[(CH_3)_2C{=}C_5H_4]_2Fe(CO)_2$ on the basis of the dipole moment (2.88 D)[148] and infrared spectra[146].

In the formation of mixed carbonyl complexes cyclopentadienone and tropolones can act as π-ligands[148–151]. The high values of the dipole moment of complex (XLVIIa), 4.4 D,[150] taken in conjunction with the infrared spectra[148,149] show the polarisation of the carbonyl group and the significant contribution of the polar structure (XLVIIb):

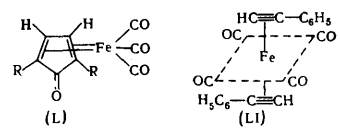


(XLVIIa) (XLVIIb) (XLVIII) (XLIX)

The ability of the iron cyclopentadienonecarbonyls to form adducts with acids and phenols of general formula $(CO)_3FeC_5H_4O.HX$, where X = Cl, Br, I, OAr and to give a negative reaction, characteristic of ketones, with phenyl- and 2,4-dinitrophenyl-hydrazines agrees with these suggestions[150].

However, this explanation can hardly be completely correct since the analogous complexes of tropoloneirontricarbonyl (XLVIII) with dipole moment 4.3 D show reactions typical of the keto-group[151]. The product of the non-polar hydrogenation of complex (XLVIII), cyclohepta-2,4-dienoneirontricarbonyl (XLIX) exhibits the same properties: at a high value of the dipole moment it forms the stable 2,4-dinitrophenylhydrazone[151] and has a C=O stretching frequency of 1661 cm^{-1}; the carbonyl group probably does not coordinate with the metal atom.

The reaction of pentacarbonyliron with phenylacetylene yields 2,5-diphenylcyclopentadienoneirontricarbonyl (L) with dipole moment 3.1 D.[152,153] This value eliminates the centrosymmetric structure (LI) suggested earlier[10,152]:



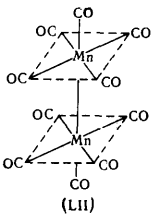
(L) (LI)

where R = C_6H_5.

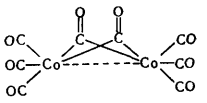
3. Polynuclear Carbonyls and Nitrosyls

The dipole moments of the dinuclear carbonyls of rhenium and manganese of composition $M_2(CO)_{10}$, determined in benzene, dioxan, and cyclohexane, have values close to 1.0 D,[103] although according to the infrared spectra[12,154–157]

and X-ray structural investigations[158,159] these complexes should have a symmetric structure[86].



(LII)



(LIII)

In this connection the assumption is made that the atomic polarisation should constitute 20–30% of the electronic: the dipole moment of both complexes should then become close to zero[103]. To explain the polarity (μ = 1.29 D)[160] of octacarbonyldicobalt $Co_2(CO)_8$ it was assumed that the CO bridges connecting the cobalt atoms are curved (LIII; C_{2v} symmetry)[14,154].

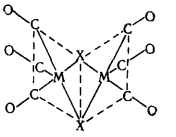
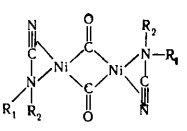
Not only CO but also other groups (NH, SC_2H_5, SeC_2H_5, PMe_2,[161,162] PR_2,[163,164] and AsR_2 [163]), halogen atoms[165], and sulphur and selenium atoms[161], and also SnR_2 [116] can act as bridging ligands in polynuclear carbonyls. Table 2 gives the values of the dipole moments of complexes with these groupings.

Model (LIV), in which the two bridging groups and two iron atoms do not lie in the same plane, was proposed to explain the polarity of the externally non-symmetric carbonyls of the $[FeX(CO)_3]_2$ type[161]. This model has C_{2v} symmetry. A similar symmetry is evidently characteristic for $[Fe(NO)_2(SC_2H_5)]_2$,[165] the halogeno(nitrosyl) complexes of cobalt[165], and the tungsten and molybdenum carbonyls of general formula $[M(CO)_4ER_2]_2$.[117,161,167] X-ray diffraction showed a similar structure for $[Fe(CO)_3(SC_2H_5)]_2$.[169] In all the complexes considered the presence of bridging groups creates a certain rigidity of structure and increases their symmetry. In those dinuclear carbonyls where the dimerisation occurs through a metal–metal bond (Table 2, compounds 21–23, 32–34) there arises the possibility of free rotation around this bond, which leads to a decrease in the symmetry of the molecule and the appearance of a comparatively high dipole moment[161,167].



(LIV)

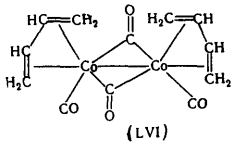


(LV)

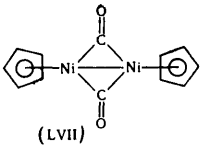
The presence of bridging CO groups was suggested on the basis of results obtained in the determination of dipole moments and investigations of the infrared spectra for the dialkylcyanoamido-complexes of nickel carbonyl (LV). The lone pair of electrons of the amine nitrogen and the π-electrons of the nitrile group take part in the formation of these complexes; the values of the dipole moments (1.5–2.0 D) are consistent with C_{2h} molecular symmetry[168].

The determination of dipole moments was an important tool for finding the structure of the polynuclear carbonyls containing organic π-ligands.

The high polarity (μ = 3.39 D) allows bis(butadiene-cobalt-tricarbonyl) to be assigned the structure with *cis*-arrangement of the CO ligands (LVI):[1,170] the dipole moment for the *trans*-configuration should be close to zero.



(LVI)

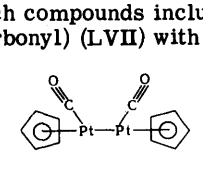


(LVII)

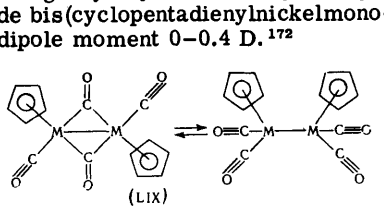
The considerable value of the dipole moment (3.02 D) of the compound bis(cyclo-octa-1,3,6-trienecobaltdicarbonyl) is connected with the angular structure of this complex[171].

The dipole moment method has proved extremely useful for solving problems of the presence or absence of carbonyl bridges in a series of dimers of cyclopentadienylmetalmonocarbonyls of general formula $[C_5H_5M(CO)]_2$. Two groups of complexes can be distinguished among these compounds: (1) those with a dipole moment close to zero, and (2) those which are polar, with a moment of ~ 2.0–3.0 D.

The first type of complex is credited with a rigidly symmetric structure, the dimerisation in which occurs by an M–M bond, and the "rigidity" by two carbonyl bridges. Such compounds include bis(cyclopentadienylnickelmonocarbonyl) (LVII) with dipole moment 0–0.4 D.[172]



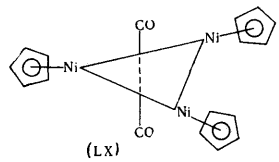
(LVIII)



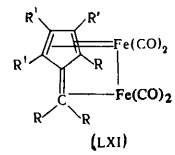
(LIX)

The appearance of polarity in the second group of complexes is connected with dimerisation solely by the M–M bond, around which free rotation is possible. The infrared and NMR spectra are inconsistent with carbonyl bridges and a symmetrical arrangement of the C=O groups in bis(cyclopentadienylplatinum-monocarbonyl)(LVIII) with dipole moment 2.6 D.[173]

Other relationships are observed between the values of the dipole moments and structure of the dimers of cyclopentadienylmetaldicarbonyls $[C_5H_5M(CO)_2]_2$. In this instance the complexes with the pure M–M bond (M = Os)[174] and the compounds with an M–M bond fixed by carbonyl bridges (M = Fe)[175] have appreciable dipole moments, respectively 2.6 and 3.1 D, due to the breaking of the carbonyl bridges in the solution and the formation of polar *cis*-structures (LIX), observed in detailed infrared spectroscopic investigations[176].



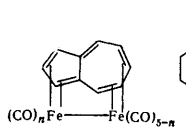
(LX)



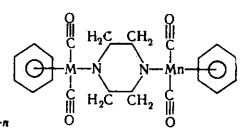
(LXI)

The zero value of the dipole moment of the polynuclear nickel complex, $(C_5H_5)_3(Ni_3(CO)_2$, indicated the centrosymmetric structure (LX),[172] and this was also confirmed by X-ray diffraction[15].

The complexes of $Fe_2(CO)_9$ with substituted fulvenes obtained by Weiss and Hübel are interesting, the fulvenes evidently acting as bidentate ligands. The polarity (3.5–4 D)[146] and the absence from the infrared spectra of bands for carbonyl bridges suggests that the probable structure for this group of complexes is (LXI). However, the number of CO groups at the iron atoms (3 : 3 or 4 : 2, as in (LXI) —remains uncertain[146].



(LXII)



(LXIII)

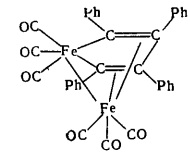
Azulene can also take part in the formation of similar complexes[177]. On the basis of the considerable polarity (μ = 3.97 D) and absence of absorption in the region for bridging CO groups, Wilkinson and coworkers ascribed the structure (LXII) to the complex with general formula $C_{10}H_8Fe_2(CO)_5$.[177]

The low dipole moment (~ 1 D) of the complex (LXIII) agrees well with its symmetric structure[178].

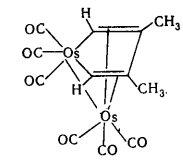
The reaction of acetylene[10,175,179] and its derivatives with iron carbonyl is very interesting. Two centrosymmetric structures were proposed for the products of the reaction of iron tetracarbonyl with acetylene and diphenylacetylene, of general formula[180]:

$$Fe_2(CO)_6(RC{\equiv}CR)_2.$$

However, the high values of the dipole moments of these complexes (μ = 2.86 D for R = H;[175] μ = 3.3 D for R = C_6H_6[180]) are against their symmetric structure. It transpired that it is more correct to regard these compounds as derivatives of tricarbonyl(ironcyclopentadienyl)irontricarbonyl (LXIV),[180] particularly as structures similar to (LXIV) have been demonstrated by X-ray diffraction for a series of reaction products of acetylenes with iron[181–183] and osmium[182] (LXV) carbonyls.

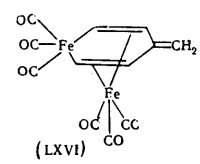


(LXIV)

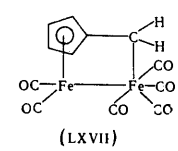


(LXV)

A non-zero value of the dipole moment allows conclusions to be drawn about the absence of a centre of symmetry for compounds[175] of the general formula $(C_2H_2)_3Fe_2(CO)_6$. One of these with dipole moment 1.7 D was given the structure (LXVI) because of its paramagnetism[175]; its isomer with a higher dipole moment (3.41 D) was assigned the structure (LXVII).[175]



(LXVI)

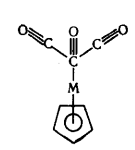


(LXVII)

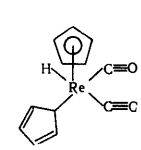
4. Cyclopentadienyl and Arenecarbonyl Compounds

The values of the dipole moments of the monocyclopentadienylmetal carbonyls lie within the range 2.9–3.5 D and to a first approximation vary little with the number of carbonyl groups in the complex[96,184,185]. The value of the moment also varies little on replacing the carbonyl groups by nitrosyl: cyclopentadienylchromiumdicarbonylmononitrosyl π-$C_5H_5Cr(CO)_2(NO)$ has μ = 3.2 D.[96]

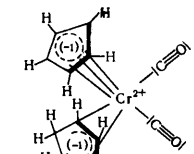
These values of the dipole moment allow the M–C_5H_5 bond moment of the bond to be estimated as ~ 2.0–2.5 D,[96] if it is assumed that the moment of the M–C–O fragment does not exceed 0.5–0.8 D.[96,105] The high polarity of the π-complexes of this type is connected with the asymmetry of their structure, for example (LXVIII).[1,6,86]



(LXVIII)



(LXIX)



(LXX)

The dipole moments of the π-cyclopentadienylmetalcarbonyls are almost independent of the solvent, which is explained by the coordination saturation of the metal atom in these compounds[185]. Bis(cyclopentadienyl)rheniumdicarbonyl hydride $(C_5H_5)_2ReH(CO)_2$, which belongs to this type of complexes, was assigned structure (LXIX) with π- and σ-bonded cyclopentadienyl rings on the basis of its high polarity (μ = 3.85 D)[31,186,187] and NMR and infrared spectra[188]. Structure (LXX), in which the CO groups are

arranged in the *cis*-position in relation to one another and the coordination number of the chromium is seven, is proposed[189] for cyclopentadienyl(cyclopentenyl)chromium-dicarbonyl $(C_5H_5)(C_5H_7)Cr(CO)_2$, from consideration of the vibrational and NMR spectra and the value of the dipole moment (3.5 D).

Arenechromiumtricarbonyls§ of the general formula $XArCr(CO)_3$, in distinction from the bisarene complexes of chromium, exhibit considerable polarity (the values of their dipole moments vary within the range 4.5–6.5 D, see Table 3). This value cannot be connected with a small moment of the C–O group (0.8 D) and it is explained by the polarisation of the metal–arene bond[31,71,191,192].

It was logical to assume that the presence of this polarisation should lead to an increase in the dipole moment of the arenechromiumtricarbonyls containing electron-donating substituents in the benzene rings and a decrease in polarity when the substituents are electron-withdrawing[31,191,193]. The values of the dipole moments of the complexes with electron-donating (compounds 2–16, Table 3) and electron-withdrawing (compounds 17–22) substituents confirm the hypothesis and there is a satisfactory correlation between Hammett's σ constants, the dipole moments, and the displacements of the C–O stretching frequencies[192].

Randel and Sutton[193] determined the dipole moments of a group of arenechromiumtricarbonyls containing from one to six methyl groups in the benzene nucleus and concluded that the moments found experimentally (in benzene) agree satisfactorily with the values calculated by the formula $\mu = \mu_0 + 0.23n$ (where μ_0 is the moment of benzenechromiumtricarbonyl and n the number of methyl groups). It was shown later that for other solvents also similar relations can be found: $\mu = \mu_0 + 0.26n$ (heptane) and $\mu = \mu_0 + 0.20n$ (dioxan)[191]. However, if it is remembered that the dipole moment values of the methyl-substituted arenechromiumtricarbonyls obtained for one or another solvent by different authors vary by 0.2–0.3 D (Table 3), the above relations must be considered to be extremely approximate. With the arenechromiumtricarbonyls the solvents have a considerable effect on the value of the dipole moment: the greatest moment is observed in solvents such as dioxan and the least in heptane; benzene occupies an intermediate position[191]. This peculiarity in the behaviour of the arenechromiumtricarbonyls, the aromatic rings of which can behave as potential acceptors of electrons is thought by Strohmeier to be explained by the formation of donor–acceptor compounds between the complex and the solvent[191]. Such an explanation agrees well with the fact that the difference in the values of the dipole moments ($\Delta\mu$) determined in dioxan and in heptane gradually decreases with increase in the number of electron-donating groups in the aryl nuclei of the complexes and reaches a minimal value for hexamethylbenzenechromiumtricarbonyl[191]. Furthermore, from this position it is not clear why $\Delta\mu$ decreases, not increases, for arenechromiumtricarbonyls with electron-acceptor substituents in the aryl nuclei (chlorine, fluorine[191], and especially an ester group[194]), and why the value of $\Delta\mu$ for naphthalenechromiumtricarbonyl is extremely low (0.14 D).[191,195]

A comparison of the dipole moments of the *p*-xylenetricarbonyl complexes of chromium, molybdenum, and tungsten (Table 3) shows that in the series Cr → Mo → W the values of the moments increase with increasing acceptor strength in the order $Cr(CO)_3$, $Mo(CO)_3$, $W(CO)_3$.[191]

The dipole moments of the cyclopentadienyl and arenemetal carbonyls of the general formula $RM(CO)_2L$, where M = Cr and L is a nitrogen base, $P(C_6H_5)_3$, are $SO_2(CH_3)_2$ groups[115], and also π-ligands (alkenes, alkynes)[197] have been determined. The results have been used to calculate

§ A review on substituted carbonyls of the metals of Group VIb appeared recently[190].

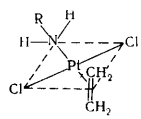
the partial dipole moments μ(M–L) of the metal–donor bond and to establish a correlation between these quantities and the stretching frequencies of the carbonyl groups of the complexes[197].

IV. COMPLEXES OF METAL SALTS WITH UNSATURATED HYDROCARBONS

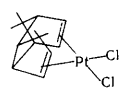
1. Complexes of Alkenes

The dipole moments of the purely alkenic complexes bis(ethyleneplatinum chloride) $(C_2H_4PtCl_2)_2$ [198] and bis-(ethylene) platinum(II) dichloride[199] have not been measured.

In 1947 Syrkin and Shidlovskaya[200] determined the dipole moment of the simplest representative of the alkene complexes (LXXI; R = H) of platinum(II) chloride $C_2H_4PtCl_2NH_3$, which was investigated in detail later by Chatt and coworkers[198,199].



(LXXI)



(LXXII)

The values obtained for complexes of the type (LXXI) (for R = p-$CH_3C_6H_4$ the dipole moment is 2.35 D; for R = p-ClC_6H_4, 1.79 D) correspond to the difference in moments $\mu_{(N-Pt)} - \mu_{(C_2H_4-Pt)}$ and since $\mu_{(N-Pt)}$ has been evaluated[201] as ~ 6 D the moment $\mu_{(C_2H_4-Pt)}$ should be 4 D.[186] Evidently this value characterises a donor–acceptor bond produced by the bonding of the π-orbital of ethylene and the dsp^2-orbitals of platinum. A bond of this type is extremely polar, therefore the comparatively low value of the dipole moment is explained by the formation of an additional dative bond from the Pt atom to the antibonding π^*-orbital of the alkene ligand[198].

This treatment of the nature of the metal–alkene bond¶, which is confirmed by X-ray diffraction[204,205] and electron diffraction investigations[206], by the prominant trans effect of the alkenes[203,207] and also by calculated data[208], is now widespread.

Determination of the dipole moment of the complex of platinum(II) chloride with bicyclopentadiene led to a conclusion about the coordination at the π-bond of the alkene[209]. For 50 years this compound had been ascribed a structure with a C–M σ-bond[210] and it was only in 1956 on the basis of the considerable dipole moment (μ = 13 D) and the infrared spectra that it was given structure (LXXII).[209]

The complexes of $PtCl_2$ with hexa-1,5-diene (6.1 D) and cyclo-octatetraene (7.0 D)[211] should probably also have structures similar to (LXXII). In the latter instance the appreciable value of the dipole moment is thought by Jensen[211] to be connected with the fact that the cyclo-octatetraene in the complex has the "boat" conformation and this is also detected in the spectroscopic investigations[212]. According to the results of crystal-chemical investigations[213] dipenteneplatinum dichloride $C_{10}H_{16}PtCl_2$, norbornadiene palladium dichloride[214] $C_7H_8PdCl_2$, and dimeric cyclo-octa-1,5-dienerhodium chloride[215] have structures similar to (LXXII).

In connection with the increasing interest in the mechanism of cationic polymerisation[216,217] papers devoted to a study of the polar properties of complexes of tin(IV) chloride with unsaturated compounds[218,219] have recently appeared.

¶ The earlier work of Gel'man[202,203] is interesting in this connection.

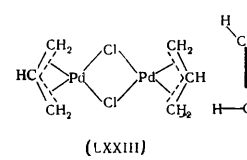
Using a method of dielectrometric titration Gol'dshtein and coworkers determined the values of the dipole moments of complexes of tin(IV) chloride with styrene (0.73 D), stilbene (0.75 D), and 1,1'-diphenylethylene (1.09 D).[218,219] The dipole moments of such complexes of $SnCl_4$ with alkenes are distinguished from the moments of the free ligands by 0.4–0.7 D and it was concluded that the products of the reaction of tin(IV) chloride with unsaturated hydrocarbons are π-complexes[218].

The existence of such complexes was shown not only in the determination of the dipole moment but also by a spectroscopic method[220,221]. Furthermore it must be borne in mind that the interpretation of the values of the dipole moments of these complexes in benzene is difficult, since according to some data $SnCl_4$ itself has a moment of 0.8–0.95 D in this solvent[16,17].

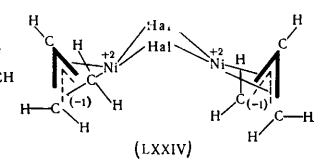
2. π-Allyl Complexes

The structure of the π-allyl complexes of the transition metals has now been adequately studied[222,223]. The largest number of dipole moment data are for bis(allylpalladium chloride) $(C_3H_5PdCl)_2$,[224,225] its methylallyl $(C_4H_7PdCl)_2$ [226] and phenyl $(C_9H_9PdCl)_2$ [227] analogues, and bis-(π-allylnickel halides) $(C_3H_5NiX)_2$.[228,229] The participation of the π-electrons of the allyl radical in the formation of such complexes is now no longer open to doubt[230–233]: it has been demonstrated in the study of the infrared[234] and NMR [235] spectra of the allyl complexes of palladium chloride, by X-ray structural investigations[236–238], and in other ways.

The dimeric nature of these complexes[225] and the results of X-ray structural analyses[236–238] allow structure (LXXIII) with μ-halogeno bridges to be ascribed to complexes of this type.



(LXXIII)



(LXXIV)

For the strictly planar structure of type (LXXIII) the dipole moment should be close to zero. Starting from this assumption, Syrkin and coworkers assumed that the nonzero value of the dipole moment of bis-(π-allylpalladium chloride) 2.23 D (for the α form) and 3.4 D (for the β) belong to the monomer[225]. However, other authors[226] state that the moment of 2.2 D obtained for bis-(π-methylallylpalladium chloride) relates to a dimer. A similar opinion is also expressed for the allyl complexes of the nickel halides[229]: the dipole moment of 1.62 D for bis-(π-allylnickel iodide) and 1.31 D for bis-(π-allylnickel bromide) are connected with dimeric molecules which exist in benzene and cyclohexane solutions.

The question naturally arises as to the reason for the polarity of the externally symmetrical dimeric π-allyl complexes of the metal halides.

The hypothesis of the donor–acceptor interaction of the molecule of the complexes (LXXVII) with the π-system of the solvent, which could have a considerable effect on the value of the moment, is improbable here, since in cyclohexane the dipole moment of this type of compound is considerable (for example, for bis-(π-allylnickel iodide) it is 1.48 D.[229] Fischer considers that to explain these values of the dipole moments of the dimeric π-allylnickel halide molecules they must have the structure (LXXIV) in

which the halogen bridges cause curvature of the molecule, destroying its symmetry[229].

Similar ideas could evidently be extended to the butadiene complexes of palladium and platinum chlorides, the structure of which has been little studied.

The dipole moments (~ 3.5 D) of the π-allyl complexes of rhodium and palladium of the type

$$[E(C_6H_5)_3]Cl_2M\text{-}\pi\text{-}C_4H_7,$$

where E = P, As, Sb, have also been determined (~ 3.5 D).[239]

In conclusion it must be noted that the structural assignment of the products of the reaction of metal chlorides with allyl hydrocarbons is of considerable importance for finding the mechanism of oxidation of alkenes[240] and for various polymerisation processes[231].

V. COMPLEXES OF THE HALIDES OF THE ELEMENTS OF GROUPS III–V WITH AROMATIC HYDROCARBONS

Interest in the complexes of metal halides with aromatic hydrocarbons has arisen in connection with the study of the mechanisms of a large number of catalytic reactions which take place with participation of aluminium chloride[241,242] and the halides of other metals[243].

A principal part in solving the problem of the existence of metal halide complexes with aromatic hydrocarbons and of their nature was played by dipole moment studies on halides in various solvents. Even in the first papers of Ulich and Nespital it was shown that aluminium bromide, which is almost non-polar in carbon disulphide, has a high dipole moment (4.9–5.2 D) in benzene[244,245]. It was found later that in aromatic solvents (benzene, toluene, *p*-xylene) the dipole moments of aluminium bromide reach values of ~ 5–6 D[248] whereas in cyclohexane[249], carbon disulphide, bromine[248], and also the melt[246], the values of μ are close to zero. These results agree with ideas about the dimerisation of $AlBr_3$ in these solvents. X-Ray structural[250], electron diffraction[251,252], and spectroscopic[253] investigations lead to the same conclusion.

The high values of the dipole moments of aluminium bromide in benzene[244–248,246] naturally raised the question of the reasons for its polarity in non-polar solvents.

The first attempt to explain this was made by Ulich and Nespital, who considered that in the benzene solution dissociation of the dimeric molecules of aluminium halides took place, leading to the appearance of non-symmetric monomers of $AlBr_3$ with a structure distorted under the influence of the solvent[244,245]. The appreciable dipole moment of aluminium iodide[246] and gallium chloride[254] in benzene (2.5 and 3.05 D respectively) responded to analogous treatment. In later investigations[246–248] although the dissociation of the dimeric molecules of aluminium halides in benzene was not contradicted, the high values of the dipole moments were connected with the formation of complexes of the monomeric molecules of the halides with the solvent.

Evidence in support of the existence of such complexes is provided by the results of the physicochemical analysis of the $AlBr_3$–C_6H_6 system[225] and the results of spectroscopic[256], thermochemical, and electrochemical[247] investigations.

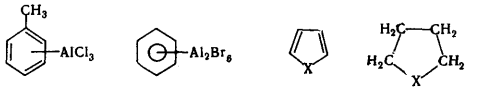
The high values of the dipole moments of antimony trichloride (~ 4.0 D)[257–259] and tribromide (3.28 D)[259] in benzene also show the interaction of SbX_3 with the solvent, leading to the formation of a complex, which is also observed by thermal analysis[260] and spectroscopy[261,262].

Similarly it is possible to explain the polarity of thallium(III) chloride (3.93 D)[263] and silver perchlorate (4.7 D)[264] in benzene, which in the last instance agrees with the existence of a molecular compound $AgClO_4.C_6H_6$[265] and also the appearance of non-zero moments for the symmetric molecules of tin(IV) chloride in benzene[266,267] and for the $SnCl_4$–naphthalene complex[268].

All the above results leave no doubt about the ability of aromatic hydrocarbons to form complexes with metal halides.

Many investigations[241,269–271] were made to explain the nature of these complexes and it became understandable only comparatively recently[271].

It is now generally accepted that aromatic compounds form π-complexes with metal halides owing to the interaction of the π-electrons of the aromatic system and the vacant orbitals of the metals. For example, the complex of toluene with aluminium chloride is ascribed the structure (XXV)[270]:



(LXXV) (LXXVI) (LXXVII) (LXXVIII)

where X = O, S.

Some recent investigations of the problem by Romm and Gur'yanova are of special interest[272]. They showed that in thoroughly dried benzene aluminium bromide keeps a dimeric structure and its dipole moment does not exceed 1 D. The authors consider that the π-complex of benzene with aluminium bromide has structure (LXXVI), and the high values of the dipole moments obtained earlier for $AlBr_3$ in aromatic solvents are connected with the formation of a ternary complex $Al_2Br_6.HBr.nAr$.[272] The results of this investigation, although not denying the possibility of the formation of π-complexes of the metal halides with aromatic hydrocarbons, merit critical examination of the values obtained earlier for the dipole moments of halides in aromatic solvents[16–17].

In determining the dipole moments of complexes of tin(IV) chloride with furan and thiophen (LXXVII) it was found that both the value of the moment of the complex and its increase during complex formation are considerably less than for saturated heterocycles (LXXVIII).[218,273] These results led to the conclusion that thiophen and furan form π-complexes with $SnCl_4$ (the dipole moment of the thiophen complex is 1.73 D, that of furan 0.99 D), but thiophan (5.0 D) and tetrahydrofuran (5.94 D) give complexes with a donor–acceptor bond owing to the *p*-electrons of the sulphur or oxygen atoms[273]. The infrared spectra of the complexes of $SnCl_4$ with thiophen and thiophan support these ideas[274].

It is remarkable that according to dielectric constant measurements of titanium(IV) chloride does not form π-complexes with benzene[275] and thiophen[276]. However, thermal analyses[277,278] and spectroscopic[278] and magnetic (EPR)[279] investigations show that $TiCl_4$ forms π-complexes with aromatic systems including benzene[279]. Therefore it must be borne in mind that in instances when the increase in dipole moment on going from the ligand to the complex is exceptionally small (< 0.5 D), the value of the moment cannot serve as a definite criterion for the absence of complex formation in the system. Only a combination of various physicochemical methods permits the behaviour of the compounds in solution to be judged.

In conclusion we note that not only metal halides but also a series of organometallic compounds are capable of

forming π-complexes with aromatic hydrocarbons. The same conclusion was reached from the results of Stromeier's work, which shows that the dipole moment of organometallic compounds in benzene is always greater than the value obtained in measurements in hexane, heptane, carbon disulphide, and other indifferent solvents [31,191,280,281].

VI. POLYMETALLIC $\pi\sigma$-COMPLEXES

Because of the rapid development of physicochemical and structural investigations in the field of bimetallic and polymetallic $\pi\sigma$-complexes [282,283], the polar properties of the organometallic compounds containing transition (M) and non-transition (M') metals are now being studied.

Kahn and Bigorgne [284,285] determined the dipole moments of bimetallic carbonyls of the type $(CO)_4Co.MX_3$, $(CO)_4Fe(MX_3)_2$, $[(CO)_4FeM'X_2]_2$, where M = Si, Ge, Sn, Pb; X = Cl, Alk, Ar, OMe.

From these results, detailed infrared investigations, and the assumption that the transition metal atom in these complexes is electrically neutral, the authors also determined the structure, found more accurately the nature of the M–M' bond [sic], and compared it with the bond in the $(CO)_4Fe–PX_3$ complexes.

On the basis of the dipole moments [286] of the recently prepared [287] carbonyl-π-cyclopentadienyls of the general formula $[\pi\text{-}C_5H_5Fe(CO)_2]_nSnX_{4-n}$, where X = Hal, Alk, Ar, conclusions were drawn about the monotonic increase in the moment with increase in the volume of X and the effect of the substituent on the polarity of the fragment $[\pi\text{-}C_5H_5Fe(CO)_2]$–Sn was discussed. This increase in the dipole moment is evidently connected with the approximation of the Fe–Sn–Fe angle to the regular tetrahedral angle (according to X-ray structural investigations [288–291] this angle is 124–126°).

---o0o---

New information has recently appeared on the study of the structure of π-complexes by the dipole moment method. The value $\mu = 1$ D allows the *cis* structure to be ascribed to pentacarbonylbis(cyclopentadienyl)vanadium $(C_5H_5)_2V_2(CO)_5$; [292] the *trans*-configuration should be without a dipole moment. A centrosymmetric structure agrees with the insignificant value of the moment of the dimer of bis(cyclopentadienyl)platinum, $[Pt(C_5H_5)_2]_2$. [293]

The dipole moment method showed that the monocarbonyls [294] and mononitrosyls [295] of rhodium(I) and rhodium(III) of the general formulae $MX(CO)L_2$ and $MX_3(EO)L_2$ (where X = Cl, Br, I, SCN; L = PR_3, AsR_3) have the *trans*-structure. Analogous complexes of ruthenium have been isolated as *cis*- and *trans*-isomers [296].

A *trans*-arrangement of the PR_3 groups and *cis*-halogens is characteristic for dicarbonylphosphinic complexes $MX_2(CO)_2(PR_3)_2$ (M = Fe, Ru, Os), [297] but only the *cis*-structure for $[PtX_2CO(PR_3)]$. [298]

Progress in the Synthesis of Perfumes Based on Pinenes†

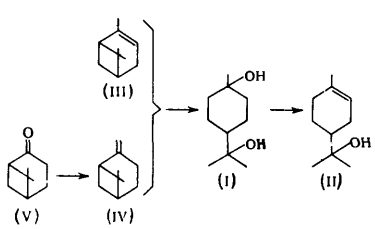
Y.-R.Naves

Turpentine was known in far antiquity. As is well known, it was obtained by steam distillation of various types of pine. Rosin and resins are obtained simultaneously.
All these products were used in the construction of ships. Turpentine was first produced in the XVIth century in North America, where there were vast areas of pine forests in North and South Carolina, Georgia, Alabama, and Virginia and where there was a market for these products, and they became widespread in the XVIIth century. The use of turpentine for the production of varnishes, paints, etc. began about 1830-1840.
There is a bibliography of 119 references.

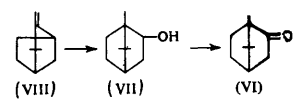
1. Turpentine and the Chemistry of Perfumes

Turpentine was first used as a raw material for the manufacture of perfumes at the end of the XIXth century. In 1827 Vogel obtained terpene (I), which Tilden in 1878 and Wallach in 1885 dehydrated to terpineol(II), and Flavitskii obtained terpineol directly from turpentine in 1879. In France the industrial production of terpineol was the consequence of work carried out by Bouchard and Bouari (1866) and Lafonte (1889).

The structure of α-pinene (III), the principal constituent of turpentine, was suggested by Wagner in 1894 and firmly established by Bayer two years later. The structure of β-pinene (IV) was established by Wallach in 1907 as a result of the synthesis of this terpene from norpinone (V). The first accurate analysis of a mixture of α- and β-pinenes was effected by Darmu in 1911 on the basis of measurements of optical rotatory dispersion.



Camphor (VI) was known in the Far East before recorded time. It was introduced into Europe by the Arabs. Reluz obtained it by the oxidation of borneol (VII) in 1841. At the end of the last century camphor became an important raw material for the manufacture of celluloid and smokeless powders. Bredt established the structure of camphor in 1893, but its synthesis, effected from the pinenes through the intermediate production of camphene (VIII), borneol, and isoborneol, was used industrially only until 1920.



Up to 1940 the pinenes were used for the production of terpineols, borneol, isoborneol, and their esters, and camphor. The position then changed sharply. This progress was due to the efforts of the producers of turpentine to increase its consumption and thanks to the wish of the synthetic perfumes industry to be freed from the use of natural ester oils, the difficulty of supply, variable quality, and high cost of which hindered the further development of this sector of industry.

I will not dwell on the papers dealing with the development of the chemistry of camphene, borneol, isoborneol, and camphor, and also terpenophenols, since most of the terpenophenols were first obtained in the USSR at the All-Union Scientific Research Institute for Synthetic and Natural Perfumes, where in this field also very interesting work is now being carried out.

This review will give the progress reached in effecting the opening of the bicyclic system of the pinenes and their derivatives into compounds of the monocyclic and aliphatic series.

The acid-catalysed decyclisation was effected even longer ago, since the production of terpineols was realised

† Paper read at the All-Union Scientific Research Institute of Synthetic and Natural Perfumes, Moscow, 1967.

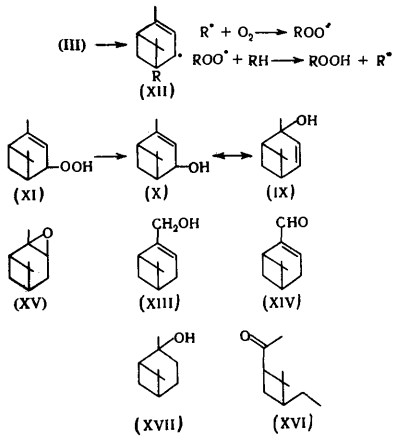
by industry seventy-five years ago. The application of this reaction to bicyclic derivatives of pinenes led to new methods for the production of menthones, menthols, carbeols, and carbone. However, the most progress was achieved in decyclisation by the pyrolysis of pinenes, pinanes, verbenols, and pinanols. These reactions opened the way to the production of aliphatic terpenes and their derivatives, such as linalool, geraniol, nerol, α- and β-citronellols, α- and β-elgenols, α- and β-citrals, citronellals, α- and β-elgenones, hydrohydroxycitronellal, and pseudoionones. The syntheses of these substances also open new paths for the production of menthols.

Many of these syntheses could not be carried out without the development of new methods for the production of verbenols, pinanols, and other similar compounds based on the production of oxides and hydroperoxides.

2. Production of Oxides and Hydroperoxides

The oxidation of α-pinene with or without the use of photosensitizers followed by the reduction of the hydroperoxides formed gives pin-3-en-2-ols (IX) and their allyl isomers—verbenols (X)—pinan-2-ols (XVII), and also verbanols.

According to Dupont[1], the primary products of the oxidation of α-pinene (III) are verbenyl hydroperoxides (XI), which are catalysts for the formation of the free radicals (XII), which initiate chain reactions. The mechanism of these reactions was also studied by Schenk and coworkers[2].



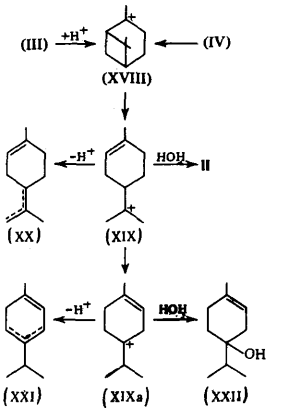
The production of hydroperoxides is accompanied by the formation of pinene oxides by the Prilezhaev reaction. As a result of all the reactions in the oxidation of α-pinene (III) after the reduction of the hydroperoxides a mixture is obtained which contains pin-3-en-2-ol (IX) (predominantly the *cis*-isomer), verbenols (X), verbenone, myrtenol (XIII), myrtenal (XIV), and α-pinene oxide (XV).[3,4] Here (−)α-pinene corresponds to (+)-pinenols, (−)-*trans*-verbenol, (+)-*cis*-verbenol, (−)-verbenone, and (+)-α-pinene oxide. The pinenols can be isomerised into the verbenols (X) by the action of hot water or dilute alcohols. The hydrohalogenation of verbenol leads to verbenyl halides, acetylation with acetic anhydride in the presence of sodium acetate gives *trans*-verbenyl acetate principally. Oxidation with chromium(VI) oxide leads to verbenone[5,6]. The hydrogenation of verbenols over copper chromite at 200°C leads to the formation of a mixture of isoverbanol and neo-isoverbanol[7].

Fischer and coworkers[8] studied the formation of hydroperoxides of pinanes. A product containing 85–90% hydroperoxide is obtained at 40–45% oxidation in 85–86% yield on the pinane used. The decomposition of the hydroperoxides in the presence of sodium methoxide leads to both 1-aceto-3-ethyl-2,2-dimethylcyclobutane (XVI) and pinan-2-ol (XVII) in 50% yield.

3. Decyclisation Catalysed by Acids

Although the opening of the four-membered ring of pinenes by acids has long been known[9,10] its mechanism was established with certainty only in 1947, by Moser[11,12]. In the presence of a proton α-pinene (III) or β-pinene (IV) form a carbonium ion (XVIII). The breaking of the four-membered ring is accompanied by transfer of the positive to the $C_{(8)}$ of the *p*-menthane system and the formation of a double bond in position 1 (XIX). This carbonium ion can be isomerised into (XXa). The removal of a proton leads either to the formation of dipentene and terpinolene (XX) or α- and β-terpineols (XXI). The migration of a double bond to $C_{(2)}$ leads to isoterpinolene and *p*-mentha-2,4-diene.

In the presence of OH ions α-terpineol (II) and terpin-1-en-4-ol (XXII) are formed:



The formation of the terpene (I) proceeds with the intermediate production of a double charged ion (XXIII). Its reaction with water and subsequent dehydration leads to α-, β-, and γ-terpineols, (II), (XXIV), and (XXV).

The formation of terpenes, which is accompanied by the formation of terpene (I) or terpineols, was long considered undesirable. It is now used for obtaining methols through menth-3-ene.

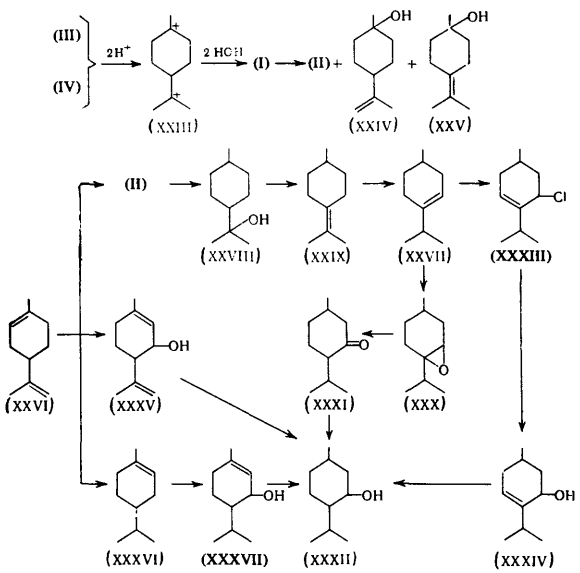
A good yield of monocyclic terpenes with a trace of camphene as impurity is obtained in the treatment of pinenes with ion-exchange resin or aluminosilicate (zeolite)[11a]. By carrying out the reaction at a certain temperature, up to 75% limonene or dipentene (XXVI) can be obtained. Limonene (XXVI) exhibits an angle of rotation opposite to that of α-pinene (III), and the same as β-pinene (IV). The optical purity is retained well.

A mixture of monocyclic terpenes with *p*-cymene and camphene as impurities undergoes disproportionation and hydrogenation. Bain and Gary[13] achieved the partial disproportionation in the presence of nickel formate, obtaining menth-3-ene in good yield. Camphene and α-pinene remained unchanged.

Partial hydrogenation over nickel at a low temperature leads to the formation of a mixture[14] of menth-2-ene and menth-4-ene. The latter readily isomerises into menth-3-ene (XXVII) on heating or under the action of acids[15]. As a result, a mixture of menthenes and *p*-cymene is obtained[16-18].

This method of synthesis of menth-3-ene is considerably more economical than the synthesis based on the dehydration of dihydro-α-terpineol (XXVIII) with subsequent isomerisation to (XXIX).[14,19]

The conversion of limonene (dipentene) and menth-3-ene into menthols was effected by different paths. Menth-3-ene (XXVII) is converted into the oxide (XXX) the isomerisation of which leads to menthones (XXXI), and subsequent hydrogenation gives a mixture of menthols (XXXII).[19]



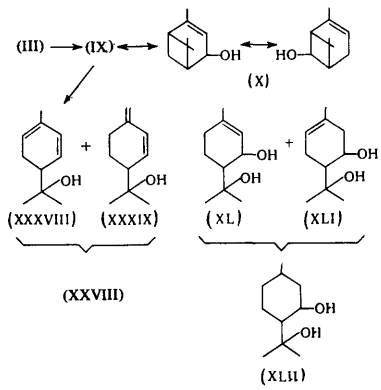
Bain and Webb converted menth-3-ene (XXVII) into 5-chloromenth-3-ene (XXXIII), hydrolysis of which gave *trans*-menth-3-en-5-ol (XXXIV). The last is readily hydrogenated into isomenthol, which can be isomerised into menthol if the temperature and duration of the reaction are sufficient[20].

The oxidation of limonene (dipentene) (XXVI) followed by reduction of the hydroperoxide leads to *p*-mentha-1,4(8)-dien-3-ol (XXXV). The oxidation of carbomenthene (XXXVI)—obtained by selective hydrogenation of dipentene—leads, after reduction, to piperitols (XXXVII), which are then hydrogenated to menthols (XXXII).

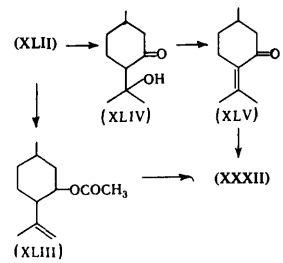
The reduction of hydroperoxides can be brought about by sodium sulphite solution, by the action of triphenylphosphine, or by alkali metal tetrahydroaluminates. The selective hydrogenation of *p*-mentha-1,8-dien-4-ol, obtainable from the hydroperoxides formed in the photosensitised oxidation of limonene (dipentene), leads to terpin-1-en-4-ol (XXII).[21]

The decyclisation of pin-3-en-2-ols (IX) and verbenols (X) takes place just like the decyclisation of α-pinene (III) but in addition a considerable proportion of *o*-mentha-4,6-dien-8-ol is formed. α- and β-8-hydroxyphellandrenes (XXXVIII) and (XXXIX), *p*-menth-1-ene-3,8- and 5,8-diols (XL) and (XLI) and 8-hydroxy-*p*-cymol are obtained predominantly. Decyclisation is brought about by the action of boiling water in the presence of aqueous solutions of zinc chloride, sodium hydrosulphite, and phosphoric acid.

8-Hydroxyphellandrenes (XXXVIII) and (XXXIX) can be converted into dehydro-α-terpineol (XXVIII) and diols into *p*-menthane-3,8-diol, that is, the menthoglycols (XLII).



The latter can be converted into cyclic acetals, which are of interest for perfumery. Reactions with acetic anhydride allow these diols to be converted into acetates of isopulegols (XLIII), from which menthols (XXXII) can be obtained. It is also possible to oxidise these diols to 8-hydroxymenthone (XLIV) which is dehydrated to pulegone (XLV) and hydrated to menthols (XXXII).



Pin-3-en-2-ols (IX) can be converted into pinan-2-ols (XVII), from which α-terpineol (II) was obtained by boiling with water[22].

Pin-3-en-2-ols (IX) and verbenols (X) are converted into verbenyl chlorides and then into verbenyl amines. By hydrolysis of the latter by Bain and Polland's method[23], the corresponding alcohols are obtained, hydrogenation of which leads to menthol.

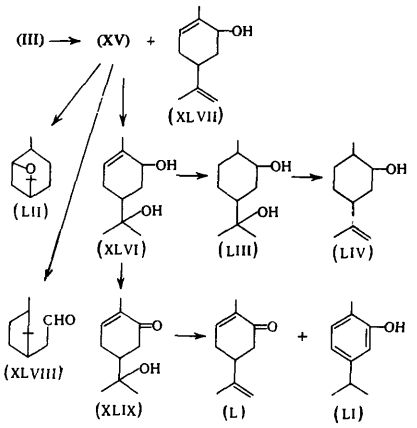
The conversion of α-pinene oxide (XV) into sobrerol or pinol hydrate (XLVI) has long been known. Klein[24], who treated α-pinene oxide (XV) with water or weak alkali solutions in the presence of an antioxidant, obtained predominantly *trans*-sobrerol (XLVI) with the impurity *p*-cymol and other hydrocarbons, and also carveols (XLVII), campholene aldehyde (XLVIII), and *p*-mentha-1,4(8)-dien-6-ol.

This method was perfected by Durbataki and Linder[25], who obtained sobrerol in quantitative yield by acting on α-pinene oxide (XV) with water saturated with carbon dioxide at 30–35°C.

Sobrerols (XLVI) can be oxidised to 8-hydroxycarbone (XLIX), dehydration of which leads to a mixture of carbone (L) and carvacrol (LI).

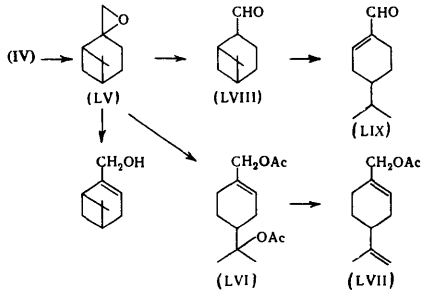
In the usual dehydration of sobrerol the products are pinol (LII) and *p*-cymol, and pyrolysis of pinol diesters gives the esters of carveol (XLVII) in good yield[26]. Thus in the pyrolysis of the diacetates at 162–205°C, 60% of a mixture of acetates of *cis*- and *trans*-carveol is obtained

together with *p*-cymol, *p*-mentha-1,5(8)-diene, pinol, and other products[27].

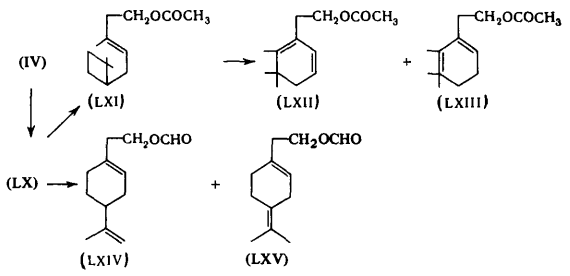


The diacetates of the dihydrosobrerols (LIII) give the acetates of dihydrocarveols (LIV). In this the dihydrocarveols retain the configuration of the dihydrosobrerols, whereas the carveols are racemised.

On treatment with a mixture of acetic acid and acetic anhydride, β-pinene oxide (LV) forms the diacetate of 7,8-dihydroxycarbomenthene (LVI), pyrolysis of which leads to perillyl acetate (LVII), *trans*-myrtanal (LVIII), and phellandral (LIX).[28] Faidutti[29] and Arbuzov[30] obtained myrtanal (LVIII) by treating β-pinene oxide (LV) with zinc chloride, as did Kergomard and Philibert-Bigou[31]. The latter, on using aluminium oxide, obtained a mixture of myrtanal, phellandral, and myrtenol (XIII), free from perillyl alcohol (LXXXV).



Nopol (LX) is an alcohol obtained by the reaction of β-pinene with formaldehyde[14]. Pyrolysis of nopol acetate (LXI) leads to a mixture of α- and β-pyronenecarbinol acetates (LXII) and (LXIII);[32] the treatment of nopol with formic acid gives homoperillyl formate (LXIV) and its isomer (LXV), a mixture of which is used in perfumery.

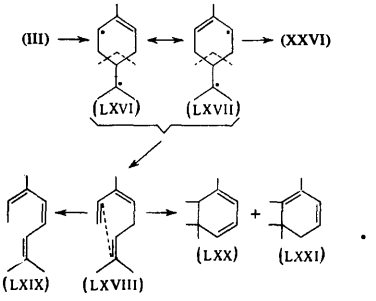


4. Radical Decyclisation

Let us examine reactions associated with the radical decyclisation of pinenes and some of their derivatives: pinanes, pinenols, verbenols, pinanols, verbanols, myrtanols, and epoxypinanes. The main aim of the decyclisation method is the production of aliphatic terpenoids.

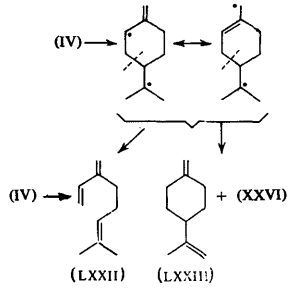
Isomerisation takes place by a radical mechanism[28,33]. Initially, the biradicals (LXVII) and (LXVI) are formed. Their peculiarity is that one of the unpaired electrons participates in the resonance structure of a hybrid of the allyl type, which determines the energy, kinetics, and structure of the products obtainable. The formation of dipentene (XXVI) from the optically active α-pinenes and of limonene from β-pinenes was explained by Burwell[34], starting from the possibility of the migration of hydrogen, which was established by molecular models.

In the decyclisation of α-pinene, in addition to dipentene (XXVI)[35,36], β-ocimenes (LXVIII) are formed, which on the one hand are isomerised into allo-ocimenes (LXIX) and on the other, are cyclised into α- and β-pyronenes (LXX) and (LXXI)[37-46]. However, it was found possible to limit these isomerisations and obtain β-ocimenes (LXVIII) in good yield:

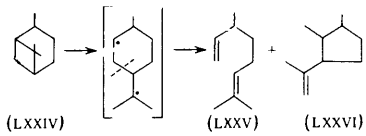


The pyrolysis of α-pinene (III) at 400–450°C leads to the formation predominantly of dipentene (XXVI); at a higher temperature, allo-ocimenes (LXIX)[47] are formed. For the production of β-ocimene (LXVIII) the time of heating had to be shortened to a few milliseconds. Blackmore effected this by using a spiral heated to 500–700°C immersed in the product heated to 50–70°C. The reaction is carried out in a flow system. The α-pinene separated by distillation is returned to the reaction zone. Under these conditions β-ocimene could be obtained in 43–47% yield calculated on the α-pinene (III) used[48,49]. Rectification of the commercial product gave a fraction with 80% ocimenes and 20% dipentene, which was used as such in many syntheses.

β-Myrcene (LXXII), limonene (XXVI), *p*-mentha-1,7(8)-diene (LXXIII), and *p*-cymene are formed in the decyclisation of β-pinene (IV)[50-52]. Myrcene can be isolated from the pyrolysate by rectification, but it is usually considered more economical to use the fraction containing 65–85% myrcene. The impurities are β-pinene, limonene, and—on long storage—camphorenes.



Thermal isomerisation of the pinanes (LXXIV) leads to 2,6-dimethylocta-2,7-diene (LXXV) with retention of the optical activity. The reaction occurs at 550–600°C, predominantly using the *cis*-pinane. The degree of conversion reaches 86%, the yield of dimethyloctadiene 64%. As a result of the cyclisation of dimethyloctadiene, irid-8-enes (LXXVI) are formed[53]:



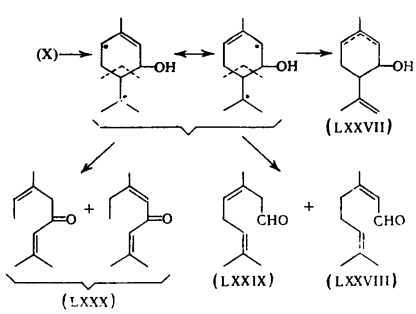
For a certain period myrcene (LXXII) was used for making the β-ocimenes (LXVIII). The isomerisation was effected with good yield in the presence of catalysts—rhodium, iridium, and their chlorides. The reaction proceeds in the presence of 0.5–2% hydrochloric acid at 80–110°C in an inert atmosphere[54]. The same method can be used to convert 2,6-dimethylocta-2,7-diene into 2,6-dimethylocta-2,6-diene and myrcenol into ocimenol.

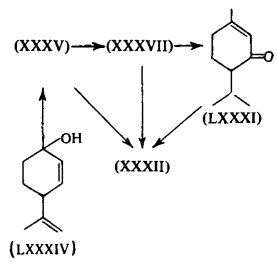
The pyrolysis of verbenols (X)—allyl isomers of pin-3-en-2-ol (IX)—leads to the formation of isopiperitenols and limonenols (LXXVII) and various aliphatic products: citrals (LXXVIII), isocitrals (LXXIX), pseudotagetones (LXXX), and also 2,2,4-trimethylcyclohex-4-enylformaldehyde[55].

The stereochemistry of these reactions is of great importance for the synthesis of (−)-menthol. (−)-α-Pinene (III) gives (−)-*trans*-verbenol with (+)-*cis*-verbenol impurity. Decyclisation of these verbenols leads to menthadienols with the same sign. A mixture of dextrorotatory menthadienols leads to (−)-menthol through the intermediate formation of (+)-neo-menthol, whereas the laevorotatory menthadienols give (+)-menthol through (+)-isomenthol. When special precautions are taken the product will contain a considerable proportion of racemic menthol. To avoid this, the production of (−)-menthol through piperitols was studied[56]. Actually, a mixture of *cis*- and *trans*-piperitols can be isomerised into (+)-*cis*-piperitol by the action of formic acid.

(−)-*trans*-Piperitenol (XXXV), obtainable from (−)-α-pinene, yields (−)-*trans*-piperitol (XXXVII), which is converted into (+)-*cis*-piperitol; the latter is isolated by distillation, then hydrogenated to (+) neo-menthol, which isomerises into (−)-menthol (XXXII). (+)-*trans*-Isopiperitenol leads to (+)-*trans*-piperitol, which is hydrogenated into (+)-isomenthol and isomerised into (−)-menthol.

Instead of this, *cis*- and *trans*-piperitols can be separated by oxidising their mixture to (−)-piperitone (LXXXI), by hydrogenation of which (+)-isomenthone is obtained and from this (−)-menthol (XXXII).





In the pyrolysis of ethers of verbenols, in addition to the esters of isopiperitenols and limonenols a significant proportion of ethers of pseudoverbenols (chrysanthenols) is formed[20]. The ethers can be readily converted into formates or hydrolysed by prolonged boiling with water. The hydrolysis of isopiperitenols leads to the formation of their allyl isomers: *cis*- and *trans*-paramentha-2,8-dien-1-ols. These are separated by fractional distillation and each of them can be converted into a mixture of *cis*- and *trans*-isopiperitenols. All these conversions proceed with retention of the optical activity.

The pyrolysis of verbanols (LXXXII) at 350–700°C leads to 2,6-dimethylocta-2,7-dien-4-ol (LXXXIII)[7,57]. At 450°C 26% of this alcohol is formed together with 19% of an acyclic aldehyde and 20% of an alcohol, which can be oxidised to tagetone and irid-8-en-4-ol (LXXXIV), which is evidently formed in the cyclisation of the alcohol (LXXXIII).

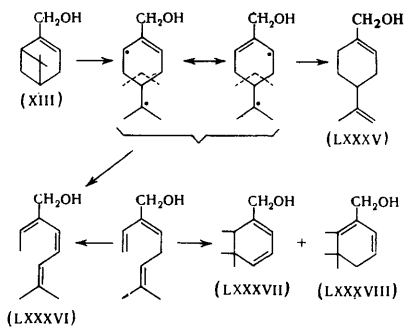
It is interesting to note that in the hydrogenolysis of a mixture of isoverbanol and neoisoverbanol over copper chromite considerable amounts of *o*-menthols are obtained[7].

The pyrolysis of verbanols leads to *cis*-*o*-menth-8-en-3-one, together with other carbonyl compounds[58].

The production of citrals and isocitrals from isopiperitenols and limonenols in an analogous manner to the production of citronellal from isopulegols was effected 40 years ago by Grignard and Doeuvre[59]. The citrals and isocitrals are readily separated by distillation, or a mixture of aldehydes and acetone is condensed in the presence of alkali and pseudoionones are obtained[60].

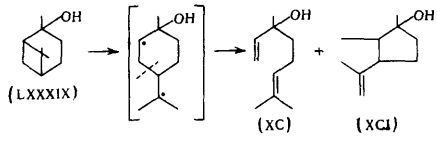
The pyrolysis of myrtenol (XIII) gives ~ 36% perillyl alcohol (LXXXV), 15% 2-methylocta-2,4,6-triene-6-carbinol (LXXXVI) and α- and β-pyronenols (LXXXVII) and (LXXXVIII)[61].

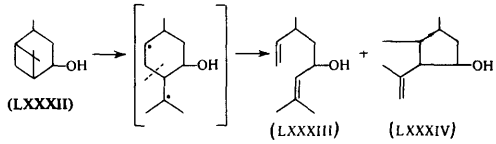
A mixture of *cis*- and *trans*-myrtenols is readily obtained from β-pinene by hydroboronation with subsequent oxidation[62] or by using aluminium alkyls[63]. By the pyrolysis of myrtanols in the vapour phase, Lemberg[64,65] obtained a mixture of 2-methylocta-2,7-dien-6-carbinol and 2-methylocta-2,7-dien-4-carbinol, which are readily separated by fractional distillation



The pyrolysis of pinanols (LXXXIX) is of great interest, since it leads to linalool (XC). Pinanols can be obtained by the hydrogenation of pin-3-en-2-ols (IX) or by starting

from hydroperoxides of pinanes. Pyrolysis is carried out at 600°C in a flow system in the absence of Lewis acids, which bring about dehydration. As a result of the cyclisation of linalool, plinols (XCI) are formed and also 2,6-dimethylocta-2,7-dien-4-ol, 3-ethyl-2,3-dimethyl-cyclobutyl methyl ketone, and α-terpineol (II). *cis*-Pinanol gives 95% linalool *trans*-pinanol 75%. (+)-*cis*- and (−)-*trans*-pinanol corresponds to (−)-linalool, (−)-*cis*- and (+)-*trans*-pinanol to (+)-linalool[66,67]. The cyclisation of linalool at 650°C leads to the formation of four stereoisomeric plinols[68].





cis-Dihydronopol, readily obtained by the catalytic hydrogenation of nopol (LX), forms, after pyrolysis at 500–600°C, a mixture containing 50% 2-methyl-6-vinyloctan-8-ol. Partial hydrogenation of this alcohol at the vinyl group gives homocitronellol (6-ethyl-2-methyloctan-8-ol).[69]

5. Conversions of Aliphatic Hydrocarbons

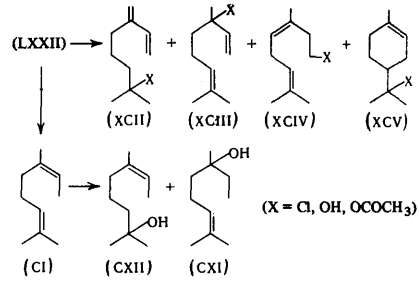
The production of almost unlimited amounts of β-myrcene (LXXII), β-ocimene (LXVIII), allo-ocimenes, and products of their partial hydrogenation, namely, 2,6-dimethylocta-2,7-diene made possible a large number of syntheses of commercial interest.

The main reactions of these hydrocarbons are as follows: (1) the addition of organic acids for the production of esters (the Bertram–Wallbaum reaction): (2) the oxidation of double bonds with subsequent isomerisation to aldehydes or ketones or hydrogenation to alcohols; (3) the production of organometallic derivatives with subsequent conversion into alcohols; (4) the addition of halogens, hydrogen halides or hypohalogen acids with subsequent pyrolysis of the hydrohalides, dehydration of the halogenohydrins to unsaturated halogen derivatives or dehydrohalogenation to epoxides; the hydrolysis of halides to alcohols or conversion into esters by reaction with salts or organic acids.

In incomplete addition, the double bonds compete with one another. In instances when it is possible allyl rearrangements take place.

Syntheses from β-myrcene (LXXII) have most value. In this way above all linalool (XC), geraniol, nerol, and their esters are obtained.

β-Myrcene is converted into the monochlorides (XCII)–(XCV). Without a catalyst the predominant products are the chlorides of myrcenol, terpineol, and borneol. The amount of these chlorides, especially myrcenyl chlorides, can be decreased by carrying out the hydrochlorination at low temperature in



the presence of an antioxidant and a catalyst—copper or a copper(I) salt[70]. The addition of hydrochloric or hydrobromic acid is controlled spectrometrically by the disappearance of the conjugated double bond. Increase in temperature and increase in the amount of catalyst decreases the proportion of linalyl chloride and increases the content of geranyl and neryl chlorides. Under optimal conditions the final concentration of myrcenyl chloride < 10%; without a catalyst, its concentration reaches 50–60%.[71] Conversion of the halides into esters in the absence of a catalyst does not give good results. The catalysts used can be bases containing nitrogen or phosphorus[72–74], for example, trimethylamine, triethanolamine, phosphonium salts or derivatives of phosphorus(III) (phosphines) capable of forming quaternary derivatives in the presence of alkyl halides, or even phosphorus[74]. The reaction proceeds in an acid medium, for example, in the presence of acetic acid, which facilitates the formation of esters of linalool[75] or in the presence of bases, which increases the yields of esters of geraniol and nerol. The use of solvents to facilitate the rearrangement is recommended, and dilute dimethyl sulphoxide is also used[73]. The yield of acetates can reach 75–95%.

To diminish the formation of myrcenyl chloride dihydrochlorination of myrcene is carried out[76,77]. This reaction was effected at 10–50°C in the presence of copper chloride. The conversion into the ester was performed in the presence of a base, for example, 1% trimethylamine. The formation of geranyl acetate and neryl acetate is facilitated by raising the temperature and increasing the duration of reaction. ~ 50% of the α-isomers are formed.

Good results were obtained in the hydrolysis of products of the addition of two molecules of hydrochloric acid[78,79]. The reaction was brought about by using an aqueous suspension of calcium carbonate in the presence of an emulsifier. In this way 2-hydroxy-2,3-dihydro-linalool, -geraniol, and -nerol were obtained. 2,3-dihydro-2-hydroxylinalool can be converted into isomers by the action of formic acid, with a yield of 73–75%. The dehydration of glycols leads to a mixture of isomers of α- and β-linalool, geraniol, and nerol. Carrying out the dehydration without appropriate precautions leads to the production of ocimenol and α-ocimenes. The production of β-ocimene from α-pinene in good yield allows β-myrcene to be replaced by this terpene.

The mixture of chlorides obtained in monohydrochlorination, which contains geraniol and neryl chlorides can be converted into citrals by the Kröhnke procedure with the

Liebermann method[80]. Pseudoionones are obtained by reaction in a medium of acetone.

The production of geraniol and nerol from pinenes made possible the synthesis of citral. It is difficult to carrv out the catalytic dehydrogenation in a directed manner. In the presence of copper catalysts disproportionation occurs, leading to the production of citronellal[81,82]. The oxidation of geraniol and nerol with chromic acid leads to citral in 80–85% yield. It gives better results than oxidation with manganese dioxide (68%) or by functional exchange[83,84]. The Openhauer reaction with aluminium alkoxides in an acetone medium leads to pseudoionones[85–89].

Whereas the oxidation of 2,3-dihydro-2-hydroxylinalool gives only 44–47% 2,3-dihydro-2-hydroxycitral, which is more readily hydrogenated to 2,3-dihydro-2-hydroxycitronellal than dehydrogenated to citral, 2,3-dihydro-2-hydroxygeraniol and -nerol can be converted over copper chromite directly into hydrohydroxycitronellal in 90–95% yield[90,91].

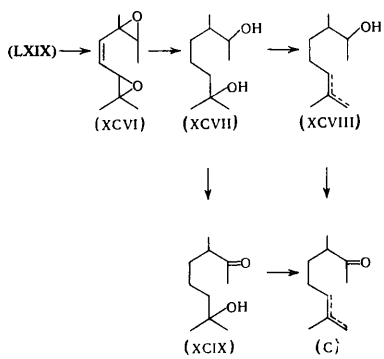
Ocimenol can be obtained from β-myrcene through the intermediate formation of a sulphone obtainable by the action of sulphur dioxide at 50–100°C. The sulphone is hydrated by 40–60% sulphuric acid and the hydrate decomposed by heating to 120–170°C.[92] The decomposition can also be brought about in the presence of 1–2% amine, for example, triethanolamine, or calcium carbonate.

By the action of hydrochloric acid at 20–110°C myrcenol and ocimenol are converted into a mixture of 2,6,6-trimethyl-2-vinyltetrahydropyran and 2,2-dimethyl-5-(1-methylpropenyl)tetrahydrofuran, used in perfumery.

2-Methylmethylene-6-oct-2-en-8-ol was obtained in 68% yield from β-myrcene by the action of di-isopentylborane (obtained by the reaction of boron hydrides with 2-methylbut-2-ene). This alcohol is readily hydrogenated to citronellol[93].

The monoepoxidation of β-myrcene to β-ocimenes takes place at the double bond in the 2,3-position. Isomerisation of monoepoxides under the action of acids[94] leads to 2,6-dimethylocta-4,6-dien-3-ols.

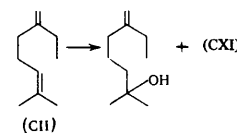
Allo-ocimenes can be used for very interesting syntheses. The polymeric peroxide which is formed on adding oxygen yields the diepoxide (XCVI) on heating; the structure of this was the subject of discussion[95–100]. This diepoxide is readily hydrogenated into *erythro*- and *threo*-2,6-dimethyloctane-2,7-diol (XCVII), partial dehydration of which gives a mixture of the *erythro*- and *threo*-isomers of the α- and β-elgenols (XCVIII), already known under the name of secondary citronellols. The pyrolysis of the diacetates of these glycols leads to acetates of α-elgenol. Oxidation of the glycols with chromic acid leads to hydroxyelgenol (XCIX), which is dehydrated into a mixture of α- and β-elgenols (C).



Theimer[101] hydrochlorinated allo-ocimenes in a flow system. Treatment of the chlorides with water in the presence of an emulsifier leads to a mixture of the alcohols 2,6-dimethylocta-3,5-dien-2-ols and 2,6-dimethylocta-2,4-dien-6-ols. Hydrogenation of this mixture gives the more stable saturated alcohols.

The syntheses starting from 2,6-dimethylocta-2,7-diene (LXXV), obtainable in the pyrolysis of pinane (LXXIV) or by partial hydrogenation of myrcene (LXXII), are of great interest.

The product of the pyrolysis of pinanes is optically active. It includes irid-8-enes (LXXVI)[102,103]. The partial hydrogenation of myrcene (LXXII) is insufficiently selective[104] and the product obtained contains 2,6-dimethylocta-2,6-diene (CI) and 2-methyl-6-methyleneoct-2-ene (CII).



2,6-Dimethylocta-2,7-diene (LXXV) can be converted into β-citronellol (CIII) through organoaluminium compounds by the action of lithium tetrahydroaluminate, or better tri-isobutylaluminium. The organometallic compound is oxidised by moist air and the aluminate formed is hydrolysed to citronellol[99,105–108]. The yield reaches 77%.

In another variant of this synthesis diborane converts 2,6-dimethylocta-2,7-diene (LXXV) into tricitronellylboron[109]; the latter is oxidised to citronellyl borate, from which β-citronellol (CIII) is also obtained by hydrolysis or oxidative hydrolysis with hydrogen peroxide[91,109]. This method, like the method via tricitronellylaluminium, was perfected by carrying out the oxidation in the presence of organo-zinc or -cadmium compounds. The yield is 80%.[110]

(−)-Citronellol is obtained from (+)-α-pinene (III) through the intermediate formation of (+)-dimethyloctadiene, and (+)-citronellol from (−)-α- and (−)-β-pinenes through (−)-dimethyloctadiene[111].

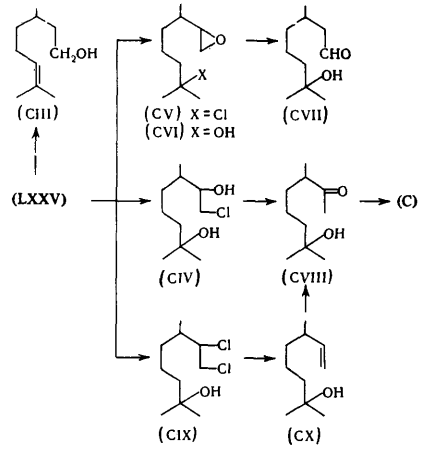
The optically active citronellols prepared in this way can rival the (+)-citronellol obtained by the hydrogenation over Raney cobalt of geraniol and nerol synthesised from α-myrcene and ocimene[112].

There are other methods of obtaining hydrohydroxycitronellol and the corresponding aldehyde, and also elgenol from 2,6-dimethylocta-2,7-diene.

The following schemes are given in Webb's patents[113,114].

A hydrocarbon (LXXV) is converted into 2-chloro-2,6-dimethyloct-7-ene, from which by the action of peracetic acid or through the chlorohydrin (CIV) the epoxychloride (CV) is obtained, hydrolysis of which by an aqueous suspension of $Ca(OH)_2$ gives 7,8-epoxy-2,6-dimethyloctan-2-ol (CVI) in good yield.

Pyrolysis of this product at 250°C leads to hydrohydroxycitronellal (CVII), which can also be obtained through the chlorohydrin. After treatment with lime at 200–210°C a mixture of products is formed, from which via the hydrogen sulphite compound a hydroxycitronellal containing 5–8% α-citronellal is isolated. On boiling the non-aldehyde fraction with sodium in isopropanol it is converted into 2,6-dimethyloct-7-en-2-ol, which can be used for the production of the epoxide (CVI).



In the conversion of the chlorohydrin (CIV) into the epoxide (CVI) a certain proportion of 2,3-dihydro-2-hydroxyelgenone (CVIII) is formed, from which α- and β-elgenones (C) can be obtained.

7,8-Dichloro-2,6-dimethyloctan-2-ol is isolated as an intermediate in the production of the chlorohydrin (CIX). After treatment with potassium hydroxide at 200°C in ethylene glycol, the allene 2,6-dimethylocta-6,7-dien-2-ol is obtained; by catalytic hydrogenation or by reduction with sodium in t-butanol it is converted into 2,6-dimethyloct-7-en-2-ol (CX), which is used again. Under the action of mercury sulphate in sulphuric acid the allene derivative forms hydrohydroxyelgenone (CVIII).

Webb also described[115] the hydrogenation of 7,8-epoxy-2,6-dimethyloctan-2-ol (CVI) to hydrohydroxycitronellol, which on passage over copper chromite forms hydrohydroxycitronellal (CVII) and α-citronellal. It can also be dehydrogenated into a mixture of α- and β-citronellals.

Under the action of hydrobromic acid after Karasch, 2,6-dimethylocta-2,7-diene and 2-chloro-2,6-dimethyloct-7-ene add on hydrogen bromide contrary to the Markovnikov rule. 2,8-Dibromo-2,6-dimethyloctane and 2-chloro-8-bromo-2,6-dimethyloctane are formed, by hydrolysis of which hydrohydroxycitronellol is obtained, which can be dehydrated to a mixture of α- and β-citronellols.

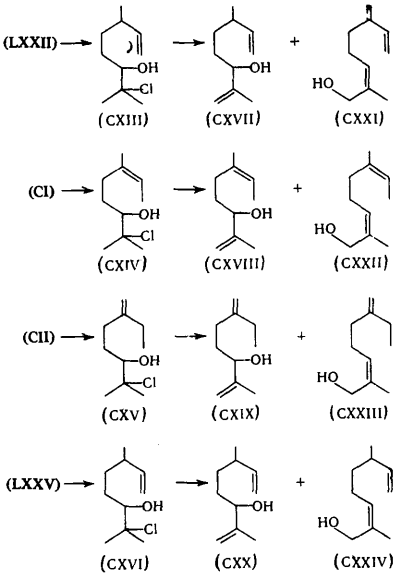
Pyrolysis of the dihalogenides leads to mixtures of the bromides of α- and β-citronellols, with the former predominating.

The production of optically active citronellals from (−)-2,6-dimethylocta-2,7-diene allows (−)-menthol to be synthesised.

We will pay some attention to the production of α-citronellol and α-citronellal free from ester oils and having a more pleasant odour than their β-isomers. It has long been known that α-citronellal is obtained by the dehydration of hydrohydroxycitronellal. It is found among the side-products in the production of hydrohydroxycitronellal by hydration of the hydrogen sulphite compound of β-citronellal. It is also known that its cyclisation into isopulegol is slower than the isomerisation of the β-isomer[7,60,116]. In the production of citral from hydrohydroxygeraniol and nerol, α-citral is formed, the odour of which, however, was not better than that of β-citral.

Partial hydrogenation of β-myrcene (LXXII) leads to not only 2,6-dimethylocta-2,7-diene (LXXV), as already stated, but also to 2,6-dimethylocta-2,6-diene (CI) and to 2-methyl-6-methyleneoct-2-ene (CII). Hydrogenation of β-ocimene (LXVIII) leads mainly to 2,6-dimethylocta-2,6-diene (CI), and hydrogenation of allo-ocimene to 2,6-dimethylocta-2,4-diene.

By the action of hydrochloric acid on 2,6-dimethylocta-2,6-diene (CI) Kitchens[117] obtained dihydrolinalyl chloride, which he hydrolysed to dihydrolinalool (CXI). In this the formation of dihydromyrcenol (CXII) was not noted. On the other hand, Webb succeeded in adding halogen to the second carbon atom of various dihydroterpenes mentioned earlier. The chlorohydrins (CXIII), (CXIV), (CXV), and (CXVI) were obtained by the addition of hypochlorous acid to myrcene (LXXII)[76]. When these products were hydrolysed and the resulting tertiary alcohol was dehydrated, the secondary alcohols (CXVII), (CXVIII), (CXIX), and (CXX), and their allyl isomers (CXXI), (CXXII), (CXXIII), and (CXXIV) were obtained.



The addition of organic acids by the Bertram–Walbaum reaction[118] takes place at the 2,3-double bond. The reaction occurs at 15° and 45°C in the presence of 1–4 parts organic acid containing 0.25–1% sulphuric acid. By replacing the latter by an acid ion-exchange resin, the reaction could be carried out continuously.

The addition of formaldehyde to β-myrcene leads, according to Sommerwell, to a mixture of 3-(4-methylpent-3-enyl)-5,6-dihydropyran and 4-(4-methylpent-3-enyl)-5,6-dihydropyran which can be converted into alcohols and their esters. On carrying out condensation in an organic acid an ester of 2-methyl-6-methyleneocta-1,7-diene-carbinol is also formed.

Webb studied the addition of formaldehyde to dihydroterpenes obtained by partial hydrogenation of β-myrcene and β-ocimene[49]. Heating is necessary, at least to 240°C, better 250–285°C. In the presence of an organic acid a lower temperature is used, for example, 130–160°C in acetic acid. Primary alcohols or their esters are obtained in this way. The alcohols can be converted into aldehydes. According to Webb's results the addition of carbinol takes place at the third carbon atom.

---o0o---

Hence the development of the chemistry of the pinenes, connected with the use of decyclisation has created a serious basis for the production of many important synthetic perfumes.

The following have been obtained:

1. Aliphatic terpene alcohols and their esters: linalool, geraniol, nerol, α- and β-citronellols, α- and β-elgenols.

2. Aldehydes and ketones and their derivatives: citral, pseudoionones, α- and β-citronellal, hydrohydroxycitronellal, α- and β-elgenones.

3. Monocyclic terpene alcohols: carveols, dihydrocarveol, isopiperitenols, piperitenols, isopulegols, menthols, and the corresponding ketones and aldehydes.

The industrial production of linalool, citral and pseudoionones on a large scale based on pinenes, together with the synthesis of these substances from acetylene made it possible to get rid of the inconvenience due to the instability, the difficulty of acquiring, and the variations in price of the essential oils which were for long the sole source of production of these materials. Synthetic perfumes are obtained at a lower price and with a greater purity than previously from the essential oils. This assists the development of the perfumery industry, especially for the production of mass perfumery. The synthetic products are used to reconstruct many essential oils. Some success was achieved, thanks to carrying out planned and unremitting investigations. It should be noted, however, that the results of these studies are still in the state of being used by only a few powerful industrial groups which produce these products in amounts ranging from a few hundreds to 1000–2000 tonnes per year.

Dimerisation of Alkenes

V.Sh.Fel'dblyum and N.V.Obeshchalova

This review discusses published work on catalysts, reaction conditions, composition of products, and mechanism, relating to the dimerisation of alkenes. It is shown that dimerisation is a very important practical method of synthesis of higher alkenes of various structures. The relationship between the type of catalyst activity and the course of the reaction is demonstrated in the specific case of the dimerisation of propene. An analysis of the activity and selectivity of catalysts is given, and the effectiveness of various methods of dimerisation is assessed from the point of view of their industrial exploitation. The most detailed discussion is given to the literature on the dimerisation of alkenes under the influence of complex organometallic catalysts, which have a very high activity. The major areas of application of dimers as intermediates in petrochemical and general organic synthesis are indicated. 139 references.

1. INTRODUCTION

Dimerisation of alkenes, unlike polymerisation, is a relatively new area of industrial organic synthesis, developed during the past decade. Previously, liquid polymers of ethylene, propene, and butenes were of relatively limited interest in the production of motor fuel constituents, lubricants, and some synthetic detergents (for example, dodecylbenzenesulphonates). The impetus for the deployment of effort in this direction was provided by Ziegler's discovery in 1952 of the selective dimerisation of alkenes by organoaluminium compounds, which demonstrated the possibility of synthesising individual higher alkenes of known structure. Ziegler's method was quickly adopted in three areas of practical importance: the preparation of but-1-ene by the dimerisation of ethylene, the synthesis of isoprene from propene, and the production of higher alkenes and primary alcohols with a linear carbon chain. The search for new dimerisation catalysts for alkenes was stimulated by a large number of papers on the use of C_4–C_6 alkenes as the starting products in dehydrogenation, oxidation, polymerisation, hydration, and other reactions. Progress in this area would obviously have been impossible but for the development of gas–liquid chromatography, infrared spectroscopy, and nuclear magnetic resonance as standard methods of analysis and identification of alkenes.

Many patents on the dimerisation of alkenes have appeared in recent years, as well as many papers on the mechanism of this reaction under the influence of various catalysts. However, a systematic review of the literature in this area has not yet been attempted: to the best of our knowledge, the present article is the first review of this subject. We shall not attempt to deal exhaustively with the existing literature, but we shall examine instead the correlation between the course of the reaction and the type of activity of the catalysts. The analysis will be made in the specific case of the dimerisation of propene, mainly because of the great practical importance of this reaction at the present time.

2. DIMERISATION CATALYSTS FOR ALKENES

A large number of dimerisation catalysts for alkenes, differing in the composition of the products and in the reaction conditions, has been described. In particular, the use of acidic catalysts for the preparation of liquid polymers (including dimers) of propene and isobutene[1,2] for use as motor fuel constituents and in the synthesis of detergents is well known. Ethylene does not dimerise under the influence of acidic catalysts. With propene, the primary dimerisation products undergo side reactions (polymerisation, isomerisation, disproportionation, etc.[3]). Hence the yield of the dimer of propene is small, and its isomeric composition is quite complex; we are therefore justified in concluding that acidic catalysts are unsatisfactory for the selective dimerisation of propene[4]. However, work on improving the selectivity of acidic catalysts is continuing, and will be discussed below.

Selective dimerisation of ethylene was first achieved with a cobalt catalyst[5]. Schultz and coworkers[6,7] have recently made a detailed study of the dimerisation of various alkenes on catalysts of this type. The main disadvantage of catalysts based on cobalt oxide is their relatively low activity, which limits the prospects of their industrial application.

The dimerisation of propene by finely dispersed potassium in a hydrocarbon medium[8] was reported in 1961. In spite of the low activity of the catalyst and of the stringent conditions of the reaction, the process has undergone considerable development in connection with the production of 4-methylpent-1-ene, an important monomer and intermediate in industrial organic synthesis.

The dimerisation of alkenes by Ziegler's method with alkylaluminium catalysts[9] offers the greatest practical interest at present. Thus, the dimerisation of propene in the presence of tripropylaluminium is the basis of an industrial method of preparation of isoprene from propene[10,11]. A process for the codimerisation of ethylene and propene to give 2-methylbut-1-ene, followed by dehydrogenation to

isoprene, has been developed[12]. The dimerisation of ethylene in the presence of triethylaluminium gives very pure but-1-ene, used in the production of high-quality polymeric products[13].

The dimerisation of alkenes under the influence of complex organometallic catalysts proceeds under mild conditions and with high yields of product. In 1961 a method of oligomerisation of ethylene with homogeneous catalytic systems of the Ziegler type was proposed in the U.S.A., based on alkylaluminium halides and nickel compounds[14], and in 1963 a method of dimerisation of propene was proposed in the U.S.S.R. using catalysts of very similar composition, as well as a method for the production of dienes by means of these catalysts[15-17]. The dimerisation of propene by alkylaluminium halides in conjunction with organic nickel salts has also been patented by the Shell Company[18].

The first reports of the dimerisation of alkenes by complex Ziegler catalysts were published almost simultaneously in West Germany[19,20], France[21], and the U.S.S.R.[22-24]. Ewers[19] used a highly active homogeneous catalyst prepared by treating nickel acetylacetonate, bis-(π-allyl)nickel, or π-allylnickel chloride with a dialkylaluminium chloride in a toluene medium. A paper by Wilke and coworkers[20] describes the dimerisation of ethylene and propene under the influence of π-allylnickel chloride in conjunction with Lewis acids and tertiary phosphines. Chauvin and coworkers[21] used the catalytic system nickel acetylacetonate–ethylaluminium dichloride. Complex dimerisation catalysts for alkenes based on various π-complexes of nickel have been proposed[25].

The dimerisation of ethylene and propene and the codimerisation of these alkenes under the influence of catalytic systems based on alkylaluminium halides and organic nickel salts[22-24], similar to the stereospecific polymerisation catalysts for butadiene[26], is characterised by very mild conditions (room temperature and normal pressure). There is a marked difference between these catalysts and alkylaluminium catalysts containing "colloidal" nickel: the latter also are dimerisation catalysts for alkenes[27], but they require more stringent reaction conditions leading to the formation of dimers of different structure.

Thus, the dimerisation of alkenes can be achieved with catalysts of quite different type. Accordingly, a variety of dimerisation mechanisms and of structures of the resulting product are observed. The specific features of the dimerisation of various alkenes are discussed in detail below.

3. DIMERISATION OF ETHYLENE

According to Cheney and coworkers[28], ethylene dimerises on a cobalt catalyst at 40°C and 50 atm pressure with a conversion of ~ 50%, and 80% selectivity with respect to butenes. The conversion of the monomer and the composition of the dimer depend on the contact time: with an input of ethylene of 72 g per 1 litre of catalyst per hour the conversion is 74% and the main product of the reaction is but-2-ene (91%); if the input is raised to 360 g litre^{-1} h^{-1} the conversion drops to 37% and the dimer contains up to 70% of but-1-ene. Treating the carrier (activated carbon) with aqueous ammonia increases the activity of the cobalt catalyst but degrades its selectivity towards dimerisation[6,7]: the yield consists of ~ 20% butenes, 60% hexenes, and 20% high-boiling hydrocarbons. The hexene fraction consists mainly of linear alkenes. A great deal of work has been published on the dimerisation of ethylene on nickel catalysts[29-35]. The above solid dimerisation catalysts have not been exploited industrially so far because they are difficult to prepare, they have low activity and stability, and for a number of other reasons.

At the present time, the dimerisation of ethylene by homogeneous catalysis (and in particular using triethylaluminium as the catalyst) is attracting most attention. By this method[9], pure but-1-ene can be obtained with high yield by withdrawing it from the reactor as soon as it is formed or by carrying out the reaction in the presence of "colloidal" nickel[27]. The dimerisation of ethylene by Ziegler's method has been studied at the Scientific Research Institute of Synthetic Alcohols and Organic Products (NIISS)[36] and at the All-Union Scientific Research Institute of Olefins (VNIIOlefin)[37]. The purest but-1-ene is obtained at low conversions of the ethylene. Thus, it is convenient to prepare a mixture of ethylene and butene (containing up to 10% of butene) and to use it as the raw material for the production of a copolymer having good mechanical properties[37]. At higher conversions of the ethylene (20%), appreciable amounts of C_6 and C_8 alkenes are produced as well as but-1-ene.[38] Chernikova[13] studied the influence of various nickel compounds (as additives to the triethylaluminium) on the rate and selectivity of the dimerisation of ethylene. She suggests that the ethylene is activated on the surface of freshly reduced nickel, and this assists its further penetration along the aluminium–carbon bond.

Various catalytic systems for the dimerisation of alkenes based on aluminium alkyls and transition metal alkoxides have been proposed. Their activity is higher than that of the aluminium alkyls[39-42]: for example, ethylene dimerises at 50–100°C and 1–10 atm in the presence of triethylaluminium and tetrabutoxytitanium with up to 65% yield of but-1-ene[41]. The dimerisation of ethylene to but-2-ene at 0°C in the presence of the triethylaluminium–cobalt acetylacetonate catalytic system has also been reported[43].

Unlike the aluminium alkyls, alkylaluminium halides by themselves dimerise alkenes only in very low yields, even under drastic conditions[44]. However, they yield active dimerisation catalysts for ethylene in conjunction with dialkyldihalogenostannanes[45].

The most active dimerisation catalysts are prepared by treating alkylaluminium halides with nickel compounds. The use of these catalysts for the production of high-molecular-weight polyethylene was patented by Ziegler[46]. The dimerisation of ethylene under the influence of catalysts of this type has also been described in a patent[14]. The reaction was carried out in the presence of the complex of nickel carbonyl with triphenylphosphine, in conjunction with ethylaluminium sesquichloride, at 100°C and 30 atm. Subsequently, more active catalytic systems were disclosed, in which the nickel compounds were salts of organic acids, phenols, enols, or sulphonic acids, which are fairly readily soluble in hydrocarbon solvents[18]. An even more active catalyst was prepared from nickel acetylacetonate, ethylaluminium sesquichloride, and triphenylphosphine[19]: in this system, 18×10^5 moles of ethylene are dimerised in 15 min at 60°C per g-atom of nickel. The yield of butenes can be as high as 94%, with a 95% content of but-2-ene. As well as butenes, catalysis by systems of this type produces hexenes, the relative yield of ethylene dimers and trimers depending on the rate at which ethylene is passed through the catalyst solution[22].

Obviously, the chlorides of the platinum group metals and their complexes with alkenes[47-50] cannot find extensive practical application as dimerisation catalysts for alkenes because they are too expensive as well as being insuffici-

ently active. Palladium chloride dimerises ethylene with up to 90% selectivity at 20–70°C and 1–40 atm.[50] The yield of butenes is found to be very sensitive to the nature of the solvent[50]. A Dutch patent[48] recommends the use of a nitro-compound as the medium for this reaction. It has been suggested[50] that palladium chloride initiates the dimerisation in the presence of hydrogen chloride by a mechanism analogous to that of the Friedel–Crafts catalysts:

$$CH_2{=}CH_2 \xrightarrow[HCl]{PdCl_2} CH_3CH_2^+\,PdCl_3^- \xrightarrow{CH_2=CH_2}$$

$$\rightarrow (CH_3CH_2CH_2CH_2)^+\,PdCl_3^- \rightarrow (CH_3CH_2\overset{+}{C}HCH_3)\,PdCl_3^- \rightarrow CH_3CH{=}CHCH_3 + PdCl_2 + HCl$$

Rhodium chloride is active in the dimerisation of ethylene at 30–50°C, whereas ruthenium chloride requires a higher temperature[51].

Cramer[52] made a detailed study of the dimerisation of ethylene under the influence of rhodium chloride in alcoholic HCl solutions, and proposed the following mechanism for the reaction:

$$\begin{array}{lcl} Rh^{III}Cl_3\cdot 3H_2O & & C_2H_4 + [C_2H_5Rh^{III}Cl_3S]^{2-} \quad (B)\\ +C_2H_4 \downarrow (1) & & +S \uparrow\downarrow -S\ (3)\\ (A)\ [Cl_3Rh^{I}(C_2H_4)_2]^- & \xrightarrow[(2)]{+H^+,\,Cl^-} & [C_2H_5Rh^{III}Cl_3(C_2H_4)S]^- \quad (C)\\ +C_2H_4 \uparrow -C_4H_8\ (6) & & +S \downarrow (4)\\ (E)\ [Cl_3Rh^{I}S(CH_3CH_2CH{=}CH_2)]^- & \xleftarrow[(5)]{-H^+,\,Cl^-} & [CH_3CH_2CH_2CH_2Rh^{III}Cl_3S_2]^- \quad (D) \end{array}$$

($S = Cl^-$, H_2O or solvent).

Activation of the catalyst (*1*) occurs by the reaction between $RhCl_3$ and ethylene with formation of a complex anion of univalent rhodium with two ethylene ligands. This is followed by fast protonation (*2*) of the complex (A) to give the ethyl derivative (B), and by addition (*4*) of a coordinated molecule of ethylene at the rhodium–carbon σ-bond (limiting step), with formation of the butyl derivative (D). The latter is rapidly converted into the complex (E) containing a butene ligand, which is rapidly replaced by ethylene, reaction (*6*). Thus, the starting complex (A) is regenerated. The author[52] introduces the ligands *S* into the formulae in order to satisfy the coordination numbers of Rh^{I} and Rh^{III} (4 and 6 respectively).

4. DIMERISATION OF PROPENE

a. Cationic Dimerisation

Catalysts of the acidic type have not gained wide acceptance in practice for the selective dimerisation of propene because of the low yields and complex composition of the dimer, due to the possibility of side reactions under the conditions of dimerisation. The reactivity of low-molecular-weight alkenes towards dimerisation under the influence of acidic catalysts increases very significantly in the series ethylene–propene–isobutene, as a result of the electronic σ,π conjugation effect. A proton (or cation) attacks the propene molecule in accordance with Markovnikov's rule:

$$CH_3{-}CH{=}CH_2 \xrightarrow{+H^+} CH_3{-}\overset{+}{C}H{-}CH_3$$

$$CH_3{-}CH{=}CH_2 + CH_3{-}\overset{+}{C}H{-}CH_3 \rightarrow CH_3{-}\underset{CH_3}{CH}{-}CH_2{-}\overset{+}{C}H{-}CH_3 \rightarrow$$

$$\xrightarrow{-H^+} CH_3{-}\underset{CH_3}{C}H{-}CH{=}CH{-}CH_3\ .$$

The resulting intermediate isohexyl carbonium ion usually interacts rapidly with the next propene molecule to give the trimer, and so on. Also, the secondary carbonium ion is not stable[53], and easily rearranges according to the scheme

$$CH_3CH\overset{+}{C}H_2CHCH_3 \xrightarrow{-H^+} \text{4-methylpent-1-ene, 4methylpent-2-ene}$$

$$\begin{array}{l} \quad\quad\quad\

and therefore the composition of the dimerisation product depends on the exact form of the catalyst and on the reaction conditions. The choice of carrier plays an important role: in particular, its porosity should not be too high[71]. A proposed dimerisation catalyst consists of sodium or lithium, dispersed on an anhydrous potassium salt[78-81]. The dimerisation of propene by a continuous method[65] at 140°C and 100 atm, and a volume velocity of 0.7 h^{-1}, on a Na/K_2CO_3 catalyst, gives a dimer of the following composition: 4-methylpent-1-ene (85%), 4-methylpent-2-ene (7%), 2-methylpent-2-ene (0.5%), 2-methylpent-1-ene (0.5%), and n-hexenes (7%). Separation of 4-methylpent-1-ene and 4-methylpent-2-ene is difficult because the boiling points are very similar. Hence, the use of a mixture of the two isomers in the polymerisation has been suggested[71]. In a Belgian patent[65], the dimer was fractionated on a column with an efficiency of 100 theoretical plates, with a 60% take off, giving a distillate containing 99.9% of 4-methylpent-1-ene.

Using potassium on granulated magnesia as the dimerisation catalyst, the product contains 55% of 4-methylpent-1-ene, 38% of 4-methylpent-2-ene, and 7% of other hexenes[82]. Polymerisation of a mixture of alkenes of approximately this composition in the presence of $AlBr_3$ has been suggested for the preparation of a liquid polymer useful for electrical insulation and as a lubricating oil additive[83]. Alkali metals on graphite[84], active carbon[85], carbon black[86], alumina[87], magnesium silicate[88], and metal hydrides[89] catalyse the dimerisation of propene mixed with methylpentenes of various compositions. These catalysts can be regenerated by being heated to 200–300°C in a stream of hydrogen[85,86].

The dimerisation mechanism of propene in the presence of alkali metals has been investigated by Shaw and coworkers[90], who suggest that the reaction involves the formation of an organometallic compound with a strongly polar M–C bond on the catalyst surface. Partial dissociation with formation of carbanions as kinetically independent particles is possible:

$$CH_3{=}CH{-}CH_3 \xrightarrow{M} [CH_3 \cdots CH \cdots CH_3]^- M^+ .$$

The allyl carbanion attacks a propene molecule. The resulting isohexyl carbanion, unlike the allyl carbanion, is not stabilised by interaction of an unshared electron pair with the double bond. It is very reactive, and extracts a proton from the next propene molecule. The end result of these transformations is the production of 4-methylpent-1-ene and simultaneous regeneration of an allyl carbanion:

$$[CH_2{\cdots}CH{\cdots}CH_2]^- M^+ + \overset{\delta^-}{CH_2}{=}\overset{\delta^+}{CH}{-}CH_3 \longrightarrow CH_2{=}CHCH_2\underset{CH_3}{\underset{|}{C}}HCH_2\ M^+ \xrightarrow{+C_3H_6} CH_2{=}CHCH_2\underset{CH_3}{\underset{|}{C}}HCH_3 + [CH_2{\cdots}CH{\cdots}CH_2]^- M^+ .$$

Isomerisation of 4-methylpent-1-ene occurs through the formation of a carbanion with migration of an allyl proton:

$$CH_3\underset{CH_3}{\underset{|}{C}}HCH_2CH{=}CH_2 + R^-M^+ \xrightarrow{-RH} \left[CH_3\underset{CH_3}{\underset{|}{C}}HCH \cdots CH \cdots CH_2\right]^- M^+ \xrightarrow{+RH} \rightarrow CH_3\underset{CH_3}{\underset{|}{C}}HCH{=}CHCH_3 + R^-M^+ .$$

The following alkali metal derivatives as well as the alkali metals themselves are used as dimerisation catalysts: hydrides[91-93], amides[94,95], and carbides[96]. The reaction conditions and the composition of the products obtained in the presence of these catalysts are about the same as when alkali metals are used. The dimerisation of propene under the influence of carbon complexes of the alkali metals has been proposed as the first stage in the synthesis of isoprene from propene[97]. A dimer containing ~ 65% of 4-methylpent-2-ene is isomerised into a mixture of 2-methylpent-2-ene and 3-methylpent-2-ene on an alumina-silica catalyst at 290°C, followed by pyrolysis at 670°C with a contact time of 0.5 s and dilution with water vapour in the molar ratio of 1 : 5.

The alkyl derivatives of alkali metals also catalyse the dimerisation of propene at temperatures between 40 and 225°C and pressures up to 250 atm.[98] Complexes of the general formula AMR_3 can also be classified with this type of catalyst, where A is an alkali metal, M is zinc, cadmium, tin, or lead, and R is hydrogen or a hydrocarbon radical[99]. Because of the low activity of these catalysts, contact times of up to 20 h are needed[99], which argues against their practical exploitation.

Thus, catalysts based on the alkali metals and their derivatives can dimerise propene, with a high yield of the desired product, but they require the application of high temperatures and pressures, and long contact times, and they are also very sensitive to impurities in the feed material. According to patent specifications[65,97], the water content of the starting propene should not exceed 0.001%, that of methylacetylene and allene 0.02%, and the oxygen content should not exceed 0.0005 wt.%†.

c. Organometallic Synthesis

The dimerisation of propene by Ziegler's method[9] in the presence of aluminium alkyl catalysts leads to the formation of pure 2-methylpent-1-ene. Due to the absence of isomerisation reactions, 2-methylpent-1-ene is obtained in up to 95% yield[27]:

$$\overset{\delta^+\ \delta^-}{al{-}CH_2CH_2CH_3} + \overset{\delta^-}{CH_2}{=}\overset{\delta^+}{CH}{-}CH_3 \longrightarrow al{-}CH_2\underset{CH_3}{\underset{|}{C}}HCH_2CH_2CH_3$$

$$al{-}CH_2\underset{CH_3}{\underset{|}{C}}HCH_2CH_2CH_3 \longrightarrow al{-}H + CH_2{=}\underset{CH_3}{\underset{|}{C}}{-}CH_2CH_2CH_3$$

$$\overset{\delta^+\ \delta^-}{al{-}H} + \overset{\delta^-}{CH_2}{=}\overset{\delta^+}{CH}{-}CH_3 \longrightarrow al{-}CH_2CH_2CH_3 \text{ etc.}$$

$(al = \frac{1}{3}Al)$

In addition to the main reaction, "anomalous" addition of propene occurs to a minor extent, giving 5–6% of n-hexenes. The selectivity for dimerisation is strongly dependent on temperature[10,11], pressure, and contact time[10]. Studies of the dimerisation kinetics[100,101] have shown that the reaction order with respect to propene is close to unity. Activation energies of 11.7[100] and 14 kcal $mole^{-1}$ [101] have been reported.

Many modifications of the Ziegler method are known. For example, additions of boron alkyls have been made to the catalyst[102] in order to increase the rate of dimerisation. For the same purpose, various metal additions have been suggested, in particular aluminium, copper, or silver[103], and also salts such as iron(III) chloride[104]. To increase the yield of the propene dimer, the reaction has

† It has recently been announced[139] that the British Petroleum Company has established the production of 4-methylpent-1-ene on a semi-industrial scale (output 2000 tonnes per annum). The bulk of this product is delivered to I.C.I. for the production of polymers. Among the possible uses of 4-methylpent-1-ene we note the dimerisation to 2-isobutyl-6-methylhept-1-ene (in the presence of aluminium alkyls), oxidation to isobutyl methyl ketone in the presence of palladium chloride, autoxidation to epoxyalcohols, isomerisation to 2-methylpent-2-ene, and halogenation[139].

been carried out in a high-boiling organic solvent[105], and the linear velocity of the reactant stream through the reactor has been controlled[106]. Aluminium alkyls containing nickel or platinum compounds[107,108] have also been used as catalysts. An interesting method of dimerisation of alkenes with an internal double bond uses an alkylaluminium containing 1–20 wt. % of alumina–silica, zeolite, silica gel, activated alumina, or other cocatalyst[109].

The Ziegler dimerisation of propene is used as the first stage in the production of isoprene from propene[10,11]. The Goodyear Company, which produces 2-methylpent-1-ene on an industrial scale, has carried out research on the use of the propene dimer as a starting material in industrial organic synthesis[110]. In the Soviet Union, work in this direction is proceeding at the Yaroslavl' Technological Institute[111].

d. Coordination Dimerisation

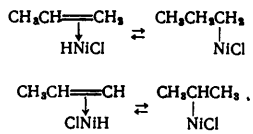
In this Section we shall discuss the dimerisation of propene under the influence of complex organometallic catalysts. The special feature of the mechanism of action of these catalysts is the formation of intermediates consisting of mixed transition metal complexes with alkene ligands. Thus, it is convenient to refer to this type of dimerisation as coordination dimerisation.

The complex catalysts of the Ziegler type, based on alkylaluminium halides and nickel compounds, are extremely active towards the dimerisation of propene under quite mild reaction conditions, and in this respect they are distinctly superior to the catalysts of the types discussed above. For example, a catalyst prepared by mixing 1 mmole of nickel acetylacetonate, 45 mmole of ethylaluminium sesquichloride, and 16 mmole of triphenylphosphine gives 2.6×10^5 moles of the propene dimer (90% yield) in 2 h at 60°C and 10 atm in a toluene medium[19]. The dimer contains 4-methylpent-2-ene (37.0%), 2-methylpent-2-ene (26.5%), 2-methylpent-1-ene (17.4%), 4-methylpent-1-ene (1.6%), 2,3-dimethylbut-1-ene (6%), 2,3-dimethylbut-2-ene (0.5%), hex-2-ene (5.6%), and hex-3-ene (5.6%).[19] A propene dimer containing 75% of methylpentenes and 20% of n-hexenes is formed in the presence of a catalytic system based on π-allylnickel iodide, aluminium bromide, and triphenylphosphine[25]. Replacing the triphenylphosphine by tricyclohexylphosphine yields a dimer containing 67% of dimethylbutenes and 31% of methylpentenes[25]. Catalysts based on π-allylnickel chloride are reported to be used for the dimerisation of propene on a laboratory scale at the Max Planck Institute (Mülheim, W.Germany).[20,112] Trialkylphosphines are added to the catalyst to increase its activity and to obtain products of desired structure[20]. At 30–50°C and 15 atm pressure the conversion of propene is 95%, and the selectivity with respect to the dimer is 88%. The Lurgi–Ruhrgas company has planned an industrial plant for the dimerisation of propene having a capacity of 80 000 tonnes per annum[112]. Its main product is expected to be 2,3-dimethylbut-2-ene, which is intended to be used for the production of 2,3-dimethylbuta-1,3-diene and motor fuel constituents[112]. Dimerisation of ethylene can be achieved in the presence of bis(cyclopentadienyl)nickel[113], and dimerisation of propene by using phosphine complexes of nickel in conjunction with Lewis acids[114].

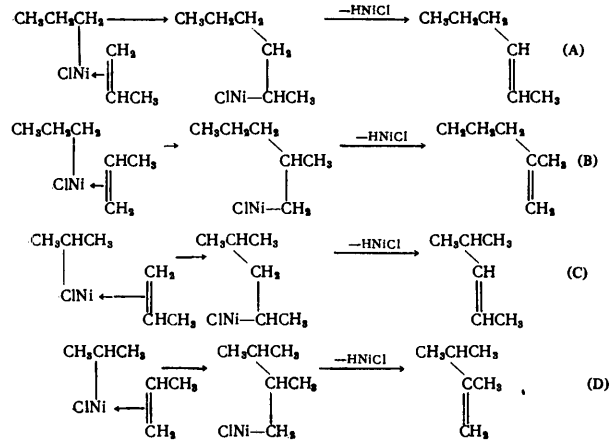
It has been suggested that the activity of complex Ziegler catalysts towards the dimerisation of alkenes[23] and similar reactions[115] arises from the formation of complex hydrides and alkyl derivatives of the transition metal, for example, HNiCl, coordinated to the alkylaluminium halide. The initiation of the dimerisation and the regeneration of the catalyst after each reaction cycle can thus be explained[115]:

$$C_3H_6 + HNiCl \rightarrow C_3H_6NiCl$$
$$C_3H_6NiCl + C_3H_6 \rightarrow C_6H_{12}NiCl$$
$$C_6H_{12}NiCl \rightarrow C_6H_{12} + HNiCl \text{ etc.}$$

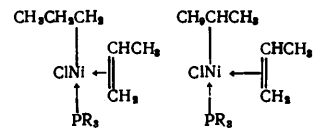
A later, more detailed mechanism for the dimerisation accounts for the structure of the propene dimer and for the influence of tertiary phosphines on the course of the reaction[116]. Two configurations of the alkene ligands are possible in the intermediate π-complexes, leading to the formation of different alkyl derivatives of the transition metal:



The subsequent coordination of a second molecule of alkene can give four types of π-complexes, leading to dimers of different structure:



Paths (B) and (D) are least likely, because of steric hindrance to the formation of the starting π-complexes. But these can be stabilised by the addition of trialkylphosphines to the system[117]:

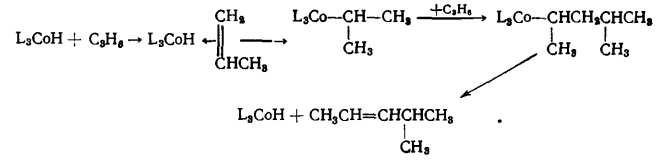


leading to the formation of 2-methylpent-1-ene and 2,3-dimethylbut-1-ene as the primary dimerisation products, which then isomerise to 2-methylpent-2-ene and 2,3-dimethylbut-2-ene respectively.

Complex catalysts based on alkylaluminium halides and nickel salts are active in the isomerisation of alkenes, which occurs under the conditions of the dimerisation reaction and determines the final composition of the reaction products[22,118]. Impurities in the starting alkene can drastically affect the rate of dimerisation of propene[24].

The dimerisation of propene under the influence of cobalt oxide deposited on active carbon can also be classified as coordination dimerisation, because the mechanism proposed by Schultz and coworkers[6] for this reaction includes the formation on the catalyst surface of π-complexes and complex alkyl derivatives of cobalt. This catalyst is peculiar in that large amounts (50–55%) of n-hexenes are formed in its presence. The catalyst is thermally unstable, and

therefore the yield of dimer decreases on raising the temperature (the conversion is 72.7% at the optimum temperature of 85°C). Diene hydrocarbon impurities poison the catalyst irreversibly. The authors suggest that the entity responsible for catalysis is a complex hydride of cobalt having at least one coordination position free to form a π-complex with the alkene[6]:



5. DIMERISATION OF BUTENES AND HIGHER ALKENES

Most of the dimerisation catalysts for ethylene and propene should be suitable, in principle, for the dimerisation of C_4 and higher alkenes. However, practically all the published data relate exclusively to acidic catalysts and organoaluminium compounds, because they offer acceptable yields of the dimers.

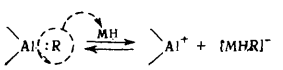
The preparation of the dimer of isobutene in the presence of acidic catalysts (aimed at producing motor fuel constituents) has been known for a long time and does not require special discussion. Higher asymmetrical dialkylethylenes, and also trialkylethylenes, undergo dimerisation similarly to isobutene. For example, 2-methylpent-1-ene in the presence of 70% H_2SO_4 at 50°C dimerises in 30 min with a yield of 80% (on the basis of the added monomer) and 95% (on the basis of the reacted monomer)[111]. High selectivity for the dimerisation of 2-methylpent-1-ene and 2-methylpent-2-ene has been reported for H_3PO_4 on kieselguhr[111] and on an alumina–silica catalyst[119]. It has been pointed out that the dimer of isohexenes boils over a very narrow range of temperatures[111]. The structure of the dimer has recently been investigated[120], and shown to include the following main components: 2,4,4-trimethyl-3-ethylhept-1-ene, 4,6,6-trimethylnon-3-ene, and 4,6,6-trimethylnon-4-ene. Polyanskii and coworkers[121] have investigated the dimerisation of isopentenes on a cation-exchange resin.

In the presence of aluminium alkyls, but-1-ene smoothly dimerises to 2-ethylhex-1-ene, and hex-1-ene to 2-butyloct-1-ene.[9] The dimerisation of butenes by this method has been studied at the Scientific Research Institute of Synthetic Alcohols and Organic Products[122,123].

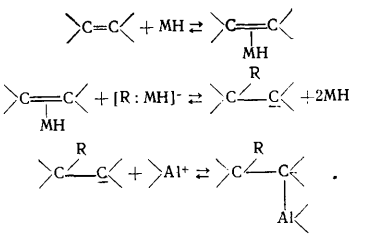
Sladkov and coworkers demonstrated that but-1-ene, but-2-ene, and their mixtures can be used to prepare 2-ethylhex-1-ene in the presence of triethylaluminium and cocatalysts[122]. They proposed a reaction mechanism which explains the role of the transition metal cocatalysts. It is assumed[123] that the interaction between triethylaluminium and the metal compounds (silver, cobalt, nickel, etc.) gives rise to "subcompounds" of the metals in a reduced state according to the scheme

$$M^{+n} \xrightarrow{+me} M^{+(n-m)}.$$

These exist as hydrides or halides (M^+H^- or M^+Cl^- respectively), which are highly electrophilic. The role of the subcompounds in substitution, isomerisation, and polymerisation reactions is discussed. Thus, polymerisation reactions are assisted by "sub-ions" through the formation of active ions from aluminium alkyls:



and they also interact with the double bond and enhance its electrophilic properties:



Alkenes with internal double bonds also dimerise in the presence of aluminium alkyls, but more slowly, and they undergo preliminary isomerisation to the corresponding α-alkenes. Thus, hept-1-ene and hept-3-ene form the same dimer[124]. Dimerisation of alkenes with 3–12 carbon atoms has been proposed[125] in the presence of aluminium alkyls containing trialkylboranes at 195–200°C. For example, hex-2-ene is converted into 2-butyloct-1-ene (in 20% yield) in 4 h under the influence of tri-isobutylaluminium and tributylboron. Similarly, 4-methylpent-1-ene and 2-methylpent-1-ene dimerise to 2-isobutyl-6-methylhept-1-ene. It is thought that trialkylborane promotes the isomerisation of the β-alkene to an α-alkene, which subsequently dimerises[125].

But-1-ene and but-2-ene dimerise at 20°C under the influence of the di-isobutylaluminium chloride–nickel oleate catalytic system (yield of dimer ~ 70%). Infrared and NMR spectral studies of the dimer have shown the presence of 3-methylheptenes, 3,4-dimethylhexenes, and n-octenes, with various positions of the double bond[126].

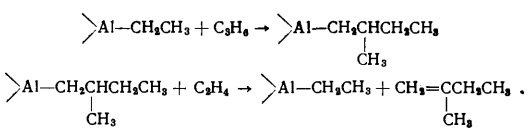
The dimerisation of butenes and hexenes over a cobalt oxide catalyst (13%) supported on carbon has been studied in detail by Schultz and coworkers[6]. After 6 h at 150°C, but-1-ene is converted (13.6% conversion) into a dimer containing 65.3% of n-octenes, 34.4% of 3-methylheptenes, and 0.3% of 3,4-dimethylhexenes. Hex-1-ene gives, after 12 h at 150°C, 18.6% of a product which after hydrogenation contains 82.8% of n-dodecane, 14.8% of 5-methylundecane, and 2.4% of 4-ethyldecane[6]. Alkenes with more than six carbon atoms are dimerised in the liquid phase at 30–40°C over alumina promoted by HF (1%) with 10–20 min contact times. The dimers are used in the production of lubricants and alcohols for the synthesis of plasticisers[127]. Dodecenes have been prepared by the dimerisation of the dimer of propene in the presence of the hydrate of boron trifluoride[128] or of the $BF_3.H_3PO_4$ complex[129].

An interesting method for the dimerisation of higher branched alkenes in the liquid phase relies on brief exposure to high-intensity radiation. The radiation can be in the form of fast electrons, X-rays, gamma rays, or radiation from nuclear reactors[130]. The dimer of di-isobutene was prepared by this method in 74% yield. The mechanism of the radiation-induced dimerisation of higher alkenes has been the object of special investigations[131].

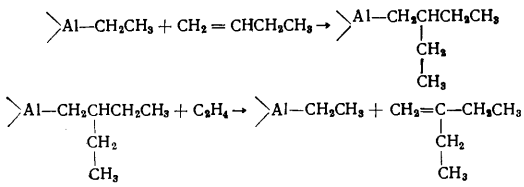
6. CODIMERISATION OF ALKENES

When a mixture of alkenes is used as the starting material, separate dimerisation of each of the alkenes can occur, or alternatively molecules of different alkenes can be combined. In the latter case the term "codimerisation" is appropriate. Most of the catalysts described above allow the codimerisation of ethylene with propene and other alkenes.

The most important application of codimerisation at present is the Ziegler[9] codimerisation of ethylene with propene (or but-1-ene) as a basis for the production of isoprene on an industrial scale[12]. The method depends on the addition of propene to triethylaluminium, followed by the replacement of 2-methylbut-1-ene by ethylene:



Similarly, 2-ethylbut-1-ene can be prepared from ethylene and but-1-ene:



The preparation of isoprene from ethylene and propene has been disclosed in a patent[132]. A mixture of 56.4 g of triethylaluminium and 12.6 g of propene was heated in an autoclave for 30–60 min at 130–140°C. After cooling, a small quantity of "colloidal" nickel was added (as a cocatalyst for the displacement step), 6.72 litres of ethylene were added, and the displacement reaction was carried out by heating the reaction mixture at 160–170°C for 2–3 h. A 20 g yield of 2-methylbut-1-ene was obtained, and subsequently dehydrogenated to isoprene at 700°C on a Fe_2O_3–MgO catalyst, using a 1 : 10 dilution of the vapour. According to another patent[133], 2-methylbut-1-ene can be obtained in ~ 90% yield by the codimerisation of ethylene and propene in a single stage, in the presence of tri-isopentylaluminium at 125–135°C, and with a 3 : 3 : 1 molar ratio of ethylene : propene : $(iso\text{-}C_5H_{11})_3Al$. An interesting method[134] for the simultaneous preparation of 2-methylbut-1-ene and 2-methylpent-1-ene relies on contacting an ethylene–propene mixture with triethylaluminium for 5–50 s at 220–300°C.

Garmonov and Chevychalova[135] prefer to carry out the addition of propene to triethylaluminium at 120–180°C and 40–50 atm, and the displacement reaction at 20°C and 15 atm in the presence of nickel (0.2% on the basis of the aluminium alkyl). Babaev[136] examined some special features of the codimerisation of alkenes in the presence of tri-isobutylaluminium. He attempted to codimerise ethylene with propene in a single stage, but the yield of isopentene did not exceed 30%. In the codimerisation of ethylene with but-1-ene at 225°C, a C_6 fraction containing up to 90% of 2-ethylbut-1-ene is formed in 30% yield[136]. It should be noted that 2-ethylbut-1-ene can be used for the preparation of isoprene by isomerisation to 3-methylpent-2-ene followed by pyrolysis[10].

Normal pentenes are the main product of the codimerisation of ethylene and propene in the presence of alkali metals on carriers[79,91,137]. For example, when potassium supported on talc is used as a catalyst at 115°C, the product obtained from ethylene and propene contains 70% of pent-1-ene, 26% of pent-2-ene, and 4% of hexenes[137]. Ethylene and isobutene undergo codimerisation on a Na/K_2CO_3 catalyst to give a mixture of 2-methylpent-1-ene and 2-methylpent-2-ene in various proportions. The codimer obtained from ethylene and but-1-ene under similar conditions contains 52% of 3-methylpent-1-ene, 21% of 3-methylpent-2-ene, and 27% of n-hexenes. Ethylene and but-2-ene give a product of the following composition: 3-methylpent-1-ene (47%), 3-methylpent-2-ene (16%), hex-2-ene (32%), and hex-3-ene (5%).[79] The product of the codimerisation of ethylene and but-2-ene has been suggested as a starting material for the production of isoprene[138].

Under the influence of complex organometallic catalysts, the alkenes undergo individual reactions as well as codimerisation[22]. When a mixture (1 : 1) of ethylene and propene is passed through a catalyst solution of di-isobutylaluminium chloride and nickel oleate (Al : Ni = 100) at 25°C and 1 atm pressure, the product contains 23% of butenes, 43% of pentenes, 22% of hexenes, and 12% of higher hydrocarbons. The pentene fraction contains 60.7% of pent-2-ene, 35.3% of 2-methylbut-2-ene, 2.6% of 2-methylbut-1-ene, and 1.4% of pent-1-ene.[22] A similar composition of the product is observed when cobalt oxide on carbon is used as the catalyst[7]. In this instance 40% of pentenes is formed, containing ~ 80% of pent-2-ene.

The codimerisation of ethylene with propene under the influence of rhodium chloride in alcoholic solution at 60°C and 1000 atm pressure for 16 h has been described[51]. The product is a mixture of pentenes and hexenes. Analytical hydrogenation of the C_5 alkenes yielded approximately equal amounts of n-pentane and 2-methylbutane.

Nuclear Magnetic Resonance in Radicals and in Radical Reactions

A.L.Buchachenko and N.A.Sysoeva

The present review examines papers devoted to the application of NMR to the study of the electronic structure of radicals, their solvation by various solvents, and the kinetics of radical reactions. The characteristic features and experimental difficulties of the NMR of radicals in the solid and liquid phases are examined as are the possibility of obtaining data on the mechanism of the delocalisation of the unpaired electron over large distances in the radicals themselves and in their complexes with solvents. It is shown how relaxation methods involving measurement of T_1 and T_2 and the dynamic polarisation of the nuclei have given information on the correlation times characterising the intensity of molecular motions in a liquid, and the energetics of these motions. The theoretical basis of these methods is examined. The last section gives the theory of the use of NMR spectra to measure the rates of various fast reactions. The results of the study of the kinetics of electron transfer and radical substitutions taking place with zero activation energy are discussed. The bibliography contains 61 references.

INTRODUCTION

The application of nuclear magnetic resonance to the study of radicals and radical reactions is a new and interesting example of the physical approach to the solution of chemical problems concerning the electronic structure of radicals, their reactivities, and their specific interactions with various molecules. These three aspects make up the contents of the present review. Chief attention is paid to the physicochemical aspects of the phenomena; purely physical aspects which are not of significant importance for chemistry are examined only briefly or not at all.

NMR in radicals gives detailed information on the properties of the molecular orbitals of the unpaired electron and on the mechanism of its delocalisation. The NMR method can give unique data on weak donor–acceptor interactions between radicals and surrounding molecules, on the dynamics of complex-formation equilibria, and on the participation of the unpaired electron in donor–acceptor interactions and the mechanism of its delocalisation in the complex.

Of greatest interest is the possibility of using the NMR method to measure the rates of fast reactions of electron transfer and also radical substitutions, taking place with zero activation energy. This range of problems will subsequently be examined in more detail. We shall restrict ourselves to organic radicals; paramagnetic ions and their complexes with organic ligands will not be considered.

I. NMR AND DELOCALISATION OF THE UNPAIRED ELECTRON IN RADICALS

The molecular orbital of the unpaired electron in radicals usually includes various atomic orbitals of many atoms in the radical. If the nuclei exhibit magnetic moments, the energy of the magnetic electron-nuclear or hyperfine interaction (HFI), measured by the method of electron paramagnetic resonance (EPR), in principle makes it possible to determine the magnitude of the spin density ρ_i. For angle-dependent atomic orbitals (p, d, etc.), ρ_i is determined from the dipole–dipole HFI, and for atomic s orbitals, ρ_i is determined from the isotropic or contact HFI.

A very important characteristic of the behaviour of an unpaired electron, in addition to the magnitude of ρ_i, is the sign of ρ_i, which determines the orientation of the electron spin in the atomic orbital with respect to the orientation of the total spin: $\rho_i > 0$ if these orientations coincide, and $\rho_i < 0$ if they are opposed. The EPR method at best can give only the relative signs of ρ_i (in the study of the EPR of radicals in diamagnetically dilute single crystals[1], or in solutions[2]). The sign of the HFI constants characterises the mechanism of the delocalisation of the unpaired electron over the radical or the mechanism of the "population" of the atomic orbitals—a very important manifestation of electron–electron interactions in the radical.

Let us now consider NMR in a radical. Let us assume that the unpaired electron is situated at an atom with nuclear spin I; the energy levels of the nucleus in a constant magnetic field H_0 with allowance for only the isotropic HFI are then given by the expression

$$E_l = -\gamma_n H_0 m_l + a_l \gamma_e m_s m_l , \qquad (1)$$

where γ_e and γ_n are the gyromagnetic ratios of the electron and the nucleus, m_s and m_i the quantum numbers of the projections of the electron and nuclear spins on the field direction (m_i takes values from $-I$ to $+I$), a_i the constant of the isotropic HFI

$$a_l = \frac{8\pi}{3}\gamma_e\gamma_n|\psi(0)|^2 \qquad (2)$$

and $|\psi(0)|_i^2$ the density of the unpaired electron at a point of the nucleus. The first term in Eqn. (1) corresponds to the Zeeman energy of the nucleus, and the last to the energy of the isotropic HFI.

The magnitude of the local field created by the unpaired electron at a point of the nucleus is $a_i/2(\gamma_e/\gamma_n)$ and for free radicals usually amounts to 10^3–10^4 Oe. This HFI is now not a perturbation of the nuclear Zeeman levels and it displaces considerably the frequency of the nuclear-resonance absorption, so that it becomes non-observable. If, however, the correlation time, that is, the duration of existence of the local field due to the HFI, becomes much shorter than the period of the Larmor precession of the nucleus in this field, this leads to a decrease in the mean value of the local field. In this instance the second term in Eqn. (1) has the form $a_i\gamma_e\langle m_S\rangle m_i$, where $\langle m_S\rangle$ is the mean value of m_S. The value of $\langle m_S\rangle$ is determined by the populations of the electron-spin states $m_S = \pm\frac{1}{2}$. In the high-temperature approximation, when the Zeeman energies are much less than kT, we have

$$\langle m_s\rangle = \sum_{m_s} N_{m_s}m_s \Big/ \sum_{m_s} N_{m_s} \simeq -\frac{\gamma_e H_0}{4kT} \qquad (3)$$

where N_{mS} represents the populations of the states m_S.

For the energy of the transitions $\Delta m_S = 0$, $\Delta m_i = \pm 1$, corresponding to the NMR spectrum we obtain the expression

$$\Delta E = \gamma_n H_0 - a_i\gamma_e(\gamma_e H_0/4kT), \qquad (4)$$

or, converting to the magnitude of the magnetic field at resonance

$$H = H_0 - a_i(\gamma_e/\gamma_n)(\gamma_e H_0/4kT),$$

where H_0 is the resonance field in the absence of HFI. The difference $\Delta H = H - H_0$ is the magnitude of the paramagnetic shift

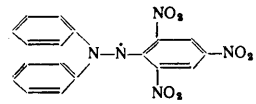
$$\Delta H = -a_i(\gamma_e/\gamma_n)(\gamma_e H_0/4kT). \qquad (5)$$

Thus the fluctuating magnetic field created by the unpaired electron at a point of the nucleus brings about a displacement of the resonance frequency of this nucleus, whose magnitude and sign are determined by the magnitude and absolute sign of the constant a_i. It is necessary only that the frequency of the fluctuations in the local field be much greater than the frequency of the Larmor nuclear precession in this field. It is evident that the paramagnetic shift of the NMR in radicals is analogous to the Knight shift of the NMR in metals, due to the contact HFI of the nuclei with the conductivity electrons[3].

The condition for observability of the paramagnetic shift is that the duration τ of the existence of the local field of the HFI should be short compared with the period of the nuclear precession in this field, that is, $\tau \ll a_i^{-1}$, where a_i is expressed in frequency units. Since the spin-lattice relaxation time T_1 in radicals is usually large, this mechanism cannot ensure that the condition $T_1 \ll a_i^{-1}$ is satisfied; the most important part is taken by the mechanism of the electron–electron exchange interactions taking place in concentrated solid or liquid solutions of the radicals. This corresponds to the mutual reorientation of neighbouring electron spins with exchange frequency ω_{ex}; in crystals of the radicals $\omega_{ex} \simeq 10^{10}$–$10^{11}$ s^{-1}, that is, the electron changes its orientation 10^3–10^4 times within the period of the nuclear precession. This is sufficient to average the local fields created by the HFI, except for the small residual fraction obeying the Boltzmann distribution; it is this HFI which is responsible for the paramagnetic shift.

1. NMR of Radicals in the Solid Phase

NMR in diphenylpicrylhydrazyl (DPPH)



has been studied in most detail.

From the structure of the radical it follows that there are four groups of equivalent protons, and in the NMR spectrum these should correspond to four lines with integral intensities in the ratio 1 : 2 : 2 : 1, proportional to the number of protons of each kind. In the first experiments, however, only two strongly overlapping lines were observed[4] and only later was it possible to resolve the spectrum completely[5]. The NMR spectrum of polycrystalline DPPH, taken in the form of the 1 : 1 complex with benzene, is shown in Fig. 1*a*. It can be seen that in addition to the four expected lines there appears in the centre an additional line which is not displaced and which corresponds to complexed benzene. If benzene is replaced by deuteriobenzene, the intensity of this line decreases sharply; there remains only a small peak which apparently corresponds to diamagnetic impurities in the radical (Fig. 1*b*). Replacement of the *meta*-protons in the picryl group by deuterium showed that the resonance of these protons is displaced considerably to low fields (Fig. 1*c*).

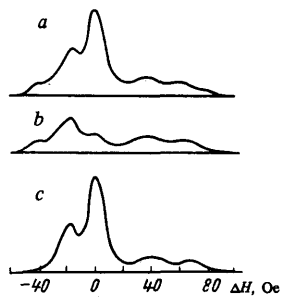


Figure 1. NMR spectra of polycrystalline DPPH at 4.2°K. *a*) DPPH in its 1 : 1 complex with benzene; *b*) DPPH in its complex with deuteriobenzene; *c*) DPPH with deuterium in the picryl group.

On the basis of these data, and also from calculations of the spin densities by the valency bond method, and from the intensities in the spectrum, it was assumed that the resonance of the *meta*-protons is displaced to low fields, and that the resonance of the *ortho*- and *para*-protons is displaced to high fields; the paramagnetic shifts and HFI constants a_H, calculated from Eqn. (5), are given in Table 1.

In view of the approximate nature of the theory and the experimental errors, the agreement is fairly good. Thus at the hydrogen atoms in the *ortho*- and *para*-positions of the phenyl rings, the spin density is negative, whereas it is positive in the *meta*-positions. These conclusions were confirmed in later work; it was shown that the

dependence of the paramagnetic shift on the magnetic field intensity and on temperature obeys Eqn. (5) satisfactorily[6].

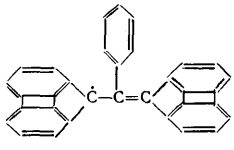
In DPPH, as in most other aromatic radicals, the unpaired electron is a π-electron and its molecular orbital is made up from the orbitals of the nitrogen atoms and the π-orbitals of the carbon atoms of the aromatic system. The isotropic HFI at the protons attached to these carbon atoms appears as a result of $\sigma-\pi$ configurational interaction, that is, partial unpairing of the electrons of the C–H bond; the signs of the spin density at the carbon atom and the hydrogen atom attached to it are opposite. This means that in DPPH there is positive spin density at the carbon atoms in the *para*- and *ortho*-positions, and negative spin density at the carbon atoms in the *meta*-positions. Thus the unpaired electron in DPPH is delocalised over the π-system of the radical; its density ρ at the carbon atoms in the rings can be determined from the familiar McConnell relationship[7] $a_H = Q\rho$, where $Q = 23.7$ Oe,[8] and the constants of the isotropic HFI at the neighbouring protons are determined either from the EPR spectra (without signs), or from NMR data, as for DPPH (Table 1).

Table 1. Paramagnetic shifts and HFI constants in DPPH.

Position of protons	ΔH, Oe	a_H, Oe (experiment)	a_H, Oe (theory) (Ref.5)
Picryl (*meta*)	−38	+2.4	+2.55
Phenyl (*meta*)	−16	+2.1	+1.55
Phenyl (*ortho*)	+37	−2.3	−2.94
Phenyl (*para*)	+62	−3.9	−2.74

An interesting feature is that the central line in the NMR spectrum of DPPH, corresponding to the protons of the benzene in the complex with DPPH, is not displaced, that is, the spin density at the atoms of the ligand in the complex is very low, although the complex itself is fairly stable.

The NMR spectrum of 1,3-bis(biphenylene)-2-phenylallyl:



shows some structure even at 77°K. At 4.2°K, two lines are clearly observed; one of these is displaced to high fields by 15 ± 1 Oe, and the other, whose intensity corresponds to ~ 70% of the total intensity of absorption, remains almost unshifted[9].

The EPR spectrum of this radical contains 9 lines with splitting 2.2 Oe. It is not known which protons produce this splitting; nevertheless, it is possible to divide all the protons in the radical into two groups: 8 protons with HFI constant 2.2 Oe, and the other 13 protons with very slight splitting. Since the radical is present in the crystal as the 1 : 1 complex with benzene, the NMR spectrum should contain two lines—one displaced (from the 8 protons) and one which is not displaced (from the 13 + 6 = 19 protons). The observed NMR spectrum shows complete agreement with these ideas. At the protons giving an HFI constant of 2.2 Oe, the spin density is negative (paramagnetic shift to high fields), that is, at the carbon atoms to which these protons are attached, the density of the unpaired π-electron is positive and is much greater than the density of the unpaired electron at the other carbon atoms.

The NMR spectrum of the pyrene radical-anion, in addition to a line which is not displaced and which corresponds to the diamagnetic original substance, contains three displaced lines[10]. The signs and magnitudes of the HFI constants are given in Table 2, which also gives for comparison the values of the same constants obtained by the EPR method; the agreement is very good.

Table 2. Paramagnetic shifts and HFI constants in the pyrene radical-anion.

ΔH, Oe	a_H(NMR)	a_H(EPR)
−35.1	+1.26	(+) 1.09
+79.1	−2.79	(−) 2.08
+140.5	−4.88	(−) 4.75

The NMR spectrum of the tri-*p*-chlorophenylammonium radical-cation at 77°K consists of two poorly resolved lines with equal intensity, one of which is displaced by 2.3 Oe to low fields, whereas the other is displaced by 3.9 Oe to high fields. These lines evidently correspond to the *ortho*- and *meta*-protons, on which the spin densities have positive signs[9].

In addition to the study of these radicals, attempts have also been made to study NMR in the polycrystalline tetramethyl-*p*-phenylenediamine radical-cation (Wurster's cation), but definite results could not be obtained[9]. This is apparently due to the fact that at fairly high temperatures the paramagnetic shifts are small, and at low temperatures the crystal is converted into an antiferromagnetic state[11].

2. NMR of Radicals in Liquids

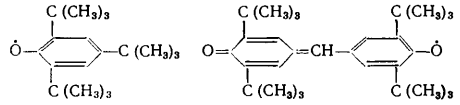
Until now we have examined the paramagnetic shift due only to the isotropic HFI. The anisotropic part of the HFI also produces a shift, whose magnitude and sign are determined by the magnitude and sign of the anisotropic HFI constant; the latter can be found from the paramagnetic shifts in single crystals of radicals. In polycrystalline specimens, the anisotropic HFI leads to marked broadening of the lines; it is for this reason that paramagnetic shifts in polycrystalline specimens can be observed only at very low temperatures, when the magnitude of the shift is greater than the width of the lines. In liquids, the anisotropic HFI is averaged by the molecular motion, and the NMR lines become much narrower.

The condition for observation of the paramagnetic shift is satisfied only in concentrated solutions of radicals. The width of the lines is determined by both the dipole and scalar relaxations (see Section II) and is usually proportional to a^2; the condition for obtaining very narrow lines $\omega_S^2 \tau_{ex}^2 \ll 1$ is difficult to satisfy for solutions of radicals,

in contrast to the situation for paramagnetic ions, where the electronic relaxation times T_{1e} are often small and $\omega_S^2 T_{1e}^2 < 1$.

Most studies have naturally been carried out with stable radicals. This, however, does not restrict the possibilities of using the method for the main task—the investigation of the mechanism of delocalisation of electrons in many-electron molecular systems.

In the NMR spectra of 2,4,6-tris-t-butylphenoxyl and Coppinger's radical:



recorded at 20° in C_6D_6, the lines of the *o*-t-butyl protons are displaced to low fields relative to the same protons in the corresponding molecules, that is, there is positive spin density at these protons; the HFI constants are +0.071 Oe and +0.049 Oe respectively, and show good agreement with the constants obtained by the EPR method (0.072 Oe and 0.049 Oe)[12]. Calculation of the spin density in these radicals shows that in the *ortho*-positions of the rings there is positive π-electron density, that is, the signs of the spin densities at the carbon atoms in the *ortho*-position and the *o*-t-butyl protons are the same; this apparently means that the chief part in delocalisation of the unpaired electron on the protons of the t-butyl groups is played by the hyperconjugation mechanism (further proof of this is given below, in section II).

Table 3.

Radical	HFI constants for the protons of the CH_3 and OCH_3 groups, Oe	
	para-position	*ortho*-position
	+0.223	—
	+0.180	+0.100
	+0.120	+0.084
	+0.075	+0.160

In aromatic nitroxide radicals (Table 3) the sign of the constant a_H on the protons of the *ortho*- and *para*-substituents also coincides with the sign of the π-electron spin density on the corresponding carbon atoms of the aromatic rings; this means that the unpaired electron appears in the atomic orbitals of the CH_3 and OCH_3 hydrogen atoms due to a hyperconjugation mechanism[13]. The values of a_H for OCH_3 in a series of radicals (Table 3) gradually decrease; this may be due to a decrease in the spin density in the rings as a result of the twisting due to steric interaction of the *ortho*-substituents[14]. The relationship between the constants a_H for OCH_3 in the *ortho*- and *para*-positions, and also between a_H for OCH_3 and CH_3 is the same as that usually observed in EPR for radicals of this type[15]. Extremely interesting characteristic featues of the delocalisation of an unpaired electron in a σ-system are observed in aliphatic nitroxide radicals[16,17]. The HFI constants in some of these radicals are given in Table 4.

Table 4.

No.	Radical	HFI constants for the protons, Oe			
		β-CH_3	β-CH_2	γ-CH	other protons
I		—0.1	0		
II		—0.2	—0.4	+0.15	
III		0 and —0.43	—0.32 and —0.46	+0.08	
IV		0 and —0.43	—0.31 and —0.46	+0.08	~0
V		0 and —0.4	—0.29 and —0.5	+0.09	

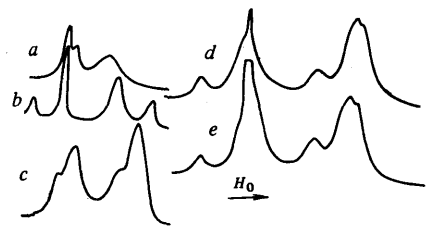


Figure 2. NMR spectra of radicals: I at 50°C (*a*); II at 36°C [16] (*b*); III at 25°C (*c*) and 60°C (*d*); IV at 60°C (*e*). Spectra recorded at 100 mHz (see Table 4).

The NMR spectra of some of these radicals are given in Fig. 2. In radicals I and II the protons of all the β-CH_3 groups are equivalent and give a single line in the NMR spectrum; the protons of the β-CH_2 groups are also equivalent. In the radicals and polyradicals III–V, the NMR signal of the protons of the β-CH_3 groups consists of two lines which are displaced considerably relative to one another. The HFI constants for these radicals differ considerably from one another for both the β-CH_3 groups and the β-CH_2 groups. This means that these groups are nonequivalent: for two of them, the constants a_H are close to

zero, and for the other two the values lie between −0.38 Oe and −0.42 Oe. The mean value of these constants corresponds exactly to the HFI constant for the β-CH_3 protons in radical II. The spatial configurations of the aliphatic rings in radicals III–V are evidently fixed, and the frequencies of the inversion transitions (of the "chair"–"boat", "chair"–"chair" type etc.) are small compared with the difference in the HFI constants of the protons of the non-equivalent β-CH_3 groups. In radical II the frequencies of these inversions are high so that the averaged HFI constant for all the β-CH_3 protons is observed.

A similar picture is observed for the protons of the β-CH_2 groups; here also they are non-equivalent in radicals III–V, but in radical II they are equivalent with a mean value for the HFI constant equal to half the sum of the HFI constants of the non-equivalent protons of the β-CH_2 groups.

These results show that the unpaired electron is delocalised over the angular orbitals, that is, by a hyperconjugation mechanism (at least on the β-carbon atoms). The presence of a π-electron on the C atom in CH_3 was also proved by the EPR method[18]; it was found that the sign of the constant $a_{^{13}C}$ for CH_3 coincides with the sign of the π-electron spin density $\rho^{\pi}_{^{13}C}$ for the same ^{13}C atom. If it is assumed that the signs of a_H and $\rho^{\pi}_{^{13}C}$ coincide (this assumption is justified by EPR spectroscopy), it follows that there is negative π-electron spin density on the β-carbon atoms. It should be noted that at the N atom the spin density is positive and large: $\rho^{\pi}_N \simeq 0.8$.[19] It is at present difficult to resolve unambiguously the problem of the mechanism of the appearance of negative spin density on β-CH_3 and β-CH_2. It is also not clear why $a_H > 0$ at the protons of the γ-CH group, in contrast to the situation for all other protons of the aliphatic ring. One reasonable explanation can be found in the assumption that there is direct spatial overlap of the γ-CH sp^3 hybrid orbitals and the π-orbital of the nitrogen atom; evidence for this is provided by the fact that a_H for γ-CH in radicals III–V is smaller by a factor of almost two than a_H for γ-CH_2 in radical II.

Recently, considerable attention has been paid to the use of the NMR method to study paramagnetic solutions of aromatic hydrocarbons in the presence of alkali metals. The radical-anions formed take part in fast electron exchange with neutral molecules of the aromatic hydrocarbons; the characteristic time of this reaction is the correlation time of the averaged isotropic HFI. The observed paramagnetic shift is similar in character to that in the examples examined above, and the magnitude of the shift is given by Eqn. (5), in the right-hand side of which appears a new factor f_M—the mole fraction of the ion-radicals (see section III for more details).

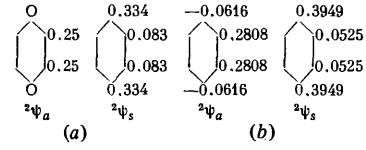
The signs and magnitudes of the isotropic HFI constants on the protons of the alkyl groups in the radical-anions of 1- and 2-alkyl substituted naphthalenes have been determined[20] (Table 5). For the α-protons, the signs of the HFI constants were determined from the NMR spectra, and their absolute values were found from the EPR spectra.

The NMR spectra of the p-xylene and p-diethylbenzene radical-anions[21,22] showed that the spin density on the α-protons of the alkyl groups is negative ($a_{CH_3} = -0.083$ Oe in the p-xylene anion and $a_{CH_2} = -0.050$ Oe in the p-diethylbenzene anion). Calculations show that the isotropic HFI for these protons appears as a result of hyperconjugation. (This can also be seen from the experimental data: the value of a for CH_2 in the p-diethylbenzene anion is less than that for CH_3 in the p-xylene anion—this situation is characteristic of the delocalisation of an electron over the angular orbitals.) This means that the sign of the spin density for CH_3 and CH_2 in these anions is the same as that of the spin density on the carbon atoms to which these groups are attached. This raises the problem of how the negative spin density appears on these carbon atoms.

Table 5. HFI constants at the α-, β-, and γ-protons of the substituents in naphthalene radical-anions.

Substituent	HFI constants × 10^3, Oe				Substituent	HFI constants × 10^3, Oe			
	α	β	γ	δ		α	β	γ	δ
1-CH_3	+3860				2-CH_3	+1810			
1-C_2H_5	+3240	− 74			2-C_2H_5	+1130	+32		
1-n-C_3H_7	+2670	−212	+64		2-n-C_3H_7	+1080	−2	+27	
1-n-C_4H_9	+2800	−155	+45	+35	2-n-C_4H_9	+1050	—	—	+20

The xylene anion can be regarded as a weakly perturbed benzene system. The degeneracy of the ground state of the benzene anion is removed by the perturbing influence of the two CH_3 groups but the splitting between the levels remains very small. EPR studies show that in 1- and 1,4-substituted benzene anions the lowest antibonding orbital is antisymmetric with respect to reflection in a plane perpendicular to the plane of the molecule and passing through the two CH_3 groups. The other orbital, which is symmetric, should have a slightly higher energy. The distribution of the spin density for each of these two orbitals is shown in the scheme below:



Since the unpaired electron occupies the lowest antisymmetric orbital $^2\psi_a$, its density at carbon atoms 1 and 4 should be equal to zero, so that the HFI splitting for the CH_3 protons should also be equal to zero. Since this splitting is not equal to zero, however, Bolton and coworkers[23] proposed three possible mechanisms which might lead to the observed effect: (a) vibronic or electronic-vibrational interactions between the symmetric and antisymmetric states; (b) thermal excitation, which with increase in temperature increases the spin population of the symmetric state; and (c) configuration interaction between the ground and excited states $^2\psi_a$ and $^2\psi_s$; mechanisms (a) and (b) should make a positive contribution to the HFI constant. Thus mechanism (c) apparently determines the sign of the HFI constant.

For a quantitative estimate of all these contributions, it is necessary to examine the results of the calculation of the spin density at all the carbon atoms in the $^2\psi_a$ and $^2\psi_s$ states[24]. These results [with allowance for the configurational interaction according to mechanism (c) and the inductive influence of the CH_3 groups] are given in scheme (b). If it is assumed that the splitting for the CH_3 in the p-xylene anion is proportional to ρ_1 (or ρ_4) with proportionality constant +25 Oe, the magnitude of this splitting should amount to −1.50 Oe. Experiment gives only −0.1 Oe, that is, the sum of the positive contributions of mechanisms (a) and (b) compensates almost completely

the contribution of mechanism (c). Thus the splitting for CH_3 is almost independent of temperature, if it is assumed that the contribution of mechanism (b) is very small and that the chief part is played by the competing mechanisms (a) and (c).

In the mono-substituted radical-anions of toluene, ethylbenzene, and cumene, the spin density on the α-protons is positive and depends markedly on temperature; this is indicated both by the NMR spectra of the anions and by EPR studies of these anions[22]. Here, the main contribution to the splitting is apparently made by mechanism (b); from the temperature dependence of the splitting at CH_3 in the toluene anion it was found that the energy gap between the $^2\psi_a$ and $^2\psi_s$ states amounts to 2.8 kcal mole^{-1}.[19]

Although the NMR method makes it possible to measure the absolute values of the HFI constants (at fairly small values of ~ 0.1–0.01 Oe), and also in a number of instances to improve the assignment of these constants made from EPR studies of the radicals, its chief role is nevertheless the determination of the signs of the HFI constants. It is for this reason that the NMR method has played an exceptional role in the development of the theory of isotropic HFI and has made an important contribution to ideas regarding the mechanisms of the delocalisation of the unpaired electron in radicals.

II. NMR AND THE SOLVATION OF RADICALS

In the condensed phase, radicals very often form complexes of the donor–acceptor type with molecules of the surrounding medium. This complex formation alters considerably the reactivity of the radicals[25], so that the study of the nature of the electronic interactions in the complex of the radical with the solvent molecules (for the sake of brevity these will subsequently be described arbitrarily as ligands) is of considerable interest. If the molecular orbital of the unpaired electron in the complex also includes the orbitals of the ligand, that is, if the unpaired electron is delocalised over the ligand, an isotropic HFI, whose magnitude and sign are determined by the mechanism of delocalisation of the electron, appears at the magnetic nuclei of the ligand. This HFI of the solvent nuclei can be detected by the NMR method, from the paramagnetic shifts or from the anomalies in the ratios of the nuclear relaxation times T_1/T_2 (single-frequency methods) or from the magnitude and sign of the dynamic polarisation of the nuclei (two-frequency methods). We shall examine briefly all these methods, and we shall analyse the "chemical" information obtained up to the present by these methods.

1. Paramagnetic Shifts of Solvent Nuclei in the Presence of Radicals

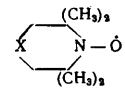
The solvation of paramagnetic species, in particular organic radicals, may be accompanied by delocalisation of the unpaired electron over the molecules of the solvent and the appearance of an isotropic HFI at the nuclei of the solvent. As with radicals, this HFI leads to a paramagnetic shift of the solvent nuclei, whose magnitude and sign are determined by the HFI constants. The only difference from the situation for radicals is in the mechanism of the averaging of the HFI aIS: in radicals, averaging of the spin fraction of the HFI takes place as a result of exchange interaction, but the condition for the observation of paramagnetic shifts of solvents is the modulation of a with a frequency τ_e^{-1} such that $a^2\tau_e^2 \ll 1$; the mechanism of the modulation of a is usually associated with the formation and decomposition of complexes of the radical with solvent molecules. The expression for the paramagnetic shift has the form (its derivation is given in section III):

$$\Delta H = -af(\gamma_e/\gamma_n)(\gamma_e H_0/4kT);$$

$f = nN/N_0$ is the mole fraction of the solvent molecules in the complex with the radicals, N the number of molecules of the radical species, N_0 the number of solvent molecules per unit volume, and n the coordination number of the solvate.

These complexes are essentially ideal models for studying the mechanism of delocalisation of the unpaired electron. Unfortunately, very little work has yet been done on the paramagnetic shifts of solvents in the presence of organic radicals.

Richards and coworkers[26] observed the paramagnetic shift of the fluorine nuclei of C_6F_6 in the presence of tris-t-butylphenoxyl; a_F is positive and amounts to ~ 4 Oe. The paramagnetic shifts of the protons of a series of solvents have been studied in the presence of nitroxide radicals



with **X** = CH_2, CO, or CHOH [27] (Table 6).

Table 6.

Solvent molecule	HFI constant for the protons, Oe			
	OH	α-CH	β-CH	other protons
H_2O	−0.56			
HOD	−0.56			
$\bar{O}H$	−1.27			
CH_3OH	−0.485	+0.066

$HCCl_3$				−0.396
H_2CCl_2				−0.088
$(CH_3CH_2)_2NH$		+0.033	+0.018	−0.051
		+0.04		−0.3

The HFI appears at the protons in the molecules of those solvents which take part in donor–acceptor interactions (of the hydrogen bonding type) with the radical (Table 6). Analysis of the HFI shows a number of characteristic features of the delocalisation of the unpaired electron in the solvate complex. Firstly, at the protons forming a hydrogen bond with the paramagnetic centre of the radical, the spin density is always negative. Secondly, at the α- and β-protons the HFI constant is positive and its magnitude decreases along the aliphatic chain. Comparison of the HFI constants for the α- and β-protons in a series of alcohols shows that at the α- and β-carbon atoms the unpaired electron is situated in angular orbitals (apparently quasi-π-orbitals) and it appears in such orbitals by a hyperconjugation mechanism. This mechanism

assumes the presence of positive π-electron spin density on the atomic orbitals of the oxygen or nitrogen in alcohols or amines; this possibly results from direct overlap of the π-orbitals of the radical and the atomic orbitals of the O and N atoms in the complex. The negative spin density on the protons taking part in hydrogen bonding then arises by a spin polarisation mechanism (as in the $\gg$CH fragment). An interesting feature is that in $\overline{\text{O}}$H, where direct overlap of the orbital of the unpaired electron with the orbitals of the O atom should be greater than in other instances, the HFI constant at the H atom is also much greater. At the protons of the amino-group, on the other hand, this constant is very small; here the negative spin density, produced by the spin polarisation mechanism, apparently compensates to a considerable extent the contribution of the positive density from the unpaired electron in the NH orbitals, partly hybridised with the electron pair of the nitrogen†.

2. Single-frequency Relaxation Methods for Studying the Solvation of Radicals

The kinetics of the change in nuclear magnetisation in NMR are usually defined by two kinetic constants: the spin-lattice or longitudinal relaxation time T_1, characterising the rate of the approach of the z component of the nuclear magnetisation to the equilibrium corresponding to the Boltzmann population of the nuclear Zeeman levels, and the transverse relaxation time T_2, determining the rate of the approach of the total x and y components of the magnetisation to zero, that is, the approach to dephasing of the nuclei (z is the direction of the external magnetic field). Physically, longitudinal relaxation corresponds to inversion of the nuclear spins (exchange of energy takes place between the spin system and the lattice). The transverse relaxation is related both to the longitudinal relaxation and to the presence of local magnetic fields which alter the frequency of precession of each spin and lead to dephasing of the nuclei; complete dephasing corresponds to zero values of the x and y components of the magnetisation of the complete spin system.

A physical model of nuclear relaxation in a liquid was proposed by Bloembergen and coworkers[28] as early as 1948. It was based on the fact that the disordered molecular motion of the species in a liquid leads to fluctuations of the local fields produced by the dipole–dipole interaction of the nuclei. A contribution to T_1 is made only by the x and y components of the fluctuating field, whereas contributions to T_2 are made not only by these fluctuations but also by the z components of the local field. The usual method for calculating T_1 and T_2 involves the determination of spectroscopic densities, that is, the Fourier transforms of the correlation functions describing the dipole–dipole interaction modulated by the molecular Brownian motion. T_1 contains the spectroscopic densities $J(\omega)$ and $J(2\omega)$, where ω is the Larmor precession frequency of the nuclei, and T_2 also contains $J(0)$, corresponding to the dephasing of the nuclei in the local fields created by the fluctuating z component.

Nuclear relaxation in the presence of paramagnetic species is described in principle in the same way. The dipole–dipole electron–nuclear interaction operator has the form

$$H' = \gamma_e\gamma_n \frac{ISr^2 - 3(Ir)(Sr)}{r^5}.$$

In polar coordinates, this can be represented in the more explicit form

$$H' = \gamma_e\gamma_n(A+B+C+D+E+F),$$

where γ_e and γ_n are the gyromagnetic ratios of the electron and the nucleus, I and S the spin operators of the nucleus and the electron, r the distance between the electron and the nucleus, and the operators A–F have the forms:

$$A = r^{-3}(1-3\cos^2\theta)I_zS_z,$$
$$B = -\frac{1}{4}r^{-3}(1-3\cos^2\theta)(I_+S_- + S_+I_-),$$
$$C = -\frac{3}{2}r^{-3}\sin\theta\cos\theta\, e^{-i\varphi}(I_zS_+ + I_+S_z),$$
$$D = -\frac{3}{2}r^{-3}\sin\theta\cos\theta e^{i\varphi}(I_zS_- + I_-S_z),$$
$$E = -\frac{3}{4}r^{-3}\sin^2\theta e^{-2i\varphi}I_+S_+,$$
$$F = -\frac{3}{4}r^{-3}\sin^2\theta e^{2i\varphi}I_-S_-,$$

where $I_\pm = I_x \pm iI_y$, $S_\pm = S \pm S_x \pm iS_y$, and the spatial parts of the operators are the spherical functions Y_2^0, $Y_2^{\pm1}$, and $Y_2^{\pm2}$. T_1 contains the spectroscopic densities $J(\omega_I - \omega_S)$, $J(\omega_I)$, and $J(\omega_I + \omega_S)$, corresponding to the correlation functions of the operators B, C, and D, and E and F, and T_2 also contains $J(0)$ and $J(\omega_S)$, corresponding to the operators A, C, and D.

Since in liquids with low viscosity the correlation time of the molecular motions τ_C is small (10^{-11}–10^{-12} s), we have $\omega_I^2\tau_C^2 \ll 1$ and $\omega_S^2\tau_C^2 \ll 1$, when all the spectroscopic densities become independent of ω and equal to $J(0)$ and $T_1 \simeq T_2$ (these become equal to the extent to which the inequality $\omega_S^2\tau_C^2 < 1$ is satisfied). This is the case of strong narrowing, when relaxation of the transverse components of the magnetisation takes place only by spin-lattice relaxation. Relaxation in the presence of most paramagnetic ions obeys this theory; equality of T_1 and T_2 is effectively observed.

An anomaly in the ratio T_1/T_2 was first observed for the protons of water in solutions of Mn^{2+} and Gd^{3+} salts, where it was found that $T_1/T_2 > 1$; this phenomenon was subsequently observed in aqueous solutions of a number of other ions.

Bloembergen[29] attributed this anomaly in the ratio T_1/T_2 to the presence of isotropic HFI of the solvent nuclei with the unpaired electron of the paramagnetic species. This interaction may take place in the complex formed by the paramagnetic species with the solvent molecules as a consequence of the finite density of the unpaired electron at the nuclei of the solvent.

The isotropic interaction aIS can be represented by the operator $H'' = aI_zS_z + \frac{1}{2}a(I_+S_- + I_-S_+)$, where the first term, whose spin part corresponds to the spin part of the operator A of the dipole interaction, makes a contribution to $J(0)$ (secular part), and the second term, with spin part similar to the operator B, makes a contribution to $J(\omega_I - \omega_S)$.

For the contribution of the interaction H'' to the relaxation to be significant, it is necessary to have mechanisms leading to time modulation of H''. Two main mechanisms of such modulation can be pictured. Firstly, change in the constant a with correlation time τ_e, which has the significance of the lifetime of the complex formed by the

† The structure of the complexes and the mechanisms of the delocalisation of the unpaired electron in complexes with hydrogen bonding and in π-complexes have been discussed in more detail elsewhere [59].

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

solvent molecule with the paramagnetic species; it is assumed that a depends markedly on distance; it is equal to a during the existence of the complex and is equal to zero when the complex decomposes. The relaxation due to this mechanism is called first-order scalar relaxation. Secondly, aIS may be modulated by the longitudinal relaxation of the spin of the electron; the correlation time of the interaction aIS then becomes the electronic relaxation time T_{1e}; this is second-order scalar relaxation. In solutions of organic radicals, T_{1e} is usually large, and the main contribution to the relaxation is made by the modulation of a.[30]

Rigorous examination of both contributions—dipole and isotropic—to the relaxation according to the scheme outlined briefly above gives the following expressions for T_1^{-1} and T_2^{-1} for $\omega_I^2\tau_C^2 \ll 1$:

$$\frac{1}{T_1} = \frac{\gamma_I^2\gamma_S^2\hbar^2 Nn}{10r_0^6 N_0}\left(3\tau_c + \frac{7\tau_c}{1+\omega_S^2\tau_c^2}\right) + \frac{1}{2}\left(\frac{A}{\hbar}\right)^2 \frac{Nn}{N_0}\left(\frac{\tau_e}{1+\omega_S^2\tau_e^2}\right), \quad (6)$$

$$\frac{1}{T_2} = \frac{\gamma_I^2\gamma_S^2\hbar^2 Nn}{20r_0^6 N_0}\left(7\tau_c + \frac{13\tau_c}{1+\omega_S^2\tau_c^2}\right) + \frac{1}{4}\left(\frac{A}{\hbar}\right)^2 \frac{Nn}{N_0}\left(\tau_e + \frac{\tau_e}{1+\omega_S^2\tau_e^2}\right), \quad (7)$$

where τ_C and τ_e are the correlation times of the dipole interaction and the isotropic HFI, N and N_0 the numbers of radical species and solvent molecules in 1 cm³, and n the coordination number of the complex. The first terms in (6) and (7) evidently correspond to the dipole contribution to the relaxation, and the second terms to the contribution of the isotropic HFI. It can also readily be seen that the ratio $T_1/T_2 > 1$ only when the correlation time τ_e is sufficiently large; with this condition, a contribution to T_2 is made by the spectroscopic density $J(0)$ produced by the secular part of the isotropic HFI. In the limit, for $\omega_S^2\tau_e^2 \gg 1$, the second term in T_1^{-1} is equal to zero, and the contribution of this term to T_2^{-1} is $\frac{1}{4}(a/\hbar)^2\frac{Nn}{N_0}\tau_e$.

It is evident that the anomaly in T_1/T_2 is greater, the greater a and τ_e (but τ_e should not be greater than a^{-1}). At small values of τ_e (weak complexes) or in weak fields (ω_S small), we may have $\omega_S^2\tau_e^2 \ll 1$, so that again $T_1/T_2 = 1$; physically, this means that although scalar interaction aIS takes place in the complex, the contribution of the secular terms $J(0)$ in T_2 becomes negligible.

The method involving determination of the ratio T_1/T_2 has found extensive application for the study of the complexes formed by paramagnetic ions with ligands; little work has been done on radicals.

The first paper was published in 1963. Gutowsky and Tai[31] determined T_1 and T_2 for protons in various solvents —chloroform, dioxan, benzene, acetonitrile, water, dichloroethane, tetramethylsilane, and cyclohexane—in the presence of DPPH and the di-t-butylnitroxide radical. T_1^{-1} and T_2^{-1} were linearly dependent on the concentration of radicals, but the ratio T_1/T_2 was found to be constant for all concentrations and equal to 1.1–1.2, that is, its value was very close to unity. For the fluorine nuclei in hexafluorobenzene and 1,3,5-trifluorobenzene, however, T_1/T_2 differed significantly from unity and amounted to 1.40–1.70. These results show that in the complexes formed by fluorine-containing molecules with radicals, the unpaired electron is delocalised over the atomic orbitals of the ligand, the constants of the isotropic HFI at the fluorine nuclei being sufficiently large (10^6–10^7 s^{-1}) to make a secular contribution to T_2. The fact that for the protons $T_1/T_2 \simeq 1$ shows that a_H may be much less than a_F. This makes it very difficult to decide whether the complex has a structure of the π-complex type, or whether there is localised interaction in the complex between the radical and the fluorine atom of the molecule.

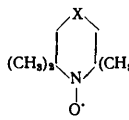
Sagdeev and Molin[32] determined T_1 and T_2 for the protons of biphenyl, naphthalene, nitrobenzene, and nitromethane in the presence of DPPH. They found that the values of T_1/T_2 differ considerably from unity and established a relationship between this deviation and the ionisation potentials of the ligand molecules. Table 7, taken from the work cited[32], illustrates this relationship. The existence of this relationship indicates that there is donor–acceptor interaction in the complexes.

Table 7. Ionisation potentials and HFI constants for protons in the presence of DPPH.

Solvent	T_1/T_2	I, eV	a, s^{-1}	References
Chloroform	1.12	11.42		31
Acetonitrile	1.13	11.96		31
Dichloroethane	1.13	11.1		31
Dioxan	1.15	9.52		31
Benzene	1.16	9.24		31
1,3,5-Trifluorobenzene	1.18	9.15		31
Biphenyl (in CCl_4)	1.42	8.3	$>1.5\cdot10^5$	32
Naphthalene (in CCl_4)	2.15	8.1	$>3.3\cdot10^5$	32
Nitrobenzene	2.3	—	$1.1\cdot10^6$	32
Nitromethane	2.6	—	$3.5\cdot10^6$	32

Paramagnetic shifts were also observed in the last four solvents. The proton lines are displaced to strong fields, that is, there is negative spin density at the protons of the ligands in the complex with DPPH; this is apparently due to a mechanism involving σ–π configurational interaction of the electrons of the C–H bond with the positive spin density of the π-system of the ligand. For CH_3NO_2, the authors cited[32] propose localised interaction of the NO_2 group with the radical, the O–N–O group being similar to the allyl group: the π-electron spin density is positive at the oxygen atoms, and negative at the nitrogen atom; on the CH_3 group the spin density appears as a result of hyperconjugation with the unpaired electron of nitrogen and has the same sign. The HFI constants determined from the magnitudes of the paramagnetic shifts using Eqn. (5) are given in Table 7.

A number of studies have been carried out in solutions of stable nitroxide radicals of the type



The formation of complexes by radicals of this type with the molecules of water, alcohols, and acetic acid was observed by the EPR method[33]; it was shown that a hydrogen bond is formed between the radical and the solvent molecules with the participation of the unpaired electron. The energy of this bond amounts to 2–4 kcal mole^{-1} and the coordination number of the complex is $n = 1$.

The relaxation times of the protons of water in the presence of the nitroxide radical with X = CO have been measured[34]. The ratios T_1/T_2 for various concentrations of the radical are given in Table 8.

At low concentrations of the radicals, T_1/T_2 is much greater than unity, that is, the unpaired electron has a

finite density at the protons of the water molecules taking part in hydrogen bonding with the radicals.

Using the value $a = -0.56$ Oe obtained from the paramagnetic shifts (see p. 804) and $T_1/T_2 = 1.5$, we readily obtain the correlation time $\tau_e = 3 \times 10^{-10}$ s.

Table 8.

Concentration of radical, M	T_1/T_2	Concentration of radical, M	T_1/T_2
$5 \cdot 10^{-3}$	1.7	$5 \cdot 10^{-3}$	1.5
$7.5 \cdot 10^{-3}$	1.5	$7.5 \cdot 10^{-2}$	1.2
10^{-2}	1.6	10^{-1}	1.1
$2.5 \cdot 10^{-2}$	1.5	1.0	1.0

An interesting feature is that at high concentrations of the radical, when the frequency of electron exchange becomes equal to $\sim 10^{10}$ s^{-1}, the ratio T_1/T_2 gradually decreases and reaches unity at a concentration of 1 M. This behaviour of T_1/T_2 can be attributed to the fact that at high frequencies of exchange ω_{ex}, τ_{ex} becomes the correlation time of the isotropic HFI, and if $\tau_{ex} < \tau_e$, $\omega_S^2\tau_{ex}^2$ decreases with increase in concentration; as a result, there is a decrease in the contribution of the secular terms in T_2. This fact provides further proof of the manifestation of HFI at the protons of water in the complex with the radical; it also confirms that τ_e at concentrations in the region of 0.5 M (when the concentration dependence of T_2^{-1} begins to deviate from linearity) is comparable with τ_{ex}, that is, $\tau_e \simeq 10^{-10}$ s^{-1}; this shows good agreement with the value of τ_e calculated above from the values of the paramagnetic shift and the ratio T_1/T_2.

In the presence of the nitroxide radical with X = CH_2 (1 M) the ratio T_1/T_2 for the hydroxyl proton of methanol amounts to 1.23;[35] here, we should apparently observe the same picture as in aqueous solutions of the radicals.

A very interesting paper on the solvation of paramagnetic oxygen molecules in water and alcohols was recently published[36]. Only the dependence of T_1 for the protons in the pure solvents and in solutions saturated with oxygen on the field intensity (or ω_S) was measured. In pure water, T_1 was independent of ω_S; this means that $\omega_S^2\tau_C^2 \ll 1$, that is, the condition for strong narrowing is satisfied. In the presence of dissolved oxygen, T_1 depended on ω_S; this means that in the expression for T_1^{-1} there appears a second term which takes account of the contribution of the isotropic HFI, with correlation time $\tau_e < \tau_C$ and with $\omega_S^2\tau_S^2$ comparable with unity. It can readily be shown that for this example Eqn. (6) can be reduced to the form

$$T_1^{-1} = \alpha\tau_c + B\frac{\tau_e}{1+\omega_S^2\tau_e^2},$$

where α and B are constants, and τ_e and $\alpha\tau_C$ can readily be found by combining the expressions for T^{-1} with different ω_S values. For the complexes formed by oxygen with water molecules, the bond energy, determined from the temperature dependence of τ_e, was found to be 2.5 kcal mole^{-1}; τ_e is of the order of 10^{-11} s. In methanol, the dependence of T_1 on ω_S is very weak, that is, either the complexes formed by oxygen with the alcohol are weak (τ_e is small) or the constant a in the complex is small.

Thus the results of this work provide an elegant and convincing proof of the existence of complexes of oxygen with water molecules, in which there is delocalisation of the unpaired electrons of the oxygen over the atomic orbitals of the ligand.

The work examined above on the study of solvation using the ratio T_1/T_2 essentially exhausts the range of work carried out by this method in solutions of organic radicals. A disadvantage of this method is that it gives no information on the sign of the HFI constant in the complex; its advantage over methods which use measurement of paramagnetic shifts lies in the possibility of determining the kinetic characteristics of the complex—the correlation time τ_e and its temperature coefficient. Thus the two methods effectively supplement one another and give extensive information on the mechanism of the delocalisation of the unpaired electron in a complex; this is illustrated by the work examined above.

3. Dynamic Polarisation of Nuclei (Two-frequency Methods)

If we have two interacting spin systems—for example, electronic and nuclear—a change in the state of one spin system (at one resonance frequency) produces a change in the state of the other spin system; this change is detected at another resonance frequency. This is the essential feature of two-frequency methods of studying nuclear-nuclear and electronic-nuclear interactions. If we have a dipole interaction in an electron–nucleus system placed in a magnetic field, the component operators may bring about different transitions with a simultaneous change in the orientation of the electronic and nuclear spins, that is, with a change in the characteristic values of the z components of the spin of the electron M and the nucleus m. It can readily be seen from the form of the operator B that it brings about transitions $\Delta M = -\Delta m = \pm 1$ (flip-flop transitions), when there is simultaneous inversion of the electronic and nuclear spins in opposite directions. The operators C and D bring about transitions with $\Delta(M + m) = \pm 1$ (ordinary transitions of the electron or nucleus between their Zeeman levels), and the operators E and F induce transitions $\Delta M = \Delta m = \pm 1$ (flip-flip transitions) with simultaneous inversion of the spins of the electron and the nucleus in the same direction[37].

The Zeeman levels for the particular case of an electron and a proton and the populations of these levels are illustrated in Fig. 3 (it must be noted that for the electron $\gamma_e < 0$ and for the proton $\gamma_n > 0$); we have $N_-/N_+ = \exp(\hbar\gamma_e H/kT)$ and $n_+/n_- = \exp(\hbar\gamma_n H/kT)$.

With saturation of the electronic transitions there is an increase in the number of electron relaxation acts $+1/2 \rightarrow -1/2$; if only flip-flop transitions take place, the nuclear spins undergo inversion in the opposite direction $-1/2 \rightarrow +1/2$, that is, the population of the lower Zeeman level of the nuclear spin system increases sharply, with a corresponding increase in the NMR signal. For complete saturation of the electronic transitions $N_+ = N_-$ and $n_+/n_- = \exp(\hbar\gamma_e H/kT)$, that is, the populations of the nuclear states obey the Boltzmann relationship, but with the Boltzmann factor $\exp(\hbar\gamma_e H/kT)$ instead of $\exp(\hbar\gamma_n H/kT)$, which is observed for statistical equilibrium in the absence of EPR saturation. This means that for complete EPR saturation the effective gyromagnetic ratio of the nucleus γ_n is equal to the gyromagnetic ratio of the electron γ_e. This phenomenon of positive dynamic polarisation of nuclei for EPR saturation is known as the Overhauser effect. It is used in physics as a method of obtaining polarised

nuclei; in chemistry the Overhauser effect is important as a method of studying the nature and mechanism of electron–nuclear interactions in radicals and their complexes with ligands.

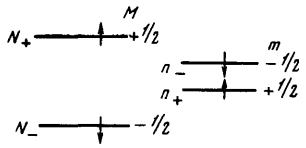


Figure 3. Scheme illustrating the Zeeman levels of the electron and the proton.

If only flip-flip transitions take place, the sign of the nuclear polarisation becomes negative. EPR saturation is then accompanied by an increase in the population of the upper Zeeman level of the nuclear spin system; relaxation of the nuclear spin is accompanied by the emission of the nuclear Zeeman frequency. This negative dynamic polarisation of nuclei is used in the production of microwave generators and amplifiers, or masers.

If we take account of all the transitions and solve the kinetic equations for the populations of the nuclear and electronic Zeeman levels, we obtain an equation relating the nuclear magnetisation $\langle I_z \rangle$ and the electronic magnetisation $\langle S_z \rangle$

$$\frac{\langle dI_z \rangle}{dt} = -\frac{1}{T_1^{II}}(\langle I_z \rangle - I_0) - \frac{1}{T_1^{IS}}(\langle S_z \rangle - S_0)$$

where I_0 and S_0 are the equilibrium values of $\langle I_z \rangle$ and $\langle S_z \rangle$ (in the absence of saturation); the constants T_1^{II} and T_1^{IS} are determined by the spectroscopic densities $J(\omega_I - \omega_S)$, $J(\omega_I)$, $J(\omega_I + \omega_S)$, and $J(\omega_I - \omega_S)$, $J(\omega_I + \omega_S)$ respectively. It can be seen from the equation that the polarisations of the spins I and S are related in such a way that a radiofrequency field with, for example, frequency ω_S, acting on $\langle S_z \rangle$, will also alter $\langle I_z \rangle$. Under steady-state conditions, $d\langle I_z \rangle / dt = 0$ and $\langle I_z \rangle - I_0 = \rho(\langle S_z \rangle - S_0)$, where $\rho = T_1^{IS}/T_1^{II}$.[30] The constant ρ is expressed in terms of the probabilities p, q, and r of the transitions produced by the operators B, C, D, E, and F respectively:

$$\rho = \frac{r - p}{r + 2q + p}.$$

The probabilities p, q, and r are calculated in the usual way via the correlation functions and spectroscopic densities. With the condition of strong narrowing, which is almost always satisfied in liquids, $p : q : r = 2 : 2 : 12$, so that $\rho = -1/2$, that is, for dipole–dipole interaction of the nuclei of the solvent with the unpaired electrons of the paramagnetic species we have negative dynamic polarisation of the nuclei.

The isotropic HFI operator produces only flip–flop transitions and if a contribution to the relaxation is made only by the isotropic HFI, we have $q = r = 0$ and $\rho = -1$, that is, in this instance there is positive polarisation, whose absolute magnitude is twice that of the negative polarisation corresponding to dipole–dipole interaction.

If both interactions make a contribution to the relaxation, ρ is a complex function of these contributions. Complete calculation of the spectroscopic densities for these interactions for $\omega_S^2 \tau_C^2 \ll 1$ leads to the following expression for ρ:[30]

$$\rho = \frac{1 - \tau_e/\sigma\tau_c\,(1 + \omega_s^2\tau_e^2)}{2 + \tau_e/\sigma\tau_c\,(1 + \omega_s^2\tau_e^2)}, \qquad (8)$$

where $\sigma = \hbar^2\gamma_n^2\gamma_e^2/r^6a^2$. It is clear that the magnitude and sign of the constant ρ contains all the "chemical" information regarding the nature of the interaction of the radical with the solvent molecules; it is usually determined experimentally from the dependence of the degree of polarisation on the level of EPR saturation (details can be found in a paper by Richards and White[38]). The magnitude and sign of ρ depend on many parameters—the magnetic field intensity, the isotropic HFI constant, viscosity, and temperature (via τ_C and τ_e).

Positive nuclear polarisation for protons was previously observed only in solutions of the alkali metals in ammonia ($\rho = -1$), in which the strongly solvated electron gives high values of a on the protons[39]. Recently, positive polarisation was observed on the protons of the t-butyl groups in tris-t-butylphenol in the presence of its radical tris-t-butylphenoxyl[40]. In the opinion of the authors cited[40], this is related to the fact that positive polarisation of these protons takes place in the radical, in which, as already noted (section I) there is considerable isotropic HFI at these protons. As a result of the exchange reaction of the radical with the phenol (see below), this polarisation appears in the phenol, and if the characteristic time of the reaction is less than the relaxation time of the protons in the molecule, this polarisation is preserved in the phenol and is detected.

An interesting feature is that in contrast to the situation for the protons of the t-butyl groups, the polarisation of the *meta*-protons in the same radical is negative, although the HFI on these protons is large ($a_H = 1.7$ Oe). This means that the contribution of the scalar relaxation is small, since there is no effective mechanism for the modulation of a (the corresponding spectroscopic densities are small).

This fact is of considerable interest in connection with the problem of the mechanism of delocalisation of the unpaired electron in the orbitals of the CH_3 groups in tris-t-butylphenoxyl. Since a necessary condition for positive polarisation is modulation of the HFI constant, and a mechanism for this modulation may be provided by internal rotation in the t-butyl groups, this means that the unpaired electron is delocalised in the t-butyl groups over the angular orbitals, that is, by a hyperconjugation mechanism. These considerations are also confirmed by data on the dynamic polarisation of ^{13}C nuclei (natural concentration) in the t-butyl groups of this radical—the sign of the polarisation is positive[41]‡.

In the presence of organic radicals it has been possible to observe the contribution of the isotropic HFI only in the polarisation of the fluorine nuclei in fluorine-containing solvents. Thus in solutions of DPPH in 1,3,5-trifluorobenzene[42], $\rho = 0.37$ (at the fluorine nuclei), that is, $-1 < \rho < 1/2$, indicating a contribution by the isotropic HFI to the polarisation of the fluorine nuclei.

‡ In principle, polarisation may be induced by the same mechanism by chemical reactions taking place with the formation of radicals. This was recently confirmed experimentally[60,61]. This is an extremely promising development from the viewpoint of kinetics and mechanism, and also in connection with the possibility of creating a "chemical" maser.

In fluorobenzene in the presence of DPPH, ρ has a value equal to approximately zero at 20°C, that is, the contributions of the dipole–dipole and isotropic interactions to the dynamic polarisation of fluorine are almost identical; with increase in temperature, however, the contribution of the isotropic interaction decreases, that is ρ increases[42]. This means that the temperature dependence of the correlation time τ_e is more marked than that for τ_c.

Eqn. (8) can be written

$$\rho = \frac{1-\alpha}{2+\alpha},$$

where

$$\alpha = \frac{\tau_e}{\sigma\tau_c}(1+\omega_s^2\tau_e^2)^{-1}$$

and

$$\ln\alpha = \ln\frac{\tau_e^0}{\sigma\tau_c^0} + \frac{e_e - e_c}{RT} - \ln(1+\omega_s^2\tau_e^2).$$

This equation was used by the authors cited[42] to calculate ϵ_e from the dependence of α on $1/T$; it shows satisfactory agreement with experiment. Using the value of ϵ_c found by Gutowsky and Tai[31] (ϵ_c = 2.5 kcal mole^{-1}), the authors cited[42] found that the energy of the bond in the complex formed by DPPH with fluorobenzene amounts to 3.3 kcal mole^{-1}.

Richards and coworkers[26,43] observed positive nuclear polarisation of fluorine in a number of fluorine-containing solvents—C_6F_6, *p*-difluorobenzene, CF_3–CCl_3, $CFCl_2$–CF_2Cl, fluorine-containing alcohols, perfluoroacetone, and hexafluoroethane—in the presence of DPPH, tris-t-butylphenoxyl, and semiquinone radicals. This shows that in the complexes formed by the fluorine-containing molecules with the radical there is strong isotropic HFI, associated with the appearance of spin density on the fluorine nuclei of the ligand.

The dynamic polarisation of ^{31}P nuclei in phosphites and phosphates in the presence of tris-t-butylphenoxyl was recently studied[44]; the sign of the polarisation is positive, that is, the radical also forms complexes with phosphorus-containing esters, in which the isotropic HFI at the phosphorus nucleus is large. The polarisation is greater in phosphites than in phosphates. The authors cited attribute this to the fact that in the phosphites the phosphorus atom has a free $3s^2$ pair, so that there is an increase in the isotropic HFI in the complex.

A large number of papers have been devoted to the dynamic polarisation of protons in the presence of organic radicals, but they are of slightly less interest from the viewpoint of "chemical" information. In most instances in these systems $\rho = 1/2$, that is, the main contribution to the polarisation is made by dipole–dipole interactions. These papers, however, contain a large amount of information on the correlation times τ_c and ϵ_c, characterising the intensity of the molecular Brownian movement in various liquids; this is of considerable interest for the kinetic theory of liquids[45,46].

Until now we have been considering those two-frequency methods in which EPR saturation at microwave frequency has led to changes in the populations of the Zeeman levels of the nuclear spin system and these changes have been detected at the NMR radiofrequency. At the present time, increasing use is being made of another version of the two-frequency method—electron–nuclear double resonance—for the study of organic radicals. The essential features are as follows. For saturation with a microwave frequency, the EPR signal decreases. If the radiofrequency is now altered slowly, it is found that at values corresponding to the resonance of a given type of nuclei, by flip–flop or flip–flip transitions, a change takes place in the populations of the electronic Zeeman levels and the EPR signal at this frequency also changes (it increases or decreases to a greater extent, depending on which transitions play the most important role). Thus in this instance detection takes place at the microwave frequency, and the NMR radiofrequency is used as a probe for the electron–nuclear interaction. This method, discovered by Feher[47], has been used successfully for a considerable time to study the structure of paramagnetic centres in crystals; only a few papers[48,49] have been devoted to the study of organic radicals in liquids. A significant advantage of double resonance is the considerable simplification of the EPR spectra and the high accuracy of the determination of the HFI constants. For example, in triphenylmethyl, which contains three kinds of magnetically non-equivalent hydrogen nuclei, the EPR spectrum consists of 196 lines of hyperfine structure, whereas the double resonance spectrum contains only six lines[49]; the double resonance spectrum of triphenylphenoxyl contains seven lines instead of 4050.[50] The most valuable feature of double resonance in radicals in single crystals, however, is that it makes it possible to determine the absolute signs of the hyperfine interaction constants. An example is provided by the determination of the signs of the HFI constants on the β-protons in the radical HOOC–$\dot{C}$H–CH_2COOH.[51]

III. NMR AND THE KINETICS OF RADICAL REACTIONS

In recent years the theory has been developed and NMR has been successfully applied, for the study of the kinetics of radical reactions, in particular electron exchange and radical substitution taking place with transfer of a hydrogen atom. The attractions of the NMR method for these purposes include not only the possibility of studying fast reactions (with rate constants of 10^8–10^9 litre mole^{-1} s^{-1}) but also, and this is most significant, the fact that this method makes it possible to study the kinetics of reactions taking place with zero heat change, that is, elementary reactions with the same initial and final states; it is extremely difficult to study the kinetics of these reactions by classical methods, although it is these reactions which are of greatest interest for the theory of reactivity. Another extremely important aspect is that it becomes possible in principle to study electronic interactions in the activated complex.

The use of the method is based on the broadening of the NMR signals from the nuclei in the molecules which are taking part in the exchange of electrons or hydrogen atoms:

$$P + D \overset{k}{\rightleftarrows} D + P \qquad (9)$$

where P is the paramagnetic species (ion or radical), and D is the diamagnetic ion or molecule. Each elementary act of this reaction leads to a change in the magnetic field acting on the resonance nuclei of the corresponding molecules, since as a result of this reaction these nuclei are found at one moment in the paramagnetic species, when they are acted on by the field of the unpaired electron, and at another moment in the diamagnetic molecule. Thus the nuclei are acted on by paramagnetic "pulses" whose intensity and frequency influence the shape and width of the NMR lines. To study the kinetics of these reactions it is possible to use the line width for any nucleus of a molecule taking part in the reaction, where there is an isotropic HFI.

In general, for reaction (9), an expression for the paramagnetic broadening of the NMR lines can be obtained either by solving Bloch's kinetic equations for the magnetisation or by means of relaxation matrices[52]

$$\Delta T_2^{-1} = \frac{f_P \tau_P a^2/4}{1 + f_D \tau_P^2 a^2/4 + 2\tau_P T_{1e}^{-1}}, \quad (10)$$

where ΔT_2^{-1} is the paramagnetic broadening; $\Delta T_2^{-1} = T_{2,PD}^{-1} - T_{2,D}^{-1}$, where $T_{2,PD}^{-1}$ and $T_{2,D}^{-1}$ are the widths of the NMR lines in the presence and absence of the paramagnetic species P; f_P and f_D the mole fractions of P and D; τ_P the lifetime of the paramagnetic species; T_{1e} the electronic longitudinal relaxation time; and a the isotropic HFI constant at the nuclei whose resonance is observed. Experimentally, it is possible to realise conditions under which Eqn. (10) is simplified. Two cases are known, described by the terms "strong pulse" and "weak pulse".

Let us examine the first—the strong pulse. For this to be realised, the following conditions are necessary.

Firstly, the lifetime of the paramagnetic species should be much shorter than the lifetime of the diamagnetic species, that is, $\tau_P \ll \tau_D$. Since $\tau_D = 1/k(P)$, and $\tau_P = 1/k(D)$, this condition requires that $(P) \ll (D)$; this is readily satisfied, and $f_D \simeq 1$.

Secondly, it is necessary that $\tau_P^2 a^2 \gg 1$. Since the frequency of precession of the nucleus in the field of the unpaired electron is equal to $a/2$, this nucleus comes out of phase with the other nuclei in the molecule D, if the paramagnetic "pulse" lasts longer than one period corresponding to the precession frequency a, that is, if $\tau_P \gg 1/a$. This means that either a or τ_P should be sufficiently large for the nuclei to come completely out of phase during the period for which the unpaired electron is in the molecule; the paramagnetic broadening on the nuclei will be the same and independent of a. For the same reason it is necessary that the electronic relaxation time or electronic exchange time $T_{1e} \gg 1/a$, that is, $T_{1e}^2 a^2 \gg 1$, so that all the nuclei are able to come out of phase before the electron alters its orientation. In this instance neither relaxation of the electron spin nor electron exchange influence the broadening. The last two conditions can be combined into one, namely, $a^2\tau^2 \gg 1$, where $1/\tau = 1/\tau_P + 1/T_e$. For the "strong pulse" case, the transverse relaxation time is determined essentially by τ_D, since $\tau_D \gg \tau_P$ and when time τ_D has elapsed (after D is converted into P) the nuclei come out of phase almost immediately. Since $a^2\tau^2 \gg 1$, the experimental criterion for realisation of the "strong pulse" case is preservation of the hyperfine structure of the EPR spectrum of the paramagnetic species.

The condition $a^2\tau^2 \gg 1$ may be satisfied, although the hyperfine structure is not observed, if $T_{1e} > T_{2e}$, where T_{1e} and T_{2e} are the longitudinal and transverse electronic relaxation times. This is due to the fact that the width of the EPR lines, determined by T_{2e}, may become greater than the splitting.

When these conditions are satisfied, Eqn. (10) becomes

$$\Delta T_2^{-1} = k(P)(D) \quad (11)$$

by means of which k can readily be found from the magnitude of the broadening and the known concentrations (P) and (D). Since the condition $\tau_P^2 a^2 \gg 1$ is most readily satisfied for large values of τ_P or small values of k, the "strong pulse" case corresponds to a slow reaction. This was first analysed by McConnell[53].

Let us now consider the second case—the "weak pulse" case—which is realised under the following conditions.

Firstly, as before, $\tau_D \gg \tau_P$. Secondly, $\tau_P^2 a^2 \ll 1$ or $\tau_P \ll 1/a$, that is, the lifetime of the paramagnetic species, during which the nuclei are exposed to the local field of the unpaired electron, is less than the period of the Larmor precession of the nucleus in this field, leading to its averaging and the production of a paramagnetic shift. A result of the reaction is modulation of the HFI constant and the consequent scalar relaxation, described above.

Here, a necessary condition is that $\tau_P \ll T_{1e}$, for if $\tau_P \gg T_{1e}$ the correlation time of the isotropic HFI becomes the electron spin relaxation time T_{1e}, which is not related to the reaction and the study of the kinetics of the reaction itself becomes meaningless.

If $T_{1e} \simeq \tau_P$, it is necessary to know T_{1e} in order to study the kinetics of the reaction. Since in time τ_P the nuclei with different values for the isotropic HFI constant a_i are able to come out of phase to different extents, the paramagnetic broadening is not the same for all nuclei and is determined by the quantity a_i^2. In this instance, $f_D\tau_P^2 a^2/4 + 2\tau_P T_{1e}^{-1} \ll 1$ and Eqn. (10) becomes

$$\Delta T_2^{-1} = \frac{1}{4}\frac{(P)}{(D)^2} a^2 k^{-1}, \quad (12)$$

from which it is possible to find k if we know a at the nuclei whose resonance is being observed. In contrast to the previous case, the broadening decreases with increase in temperature, since it is inversely proportional to the rate constant k. The condition $\tau_P^2 a^2 \ll 1$ is readily satisfied at small values of τ_P, that is, at large values of k, so that these conditions correspond to fast reaction or fast exchange; it was examined first by Bloembergen[29].

These are the conditions and chief characteristic features of the two extreme limits, which might be described respectively as the limits of deep low-frequency modulation and superficial high-frequency modulation.

The paramagnetic shift produced by reaction (9) has the form

$$\Delta H = -a f_P (\gamma_e/\gamma_n)(\gamma_e H/4kT)\left(1 + \frac{f_D\tau_P^2 a^2}{4}\right). \quad (13)$$

For $\tau_P^2 a^2 \ll 1$ ("weak pulse")

$$\Delta H = -a f_P (\gamma_e/\gamma_n)(\gamma_e H/4kT), \quad (14)$$

which coincides with the expression for the paramagnetic shift in polycrystalline radicals, where $f_P = 1$, Eqn. (5). Eqn. (14) is also used to determine the constants a from the paramagnetic shifts of a solvent in the presence of radicals forming complexes with the solvent (see section II).

The first report of the use of NMR in the kinetics of organic reactions appeared in 1956. Bruce and coworkers[54] measured the rate constant for electron transfer from tetramethyl-*p*-phenylenediamine to the corresponding Wurster's radical-cation in acetic acid at pH 3.2. In the presence of Wurster's cation, the NMR lines of the solvent (water, acetate ion) undergo very little broadening, whereas the lines of the ring and methyl protons of the reacting diamine undergo broadening equally strongly and in proportion to the concentration of the cation; this shows that the "strong pulse" case is realised, and the constant calculated from Eqn. (11) was found to be 2.5×10^4 litre mole^{-1} s^{-1}.

The kinetics of this reaction were recently studied in detail by the NMR method over a wide pH range in D_2O.[55] The original amine was taken in the form of its dihydrochloride, so that the reaction mixture contained equilibrium quantities of the dihydrochloride, the monohydrochloride, and the free base. The broadening of the lines was the same for the methyl and ring protons of the amine ("strong pulse"). The rate constants showed a marked dependence on pH, decreasing with decrease in pH; this

shows that the tendency to take part in electron transfer differs considerably for the base (the amine) and its salts (the mono- and di-hydrochlorides). If it is assumed that only the free base takes part in electron exchange with the cation-radical, it is possible to calculate the true rate constant for this bimolecular reaction; it was found that over the wide pH range 2.7–6.1, this constant does in fact remain constant and is equal to $(1.5 \pm 0.7) \times 10^8$ litre mole^{-1} s^{-1} at 20°C.

The conclusion that only the free base takes part in electron transfer is also confirmed by data obtained by Johnson[56], who studied the same reaction in acetonitrile, with all the amine in the form of the base. In contrast to the earlier work, where the "strong pulse" case was realised, the broadening of the methyl and ring protons of the amine in acetonitrile was found to be proportional to the square of the HFI constants at these protons (6.76 Oe and 1.97 Oe), and the rate constant determined from Eqn. (12) amounted to $\sim 2 \times 10^8$ litre mole^{-1} s^{-1}; this agrees with the true rate constant determined in the previous paper. Thus in acetonitrile, in which electron exchange takes place rapidly, the "weak pulse" case is realised. A similar difference in the broadening of the NMR lines of different protons was observed in diethyl-*p*-phenylenediamine in aprotonic solvents, and also in the di-cations of ethyl- and methyl-viologen in the presence of their paramagnetic mono-cations; here, the fast exchange case ("weak pulse") applies throughout[56].

An interesting example was observed in a study of the kinetics of electron transfer in *p*-xylene[21] in the presence of its anion-radicals, obtained by the reaction of *p*-xylene with potassium. Since the HFI constants *a* for the ring and methyl protons in the anion differ considerably (5.34 Oe and 0.08 Oe respectively), both cases are realised in electron exchange—"strong pulse" for the ring protons and "weak pulse" for the methyl protons. The broadening of the ring protons increases with increase in temperature, whereas the broadening of the methyl protons decreases—in accordance with Eqns. (11) and (12). For this particular case, Johnson[56] proposed a method for determining *k*, which does not require a knowledge of the concentration of paramagnetic species P. In actual fact, by combining Eqns. (11) and (12) for the broadening of the lines for different protons, one can immediately obtain *k* and the concentration of paramagnetic species (P).

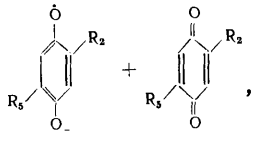
The following expression was obtained for the rate constant for electron transfer in the system formed by *p*-xylene and the *p*-xylene anion[21]:

$$k = 10^{12} \exp(-6200/RT) \text{ litre mole}^{-1} \text{ s}^{-1}.$$

These constants are much smaller than the constants obtained for the same reaction in the absence of potassium (when the anions are obtained by electrolysis). This shows that the constants given above relate to the slower exchange of *p*-xylene with an ion pair:

$$P^-K^+ + D \rightleftarrows D + P^-K^+ .$$

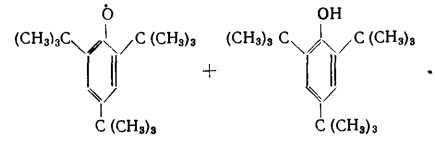
The rate constants for electron transfer in the quinone–semiquinone system



where $R_2 = -CH(CH_3)_2$ or $-OC_2H_5$, and $R_5 = H$ or OC_2H_5, were found to be close to 10^8 litre mole^{-1} s^{-1}.

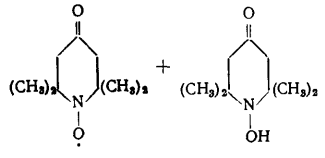
An anomalous ratio $T_1/T_2 > 100$ is observed at the α-proton in $-CH(CH_3)_2$ and at the methylene protons in $-OC_2H_5$; this anomaly may appear for the "weak pulse" case; the correlation time of the isotropic HFI—Eqn. (7)—becomes τ_P.[57]

Radical substitutions have been the subject of only one paper, by Kreilick and Weissman[58], who studied the kinetics of hydrogen atom transfer from tris-t-butylphenol to tris-t-butylphenoxyl:



The reaction was carried out in CCl_4 in the presence of $Si(CH_3)_4$ as internal standard. The NMR of a solution of the phenol in CCl_4 gives four lines: two from the protons of the non-equivalent *o*- and *p*-t-butyl groups and two from the *meta*-protons and the hydroxyl proton. With increase in the concentration of the radical, the lines for the t-butyl and *meta*-protons broaden to equal extents, in proportion to the concentration of radicals ("strong pulse"). The correction for the dipole–dipole electron–nuclear broadening was determined from the broadening of the tetramethylsilane protons; this correction was very small. The constant *k*, determined from Eqn. (11), amounted to 300 litre mole^{-1} s^{-1} at 30°C, and the activation energy for the reaction was 1.0 ± 0.5 kcal mole^{-1}.

In the paper cited, the correction for the dipole–dipole broadening was introduced wrongly (this is pointed out by the authors themselves), since the correlation time τ_C of the dipole–dipole interaction of the tetramethylsilane and phenol protons with the unpaired electron of the radical should be different. In our study of the same reaction[59], the dipole–dipole correction was determined from the broadening of the lines of tris-t-butylbenzene, for which τ_C should be very close to τ_C for tris-t-butylphenol; the constant *k* at 25°C was found to be 400 litre mole^{-1} s^{-1}, which is very close to the constant obtained by Kreilick and Weissman. Moreover, we determined the rate constant for the analogous reaction



from the broadening of the lines of the methyl protons: $k = 130$ litre mole^{-1} s^{-1} at 25°C; here the dipole–dipole correction was determined from the broadening of the lines of the methyl protons of the corresponding amine.

The behaviour of the NMR line of the hydroxyl proton is of greatest interest, since as a result of each act of the reaction, the initial and final states of this proton remain unchanged: it always remains in a diamagnetic molecule, with the exception of the activated complex. For the broadening of its NMR line we can use Eqn. (10), in which $f_P = f_{act}$—the mole fraction of the activated complexes; it can readily be shown that $f_{act} = k(P)\tau_{act}$—also τ_P becomes the lifetime of the activated complex τ_{act}, and *a* is equal to the HFI constant in this complex a_{act}. Then for $\tau_{act} T_1^{-1} \ll 1$ we have

$$\Delta T_2^{-1} = k(P) \frac{\tau_{act}^2 a_{act}^2/4}{1 + \tau_{act}^2 a_{act}^2/4} . \qquad (15)$$

In the paper by Kreilick and Weissman, this equation was used to determine τ_{act} with arbitrary assumptions regarding the magnitude of a_{act} (20 Oe). These estimates of τ_{act} ($\sim 10^{-9}$ s) are hardly meaningful; it is more appropriate to determine a_{act} by giving τ_{act} a definite reasonable value.

There are, of course, fundamental difficulties in this approach. It is necessary first of all that the rate constant k be sufficiently high (fast reactions). Moreover, the formation of the activated complex may be preceded by the formation of ordinary donor–acceptor complexes (for example, by hydrogen bonding), so that a contribution to ΔT_2^{-1} will be made not only by states close to the top of the potential barrier for the reaction but also by these donor–acceptor complexes (this situation apparently was observed in the work of Kreilick and Weissman[58]). Moreover, formula (15) does not take account of the anisotropic HFI, although this interaction itself will produce additional broadening in states lying close to the top of the barrier. All these features make it difficult at present to determine the HFI constants in an activated complex.

Methods of Thermokinetic Analysis of Chemical Reactions

V.S.Livshits

The theoretical foundations of the thermokinetic method of investigating chemical reactions are discussed. An analysis is made of the method as applied to the kinetics of adiabatic and non-adiabatic reactions, including heterogeneous catalysis. Methods of calculating kinetic parameters from experimental thermokinetic curves by different versions of the method are discussed. New ways of applying the thermokinetic method to studies of heterogeneous catalysis in flow systems are proposed. Examples are given of the use of the thermokinetic method in studies of a wide range of chemical reactions. The advantages of the thermokinetic method are briefly assessed. 50 references.

I. INTRODUCTION

Whenever possible, kinetic measurements are made under isothermal conditions: this tendency is fully justifiable, since isothermal kinetics are usually easy to treat mathematically.

However, there is a large group of reactions which cannot be made to take place isothermally because of the large thermal effects involved. These include reactions in media of low thermal conductivity and fast reactions with high initial concentrations of reactant and leading to explosion or ignition.

Most of the industrially important polymerisation and polycondensation reactions are strongly exothermic and usually proceed with appreciable self-heating. A number of variants of the thermometric method, based on measurements of temperature as a function of time, have been proposed for kinetic studies of reactions of this type.

There are also reactions (for example, the formation of condensation oligomers) which can only be taken to completion by gradually raising the temperature. These reactions can be investigated by thermokinetic methods, based on programmed heating[1].

Theoretical and experimental results relating to the thermokinetic method are scattered among journals for different fields, depending on the type of reaction being studied. Hence, there was a need for a review article and for a systematisation of existing methods.

The present article is devoted to an analysis of methods of treating experimental thermokinetic data so as to extract from the data the variation with time of the extent of reaction, the rate constants, and the activation energies. We shall review the most important publications up to 1968, and we shall briefly characterise the thermal regime and the current applications of thermokinetic methods. We shall be little concerned with the design of detectors used in the thermokinetic method, of calorimeters, and with other experimental problems, because they are exhaustively discussed in a number of monographs[2-5].

II. HOMOGENEOUS REACTIONS

1. Adiabatic Regime

The simplest relationship between ΔT and the extent of reaction is obtained with adiabatic reactors, and also with pseudo-adiabatic calorimeters provided with automatic compensation for the heat losses which occur when a temperature difference arises between the wall of the reaction vessel and the mass of reactant[6].

In these instances, as may be shown from the heat balance equation for an adiabatic reaction, the relationship between the conversion α and the temperature T at time t is of the form

$$\alpha = \frac{T - T_0}{T_{ad} - T_0} = \frac{\Delta T}{\Delta T_{ad}} \qquad (1)$$

where

$$\Delta T_{ad} = T_{ad} - T_0 = \frac{Q_p}{\bar{C}_p}$$

where Q_p is the heat of reaction, cal mole^{-1}; $\bar{C}_p$ the mean heat capacity of the reaction mixture, cal mole^{-1} deg^{-1}; and T_0 the initial temperature of the surrounding medium.

In the absence of reliable values for Q_p and $\bar{C}_p$, the experimenter can determine only the conversion α_{max}, corresponding to the maximal observed value of ΔT. Then,

$$\Delta T_{ad} = \Delta T_{max}/\alpha_{max}.$$

The steepness of the experimental plots of ΔT against t depends, as can readily be seen, not only on the rate constant at $T = T_0$ but also on the activation energy E. This follows from the kinetic equation for an adiabatic reaction[7]:

$$\frac{dT}{dt} = k_0 (T_{ad} - T)^n \exp(-E/RT) \left(\frac{x_0}{T_{ad} - T_0}\right)^{n-1}, \qquad (2)$$

or

$$\frac{dT}{dt} = k_0 \left(\frac{C_p}{Q_p}\right)^{n-1} (T_{ad} - T)^n \exp\left(-\frac{E}{RT}\right), \qquad (2a)$$

where n is the order of the reaction, k_0 the pre-exponential factor, and x_0 is the initial concentration of reactant.

An expression for the activation energy can be obtained from the logarithmic form of this equation[6,8,9]. The activation energy is then given by the slope of the linear plots of $\ln \frac{dT/dt}{(T - T_0)^n}$ against $1/T$ or $\ln \frac{dT}{dt}$ against $1/T$, which is equal to $-E/R$.

It should be noted that the integral form of Eqn. (2) cannot be expressed[10] in simple functions in the general case, even with $n = 1$.

Livshits suggested[11] that the activation energy of non-isothermal (including adiabatic) reactions could be determined from the position of the point of inflection of experimental plots of T against t. This point, corresponding to maximal reaction rate, is reached when the "temperature" acceleration (or retardation) of the adiabatic reaction is fully compensated by the "concentration" retardation (or acceleration).

Table 1. Types of non-isothermal reaction with extreme dependence of rate upon time.

Type of reaction and $\varphi(\alpha)$	$\frac{d\varphi(\alpha)}{dt}$	Thermal effect, Q_p	Thermal regime up to point of inflection (dT/dt)
nth order reaction, $(1-\alpha)^n$ with $n > 0$*	<0	>0	>0
nth order reaction with retardation, $(1-\alpha)^n$ with n <0*	>0	<0	<0
Autocatalytic first-order reaction, $(1-\alpha)\alpha$ with $0.5 < \alpha < 1$	<0	>0	>0
Ditto, $(1-\alpha)\alpha$, with $0.5 > \alpha > 0$	>0	<0	<0
α^n; $n > 0$	>0	<0	<0
α^n; $n < 0$	<0	>0	>0
First-order reaction with retardation, $(1-\alpha)/\alpha$	<0	>0	>0

* With zero-order reactions $n = 0$, and the rate of non-isothermal reaction continuously increases ($Q_p > 0$) or decreases ($Q_p < 0$). In this case the activation energy is determined by the slope of the linear plot $\ln(dT/dt) = f(1/T)$, which is equal to $-E/R$.

To analyse this method, we note that the kinetic equation of an adiabatic reaction can be expressed in the general form;

$$\frac{d\alpha}{dt} = k_0 \varphi(\alpha) f(T). \qquad (3)$$

The quantity $d\alpha/dt$ goes through a maximum if the time changes of $\varphi(\alpha)$ and $f(T)$ are equal and opposite. It can be shown that this condition is realised in a number of instances, listed in Table 1.

Since $f(T) = \exp(-E/RT)$, and k_0 is not a function of T, E can be determined at the instant corresponding to the point of inflection (that is, $d^2\alpha/dt^2 = 0$) if the form of $\varphi(\alpha)$ is known.

Hence, by differentiating Eqn. (3) and equating the second differential to zero, a direct relationship is obtained between the activation energy and the temperature T_i of the reaction mixture at the point of inflection of the thermokinetic curve. Expressions for the activation energy of reactions obeying different kinetic laws are given in Table 2.

2. Non-adiabatic Non-isothermal Reactions

The heat balance equation for a non-isothermal reaction is of the form

$$m_0 Q_p \frac{d\alpha}{dt} - H\frac{dT}{dt} - \beta(T - T_0) = 0 \qquad (4)$$

where H is the effective heat capacity of the system, cal deg^{-1}; β the heat transmission coefficient, cal deg^{-1} s^{-1}; and m_0 the number of moles of reactant.

Table 2. Activation energy of various adiabatic reactions.

Kinetic law	Expression for the activation energy	Kinetic law	Expression for the activation energy
$(1-\alpha)^n$ $n \neq 0$	$E = \frac{nRT_i^2}{\Delta T_{ad} - \Delta T_i}$	α^n; $n \neq 0$	$E = -\frac{nRT_i^2}{\Delta T_i}$
$(1-\alpha)\alpha$	$E = \frac{RT_i^2(2\Delta T_i - \Delta T_{ad})}{\Delta T_i (\Delta T_{ad} - \Delta T_i)}$	$(1-\alpha)/\alpha$	$E = \frac{RT_i^2 \Delta T_{ad}}{\Delta T_i (\Delta T_{ad} - \Delta T_i)}$

Integration of Eqn. (4) for the initial conditions $\alpha = 0$, $t = 0$, and $T = T_0$ gives

$$m_0 Q_p \alpha = \int_0^T \beta(T - T_0)\,dt + H(T - T_0). \qquad (5)$$

For the condition[12,13] $T_0 = \text{const}$ the T–t curve can be transformed into an α–t curve by graphical integration once H and β have been evaluated. For relatively small values of ΔT it can be assumed that β and H are constant.

In the more general case we can assume

$$\beta = \beta_0 T_0^l; \quad H = H_0 + a(T - T_0),$$

where β_0, H_0, l, and a are constant.

Using Newton's law of cooling it can be shown[12] that the extent of conversion at time t is given by

$$\alpha = \frac{\int_t^\infty (T - T_0)\,dt + \int_0^t (T - T_0)\,dt}{\int_0^\infty (T - T_0)\,dt}. \qquad (6)$$

The integral $\int_t^\infty (T - T_0)dt$ is evaluated from the cooling curve by measuring the area under the curve between T and T_0. The second integral is equal to the area under the thermokinetic curve between 0 and t, and the integral in the denominator is equal to the area under the whole of the experimental curve, including the cooling period, up to the temperature T_0.

Evreinov and Entelis[13] used this method[12] in a modified form, which required the determination of β and H using Eqn. (5).

The β coefficient is evaluated from the cooling of copper specimens[14] or by electrical heating to the temperature T_{lim} at which the rate of heat evolution is equal to the rate of heat loss. Hence

$$\beta = \frac{0.2390\,N}{T_{lim} - T_0},$$

where N is the power dissipation of the heater in joules.

Also, the value of H/β, equal to

$$\frac{\int_t^\infty (T - T_0)\,dt}{T - T_0}$$

is obtained from the cooling curve. It is important to note that separate determination of H and β is not necessary: the first integral in the numerator of Eqn. (6) can be replaced by $H/\beta(T - T_0)$.

This type of treatment can be used as long as $T_0 = \text{const}$. If on the other hand the reaction is carried out under programmed heating, the quantity T_0 in Eqn. (6) must be replaced by the temperature of the surroundings for which the function $(T - T_0)$ is a maximum[15].

Methods of integration of non-isothermal kinetic equations with arbitrary temperature laws are given by Emanuel' and Knorre[16].

The more complicated case when the effective activation energy varies with extent of conversion has also been considered[14,17]. In this case, the functions $T = f(\alpha)$ and $\frac{d\alpha}{dt} = \varphi(\alpha)$ are obtained from Eqn. (6) and by graphical differentiation of the experimental T–t curve. The variation of the non-isothermal rate with reciprocal temperature is then determined for a number of values of α. Hence, using the equation $\frac{d\alpha}{dt} = k_0 \exp\left[-\frac{E(\alpha)}{RT}\right]\varphi(\alpha)$, the activation energy can be evaluated for the chosen values of α.

The non-isothermal rate is related to the isothermal rate of reaction at temperature $T = T_*$ by the equation

$$\left(\frac{d\alpha}{dt}\right)_{\substack{\text{isot}\\ T=T_*}} = \left(\frac{d\alpha}{dt}\right)_T \exp\left[\left(E/R\left(\frac{1}{T} - \frac{1}{T_*}\right)\right)\right]. \qquad (7)$$

An original method of treating thermokinetic data has been described by Korolev and coworkers[18]. Since the most commonly used reaction vessels are cylindrical, these authors considered the heat balance equation for an infinite cylinder of radius r:

$$\rho C \frac{dT}{dt} = \lambda\left(\frac{d^2T}{dr^2} + \frac{1}{r}\frac{dT}{dt}\right) + q(t)\,, \qquad (8)$$

where $q(t)$ is the rate of heat evolution, ρ is the density, λ is the thermal conductivity, and C is the heat capacity.

Eqn. (8) can readily be solved by a Laplace transform. Putting

$$\bar{z} = \int_0^\infty e^{-pt} T\,dt$$

and

$$\bar{q}(p) = \int_0^\infty q(t) e^{-pt}\,dt$$

and integrating Eqn. (8) multiplied by e^{-pt} between the limits $0 < t < \infty$, we obtain

$$C p\bar{z} = \lambda\left(\frac{d^2z}{dr^2} + \frac{1}{r}\frac{dz}{dr}\right) + \bar{q}(p)\,. \qquad (9)$$

The solution which satisfies the condition of symmetry with respect to $z\frac{dz}{dt}$ at $r = 0$ is a Bessel function of the first kind, of purely imaginary argument. Carrying out the series expansion, and after some transformations, we obtain

$$q(t) = \frac{4\lambda}{r_0^2}\left(T + \frac{r_0^2}{4} t_r \frac{dT}{dt}\right) \qquad (10)$$

where t_r (the relaxation time) is of the order of several minutes, and can be determined experimentally from the cooling and heating curves of the reaction mixture.

When applied to an adiabatic process, Eqn. (8) takes the form

$$q(t) \simeq \rho C \frac{dT}{dt}\,. \qquad (11)$$

In the proposed method[18], the portions of the thermokinetic curve for which $dT/dt = \text{const}$ are analysed. Under these conditions the reaction rate w is

$$w = \frac{dT}{dt} \cdot \frac{\bar{C}_p}{Q_p}\,.$$

If the rate of heat removal is equal to the rate of heat evolution (isothermal process), Eqn. (10) takes the form

$$q(t) = \frac{4\lambda}{r_0^2} T\,. \qquad (12)$$

In the case of a non-isothermal, non-adiabatic process the quantity $\frac{\rho C}{\lambda} r_0^2$ needed for the calculation is evaluated from the cooling rate of the reaction mixture from temperature T to T_0. Thus for a cylinder,

$$T = T_0 \exp\left(-\frac{\mu_1^2 \chi t}{r_0^2}\rho C\right) \qquad (13)$$

where μ_1 is the first root of the zero order Bessel function of the first kind ($\mu_1 = 2.401$).

Since the temperature [difference] falls by a factor of e in time t_r,

$$t_r = \frac{\mu_1^2 \lambda}{r_0^2 \rho C} = 1,$$

whence the desired quantity is

$$\frac{\rho C}{\lambda} r_0^2 = \mu_1^2 t_r\,.$$

In another group of methods of thermokinetic analysis of reactions, the heat evolution in the reaction mixture is reproduced by the application of current pulses of known power.

The design proposed by Skuratov and coworkers[19] is based on a double calorimeter, with cells of identical heat capacity. Current pulses of power equivalent to the rate of heat evolution in the working cell are applied to the reference cell. The kinetic curve is a plot of the square of the current in the reference cell against time. The area under the kinetic curve, multiplied by the appropriate proportionality factor, is a measure of the total heat evolution during the experiment.

The automatic calorimeter used by Anderson for emulsion polymerisation studies[20] is even more convenient. This calorimeter operates on the following principle. The adiabatic heating produced by the reaction and measured by a sensitive thermocouple is converted into electrical power, which is applied to the reactor in the form of pulses and measured by a wattmeter. The power of the pulses is automatically controlled at the level corresponding to constant total rate of heat evolution, that is, to the difference between the power in the absence of chemical reaction and the rate of thermochemical heat evolution. Special calibration is not needed to calculate the conversion at a given instant and the heat of polymerisation, since a power of 1 W is equivalent to a rate of heat evolution of 0.2390 cal s^{-1}.

III. HETEROGENEOUS EXOTHERMIC REACTIONS

The thermal regime of heterogeneous exothermic reactions was first discussed by Frank-Kamenetskii[21]. Depending on the rate of removal of heat, two stable temperature regimes were shown to be possible: the lower in the activation-controlled and the upper in the diffusion-controlled region. The steady-state heating of the surface in the upper regime can be used to evaluate the kinetic parameters.

The critical condition[21] leading to ignition for a first-order surface reaction is of the general form

$$\delta_{crit.} = \theta^2 e^{\theta} \tag{14}$$

and

$$\nu = e^{-\theta}(\theta - 1) \tag{15}$$

where

$$\delta = \frac{Q_p}{\beta}\frac{E}{RT_0^2}k_0 \exp(-E/RT_0)\, x_v$$

$$\theta = \frac{E}{RT_0^2}(T - T_0)$$

$$\nu = \frac{k_0 \exp(-E/RT_0)}{\gamma}.$$

Here x_v is the molar concentration of reactant in the bulk, γ is the mass transfer coefficient, defined by the expression

$$\gamma = \frac{(Nu)D}{d}$$

where (Nu) is the Nusselt criterion, D is the diffusion coefficient of the reactant, and d is the characteristic linear dimension of the system.

Rozovskii and coworkers have shown that the kinetic parameters of heterogeneous reactions of zero[22] and non-zero[23] order can be determined from the critical ignition condition.

For a zero-order reaction the critical ignition condition has the form

$$\delta_{crit.} = \frac{Q_p k_0 \exp(-E/RT_0')\, E}{\beta' R (T_0')^2}, \tag{16}$$

where the primes denote the values of the parameters corresponding to the onset of ignition.

By experimenting with different heat evolution conditions (through changes in linear velocity, which in turn produce a change in the ignition temperature T_0'), the following relationship between T_0 and δ_{crit} can be obtained:

$$\frac{\beta'_{(1)}\delta_{crit\,(1)}(T'_{0(1)})^2}{\beta'_{(2)}\delta_{crit\,(2)}(T'_{0(2)})^2} = \exp E/R\,(T'_{0(1)} - T'_{0(2)}). \tag{17}$$

Taking logarithms, and ignoring the term $\ln \frac{\delta_{crit(1)}}{\delta_{crit(2)}}$, we arrive at an expression for the activation energy involving only the ignition temperatures and the ratio of the heat transmission coefficients, which can be replaced by the ratio of the linear velocities raised to the power $s = 0.65$:

$$E = \frac{RT'_{0(1)}T'_{0(2)}\left(\ln\frac{\beta'_1}{\beta'_2} + 2\ln\frac{T'_{0(1)}}{T'_{0(2)}}\right)}{T'_{0(1)} - T'_{0(2)}} \tag{18}$$

(where the numbers in brackets refer to the number of the experiment). The rate constants at the ignition temperature are calculated by the formula

$$k = \frac{\delta_{crit}\beta' R (T_0')^2}{Q_p E}. \tag{19}$$

The quantity δ_{crit} is evaluated by one of the approximate formulae as a function of the parameter $b = \frac{RT_0}{E}$:

$$\delta_{crit} \simeq \frac{1+b}{e} \quad \text{or} \quad \delta_{crit} \simeq \frac{1+b+b^2}{e}.$$

The rate constants at any other temperature T are calculated by the formula

$$k_T = k_{T_0} e^{\frac{E(T-T_0)}{RTT_0}}$$

which is equivalent to Eqn. (7).

If the order of the reaction is not zero, the expression for the activation energy from the results of two experiments retains the form of Eqn. (18), but the pre-exponential factor is found from the equation

$$f(x_{i\,surf})\,k_0 = \frac{\delta'_{crit}\beta' k (T_0')^2}{Q_p E \exp(-E/RT_0')} \tag{20}$$

and the order n of the reaction with respect to the ith component is found from the variation of T_0' with $x_{i,surf}$ according to the equation

$$\lg \delta_{crit} + 2\lg T_0' + \frac{E}{4.575\,T_0'} = n_i \lg x_{i,surf} + A,$$

where A is a constant.

All the formulae used in this Section have been derived from the heat balance equation

$$\beta(T - T_0) = Q_p k_0 \exp(-E/RT) f(x_{i,surf}),$$

where $i = 0, 1, 2$.

It must be stressed that only the critical ignition temperature depends on the value of the heat transmission coefficient, which varies with the flow velocity. However, the steady state heating of the surface is independent of the gas flow velocity, as shown by Buben for the catalytic oxidation of hydrogen and ammonia on platinum[24].

In conclusion, we note that the thermokinetic methods of investigation of heterogeneous catalytic reactions lead to equations of the same mathematical form as those obtained for homogeneous processes. However, in the latter case one makes experimental plots of T against t, whereas in catalytic reactions the steady state heating of the surface at a particular point is observed as a function of the position of that point along the layer of catalyst.

It is evident that a definite contact time and extent of conversion must correspond to each cross-section of the catalyst in an integral reactor once a steady state is established. Thus, having determined the temperature distribution (in a uniform thermal field from the electric heater) along the catalyst column, the required kinetic parameters can be calculated from the formula given in Section II.

IV. SPECIAL FEATURES OF THERMOKINETIC METHODS FOR THE STUDY OF FAST REACTIONS

When applied to fast reactions, in which the half-life $\tau_{1/2}$ is of the order of 1 s or less, thermokinetic methods exhibit some specific features both in apparatus design and in the significance of the mathematical equipment.

We shall briefly discuss the thermometric methods of monitoring fast reactions, originally put forward in both a static and a flow variant.

In the first variant[25], the gas mixture in the reaction vessel is irradiated through a special window with ultraviolet light capable of initiating the reaction and of specific

intensity I_0 at the entry window. The absorption of light by the gas creates an intensity gradient in the vessel, and therefore the rate of thermochemical heat evolution decreases with increasing distance from the entry window. With a finite rate of heat transfer over the cross-section of the reactor, an easily detectable temperature gradient arises. An expression relating the temperature rise ΔT in the central zone of the reactor to the extinction coefficient ϵ and to the distance X from the window for an initial pressure P can easily be obtained from the heat balance condition:

$$\Delta T = \frac{I_0 h\nu\,[1-\exp(-\varepsilon X)]}{\lambda\varepsilon} \qquad (21)$$

where h is Planck's constant, ν is the frequency of the light used to initiate the reaction, λ is the thermal conductivity of the gas. A modification of the static variant, known as the thermal maximum method, has been developed for fast liquid-phase reactions.

In this method[26] a bulb containing one of the reactants is broken in a solution of the second reactant under standard conditions of fast stirring. If the reaction is exothermic, we observe a temperature rise determined by the value of the rate constant and by the efficiency of the heat exchange. This rise goes through a maximum, with time, if the order of the reaction differs from zero. The rate constant k_1 for a first-order reaction† is calculated from the equation[26]

$$\frac{\Delta T_{max}}{\Delta T_{ad}} = (k_1/k_2)^{\frac{k_2}{k_2-k_1}} \qquad (22)$$

where the cooling constant k_2 is defined by Newton's law

$$-\frac{dT}{d\tau} = k_2(T-T_0). \qquad (23)$$

If the heat of the reaction is not known, the adiabatic heating is obtained by measuring ΔT_{max} for a series of increasing concentrations of the first reactant and extrapolating to infinity. The rates of reactions with $\tau_{1/2}$ of the order of 0.2 s can be studied by this method[27].

The flow variant of the method is applicable both to liquid-phase[28] and to gas-phase[29] reactions: it is usually called the continuous flow method.

In the method developed by Roughton[28]‡ two streams of liquid reactants moving with a linear velocity of the order of metres per second are efficiently mixed and led into a capillary provided with a sensitive thermocouple whose junction can be moved controllably. Under the given conditions the reaction proceeds adiabatically§. Hence, the temperature rise (of the order of 0.2–0.3 deg) can easily be correlated with the extent of conversion. The variation of the conversion along the length of the capillary allows the rate constant to be determined to a reproducibility of ±7% at the lowest values of $\tau_{1/2}$ investigated (~ 0.1 s). When the flow method is applied to gas-phase reactions, substantial changes are necessary not only in the dimension of the apparatus and in the linear velocity, but also in the method of treatment of the results of the measurements: this is because of the non-adiabaticity of the process and of the need to use heat transfer equations in partial differential form (Laplace transform)[29].

† For a second-order reaction the equation involves complex functions.

‡ Sometimes wrongly transliterated in Russian as 'Роутон'.

§ Control experiments must be made to test whether the heat of mixing of the reactants is zero.

V. NON-STATIONARY THERMOKINETIC METHODS

Non-stationary kinetic methods are used when the number of kinetic constants to be determined is greater than the number of kinetic equations which can be written in the quasi-stationary approximation. We shall discuss the application of non-stationary thermokinetic methods by considering two examples: radical polymerisation and enzyme catalysis with Michaelis–Menten kinetics.

1. Radical Polymerisation of Vinyl Monomers

According to the kinetic equations for radical polymerisation, the rate of decrease of the monomer concentration is

$$-\frac{d[M]}{dt} = w_i^{1/2}\frac{k_p}{k_t^{1/2}}[M] \qquad (24)$$

where [M] is the monomer concentration, w_i is the rate of initiation, and k_p and k_t are the rate constants for chain propagation and chain termination respectively.

As can be seen from Eqn. (24), a study of the stationary radical polymerisation kinetics can only lead to a combination of the k_p and k_t constants ($k_p/k_t^{1/2}$).

Bengough and Melville[30] developed an inertia-free method involving measurements of the adiabatic heating of the mixture undergoing polymerisation during the initial period of the reaction under continuous illumination (photoinitiation), and calculation of the mean lifetime τ of the radicals. The extent of conversion at time t after the beginning of irradiation such that $t \gg \tau$ (in practice, $t > 5\tau$) is given by the expression

$$\alpha = \frac{\Delta T}{\Delta T_{ad}} = \frac{k_p}{k_t}\left(\frac{t}{\tau} - \ln 2\right). \qquad (25)$$

The quantity $\tau \ln 2$, and hence τ, is evaluated from the intercept of the linear plot of α against t (of slope $k_p/k_t\tau$) on the ordinate axis. From a knowledge of k_p/k_t and $k_p/k_t^{1/2}$, the two kinetic constants can be evaluated separately. One advantage of this method is the possibility of measuring conversions of the order of 10^{-4} mol.%.

Bagdasar'yan and Revzin[31] developed an original non-stationary kinetic method of determining k_p and k_t by observing the change in the adiabatic temperature rise accompanying a sudden decrease in the intensity of the irradiation responsible for initiation after a steady rate of polymerisation has been set up (background initiation method), In this method, the steady-state rate before and after the decrease in the rate of initiation must be known, as well as ΔT_{ad}. Thus, the non-stationary kinetic method can be used both in the early stages and in the late stages of a polymerisation reaction.

2. Enzyme Catalysis

The classical scheme of enzyme catalysis includes the formation of an intermediate enzyme–substrate (ES) complex, which subsequently decomposes with formation of the product P and can also partially dissociate into the starting components:

$$E + S \underset{k_{-1}}{\overset{k_{+1}}{\rightleftarrows}} ES \xrightarrow{k_2} E + P, \text{ with } k_{+1} \gg k_2.$$

By the conventional methods[32], only k_2 and the Michaelis constant K_m can be determined:

$$K_m = \frac{k_{-1} + k_2}{k_{+1}}.$$

By using low-inertia (including thermometric) methods of monitoring the reaction, the continuous flow method can detect the formation of the enzyme–substrate complex when the reaction leading to product formation is in a non-stationary (accelerating) regime. By extrapolating the linear (stationary) portion of the kinetic curve to the time axis, the mean lifetime τ of the enzyme–substrate complex can be determined. Knowing τ and the initial concentration of the substrate $[S_0]$, we can determine k_{+1} from the equation

$$\tau = \frac{1}{k_{+1}[S]_0},$$

and hence arrive at k_{-1} from the value of K_m.[33]

Another variant of the treatment of the experimental data, proposed by Roughton[34], yields the product $k_{+2}k_2$ from the curve for product accumulation during the non-stationary period.

To conclude this section, we note that the temperature jump method proposed by Eigen[35], which can be applied to systems at equilibrium, is sometimes classified among the non-stationary thermokinetic methods. The method relies on the practically instantaneous (10^{-6}–10^{-7} s) rise in temperature by 10–12 deg obtained by discharging a high-voltage condenser or by a laser flash, followed by observation of the relaxation of the system, that is, its approach to a new equilibrium. The method has also been applied to enzyme reactions, but even in the case of unimolecular reactions the measured relaxation time is a measure only of the sum of the rate constants for the forward and the reverse reaction.

VI. EXAMPLES OF THE USE OF THERMOKINETIC METHODS

Thermokinetic methods have been used to study the kinetics of a number of liquid-phase reactions (hydrolysis of esters[12,26], polycondensation of diacyl chlorides and glycols[13], polymerisation of styrene[15], alkene oxides[36], ethylenediamine[50], and oligoacrylates[37] in bulk). The polymerisation kinetics of styrene have been studied[20] by compensation calorimetry.

Thermokinetic studies of fast gas reactions include the photochemical dissociation of ethylene[25] and the reaction of boron trifluoride with aliphatic amines[29].

The adiabatic nature of thermal explosion and thermal ignition was established by Semenov[40], and the use of the adiabatic regime for studying these reactions has been discussed in monographs by Zel'dovich and Voevodskii[7], Frank-Kamenetskii[21], and Kondrat'ev[41]. A great deal of work has been devoted to the application of thermokinetic methods in studies of topochemical reactions (thermal decomposition of inorganic compounds, using differential thermography[8], decomposition of explosives[6,42], and thermal degradation of polymers[43]). The kinetics of various heterogeneous processes (adsorption, dissolution) have been investigated calorimetrically[2]. Critical ignition conditions have been used to study the kinetics of a heterogeneous catalytic reaction (the synthesis of alcohols from CO and H_2[44]).

The application of fast thermokinetic methods has been described in conjunction with the hydration of acetaldehyde[27], the preparation of polyamides[45] and polyesters[46], etc. Non-stationary thermokinetic methods have been used to study the polymerisation of vinyl acetate, acrylates[30], and oligoacrylates[47]. The kinetics of the formation of the enzyme–substrate complex in the cataly is of ribonuclease[58] and of chymotrypsin[49] have bee investigated by the temperature step method.

There can be no doubt that the number of investigations by thermokinetic methods will increase rapidly, in parallel with advances in the experimental techniques of this rapidly developing branch of chemical kinetics.

VII. ADVANTAGES OF THERMOKINETIC METHODS

Thermokinetic methods have unique advantages in the study of the kinetics of strongly exothermic reactions, in which isothermal conditions cannot be maintained, and of reactions in highly viscous media, which preclude effective stirring. In most of the variants of the thermokinetic method the whole of the kinetic curve can be obtained in a single experiment. The use of rising temperature conditions for the reaction (by exothermic self-heating or by programmed heating) enables the kinetics to be studied at extreme stages of the reaction, which is not always possible under isothermal conditions. Lastly, the thermometric method (applied to reactions of known kinetic law) allows the effective activation energy to be evaluated from a single experimental curve[11].

The Differentiating Action of Oxygen-containing Solvents on the Strengths of Acids

V.I.Dulova, N.V.Lichkova, and L.P.Ivleva

The present review examines the differentiating action of various oxygen-containing solvents on the strength of acids, chiefly carboxylic acids, and nitrophenols. The strength of the acids in these solvents is characterised by the dissociation constants (dielectric constant of solvent > 10) or by the conversion constants (dielectric constant of solvent < 10). The constants were determined by the buffer-free indicator method. The bibliography contains 143 references.

3. Esters 828

I. INTRODUCTION

In the study of electrolytes in non-aqueous solvents, it is often found that the change in their strength is different from that observed in water. This effect of the solvents is called their "differentiating action".

The differentiating action of solvents on the strength of electrolytes, in particular acids, is an important problem in the general theory of solutions. This problem is also of considerable importance in the examination of the reactivities of substances and the mechanisms of reactions in solution. The ability of various non-aqueous solvents to

differentiate the strength of electrolytes is used successfully in chemical analysis. Non-aqueous titration has been finding increasing application in recent years, as indicated by the large number of papers devoted to this topic. These papers have been reviewed by Palit and coworkers[1] and by Kreshkov and coworkers[2-4].

A number of workers have studied the theory of the differentiating action of non-aqueous solvents on the strength of electrolytes. The concept of differentiating and levelling solvents was first introduced by Walden[5,6].

Considerable advances in the theory of electrolyte solutions and in particular the theory of the differentiating action of non-aqueous solvents on the strength of electrolytes have also been made by Soviet workers, particularly Izmailov and coworkers, who have continued the creative development of Mendeleev's ideas on the chemistry of dissolution and who have also introduced the achievements of the physical theory of solutions into the development of general ideas regarding solutions.

Previously, Brönsted[7,8], who studied the strength of acids in non-aqueous solutions, considered that the differentiating action of a solvent depends on its basic strength and dielectric constant. According to his theory, all acids with the same charge, even if of different character, show the same change in strength on going from one solvent to another.

Izmailov[9] showed that the strength of acids with the same charge but of different character (carboxylic acids and nitrophenols) change in different ways on going from water to various non-aqueous solvents. The magnitude of the relative change in the strength of the given acids characterises the differentiating action of the solvents.

According to Izmailov's quantitative theory of the influence of solvents on the strength of electrolytes[10-16], it is necessary, in the examination of the differentiating action of solvents on the strength of acids, to take account of the composition of the products of the reaction of the acid with the solvent, the dielectric constant (DC) and acid–base properties of the solvent, and the solvation of the anions of the acid by solvent molecules.

Hydroxyl-containing solvents may give reaction products with the 1 : 1 composition (with nitrophenols) or the 1 : 2 composition (with carboxylic acids). Solvents which do not contain hydroxyl can give reaction products with the 1 : 1 composition with both types of acid. The difference in the compositions of the products of the reactions of these solvents with acids of different character, compared with those for water, is responsible for their differentiating action. The differentiating action of solvents increases with decrease in the DC and with increase in the acidity of the solvents, and also with change in the energy of solvation of the anions of carboxylic acids.

An extensive review of papers on the differentiating action of non-aqueous solvents on the strength of electrolytes has been made by Izmailov[17,18]. Where necessary, we used material from this review in the examination of the differentiating action of oxygen-containing solvents on the strength of acids.

The present review examines chiefly oxygen-containing solvents of four classes: alcohols, ethers, ketones, and esters; the differentiating properties of acetic anhydride are also examined. The differentiating action of carboxylic acids as solvents was studied in detail by Izmailov and Shkodin[19-23]. They showed that the differentiating action of these solvents on the strength of acids depends chiefly on their DC. This class of solvent will not be examined in the present review.

II. DETERMINATION OF THE STRENGTH OF ACIDS IN SOLUTION

According to Izmailov's theory[10-16], the behaviour of acids in a solvent can be represented as follows:

$$HA + (m+n)M \rightleftarrows HAM_n + {}_mM \rightleftarrows MH_s^+ + A_s^- \rightleftarrows MH_s^+ \cdot A_s^- . \quad (1)$$

The strength of an acid is characterised by the dissociation constant. Electrometric methods, however, measure only the value of K_{form}, which is equal to

$$K_{form} = \frac{[MH_s^+][A_s^-]\gamma^2}{[HA] + [HAM_n] + [MH_s^+ \cdot A_s^-]} . \quad (2)$$

The symbols in Eqn. (2) correspond to scheme (1); γ represents the mean activity coefficient of the ions.

In solvents with high DC, there are almost no associates, so that in these solvents the effective quantity K_{form} and the dissociation constant K_{diss} are equal:

$$K_{form} = K_{diss}\frac{[MH_s^+]^2\gamma^2}{C - [MH^+]\gamma} , \quad (3)$$

where C is the total concentration of acid. In solvents with high DC, electrometric, spectrophotometric, and indicator methods give the same values for the dissociation constants of acids.

In solvents with low DC, however, some of the ions are combined in ion pairs, and these cannot be detected by electrometric measurements. The formation of ion pairs is taken into account in spectrophotometric and indicator methods for determining the strength of acids, where they are regarded as free ions. This explains why in solvents with low DC the values of the dissociation constants of acids and bases determined by electrometric methods are smaller than the values of these constants found by spectrophotometric and indicator methods. This is illustrated in Table 1.

Table 1. pK values for acids in n-butanol.

Acids	pK, electrometric method (Refs.17 and 18)	pK, indicator method (Ref.24)
Acetic	10.35	9.22
Monochloroacetic	8.50	7.31
Dichloroacetic	7.30	6.09
Trichloroacetic	6.30	5.11
Benzoic	10.24	9.18
o-Nitrobenzoic	8.50	7.27
m-Nitrobenzoic	9.15	7.66
p-Nitrobenzoic	9.10	7.74
α-Dinitrophenol*	8.36	6.92
Picric	4.50	3.21

* Presumably 2,6-dinitrophenol, here and subsequently (Ed. of Translation).

The dissociation constants of acids determined by Izmailov using an electrometric method in 50% aqueous acetone are close to the values obtained using the indicator method[25], but in pure acetone[9,25] the two methods give different values. For all acids the dissociation constants determined by the electrometric method are slightly less than the constants obtained by the indicator method (see Table 2). A similar difference was observed by Izmailov and Gurevich[26] in the values of the dissociation constants of picric acid in butanol, found by electrometric and spectrophotometric methods.

In solvents with high dielectric constant, the dissociation constant of an acid is determined by the expression

$$K_{HA} = \frac{[H^+]^2\gamma^2}{(C-[H^+])\,\gamma_{HA}},$$

where γ is the mean activity coefficient of the ions of the acid. γ_{HA}, as the activity coefficient of a non-electrolyte, is close to unity. Since experimental measurements give not $[H^+]$ but $[H^+]\gamma$, and since for most non-aqueous solutions the values of γ are unknown, it is necessary to make the approximation of replacing $[H^+]$ by $[H^+]\gamma$ in the equation for the dissociation constant of the acid. This can be done for dilute solutions, in which γ does not differ greatly from unity. When these approximations are introduced, we obtain for the dissociation constant the expression

$$K_{HA} = \frac{[H^+]^2\gamma^2}{C-[H^+]\gamma}. \quad (4)$$

Table 2.

Acids	50% aqueous acetone		Acetone	
	pK, electrometric method (Ref.17)	pK, indicator method (Ref.25)	pK, electrometric method (Ref.17)	pK, indicator method (Ref.25)
Formic	5.23	5.06	—	9.57
Acetic	6.26	5.86	12.55	10.6
Monochloroacetic	4.28	4.41	9.80	9.21
Dichloroacetic	—	3.17	—	7.70
Trichloroacetic	2.20	2.19	—	6.51
Salicylic	4.18	4.39	9.53	9.08

For a basic indicator in a solution of an acid, we have the equilibrium

$$I_B + H_s^+ \rightleftarrows Ind\,H_s^+. \quad (5)$$

The constant for this equilibrium—the conversion constant of the indicator—is given by the relationship

$$K^I = \frac{[H^+]\gamma\,[I_B]}{[Ind\,H^+]\varkappa} \quad (6)$$

where I_B is the basic form of the indicator, $IndH^+$ the acid form of the indicator, and $\varkappa$ the activity coefficient of the ions of the indicator.

It follows from Eqn. (6) that $[H^+]\gamma = K^I_a$, where $a = \frac{[IndH^+]\varkappa}{[I_B]}$.

We then have

$$K_{HA} = \frac{(K^I a)}{C-K^I a}. \quad (7)$$

The value of K^I can be found[27-29] by solving Eqn. (7) for two acid concentrations C_1 and C_2, at which $a_1 = 1.2$ and $a_2 = 0.8$. It should be noted that the value of C determined colorimetrically is more accurate, the closer it is to unity. When the values of C_1 and C_2 are close to one another, it may be assumed that the mean activity coefficients of the ions of the acid are equal at these concentrations. In this instance we have for K^I the expression

$$K^I = \frac{a_1^3C_2 - a_2^3C_1}{a_1a_2(a_1-a_2)} = \frac{1.44C_2 - 0.64C_1}{0.384}. \quad (8)$$

The determination of K^I is carried out in dilute solutions of strong acids. The calculation of the dissociation constant of a monobasic acid in determinations with an indicator for which K^I has been found is carried out from Eqn.(7) for the acid concentration at which $a = 1$. The following relationship then yields the required constant K_{HA}:

$$K_{HA} = \frac{(K^I)^2}{C-K^I}. \quad (9)$$

If the acid being studied is much weaker than the acid $IndH_s^+$, $[H^+] \ll C$ in the equation for the dissociation constant. In this instance the dissociation constant is calculated using the equation

$$K_{HA} = \frac{(K^I)^2}{C}.$$

Most dissociation constants given by the data of the authors of the present review were obtained for the conditions indicated above. These conditions were achieved by choosing suitable indicators.

To determine the value of K_{HA} in media with low DC, use has been made[30] of the equation

$$K_{HA} = \frac{(K^I)^2 a}{C-K^I a}a^n, \quad (10)$$

where n is a coefficient which takes account of the association of the indicator and acid species. For $a = 1$, $a^n = 1$ for all values of n, so that the value of K_{HA} in this instance is also given by expression (9).

It is better to determine the values of a with a spectrophotometer than with a colorimeter, particularly for a two-colour indicator. When the basic form of the indicator exhibits appreciable absorption at the maximum of the spectroscopic curve of the acid form, it is suggested that a correction be introduced in the calculation[27,28] or that the method of Komar'[31] be used.

The determination of the dissociation constants of bases can be carried out analogously[32].

The method which we proposed for determining the conversion constants of indicators and the dissociation constants of acids and bases was verified for aqueous solutions[27,28]. The agreement in the values found with several acids indicates that the determination of the conversion constant of the indicator in a given solvent is correct. Table 3 gives as examples the values of the conversion constants of indicators obtained with various acids in ethylene glycol.

Several indicators are usually employed to determine reliably the dissociation constant of an acid in a given solvent. The values of pK for the dissociation of a given acid in a given solvent, obtained using different indicators and hence at different concentrations of the acid, differed in our determinations by not more than 0.2 pK unit. This is illustrated in Table 4. The reliability of the determination of dissociation constants by the indicator method which we proposed is also confirmed by the fact that the observed values of the constants differ little from the values measured using the spectrophotometric method (see Table 5).

The buffer-free indicator method for determining the dissociation constants of acids and bases has a number of advantages over other indicator methods. This method makes it possible to determine the dissociation constants of acids and bases and the conversion constants of indicators when none of these quantities are known.

The buffer-free indicator method in non-aqueous solutions should find wider application than the buffer method,

since many salts are sparingly soluble in non-aqueous solvents. Moreover, the ionic strength has a significant influence on the determination in non-aqueous solvents at ionic concentrations at which in water its influence could be neglected. It therefore becomes necessary to take account of the activity coefficients of the ions, but for most non-aqueous solvents these quantities are unknown. An advantage of the indicator method which we have proposed is that with slight approximation it becomes unnecessary to know the activity coefficients of the ions in a given solvent.

Table 3. Determination of the conversion constants of indicators with respect to various acids in ethylene glycol[33].

Acid	Indicator	
	Naphthyl Red	Quinoline Blue
Naphthalene-2-sulphonic	$3.50\cdot10^{-4}$	$2.30\cdot10^{-4}$
Dichloroacetic	$3.20\cdot10^{-4}$	—
Trichloroacetic	$3.80\cdot10^{-4}$	—
Picric	—	$2.43\cdot10^{-4}$

Table 4. Dissociation constants of acids in ethylene glycol[33].

Acids	K_{HA} relative to Quinoline Blue	K_{HA} relative to Naphthyl Orange	K_{HA} relative to Methyl Yellow	Mean K_{HA}	pK	ΔpK
Formic	$(2.42\pm0.38)\cdot10^{-5}$	—	—	$2.4\cdot10^{-5}$	4.62	0.87
Acetic	$(2.50\pm0.17)\cdot10^{-6}$	—	—	$2.5\cdot10^{-6}$	5.60	0.84
Monochloroacetic	$(7.97\pm1.12)\cdot10^{-5}$	$(6.65\pm0.01)\cdot10^{-5}$	—	$7.3\cdot10^{-5}$	4.14	1.27
Dichloroacetic	—	—	$(9.77\pm0.03)\cdot10^{-4}$	$9.8\cdot10^{-5}$	3.01	1.71
Benzoic	$(6.40\pm0.04)\cdot10^{-6}$	—	—	$6.4\cdot10^{-6}$	5.19	0.99
p-Nitrobenzoic	$1.98\cdot10^{-5}$	—	—	$2.0\cdot10^{-5}$	4.70	1.28
m-Nitrobenzoic	$1.85\cdot10^{-5}$	—	—	$1.9\cdot10^{-5}$	4.72	1.28
Salicylic	$(8.47\pm0.9)\cdot10^{-5}$	$(5.50\pm0.66)\cdot10^{-5}$	—	$7.0\cdot10^{-5}$	4.15	1.18
α-Dinitrophenol	$(5.33\pm0.38)\cdot10^{-5}$	—	—	$5.3\cdot10^{-5}$	4.28	0.16
β-Dinitrophenol*	$(5.01\pm0.3)\cdot10^{-5}$	—	—	$5.0\cdot10^{-5}$	4.30	0.53
Boric	$(2.74\pm0.06)\cdot10^{-6}$	—	—	$2.7\cdot10^{-6}$	5.57	−3.69

Note. ΔpK is the difference between the pK values found for the given acid in the solvent used and in water.

* Presumably 3,5-dinitrophenol, here and subsequently (Ed. of Translation).

Table 5. pK values for picric acid.

Alcohol	Spectrophotometric method	Indicator method
t-Butyl[34]	4.43	4.75
n-Hexyl[34]	4.23	4.36
n-Butyl[24]	3.26*	3.21

* Value obtained by Izmailov and Gurevich[26].

It should be noted that the graphical method usually employed to determine the conversion constants of indicators and the dissociation constants of acids or bases is difficult in solvents with low DC, since the regular features of the change in the ratio $[IndH^+]/[Ind]$ with change in acid concentration is complicated by the phenomena of ion association. In solvents with low dielectric constant the strength of acids is characterised by the equilibrium constant for the formation of ion pairs from molecules of the acid:

$$HA \rightleftarrows H_s^+A_s^- . \qquad (11)$$

Following Izmailov, the constant K_{tr} for equilibrium (11) is called the transformation constant (see scheme 1). These equilibrium constants for acids were determined by Kolthoff and Bruckenstein[35], using the indicator method. They examined the following equilibrium between acid and indicator:

$$I_B + HA \rightleftarrows IH_s^+ \cdot A_s^- . \qquad (12)$$

This equilibrium is established in an indifferent solvent, but in a non-indifferent solvent the following equilibrium is energetically more probable:

$$I_B + H_s^+ \cdot A_s^- \leftrightarrows IH_s^+ \cdot A_s^- . \qquad (13)$$

It is evident that the constant for equilibrium (12) depends on the strength of the acid. We proposed a method[29,36] for determining the strength of an acid using the constant for equilibrium (13), that is, the transformation constant of the indicator K_{tr}^I, which is independent of the strength of the acid with which the determination is carried out.

Solvents whose DC are low, but not too low, contain both free ions and ion pairs. For the separate determination of these species, and hence the determination of the constants K_{diss} and K_{tr}, it is necessary to use both electrometric and spectrophotometric or indicator methods. In non-aqueous solvents, particularly those with low DC, the electrometric measurements are often difficult, and comparatively few data are available for these solvents. Difficulties are also encountered in the spectrophotometric determinations, due to the fact that the absorption maxima of the acids or their ions and the solvent are close together, or due to photolysis.

The data obtained by the authors of the present review on the determination of the strength of acids by the indicator method are conditional. Since methods were not available for the separate measurement of the concentrations of free ions and ion pairs, conditional values of the dissociation constants were calculated from the data obtained in solvents with DC > 10, and for solvents with DC < 10 the overall effect was related to the conditional value of the transformation constant of the acid.

1. Alcohols and Ethers

Data on the strength of acids in various alcohols have been obtained by a variety of methods[17,18,37-46]. In an analysis of published data on the strength of acids in methanol, ethanol, and n-butanol, obtained from electrometric measurements, Izmailov[17,18] concluded that alcohols produce a marked decrease in the dissociation constants of all acids, but that the decrease in strength in alcohols compared with water is not quite the same for carboxylic acids and nitrophenols. Izmailov noted that the specific influence of alcohols on the strength of acids is shown more clearly in n-butanol. Thus alcohols differentiate the strength of acids to a slight extent, although they are typical levelling solvents with respect to salts[5,6,47]. The slight increase in the differentiating action of alcohols on the strength of acids in the series methanol (DC = 31.5), ethanol (DC = 24.0), and n-butanol (DC = 17.0) was attributed to the decrease in the DC of the alcohols in this series.

We used the buffer-free indicator method to study the strengths of a series of acids of different character in various primary, iso-, secondary, and tertiary alcohols, and also in alcohols with two functional groups: ethylene glycol, 2-chloroethanol, diethylene glycol, and diacetone alcohol [24,33,34,48-53]. In alcohols with intermediate DC values, the dissociation constants of the acids were calculated, and in alcohols with DC less than 10, the transformation constants were calculated. The results are given in Table 6, which also gives the pK values for the acids in water [17,18]. The decrease in the strengths of carboxylic acids in alcohols relative to their strengths in water is different for different acids; the strengths of nitrophenols change to a smaller extent.

The change in the strength of acids on going from water to a non-aqueous solvent is characterised by the quantity $\Delta pK = pK_{\text{in alcohol}} - pK_{\text{in water}}$. The greater the quantity ΔpK, the greater the decrease in the strength of acids in the given solvent compared with water. The values of ΔpK obtained for the alcohols studied are given in Table 7. The decrease in the strength of *o*-nitrobenzoic acid on going from water to alcohols is greater than the decrease in strength shown by all other carboxylic acids. This phenomenon can be explained on the basis of the steric effects arising in the reaction of the molecules and ions of this acid with the solvent. In the *o*-nitrobenzoic acid molecule, an intramolecular hydrogen bond may be formed between the NO_2 and COOH groups, and this is broken on interaction with the solvent. Thus the reaction of the molecules of this acid with the solvent depends on steric effects to a greater extent than the reaction of other carboxylic acids whose molecules do not contain an intramolecular hydrogen bond. For salicylic acid, whose molecule contains a hydroxyl group in the *ortho*-position, an effect similar to that observed for *o*-nitrobenzoic acid should have been found. However, the decrease in the strength of this acid on going from water to alcohols was found to be approximately the same as that for other carboxylic acids. As noted above, the strength of an acid depends on the reaction of the acid with the solvent and on the subsequent solvation of the ions formed. Thus the observed contradictions are apparently explained by the suggestion [54-57] that the salicylate ion formed on ionisation of the acid contains an intramolecular hydrogen bond and is stable.

The decrease in the strength of nitrophenols on going from water to alcohols with two functional groups is slightly smaller than that observed for carboxylic acids, but the

decrease in strengths is almost the same in diethylene glycol.

It is convenient to estimate the differentiating action of solvents from graphs giving the dependence of pK for the acids in alcohol on their pK values in water. As already noted[17], different straight lines are obtained graphically for acids of different character (carboxylic acids and nitrophenols) in differentiating solvents. For some acids, particularly *o*-nitrobenzoic acid, the pK values do not lie directly on the straight line for carboxylic acids, because of the specific interaction of the acid with the solvent. The differentiating properties of a given solvent can be estimated from the distance between the straight lines on the graph of the dependence of pK for the acids in the non-aqueous solvent on the pK values for the acids in water. This distance (Δ'pK), expressed in pK units, gives the difference between the change in the strength for acids of different chemical character on going from water to the non-aqueous solvent expressed in orders of magnitude. The Δ'pK values obtained from data on the strength of acids in alcohols (Table 6) are given in Table 8.

Table 8. Differentiating action of alcohols.

Alcohols	DC	Δ'pK (from graphs)	Alcohols	DC	Δ'pK (from graphs)
Benzyl	13.1	1.0	Isopentyl	15.5	1.9
n-Butyl	17.1	1.8	t-Butyl	10.9	2.4
n-Pentyl	13.9	1.9	Phenol	10	−0.8*
n-Hexyl	13.3	1.5	Cyclohexanol	15.0	2.5
n-Heptyl	12.0	1.7	Ethylene glycol	37.70	≈1.0
n-Octyl	10.34	2.0	Diethylene glycol	31.69	1.1
n-Decyl	<10	1.6*	2-Chloroethanol	25.8	0.8
t-Butyl	17.7	1.9	Diacetone	18.2	1.6*

* Estimated approximately from the data in Table 6.

On going from n-butanol to n-octanol in the series of normal alcohols, the differentiating properties change little, although the DC values of the alcohols decrease. Thus the differentiating properties of these alcohols cannot be attributed to the influence of their DC.

The differentiating properties of alcohols are influenced by their acid–base properties. The acidity of simple aliphatic alcohols decreases with increase in the electron-donating properties of the alkyl group[58]. Work by Gerrard and Macklen[59-61] on the solubility of hydrogen chloride in alcohols showed, however, that n-butanol, n-hexanol, n-heptanol, and n-octanol have almost identical electron-donating properties. Thus for the example of these normal alcohols it is possible to follow the influence of one predominant factor—the increase in the length of the alkyl radical of the alcohol—on the differentiating properties of the alcohol.

It can be seen from the results obtained that the increase in the length of the alcohol radical from butanol to decanol has little influence on the differentiating properties of the alcohol, since the increase in the radical of the primary alcohol hardly affects the screening of the functional group of the alcohol and does not produce any significant steric effects in the reaction of the molecules of these solvents with carboxylic acid dimers.

Comparison of the differentiating properties of the normal alcohols and iso-alcohols leads to the conclusion that branching of the radical in the alcohol molecule at a carbon atom which is not joined to a hydroxyl group produces little change in the differentiating properties of the alcohols.

Of the alcohols with one functional group which we studied, benzyl alcohol shows the weakest differentiating properties. The DC of this alcohol is almost the same as that of n-hexanol. The weak differentiating properties of benzyl alcohol can probably be attributed to the fact that it exhibits stronger acidic properties than the other normal alcohols, and its radical has little steric effect on the reaction of two molecules of the alcohol with a molecule of the carboxylic acid. Thus carboxylic acids are stronger acids in benzyl alcohol than in other alcohols.

The more acidic solvent, phenol, with a planar radical, produces a change in the relative strength of acids which is the opposite of that observed for alcohols, in spite of the fact that phenol has a low DC. The decrease in the strength of carboxylic acids in phenol is less than that shown by nitrophenols.

The secondary alcohol cyclohexanol is a differentiating solvent, although its DC is of the same order of magnitude as the DC of normal alcohols, iso-alcohols, and benzyl alcohol. It is also a more basic solvent than the alcohols already considered. Thus the marked differentiating action of this alcohol on the strength of acids is apparently related to the spatial complexity of its radical.

t-Butyl alcohol is also a strongly differentiating solvent.

It may be concluded that the differentiating properties of secondary and tertiary alcohols are related to the spatial complexity of the radicals of these alcohols close to their functional groups; this creates considerable steric hindrance in the reaction of the molecules of these alcohols with carboxylic acid dimers.

Of the alcohols studied, ethylene glycol has the highest DC, so that it should exhibit weaker differentiating properties than the other alcohols. The data obtained, however, indicate that ethylene glycol is a slightly stronger differentiating solvent than benzyl alcohol and 2-chloroethanol—solvents with smaller DC.

Published data[58-70] show that all the alcohols studied differ little in acid–base properties, with the exception of ethylene glycol and 2-chloroethanol.

2-Chloroethanol is the most strongly acidic of the alcohols studied, so that despite the fact that its radical is more complex than the radical of benzyl alcohol, it exhibits weaker differentiating properties.

Although ethylene glycol has a high DC and is a more acidic solvent than benzyl alcohol, its differentiating action on the strength of acids is approximately the same, so that its radical produces greater steric hindrance in the reaction with carboxylic acid dimers than benzyl alcohol. The strength of boric acid has been determined in ethylene glycol; boric acid reacts with this solvent to form a complex which behaves as a monobasic acid[71].

Diethylene glycol is $\beta\beta'$-dihydroxydiethyl ether. The presence of the ether group explains why it is a stronger base than ethylene glycol. The oxygen of this ether group can react with acids. This atom is screened to a greater extent, however, than the oxygen of the hydroxyl group, so that the differentiating properties of diethylene glycol are stronger than those of ethylene glycol.

From its DC, the differentiating properties of diacetone alcohol should be the same as those of isobutyl alcohol, but on the basis of the structure of its radical it should exhibit stronger differentiating properties than all other alcohols. According to the studies of Badger and Bauer[72,73], diacetone alcohol contains an intramolecular hydrogen bond. These authors also compare the structure of this alcohol

with that of t-pentyl alcohol. Thus the molecule of this alcohol should create greater steric hindrance in its reactions not only with carboxylic acids but also with nitrophenols. As a result, the change in the relative strength of acids of different character is approximately the same in this solvent as in isobutyl alcohol.

As noted above, one of the factors influencing the differentiating properties of solvents is the difference in the solvation of the anions of acids of different character by these solvents. Izmailov and coworkers[74-78] showed that on going from water to levelling solvents the change in the solvation energy of the molecules becomes greater than the change in the solvation energy of the ions; in differentiating solvents, however, the opposite relationship is observed. Thus in the examination of the differentiating properties of solvents it is necessary to take into account the reaction of both the ions and the molecules of the acid with the molecules of the solvent.

To obtain information on the relative change in the energy of solvation of the anions of carboxylic acids and nitrophenols in the alcohols studied, we determined the heats of dissolution of the diethylammonium salts of carboxylic acids and nitrophenols[79-81]. The heats of solvation of the ions in different solvents are fairly close, but, as shown by Izmailov[82], even slight differences in the values lead to a marked change in the strength of the acid.

Table 9. Heats of dissolution ΔH, kcal mole^{-1}, of diethylammonium salts in alcohols and cyclohexane[79-81].

Diethylammonium salt	Water (27°C)	Water (41°C)	2-Chloroethanol (27°C)	Benzyl alcohol (27°C)	Ethylene glycol (27°C)	Diethylene glycol (27°C)	Cyclohexanol (41°C)	t-Butyl alcohol (27°C)	Cyclohexanol (27°C)

* Sparingly soluble salt.

In the analysis of the data in Table 9 it is necessary to take into account the familiar ideas of physical chemistry, according to which an increase in the exothermicity of the dissolution of a given salt in different solvents is due to an increase in the energy of solvation of its ions.

The data in Table 9 indicate that the relative exothermic nature of the solvation of the anions of acids increases in the order: t-butyl alcohol, ethylene glycol, diethylene glycol, benzyl alcohol, 2-chloroethanol. The most strongly exothermic process is the solvation of the salts in 2-chloroethanol, and this is evidently related to the fact that the acidic properties of this alcohol are stronger than those of the other alcohols. With increase in the acidity of the alcohol, the hydrogen bond which it forms with the ions of the acids studied disappears.

It can be seen from the heats of dissolution of the salts (Table 9) that the exothermic nature of the solvation of the anions of the acids decreases considerably on going from water to cyclohexanol (with the exception of salicylate). For the salts formed by nitrophenols, the changes in the heats of solvation are not large. Thus the differentiating properties of cyclohexanol are related to the fact that the heats of solvation of the anions of carboxylic acids are smaller in cyclohexanol than in water.

The heats of solvation of the salicylate ion in different alcohols are approximately the same (judging from the heats of dissolution of diethylammonium salicylate, given in Table 9). This can be attributed to the fact that the salicylate ion contains an intramolecular hydrogen bond, so that it reacts weakly with the OH group of the solvent and the spatial complexity of the radical of the solvent has no significant influence on the heat of solvation of this ion.

As already noted, in the examination of the differentiating properties of solvents it is necessary to take into account the reaction of not only the ions but also the molecules of the acid with the molecules of the solvent. Izmailov showed that the energy of solvation of the molecules of acids depends on the strength of the complex formed between the acid and the solvent. If the solvent is more basic, the energy of solvation of the molecules will be greater, and the solvation will become more exothermic. On the basis of the data which we obtained[79] (Table 10) it may be concluded that the change in the integral heats of dissolution of benzoic and salicylic acids and α-dinitrophenol on going from the levelling solvent benzyl alcohol to the differentiating solvent cyclohexanone (a ketone) is not large. The energy of the reaction of the molecules of the acids with cyclohexanone is greater than that for benzyl alcohol, since cyclohexanone is a slightly more basic solvent than benzyl alcohol.

Table 10. Integral heats of dissolution of acids[79] (27°C).

Acids	ΔH, kcal mole^{-1}	
	cyclohexanone	benzyl alcohol
Benzoic	3.5	4.7
Salicylic	2.1	3.8
α-Dinitrophenol	3.9	5.3

It may therefore be concluded that the differences in the differentiating properties of alcohols are related chiefly to differences in the energies and heats of solvation of the anions of carboxylic acids compared with the anions formed by nitrophenols. The increase in the differentiating action of the solvents is related to the decrease in the exothermic nature of the solvation of the ions of the carboxylic acids. The exothermic nature of the solvation of the anions of carboxylic acids in turn decreases with increase in the spatial complexity of the radicals of the alcohols.

It follows from the foregoing that the differentiating action of alcohols on the strength of acids is due to a number of factors: the spatial complexity of the radicals of the solvent, the difference in the solvation of the anions of acids of different character (this also depends on the spatial complexity of the solvent molecules), and the acidity of the solvent. Both levelling and differentiating solvents can be found among alcohols, depending on the combination of these factors.

Like alcohols, ethers contain an alkoxy-oxygen, which is screened by two radicals. Thus the reaction of ethers

with acids should be influenced considerably by steric factors associated with the screening of the functional group of the ether by the radicals. This is indicated by published data[83-86] on the basis of which we should expect that the differentiating properties of ethers will also depend to a marked extent on the nature and spatial complexity of their radicals.

We studied the strength of various carboxylic acids and nitrophenols in various ethers: diphenyl (diphenyl oxide), methyl phenyl (anisole), diethyl, dibenzyl, di-(2-chloroethyl) (Chlorex), dibutyl, and di-isopentyl[36,87,88]. All these ethers, with the exception of Chlorex, have low dielectric constants (in the range 2–5), so that the strength of acids in these solvents should be characterised by the transformation constants, which we determined by the proposed method. The transformation constants of picric acid were first determined spectrophotometrically. We recorded the spectra of solutions of picric acid in the ethers and with the addition of a strong base in the range 370–470 nm. The spectra of solutions of picric acid in a given ether with the addition of an excess of diethylamine or piperidine coincided. The spectroscopic curves for the picrate solutions show a slight maximum in the range 400–420 nm, characteristic of the associated ions of picric acid[89]. We calculated the values of the transformation constants for picric acid in ethers from the absorption at various wavelengths in the spectral range studied. It was found that the calculated values of the constants remained almost constant in the wavelength range 440–480 nm. With decrease in wavelength, however, the values of the constants gradually increased. This is apparently due to the fact that in this range, absorption by molecules of the acid increases gradually towards shorter wavelengths, and this was not taken into account in the calculation. Table 11 therefore gives the mean values of pK_{tr} for picric acid, calculated for the wavelength range 440–480 nm. The calculation of the transformation constants of picric acid was based on the assumption that the ionic associates obtained by the reaction of picric acid with strong bases (diethylamine or piperidine) and with ethers acting as bases have the same absorption spectra in the range used for the calculations; molecules of picric acid do not absorb in this range. Justification for this assumption is provided by the agreement observed in the dissociation constants of picric acid in alcohols, determined by spectrophotometric and indicator methods. The spectrophotometric determination of the dissociation constants of this acid was based on the same assumptions as the determination of its transformation constants in the ethers. The transformation constants of the indicators were then determined with respect to picric acid, and the values were used to determine the transformation constants of carboxylic acids and dinitrophenols.

Examination of the pK_{tr} values for the acids in the ethers studied (Table 11) shows that the strengths of nitrophenols in the ethers studied do not differ greatly. The strengths of carboxylic acids in ethers with different radicals, however, differ sharply and a correlation is not observed between the basic strength of the ethers and the strengths of carboxylic acids in these ethers.

According to published data[61,90-95], the ethers studied can be arranged in the following order of increasing basic strength: diphenyl oxide < anisole < Chlorex < dibenzyl ether < diethyl ether < dibutyl ether.

In diphenyl oxide—the ether with the lowest basic strength—the carboxylic acids are much weaker than in the more basic diethyl ether, and the value of K_{tr} for trichloroacetic acid is smaller by almost three orders of magnitude in dibutyl ether than in diphenyl oxide. The strength of the carboxylic acids decreases with increase in the spatial complexity of the radicals of the ether (Table 11). The differentiating action of ethers is characterised by the values of $\Delta' pK_{tr}$, found from graphs giving the dependence of the values of pK_{tr} in the corresponding ether on the pK values in water (Table 12).

Table 11. pK_{tr} values for acids in ethers[36,87,88].

Dibenzyl	0.2
Diethyl	1.5
Dibutyl	2.0
Chlorex	1.2*

* $\Delta' pK$.

Examination of the results obtained shows that diphenyl oxide is a levelling solvent and that in this solvent we even observe a slight relative decrease in the strength of nitrophenols compared with carboxylic acids. We observed a similar but more clearly defined influence on the strength of acids in phenol. Anisole and dibenzyl ether show a very slight differentiating action, whereas ethers with saturated radicals are strongly differentiating solvents, and this property becomes more marked with increase in the size of the radicals. Diethylammonium and piperidinium picrates are insoluble in isopentyl ether, so that only the concentrations of picric and trichloroacetic acids at which half of the indicator Naphthyl Red is converted into the acid form were determined. These data[88] show that the differentiating properties of di-isopentyl ether are similar to those of dibutyl ether, that is, di-isopentyl ether is a strongly differentiating solvent. For Chlorex, $\Delta' pK$ = 1.2, and this characterises it as a differentiating solvent, although its differentiating properties are weaker than those of the other ethers having saturated radicals studied.

Ethers are solvents which cannot act as proton donors, so that it might be expected that they would all be differentiating solvents. The observed variation between their differentiating properties, which depend on the structure of the radicals in the ether molecule, indicates that steric factors have a marked influence on the reaction of the carboxylic acid dimers with the molecules of the ether.

To investigate the factors influencing the differentiating properties of ethers, we studied the heats of dissolution of benzoic acid and two dinitrophenols, and also diethylammonium β-dinitrophenolate, benzoate, and trichloroacetate in anisole, Chlorex, and dibutyl ether. The results[88] indicate that the relative change in the heats of dissolution of the acids and their salts on going from a levelling ether to a differentiating ether is not large, and its nature is such that it cannot explain the variation in the differentiating properties of ethers.

Information on the mechanism of the reaction of carboxylic acids with alcohols can be obtained from the infrared spectra of solutions of these acids in the alcohols.

Izmailov and coworkers[89,96,97] previously studied the reaction of carboxylic acids with alcohols from the Raman spectra in the range of the ν_{max} band of the C=O group. Only the reaction of carboxylic acids with weakly differentiating alcohols was studied.

Carboxylic acids exist in the form of dimers. The monomeric form of the acid is produced in solution as a result of the reaction of the acid dimers with solvent molecules. In the acid dimer, the hydrogen bond between the hydroxyl group of the acid and the carbonyl oxygen is stronger than that between this oxygen and the hydroxyl group of the alcohol which reacts with the acid, because the hydroxyl group of the acid has a greater tendency to give up a proton than the hydroxyl group of the alcohol. Thus breakdown of the dimer should take place as a result of the reaction of the oxygen of the hydroxyl group of the alcohol with the hydrogen of the hydroxyl group of the acid. To determine how carboxylic acids react with levelling and differentiating alcohols, we studied the infrared spectra of trichloroacetic acid in various alcohols, examining the region of the stretching vibrations of the C=O and OH (OD) groups of the acid[98].

No significant displacement of the main ν_{max} band due to the C=O group was observed on going from one alcohol to another. This indicates that the alcohols which we studied influence the position of the band due to the carbonyl group of the acid in the same way.

We assigned the main intense band (~ 1750 cm^{-1}) to the vibrations of the C=O group of the acid monomers, since it may be assumed that the carboxylic acid dimers are broken down in solvents capable of forming a strong hydrogen bond with the acid molecule. In this connection it may be noted that according to data obtained by Izmailov and coworkers[89,97] and ourselves[98], the νC=O band of the acid dimers in the infrared and Raman spectra was observed only in fairly concentrated solutions of acetic acid in alcohols.

In the infrared spectra of solutions of trichloroacetic acid in strongly differentiating solvents (cyclohexanol and t-butyl alcohol) we observed a weak band in the range 1700–1715 cm^{-1}, which may be assigned to the vibrations of the C=O group of the acid dimer. On dilution, the intensity of this band decreased, and the intensity of the band due to the C=O group of the acid monomers increased. In the spectra of solutions of trichloroacetic acid in weakly differentiating alcohols, we did not observe the band due to the C=O group of the acid dimers. It can evidently be assumed that the given solvents react more strongly with trichloroacetic acid than do differentiating solvents. Thus the quantity of dimers in these solvents is not large and has no influence on the stretching vibrational band of the carbonyl group of the acid. This also agrees with the fact that trichloroacetic acid is a weaker acid in strongly differentiating alcohols than in levelling alcohols.

Thus the data obtained indicate that the probability of reaction of carboxylic acids with strongly differentiating alcohols is less than that for levelling alcohols. This can be related to the steric effects which must be taken into account in the reaction of carboxylic acids with differentiating solvents.

We studied the infrared spectra of CCl_3COOH and CCl_3COOD in anisole and dibutyl ether[98]. These data give information on the reaction of the carboxylic acid with solvents containing alkoxy-oxygen. Study of the spectra indicated that the hydrogen bond formed by ethers with the hydroxyl group of the acid is stronger than that formed by alcohols. The νOH bands for the acid monomers in ethers lie in the range 2800–3100 cm^{-1}. The corresponding νOD bands in ethers should be displaced towards lower frequencies[99,100]; they appear at 2180 cm^{-1} in dibutyl ether and at 2270 cm^{-1} in anisole. It can be seen from these data that the hydrogen bond formed by trichloroacetic acid with dibutyl ether is stronger than that formed with anisole. This agrees with the fact that dibutyl ether is a more basic solvent, that is, it has a stronger electron-donating power than anisole.

The bands observed in the range 2550–2600 cm^{-1} in the spectra of CCl_3COOH were assigned to the vibrations of the OH group of the acid dimers. In the spectra of CCl_3COOD in ethers the corresponding bands due to the vibrations of the OD bonds of the acid dimers lie in the range 2030–2060 cm^{-1}.

The frequency of the stretching vibrations of the C=O group of the acid in ethers at 1765–1770 cm^{-1} is slightly greater than that of the band in alcohols (1750 cm^{-1}); this can be attributed to the absence of the perturbing influence of the hydrogen bond on the carbonyl group.

Ginzburg and Abramovich[101], in a study of the reaction of trichloroacetic acid with ethers, showed that in equimolar mixtures of the acid and ethers in CCl_4 the absorption band of the carbonyl group of the acid dimers appears in the form of a shoulder. In our studies, carried out in ethers without an inert solvent, there was almost no trace of a band due to the acid dimers in this range. The presence of bands characteristic of hydrogen bonds formed by the OH (OD) group of the acid, however, indicates that the solutions studied contain some acid dimers. The relative concentration of dimers is greater in dibutyl ether than in anisole, that is, the probability of reaction of the acid with dibutyl ether is less than that for anisole, although the hydrogen bond formed by the trichloroacetic acid molecules with dibutyl ether is stronger than that formed with anisole. This agrees with the data obtained by Ginzburg and Abramovich[101], according to which dibutyl ether, in its reaction with trichloroacetic acid, appears to exhibit weaker electron-donating properties than propyl and ethyl isobutyl ethers. It may therefore be concluded that the relative decrease in the strength of trichloroacetic acid in dibutyl ether compared with anisole is due not so much to the strength of the hydrogen bond between the acid and the ether as to the probability of its formation.

We also recorded the infrared spectra of diethylammonium trichloroacetate in the alcohols studied[98]. No significant displacement of the band due to the asymmetric stretching vibrations of the carboxylate ion (1680 cm^{-1}) in different alcohols was observed. The difference in the

reactions of the trichloroacetate ion with alcohols apparently does not influence the frequency of the asymmetric stretching vibrations of the carboxylate ion.

2. Ketones

The strengths of many acids in acetone and aqueous acetone mixtures were studied by Izmailov and coworkers[9], using electrometric methods. They showed[102,103] that the differentiating action of acetone is due to the formation of a reaction product with 1 : 1 composition by the carboxylic acids and the ketone, in contrast to the product with the 1 : 2 composition obtained in water and alcohols[96,103,104].

The authors cited also showed that the differentiating action of acetone on the strength of acids is related to a decrease in the solvation energies of the anions of the carboxylic acids compared with their solvation energies in water. The solvation energies of the anions formed by nitrophenols in acetone differ comparatively little from their energies of solvation in water[105,106].

We used the buffer-free indicator method to study the strength of acids in various ketones, including acetone[25,107,108]. The pK values for acids in these solvents, and the values of ΔpK and Δ'pK, are given in Tables 13, 14, and 15 respectively.

Table 13. pK values for acids in ketones[25,107,108] and acetic anhydride[109].

Acids		Solvents				
		acetone	acetophenone	benzophenone	cyclohexanone	acetic anhydride
	DC	20.7	17.39	13.3	18.3	20.7
	°C	20±2	20±2	53±2	22±2	22±2
Formic		9.57	8.61	—	8.83	—
Monochloroacetic		9.21	8.31	—	8.16	8.73
Acetic		10.62	10.03	—	—	—
Dichloroacetic		7.70	7.41	7.96	6.85	7.84
Trichloroacetic		6.51	6.26	6.14	5.66	6.78
Propionic		—	10.07	—	—	—
Benzoic		—	9.80	—	—	—
Salicylic		9.08	8.14	—	8.01	—
o-Nitrobenzoic		—	8.14	—	8.23	—
m-Nitrobenzoic		—	8.62	—	8.68	—
p-Nitrobenzoic		—	8.72	—	8.70	—
α-Dinitrophenol		7.55	7.36	—	7.32	—
β-Dinitrophenol		7.77	7.47	—	7.33	—
Picric		4.14	4.55	5.29	4.24	5.97

The results (Tables 13–15) show that all the ketones which we studied are differentiating solvents. The basic strengths of the ketones studied are similar[90,110–112], but if we nevertheless arrange them in order of increasing basic strength—benzophenone < acetophenone < acetone < cyclohexanone—and compare the order with the order of the pK values for picric acid in the same solvents, we may conclude that the strength of picric acid increases in accordance with the increase in the basic properties of the ketone. The strengths of carboxylic acids in all the ketones decrease considerably compared with the values for water, and the decrease is much greater than that for nitrophenols.

The ketones which we studied exhibit similar differentiating properties, but when the methyl radicals in the acetone molecule are replaced by phenyl radicals (Table 15), the differentiating properties of the corresponding ketones decrease. Although the effect is weak, ketones apparently show steric effects in the reaction of the carboxylic acid dimers with the solvent. The fact that the influence of the radicals of the ketones on the differentiating properties of these solvents is slight can be attributed to the fact that the radicals in ketones are further removed from the oxygen than in alcohols and ethers.

Table 14. ΔpK values for acids.

Picric	3.64	3.75	4.49	3.44	5.17

To investigate the influence of differences in the solvation of the anions of acids of different character on the differentiating properties of ketones, we studied the heats of dissolution of diethylammonium salts in cyclohexanone. The results (Table 9) show that in cyclohexanone, as in acetone, there is a relatively greater decrease in the solvation energy of the anions of carboxylic acids, compared with the anions of nitrophenols, on going from water to the ketone.

Table 15. Differentiating action of ketones and acetic anhydride.

Solvent	Δ'pK
Acetone	2.5
Acetophenone	1.7
Benzophenone	1.3
Cyclohexanone	1.6
Acetic anhydride	1.1

All the ketones studied are differentiating solvents and can be used in non-aqueous titration.

Tables 13–15 also give data on the strength of acids in acetic anhydride[109] and its differentiating properties. The data show that acetic anhydride is a differentiating solvent, although its differentiating action is weaker than that of ketones. Because of the acidic properties of acetic anhydride, acids dissolved in this solvent are slightly weaker than in ketones.

Table 16. Values of pK_{tr} and pK_{diss} for acids in esters.

3. Esters

Esters are solvents which contain a carbonyl group, like ketones, but they also contain alkoxy-oxygen, that is, they have a compound functional group.

Most workers[113-117] consider that esters react with acids chiefly through the carbonyl oxygen, but some authors[114-116] conclude that reaction between the acids and the alkoxy-oxygen of the ester is also possible.

Esters form reaction products with the 1:1 composition both with acids and with nitrophenols[113]. According to Izmailov's theory, esters should be differentiating solvents. The oxygen atoms in the ester molecule, however, may be screened to some extent by the radicals, so that steric effects may be observed in the reaction with carboxylic acid dimers. It is therefore to be expected that esters with different radicals and different structures may show varying differentiating properties.

We studied the strength of acids (chiefly carboxylic acids and nitrophenols)[118-121] in eleven esters and an acetone–benzene mixture with an acetone mole fraction of 0.305 (DC = 6)[122]. The strengths of the acids were determined by the buffer-free indicator methods described above. In most of the esters with low DC which we studied, we determined the transformation constants of the acids and the indicators; in two esters with larger DC values (ethyl monochloroacetate and acetoacetic ester) we determined the dissociation constants of the acids. The results are given in Table 16.

The strengths of the acids depend on the basic strength of the solvent. The basic nature of the esters was studied by various methods: from the ionisation potentials[123-128], the solubility of HCl[59,60], the shifts in the infrared spectra on reaction with the OD group of methanol[90,92,129-132], and the Taft constants[133].

On the basis of published data, the esters which we studied can be arranged in order of decreasing basic strength. This order is given in Table 17, which also gives the values of pK for the transformation of picric and trichloroacetic acids.

Table 17.

	Esters	pK_{tr} for picric acid	pK_{tr} for trichloroacetic acid
decreasing basic nature ↓	Tributyl phosphate	0.44	3.32
	Butyl acetate	0.70	1.14
	Tricresyl phosphate	1.11	—
	Ethyl acetate	1.12	1.60
	Triphenyl phosphate	1.31	2.69
	Phenyl acetate	1.33	1.51
	Ethyl benzoate	1.60	1.92
	Diethyl carbonate	1.77	2.54
	Benzyl acetate	1.82	2.57
	Acetoacetic ester	4.65	6.28

With decrease in the basic strength of the esters there is an increase in the value of pK for picric acid, that is, a decrease in its strength (Table 17). This relationship is not observed for trichloroacetic acid. For example, in the most basic ester—tributyl phosphate—pK_{tr} for trichloroacetic acid is greater than the values in other esters which are less basic. Thus the change in the strength of nitrophenols in esters is related chiefly to the basic nature of these solvents, whereas the strengths of carboxylic acids are determined not only by the basic nature of the ester, but also by other factors.

In all esters, the decrease in the strengths of carboxylic acids on going from water to the ester is greater than the decrease in the strengths of the nitrophenols. This characterises the esters as differentiating solvents. The differentiating action of esters is illustrated by Table 18, which gives the $\Delta' pK$ values determined graphically from the data in Table 16. The results show that the differentiating action of the esters which we studied on the strength of acids varies between different esters (Table 18). The differentiating action of esters does not depend on their dielectric constant.

Although the esters of acetic acid have similar dielectric constants, their differentiating properties differ considerably. The differentiating action of diethyl carbonate—an

ester with low dielectric constant—on the strength of acids is similar to that of ethyl acetate—a solvent with high dielectric constant. Acetoacetic ester, with high DC, is a strongly differentiating solvent.

Examination of Table 18 shows that the differentiating properties of esters depend on the nature and spatial complexity of the radical of the alcohol group.

Table 18. Differentiating action of esters.

Solvents	DC	$\Delta' pK_{tr}$	Solvents	DC	$\Delta' pK_{tr}$
Butyl acetate	5.01	2.0	Benzene + acetone	6.02	1.2
Benzyl acetate	5.10	1.4	Tributyl phosphate	7.97	3.2
Ethyl acetate	6.02	1.6	Triphenyl phosphate	—	1,4*
Phenyl acetate	5.35	0.6			$\Delta' pK$
Diethyl carbonate	2.82	1.6	Acetoacetic ester	15.70	2.0
Ethyl benzoate	6.02	1.2	Ethyl monochloroacetate	20.00	0.8

* Estimated from data in Table 17.

The data in Table 16 show that the strengths of carboxylic acids in esters of acetic acid decrease with increase in the spatial complexity of the alkoxy-radical. In accordance with this, the differentiating properties of these solvents decrease in the order: butyl acetate > ethyl acetate > benzyl acetate > phenyl acetate. Thus the reaction of carboxylic acids with esters is influenced by steric effects depending on the size and complexity of the alkyl radical.

Ethyl acetate and diethyl carbonate exhibit the same differentiating action on the strengths of carboxylic acids and nitrophenols. It may be assumed that the identical differentiating action is determined by the identical degree of screening of the functional groups of the ester in these compounds.

Ethyl benzoate is a slightly weaker differentiating solvent than diethyl carbonate and ethyl acetate, since its acidic group contains the planar phenyl radical. Ethyl monochloroacetate is a weak differentiating solvent. This can apparently be attributed to the reduced electron-donating power of its functional group associated with the presence of the chlorine atom in its molecule[134,135].

The data in Table 16 show that the strengths of not only carboxylic acids, but also nitrophenols, are low in ethyl monochloroacetate, compared with ethyl acetate and other esters of carboxylic acids. We also studied the differentiating properties of acetoacetic ester (Table 16), which under ordinary conditions contains keto- and enol-forms. In pure acetoacetic ester under normal conditions, the keto form predominates (93%). This ester is a strongly differentiating solvent (Table 18). We purified acetoacetic ester in an all-glass distillation apparatus. These distillation conditions, and also the addition of acids, displace the equilibrium towards the formation of the enol form. In the liquid state, as a result of intramolecular hydrogen bonding, the enol form is present as a chelate compound[136] in which there is particularly strong steric hindrance to the reaction with carboxylic acid dimers. This is apparently also responsible for the differentiating properties of acetoacetic ester.

Esters of phosphoric acid can be arranged in the following order of decreasing differentiating properties: tributyl phosphate > tricresyl phosphate > triphenyl phosphate. The fact that tributyl phosphate has the strongest differentiating action can be attributed to the spatial complexity of its molecule, resulting from the large butyl radicals arranged at the apices of a tetrahedron[137,138]. In triphenyl phosphate the planar phenyl radicals also lie at the apices of a tetrahedron, but in contrast to the situation in tributyl phosphate, the axes of the phenyl radicals are parallel to one another[139]. This is apparently responsible for the fact that the steric hindrance to the reaction with carboxylic acid dimers is less for triphenyl phosphate than for tributyl phosphate.

Tributyl phosphate exhibits specific differentiating properties. Differentiation within the class of carboxylic acids is observed in this solvent: the chloroacetic acids are weaker than the nitrobenzoic acids. The behaviour of mineral acids in tributyl phosphate is also unusual: in this solvent, hydrochloric and sulphuric acids are weaker than picric acid[120]. In accordance with published data[140,141], we regarded sulphuric acid in tributyl phosphate as a monobasic acid. The transformation constants which we obtained[120] by the indicator method for hydrochloric and sulphuric acids in tributyl phosphate are close to one another. Hesford and McKay[142] determined the dissociation constants of these acids in tributyl phosphate from their electrical conductivities. The values which they obtained are also close to one another. The first dissociation constant of sulphuric acid was calculated.

The replacement of the butyl radicals by cresyl or phenyl radicals in the phosphoric acid ester leads to a decrease in the differentiating power of the solvent.

The stronger differentiating action of the esters of phosphoric acid compared with the esters of acetic acid can be attributed both to the structure of the molecules of the phosphoric acid esters and to the nature of phosphoric acid. The molecules of the esters of phosphoric acid have a tetrahedral shape, in which one of the apices is occupied by the phosphoryl oxygen, whereas the molecules of the esters of acetic acid have a planar structure, with *cis*-arrangement of the radicals[143].

Table 19. Integral heats of dissolution of salts[120,121] at a dilution of 1:400 (27°C).

Diethylammonium salts	ΔH, kcal mole^{-1}		
	water	benzyl acetate	tributyl phosphate
Picrate	4.8	5.0	3.1
β-Dinitrophenolate	4.7	6.9	2.5
Benzoate	insol.	2.5	10.9
Salicylate	2.8	4.0	3,8
Trichloroacetate	1.8	6.6	6.8
Acetate	—0.8	3.9	9.1

To estimate the influence of the solvation of the anions of the acids by different esters on the differentiating properties of the latter, we determined the integral heats of dissolution of the diethylammonium salts of various carboxylic acids and nitrophenols in benzyl acetate (a weakly differentiating solvent) and tributyl phosphate (the strongest differentiating solvent)[120,121]. The results (Table 19) show that the solvation of the anions of carboxylic acids in esters is much more endothermic than that in water. The solvation of the anions of nitrophenols in benzyl acetate is

slightly less exothermic than that in water, whereas in tributyl phosphate the opposite relationship is observed.

Comparison of the heats of solvation of the anions of the acids in the two esters (Table 19) indicates that the difference in the differentiating action on the strength of acids shown by tributyl phosphate and benzyl acetate is related not only to the factors examined above but also to a difference in the solvation of the anions of the carboxylic acids. The decrease in the solvation of the anions of the carboxylic acids in tributyl phosphate can be attributed to steric effects in the reaction of these anions with the ester.

Thus the differentiating action of esters depends on steric effects produced in the reaction of their molecules with both the molecules and the anions of carboxylic acids.

On the basis of our studies, esters can be recommended as differentiating solvents for the titration of acids.

Tributyl phosphate is a specific differentiating solvent. Picric acid and trichloroacetic acid can be determined separately in the presence of one another in this solvent. In this solvent it is also possible to determine separately chloroacetic and nitrobenzoic acids, which have similar strengths in water. This has been confirmed by our experiments [121] on colorimetric and high-frequency titration.

---o0o---

The change in the strength of acids of different character on going from water to oxygen-containing solvents (alcohols, ketones, ethers, and esters) depends on steric effects in the reaction of the molecules and anions of the acids with the solvent molecules. Increase in the spatial complexity of the solvent molecules and increase in the screening of the oxygen of the functional group lead to a relative decrease in the strengths of carboxylic acids; this is responsible for the differentiating action on the strength of acids in a given solvent.

Steric factors are particularly important in the reaction of carboxylic acid dimers with the alkoxy-oxygen of the solvents (alcohols and ethers).

The differentiating action of primary alcohols depends little on the size and degree of branching of their radical. Secondary and tertiary alcohols have a stronger differentiating action on the strength of acids than primary alcohols.

Ethers with sterically simple radicals (diphenyl oxide and anisole) are almost levelling solvents. The differentiating action of ethers with saturated radicals on the strength of acids increases considerably with increase in the size and complexity of their radicals.

The difference in the strengths of carboxylic acids in solvents containing alkoxy-oxygen is determined not so much by the basic nature of the solvent and hence the strength of the hydrogen bond formed as a result of the reaction of the carboxylic acid dimers with the molecules (in the case of alcohols, with the molecular associates) of the solvent as by the probability of formation of this bond, which depends on steric factors.

Ketones and esters are differentiating solvents, but the differentiating properties of these compounds also depend on the spatial complexity of their molecules and are determined by the relative decrease in the strength of carboxylic acids in these solvents.

Examination of the behaviour of the acids which we have studied in oxygen-containing solvents leads to the general conclusion that the strengths of acids in solvents depend on the spatial complexity of both the molecules and the ions of the acid and the molecules of the solvent. The differentiating properties of a solvent are determined to a considerable extent by steric effects in the reaction of the electrolyte with the solvent.

Active Centres in the Polymerisation of Hydrocarbon Monomers by Anionic Coordination

S.S.Medvedev

Several aspects are discussed of the nature and character of the active centres in the polymerisation of diene hydrocarbons (mainly butadiene) initiated by organic compounds of alkali metals or by cobalt and nickel complexes. Such polymerisations occur by a complicated mechanism of anionic coordination, characterised by the presence of active centres in the form of polarised bonds between carbon and metal atoms (the alkali metals and the transition metals in the complexes). The coordinating and anionic functions of the active centres, their combination, and mutual transitions are discussed for the polymerisation of butadiene and other hydrocarbon monomers in the presence of organic compounds of alkali metals.
The Section on polymerisation initiated by complex cobalt catalysts reports research on the role of small amounts of water in the formation and breakdown of the initial active centres. The last Section examines the formation of active centres from complexes of the π-allylnickel halide type and the mechanism of their participation in the polymerisation of butadiene

CONTENTS

I. Introduction 834
II. Nature of active centres in polymerisation in the presence of organic compounds of alkali metals 834
III. Active centres in the polymerisation of butadiene in the presence of complex catalysts based on cobalt and nickel 838

I. INTRODUCTION

Great attention has recently been paid to problems of polymerisation by ionic coordination, because of the wide possibilities it offers for the directed control of the composition and the structure of the polymer chains. However, the study of these processes—especially those which occur in the presence of complex catalysts containing transition metals in various states and combinations—encounters considerable theoretical and experimental difficulties.

An approach which will bring us closer to an understanding of several fundamental aspects of these systems, in particular problems associated with the nature of the active centres of chain propagation, may be to investigate polymerisation in the presence of alkali metals and their organic compounds. These processes represent simpler systems, but cover a wide range of phenomena, while allowing the structure of the active centres to be varied in a known manner, and thereby enabling various types of configuration and relative arrangement of the monomeric units to be realised in the growing polymer chains. In this sense they can serve as simplified models for the discussion of more complicated catalytic polymerisation systems.

Polymerisation in the presence of an alkali metal (sodium) was first used in 1932 in the Soviet Union to obtain synthetic butadiene rubber on the industrial scale by S. V. Lebedev's method.

In 1936 the first kinetic investigation, which used a vacuum technique, was published[1] on the vapour-phase polymerisation of butadiene on thin films of metallic sodium deposited on the walls of the reaction vessel. This work established that polymerisation takes place in a layer of butadiene which deposits on the walls of the vessel (Fig. 1).

The induction period is due to the presence of unchanged metallic sodium (initiation reaction). After the metallic mirror has disappeared, the process occurs at a constant rate. Prolonged interruption of the process (by pumping off the butadiene) with subsequent introduction of butadiene to the appropriate pressure did not affect the rate of polymerisation.

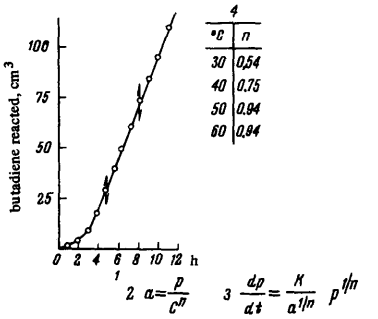

Figure 1. Gas-phase polymerisation of butadiene on metallic sodium mirrors:
1) dependence of conversion of butadiene on time at constant pressure p (the arrows denote interruptions); *2*) a = partition coefficient of butadiene between gas and polymer phases; *3*) rate of polymerisation at constant volume; *4*) dependence of coefficient n on temperature*.

* Curves *2* and *3* have apparently been overlooked (Ed. of Translation).

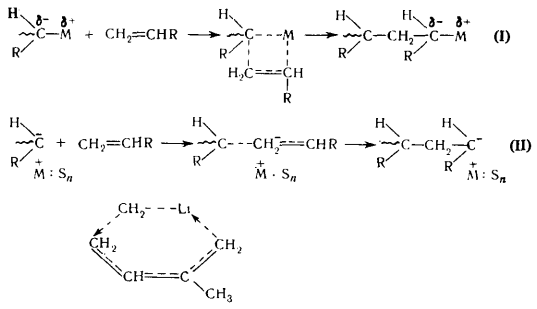
These experiments revealed a novel type of active centre for the growth of polymerisation chains, distinguished by the absence of chain termination and by thermodynamic stability. It was assumed that chain growth took place by incorporation of the monomer in the carbon–sodium bond. These phenomena were subsequently interpreted in terms of "chain catalysis" [2]. In present-day terminology—which is admittedly not perfect—these centres, the first to be discovered, can be termed "live" active centres.

II. NATURE OF ACTIVE CENTRES IN POLYMERISATION IN THE PRESENCE OF ORGANIC COMPOUNDS OF ALKALI METALS

As was mentioned above, the scientific interest and practical value of these processes are due to the presence of a definite relation between the nature of the initiator

(catalyst) and the structure of the active centres for chain growth, which in turn determine the composition, structure, and dimensions of the polymer chains, and to considerable extent the properties of the resulting polymers.

Many research papers have appeared[1-40] on these processes, and the results together with other published data enable the characteristics of the reactions of chain growth to be established. These characteristics can be represented by the scheme



where M is an alkali metal. Two types of active centres for chain growth are shown, differing in the nature of the C–M bond, which determines the rate of the elementary acts of growth and coordination of monomer units in the growing chains.

In the first type the active centres consist of polarised C–M bonds, in which covalent (exchange) forces play an important part. The transition state in reactions of chain growth may be supposed in this case to be a four- or six-membered ring (for vinyl or diene monomers respectively). The metal atom is directly involved in the growth reactions. The two-centre character of the active group determines the system of coordination of a monomer unit in the growing chain. For this reason we shall term this type of process the *coordination mechanism* of the growth of polymer chains.

The second type of active centre is characteristic of chain-growth reactions occurring by an *anionic mechanism*. Increasing polarisation of the C–M bond results in charge separation, depending on the nature of the alkali metal and the properties of the medium: only a certain Coulombic interaction is preserved between the carbanion and the counter ion, an *ion-pair* being formed. In this case the transition state of the growth reactions has a linear structure (one-centre type of active group), and the coordinating effect of the counter ion is small. With further weakening of electrostatic interaction between the ion and the counter ion under the influence of solvation of the latter by strong electron-donor solvents, *free carbanions* are produced. Processes occurring on ion-pairs with complete separation of charges and on free ions may be supposed to involve transition states of analogous structure. The difference is probably that with ion-pairs the growth reactions had to be inhibited by the fact that the solvated counter ion must move along the growing chain.

Actual polymerisation processes initiated by alkali metals and their organic compounds combine in most cases features of both mechanisms, and are processes of *anionic–coordination polymerisation*.

The term "mechanism" may lead to a wrong idea of the essential nature of these processes. It must not be thought that two different types of centres are involved, one of which is responsible for the occurrence of the process by an anionic mechanism, while the other causes polymerisation by a coordination mechanism. The essential point is that the same active centre possesses both anionic and coordinating functions at the same time, but they are combined to different extents depending on the nature of the metal, the properties of the medium, and the temperature. In the limit the predominance of one function or the other may result in either an anionic or a coordination mechanism.

A characteristic feature of processes of anionic–coordination polymerisation is the presence of a reactive C–M bond in the growing chains, the state of this bond—primarily its degree of polarisation—determining the possible relative importance of anionic and coordination mechanisms, the overall rate of the process, and the composition and structure of the polymer chains. Decrease in the degree of polarisation of the C–M bond is accompanied by an increase in the coordinating power of the alkali metals in the active centres. With a given monomer in the absence of electron-donor compounds, this increase in the coordinating factor varies in parallel with the ionisation potentials of the alkali metals:

$$\begin{array}{ccccc} K & < Na & < Li \\ 4.32 & 5.09 & 5.37 \end{array}.$$

Another important characteristic of metals in active centres, affecting the degree of polarisation of the C–M bond, is the presence of vacant orbitals in the metal atoms, as also the ionic radii determining their electron-acceptor properties. The lower the vacant orbitals and the smaller the ionic radii, the stronger is the solvation (or complex formation) of the metal atoms by electron-donor solvents

$$\sim CH_2\overset{\delta-}{C}H-\overset{\delta+}{M} + nS \rightarrow \sim CH_2\overset{\delta_1-}{C}H-\overset{\delta_1+}{M}:S_n$$
$$\qquad\qquad R \qquad\qquad\qquad\qquad R$$

where $\delta_1 > \delta$ and S is an electron donor. Solvation tends to increase the polarity of the C–M bond and also the proportion of the anionic process. The coordinating power of metals in active centres falls in the same sequence as the atomic radius of the metals decreases:

$$\begin{array}{ccccc} Li & > Na & > K \\ 0.6 & 0.95 & 1.33 \end{array}.$$

The simultaneous development of anionic and coordination mechanisms can be conveniently examined with the anionic–coordination polymerisation of butadiene as example, this leading to the formation of polymer chains containing monomer units differing in structure (1,2, *cis*-1,4, and *trans*-1,4). Table 1 shows that, in hydrocarbon solvents, where solvation of the counter ion† by the monomer is negligible, the coordinating power of the counter ion is most clearly apparent in lithium active centres, the preferential formation of 1,4-polybutadiene. With sodium and potassium centres the extent of participation of the coordinating factor in chain growth diminishes in the sequence K < Na < Li, this being accompanied not only by formation of 1,2-structures but also by decrease in the relative content of *cis*-1,4-structures in the polybutadiene chains. The relative content of *trans*-1,4-structures remains almost constant.

The introduction of an electron-donor compound, which causes solvation of the counter ion, increases the importance of the anionic process (formation of 1,2-structures). These effects are especially marked in the presence of lithium centres, are weaker with sodium centres, and are weak in the presence of potassium centres, in conformity with the solvation sequence Li > Na > K, as is evident

† For simplicity we shall henceforth term C in the C–M bond the anion, and M the counter ion, independently of the mechanism of the process.

from Table 1, which gives experimental results for the addition of triethylamine (TEA, a weak electron donor) and tetrahydrofuran (THF, a strong electron donor). Lowering the temperature, by favouring solvation of the counter ion, increases the role of the anionic factor. In pure tetrahydrofuran, owing to the breakdown of covalent (exchange) interaction between the carbanion and the counter ion, chain growth takes place on *ion-pairs*. Differences associated with the nature of the alkali metals are then smoothed out, and the mechanism of the process becomes predominantly anionic (preponderant formation of 1,2-structures).

Table 1. Effect of conditions of polymerisation on structure of polybutadiene[18].

Li	THF	—	—	—50	91	—	9

Similar results on the nature of the active centres and on the combination of anionic and coordination factors depending on the nature of the alkali metals and the properties of the medium have been obtained, in conformity with the ideas developed, in investigations of the composition of copolymers[14,15] and of chain-transfer reactions[14,29].

Examination of rates of growth in the anionic–coordination polymerisation of isoprene, butadiene, and styrene has established that these processes take place by a mechanism of "live" chains. Yet it was found that the rate of the process does not depend on the first power of the initiator concentration, as should have been the case with "live" chains, but is given by the equation

$$v = k_p[M][C]^{1/n} \qquad (1)$$

where [C] is the initiator concentration and $n > 1$ is a constant. The explanation given for these deviations was that in non-polar media the growing chains, with a polar group at the end, form stable association complexes, and these break down into non-associated growing chains in conformity with the equilibrium

$$(M-P)_n \rightleftarrows (M-P)_{n-1}M-P \qquad (2)$$

where P is the polymer chain.

The presence of association complexes in the reaction system has been confirmed by viscosimetric and spectrophotometric methods[25]. The complexes can be supposed to have either a layer or a coiled structure.

Only isolated, non-associated growing chains are active in acts of chain growth. The constant n in Eqn. (1) is a measure of the degree of association, and varies with the nature of the polymer, having values 2 for polystyrene, 3–4 for polyisoprene, and 5–6 for polybutadiene[17].

It was not possible to estimate the equilibrium constants (2) in the case of lithium centres. This constitutes the main obstacle to determining the individual growth rate constants in coordination polymerisations occurring in hydrocarbon media under the influence of alkali-metal compounds.

Several difficulties in determining chain-growth constants arise also from the isomerisation of active centres into centres of diminished activity, discovered spectrophotometrically[41,25]. However, these difficulties are eliminated by conducting the polymerisation at low temperatures (at or below −50°C).

On the introduction of electron-donor additives—tetrahydrofuran, triethylamine, etc.—into hydrocarbon media, the association complexes break down owing to solvation of the counter ions of growing chains in the complexes. Individual growing chains are then formed, with different degrees of solvation of the counter ions in the active centres depending on the electron-donor properties of the medium. The coordinating power of the C–M bond in chain-growth reactions depends substantially on the degree of solvation of the counter ions by the electron-donor compounds. These factors explain the lack of correlation between the rate of polymerisation on potassium active centres and the microstructure of the resulting polybutadienes[37].

Table 2. Effect of additions of tetrahydrofuran on the rate of chain growth in the polymerisation of butadiene and on the structure of the resulting polymers ($[M]_0 = 1$ M; initiator concentration. [KR] = 0.003 M; temperature −50°C).

Solvent	THF, total %	Rate of chain growth $10^3 v$, $M \cdot s^{-1}$	1,2-Structure, %
Cumene	—	0.0012	56
Cumene	2.7	0.012	56
Cumene	4.7	0.018	58
Cumene	20.0	0.21	64
Cumene	44.0	2.4	66
THF	—	15.6	85

Table 2 shows that the sharp changes in rate of polymerisation caused by the addition of an electron donor to the hydrocarbon medium are accompanied by slight changes in the microstructure of the resulting polymers. In view of the fact that potassium active centres form less stable association complexes and possess diminished electron-acceptor power (compared with lithium and sodium centres), this can be explained by the tendency of added tetrahydrofuran to favour formation from the association complexes of individual, non-associated growing chains, the number of which increases and causes an increase in the rate of polymerisation. However, the degree of solvation of the active centres, which affects their coordinating power, is small, and remains more or less constant as long as association complexes are present in the system. It is significant that, when the degree of solvation of the counter ions is small, covalent (exchange) forces are involved as well as electrostatic forces in the C–M bonds, and to some extent determine the proportion of the coordination mechanism in the chain-growth reactions. It is seen from Table 2 that, even in media containing 44% of tetrahydrofuran, ~ 34% of 1,4-structures are present in the polymer chains. In pure tetrahydrofuran, solvation of the

counter ion increases, covalent interaction in the C–M bonds contracts (screening of the counter ion by the solvate sheath), and the chain-growth reactions take place by an anionic mechanism.

1. Spectrophotometric Investigation of Active Centres for Chain Growth

The first spectrophotometric investigations of the C–M bond in lithium, sodium, and potassium active centres for polyisoprene, polybutadiene, and polystyrene showed that the position of the absorption band maximum λ_{max} is independent of the nature of the metal or the properties of the medium[42]. However, such dependence of the spectra has been detected in the corresponding triphenylmethyl, fluorenyl, indenyl, and 1,1-diphenylbutyl organometallic compounds (λ_{max} shifts to longer wavelengths with increase in polarity of the C–M bond)[25]. Detailed examination of the phenomena led to the conclusion that the spectra found for the first group of compounds ("live" chains of polyisoprene, polybutadiene, and polystyrene) relate not to individual growing chains but to their association complexes, which are characterised by great stability and are present in great quantity. The presence of bulky substituents in the second group of compounds and the consequent steric hindrance prevent the formation of stable association complexes, which readily break down even under relatively slight action by electron donors. Discrete transitions of active centres (the C–M bond) from one form to another depending on the nature of the medium are illustrated by the spectral pattern of 1,1-diphenylbutyl-lithium systems (Table 3).

Table 3. Ultraviolet spectra of 1,1-diphenylbutyl-lithium systems[25].

Solvent	λ_{max}, nm	Temp., °C
Hexane	410	25
Triethylamine	437	25
Hexane + 0.3% THF	440	25
Hexane + 0.3% THF	490	−80
THF	490	25

A sharp change in λ_{max} is observed on passing from hexane (unsolvated counter ions) to triethylamine or to a 0.3% solution of tetrahydrofuran (degree of solvation of counter ions small). A second transition, to completely solvated counter ions, occurs in solutions of pure tetrahydrofuran or when the temperature is lowered to −80°C, which favours solvation.

It has since been shown, by spectrophotometric combined with kinetic methods[30,17], that the degree of association and the stability of the association complexes of lithium active centres in hydrocarbon media depends on the carbanion component in the C–M bond, increasing in the sequence—1,1-diphenylethylene < α-methylstyrene < styrene < isoprene < butadiene.

It has also been established by conductometric methods that, in the polymerisation of α-methylstyrene in electron-donor solvents, the presence of steric hindrance in poly-α-methylstyrene, impeding the formation of association complexes in hydrocarbon media, promotes the dissociation of ion-pairs into free ions[40].

To elucidate the nature of the C–M bond in non-associated growing chains, spectrophotometric investigations have been made under conditions of the maximum concentration predominance of these forms, i.e. at concentrations below 10^{-5} M.[17,42,43]

Development of a special technique for spectrophotometric measurements at high dilutions with live lithium–polystyrene chains as example has shown that change in the concentration of lithium centres in toluene solution from 10^{-3} M to $\ll 10^{-5}$ M is accompanied by a shift in the absorption band maximum λ_{max} of 18 nm to shorter wavelengths. This band corresponds to non-associated and non-solvated active centres of growing chains[30].

The spectrophotometric research results cited support the earlier suggestion that in hydrocarbon media the C–M bond is a polarised bond, not an ion-pair.

2. Active Centres in Pure Electron-donor Media

It has been shown above that the metal atom in the active centres undergoes two types of interaction—with the end of the growing chain and with electron-donor molecules C...M...S_n—the relative strengths of anionic and coordination mechanisms of chain growth depending on the intensity and character of these interactions (exchange and electrostatic forces, solvation). It may be assumed that in pure and strong electron-donor media chain growth will take place solely by the anionic mechanism.

Table 4. Chain-growth rate constants in the anionic polymerisation of butadiene in different solvents, $M^{-1} s^{-1}$.[26]

Counter ion	Tetrahydrofuran						Dimethyl ether	
	+10°C	−30°C	−43°C	−56°C	−82°C	−96°C	−30°C	−56°C
Li	0.85	0.14	—	0.03	—	—	2.2	1.0
Na	5.4	1.8	1.05	0.60	0.40	0.29	23	8
K	70	17	—	3.1	—	0.16	—	16

This conclusion is to some extent confirmed by a detailed investigation of these processes[28], since the variation in the chain-growth rate constants found for the polymerisation of butadiene in tetrahydrofuran over the temperature range from +10° to −56°C corresponds to the sequence Li < Na < K, which is characteristic of an anionic mechanism (Table 4). However, the same investigations have shown that certain restrictions must be placed on this conclusion. It is seen from Table 5 that the microstructure of the polybutadiene formed in tetrahydrofuran medium depends on the temperature and the nature of the metal in the active centre of the growing chains.

The existence of such a relationship, which is shown especially clearly with potassium and caesium active centres and at relatively high temperatures, indicates that the counter ions are to some extent involved in chain growth. The type of dependence on the nature of the metal and the temperature also corresponds to processes of anionic coordination, not purely anionic processes.

In connection with the results obtained, the question arises of the formation of free ions and the part they play in these processes. The decisive role of free ions in the polymerisation of styrene in electron-donor media has been established by Szwarc[44] and by Schulz[45]. However,

the fact that the polymerisation of butadiene under analogous conditions follows the rules of anionic coordination throws considerable doubt on the role of free ions in this system. In fact, direct conductometric examination of these systems not only has strengthened these doubts but has led to the opposite conclusions[33].

Table 5. Microstructure of polybutadiene obtained in tetrahydrofuran[26,32].

Counter ion	Structure,%*	Temperature, °C				
		+40	+10	−30	−56	−96
Li	1	84.0	85.9		91.0	
	2	8.4	7.6	—	9.0	—
	3	7.6	7.2		0	
Na	1		79.3	82.9	88.0	92.7
	2	—	15.5	15.6	12.0	7.3
	3		5.2	1.5	0	0
K	1	56.6	63.5	76.4	83.5	88.3
	2	36.5	30.4	20.7	14.8	11.7
	3	6.7	6.1	2.9	1.7	0
Cs	1		60.6	72.7	82.9	89.0
	2	—	31.4	27.3	17.1	10.9
	3		8.0	0	0	0

* 1 = 1,2-structure; 2 = *trans*-1,4; 3 = *cis*-1,4.

One piece of evidence for the decisive role of free ions in the polymerisation of styrene has been the correspondence between kinetic and conductometric results[44]. However, such correlation has been found to be completely absent in the polymerisation of butadienes[33]: the reactivity of the active centres increases according to the nature of the counter ion in the sequence Li < Na < K (see Table 4), whereas the ability of the centres to dissociate into free ions increases in the opposite sequence K < Na < Li (Table 6).

Table 6. Dissociation constants of live polymers at 25°C ($10^7 K_{diss}$, M).[33]

Counter ion	Carbanion				
	butadiene	styrene	anthracene	butadiene	styrene
	Tetrahydrofuran			Dimethyl ether	
Li	0.85	1.7	—	31	43
Na	0.82	1.0	9.0	5.5	22
K	0.55	0.58	—	2.2	3.2

Thus in electron-donor media the behaviour of active centres in the polymerisation of butadiene is determined not by free ions, although their concentration in these systems is comparable with the concentrations in the case of styrene, but by ion-pairs. This conclusion is further supported by the fact that addition of potassium tetraphenylborate, which lowers the concentration of free carbanions, does not affect the rate of polymerisation of butadiene or the microstructure of the polybutadiene.

Hence it follows that results obtained with one monomer cannot be extended to other monomers without first carefully studying their behaviour, for, as has been shown with butadiene and styrene, different results are obtained depending on the nature of the monomer.

III. ACTIVE CENTRES IN THE POLYMERISATION OF BUTADIENE IN THE PRESENCE OF COMPLEX CATALYSTS BASED ON COBALT AND NICKEL

It has been established above that, in the polymerisation of hydrocarbon monomers, the active centres for growth of polymer chains can be of different types—covalent bonds of various degrees of polarisation, ion-pairs, and free ions—depending on the nature of the alkali metals, the proporties of the medium, and the temperature. The structure of complex catalytic systems containing transition metals is, of course, considerably more complicated, and development of their properties is more diverse than with the alkali metals. The ability of transition metals to exist in different states of oxidation, their tendency to various types of complex formation (σ-, π-, and n-complexes), donor–acceptor interaction, and the varied configuration of the complex systems create a certain boundary between the behaviour of the alkali metals and that of the transition metals in processes of ionic–coordination polymerisation.

Nevertheless, these two types of processes exhibit several common features, and therefore the generalisations applicable to ionic–coordination polymerisation occurring in the presence of alkali metals and their organic compounds may serve as an approach to the consideration of the more complicated type of processes, as remarked at the beginning of the paper.

Many published studies of the polymerisation of hydrocarbon monomers (in particular of butadiene) in the presence of complex cobalt and nickel catalysts indicate that the active centres for growth of the polymer chains are $C^{\delta-}-M^{\delta+}$ bonds (where M represents the transition metal) polarised in the direction characteristic of anionic–coordination processes. The degree of polarisation of this bond depends on the structure of the bimetallic complex, the nature of the ligand, the transition metal, and the properties of the medium. The formation of ion-pairs and especially of free ions in these processes, occurring in non-polar hydrocarbon media, is improbable. Certain kinetic features of these systems will be further considered from this point of view.

In many investigations on processes of this type no clear distinction is made between homogeneous and heterogeneous processes, despite the fact that the structure of the active centres and their development in acts of chain growth depend fundamentally on the properties of the reaction media.

The present paper discusses only processes taking place in homogeneous—mainly hydrocarbon—media. Since these processes are extremely sensitive to various impurities, which when present in minute quantities affect polymerisation, and are sometimes difficult to determine by the usual analytical methods, procedures have been developed for purifying the starting materials and also a vacuum dilatometric method, which practically eliminate their presence in the reaction medium and their influence on the processes under investigation.

1. Polymerisation of Buta-1,3-diene in Benzene Solutions in the Presence of the Complex System $CoPy_2Cl_2 + R_2AlCl$

A considerable amount of work has been done[46–51] on the polymerisation of buta-1,3-diene in the presence of complex "cobalt" catalysts, with many interesting observations and several hypotheses on their mechanism. In particular, it has been shown that these processes involve the

formation of polybutadiene chains in which *cis*-1,4-units greatly preponderate (95–98%), this being characteristic of a coordination mechanism.

Nevertheless, many fundamental questions associated with the behaviour of active centres in the systems still remain unanswered, and attempts to settle them have led to contradictory results. Researches with the aim of helping to fill this gap have been conducted in the Lomonosov Moscow Institute of Fine Chemical Technology[34,52-54]. These investigations of the polymerisation of butadiene in the presence of a catalytic system comprising $CoPy_2Cl_2$ and R_2AlCl (where Py represents pyridine, and R isobutyl or ethyl) have established an extremal dependence of the initial rate of polymerisation and increase in molecular weight of the polymers on the concentration of water added in small amounts to the initial reaction mixture. However, the small number of experiments and the order in which water was added in these investigations did not permit accurate determination of the actual concentrations of added water or the corresponding positions of the maxima on the plot of initial rate of polymerisation against initial concentration of water.

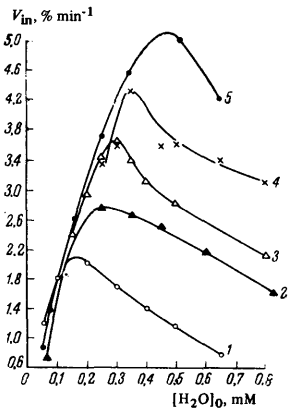

Figure 2. Dependence of initial rate of polymerisation of 1.56 M butadiene on initial concentration of water at 21°C with $[Al]_0/[Co]_0 = 400$ and cobalt concentrations ($[Co]_0$, mM) of:
1) 0.010; *2*) 0.012; *3*) 0.014; *4*) 0.017; *5*) 0.020.

Further examination of these systems by Volkov[55] using an improved dilatometric method has led not only to a more exact determination of the initial concentration of water and the corresponding position of the maxima but also to the possibility of assessing the main features of these processes associated with the properties of the active centres under various conditions. However, the main problem of the structure of the initial complex and its active forms could not be solved unambiguously even in these investigations, owing to the need to conduct the processes at extremely low concentrations and to the instability of the complex system during polymerisation.

In particular, the instability of the initial pure catalytic system is shown by the fact that the polymerisation of butadiene proceeds at a negligible rate, forming a polymer of low molecular weight, and after 2–3% conversion it stops completely. Separate experiments have established that irreversible breakdown of the whole catalytic system has occurred.

On the addition of water the rate increases sharply over the concentration range 0.05–0.8 mM, passes through a maximum, and then falls slowly. The molecular weight of the resulting polymer increases with increase in the initial concentration of water.

These phenomena are illustrated in Fig. 2, which shows the dependence of the initial rate of polymerisation V_0 on the initial concentration of water $[H_2O]_0$ for various initial concentrations of the complex cobalt catalyst $[Co]_0$ at a constant butadiene concentration of 1.56 M and a temperature of 21°C. The ratio between the aluminium and the cobalt components of the combined catalyst was also maintained constant at $[Al]_0/[Co]_0 = 400$. It was shown that, provided that this ratio exceeds 200, further increase in $[Al]_0$ has no effect on the rate of polymerisation[56]. The phenomena illustrated in Fig. 2 therefore depend solely on the initial concentrations of the cobalt component of the catalyst $[Co]_0$ and of the added water $[H_2O]_0$.

It must be remarked that Fig. 2 represents only those reactions which start and are complete in the initial stage of the process and which are very rapid. Among them are formation of the catalytic complex from the initial components, interaction of cobalt complex with water, initiation of the monomer, and reactions leading to a fall in rate after the system has reached the maximum rate of polymerisation V_{max}.

It is evident from Fig. 2 that water tends to favour both formation of an active catalytic system and increase in its activity by increasing the concentration of active centres produced from the initial catalyst as the concentration of added water increases. When the maximum rate of polymerisation is reached, the active centres acquire their greatest stability. Further increase in $[H_2O]_0$ leads to irreversible breakdown of the active centres, which may be supposed to involve their hydrolysis. The conditions under which the maximum rate of polymerisation is reached are listed in Table 7.

Table 7. Conditions for maximum rates of polymerisation.

$[Co]_0$, mM	$V_{0,max}$, % min^{-1}	10^3k, M^{-1} min^{-1}	$[H_2O]_{0,max}$, mM	$\alpha = \frac{[H_2O]_{0,max}}{[Co]_0}$
0.010	2.20	0.55	0.16	16.0
0.012	2.80	0.51	0.25	20.8
0.014	3.65	0.56	0.30	21.4
0.017	4.30	0.56	0.35	20.6
0.020	5.05	0.53	0.45	22.50
				Mean = 21.4

The highest rates of polymerisation and the greatest stability of the active centres are governed by a constant ratio of the initial concentrations of water and the cobalt complex of

$$[H_2O]_0/[Co]_0 = \alpha = 21.4.$$

It follows from Table 7 that the rate of polymerisation in the neighbourhood of the maximum is

$$V_{max} = K_{gr} \cdot K' ([Co]_0 [H_2O]_0)^{1/2} [M]_0,$$

while the concentration of active centres is

$$[\overset{*}{Co}]_{max} = K' ([Co]_0 [H_2O]_0)^{1/2}.$$

Table 7 includes values of the rate constant, which is given by the product $K = K_{gr}K'$.

Polymerisation involving fractional powers of the initiator concentration is not altogether usual with processes in which complex catalysts take part. It is true that a similar relationship is observed when organic compounds of the alkali metals are used as catalysts, and has recently been found (see next subsection) in the polymerisation of butadiene under the influence of π-allyl complexes of nickel. In all these cases the catalyst is associated, being present in particular as dimers, and only their dissociation products possess active properties. It is possible that analogous phenomena take place in the present case.

Thus the highest concentration of initial active centres occurs in the region of the maximum (Fig. 2). The fact that fall in the initial rate of polymerisation following the maximum is due to decrease in the number of initial catalytic centres—not to termination of the growing chains—follows from the linear increase in the molecular weight of the polymers in this region (see below).

It may be supposed that the irreversible breakdown of the initial active centres is due to hydrolytic reactions, when water is present in the system in concentrations exceeding the possible increase in the number of active centres. Hence it follows that decomposition is caused by the excess of water $[H_2O]_0 > [H_2O]_{max}$.

Water has been regarded above as taking part directly in all interactions with the cobalt centre of the catalytic complex. However, the presence of R_2AlCl in large excess can hardly be of no consequence with respect to water. On the other hand, keeping a solution of R_2AlCl, water, and butadiene in benzene under the conditions of the maximum following addition of $CoPy_2Cl_2$ produced no change in the process of polymerisation. This indicates that no bonding of water into any stable compounds occurs as a result of interaction of water with R_2AlCl, but a few unstable active compounds, of enhanced electron-acceptor ability, may be formed, e.g.

$$R_2Al\overset{\delta-}{\underset{OH}{\overset{Cl}{<}}}\cdots\overset{\delta+}{H}.$$

As noted earlier, hydrolytic reactions occur at concentrations of water exceeding $[H_2O]_{max}$, and these affect also the R_2AlCl. However, the stable products are inactive towards polymerisation. Several investigators regard aluminium oxide as having an activating function[57]. However, replacement of water by an equivalent amount of aluminium oxide diminished the activity of the catalytic system, and the process ceased at 8–10% conversion.

It follows from the above facts that rapid formation of active centres takes place at the very start of the process, on mixing the initial components, their concentration being determined, it may be supposed, by the further development of polymerisation with time.

This hypothesis is supported by kinetic data obtained under conditions of the maximum $[H_2O]_0 = \alpha[Co]_0$ and with excess of water $[H_2O]_0 > \alpha[Co]_0$. It is seen from Fig. 3 that the rate of polymerisation is actually almost constant up to 30% conversion (curves *3–5*), whereas curves *1* and *2*, obtained in experiments with $[H_2O]_0 < \alpha[Co]_0$, show a fall in rate with time, which indicates that processes leading to breakdown of the active centres occur in these systems.

These phenomena, occurring with small additions of water, can be explained by the decrease with time in the number of initially formed active centres—equivalent in number to $K'([Co]_0[H_2O]_0)^{\frac{1}{2}}$—owing to distribution of the water among the many cobalt centres free from water, which causes instability of the catalytic system as a whole. The development of instability of the system in the range up to the maximum, accompanied by decomposition of the catalyst, can be illustrated by the results plotted in Fig. 4. Curve *1* shows the dependence of the percentage conversion on the time. The spontaneous breakdown of active centres in the catalyst, which is responsible for the decrease in the rate of polymerisation with time, is described by a unimolecular law.

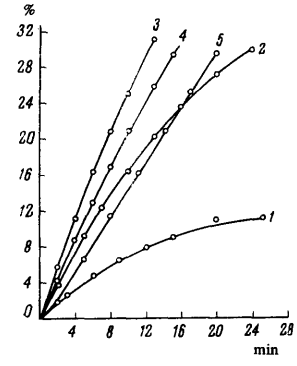

Figure 3. Dependence of percentage conversion of 1.56 M butadiene on time at 21°C with $[Co]_0 = 0.012$ mM, $[Al]_0/[Co]_0 = 400$, and concentrations $[H_2O]_0$ (mM):
1) 0.06; *2*) 0.12; *3*) 0.25; *4*) 0.60; *5*) 0.80.

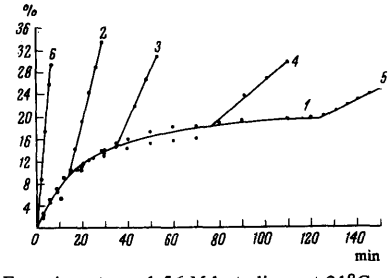

Figure 4. Experiments on 1.56 M butadiene at 21°C with $[Co]_0 = 0.017$ mM, $[H_2O]_0 = 0.05$ mM, and 0.30 mM H_2O added during polymerisation, after (min):
1) no water added; *2*) 15; *3*) 35; *4*) 75; *5*) 125; *6*) 0 (i.e. $[H_2O]_0 = 0.35$ mM, corresponding to $[H_2O]_{max}$).

The straight lines *2–5* in Fig. 4 represent the kinetic effects due to the addition of water in amounts such that its total concentration would equal that corresponding to the conditions of the maximum and described by the straight line *6*. These results show that (1) the rate of processes occurring on the introduction of water at various stages in polymerisation is lower than the maximum rate, although the total added water corresponds to that for the maximum; (2) the rate of these processes falls with increase in the time of introduction of the additional amounts of water; and (3) the rate of freshly occurring processes is constant with time, as is that of the processes occurring in the presence of excess of water, which indicates transition of the initial system from the condition $[H_2O]_0 < \alpha[Co]_0$ to the condition $[H_2O]_0 > \alpha[Co]_0$.

The above generalisations apply to the polymerisation of butadiene, the rate of which is determined by the concentration of the initial active centres, not by chain growth or chain termination. In the region of the maximum, where the system acquires its greatest stability, the rate of polymerisation during the process depends solely on the first power of the varying concentration of the monomer.

The mean molecular weight of the polymers $\overline{M}_\eta$ increases with increase in the concentration of initial water $[H_2O]_0$ and is independent of the extent of polymerisation. Fig. 5 shows that $\overline{M}_\eta$ is a linear function of the initial concentration of water, the major part of the graph relating to the region following the maximum, i.e. to the region in which the rate of polymerisation falls. These results, together with those cited earlier, show that chain termination does not occur in the course of polymerisation, but chain-transfer reactions are clearly evident, and determine the molecular weight of the polymers formed.

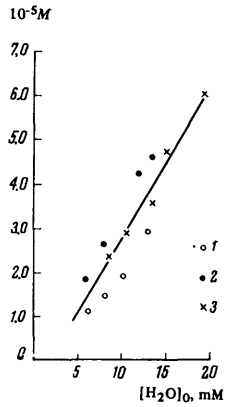

Figure 5. Dependence of molecular weight of polymers on initial concentration of water at 21°C with initially 1.56 M butadiene, $[Al]_0/[Co]_0 = 400$, and concentrations ($[Co]_0$, mM): *1*) 0.010; *2*) 0.012; *3*) 0.017.

Timofeeva [56] has studied the nature of the carrier for the growing chains.

These investigations have established that, with constant initial concentrations $[H_2O]_0$ and $[Co]_0$, the dependence of the reciprocal of the molecular weight on the initial concentration $[R_2AlCl] = [Al]_0$ is described, over a wide range of concentrations, by the relation

$$\frac{1}{\overline{M}_\eta} = a[Al]_0 + C$$

where a and C are constants. These results are consistent with Fig. 5, which shows that the increase in $\overline{M}_\eta$ with increase in $[H_2O]_0$ is smaller the greater the initial concentration $[Al]_0$.

Thus the mean molecular weight of the polymers depend on two factors—(1) interaction with R_2AlCl, which favours chain transfer, and (2) the effect of $[H_2O]_0$, which promotes chain propagation—the ratio $[Al]_0/[H_2O]_0$ reflecting the effect of the two factors, acting in opposite directions, on the molecular weight of the resulting polymers. The reciprocal of the mean degree of polymerisation $\overline{P}_\eta$ can be written

$$\frac{1}{\overline{P}_\eta} = \frac{K_{tr}[Al]_0}{K_{gr}[H_2O]_0}[M]_0$$

where K_{tr} and K_{gr} are constants representing chain transfer and chain propagation respectively. Fig. 6 shows that the direction in which $\overline{M}_\eta$ varies with the initial ratio $[Al]_0/[H_2O]_0$ corresponds to the above equation.

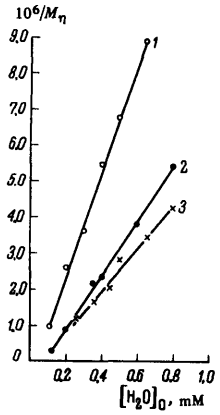

Figure 6. Dependence of $1/M_\eta$ on the ratio $[Al]_0/[H_2O]_0$ under the same conditions as for Fig.5.

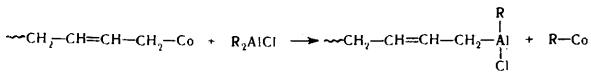
The activity parameters of the bond $C^{\delta-}-M^{\delta+}$, on which the microstructure of the polymer chains depends, exhibit considerable stability: under all the conditions employed, polymers containing an overwhelming preponderance (~ 98%) of *cis*-1,4-units are formed, with the exception of polymers of low molecular weight, produced when this catalytic system is used in the absence of water. In the latter case the molecular chains comprise 74.2% of *cis*-1,4-units and 21.4% of 1,2-units.

The carbon–cobalt bond may be either a polarised covalent bond, a bridging bond, a π-allyl bond, etc. Without prejudging the nature of the bond, which requires special consideration, we can confine ourselves to the hypothetical scheme



to illustrate the chain-transfer reactions.

As an electron-acceptor agent, water solvates the cobalt atoms, increases its fractional positive charge, and strengthens the carbon–cobalt bond. The degree of solvation probably increases even after the concentration of water has reached a twentyfold excess over that of cobalt, which is necessary to stabilise the active centre and suppress chain-transfer reactions.

Other electron-acceptor compounds, such as aluminium trichloride, tin tetrachloride, and hydrogen chloride, also tend to strengthen the carbon–cobalt bond, but the concentration curves for the rate of polymerisation do not pass through a maximum, since these compounds are

devoid of the electron-donor properties which water possesses in some measure, as noted previously. The rate of polymerisation reaches a limit as their concentration increases.

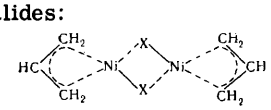
Strong electron-donor compounds (ethers, amines, tetrahydrofuran) tend to break down the active centres [58,59]. This may be supposed to be linked with a tendency to form ion-pairs, which are unstable in the case of the transition metals.

Weak electron donors, such as e.g. dialkyl sulphides, promote polarisation of the carbon–cobalt bond and, as might have been expected by analogy with the alkali metals, change the structure of the polymer units in the direction of forming 1,2-structures [60].

Thus the regularities which have been found determine the nature and the concentration of the initial active centres and the way in which they vary with the initial concentration of water, and correctly describe the changes in the molecular weight of the polymers formed by the polymerisation of butadiene in the presence of the complex system consisting of $CoPy_2Cl_2$, R_2AlCl, and H_2O.

2. Active Centres in the Polymerisation of Butadiene initiated by Nickel Complexes of the π-Allyl Type

The polymerisation of butadiene under the influence of nickel complexes of the π-allyl type now occupies an important place in researches aimed at elucidating the mechanism of polymerisation processes occurring in the presence of complex compounds of transition metals. A comprehensive study of the π-allyl type of complexes has led to several important conclusions on the dependence of their structure on the nature of the metal and the properties of the medium [61–63]. In particular, the structure of the bis-π-allylmetal halides has been established by the application of physical methods [64,65]. The diagrammatic representation of these complexes can be extended also to π-allylnickel halides:



(III)

where X = Cl, Br, I. However, no kinetic investigations were undertaken, which might have given important additional information on the nature of the active centres and their role in the polymerisation of butadiene. Lazutkin and Vashkevich [66] carried out the research necessary to obtain this information, their results being given later.

The pure complexes listed in Table 8 have been obtained by a new method of synthesis [67], and used as polymerisation catalysts. All operations in the preparation, purification, and dispensing of the starting materials and in polymerisation were conducted in a completely sealed apparatus,

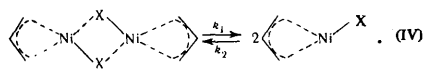
Table 8. Dependence of rate constant on nature of halogen and allyl group in nickel complexes.

Complex	Rate constant (65°C), $M^{-1/2}\,h^{-1}$	Activation energy, kcal mole^{-1}	Pre-exponential factor $10^{-10}A$
π-Allylnickel iodide	1.620	15.3	1.150
π-But-2-enylnickel iodide	1.170	15.2	0.710
π-Methylallylnickel iodide	1.320	15.0	0.590
π-Allylnickel bromide	0.130	15.2	0.078
π-But-2-enylnickel bromide	0.120	15.3	0.085
π-Allylnickel chloride	0.017	15.5	0.015
π-But-2-enylnickel chloride	0.010	—	—
π-Methylallylnickel chloride	0.017	15.5	0.015

which had first been conditioned under a high vacuum. It was found that, independently of the nature of the halogen or the substituents in the allyl group of the initial catalytic complex, the rate of polymerisation in benzene solution was given by

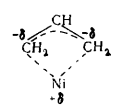
$$-\frac{d[M]}{dt} = k[Cat]^{1/2}[M].$$

This type of dependence of rate of polymerisation on the initial complex, which is unusual for complex systems, indicates that the active centres for chain growth are not dimeric molecules of the original complex but dissociation products:



(IV)

The activity of a monomeric nickel centre is due to its valency unsaturation together with its considerable solvation by benzene. The first stage in formation of an active centre may be addition of a monomer molecule as an adduct to the nickel atom, followed by its rearrangement into a polarised π-allyl bond.

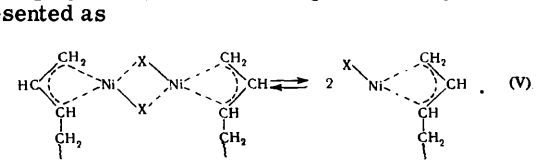


Dissociation of the initial complex is confirmed by the values of the Arrhenius parameters listed in Table 8. The total activation energy is surprisingly stable: for all the catalysts investigated, independently of the nature of the halogen and the allyl group, E_{act} = 15.0–15.5 kcal mole^{-1}. The pre-exponential factors also are practically independent of the nature of the substituent in the allyl group, but they increase substantially with the volume of the halogen atom, in the sequence Cl < Br < I. The increase in volume of the halogen atoms and the consequent steric hindrance constitute the main factor responsible for the increase in rate of polymerisation in the same sequence (Table 8).

All the facts which have been found fit the following kinetic scheme of polymerisation reactions:

1. $A_2 \underset{k_2}{\overset{k_1}{\rightleftarrows}} 2\mathring{A}$
2. $\mathring{A} + M \xrightarrow{k_{in}} \mathring{A}M$
3. $\mathring{A}M_n + M \xrightarrow{k_{gr}} \mathring{A}M_{n-1}$
4. $\mathring{A}M_n + \mathring{A}M_m \underset{k_4}{\overset{k_3}{\rightleftarrows}} M_nA_2M_m$

where A_2 is the initial complex, $\mathring{A}$ the monomeric active centre, M the monomer, and $M_nA_2M_m$ an inactive complex attached to polymer chains. The equilibrium system can be represented as



(V)

The dependence of the rate of polymerisation on the square root of the concentration of the initial complex, which is found to hold over a wide range of concentrations and at various temperatures, leads to two conclusions: (*a*) the equilibrium systems (IV) and (V) are governed by

similar parameters; and (*b*) in the equation for the equilibrium constant

$$K_{eq} = \frac{k_1}{k_2} = \frac{[A^*]^2}{[A_2]} = \frac{(2\alpha)^2[A]}{1-\alpha},$$

the degree of dissociation $\alpha \ll 1$, and then $[A^*] = K_{eq}^{\frac{1}{2}}[A_2]^{\frac{1}{2}}$.

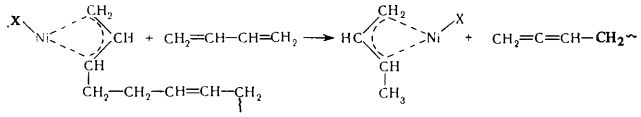
The rates of all the polymerisation processes investigated are given by the general equation

$$-\frac{d[M]}{dt} = K_{gr}K_{eq}^{1/2}[A_2]^{1/2}[M]$$

the changes in rate found with the chloride, bromide, and iodide complexes being determined mainly by variations in K_{eq} under the influence of the volume factor.

trans-1,4-Polybutadiene was always obtained in the presence of iodide and bromide complexes of nickel. The use of chloride complexes of nickel also yields polybutadiene in which *trans*-1,4-units predominate. Sometimes small quantities of *cis*-1,4-structures were also observed, but this cannot be attributed to a specific coordinating effect of the chlorine atoms in the complex. These structural deviations can rather be explained by impurities resulting from decomposition of the complex during prolonged polymerisation, which may last several days.

Chain-terminating reactions, which would have resulted in irreversible deactivation of the active centres, are absent from these processes. The mean molecular weights of the polymers formed are extremely low, varying over the range 10 000–35 000 depending on the condition and the nature of the nickel complexes. Chain-transfer reactions, which determine the molecular weight of the polybutadienes, probably occur as follows:



perhaps with intermediate formation of a hydride bond Ni–H.

Some Aspects of the Modification of Active Centres

The active centres of π-allylnickel halides are extremely sensitive to various substances—oxygen, iodine, Lewis acids, etc.—some of which break down the active centres, whereas others produce new centres possessing a different, sometimes enhanced, activity and, what is especially important, a different stereospecificity.

The system comprising $(NiC_3H_5Cl)_2$ and $TiCl_4$ is one of the large number of such examples[68]. When those substances are mixed in a heptane solution of butadiene, a precipitate of $(NiC_3H_5Cl)_2.TiCl_4$ is formed, and is a new catalyst. It contains all the nickel from the complex (the solution contains only titanium tetrachloride, and possesses no active properties). Polybutadiene of high molecular weight formed on the modified catalyst contains more than 90% of *cis*-1,4-units. This example illustrates an important fact of fairly wide validity: the addition of Lewis acids to solutions of π-allyl systems transfers the process of polymerisation to a heterogeneous phase, thereby changing the parameters of the reactive carbon–hydrogen bond not only owing to formation of a π-allyl complex differing in molecular structure but also in its phase constitution. This is especially significant in the consideration of the phenomena of stereospecificity, which is changed by additions to the reaction medium or the presence of substance of different type.

Another example of processes of this type is provided by results obtained in an investigation of the effect of added allyl halides on polymerisation systems containing π-allylnickel halides[69]. When various quantities of allyl bromide (ABr) are added to a benzene solution of butadiene and π-allylnickel bromide (π-ANiBr), the initial concentration of which in the mixture was the same (Fig. 7), the rate of polymerisation of the butadiene at first increases with increase in the initial concentration $[ABr]_0$, but after an optimum initial ratio is reached, in the present case $[\pi\text{-ANiBr}]_0/[ABr]_0 \simeq 0.5$, remains constant during some initial period (straight line *3*). It is interesting that with high $[ABr]_0$ concentrations the rate of polymerisation tends to a limit, and this occurs sooner the lower the initial ratio $[\pi\text{-ANiBr}]_0/[ABr]_0$ (curves *5* and *4*), which indicates complete decomposition of the initial catalyst (decolorisation of the solution).

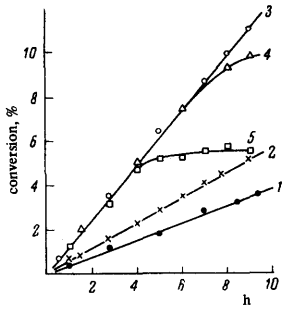


Figure 7. Polymerisation of 1.6 M butadiene in presence of 0.011 M π-allylnickel bromide at 49.3°C and allyl bromide concentrations (M) of: *1*) 0; *2*) 0.00187; *3*) 0.0242; *4*) 0.0512; *5*) 0.1624.

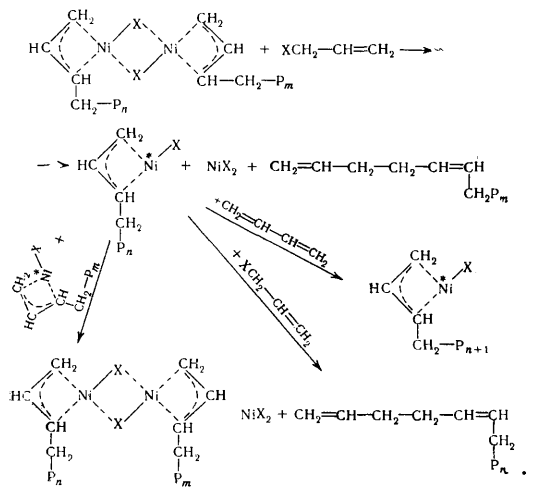
It is especially significant in these phenomena that decomposition of the initial complex π-ANiBr is accompanied by separation of NiX_2 as a highly disperse powder, which with the A_2 or A forms of the initial complex probably forms a new heterogeneous catalyst possessing enhanced total activity. The reactions which are involved in this process can be represented by the scheme



Similar phenomena take place on the addition of various amounts of allyl chloride (ACl) to the system containing π-ANiBr. The difference is that decomposition of the π-ANiBr complex occurs more slowly and with an induction period in the presence of ACl, and a higher $[\pi\text{-ANiBr}]_0/[\text{ACl}]_0$ ratio is required to produce a limiting state than when ABr is added. The total activity of the new complex on nickel chloride is increased several times.

The above results show that the polymerisation of butadiene in systems consisting of π-allylnickel halides and allyl halides involves complicated homogeneous and heterogeneous processes in which active centres of two different types take part, the nature and concentration of which depend on the initial ratio $[\pi\text{-ANiX}]_0/[\text{AX}]_0$ (where the X are halogen atoms which may be the same or different) and on the degree of conversion of the butadiene. The two types of active centres differ in stereospecificity: the homogeneous centres promote formation of *trans*-1,4-polybutadiene, whereas the heterogeneous centres result in preferential formation of *cis*-1,4-units of polybutadiene.

Both types of centre are present together in polymerisation processes, the relation between them being determined by the conditions mentioned above. For this reason the polybutadiene formed in systems containing π-allylnickel bromide have a mixed microstructure depending on the nature of the additions (see Table 9).

Table 9.

Addition	*cis*-1,4, %	*trans*-1,4, %	1,2, %
Allyl bromide	41—74	24—56	2—3
Allyl chloride	76	21	2—3

The facts discussed above provide further confirmation of the need to take into account heterogeneous reactions in the polymerisation of butadiene when considering problems of stereospecificity on the introduction of additives to systems containing the π-allylnickel halide type of complexes.

Relative Strength of CH Acids

A.I.Shatenshtein and I.O.Shapiro

The problem of the differentiating action of solvents on the relative strength of acids is examined from the point of view of the modern theory of acid-base equilibrium, according to which hydrocarbons and their derivatives behave under appropriate conditions as acids. Methods are described for determining the strength of such CH acids. The factors on which the differentiating effect of solvents depends are discussed. The most detailed consideration is given to the question—newly posed in the literature—of the possible causes of the change in the relative kinetic acidity of CH acids produced by solvents, which has been established by measuring the rate of the protophilic isotopic exchange of the hydrogen in them with bases. The bibliography contains 110 references.

I. INTRODUCTION

The essential nature of acid–base reactions and acid–base catalysis was explained by Brønsted's theory[1-5], which not only summarised many phenomena occurring in aqueous and non-aqueous solutions and gave a quantitative description of these phenomena but was also able to make predictions. In the course of time, however, facts accumulated which indicated that the theory was limited and imprecise[6,7]. Thus the discovery of the differentiating action of solvents on the relative strengths of acids and bases contradicted the theory. The mechanism of protolytic processes was found to be more complicated than was postulated by the theory, and substances which according to it were aprotic, i.e. incapable of acting as either acids or bases, could take part in such processes. It became obvious that the theory of acids and bases must be reexamined and refined, by changing the actual definitions of concepts. According to the new definitions[3,8] a *base* is an electron-donor reagent, which possesses affinity for a proton; an *acid* is an electron-acceptor reagent, whose hydrogen takes part in an equilibrium reaction with a base. An

acid combines with a base by means of a hydrogen bond or donates a proton to it. All substances containing hydrogen can under appropriate conditions react as acids. These include all organic compounds, among which are hydrocarbons[8,9]. They are termed carbo-acids or *CH acids*, since the hydrogen is combined with a carbon atom. Our knowledge of hydrocarbons, as of acids and their conjugate bases (carbanions), has greatly increased during recent years[6,10,11], while proof of the acidic function of hydrocarbons has now very greatly extended the acidity scale, which now covers about fifty pK_a units.

New methods were required for the quantitative assessment of the acidity of hydrocarbons, and it was proposed[6,9,14] to supplement methods of determining the equilibrium ionisation constants of the hydrocarbons, i.e. their thermodynamic acidity[12,13], by determining the kinetic acidity of hydrocarbons and their derivatives by measuring the rate constants for the isotopic exchange of hydrogen with strong bases. This method was intended for establishing the strength of very weak CH acids, right down to saturated hydrocarbons, and had the advantage of enabling a quantitative estimate to be made of the acidity of individual carbon–hydrogen bonds in organic molecules[15,16].

A prerequisite for use of the kinetic method to measure the acidities of organic substances is correlation between the rate constants and the ionisation constants of the acids. Correlation of this type was first expressed in the form of Brønsted's relation[17] (in logarithmic form $\lg k = \alpha \lg K + G$, where k is the rate constant, K is the equilibrium constant, and α and G are constants). The Brønsted relation is the prototype of the Hammett equation and its modifications. The physical meaning of all these equations reduces to a statement of the principle of the linearity of free energies[18-21].

An important conclusion of Brønsted's quantitative theory of acid–base equilibrium is that the relative strength of equally charged acids is independent of the solvent (S or M): i.e. $\lg (K_i/K_0)_S - \lg (K_i/K_0)_M$ is constant (where K_i is the ionisation constant of any acid and K_0 that of the standard acid). If values of $\Delta pK = pK_0 - pK_i$ in any two solvents are plotted along the coordinate axes, the points should lie on a common straight line passing through the origin at an angle of 45° to the horizontal axis. Actually, however, if the solvents differ in physical and chemical properties, the points for acids differing in structure lie on more than one straight line. This shows the differentiating effect of solvents on the relative strengths of acids as expressed by the value of ΔpK.

The present paper is concerned mainly with the differentiating action of solvents on the kinetic acidity of CH acids determined from the isotopic exchange of hydrogen. This question has been posed recently, and little work has yet been done on it. First it is necessary to consider briefly the factors on which depends the differentiating effect of solvents with respect to the strength of acids, and to indicate the methods which are available for determining the strengths of CH acids.

II. FACTORS DETERMINING THE DIFFERENTIATING EFFECTS OF SOLVENTS

1. Correlation of Thermodynamic and Kinetic Acidities

Arndt and Eistert[22] were the first to emphasise the necessity of introducing the concept of the proton lability of compounds, and to note that the dissociation constant K of an acid is by no means a simple function of the lability of the hydrogen it contains. In their opinion a parallelism between the dissociation constants of acids and the proton labilities of hydrogen in them, i.e. kinetic parameters, is possible only with compounds of similar structure. This was confirmed by Pearson and Dillon[23], who measured, from the rate of bromination, rates of ionisation in aqueous solution for a large number of CH acids containing one or more strongly polar groups (carbonyl, ethoxycarbonyl, nitrile, nitro, and sulpho). They compared the values of $\lg k$ and pK_a for the acids, the latter parameters being determined either by them or by other workers, e.g. potentiometrically or by some other method.

While a general correlation was observed between $\lg k$ and pK_a for a series of acids, large departures from it were found. The reasons for deviations from the Brønsted relation have been discussed in detail by Bell[5,24,25], Leffler, Grunwald[19,26,27], etc. The deviations are determined by the structure and the conditions of solvation of the initial substances, the transition states, and the reaction products. If the structure of the transition state on ionisation of the acid is close to the structure of its anion, the parameters tending to enhance the stability of the latter will stabilise also the transition state, and this should favour an increase both in the equilibrium constant and in the rate constant of ionisation; in this case correlation can be expected between $\lg k$ and pK_a.

Let us write the equation for the ionisation of CH acids by a base B in the form

$$\equiv C-H + B \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \equiv C^- + BH^+ \qquad (1)$$

where k_1 is the ionisation rate constant, k_{-1} is the rate constant of the reverse reaction (addition of the acid proton to the carbanion $\equiv C^-$), and $k_1/k_{-1} = K_a$ is the ionisation equilibrium constant.

Cram[10] notes that a linear correlation between rate constants and equilibrium constants of ionisation requires constancy of the rates of recombination of various carbanions with a proton having the same donor: in fact, if k_1 is constant, it follows that $k_1 = \text{const} \times K_a$.

2. Differentiating Action of Solvents on Thermodynamic Acidity

The reasons for the differentiating action of solvents on thermodynamic acidity have been discussed by Izmailov[7]. He shows that the dissociation of protolytes involves a series of equilibria—solvation of molecules and ions of the acids, ionic association—and deduces an equation for the dependence of the difference ΔpK_a between the dissociation constants of the acid in two solvents M and S on their properties, in particular their activities (a_M and a_S, the standard state being a vacuum), and on the energy of solvation of the molecules (A'_{mol}, A_{mol}) and the ions (A'_{ion}, A_{ion}) of the acid:

$$\Delta pK_a = \lg \frac{a_M}{a_S} + \lg \frac{K_{a(MH^+)}}{K_{a(SH^+)}} + \frac{\Sigma A'_{ion} - \Sigma A_{ion}}{2.3RT} - \frac{A'_{mol} - A_{mol}}{2.3RT} \qquad (2)$$

$K_{a(MH^+)}$ and $K_{a(SH^+)}$ being the thermodynamic acidities of the lyonium ions MH^+ and SH^+ respectively in M and S.

The first two terms in Eqn. (2) are the same independently of the structure of the acid. Hence the differentiating effect of solvents on the dissociation constants of acids depends on the relative solvation energies of the ions and molecules of the acid in the solvents. If the acids are similar in structure, the last two terms in Eqn. (2) differ

little in magnitude. This is not observed when acids differing in structure are compared in solvents of different types, and then a differentiating effect is observed.

Izmailov has also suggested that values of ΔpK_a should be measured by a method of single null activity coefficients γ_0, which represent the change in energy of a substance on passing from an infinitely dilute solution in any non-aqueous solvent to an infinitely dilute aqueous solution:

$$\Delta pK_a = 2 \lg \gamma_{0(ion)} - \lg \gamma_{0(mol)}. \quad (3)$$

The same equation has been deduced subsequently by Grunwald[28].

Differences in the energy of interaction of acid molecules differing in structure with solvents of different chemical types result from the formation of solvates differing in composition, stability, and polarity. According to Izmailov the solvates—not molecules of the acid itself—undergo ionisation. The differentiating action of solvents on the relative strengths of acids is due to differences in the solvation energy of ions and molecules by the solvent, differences in the solvation energy of the anions being especially important. This point was subsequently stressed also by Parker[29-31].

Equations (2) and (3) are thermodynamic in character, and do not reveal the nature of the forces responsible for solvation of the acid molecules and ions. Account must be taken[29] of the following parameters—proton affinity of the solvent molecule, its ability to form a hydrogen bond or other type of donor–acceptor interaction with the acid or with the anion, forces of electrostatic dipole–dipole and ion–dipole interaction, and also dispersion interaction between solvent molecules and acid anion—the last depending on the polarisability and the ionisation potentials of the solvent molecule and the anion, and on the radius of the latter. The electrostatic component of the solvation energy is a function of the dipole moments of acid and solvent molecules, the dielectric constant of the latter, and the ionic charge and radius (for further details see Refs. 7, 19, and 32–34).

3. Relative Rates of Steps and Transition-state Structures in Protophilic Isotopic Exchange of Hydrogen

Arndt and Eistert[22] pointed out that measurement of the rate of deuterium exchange could suitably be used for determining lability of hydrogen in organic compounds. They considered that signs of proton lability were absent with fluorene and triphenylmethane, for example, since these compounds exhibited no isotopic exchange of hydrogen with deuterioalcohol.

A kinetic method for the quantitative determination of the acid and basic properties of hydrocarbons follows from the concept of the protolytic nature of heterolytic isotopic exchange, in which hydrocarbons take part as acids or bases[35]. This idea arose and was justified during investigation of the isotopic exchange of hydrogen in hydrocarbons with non-aqueous solvents which are strong bases or acids[6].

In 1950 Shatenshtein and Vyrskii[14] proposed the use of liquid ammonia for determining the kinetic acidity of hydrocarbons. Because of the protophilic nature of ammonia and the high proton affinity of the amide ion, which catalyses exchange reactions in liquid ammonia, hydrogen can be exchanged for its isotopes even in saturated hydrocarbons, which are then reacting as very weak CH acids. This placed the kinetic method for determining the acidity of hydrocarbons on a practical course, and led to many analogous investigations in the USSR and abroad (see e.g. Tupitsyn and Zatsepina[36-38], Streitwieser[11,39-43], Schriesheim[44], Ebel[45], etc.).

It follows from subsection 1 that a condition for the kinetic method of determining the strength of CH acids to be applicable is a linear relation between their ionisation rate and equilibrium constants. And this in turn presupposes a direct relation between the measured rate constant of isotopic exchange and the ionisation rate constant of the CH acid involved in the exchange reaction.

The problem of the relation between the experimental rate constant of hydrogen exchange and the rate constants of its individual stages is closely linked with that of the structure of the transition state in the rate-determining stage of the isotopic exchange of hydrogen. Information on these questions is obtained by measuring the deuterium–tritium kinetic isotope effect (k.i.e.), i.e. the ratio of the rate constants for the exchange of deuterium and tritium respectively present in the same bonds with a carbon atom (k_D/k_T). The k.i.e. of reactions involving the protophilic exchange of hydrogen isotopes were first determined by Yakushin[46-49] in a series of studies in the Isotopic Reactions Laboratory of the Karpov Institute.

In exchange reactions with liquid ammonia (in absence of a catalyst and catalysed by potassamide) and also with aliphatic amines (methylamine and ethylamine) the ratio $(k_D/k_T)_{0-25\,°C}$ varied from 1.9 to 2.7 for different systems. Within these limits the ratio has a tendency to increase if the base becomes more protophilic or the reactivity of the CH acid increases.

Analysis of k.i.e. measurements combined with other data on protophilic substitutions of hydrogen (in particular on metallation reactions) has led to a two-stage mechanism[48,49]. The first stage consists in attack by the base B^- on the hydrogen atom combined with the carbon atom, the bond being stretched or in the limit ruptured with formation of the carbanion $\equiv C^-$:

$$\equiv C - D(T) + B^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \equiv C^- + D(T)B. \quad (4)\dagger$$

In the second stage a proton of the solvent molecule HB adds to the intermediate carbanion, to give a compound differing in isotopic composition:

$$\equiv C^- + HB \xrightarrow{k_2} \equiv CH + B^-. \quad (5)$$

The scheme does not include the gegenion (the metal cation), which is incorrect, since the gegenion can in principle be involved in the transition state.

If the bond with the hydrogen isotope is completely ruptured in the transition state, the k.i.e. value is calculated by means of the equation[50]

$$k_D/k_T = e^{N_0(h\nu_{C-D} - h\nu_{C-T})/2RT} \quad (6)$$

where k_D and k_T are the rate constants for exchange of protium by deuterium and by tritium, ν_{C-D} and ν_{C-T} are the C–D and C–T stretching frequencies, and $(k_D/k_T)_{25\,°C} = 2.6$. If deformation vibrations are also perturbed, $(k_D/k_T)_{25°C} = 3.2$.

It follows from theory[50-52] that maximum values of k.i.e. correspond to the case in which the reaction velocity is limited by the first stage (4), while its transition state has a linear three-centre structure $[C^{\delta-} \ldots D^{\delta+}(T) \ldots B^{\delta-}]^-$, the hydrogen isotope being located at the centre of symmetry

† The right-hand side of Eqn.(4) can also be written $\equiv C^- \ldots D(T)B$, to show that the carbanion is solvated, and then

$$\equiv C^- \ldots D(T)B \xrightarrow[HB]{k_2} \equiv CH + B^-$$

and the force constants of the C–D(T) and B–D(T) bonds being equivalent one to the other. According to Westheimer[51] disturbance of the symmetry of the linear three-centre transition state produces a decrease in k.i.e.

Bell[53] has shown that the degree of equivalence of the force constants of the bonds with the hydrogen atom in the transition state is measured by the difference in pK_a between the reactant CH acid and the conjugate acid of the reactant base. A symmetrical transition-state structure corresponds to $\Delta pK_a \simeq 0$; conversely, if ΔpK_a is large, the transition state is very unsymmetrical, and the ratio k_D/k_T differs little from unity.

The above experimental values of k_D/k_T, obtained from a study of exchange reactions with liquid ammonia and amines, are close to the theoretical maximum value. This enabled a two-stage mechanism to be considered, and the first stage of the reaction to be accepted as the limiting stage, while the transition state was almost symmetrical[46–49]. The results and the principal conclusions of this work[46–49] have been confirmed by Streitwieser[11,39–42], Tupitsyn[36–38], and Ebel and his coworkers[45].

For reactions occurring under steady-state conditions the concentration of the intermediate carbanion is constant, and the equation[10,36,54,55]

$$k = \frac{k_1 k_2}{k_{-1} + k_2} \qquad (7)$$

links the experimental rate constant of the exchange reaction k with the rate constants of the stages k_1, k_{-1}, and k_2.

Let us suppose that the rate of the exchange reaction is limited by ionisation of the C–D(T) bond, while the intermediate carbanion is relatively stable. If $k_2 \gg k_{-1}$, we can neglect k_{-1} in the denominator of Eqn. (7). Hence $k = k_1$: i.e. the observed rate constant of the exchange reaction is equal to the rate constant for ionisation of the C–D(T) bond. In such case measurement of the kinetics of hydrogen exchange (in particular with liquid ammonia or with amines) adequately characterises the acidity associated with the given bond.

Kinetic studies of the protophilic isotopic exchange of hydrogen in C–H bonds with dimethyl sulphoxide catalysed by an alkali-metal t-butoxide has shown[56] substantial differences in the relative kinetic acidities of certain CH acids compared with those found from measurements in solutions in ammonia. A similar phenomenon was noted by Streitwieser[57] on comparing his kinetic measurements on exchange reactions in cyclohexylamine with Schriesheim's measurements[44] in dimethyl sulphoxide (for fuller details see below). Deuterium–tritium exchange with dimethyl sulphoxide gave[56,58–60] a value of k_D/k_T close to unity.

For deuterium–tritium exchange involving the methyl group of toluene in the dimethyl sulphoxide–potassium t-butoxide system Jones[61] has explained the low k.i.e. on the basis of Bell's conclusions[53], considering that, since the difference in pK_a between toluene and t-butyl alcohol is large ($\Delta pK_a \simeq 20$), the ionisation stage corresponds to an extremely unsymmetrical transition state. In this state the proton is far closer to the base (B^-) than to the benzyl anion (A^-): i.e. $[A^{\delta-} \ldots H^{\delta+} B^{\delta-}]^-$.

Cram[10,54,62] had earlier observed a low value of k.i.e. for racemisation catalysed by a t-butoxide in dimethyl sulphoxide. In his opinion, supported by Streitwieser[57,63] and by Schriesheim[60], the reason for the low k.i.e. is that the rate of the exchange reaction is limited by a stage—the second one (Eqn. 5)—which is insensitive to isotopic replacement of hydrogen in the CH acid. Its low rate may be due to the fact that t-butyl alcohol formed in the first stage (Eqn. 4) slowly diffuses away from the carbanion, which is again able to capture a heavy isotope of hydrogen: i.e. $k_2 \ll k_{-1}$‡. In such case the term k_2 in the denominator of Eqn. (7) can be neglected, so that $k = k_1 k_2 / k_{-1} = K k_2$. Thus there is no direct relation between the rate constants of the exchange reaction and of ionisation. If Cram's treatment is correct, the low value of k.i.e. is an indication that measurements of the rate of the exchange reaction in the given medium do not give a correct idea of the strength of the CH acid. We shall return to the discussion of this question again.

III. DETERMINATION OF STRENGTH OF CH ACIDS

The acidity of hydrocarbons was first measured by Conant and Wheland[12], and the acidity scale was improved and extended by McEwen[13]. In these studies a colorimetric method was used to examine metallation equilibria in benzene or ethereal solution

$$RH + R'M \rightleftarrows R'H + RM \qquad (8)$$

where RH and R'H are hydrocarbons, while RM and R'M are their metal derivatives. With pK_a for one substance taken as standard (on McEwen's scale methanol has $pK_a = 16$), the difference in pK_a is determined. Thus the scale depends on the standard adopted. This work, undertaken in the 1930s, has been continued only recently by Streitwieser and his coworkers[64,65], who have measured the equilibrium constants between lithium or caesium cyclohexylamide and hydrocarbons (mainly fluorene derivatives) in cyclohexylamine, with phenylfluorene having $pK_a = 18.49$ taken as standard

Several papers, mainly by American workers[62,66–72], have reported the use of an indicator method of determining Hammett's acidity function[73] for measuring the pK_a of CH acids. The function H_- represents the ability of a base to detach a proton from an electrically neutral acid HA. By definition

$$H_- = \lg \frac{a_{H^+} f_{A^-}}{f_{HA}} = pK_a + \lg \frac{A^-}{HA} \qquad (9)$$

where a_{H^+} is the proton activity, f_{HA} and f_A are the activity coefficients of the acid and its anion, and HA and A^- are their concentrations. In dilute aqueous solution the H_- scale is identical with the usual pH scale, which is its virtue (papers on the acidity function H_- have been reviewed[74]).

The function H_- has been determined for many systems containing bases (e.g. mixtures of dimethyl sulphoxide with water or alcohol, in which tetra-alkylammonium hydroxides, caustic alkalis, or alkoxides are dissolved—for reviews of several systems see Refs. 74–76).

Kuhn and his coworkers[77–80] have successfully used spectrophotometric measurements combined with H_- data to determine the pK_a of strongly acidic polycyclic ethylenic and other hydrocarbons containing a large number of fused rings (e.g. trisbiphenylenylvinylmethane, $pK_a = 6.2$).

Ritchie[32,33] has recently been able to develop a technique for the potentiometric determination of pK_a for CH acids using a glass electrode in non-aqueous solvents, in particular in dimethyl sulphoxide, this method being suitable for the determination of high values of pK_a (~ 30).

Apart from the above, other methods have been suggested for assessing the equilibrium acidities of hydrocarbons, e.g. by estimating the relative stability of carbanions,

‡ It is assumed[63] that the return stage (k_{-1}) is especially rapid if conversion of the carbanion into the hydrocarbon involves only slight changes in structure.

including those of saturated hydrocarbons, by measuring equilibria in which organometallic compounds are involved. Thus Applequist[81] recommended study of an equilibrium of type

$$RX + R'M \rightleftarrows RM + R'X \qquad (10)$$

(where X = I and M = Li) coupled with equilibrium (8). Dessy[82,83] has shown that a similar stability sequence of the carbanions is obtained by studying a series of exchange equilibria between organomercury and organomagnesium compounds

$$RMg + R'Hg \rightleftarrows RHg + R'Mg\,. \qquad (11)$$

In this paper we are unable to give results obtained by different workers or discuss the reasons for differences in the values of pK_a for the same hydrocarbons obtained by different methods and especially in different solvents, where the differentiating effect of the medium is exhibited[11,18,32,33,65,68]. Discrepancies between the values of pK_a depend both on the method of determination and the standard adopted and on the properties of the solvent, especially on the structure of the CH acids, and even on the nature of the gegenion. Work done before 1965 has been surveyed comprehensively in Cram's book[55], which has been translated into Russian[10].

The suitability of the kinetic method for determining the acidity of hydrocarbons from the rate of isotopic exchange of hydrogen first received a theoretical basis[14] from the existence of a correlation between the logarithm of the rate constant of deuterium exchange with liquid ammonia (the first numeral in the parentheses is the rate constant) and the pK_a value for the same hydrocarbon determined by McEwen[13] (the second numeral in parentheses)—indene (0.4, 21), fluorene (0.02, 25), triphenylmethane (2×10^{-7}, 33), diphenylmethane (7×10^{-9}, 35)—and similar papers have appeared since then.

Dessy[84] has compared McEwen's results[13] with the exchange rate constants (in a dimethylformamide–deuterium oxide–triethylamine mixture) of cyclopentadiene (0.011, 14–15), acetophenone (2.2×10^{-4}, 19), phenylacetylene (6.6×10^{-5}, 21), and fluorene (2.2×10^{-6}, 25). Streitwieser[11,85] has shown a linear relation between the relative rate constant measured in methanol with sodium methoxide as catalyst and the pK_a value which he determined in cyclohexylamine: 9-phenylfluorene (47, 18.5), benzo[*c*]fluorene (26.3, 19.4), benzo[*a*]fluorene (7.6, 20), 4,5-methylenefluorene (1.93, 22.6), fluorene (1, 22.9), and benzo[*b*]fluorene (0.60, 23.2).

A rather more indirect comparison establishes[86] a linear relation between the kinetic acidities of 9-substituted fluorenes determined in methanolic solution (45°C) and the dissociation constants of acetic acids having the same substituents (CH_3, CH_3CH_2, $C_6H_5CH_2$, CH_3OCH_2, CF_3).

The good correlation between the thermodynamic and the kinetic acidities of hydrocarbons induced Cram (Ref. 10, p. 28) to try to set up a single acidity scale for hydrocarbons, based both on equilibrium and on kinetic measurements made by McEwen[13], Streitwieser[11], Applequist[81], and Dessy[84] (including Wooding and Higginson's data[87] for acetylene). This scale is named after the authors as the MSAD scale. Cram[10] stresses that "subsequent work will undoubtedly lead to modification of this scale".

Mention may be made also of comparisons between the results of polarographic measurements and data on the stability of carbanions obtained by an independent method. Streitwieser[88] notes that only limited application can be made of the polarographic reduction of benzyl chlorides and polycyclic arenemethyl chlorides for determining the stability of carbanions.

Dessy[83] used the polarographic reduction of organomercury compounds for this purpose. Reutov, Beletskaya, and their coworkers[89,90] proposed a polarographic scale of CH acidity based on the correlation

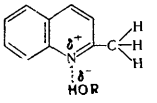
$$\alpha E_{1/2} = f(pK_a) \qquad (12)$$

where $E_{1/2}$ is the half-wave potential in the polarographic reduction of symmetrical organomercury compounds R_2Hg, α the electron transfer coefficient, and pK_a the ionisation equilibrium constant of the acid RH on the MSAD scale. Hence a correlation is observed between electrochemical kinetic data and the strengths of CH acids.

However, correlation is not always found between kinetic and thermodynamic values. The principal question in which we are interested in this paper is the differentiating effect on the relative kinetic acidity of CH acids determined by measuring the rates of isotopic exchange of hydrogen. Section II contains a general discussion of the factors which may govern the appearance of a differentiating effect.

We shall now show with actual examples that the change in the relative kinetic acidity can be caused both by specific solvation of the acids themselves, as a consequence of which the lability of the hydrogen varies, and by phenomena occurring during the reaction whose rate is used to measure the kinetic acidity.

For example, a comparison of the rates of isotopic exchange of hydrogen in certain hydrocarbons and nitrogen heterocycles with liquid ammonia and with alcohols showed[91] that the rate of exchange of hydrogen in a methyl group of the heterocycle is abnormally high in alcoholic solutions. Whereas the rate constant for the exchange of hydrogen in a methylene group in the hydrocarbon (indene, fluorene) with ammonia exceeds that with ethanol by factors of 10^7–10^8, hydrogen in the methyl group of quinaldine exchanges more rapidly with ethanol than with ammonia by a factor of 25. This is explained by specific solvation of the quinaldine molecule in alcoholic solution by formation of a hydrogen bond between the alcoholic hydroxyl and the nitrogen atom, which thus acquires a positive charge



Displacement of the electrons forming the methyl CH bonds towards the nitrogen facilitates protonation of these hydrogen atoms. The effect is stronger the more acidic the alcohol, and hence the higher the energy of the hydrogen bond: ethylene glycol (90, 547) > methanol (30, 50) > ethanol (20, 12) > propan-2-ol (7, 1) (the parentheses indicate the rate constants of the exchange reaction $10^7 k_{120°C}$ s^{-1} and the relative ionisation constants of the alcohol[92]).

An analogous differentiating effect is observed[93] on comparing the rates of deuterium exchange in the methyl group of quinaldine and in the methine group of triphenylmethane with ethylenediamine and aminoethanol. Owing to the more protophilic character of the former solvent, the hydrogen in triphenylmethane is exchanged five times as rapidly as in quinaldine, whereas with the latter solvent the hydrogen in quinaldine exchanges eight times as rapidly as in the hydrocarbon, because of the formation of a hydrogen bond between the alcoholic hydroxyl and the heterocyclic nitrogen atom.

In the above examples the differentiating action of the solvent on the kinetic acidity was due to the specific solvation in the ground state of molecules of CH acids distinguished from the others by their structure. Let us now

turn to examples which reveal the effect of catalytic systems in different solvents on kinetic acidities also determined by hydrogen exchange, where the differentiating effect depends on phenomena associated with the course of the reaction itself.

Mention has already been made (Section II, 3) of the very large differences in relative kinetic acidities which we have found[56] on comparing the kinetics of deuterium exchange with dimethyl sulphoxide (catalysed by potassium or lithium t-butoxide) and with liquid ammonia (catalysed by potassamide). Thus the rate constants for exchange with dimethyl sulphoxide of C–D bonds in the methyl group and in the ring of toluene were found to differ by factors of 10^6 instead of the 10^2 on exchange with ammonia[56].

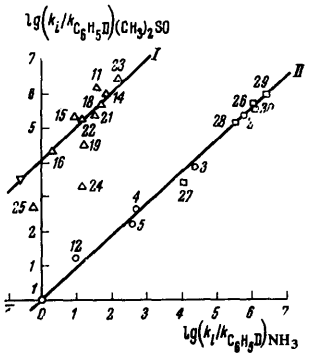


Figure 1. Comparison of kinetic acidities, determined in liquid ammonia with potassamide as catalyst, and in dimethyl sulphoxide with potassium t-butoxide as catalyst, for the exchange of deuterium in:
I) alkyl groups; II) the benzene ring and alkylthio-groups.

In Fig. 1[94] values of $\lg(k_i/k_{C_6H_5D})_{(CH_3)_2SO}$ are plotted against $\lg(k_i/k_{C_6H_5D})_{NH_3}$ for a series of CH acids (a key to the numbering of the compounds in Fig. 1 and the following diagrams will be found in Table 1). The points for the methyl groups in toluene, the xylene isomers, and the tolyl ethers (other than the *para*-isomers) and for the alkyl groups in alkylbenzenes lie on the straight line *I*, while those for benzene derivatives containing an *ortho*-deuterium atom are grouped about the straight line *II*. Points for alkylthio-groups attached to a benzene ring lie on the same line. The postulate that one reason for such a differentiating effect may be unequal conditions of solvation by the two solvents of transition states differing in structure is supported by the fact that the position of the deuterium atom in the toluene molecule, for example, does not affect the heat of solvation of the latter. Yet replacement of the solvent may have unequal effects on the heats of solvation of the transition states in the exchange of deuterium in the alkyl group and in the aromatic ring. Since the contribution of the heat of solvation of the transition state lowers the activation energy of the reaction *E*,[95] the unequal differences in the heats of solvation of the transition states by the two solvents will result in a differentiating action on the relative kinetic acidity of CH acids differing in structure. Tentative values of the activation parameters calculated from kinetic measurements (Ref. 6, p. 135) agree[96,97] in general with the above hypothesis.

The activation energies for exchange with ammonia catalysed by potassamide of hydrogen in the side-chain of alkylbenzenes (*14–16*)§ and in the ring of substituted benzene (*6–8*, *10*) have similar values of about 14.5–16.0 kcal mole^{-1}, and variations in the rates of the exchange reactions are associated with differences in the pre-exponential term. The activation energies for deuterium exchange in the dimethyl sulphoxide–potassium t-butoxide system are about 5–6 kcal mole^{-1} smaller for the substituents in alkylbenzenes than for the aromatic ring[94] (17.5–18.2 kcal mole^{-1} for compounds *14* and *15* compared with 23.0–24.5 kcal mole^{-1} for *3–5*)¶. Heats of solvation of benzene and toluene in dimethyl sulphoxide are the same within 0.25 kcal mole^{-1}.[99] On considering the origin of the differences in solvation energy of the transition states of deuterium exchange occurring in dimethyl sulphoxide and in ammonia, one is struck by the differing polarity of these solvents (Table 2, in which μ is the dipole moment and ϵ the dielectric constant). They differ also in their proton-donor properties, which are weakly developed in the CH bonds of dimethyl sulphoxide.

The transition states for the ionisation of CH acids are similar in structure to the carbanions. The dipole moment of the solvent, the effective charge, and the polarisability of the ions have a substantial effect on the ion–dipole and dispersion interaction energies. Molecules of proton-donor solvents are capable of forming a hydrogen bond with

§ Here and subsequently italic numerals relate to the numbering of compounds in Table 1.

¶ Still, tentative data suggest that a decrease in activation energy by 3–4 kcal mole^{-1} for the exchange of hydrogen in the alkylthio-groups[98] of methyl phenyl sulphide and ethyl phenyl sulphide compared with data for the aromatic ring in benzene derivatives applies to exchange both with liquid ammonia and with dimethyl sulphoxide. Thus this phenomenon requires further investigation.

the carbanion. Dimethyl sulphoxide can interact with a carbanion, since its sulphur atom is positively charged. Consequently new possibilities of solvation of the transition state appear when the solvent is changed. Nevertheless, their realisation depends on the structural peculiarities of the carbanion, especially those producing a particular degree of localisation of the negative charge on the carbon atom[94] (cf. Ref. 30). On these principles it becomes understandable that a differentiating effect should be developed when the acidities of CH acids (carbanions) differing in structure are compared in solvents which differ markedly in polarity and in proton-donor and other properties.

Table 2. Kinetic isotope effects of hydrogen exchange and polar properties of solvents.

Solvent	Catalyst	Temp., °C	k_D/k_T	μ, D	$\epsilon_{25°C}$
NH_3	KNH_2	0	2.7*	1.46	16.9
$C_6H_{11}NH_2$	$C_6H_{11}NHLi$	50	2.7	1.32	4.5(22°)
$(CH_3)_3COH$	$(CH_3)_3COK$	50	1.9*	1.66	12.3**
$(CH_3)_2SO$	$(CH_3)_3COK$	25	1.2	4.3***	46***
$(CH_3OCH_2)_2P(O)CH_3$	$(CH_3)_3COK$	25	1.3	3.6***	24.2***

* Determined by F.S.Yakushin.
** Mixture of 70 vol.% of t-butyl alcohol and 30 vol.% of 2,5,8-trioxanonane (dielectric constant of mixture ~10).
*** Determined in Yu.Ya.Fialkov's laboratory.

Let us now compare the kinetic acidities of a series of CH acids determined in dimethyl sulphoxide and in a mixture of t-butyl alcohol and 2,5,8-trioxanonane (diglyme), with an alkali-metal t-butoxide as catalyst. When

$$\lg (k_i/k_{(C_6H_5)_2CD_2})_{(CH_3)_2SO}$$

is plotted against

$$\lg (k_i/k_{(C_6H_5)_2CD_2})_{t\text{-}C_4H_9OH}$$

(Fig. 2), the points for five-membered heterocycles—thiophen[58,100], selenophen[101], and some of their derivatives containing a 2-deuterium atom—lie on a straight line (*I*), whereas the points for mono- and di-methylnaphthalenes[102], in which alkyl groups take part in the exchange reaction, are located near the straight line *II*. (Differentiation between the positions of the points for α- and β-isomers begins to show.) A common feature of the graphs in Figs. 1 and 2 is that points representing the acidity of C–H bonds in aromatic or heteroaromatic rings lie on one straight line, whereas points obtained from deuterium-exchange kinetics for methyl groups attached to the aromatic ring are on a second straight line. Furthermore, t-butyl alcohol, like liquid ammonia, differs from dimethyl sulphoxide in polar and proton-donor properties. Ammonia and t-butyl alcohol belong to one group of solvents, while dimethyl sulphoxide belongs to another group among those listed in Table 2. Cyclohexylamine is akin to ammonia both in chemical properties and in its dipole moment.

No differentiating effect is apparent when relative kinetic acidities are compared in solvents belonging to the same group in Table 2. In fact, if values of $\lg (k_i/k_{C_6H_5D})$ in ammonia[6,15] are plotted against those in cyclohexylamine[11,40–42], fifteen points for aromatic compounds lie on the straight line passing through the origin at an angle of 45° to the horizontal axis, independently of whether the exchangeable deuterium atom is present in the benzene ring or in an alkyl group (Fig. 3). Only the points for *o*-deuteriobiphenyl (*6*) and for cumene containing a deuterium atom in the methine group (*16*) lie away from the straight line. This is probably due to steric hindrance, for the cyclohexylamide ion and the cyclohexylamine molecule are larger than the amide ion and the ammonia molecule. It is noteworthy that the enthalpies of activation $\Delta H^{\neq}$ of the catalytic exchange reactions of benzene and of the methyl group in toluene with cyclohexylamine (13 and 15 kcal mole^{-1}),[42] as of the catalytic exchange with ammonia, are similar in magnitude and also differ little from that for the exchange of benzene with ammonia (15 kcal mole^{-1}).[103]

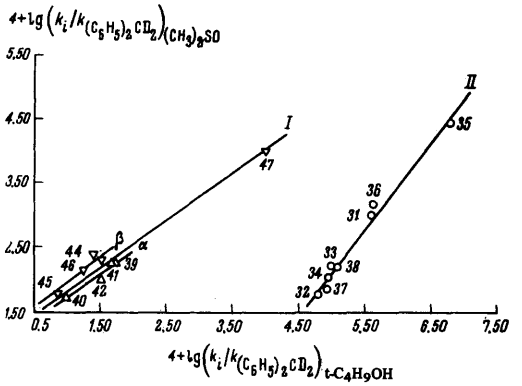

Figure 2. Comparison of kinetic acidities, determined in a mixture of t-butyl alcohol and 2,5,8-trioxanonane with potassium t-butoxide as catalyst, and in dimethyl sulphoxide with lithium butoxide as catalyst, for the exchange of deuterium in:
I) methyl groups; II) thiophen and selenophen rings.

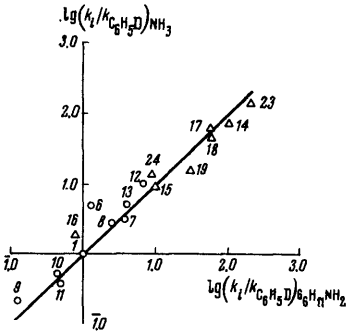

Figure 3. Comparison of kinetic acidities determined in cyclohexylamine with lithium cyclohexylamide as catlyst, and in liquid ammonia with potassamide as catalyst.

Fig. 4 compares the relative acidities $\lg (k_i/k_{C_6H_5CD_3})$ for a series of CH acids determined in catalytic systems with solvents—dimethyl sulphoxide[94] and methylbismethoxymethylphosphine oxide (medifos) $(CH_3OCH_2)_2PO.CH_3$ [104]—belonging to the second group in Table 2. In this case, too, the points for CH acids of different structural types, which in Fig. 1 are located on two straight lines, lie on one straight line. This also contains the point *24*, which in Fig. 1 occupied a position between the two straight lines.

The discussion and the facts lead to the conclusion that the differentiating action of the given solvents on the kinetic acidity of the CH acids listed in Table 1 depends on the structure and the solvation of the transition states formed during the protophilic isotopic exchange of hydrogen, at

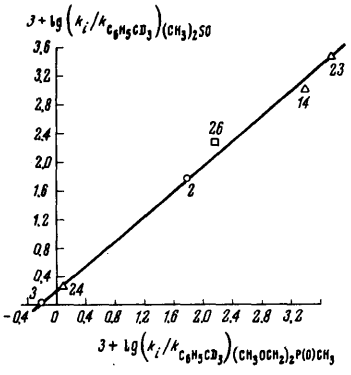

Figure 4. Comparison of kinetic acidities determined in methylbis-methoxymethylphosphine oxide and in dimethyl sulphoxide, with potassium t-butoxide as catalyst.

the ionisation stage of the CH acid. We shall not consider here the question of the structural features of the CH acids which predetermine the appearance of a differentiating effect in the catalytic systems assigned to different groups in Table 2.

Let us now consider the influence of solvents on the structure of the transition states and on the relative rates of the stages in the exchange reactions, which are shown in the k.i.e. value. Table 2 shows that the above division of solvents into two groups applies to a first approximation also to the ratios k_D/k_T, which have been determined[48,58,59] by measuring the rates of exchange of the heavy isotopes of hydrogen in the aliphatic bonds in toluene or diphenylmethane. Experiments with ammonia and cyclohexylamine have given k.i.e. values which are close to those calculated theoretically (Section II, 3). Hence it may be supposed that the stages of exchange reactions, the structure of the transition states, and their solvation are similar in these solvents, so that comparison of the relative kinetic acidities determined in them naturally reveals no differentiating effect, while measurements give a correct idea of the relative strength of the CH acids, since Brønsted's relation is observed. This is probably applicable also to the systems containing t-butyl alcohol which have been studied (Fig. 2), although this compound differs from ammonia and cyclohexylamine in its chemical properties, in that, being an OH acid, it is a stronger donor of protons. Differences in specific solvation are therefore possible, as we have seen, for example, in the solvation of heterocyclic molecules (p. 849). Alcohols readily solvate anions by hydrogen bonding.

Low k.i.e. values, close to unity, have been found[55,58-60] for exchange reactions in solvents belonging to the second group in Table 2 (dimethyl sulphoxide and methylbismethoxymethylphosphine oxide). As noted above (Section II, 3), there are two views (Jones[61] and Cram[10,54,62]) on the reason for the low k.i.e. in hydrogen exchange with dimethyl sulphoxide catalysed by an alkali-metal t-butoxide[59]. The former considers only the degree of symmetry of the transition state (within the framework of a linear three-centre model), whereas the latter view regards the second—not the first—stage in the exchange reaction as rate-determining.

With regard to the explanation put forward by Jones (cf. Ref. 59), account must undoubtedly be taken of the degree of symmetry of the transition states in reactions in which the C–H bond is broken. Actually, the transfer of a proton (deuteron) from 9-methylfluorene to the 5-methylphenanthren-4-yl carbanion[105] and from triphenylmethane to the dimsyl anion [anion derived from dimethyl sulphoxide][106] has k_H/k_D ratios of 4.2 and 4.7 respectively (or on conversion by means of Swain's equation[107] the k_D/k_T ratio is 1.9 and 2.0). The high k.i.e. value is consistent with the conclusion on the symmetry of the transition state, since, in conformity with Bell's principle, the difference in pK_a is close to zero (for the first reaction $\Delta pK_a = 19.7 - 20 \simeq 0$, whereas for the second reaction $\Delta pK_a = 29 - 33 = -4$[67,68,106]). For isotopic exchange between diphenylmethane and dimethyl sulphoxide catalysed by lithium t-butoxide, however, $(k_D/k_T)_{25°C} = 1.3 \pm 0.1$, although $\Delta pK_a = 30 - 28 = 2$,[67,68,106] and if the view of Jones is accepted, the higher k.i.e. value can be expected. It may be noted also that, for all the substances, differing in acidity, investigated by us[59], almost identical values of the ratio $(k_D/k_T)_{25°C}$ have been obtained (values indicated in parentheses): $\alpha(d)t$-diphenylmethane (1.3 ± 0.1), $2(d)t$-thiophen (1.3 ± 0.1), $2(d)t$-furan (1.5 ± 0.1), $(d)t$-methyl phenyl sulphide (1.2 ± 0.1), $\alpha(d)t$-toluene (1.2 ± 0.1), and o-$(d)t$-diphenyl ether (1.1 ± 0.1 measured at 50°C).

Nevertheless, a considerable k.i.e. ($k_H/k_D = 4.4$ at 55°C) is observed for the isomerisation of pent-1-ene catalysed by potassium t-butoxide in dimethyl sulphoxide[108], although on the MSAD scale (Ref. 10, p. 28) the values of pK_a for pentene and toluene are similar. In Schriesheim's opinion[108] proton transfer to the carbanion takes place intramolecularly in the isomerisation of an alkene, i.e. by a different mechanism from that operative in isotopic exchange.

The small kinetic effect observed in isotopic exchanges with dimethyl sulphoxide catalysed by alkali-metal t-butoxides is apparently due to some specific features of exchange reactions in these systems, as a consequence of which the rates of the reactions are limited at a stage which is unaffected by labelling the substance with heavy isotopes.

In this connection we note[59] that for the exchange reaction between the methylene groups in indene and fluorene, one of which is labelled with deuterium and tritium, the k_D/k_T ratio lies in the range 1.0–1.3. The reaction has been conducted[109] in ethylene glycol ethers, tetrahydrofuran, and dioxan with lithium t-butoxide as catalyst. The role of the solvent in the reaction is merely to solvate the cation and to polarise its bond with the anion: the solvent does not take part in the exchange reaction. The concentration of hydrocarbons in the solution is low, and the rate of the exchange reaction is probably limited at the stage of proton transfer from the C–H bond of the hydrocarbon to the carbanion, so that the k.i.e. is close to unity. We recall that solvents belonging to different groups in Table 2 differ in their proton-donor power. The first group, having high k.i.e., contains OH and NH acids, whereas the second group contains CH acids (dimethyl sulphoxide and the phosphine oxide), and it is for the latter solvents that the k.i.e. is small.

It must also be noted[59] that alkali-metal t-butoxides are strongly associated in ethereal solutions (this applies also to solutions in dimethyl sulphoxide, where the degree of association is lower[110]). It is possible that a two-stage scheme for the exchange reaction and a linear three-centre model for the transition state are unrealistic in the given case.

It must be borne in mind, of course, that the k.i.e. value in a given catalytic system may vary in some cases depending on the substance studied. Moreover, examples are known of a considerable change in k.i.e. for different bonds in the same substance undergoing exchange reactions in the same system[63].

Intensive research is now being conducted both on the theory of the kinetic isotope effect and on its determination in hydrogen exchanges occurring in different systems.

In Streitwieser's view[11,57] the differentiating effect observed on passing from cyclohexylamine to dimethyl sulphoxide is determined by the fact that in the latter solvent, depending on the structure of the carbanion, the ratio changes between the rate of diffusion from the carbanion of a molecule of the heavy alcohol formed from the alkoxide and the rate of return of the heavy hydrogen isotope from the alcohol to the carbanion. But different k.i.e. values can be expected for exchange reactions with dimethyl sulphoxide of those CH acids whose relative kinetic acidity changes unequally on change in the solvent (from cyclohexylamine or ammonia to dimethyl sulphoxide). However, the facts are not consistent with this conclusion, since practically identical values of k_D/k_T have been obtained[59] in dimethyl sulphoxide for several substances whose points lie on different straight lines in Fig. 1.

The discussion has shown that, if systems for which the k.i.e. values differ little from those calculated theoretically are used in determining kinetic acidity by the isotopic exchange of hydrogen, the measurements will be highly likely to give correct ideas of the relative strengths of CH acids (effects of specific solvation in the ground state of their molecules are disregarded). The applicability, for measurements of kinetic acidity, of systems in which the exchange reaction is characterised by a low k.i.e. is not such an unambiguous question. However, it would be wrong to conclude that catalytic systems such as those comprising dimethyl sulphoxide and an alkali-metal t-butoxide are completely unsuitable for such measurements[11,57]. Figs. 1 and 2 show that, within a group of structurally similar substances, a correlation has been established empirically between the relative acidities in systems belonging to different groups in Table 2†. However, there are deviations due to structural causes, e.g. for substances which contain, together with a *para*-methyl group, an electron-donor substituent (methyl, methoxyl, dimethylamino).

The results reported in this paper indicate that, in the present state of our knowledge, the problem of determining not only kinetic but also thermodynamic acidity is quite complicated owing to the variety of types of interaction between substances and solvents, as well as catalysts, in ground and transition states. Therefore the appearance of differentiating effects can by no means always be foreseen. This applies especially to the least studied, CH acids. Further, intensive research is required in this important field of theoretical organic chemistry, especially as the generalisations made will be extremely useful also for synthetic organic chemistry.

† In a more recent paper[63] Streitwieser remarks that, if the rate constant k_2 has the same value for a series of similar substances, the ratio of the experimental rate constants corresponds to that of the equilibrium acidities, since the second factor in the formulae $k = Kk_2$ cancels out. This can occur when reaction between the carbanion and the solvent is controlled by diffusion of B(*d*)*t*.

Highly Disperse Aerosols

N.A.Fuks and A.G.Sutugin

The properties of highly disperse aerosols of particle size ⩽100 Å are described, together with methods for their production and investigation. This class of aerosols, which has not hitherto been investigated systematically, is of great interest for the theory of the formation of condensation aerosols, the problem of atmospheric pollution and the fight against it, rocket technology, etc.

Special attention is paid to the theory of the formation of highly disperse aerosols, their coagulation, the diffusion method for determining particle size, the preparation of highly disperse materials via the aerosol state, i.e. questions to which the Reviewers have paid special attention in their publications. The bibliography contains 48 references.

4. Rate of coagulation of highly disperse aerosols 861

1. INTRODUCTION

In the present paper the term highly disperse aerosols (h.d.a.) is used in the sense of aerodisperse systems having a particle radius of around 10–100 Å, i.e. a Knudsen number (ratio of mean free path of gas molecules to particle radius $Kn = \lambda/r$) exceeding unity at atmospheric pressure. The most important property of h.d.a. must be that processes involving the transfer of momentum, energy, and mass from the particles to the medium and *vice versa* are described by the formulae of the kinetic theory of gases: i.e. the particles can be regarded simply as large gas molecules. Therefore the resistance of the gaseous medium to movement of the particles, the rate of their evaporation and of heat transfer to them, and also the rate of thermophoresis of the particles are proportional to the square of their radius. Since the apparent mean free path λ' of the particles themselves is $660\rho^{1/2}$ and $220\rho^{1/2}$ Å for those of radius 10 and 100 Å respectively, where ρ is the density of the particles[1], the "aerosol Knudsen number" λ'/r also exceeds unity in h.d.a.; therefore their rate of coagulation is more or less accurately represented by the well known formula for the number of collisions between gas molecules with $r \simeq 10$ Å, and approximately with $r \simeq 100$ Å, the rate of coagulation increasing with increase in particle size.

The vapour pressure of h.d.a. particles appreciably exceeds the normal vapour pressure of the material of the particles (by several 10% for $r \simeq 100$ Å and several times for $r \simeq 10$ Å). The scattering of light by the particles obeys Rayleigh's law accurately, while the intensity of the scattered light is so small that it is impossible to determine the particle size and concentration by macroscopic methods, and the particles are invisible in the ultramicroscope.

The Brownian motion of h.d.a. particles is so intense, while their inertia and rate of sedimentation under the influence of gravity are so small, that the deposition of h.d.a. on walls, streamlined obstacles, etc. occurs solely as a consequence of diffusion. The charge acquired by the particles in a bipolarly ionised atmosphere does not exceed 1 unit, the percentage of charged particles falling with decrease in their size.

In all the respects mentioned here, h.d.a. differ markedly from aerosols of particle radius ⩾ 0.1 μm, which have hitherto been the main subject of aerosol investigations. It is noteworthy also that, in view of the above fact concerning the charges on h.d.a. particles, their electrical mobility exceeds 0.001 V cm s^{-2}; thus the charged portion of atmospheric h.d.a. belongs, in the terminology of aerophysicists, to "intermediate" atmospheric ions.

2. FORMATION OF HIGHLY DISPERSE AEROSOLS

Although aerosols obtained by mechanical pulverisation or electrostatic sputtering of liquids and solids quite often contain very fine as well as coarse particles, relatively few of the former are formed, and their presence has little effect on the properties of such aerosols. The present h.d.a., in which all or most of the particles have the size indicated above, can be produced only by condensation. This is usually "physical" condensation of the supersaturated vapour of substances† having a very low vapour pressure at room temperature, the supersaturation being produced by rapidly cooling the vapour. This category includes also aerosols obtained in the spark, corona, and arc discharges, and by the explosion of wires. If, however, the supersaturated vapour is formed by a gaseous chemical reaction, condensation of the vapour is complicated by the fact that reaction takes place both in the gas phase and on the surface of already formed particles, the latter process quite often being catalytic in character and preponderating considerably over the former. Mention must be made also of "molecular" aerosols formed in certain chemical processes. Kogan[2] has shown that, in the photochemical decomposition of $Fe(CO)_5$ vapour under certain conditions, aerosols are formed whose particles consist of individual $Fe_2(CO)_9$ molecules. This is essentially $Fe_2(CO)_9$ vapour in a state of immense supersaturation, but possessing all the typical properties of aerosols; in particular, its particles may cause the condensation of supersaturated vapours of high-boiling liquids, i.e. act as "molecular condensation nuclei". Another analogous example is provided by "atomic" aerosols formed by the radioactive disintegration of emanations[3].

† We are concerned here, of course, with spontaneous condensation, since the concentrations of the particles thus formed exceed by several orders of magnitude the possible concentration of foreign condensation nuclei, including gaseous ions.

The size of particles formed by physical condensation depends primarily on the relative rates of formation of condensation nuclei and of their growth by the condensation of vapour on them. It follows from the modern theory of spontaneous condensation that the former rate increases far more rapidly than does the latter with increase in supersaturation of the vapour: i.e. finer particles should be obtained with increase in supersaturation. In fact, with the same initial concentration of the vapour and temperature of the vapour–gas mixture, rapidly cooled to room temperature, the degree of dispersion of the resulting aerosol is greater the less volatile the substance, i.e. the greater the supersaturation. This is shown especially clearly with compounds belonging to the same homologous series: increase in molecular weight produces a regular increase in the degree of dispersion of the aerosol.

On the other hand, the time during which supersaturation is produced, e.g. the rate of cooling of a mixture of vapour and gas, is of very great importance here. With slow cooling the degree of supersaturation actually remains slight throughout, since vapour is continuously removed from the system by condensing on already formed particles, foreign condensation nuclei, and the walls of the vessel; therefore coarsely disperse aerosols are formed. The more rapidly the system is cooled, the greater the actual supersaturation and degree of dispersion of the resulting aerosol.

The theoretical conclusion that the particle size of the aerosol diminishes with increase in the degree of supersaturation appears to contradict the firmly established fact that coarser aerosols are obtained with increase in the initial concentration of the vapour while the rate of cooling is maintained. Some part is played here by the increased evolution of heat of condensation that accompanies increase in concentration of the vapour, which tends to slow down cooling. However, the main reason is probably linked with the secondary process of coagulation of the particles. With the immense particle concentrations which are produced at the extremely large supersaturations necessary for the formation of h.d.a., the rate of coagulation is extraordinarily high. Let us suppose that the size or number of particles in condensation aerosols can be determined 0.1 s after their formation. Then it follows from the theory of coagulation that, with any initial particle concentration exceeding 10^{12} cm^{-3}, the concentration has fallen to about the same value of 2×10^{10} cm^{-3} at the instant of examination. The mean mass of particles formed by coagulation will clearly be proportional to the initial concentration of the vapour. In particular, if the vapour pressure of the substance at the temperature of condensation is extremely small, it may be assumed that all collisions between vapour molecules, between them and molecular aggregates, and also between these aggregates will result in their sticking together ("avalanche" condensation). In this case the mean mass of the particle aggregates will also increase with increase in concentration of the vapour.

Coagulation is accompanied by other significant processes in the particles of h.d.a. Quite often particles, which are initially spherical in shape and amorphous in structure, are gradually converted into small crystals even at low temperatures[4,5]. This ordering process takes place far more rapidly at high temperatures, in particular when the particles are heated by the electron beam in an electron microscope. Still more important changes take place in the structure of aggregates. In general, the coagulation of aerosols involves the formation of extremely loose aggregates, in which the area of contact between the particles is negligible, so that they are extremely unstable. In the first stage of condensation, however, when the temperature of the system is still high, the atoms (or ions) in the particles are highly mobile, and intense sintering and recrystallisation of the particles takes place in the aggregates. Coarse particles are known to sinter at temperatures above the "Tammann point" ($\sim 0.6\,T_m$, where T_m is the melting point on the absolute temperature scale), whereas in very fine particles sintering is already possible at considerably lower temperatures[6]. Particles in the form of liquid droplets (and very fine droplets can be extremely strongly supercooled) coalesce on contact.

In most cases coagulation which has begun at a high temperature continues as the system is cooled, so that both dense coalesced, sintered, or recrystallised "primary" aggregates and loose "secondary" aggregates can be formed (aggregates in certain carbon blacks, for example, possess such a structure).

It must be stressed that there is a fundamental difference between aerosols comprising individual particles having radii of the order of 10–100 Å and aerosols containing more or less coarse aggregates of such particles. Only the former possess the characteristic properties of h.d.a. mentioned at the beginning of the paper, but aggregation of the particles is unavoidable on their sedimentation, and the powdered deposits thus obtained from uncoagulated and from coagulated aerosols (the latter containing only loose aggregates) are practically indistinguishable in properties. Coagulated h.d.a. are also of interest in view of the great practical value of such highly disperse powders.

Cooling of a mixture of vapour and gas, with the formation of condensation aerosols, can proceed uniformly throughout the volume of the mixture (when it is expanded adiabatically) or else under non-uniform conditions, when the temperature and the supersaturation differ at different points in the system (when the mixture of vapour and gas is mixed with a cold gas or when it is cooled externally). It is very difficult to produce in a Wilson chamber the high supersaturations necessary for formation of h.d.a.; this is far more easily achieved in supersonic nozzles[7,8]. Unfortunately, the h.d.a. formed in them vaporise extraordinarily rapidly, and they can be investigated only by indirect methods[9,10].

The most important method of obtaining h.d.a. is by mixing. This is achieved most simply by heating a weighed portion of the substance in a closed vessel[11–13], when mixing occurs by means of convection currents, and formation of the aerosol is almost uncontrollable. Furthermore, the resulting aerosol cloud is fairly slowly diluted with a neutral gas, and as a result a strongly coagulated and extremely polydisperse aerosol is obtained. In a similar method—the preparation of h.d.a. by exploding a wire[14,15]—mixing occurs far sooner, but in this case, too, the process of mixing is uncontrolled. A better method, enabling aerosols to be obtained which are more highly disperse and uniform in particle size, is mixing in a flow.

There are two ways—in a mixer and in free space—in which such mixing can be accomplished. In the former case the processes of mixing and condensation take place in the mixer itself, a considerable portion of the vapour condensing on the walls of the mixer. This lowers substantially the yield of aerosol, but on the other hand it helps to maintain a constant degree of supersaturation in the mixer, and hence a constant concentration and degree of dispersion of the resulting aerosol, and it diminishes the harmful effects of fluctuations in temperature and concentration of vapour in the mixture with air. This "buffering" action of mixers is especially apparent when for-

eign condensation nuclei are introduced into a cold gas flow with the aim of obtaining more monodisperse aerosols: at low concentrations of the nuclei almost all the vapour condenses on the walls, the actual degree of supersaturation in the mixer being practically independent of the rate of condensation in space, and as a consequence the size of the resulting particles is independent of their concentration[16].

When streams of gases are mixed in free space, the whole of the vapour is converted into an aerosol. There is no necessity for two streams to be present: a free turbulent stream of a hot mixture of vapour and gas, escaping from a nozzle into a cold, stationary gas, mixes with the latter sufficiently rapidly for h.d.a. to be formed. This method is preferable for the preparation of large quantities of h.d.a., but it has been less studied than has the preceding method.

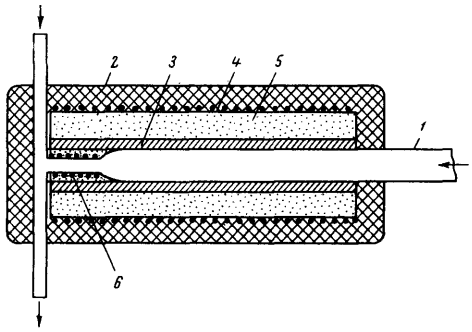

Figure 1. Generator for h.d.a.:
1) quartz tube; *2*) thermal insulation; *3*) steel tube; *4*) heating coil; *5*) ceramic tube; *6*) heating coil.

In the Laboratory for the Physics of Aerodisperse Systems at the Karpov Institute the formation of h.d.a. of sodium chloride has been studied by the method of mixing in a T-piece[17]. The generator illustrated in Fig. 1 was used. A quartz tube of diameter 20 mm, filled with ceramic rings coated with a layer of sodium chloride, was placed in an electric furnace operated with a stabilised voltage. The narrow part of the tube, which served as a superheater, was heated by a separate winding. In the steady state the temperature of the tube was maintained constant to 1 deg. The temperature profile along the axis of the tube shows that vaporisation of the salt took place under conditions of almost complete saturation with sodium chloride vapour of nitrogen flowing through the tube at a rate of 100–200 cm^3 min^{-1}. This is very significant, since work in which salt had been deposited as a thin layer on the surface of a nichrome coil had revealed a gradual fall in concentration of the vapour in the gas stream[18,19]; in this case the gas had obviously been far from saturated with the vapour, and recrystallisation of the salt on heating had caused a considerable decrease in the rate of evaporation.

The nitrogen and sodium chloride vapour leaving the tube were mixed in a T-piece with cold, filtered air flowing at a rate of 10–20 litres min^{-1}. In the absence of a superheater the vapour condensed completely on the walls of the mixer; with the superheater present, 90–99.9% of the vapour condensed on the walls depending on the experimental conditions. It was established by the method described on p. 860 that the h.d.a. obtained in this way were fairly monodisperse; the radius of the particles could vary from 7 to 50 Å, and the counted concentration from 10^2 to 10^7 cm^{-3}. The polydispersity of the h.d.a. increased appreciably at a radius of 50 Å. At the above concentrations the degree of coagulation of the h.d.a. was negligible. Both the size and the concentration of the particles increased with rise in the temperature of the furnace and with the rate of flow of nitrogen in it, i.e. with increase in the concentration of the h.d.a. by weight. A similar procedure was used to prepare h.d.a. from a series of alkali-metal halide salts.

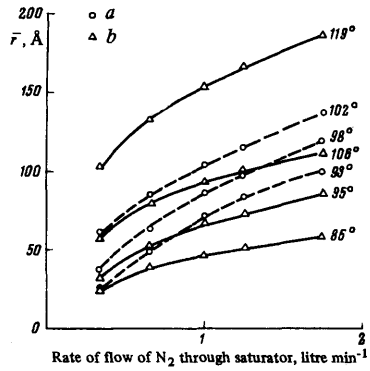

Figure 2. Dependence of mean particle size of dioctyl sebacate on conditions of operation of KUST apparatus, for air containing condensation nuclei (2×10^7 cm^{-3}) flowing at (litres min^{-1}): *a*) 11.0; *b*) 6.0. The temperature (°C) of the saturator are indicated on the curves.

Dioctyl sebacate h.d.a. have been prepared[20] by means of the KUST generator designed by Kogan and Burnasheva[16], in which the flows were mixed in a spray type of mixer: here a mixture of vapour and air escapes from a circular orifice, is mixed with a stream of cold air emerging from a concentric annular slit, and enters a diffuser. Condensation nuclei—the sodium chloride h.d.a. mentioned above, having $\bar{r} = 17$ Å—were used to obtain more monodisperse aerosols. In this way aerosols of dioctyl sebacate were prepared having $\bar{r}$ between 30 and 300 Å. Fig. 2 shows that the particle size increases with rise in the temperature at which the nitrogen is saturated by dioctyl sebacate vapour and with increase in the rate of flow of nitrogen through the saturator, as with the sodium chloride h.d.a. discussed above. In the present case, however, the degree of dispersion of the h.d.a. could be controlled also by varying the concentration of condensation nuclei: with increase in the latter above a certain limit (see above) the particle size understandably diminished.

By mixing gas flows in mixers, h.d.a. can very conveniently be obtained with controllable properties and a fairly high degree of monodispersity, but this method is unsuitable for the accurate study of the formation of aerosols by

physical condensation, since in the present case the process is greatly complicated by the condensation of vapour on the walls of the mixer. This disadvantage is absent when free streams are mixed, a method by which h.d.a. have been obtained from several substances in the Laboratory for the Physics of Aerodisperse Systems. Since there are no losses of material in this case, the concentration by weight of the resulting aerosols was considerably higher than in mixers, and the aerosols were strongly coagulated. The particle size in the aggregates was therefore determined from the specific surface of the deposited h.d.a.

The formation of h.d.a. has been studied in the greatest detail from molybdenum trioxide[21] and from silver[22]. The generator used differed from the apparatus illustrated in Fig. 1 by the absence of the T-piece: the narrow portion of the quartz tube (the superheater) terminated in a circular orifice, from which a stream of the hot mixture of vapour and air escaped into cold air, the molybdenum trioxide being placed in a boat in the furnace. Here vaporisation did not occur under saturated conditions, and the concentration of vapour in the mixture could be controlled both by the temperature of the boat and by the rate of flow over it. The aerosol formed in the turbulent stream was sucked without loss into an electrostatic precipitator, where it settled out. The specific surface of the deposit was determined by the BET method, and thence the mean particle radius was calculated.

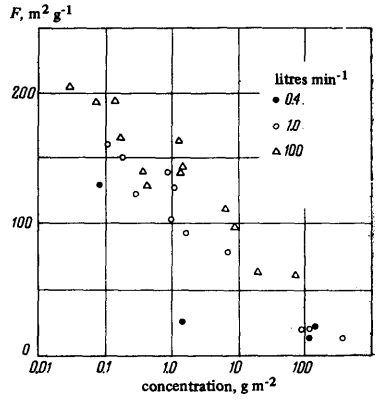

Figure 3. Dependence of specific surface of MoO_3 powders on concentration of vapour and rate of flow of air through producer (diameter of nozzle 2 mm, temperature at outlet from nozzle 820°C).

The content of molybdenum trioxide in the hot mixture of vapour and air is plotted as abscissa in Fig. 3, from which it is evident that the mean particle size in the aggregates increases with increase in concentration of the vapour. As already mentioned above, this is probably explained by coagulation of the aerosol at temperatures at which the particles in the aggregates coalesce or sinter. At low vapour concentrations the effect of coagulation is weaker, and the particle size is almost independent of concentration: the higher the latter, the stronger the influence of coagulation. The diminished particle size with increase in rate of flow is probably due to the accelerated dilution of the aerosol, so that it is less coagulated. In this case the effect of rate of flow will also clearly increase with vapour concentration.

Calculations on the formation of a silver aerosol, examination of electron micrographs of samples of the aerosol withdrawn at various stages in the process of formation, and investigation of the effect of heating on the specific surface of powders obtained by precipitating silver aerosols have shown that at vapour concentrations of 10^{14}–10^{16} mol. cm^{-3} coagulation plays a decisive part in producing the size distribution of the aerosol[22]. The final result is determined by the ability of the particles to coalesce and sinter on coagulation. As the aerosol cools, the coarse particles lose their ability to coalesce on collision, and merely sinter. This course of the process probably explains the spherical shape of the primary particles in certain aggregated aerosols of condensation origin, e.g. in carbon black aerosols. Other workers[13,23] have also concluded that coagulation, accompanied by coalescence of the particles, plays a decisive part in the formation of concentrated h.d.a.

A procedure analogous to that which has been described[21] has been used to obtain h.d.a. of bismuth molybdate, nickel chloride, and metallic silver. Allowing streams of argon containing the vapours of zinc, cadmium, bismuth, and tin(II) oxide to escape into air has yielded h.d.a. of the corresponding oxides and tin(IV) oxide having approximately the same particle size as with molybdenum trioxide, and in the case of tin dioxide $\bar{r} \simeq 15$ Å.

The preparation of h.d.a. by the decomposition of certain compounds in the plasma must also be included among processes in which aerosols are formed by the mixing of flows at different temperatures. As a consequence of the high temperatures reached in plasmas, the vapour formed by a chemical reaction probably becomes supersaturated only during cooling of the flow, and condensation is preceded by the chemical reaction. Examples of such processes are the preparation of carbon black by the decomposition of benzene vapour in the plasma, described by Sofronov[24], and the formation of nickel h.d.a.[25] by the decomposition of nickel pentacarbonyl.

3. DETERMINATION OF CONCENTRATION AND PARTICLE SIZE OF HIGHLY DISPERSE AEROSOLS

Only one method—enlarging the particles by condensing vapour on them—is in practice available for determining the number of particles in h.d.a. per unit volume. This method, which was proposed by Aitken as long ago as the nineteenth century, is based on the fact that condensation of a vapour on aerosol particles is possible at supersaturations which are insufficient for spontaneous condensation. Originally, water droplets formed by the adiabatic expansion of an aerosol containing water vapour were counted visually, but this method was too slow and laborious. At the present time, therefore, meteorologists employ photoelectric counters[26,27] to count "atmospheric condensation nuclei", these measuring the weakening or scattering of light by the aqueous mist formed on the adiabatic expansion of saturated air in the counter chamber. The counter is first calibrated by means of aerosols containing a known concentration of particles.

Use of the KUST apparatus mentioned above is considerably more convenient for laboratory investigations of h.d.a.[16] The test aerosol is mixed in a spray mixer with a gas flow containing the vapour of a high-boiling liquid, after which the concentration of droplets in the fairly monodisperse

fog formed is measured either visually or with a photoelectric particle counter. The great advantage of the KUST apparatus is that, at particle concentrations not exceeding 10^4 cm^{-3}, the size of the droplets formed by condensation no longer depends on the particle concentration. It is therefore sufficient to determine with a nephelometer the intensity of light scattered by the fog formed in the apparatus at one definite particle concentration in order to obtain the whole calibration graph (straight line). For relative nephelometric determinations of concentration, however, calibration is not required at all, since the nephelometer readings are proportional to the particle concentration.

To determine the absolute concentration of h.d.a. particles we had to ascertain the completeness of their "development" in the KUST[28]. For this purpose the particles were developed with an increasing degree of supersaturation of the vapour of the liquid developer (dibutyl phthalate). It was found that, in agreement with theory, there exists for each particle size a definite minimum supersaturation, at which all the particles are developed, further increase in the supersaturation (until spontaneous condensation begins) leading merely to enlargement of the fog droplets without change in their number. The minimum supersaturation necessary clearly increases with decrease in particle size. According to Kogan's hypothesis, liquids of extremely low vapour pressure, e.g. dioctyl sebacate, must be used to develop very fine particles; in this way he was able to develop "molecular" nuclei[2].

In view of the extremely large diffusion coefficient of particles having radii of around 10–30 Å, considerable losses of such particles from diffusion and thermophoresis to the walls were to be expected in the KUST apparatus. The design of the KUST mixer was therefore modified as shown in Fig. 4: the aerosol flows through the central orifice, while nitrogen containing superheated dibutyl phthalate vapour flows through the annular slit (the opposite to what occurs in the KUST apparatus). In this mixer the thermophoresis of particles preceding the mixing zone takes place from the walls towards the axis, and thus opposes the deposition of particles on the walls by diffusion.

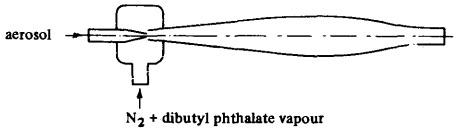

Figure 4. Mixer for developing aerosols.

Actually, the losses on the passage of an h.d.a. through a "blank" new mixer (i.e. in the absence of the vapour) were only 4% for $\bar{r}$ = 45 Å and 5.5% for $\bar{r}$ = 25 Å. Since these losses are caused by the diffusion of particles to the walls of the diffuser, the losses should be still smaller when the particles are enlarged by condensation. The fact that particles had sufficient time to be enlarged before they started to settle in the diffuser was established in special experiments.

In order to be able to utilise the above specific property of the KUST apparatus at concentrations exceeding 10^4 cm^{-3}, accurate dilution of h.d.a. was required. For this purpose an aerosol diluter was constructed[28], in which the deposition of h.d.a. by diffusion was insignificant, so that the dilution factor in such diluters varied little with particle size. The diluter was calibrated directly for each mean particle size at low h.d.a. concentrations under conditions of proportionality in the KUST apparatus, diluters having a dilution factor of around 10 being calibrated directly, while several diluters were connected in series for greater dilutions. The particle concentration in a developed diluted h.d.a. of droplet radius ~ 0.3 μm was determined by the classical ultramicroscopic method.

A large number of methods are theoretically available for determining particle size in h.d.a., but their applicability is greatly restricted in practice. Mention may be made of growing liquid h.d.a. particles in binary vapour mixtures[29,30], determining the size of sodium chloride particles by photometry of the flashes appearing on introduction of the particles into a hydrogen flame[31], and calculation of the radius from measurements of the capture coefficient for light ions[32].

Although a resolving power of the order of 5 Å has been achieved in modern electron microscopes, for several reasons no-one has yet been able to determine particle sizes less than 20–30 Å by this method, while for several substances the limit is considerably higher. In particular Megaw and Wiffen have found[33] that platinum and nickel particles of ~ 50 Å are either transparent to the electron beam or vaporise under its influence, and Young and Morrison[34] were unable to obtain micrographs of sodium chloride particles smaller than 200 Å.

Rich[35] suggested that, since the steady-state distribution of charges on aerosol particles in a bipolarly ionised atmosphere is given approximately by the Boltzmann formula and, as mentioned in the Introduction, h.d.a. particles are unable to carry more than one elementary charge, their size can be calculated from measurements of the percentage of charged particles. It must be borne in mind, however, that many hours are required for the charge on h.d.a. to reach a steady state under conditions of natural atmospheric ionisation, and therefore the aerosol must be subjected to extremely intense artificial ionisation—which is not usually done—for this method to be applied. Moreover, it is impossible by this method to obtain even a rough idea of the degree of polydispersity of the aerosol.

The well known method of determining the mobility of particles ("heavy" ions) in an electric field[36] permits the size distribution of only the charged particles to be measured. As the percentage of charged particles increases with increase in their size, this method will definitely overestimate particle size in the case of a polydisperse h.d.a.

Since the ability of particles to cause a vapour to condense depends not only on their size but also on their wettability, the presence of surface contamination, etc., the method of determining the particle size of h.d.a. from the critical degree of supersaturation of a vapour cannot give any reliable results[37].

An extremely simple and convenient method for determining the degree of dispersion of aerosols is based on measurement of the specific surface of a deposited aerosol from adsorption isotherms, but this method does not enable individual particles to be distinguished from aggregates, and it gives the mean size of primary particles and primary (i.e. coalesced or sintered) aggregates; on the other hand, in the case of h.d.a. which are highly concentrated by weight, in which a high degree of aggregation is unavoidable, only this method and electron microscopy are applicable in practice.

In several cases the Debye–Scherrer X-ray method, based on the broadening of the lines in the powder diagrams of very fine crystalline particles, proves to be extremely useful. It must only be remembered that the particles may consist of several crystallites, and results given by the Debye–Scherrer method relate to the dimensions of these latter. On the other hand, h.d.a. particles are quite often amorphous, and this can be established only by X-ray examination.

The most convenient way of measuring the particle size of h.d.a. is probably the diffusion method, based on passage of the h.d.a. through a circular or plane-parallel channel (or a "diffusion battery" comprising several channels) with measurement of the breakthrough (the ratio of the h.d.a. concentration at the outlet to that at the inlet to the channel). By means of the formulae deduced by Townsend and subsequently refined[38] the diffusion coefficient of the particles and hence their size can be calculated from the breakthrough value. Calculation shows that the charge on the h.d.a. particles has practically no effect on their breakthrough[39,40]. For a long time this method was employed only to determine mean particle size, but during recent years a series of attempts has been made to use it to determine the particle size distribution. The greatest theoretical interest is presented by Twomey's work[41], which showed that the distribution curve can be found from the curve of breakthrough against length of channel or rate of flow by means of the inverse Laplace transformation. Unfortunately, relatively small, unavoidable errors in the measurement of breakthrough lead to very large errors in the distribution function calculated in this way, and Twomey's method is probably applicable only to extremely polydisperse, e.g. atmospheric, aerosols. A method proposed by Pollak and Metnieks[42] enables the particles in an aerosol to be divided only into a small number of fractions.

The Laboratory for the Physics of Aerodisperse Systems uses a method based on the hypothesis that the particle size distribution in an aerosol is a logarithmic normal distribution[17,43]. This distribution is in fact observed more or less accurately in most aerosols, of both condensation and dispersion types. A computer has been used to calculate breakthrough curves through the channel as a function of the parameter $\mu = Dl/h^2\bar{u}$ (where $\bar{u}$ is the mean rate of flow in the channel, l its length, D the diffusion coefficient, and h the radius of a cylindrical channel or the half-width of a plane-parallel channel) for h.d.a. having different mean geometrical radii r_g and geometric standard deviation β_g. The breakthrough having been measured for a series of values of μ, the curve is selected which best fits the experimental points, and hence r_g and β_g are found. Then the Einstein–Millikan formula

$$D = kT[1 + A(\lambda/r) + (\lambda/r)\exp(-\gamma r/\lambda)]/6\pi\eta r \qquad (1)$$

(where η is the viscosity of the gas, λ is the mean free path of the gas molecules, and A, B, and γ are coefficients whose values are known for a series of substances) is used to calculate the size distribution curve for the particles regarded as spherical. For $r \leq 50$ Å, we can now use the simpler formula of gas kinetics

$$D = kTQ\lambda/6\pi r^2\eta \qquad (2)$$

in which we put $Q = 1.15$.

The apparatus used in the Laboratory for the Physics of Aerodisperse Systems to determine the particle size of h.d.a. by the diffusion method[17] is shown diagrammatically in Fig. 5. The aerosol leaves the producer A, is cooled to room temperature in the condenser B, and passes through the diluter D, where its concentration is brought to $\sim 10^4$ cm^{-3}. To obtain the desired rate of flow through the diffusion battery G (measured by means of the flowmeter F), part of the aerosol has been allowed to escape through E. After the battery the h.d.a. enters the KUST apparatus M and the nephelometer L. If the concentration of aerosol in the battery is to be diminished, part of it is passed through the filter K, and is mixed with the aerosol in such a way that the rate of flow in the KUST apparatus remains constant. To investigate h.d.a. having a mean particle radius of 25 Å, a set of diffusion batteries, differing in length and comprising eight cylindrical channels, is used. Over the mean particle radius range 25–100 Å, a set of sixty-channel batteries is used. For the investigation of aerosols of lower degree of dispersion, use can advantageously be made of measurement of deposition in plane-parallel slits.

With h.d.a. of particle radius ~ 10 Å, a difficulty is met when the diffusion method is used, in that all calculations for diffusion precipitation in channels start from the assumption that a parabolic flow profile has been formed in

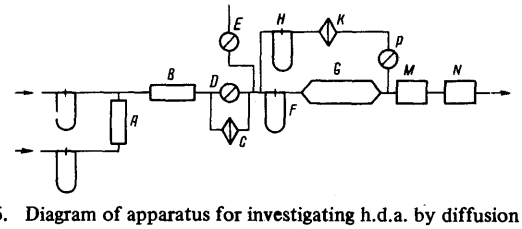

Figure 5. Diagram of apparatus for investigating h.d.a. by diffusion method.

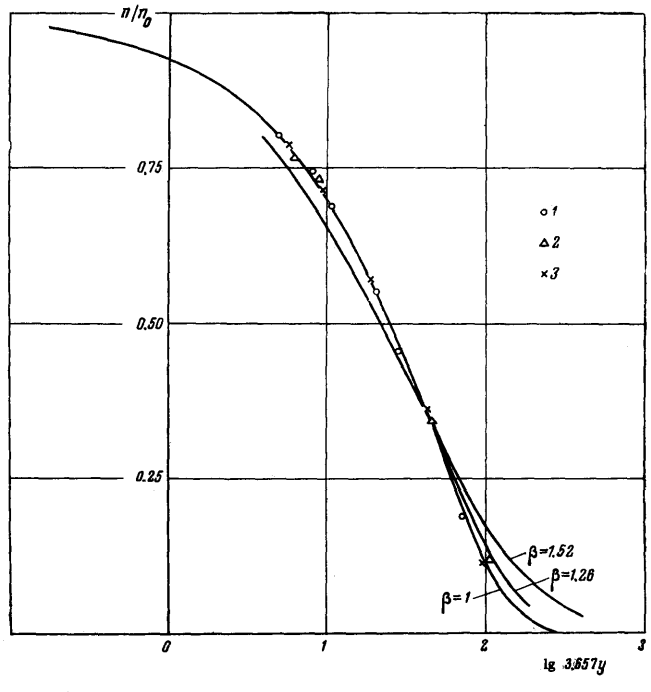

Figure 6. Theoretical curves and experimental values of breakthrough of sodium chloride aerosol through a battery of circular channels for different values of $\bar{r}$ (Å):
1) 11.8; *2*) 9.7; *3*) 7.0.

them. Naturally, the channels contain an entry section, deposition in which is significantly greater than calculated by the above method. It is very difficult to calculate theoretically the errors arising in this way, and the appropriate correction has been found experimentally.

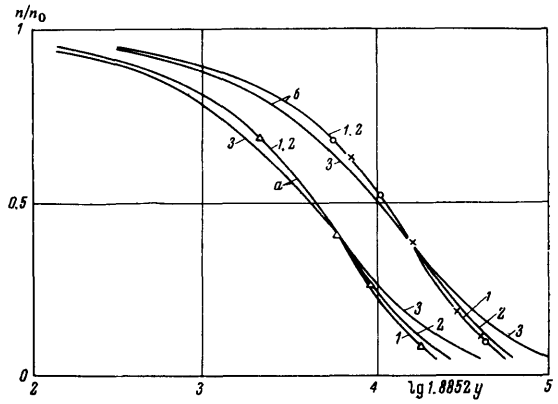

Figure 7. Diffusion breakthrough of dioctyl sebacate aerosols through an annular slit for different values of $\bar{r}$ (Å):
a) 100; *b*) 160; and of β_g: *1*) 1.0; *2*) 1.26; *3*) 1.54.

Fig. 6 illustrates the results of the measurements of particle size in sodium chloride h.d.a. mentioned in Section 2. The full lines have been calculated for different values of β_g (above the point of intersection the curves for $\beta_g = 1$ and 1.26 practically coincide). As is evident from Fig. 6, β_g is in any case less than 1.26 for the aerosols investigated. Fig. 7 shows analogous results for dioctyl sebacate h.d.a.[20] having a mean radius of 100 Å.

We thus see that the mean particle size of h.d.a. can be fairly accurately determined by the diffusion method, and the dispersion of sizes less accurately.

4. RATE OF COAGULATION OF HIGHLY DISPERSE AEROSOLS

As stated in the Introduction, the coagulation of h.d.a. takes place by a gas-kinetic mechanism: i.e. the coagulation constant K is given by the formula for the number of collisions between gas molecules. Nevertheless, a fairly substantial correction must be made to this formula for particles of radius 100 Å, i.e. for the upper limit which we adopted for the size of h.d.a. particles. No reliable experimental data on the magnitude of the coagulation constant of h.d.a. had been obtained until recently.

The chief difficulty in measuring the rate of coagulation of h.d.a. is the considerable loss of particles on the walls of the apparatus and connections due to the high diffusion coefficient of h.d.a. particles, which renders inapplicable the classical method, determination of the particle concentration in samples withdrawn from the chamber at intervals. Therefore a flow method was used in the Laboratory for the Physics of Aerodisperse Systems: an aerosol having a previously measured large counter concentration was passed with streamline motion through a vertical tube of capacity 2 litres.[28] Nephelometric measurements were made of the ratio of the concentrations entering and leaving the tube and of the mean residence time of the h.d.a. in the tube. In a separate experiment a greatly diluted non-coagulating h.d.a. was passed through the tube, and the correction for the diffusion losses of particles was determined.

The rate of flow varied from 10 to 17 litres min^{-1}, and the Reynolds number from 300 to 500. In order to diminish diffusion losses, the central portion of the flow (about half the total flow) was withdrawn isokinetically from the tube. It was established by special experiments that transverse mixing by convection did not occur in the cylindrical part of the tubes. Nevertheless, 6–14% of the particles, depending on the particle size and the rate of flow, were lost by diffusion in the tubes.

When the flow was made visible by means of an optically dense aerosol, appreciable circulation was observed in the diffusers, and most of the loss undoubtedly occurred in them. Since their volume was considerably less than that of the cylindrical portion of the tubes, it could be assumed that these losses preceded coagulation of the aerosols. The degree of coagulation (the ratio of the counted concentrations before and after coagulation) was therefore calculated by means of the formula $\epsilon = (n_1/n_2)/(n_1'/n_2')$, where n_1'/n_2' is the concentration ratio for the diluted (non-coagulating) aerosol, and n_1/n_2 the ratio for the undiluted (coagulating) aerosol.

To determine the residence time of the aerosol in the tube, which is practically identical with the coagulation time, pure air was first passed through the tube, and then after a certain time a coarse mist (or conversely), and the concentration of the mist emerging from the tube was determined as a function of time by means of a nephelometer. The mean residence time of the h.d.a. in the tube was calculated from the elution curves obtained.

These experiments gave mean values of K of 13.4×10^{-4} and 15.0×10^{-10} cm^3 s^{-1} for mean radii $\bar{r}$ of 25 and 45 Å respectively, the corresponding standard deviations being 11.5% and 12.5%. A detailed analysis of the sources of error in these measurements showed that the total square error in the value of K is 11.0%.

Comparison of experimental and theoretical values of K showed the latter to be considerably smaller (4.82 and 6.45×10^{-10} cm^3 s^{-1}). Such a large discrepancy is probably due to the effect of intermolecular forces on the coagulation constant. The "time lag effect" in intermolecular forces is known to diminish their magnitude at distances exceeding 200 Å so much that these forces play no appreciable part in the coagulation of coarse aerosols. With particles of radius 25 and 45 Å, on the other hand, the time lag effect can be neglected, and the potential for the intermolecular forces between two spherical particles can be calculated by means of Hamaker's[44] formula

$$V(\rho) = \frac{A}{6}\left[\frac{2r^2}{\rho^2} + \frac{2r^2}{\rho^2 - 4r^2} + \ln\left(1 - \frac{4r^2}{\rho^2}\right)\right] \qquad (3)$$

where ρ is the distance between the centres of the particles and $A = \pi q^2 \beta/6$, in which q is the number of molecules per unit volume of the substance and β is London's constant. The latter was determined for sodium chloride by Mayer from its ultraviolet absorption bands[45], and found to be $\beta = 1.8 \times 10^{-56}$ erg $Å^6$. The theory of collisions between gas molecules when forces of attraction operate between them shows that with this value of β the molecular forces increase the number of collisions, and hence the coagulation constant, by a factor of 2.19, independently of the particle size. From this we obtain theoretical values of 10.5 and 14.1×10^{-10} cm^3 s^{-1} for K, which show considerably

better agreement with the experimental results. The remaining discrepancy may be due to some polydispersity of the aerosols, which appreciably increases their rate of coagulation.

A coagulation constant of 13.4×10^{-10} cm^3 s^{-1} has been obtained[46] for dioctyl sebacate aerosols having $\bar{r} = 100$ Å. The gas-kinetic formula disregarding intermolecular forces gives $K = 10.5 \times 10^{-10}$ cm^3 s^{-1}, but this formula is not applicable in this case. A formula deduced by one of the present Reviewers[47], which is applicable at small Knudsen aerosol numbers exceeding unity, gives $K = 12.0 \times 10^{-10}$ cm^3 s^{-1} (without taking into account molecular forces).

It is curious that, for the coagulation of h.d.a., many authors use Smolukhovskii's formula even at the present time, substituting in it Eqn. (1) for the diffusion constant, and obtain excessively large values for the coagulation constant[48]. Without making due allowance for diffusion losses, some of these authors obtain the same excessively large experimental values for the coagulation constant.

---o0o---

The systematic study of highly disperse aerosols began only quite recently, and it is still early to speak of their application to physics and technology, but we can already point to a number of problems in whose solution h.d.a. may prove useful. For the theory of the condensation of a vapour it would be extremely important to establish the relation between the critical supersaturation and the particle size of h.d.a., and for meteorology to determine the size of solution droplets formed in h.d.a. from hygroscopic substances at a given atmospheric humidity. By measuring the rate of vaporisation of h.d.a. particles (from the increase in their diffusion coefficient) of substances having a sufficiently low vapour pressure, we can determine the latter for particles which are so fine that the Kelvin equation cannot be applied. It may be hoped that refinement of the technique for measuring the coagulation constant of h.d.a. will yield a new method for evaluating intermolecular forces.

The finely divided powders obtained when h.d.a. settle out are also of great interest. In view of their immense specific surface and the structural disorder of the particles, they probably possess great chemical activity, and may find use as catalysts. Interesting data in the investigation of various physical phenomena depending on particle size—magnetic properties, the Mössbauer effect, etc.—can be obtained by the use of such powders. By measuring the heat of dissolution of finely divided powders of certain salts, it has been possible to determine their specific surface energy. It may prove possible to obtain high-quality diffusion membranes by sintering finely divided metal powders.

Formation of Donor-Acceptor Complexes

E.N.Gur'yanova

Results are summarised for the main principles governing the formation of complexes of type σn, νn (of halogens, metal halides, and organometallic compounds with various amines, ethers, and sulphides). The dipole moments and the heats of formation of the complexes are examined as the most important parameters characterising the properties of donor-acceptor bonds. Methods of determining these parameters are analysed.
Special attention is paid to the character of the relation between the degree of charge transfer and the energy of intermolecular bonds.
Two aspects of the problem of the donor properties of amines, ethers, and sulphides—the effect of molecular structure on the donor properties of the heteroatom, and the conditions for overlap of orbitals involved in the formation of donor-acceptor bonds—are discussed.
A method for determining the energy of p_π-conjugation in aromatic compounds containing a heteroatom is briefly described.
The list of references contains 81 items.

1. INTRODUCTION

The nature of the intermolecular bonds in compounds of donor–acceptor type has remained a matter of controversy. The interpretation of π-complexes as charge-transfer complexes[1] is open to doubt[2]. It is supposed that the relatively low bond energies in π-complexes may be due to van der Waals forces, dipole–dipole interaction, and polarisation forces, and are not associated with charge transfer. A large number of molecular compounds are known whose formation is accompanied by a considerable change in dipole moments, which indicates a displacement of electron density or a transfer of charge from one component to the other on complex formation.

Within the very wide range of properties of intermolecular bonds it is impossible to draw a sharp distinction between strong and weak complexes. It is probable that the formation of intermolecular bonds between two valency-saturated molecules involves the maximum development of all possible forces—including polarisation, dipole–dipole, and van der Waals forces—and use is also made of the valency expansion possibilities of atoms and molecules responsible for donor–acceptor interaction. Each factor makes its contribution to the overall effect of formation of a molecular compound. Specific properties of molecular compounds and of intermolecular bonds will appear depending on how large a particular contribution is, the latter being determined by the composition and structure of the initial molecules.

The present Review will survey molecular compounds in which the transfer of charge predominates over other forces: i.e. compounds will be examined to which there is every justification for applying the term "charge-transfer complexes". Complexes formed by metal halides with various amines, ethers, sulphides, and also with certain aromatic compounds will be considered. It is supposed that the formation of intermolecular bonds in compounds of this type is accomplished mainly by partial transfer of an electron (or displacement of electron density) from the donor molecule to the acceptor molecule.

A necessary condition for the formation of an additional bond between two valency-saturated molecules is the presence of an occupied orbital of sufficiently high energy in the donor molecule and the presence of a sufficiently low unoccupied molecular orbital in the acceptor molecule. If electron transfer from a high filled orbital of one molecule to a lower free orbital of another is energetically favourable, a donor–acceptor bond is formed.

From the point of view of the theory of localised pairs, such an intermolecular bond is similar to an ordinary chemical bond produced by a pair of electrons in the field of two nuclei. The fundamental difference is that each atom supplies one electron to the formation of an ordinary chemical bond, whereas here one molecule—the donor—supplies the pair of electrons, while the second molecule—the acceptor—provides the vacant molecular orbital. Consequently, the properties of intermolecular bonds have many features in common with those of ordinary chemical bonds, as will be shown later, but they also exhibit their own specific characteristics.

Thus intermolecular bonds are formed by interaction between quite definite molecular orbitals in electron-donor and electron-acceptor molecules. The properties and the stereochemistry of such complexes will depend to a considerable extent on which orbitals are involved in forming the bond.

The existing classification[3] of molecular compounds of donor–acceptor type is based on the type of orbitals involved in bond formation. According to this, all molecules capable of developing donor properties, i.e. of donating an electron on interaction with other molecules, can be divided by means of the structural criterion into three groups—n, σ, and π—in the first of which the energetically highest orbital is the lone pair of n-electrons of the heteroatom (R_2O, R_2S, R_3N, etc.), in the second the pair of electrons of the σ-bond (R–Hal), and in the third a pair of π-

electrons of unsaturated and aromatic compounds having a sufficiently low ionisation potential.

Acceptor molecules can also be divided structurally into three groups—v, σ, and π—the lowest molecular orbital in the first being the vacant v-valency orbital of the metal atom (metal halides, certain organometallic compounds), in the second the non-bonding σ-orbital (I_2, ICl, Br_2, etc.), and in the third the system of π-bonds (aromatic and unsaturated compounds containing electron-acceptor substituents). In principle any donor is able to form a compound with any acceptor. It is all determined by the energetics of these processes. The same atom or molecule can act sometimes as a donor, sometimes as an acceptor, depending on its partner.

Donor–acceptor complexes can be classified as follows:

nv ($R_2O \cdot BX_3$)	σv ($RX \cdot BX_3$)	πv ($Ar \cdot BX_3$)
$n\pi$ ($R_2O \cdot Ar$)	$\sigma\sigma$ ($RX \cdot I_2$)	$\pi\sigma$ ($Ar \cdot I_2$)
$n\sigma$ ($R_2O \cdot I_2$)	$\sigma\pi$ ($RX \cdot Ar$)	$\pi\pi$ ($Ar \cdot Ar$).

The largest number of investigations have been concerned with complexes of types $\pi\pi$ and $\pi\sigma$. Comprehensive monographs[4,5] and reviews[6-8] have been published. Complexes with σ-donors have been least studied. As already stated, the present Review will survey mainly the results of our investigations on complexes of types nv, $n\sigma$, and partly πv.

From general ideas on donor–acceptor interaction it may be supposed that the most important parameter, on which the properties of intermolecular bonds and of the complexes largely depend, is the magnitude of the charge transferred from donor to acceptor.

One way to test experimentally the concept of intermolecular bonds as charge-transfer bonds is to investigate the type of relation between the degree of charge transfer and the stability of the resulting bonds. The degree of charge transfer can be assessed from the dipole moment of the intermolecular bond, and the stability from the heat of formation of the complexes. These two parameters will be examined later as the most important for characterising a donor–acceptor bond. The dipole moments of complexes have been investigated quite widely[9], but considerably fewer data are available on their heats of formation[10,11].

2. DETERMINATION OF DIPOLE MOMENTS AND HEATS OF FORMATION OF MOLECULAR COMPOUNDS

The usual method for determining the dipole moments of molecules in dilute solution is not very suitable for the investigation of molecular compounds, owing to possible dissociation into their components[12-15]. In several investigations attempts were made to overcome this difficulty by allowing for the dissociation constant of the complex, which was found by some other method; this necessitated additional experiments, and did not always yield the desired results.

More accurate results can be obtained by a method[16-19] in which the molecular polarisation of the complexes is determined by measuring the dielectric constant and the density (or refractive index) of a series of isomolar solutions. The experimental values of the polarisation for a range in which one component is present in excess, i.e. a range in which dissociation of the complex is suppressed, are extrapolated to infinite dilution. However, this method is extremely laborious, and exhibits the general defects associated with the extrapolation of experimental values of molecular polarisation to infinite dilution.

Dielectrometric titration must be acknowledged as experimentally the simplest method, giving the most accurate results for the dipole moments of molecular compounds[20-22]. It consists essentially in measuring the dielectric constant ϵ and the density d of solutions of the component A in an inert solvent ($C_A \simeq 0.05$–0.1 M) with successive addition of small portions of the component D.

The experiment is conducted in a measuring cell with stirring of the solution, which enables ϵ–C_D and d–C_D curves to be obtained (the latter by a float method) over a wide range of concentrations C_D for the same initial solution of component A. The design of the measuring cell enables experiments to be conducted in an atmosphere of a dry inert gas.

If the components A and D do not interact, linear ϵ–C_D and d–C_D relations are observed. In such case all that is required is to determine the dipole moment of the added substance D in a solvent containing a small quantity of substance A.

If a complex having a different dipole moment from that of the added component D is formed in the system, the dielectrometric titration curve for 1 : 1 complexes of moderate stability usually has the form mnl (Fig. 1). Extrapolation (by Hedestrand's method) of the initial portions of the ϵ–C_D and d–C_D curves gives the dipole moment of the compound AD when dissociation is suppressed. Extrapolation of the second portions of the curves (following the inflection) gives the dipole moment of the added substance D.

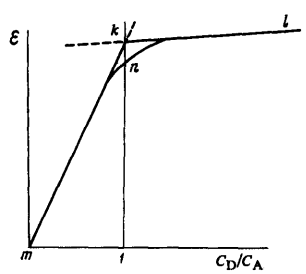

Figure 1. General form of dielectrometric titration curves for systems of the type A + D ⇌ A.D.

The parameters α and β in Hedestrand's equation are determined from the relations

$$\alpha = \frac{\varepsilon_s - \varepsilon_b}{C_{AD}}, \quad \beta = \frac{d_s - d_b}{C_{AD}},$$

where ϵ_s and d_s are the extrapolated values of the dielectric constant and the density of the solution at the point k (Fig.1), and ϵ_b and d_b are the dielectric constant and the density of benzene.

The departure of the experimental curve mnl from the extrapolated mkl is due to dissociation of the complex into its components. The magnitude of this deviation enables the equilibrium constant of the complexing reactions to be determined, and the thermodynamic parameters of the complex from the temperature dependence of the equilibrium constant[23,24].

In the case of complexes which are only slightly dissociated in solution the $\epsilon - C_D$ curves have the form *mkl* (Fig. 1), and dielectrometric titration gives values for the dipole moment which are close to those obtained by the usual method. With complexes which are dissociated the two methods show very substantial differences, the usual method giving incorrect results for the dipole moments in such systems.

Dielectrometric titration will give valuable information on complex formation in more complicated systems than 1 : 1 complexes. For example, investigation of the complexes formed by tin and titanium tetrachlorides with ethers and sulphides revealed that the processes took place in stages. Fig. 2 shows $\epsilon - C_D$ curves for the complexes of tin(IV) chloride with certain sulphides[25]. It is clearly evident that a 1 : 1 complex having a large dipole moment is formed initially when a sulphide is added to a solution of the tin chloride in benzene; this is followed by addition of a second molecule of the sulphide, accompanied by a decrease in the overall dipole moment of the complex. The process is complete with formation of a 1 : 2 complex, and the slope of the straight line following this ratio of the components corresponds to the dipole moment of the added sulphide.

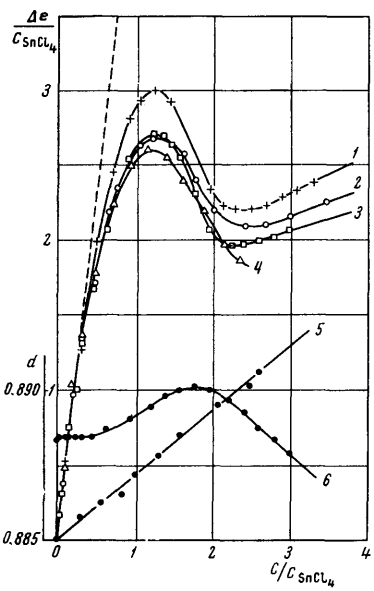

Figure 2. Curves for the dielectrometric titration of 0.05–0.15 M $SnCl_4$ in benzene with:
1) dibutyl sulphide; *2*) dinonyl sulphide; *3*) dioctyl sulphide; *4*) dihexadecyl sulphide; *5*) diphenyl sulphide; *6*) density of solutions of $SnCl_4 + (C_8H_{17})_2S$.

Valuable information on complexing processes has been obtained where more than one donor atom is present. Forward and back titration, e.g. in the aluminium bromide–dioxan system, has enabled the composition, structure, and mutual convertibility of 1 : 1 and 2 : 1 complexes to be established[26]. This procedure may be extremely useful for investigating complex formation by polymer molecules.

Thus dielectrometric titration enables the process of complex formation to be followed, the composition of the resulting complexes to be determined, and their dipole moments to be measured under conditions such that dissociation is suppressed. It is possible by this method to determine the equilibrium constants of the complexing reactions, and from their temperature dependence to find the thermodynamic parameters of the complexes[23,24].

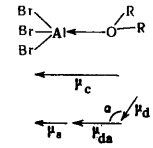
Investigation of the aluminium bromide–benzene system by dielectrometric titration[27] has led to the conclusion that the large dipole moment (exceeding 5 D), usually attributed to a complex of aluminium bromide with benzene, is due to water present as impurity in the benzene and the formation of a highly polar ternary complex $Al_2Br_6.HBr.nC_6H_6$. The true dipole moment of the complex of aluminium bromide with benzene proved to be ~ 1.0 D.

The heat of complex formation in the gas phase, with the energy of rearrangement of donor and acceptor molecules accompanying complex formation taken into account, is a direct measure[10] of the energy of the donor–acceptor bond. Among several methods[5,10] for determining heats of complex formation the most convenient—both experimentally and in the wide range of varied systems covered—is their measurement in solution. However, the effect of the solvent must then be allowed for. Several workers have shown[28–30] that heats of complex formation in inert solvents are close to the values in the gas phase.

Calorimetric titration is the most convenient method for obtaining actual data on heats of formation of molecular compounds which dissociate in solution[31]. Valuable information on the state of the compounds in solution is provided by cryoscopic titration[32]. Correlation of the results obtained by dielectrometry and calorimetry with the results of this method enables more unambiguous answers to be given to the questions of what complex and what state the measured parameters relate to.

3. STRUCTURE OF COMPLEXES OF DONOR–ACCEPTOR TYPE

The overall dipole moment of a complex μ_c can be written as the sum of three terms: $\mu_c = \mu_d + \mu_a + \mu_{da}$, where the right-hand side represents the dipole moments of the donor portion of the complex, the acceptor portion of the complex, and the donor–acceptor bond respectively. With the complex of aluminium bromide and ether, for example, resolution of the overall dipole moments μ_c into its components can be represented by the scheme



Hence, in order to evaluate μ_{da} from the experimental value of μ_c, it is necessary to know the magnitude and the relative orientation of μ_d and μ_a. Since complex formation involves in several cases rearrangement of both acceptor and donor molecules, the experimental data can be analysed provided that the structure of the molecular compounds is known. Structural investigations of complexes also provide information on the type of molecular orbitals involved in the formation of intermolecular bonds.

Extensive X-ray investigations[33,37] of complexes formed by halogens X_2 (Cl_2, Br_2, I_2, ICl) with aromatic hydrocarbons and with compounds containing oxygen, nitrogen, and

sulphur have shown that roughly the same kind of changes in the molecules accompany complex formation in all these systems.

In all X_2.D complexes the donor–acceptor bond X← D is located in line with the X–X bond: X–X←D has an XXD angle of 178–180°. Thus the two halogen atoms in the complex are not equivalent. The length of the X–X bond increases on complex formation, the elongation being greater the more stable the complex. Thus in the comparatively stable complexes formed by iodine with dibenzyl sulphide and with trimethylamine the increase in length of the iodine–iodine bond is 0.15 and 0.20 Å respectively. In the less stable complexes formed by chlorine and by bromine with benzene the X–X bonds are of practically the same length as in the free molecules. The lengths of the intermolecular bonds X–D are also associated with the stability of the complexes.

The orientation of donor molecules relative to the donor–acceptor bond differs with amines, ethers and sulphides.

The complex of dibenzyl sulphide with iodine[34] has an angular configuration (Fig. 3). The mirror plane of the molecule passes through the I–I←S line between the benzyl groups. The interatomic distances and angles in the sulphide molecule remain practically unchanged on complex formation. An analogous angular configuration has been found[35,36] in the complex of iodine with dithian. The angular configuration of the complexes formed by iodine with sulphides can be regarded as evidence that the donor pair of electrons in the sulphide molecule is the $3p^2$ lone pair of the sulphur atom.

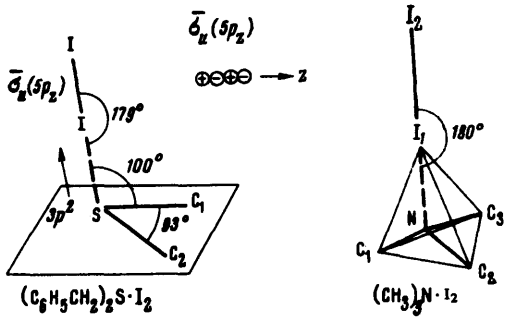


Figure 3. Structure of the complexes $(C_6H_5CH_2)_2S.I_2$ and $(CH_3)_3N.I_2$.

The trimethylamine molecule has a tetrahedral configuration[37] ($\alpha = 180°$) in its complex with iodine (Fig. 3). This indicates that the lone pair of electrons of the nitrogen atom takes part in the intermolecular bond in the sp^3 state.

The valency angle of oxygen in its complexes with halogens is not reliably known. X-Ray examination of the complex of dioxan with iodine chloride yields[38] 178° for the OICl angle, and a value of 160° has been found[39] from examination of the complex of dioxan with iodine.

X-Ray and electron-diffraction investigations of the complexes formed by boron trifluoride with amines[40–42] and with diethyl ether and by aluminium bromide with hydrogen sulphide[43] have shown that the acceptor portion of these complexes has a tetrahedral conformation. The amine molecules undergo no fundamental rearrangement on complex formation with boron trifluoride. Thus the angles at the nitrogen in the complexes formed by this halide with ammonia, methylamine, and trimethylamine are close to the tetrahedral angles (107–114°), while the length of the carbon–nitrogen bond in trimethylamine is 1.50 Å,[41] these being close to the parameters in free trimethylamine. The lengths of the boron–nitrogen, boron–oxygen, and aluminium–sulphur donor–acceptor bonds (1.53–1.60,[41,42] 1.52,[40] and 2.40 [43] Å) are close to or slightly exceed the sum of the covalent radii (1.58, 1.54, and 2.30 Å respectively).

Little work has been done on establishing the structure of the complexes formed by tetrahalides of Group IV metals. Tin and titanium tetrahalides give with oxygen and sulphur compounds complexes of two types—MX_4.D with five-coordination of the metal atom, and MX_4.2D with six-coordination of the metal—the process of complex formation taking place in stages[22,35,44,45].

It has been established by means of dipole moments that $TiCl_4.R_2S$ complexes[46] have the tetragonal pyramidal conformation *I* (Fig. 4), and $SnCl_4.R_2S$ complexes the trigonal bipyramidal conformation *II*. A bipyramidal structure has been found also by X-ray analysis for the 1 : 1 complex of trimethyltin chloride with pyridine[47].

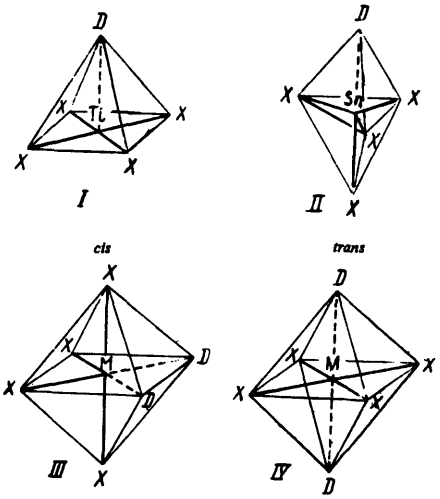

Figure 4. Conformation of complexes of tin and titanium tetrahalides.

For compounds having the composition MX_4.2D an octahedral conformation is the most probable, two isomers being possible here, with the donor molecules in *cis*- and *trans*-positions in the octahedron (*III* and *IV*, Fig. 4). An octahedral structure with *cis*-arrangement of the donor molecules has been established by X-ray examination for the complex $SnCl_4.2POCl_3$.[48] The same structure has been found for the complexes $SnCl_4.2SeOCl_2$ [49] and $TiCl_4.2POCl_3$.[50] A *cis*-octahedral structure has been established also for the dimeric compounds $SnCl_3OCH_3.CH_3OH$ and $SnBr_3OCH_3.CH_3OH$.[51] In contrast to this, a *trans*-octahedral conformation has been found[52] for the complex of tin tetrachloride with tetrahydrothiophen $SnCl_4.2C_4H_8S$.

The first use has been reported[53] of nuclear quadrupole resonance (n.q.r. of halogen atoms) for solving problems of *cis–trans*-isomerism in octahedral complexes. It has been established by the method of molecular orbitals that the n.q.r. frequency shifts and the character of the n.q.r. splittings differ for *cis*- and *trans*-isomers of octahedral complexes of Group IV metal halides with *n*-donors. Fig.5 illustrates the relation between the structure of the isomers and the corresponding form of n.q.r. spectra. Fig. 5 includes also a suggested scheme of splitting for the bipyramidal complex $MX_4.D$, in which the coordination number of the metal is 5. The large splitting in the spectrum of the *cis*-isomer has been found to be due to the chemical non-equivalence of axial and equatorial halogen atoms.

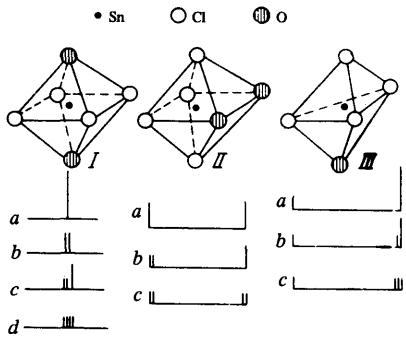

Figure 5. Splitting of nuclear quadrupole resonance spectra of complexes formed by tetrahalides of Group IV metals with *n*-donors.

The structure of several complexes of tin(IV) chloride has been established from the character of the splitting in the n.q.r. spectra: n.q.r. data[53] show that the complexes $SnCl_4.2POCl_3$ and $SnCl_4.2C_2H_5OH$ have the *cis*-structure *III* (Fig. 4), the complex $SnCl_4.2(C_2H_5)_2O$ has the *trans*-structure *IV* (Fig. 4), and the complexes $SnCl_4.CH_3O[CH_2]_2OCH_3$ and $SnCl_4.CH_3O[CH_2]_4OCH_3$ have a *trans*-chain structure (Fig. 6).

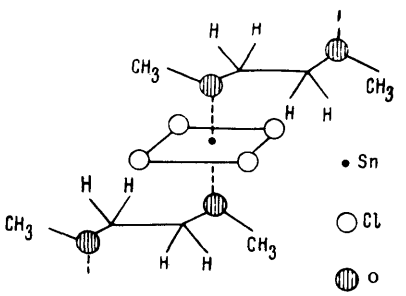

Figure 6. Structure of the complex $SnCl_4.CH_3O[CH_2]_2OCH_3$ in the solid state.

It may be noted that data on the structure of complexes obtained by X-ray examination and from nuclear quadrupole resonance, as well as most of the published data obtained by infrared spectroscopy[54–58], relate to the crystalline solid state. The method of dipole moments enables an assessment to be made of the state of complexes in solution.

A detailed investigation of the complexes formed by titanium tetrachloride with various sulphides led to the conclusion[45] that, in solution, the octahedral complexes $TiCl_4.2R_2S$ consist of a mixture of *cis*- and *trans*-isomers (*III* and *IV*, Fig. 4), with an approximately random distribution of donor molecules among the apices of the octahedron.

The dipole moments suggest that the complexes $SnCl_4.2R_2S$ are also present in solution (in benzene) as a mixture of *cis*- and *trans*-isomers[46]. On crystallisation the equilibrium may be displaced towards formation of either form. Such a situation is observed, for example, in the tin(IV) chloride–thiolan system: in benzene the complex $SnCl_4.2C_4H_8S$ is a mixture of isomers (dipole moment 5.0 [44]), but in the solid state it has the *trans*-structure[52].

Extremely interesting results have been obtained from an investigation of the complexes $SnCl_4.RO[CH_2]_2OR$ in benzene (dipole moments) and in the solid state (n.q.r.). Compounds of the type $RO[CH_2]_nOR$ or $RS[CH_2]_nSR$, whose molecules contain two donor atoms, enable octahedral complexes of definitely *cis*-structure to be obtained with titanium and tin tetrachlorides at values of $n = 2, 3$. The dipole moments of such complexes reach 9–10 D.[45,46,59] It was found that in benzene the complex $SnCl_4.RO[CH_2]_2OR$ was monomeric and had the *cis*-structure, and in the crystalline state it had a *trans*-chain structure[53].

Thus all the results obtained indicate unambiguously that the structure of octahedral complexes formed by tetrahalides of Group IV metals with *n*-donors may change on passing from one state to another. The character of the changes differs in different systems. This fact was further taken into account when considering the experimental dipole moments of the complexes.

4. DEGREE OF CHARGE TRANSFER AND STABILITY OF INTERMOLECULAR BONDS

Examination of the dipole moments and heats of formation of complexes formed by iodine with organic sulphides varying in structure has led[24,60] to the establishment of direct proportionality between the dipole moments of intermolecular bonds (μ_{da}) and the heats of formation of the complexes ($-\Delta H$). A similar $\mu_{da}-\Delta H$ relationship has been found in complexes formed by tin tetrachloride with organic sulphides[46]. It has been confirmed[61] for the complexes formed by iodine with amines and with ethers.

The value of μ_{da} is in general a complicated function of several parameters. Besides the displacement of electron density from donor to acceptor, a dipole moment may appear here, as in ordinary chemical bonds, as a result of a difference in size of the atoms, of a state of hybridisation. Contributions due to the difference in size of the atoms forming the bond (homopolar dipole) and to the change in hybridisation of the *n*-donors (atomic dipole) are probably small, especially as the molecules of donors (amines, ethers, sulphides) do not undergo any substantial changes on complex formation. Hence it may be assumed to a first approximation that the main contribution to the value of μ_{da} is made by the displacement of electron density from donor to acceptor, or the degree of charge transfer. The latter can be determined from the experimental values of μ_{da} and the interatomic distances r as the ratio μ_{da}/er, where e is the charge on the electron.

An attempt has been made[62] to ascertain whether a linear relation between μ_{da}/er and ΔH is characteristic of

narrow series of analogous complexes or whether it is general for the complexes under discussion. The range of materials investigated was therefore considerably extended, by determining the dipole moments and heats of formation of the complexes formed by tin and titanium tetrachlorides and tetrabromides with sulphides, ethers, and nitriles. Published data on the dipole moments and the heats of formation of the complexes were surveyed.

Table 1. Dipole moments, degrees of charge transfer, and heats of formation of donor–acceptor bonds in complexes[62].

No.	Complex	μ_c	μ_d	μ_{da}	r	$\frac{\mu_{da}}{er}$	ΔH

Since the relationship proved to be general in character, it appears desirable to examine the results of this work in greater detail. Table 1 gives the formulae of the complexes, the values of μ_c, μ_d, μ_{da}, and r, and also the parameters μ_{da}/er and the heats of formation ΔH per donor–acceptor bond. In the determination of μ_{da} (see scheme at beginning of Section 3) from the experimental values of μ_c, account was taken of the structure of the complex and the values of μ_d and μ_a. The molecules of amines, ethers, sulphides, and nitriles give donor–acceptor bonds involving the lone pair of the corresponding heteroatom. It can be assumed to a first approximation that μ_d in the complex is equal to the dipole moment of the initial molecule. With regard to the relative arrangement of the μ_d and μ_{da} vectors, it follows from what has been said above that the angle α between them can be taken to be 100° in the sulphide complexes, 150–160° in the ether complexes, and 180° in the complexes with amines and nitriles.

The dipole moments of the acceptor part of the complexes μ_a were determined in conformity with the structure of the complex and the moments of the M–Hal bonds. The conformation of a tetragonal pyramid (*I*, Fig. 4) was adopted for the five-coordinate complexes $TiX_4.D$, a trigonal bipyramid (*II*) for the five-coordinate complexes $SnCl_4.D$, and an octahedral conformation for the six-coordinate complexes $MX_4.2D$. For the third group, only data relating to complexes of definitely *cis*-structure (*III*, Fig. 4) have been considered. The dipole moments of the M–X bonds were taken to be as follows[65]: Sn–Cl 3.0 D, Sn–Br 2.9 D, Ti–Cl 2.2 D, and Ti–Br 2.1 D.

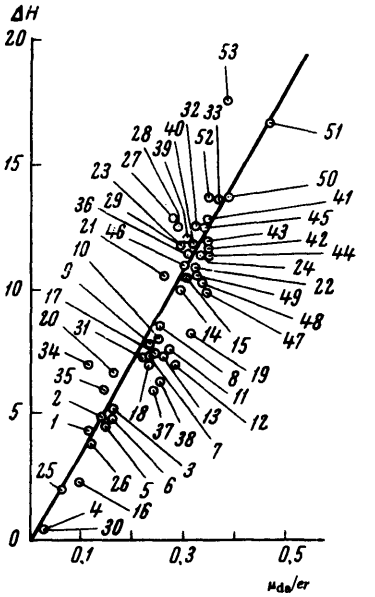

Figure 7. Dependence of ΔH on μ_{da}/er for complexes of I_2, $SnCl_4$, $SnBr_4$, $TiCl_4$, $TiBr_4$, $(CH_3)_3B$, and BF_3 with amines, ethers, and sulphides (numbering of points corresponds to Table 1.).

A tetrahedral structure was adopted[40] for the complexes formed by boron trifluoride with dimethyl ether and with tetrahydrofuran and by trimethylboron with ammonia and with trimethylamine, the bond dipole moments being 1.6 D for the boron–fluorine bond[64,65] and 0.3 D for the boron–methyl bond[65].

The data in Table 1 show that a definite relation exists between the parameters μ_{da}/er and the heats of formation of the coordinate bonds $-\Delta H$: the greater the degree of charge transfer, the larger the heat of formation, and hence the more stable the intermolecular bond. This is especially clearly evident from Fig. 7.

The equation to the straight line, found by the method of least squares, is

$$\Delta H = 35.3 \frac{\mu_{da}}{er} \qquad (1)$$

The results in Table 1 cover more than fifty diverse systems. From this it may be concluded that the relation established between the degree of charge transfer and the stability of the intermolecular bond is general for donor–acceptor complexes of type $n\nu$, $n\sigma$.

The direct proportionality between the degree of charge transfer and the energy of formation of a coordinate bond can be regarded as quantitative evidence of the correctness of the view that intermolecular bonds of this type are charge-transfer bonds.

A theoretical basis for the experimental relation (1) can be obtained from Mulliken's theory of charge-transfer complexes[1,3]. The wave function of the ground state of a complex A.D is written to a first approximation in the form

$$\psi = a\psi_0(\mathrm{A, D}) + b\psi_1(\mathrm{A^- — D^+}) \qquad (2)$$

in which ψ_0 is the wave function of the "bondless" structure and ψ_1 the wave function corresponding to the structure with transfer of charge. Solution of this equation for the case in which $a > b$ gave relations[1] between certain parameters of the complexes.

On the basis of these relations the equation

$$\Delta H = \frac{h\nu}{a^2\left(1+\frac{a}{b}S_{01}\right)\left(1+\frac{b^2}{a^2}+\frac{b^{*2}}{a^{*2}}\right)} \cdot \frac{\mu_{da}}{er} \qquad (3)$$

has been deduced[24,61], linking the degree of charge transfer μ_{da}/er with the energy of formation of the complex ΔH. Here $h\nu$ is the energy of the electronic transition corresponding to the charge-transfer band, a and b are the coefficients in Eqn. (2), a^* and b^* are the coefficients in the analogous equation describing the excited state, and $S_{01} = S\psi_1\psi_0 d\tau$ is the overlap integral of the functions ψ_0 and ψ_1 (Eqn. 2).

The large majority of investigations[4–6] on charge-transfer complexes have involved studying the corresponding ultraviolet or visible absorption bands. Equation (3) shows how the position of the charge-transfer band is related to the degree of charge transfer and the energy of the intermolecular bond. It enables experimental values of μ_{da}/er and ΔH to be used to predict the position of the corresponding bands. This is of great value, especially in view of the fact that hardly any work has been done on charge-transfer bands for complexes of type $n\nu$.

The necessary and sufficient condition for a linear relation between μ_{da}/er and ΔH is that the coefficient

$$\frac{h\nu}{a^2\left(1+\frac{a}{b}S_{01}\right)\left(1+\frac{b^2}{a^2}+\frac{b^{*2}}{a^{*2}}\right)} = K \qquad (4)$$

should be constant for different complexes. The problem of the constancy of K (Eqns. 3 and 4) for different complexes, and how close it is to the slope (35.5 kcal or 1.5 eV) of the experimental straight line (1), can be approached in various ways.

We can use the charge-transfer bands $h\nu$ known for certain complexes to calculate K (Eqn. (4) and compare the result with the experimental value (1). Or, if the charge-transfer bands are unknown, we can start with experimental values of ΔH and μ_{da}/er, predict the position of the bands by means of Eqn. (3), and verify the result experimentally.

Corresponding calculations of K using values of $h\nu$ for a series of iodine complexes have shown[62] entirely satisfactory agreement with the experimental value of K. In addition, experimental values of μ_{da}/er and ΔH have been used to predict and to find previously unknown charge-transfer bands in a series of complexes of tin and titanium tetrachlorides with ethers and sulphides.

It has been shown that the experimentally established linear relation between degree of charge transfer and energy of the donor–acceptor bond can be described by Eqn. (3), obtained on the basis of Mulliken's theory.

The presence of direct proportionality between values of ΔH and μ_{da} for the same acceptor with a group of similar donors can be used to estimate values of μ_a. In this way dipole moments have been determined[62] for the iodine molecule in complexes with sulphides and amines (0.8–1.0 D). These values have been taken into account in determining μ_{da} in the corresponding complexes. An analogous estimate[62] of the dipole moment of the tin–chlorine bond in five-coordinate complexes of tin(IV) chloride with organic sulphides gives 3.0 D, practically identical with the dipole moment of this bond in the tin tetrachloride molecule[63].

5. DONOR PROPERTIES OF AMINES, ETHERS, AND SULPHIDES

Two aspects of the problem of the donor properties of molecules containing a heteroatom—the influence of the structure of the molecule on the donor properties of the heteroatom and the comparative donor properties of amines, ethers, and sulphides of similar structure—will be considered. The effect of molecular structure on donor properties is revealed most clearly in sterically unhindered complexes. The complexes formed by iodine with amines, ethers, and sulphides meet these requirements most closely.

* Dipole moments of the sulphides in the presence of iodine (~0.04 M).

Table 2 gives[66] dipole moments and dissociation constants for complexes of iodine with sulphides of different structures. Various dialkyl sulphides (C_2–C_{16}) both straight-chain and iso-structures, form with iodine complexes of almost identical stability, their dipole moments being 4.6–5.6 D.

In contrast, aromatic and $\alpha\beta$-unsaturated sulphides exhibit very weak donor properties towards iodine. The dipole moments of diphenyl sulphide and thiophen, measured in the presence of iodine (0.05–0.1 M), are close to the values in the pure solvent. Proof that the diminution in donor properties in this case is not due to steric hindrance is provided by the fact that the saturated analogues—dicyclohexyl sulphide and thiolan—form with iodine under

the same conditions stable compounds having dipole moments and dissociation constants close to the corresponding values for complexes of iodine with dialkyl sulphides.

If the C=C double bond or the aromatic ring is moved away from the sulphur atom, as occurs in $\beta\gamma$-unsaturated compounds, the sulphur atom is able to form a donor–acceptor bond with iodine. Dibenzyl sulphide and diallyl sulphide behave towards iodine in a fundamentally similar manner to dialkyl sulphides, but the dipole moments of the complexes are considerably smaller.

The differences in the behaviour of $\alpha\beta$- and $\beta\gamma$-unsaturated compounds of sulphur compared with saturated compounds is probably explained by a greater or smaller degree of interaction of the lone pair of electrons of the sulphur atom, responsible for complex formation, with the π-electrons of the unsaturated systems.

Table 3. Dipole moments and thermodynamic constants of complexes I_2.D of iodine with amines, sulphides, and ethers.

Donor	μ_c	μ_{da}	$-\Delta H$	$-\Delta S$	$-\Delta F_{298°}$	$K_{298°}$

* Dipole moments of the sulphides measured in the presence of iodine.

** It is not clear whether thiophen or tetrahydrothiophen is intended here (Ed. of Translation).

Analysis of experimental data on the effect of the structure of the radicals on the donor properties of the heteroatom has shown that the Hammett–Taft rule is satisfied in sterically unhindered complexes. For complexes of iodine with sulphides the equation[25,26] is $-\Delta H = 7.7 - 6.7\,\Sigma\sigma^*$. The large value (6.7) of the coefficient indicates that the complexing reactions are very sensitive to change in the electron density on the heteroatom. An analogous effect of molecular structure on the donor properties of the heteroatom is observed in complexes of iodine with amines and with ethers[24,61,67], as is well illustrated by the data in Table 3.

Complexes with other acceptors, however, begin to exhibit the effect of the steric factor, which makes corrections necessary. The length and the branching of the aliphatic radicals R in ethers ROR have been shown[59] to have an immense influence on their complexing power towards tin(IV) chloride. In the analogous but more stable complexes of the latter with sulphides[22,25,46] the effect of the steric factor is less important, the size of the heteroatom also being of significance.

With aluminium tribromide and also with gallium trichloride aliphatic amines, ethers, and sulphides, independently of the length or degree of branching of the radicals, form complexes having approximately the same degree of charge transfer and stability of their intermolecular bonds[21,68,69].

The donor (or basic) properties of ethers and amines are often assessed from the displacement of the γ_{OD} band in the infrared spectrum of deuteriomethanol on interaction of the latter with the donor (Gordy's method). It is clear from the above that the basicity sequences obtained by this method may be completely different when other acceptors are used. This must be borne in mind in interpreting experimental data in terms of donor–acceptor interaction.

Let us compare the donor properties of amines, ethers, and sulphides of analogous structure. From the ionisation potentials of amines, sulphides, and ethers of similar composition (Table 4) it may be expected that, according to the degree of charge transfer and the stability of the intermolecular bonds with the same acceptor, the sequence of the compounds will be amines > sulphides > ethers. Such a sequence of donor properties is actually observed in the complexes with iodine[61] and tin(IV) chloride[62] and bromide[62].

Table 4. Ionisation potentials (eV) of some amines, sulphides, and ethers[70,71].

Amines	I	Sulphides	I	Ethers	I
$(CH_3)_3N$	7.82	$(CH_3)_2S$	8.68	$(CH_3)_2O$	10.0
$(C_2H_5)_3N$	7 50	$C_2H_5SCH_3$	8.55	$C_2H_5OCH_3$	9.81
$(C_3H_7)_3N$	7.23	$(C_2H_5)_2S$	8.48	$(C_2H_5)_2O$	9.53

In the complexes with titanium(IV) chloride and bromide[62] ethers and sulphides have closely similar donor properties, but in the complexes with aluminium tribromide and trichloride the sequence changes, ethers proving to be stronger donors than are sulphides. According to the degree of charge transfer and the stability of the intermolecular bonds the complexes are arranged in the sequence[68,69]

$$AlBr_3 \cdot R_3N > AlBr_3 \cdot R_2O > AlBr_3 \cdot R_2S\ .$$

The same sequence is observed in the complexes with boron trifluoride[68].

The question arises why ethers, which have a higher ionisation potential than have sulphides, are more active donors towards aluminium and boron halides than are the corresponding sulphides. A possible explanation, that this is due to the specific character of halides of Group III elements, in particular their strength as acceptors, is untenable, since in the complexes with gallium trichloride the strength of the donor–acceptor bonds and the degree of charge transfer vary in the sequence[21,68]

$$GaCl_3 \cdot R_3N > GaCl_3 \cdot R_2S > GaCl_3 \cdot R_2O\ .$$

Sulphides are more active donors than are ethers towards gallium trichloride. A similar sequence[72] of variation in donor properties is found in the gallium tribromide and tri-iodide complexes.

An extremely important factor in the formation of ordinary chemical bonds, by means of a pair of electrons in the

field of two nuclei, is the degree of overlap of the corresponding orbitals. This factor has been found to play a quite important part also in the formation of donor–acceptor bonds. Table 5 gives the overlap integrals of the corresponding orbitals involved in the formation of intermolecular bonds, calculated by the Slater approximation[73].

Table 5. Overlap integrals of intermolecular bonds.

Acceptor	Donor				Experimental sequences	Ref.
	N($2sp^3$)	S($3p$)	O($2sp^3$)	O($2sp^2$)		
I ($5p$)	0.29	0.23	0.14	0.14	I—N>I—S>I—O	24.61
Sn ($5d^2sp^3$)	0.42	0.36	0.28	—	Sn—N>Sn—S>Sn—O	62
Ti ($3d^24sp^3$)	—	0.36	0.38	—	Ti—S≃Ti—O	62
Ga ($4sp^3$)	0.49	0.41	0.41	0.43	Ga—N>Ga—S—Ga—O	68
Al ($3sp^3$)	0.48	0.38	0.42	0.40	Al—N>Al—O>Al—S	68.69
B ($2sp^3$)	0.60	0.47	0.54	0.52	B—N>B—O>B—S	68
O—H($1s$)	0.48	0.36	0.42	0.43	O—H...N>OH···O>OH...S	

In the complexes of amines, sulphides, and ethers with iodine and with tin tetrahalides the overlap integrals vary in the same sequence as do the ionisation potentials of the corresponding donors. These two factors operate in the same direction, ensuring the sequence—amines > sulphides > ethers—for the donor properties. In the complexes of titanium tetrahalides the overlap integrals are closely similar with ethers and with sulphides. This is probably the main reason for the almost identical stability of the intermolecular bonds in complexes of titanium(IV) chloride and bromide with ethers and with sulphides.

Gallium–sulphur and gallium–oxygen intermolecular bonds have equal overlap integrals. Here the sequence of donor properties—amines > sulphides > ethers—corresponds to the differences in the ionisation potentials.

In the complexes of boron and aluminium halides the overlap integrals of the aluminium–oxygen intermolecular bonds are larger than those of the aluminium–sulphur bonds. This fact obviously plays a decisive part and is responsible for the greater stability of the bonds in ether than in sulphide complexes, in spite of the opposite relationship of the ionisation potentials. It is interesting that the same sequence of donor properties—amines > ethers > sulphides—is observed also with hydrogen bonds. Preliminary calculations of the overlap integrals of the corresponding orbitals (Table 5) confirm this sequence.

Comparison of data (Table 5) relating to aluminium and boron halides with those for systems containing hydrogen bonds shows that the observed relationship of the donor properties of ethers and sulphides is not linked with the strength of the acceptor, as would appear at first glance, but is actually determined by the degree of overlap of the corresponding orbitals.

Thus the results which have been cited show that the conditions of overlap of the orbitals involved in the formation of intermolecular bonds are of paramount significance in the formation of donor–acceptor bonds, and in considerable measure determine the properties of the latter.

When the donor properties of various compounds containing a heteroatom are to be compared, account must be taken of the whole set of parameters governing the formation of intermolecular donor–acceptor bonds.

6. DETERMINATION OF ENERGY OF P_π-CONJUGATION IN AROMATIC COMPOUNDS CONTAINING A HETEROATOM BY THE METHOD OF COMPLEX FORMATION

Investigation of the donor power of amines, ethers, and sulphides towards iodine, and of ethers and sulphides towards tin and titanium tetrahalides, has shown that aromatic compounds, unlike aliphatic compounds, do not give with these acceptors complexes which are stable in solution. The chief reason for the marked weakening of the donor properties of aromatic compared with aliphatic compounds is, as mentioned above, interaction of the lone pair of electrons of the heteroatom responsible for complex formation with the system of π-electrons of the aromatic radicals (p_π-conjugation).

In contrast to the above, relatively weak acceptors—the halides of aluminium, gallium, and also boron—yield with aromatic amines, ethers, and sulphides stable complexes, whose dipole moments are close to those of the corresponding complexes with aliphatic donors.

Detailed investigation of the properties of the complexes formed by aluminium tribromide and gallium trichloride with aromatic compounds has shown[68,74–76] that the formation of intermolecular bonds is accompanied by the breakdown of p_π-conjugation. This is clearly demonstrated, for example, on comparing the ultraviolet spectra of anisole and its complex with aluminium tribromide. The spectrum of anisole changes abruptly on complex formation, and approaches that of benzene. The absorption bands in the region of 219 and 270 nm, attributed[77–80] to conjugation of the lone pair of electrons of the oxygen atom with the system of π-electrons of the ring, disappear on complex formation.

Analogous changes in spectra, indicating breakdown of p_π-conjugation in heteroaromatic compounds on complex formation with aluminium tribromide and with gallium trichloride, have been observed[68] in systems containing phenetole, diphenyl ether, 2-methoxynaphthalene, and their sulphur analogues.

The destruction of p_π-conjugation in aromatic compounds accompanying complex formation should, of course, be evident in the energetics of the complexing reactions.

Table 6 shows that corresponding complexes with aliphatic and aromatic ethers have closely similar dipole moments. Taking the complexes of aluminium bromide with ethers as example, we can examine the contributions made by the acceptor molecule μ_a and the donor molecule μ_d to the overall dipole moment of the complex μ_c (see scheme at beginning of Section 3). If a tetrahedral conformation is assumed for the bonds about the aluminium atom in the complex, μ_a will be close to the dipole moment of the aluminium–bromine bond. Unfortunately, this quantity is unknown, but it can obviously be assumed, to an adequate degree of approximation, to be the same in all complexes of aluminium bromide with ethers.

The dipole moments of aliphatic and aromatic (unsubstituted) ethers are closely similar at 1.15–1.30 D.[9] The angle α can also be regarded as the same in all these complexes. It therefore follows from the equality of μ_c for complexes of aluminium bromide with aliphatic and with aromatic ethers that the dipole moments of the donor–acceptor bonds μ_{da} are also equal in these complexes.

It has been shown above that there is direct proportionality between μ_{da}/er and ΔH for complexes of donor–acceptor type. Consequently the equality of values of μ_{da} in complexes formed by aluminium tribromide with aliphatic and with aromatic ethers should imply equality of the formation enthalpies of the intermolecular bonds in these complexes.

The total heat of complex formation in an inert solvent can be represented by three components:

$$\Delta H = \Delta H_{da} + \Delta H_a + \Delta H_d$$

where ΔH_{da} is the heat of formation of the donor–acceptor bond and ΔH_d and ΔH_a are the energies or rearrangement of donor and acceptor molecules on complex formation. In the complexes of aluminium bromide with ethers the term ΔH_a can be regarded as constant. Hence in the series of complexes of aluminium bromide with aromatic and aliphatic ethers the quantity $\Delta H_{da} + \Delta H_a$ is the same, and differences in the experimental heats of complex formation ΔH are determined by the term ΔH_d, the energy of rearrangement of the donor molecule. No substantial quantity of heat—of the order of 0.3 kcal mole^{-1} [40]—is required for the molecular rearrangement of aliphatic ethers on complex formation. Therefore the differences in the values of ΔH for complexes of aluminium bromide with aliphatic and aromatic ethers (Table 6) can be ascribed to the energy of rearrangement of the corresponding aromatic ethers.

It has been established spectroscopically[68,74,76] that the rearrangement of aromatic ethers accompanying complex formation consists in the disruption of p_π-conjugation, so that the energy of rearrangement of an aromatic donor is the p_π-conjugation energy. The latter has been determined[68,75] as the difference between the mean value of ΔH for complexes of aluminium bromide with aliphatic ethers (23.3 kcal mole^{-1}) and the corresponding values of ΔH for its complexes with aromatic ethers.

An analogous analysis of the ultraviolet spectra, dipole moments, and heats of formation of complexes with sulphides and amines, as well as of the aluminium chloride, gallium chloride, and boron fluoride complexes with aliphatic and aromatic amines, ethers, and sulphides, has enabled the energies of conjugation E_j in the corresponding molecules to be determined. The accuracy of the determination is 0.8–1.0 kcal mole^{-1}.

Table 7 gives values of E_j found[68] by the method of complex formation with various acceptors. It is seen that closely similar values of the p_π-conjugation energy are obtained for the same donor by complex formation with four different acceptors. The slight discrepancy of 1–1.5 kcal mole^{-1} is primarily due to the steric factor. Among the acceptors investigated the steric effect is least in the aluminium bromide complexes, and greatest in the complexes of boron trifluoride. The most reliable values of E_j are those obtained in the aluminium bromide complexes.

Table 7. Energies of p_π-conjugation (E_j, kcal mole^{-1}) in aromatic ethers, sulphides, and amines obtained by complex formation with various acceptors.

Donor	Acceptor			
	$AlBr_3$	$AlCl_3$	$GaCl_3$	BF_3

$(C_6H_5)_2NCH_3$	14.9	14.8	17.0	—

The identical values of E_j obtained in complexes with different acceptors confirm the correctness of the initial premises, and indicate that the direct proportionality established between the degree of charge transfer and the energy of the intermolecular bond is applicable to complexes of halides of Group III elements: i.e. it is actually a general characteristic of donor–acceptor bonds.

Published information on the energy of p_π-conjugation is extremely scanty and contradictory[68]. Values have usually been obtained from the heats of combustion of the compounds. Comparison of E_j for a number of amines, ethers, and sulphides indicates that the heteroatoms are arranged in the sequence—N > O > S—according to their capacity for p_π-conjugation with aromatic systems.

The values found for E_j provide a quantitative explanation of why certain aromatic donors form complexes with some acceptors and not with others (with similar values of the steric factor). It is obvious that, if the energy of formation of an intermolecular bond by a donor with a particular acceptor is less than or similar to the p_π-conjugation energy, no complex is formed.

An excellent illustration of the above is provided by complex formation between boron trifluoride and aromatic ethers. The heat of reaction of boron trifluoride with aliphatic ethers is 10–12 kcal mole^{-1}. The destruction of p_π-conjugation in anisole and phenetole requires 7–8 kcal mole^{-1}, and in diphenyl ether ~ 11 kcal mole^{-1}: with this last compound the heat of reaction should be close to zero. Hence boron trifluoride will give quite stable complexes with anisole and with phenetole, but will not form complexes with diphenyl ether.

This also explains the absence of complexes of type $n\sigma$ between iodine and aromatic amines, ethers, and sulphides, as well as of complexes of tin and titanium tetrachlorides with certain aromatic ethers and sulphides.

This method of determining the energy of p_π-conjugation can probably be applied not only to nitrogen, oxygen, and sulphur compounds but also to aromatic compounds of other elements, as well as for estimating the energy of p_π-d_π bonding in organometallic compounds[81].

Organomagnesium Compounds and Their Complexes as Polymerisation Initiators

B.L.Erusalimskii, I.G.Krasnosel'skaya, and I.V.Kulevskaya

This the first review devoted specifically to polymerisation processes initiated by organomagnesium compounds. Attention is concentrated mainly on the anionic polymerisation of unsaturated monomers (hydrocarbons, acrylates, nitriles, vinylpyridines, halogeno-derivatives, etc.). The review also includes short sections on the anionic polymerisation of carbonyl derivatives and cyclic monomers, on cationic polymerisation, and on initiating systems of the Ziegler-Natta type. The bibliography contains 215 references.

CONTENTS

I. Introduction	874
II. Anionic polymerisation of unsaturated monomers	874
III. Polymerisation of carbonyl derivatives and cyclic monomers	880
IV. Cationic polymerisation	881
V. Ziegler-Natta initiating systems	881

I. INTRODUCTION

Until quite recently organomagnesium derivatives occupied a very modest position among the organometallic compounds used as initiators for anionic polymerisation. This was due to their relatively low reactivity towards non-polar unsaturated monomers (i.e. hydrocarbons of the vinyl and diene types), on which most of the research on anionic polymerisation was concentrated for a long time. With studies on the anionic polymerisation of polar monomers, organomagnesium initiators have begun to attract substantially more attention, since in these cases they are quite comparable in efficiency with many organic derivatives of the alkali metals. The considerable experimental data which have now accumulated on polymerisations initiated by organomagnesium compounds have not yet been reviewed and we have therefore attempted to fill this gap. Modern ideas on the composition and structure of organomagnesium compounds have been discussed in detail in the recently published reviews by Wakefield[1] and by Ashby[2].

II. ANIONIC POLYMERISATION OF UNSATURATED MONOMERS

Among studies of the polymerisation of anionic systems by organomagnesium compounds and their complexes, investigations on various polar unsaturated monomers are of the greatest interest. These processes are often highly efficient and stereospecific. Non-polar and low-polarity monomers exhibit a very limited tendency to polymerisation in such systems.

1. Hydrocarbons

Gilman[3-5] and Kinney[6] showed that unsaturated hydrocarbons of the ethylene and diene series do not react with organomagnesium compounds under ordinary conditions. Instances of the addition of alkylmagnesium halides to unsaturated hydrocarbons were established by Fuson[7-10] for compounds of the fluorene and fulvene series containing highly reactive double bonds—dibiphenylylene-ethylene, tetraphenylfulvene, etc.

The first results on the polymerisation of unsaturated hydrocarbons in the presence of organomagnesium compounds were obtained by Ziegler[11], who found that solid polymers were formed in C_2H_4–RMgX(or R_2Mg) systems at 100–150°C and pressures from 100 to 1000 atm. Raising the temperature enables several other hydrocarbon monomers to be polymerised with the same initiators. Wang Fo-sung, Dolgoplosk, Erusalimskii, et al.[12-14] have shown that polymerisation of various diene hydrocarbons with initiators of the above type at 90°C and above is feasible, but even under these conditions the rate of polymerisation is low. When isoprene is bulk-polymerised at 90°C with an initiator concentration of about 0.003 M, the rate does not exceed 1% h^{-1}. Still lower rates characterise the polymerisation of butadiene and 2,3-dimethylbutadiene. Kinetic data on the consumption of the initiator have established

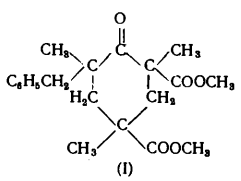
that in the isoprene–$(C_4H_9)_3Mg_2I$ system the rates of initiation and growth are comparable. Thus with an initiator/monomer ratio of 0.01 complete exhaustion of the initiator was observed when 20% of the monomer had been converted. The polyisoprene obtained in the presence of various organomagnesium compounds under these conditions contains 3,4-links as the main structural units (93–99%). The contents of *cis*-1,4-, *trans*-1,4-, and 1,2-links in polybutadiene are 30%, 45%, and 25% respectively (with $(C_4H_9)_3Mg_2I$ as initiator and a polymerisation temperature of 100°C).

Ordinary magnesium alkyls and alkylmagnesium halides are inert towards styrene (at least up to the temperature of its thermal polymerisation). According to Champetier et al.[15] the magnesium–biphenyl–hexametapol [hexamethylphosphoric triamide] system is effective for the polymerisation of styrene and α-methylstyrene.

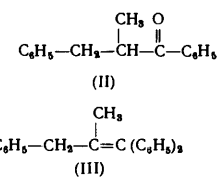
2. Acrylates and Methacrylates

The ability of organomagnesium compounds to initiate the polymerisation of acrylic esters was discovered by Landler[16] in 1949, but systems of this type began to attract significant attention only from the end of the 1950s. Several publications on this question[11,17–28] deal with the effect of the polymerisation conditions on the microstructure of the resulting polymers. Research has also been done[29–41] on the mechanism and the kinetics of the processes involved.

As in other anionic polymerisations of polar monomers, the processes occurring in these systems are complicated by secondary reactions of the initiator with functional groups in the monomer and the polymer chain. According to Goode[29–32] polymerisation in the methyl methacrylate–phenylmagnesium bromide system at 0°C is accompanied by formation of the compounds



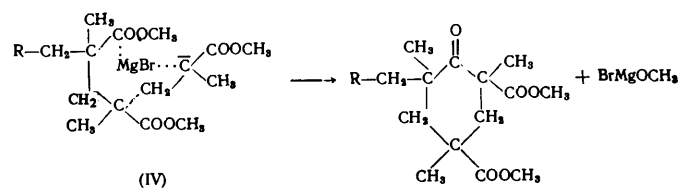
(I)



(II)

(III)

Under the above conditions the relative contents of the polymer and of the compounds (I)–(III) among the reaction products were respectively 96%, 3%, 1%, and 0.1%. Infrared and ultraviolet spectroscopy has established the presence of a large number of short chains in the polymer, the scheme



(IV)

being suggested for their formation.

In a study of the interaction of methyl methacrylate and methyl acrylate with butylmagnesium bromide Tsuruta[33] established that the initiator is consumed mainly in secondary reactions (1,4-addition, interaction with the carbonyl group, metallation with formation of butane)†.

† Similar facts have been established for butyl-lithium, which under similar conditions is consumed predominantly in the formation of butane (55%) and in addition to the carbonyl group (20%)[42].

Studying the kinetics of polymerisation in various organomagnesium halide–methyl methacrylate systems, Watanabe et al.[34–38] and Allen and Moody[39,40] found that the temperature dependence of the rate passes through a maximum, the position of which (the inversion temperature T_i) is determined by the nature of the initiator. In individual cases the reaction orders were also established (Table 1). According to Allen and Moody the inversion phenomenon is due to an increase in the part played by deactivation reactions over a certain temperature range, while the rate of initiation varies little with temperature. Glusker et al.[43–45] have shown that the initiator reacts rapidly with the monomer, but only a small fraction of it forms macromolecules: most of it is consumed in oligomerisation, which is complete after a few minutes, whereas polymerisation lasts under the same conditions for hours. It is suggested that the change which occurs at the inversion temperature in the order of reaction with respect to the monomer (Table 1) represents a change in the way in which the concentration of active centres formed in the initial stage depends on the concentration of the monomer. In this sense the inversion temperature can be regarded as the temperature at which a change occurs in the relative rates of oligomerisation and polymerisation. This ratio in turn determines the fraction of initiator molecules which bring about formation of macromolecules.

Table 1. Kinetics of polymerisation in butylmagnesium bromide–methyl methacrylate systems.

Solvent	Order of reaction with respect to		T, °C	T_i, °C	Ref.

5.0	C_6H_5MgBr	0.20	ether–toluene	−40	—	—	stereoblock	39

For systems containing ethyl-, phenyl-, and butyl-magnesium bromides the overall activation energy determined below the inversion temperature was 8 ± 0.3, 10 ± 5, and 13 ± 3 kcal mole^{-1} respectively[40]. In various systems of this type the initial rate of polymerisation has been found to depend on the nature of the radical in the organomagnesium compound. When the process is conducted in a 1:9 mixture of diethyl ether and toluene in the presence of various alkylmagnesium bromides, the rate increases in the sequence R = C_2H_5, $n\text{-}C_3H_7$, $n\text{-}C_4H_9$, $n\text{-}C_6H_{11}$, C_6H_5, $s\text{-}C_4H_9$.[39] The mechanism of this phenomenon has not been

* Polymerisation occurs only at the double bond.

specially investigated, and the observed differences may be attributed to variation in either the initiation rate constant or the fraction of initiator molecules which form active growth centres. The latter hypothesis is the more plausible.

Watanabe et al.[36] have studied the effect of various complexing agents (KA) on the rate of polymerisation in the methyl methacrylate–butylmagnesium bromide system at [A]/[In] ratios up to unity. Among the large number of compounds used, only pyridine, dioxan, diphenylamine, and diethylamine were found to have an activating effect. It is supposed that new, more active organomagnesium compounds are formed.

The polymerisation of acrylic and methacrylic esters with organomagnesium compounds often occurs stereospecifically. The influence of the polymerisation conditions on the character of the polymers and on the rate of the process can be judged from Tables 2 and 3. The mechanism of the formation of stereoregular polymers, suggested by various authors for systems of this type, is discussed in Reich and Schindler's monograph[46]‡. As for other anionic systems, it is assumed that the decisive stage is formation of a coordination complex of the growing chain and the monomer, which in the case of the ester complexes of organomagnesium compounds would involve displacement of the ester by the monomer. Watanabe[37] explains the role of the nature of alkyl and halogen in the organomagnesium compound by their forming part of a gegenion, to which he assigns the formula $[RMg_2X_2]^+$. Roha[47], examining the known experimental facts in terms of the effect of ionic factors on the structure of the chain, notes that organomagnesium initiators exhibit greater stereospecificity§ than do alkali-metal alkyls, and he attributes this to the relatively less ionic character of organomagnesium compounds. The formation of isotactic polymers of higher molecular weight than the atactic polymers, which is noted in several cases, is explained by Goode[29–32] on the assumption that the deactivating reactions limiting the growing chains take place predominantly when the latter are highly ionic in character, i.e. under conditions which do not ensure formation of isotactic polymers.

Study by nuclear magnetic resonance spectra of the effect of the polymerisation temperature on the structure of polyacrylates formed in the presence of phenylmagnesium bromide and diphenylmagnesium has shown[48–53] that the mode of opening of the double bond is determined at the very start of the reaction. Subsequent variation in temperature has no effect on the structure of the polymer.

3. Nitriles

The ability of organomagnesium compounds to add at the double bond of unsaturated nitriles was first established in 1923 for vinylacetonitrile[66,67]. Investigation of the polymerisation of acrylonitrile and methacrylonitrile originated in a paper by Beamen[68] in 1948, which established that it was possible to obtain polymers of low molecular weight by conducting the process in the presence of butylmagnesium bromide in ethereal medium at temperatures between 20° and −75°C. Acrylonitrile polymers of low molecular weight were also obtained by Terent'ev and Kost[69] and by Askarov et al.[70,71] by the action of several other organomagnesium compounds in ethereal[69,70] and hydrocarbon[71] media. The formation of short chains in all these cases was probably due to an unfavourable ratio of monomer and initiator concentrations. As the work of Erusalimskii, Kulevskaya, et al.[72–78] has established, polymers of molecular weight up to 5×10^5 are formed when polymerisation is conducted in organomagnesium halide–acrylonitrile–hydrocarbon systems at −75°C with the ratio $[M]/[In] \simeq 100$, where [M] is the concentration of monomer and [In] the concentration of initiator¶. Study of the mechanism and kinetics of this process, which has been investigated

‡ Some of the papers which we have cited on the mechanism of the polymerisation of methyl methacrylate are considered in greater detail in this monograph.

§ For example, poly(methyl methacrylate) formed under the influence of phenylmagnesium bromide at −20°C comprises 99% of isotactic sequences[28].

¶ The formation of acrylonitrile polymers of high molecular weight by the use of organomagnesium halides has been reported in a patent[79].

in greatest detail in the acrylonitrile–butylmagnesium chloride–toluene system[74-77], shows that only a small fraction (about 0.01) of the initiator molecules form growing chains. A specific deactivation reaction affects only the initiator, and does not extend to active growth centres, as is indicated by several factors consistent with the development of polymerisation through "live" polymers. These results, together with the finding that the reaction was of the first order with respect to the initiator (for the system containing butylmagnesium chloride) and of the second order with respect to the monomer, while the molecular weight of the polymer was independent of the monomer concentration, led to the following scheme for the process

$$\begin{array}{l} \mathrm{In} + \mathrm{M} \rightleftarrows (\mathrm{In}\cdot\mathrm{M}) + \mathrm{M} \overset{K}{\rightleftarrows} (\mathrm{In}\cdot\mathrm{M}_2) \xrightarrow[k_1]{} \mathrm{M}^* \\ \qquad\qquad\qquad\quad \searrow^{k_3} \\ \qquad\qquad\qquad\quad \text{inactive compounds} \\ \mathrm{M} + \mathrm{M}^*_{n-1} \xrightleftharpoons{\text{rapid}} (\mathrm{M}^*_{n-1}\cdot\mathrm{M}) \xrightarrow[k_2]{\text{slow}} \mathrm{M}^*_n \end{array} \qquad (3)$$

In this scheme the intermediate complexes In.M and In.M_2 are formed, K is the equilibrium constant, k_1, k_2, and k_3 are the rate constants of initiation, growth, and deactivation respectively, and M* is an active centre.

It follows from Eqn. (3) that the proportion of the initiator which forms active centres is determined by the ratio of the rates of initiation and deactivation, i.e. $Kk_1[\mathrm{M}]^2/k_3$. This quantity can also be expressed in terms of the ratio of the experimental molecular weight $\bar{M}_{\mathrm{exp}}$ to the theoretical value $\bar{M}_{\mathrm{th}}$ calculated from [M], [In], and the degree of conversion. Hence

$$\frac{Kk_1}{k_3}[\mathrm{M}]^2 = \frac{M_{\mathrm{exp}}}{\bar{M}_{\mathrm{th}}} \quad .$$

It has been shown[74,77] that a linear relation exists between $\bar{M}_{\mathrm{exp}}/\bar{M}_{\mathrm{th}}$ and $[\mathrm{M}]^2$, which supports the suggested scheme.

The same papers[74,77] record peculiarities of the process depending on the nature of the initiator. In particular, the reaction is of the second order with respect to the initiator and of the first order with respect to the monomer when $(C_4H_9)_3Mg_2I$ is used and (unlike the situation with C_4H_9MgCl and $(C_4H_9)_2Mg$) the polymers formed have a relatively wide molecular-weight distribution. This last feature has been interpreted in terms of the presence of different active centres in equilibrium[80]:

$$\mathrm{RMgI} + \mathrm{R_2Mg} \rightleftarrows \mathrm{R{-}Mg}\overset{\mathrm{R}}{\underset{\mathrm{I}}{\diagup\diagdown}}\mathrm{Mg{-}R} \quad .$$

Consistency of this view with experiment has been confirmed by Bresler et al.[81]

The polymerisation of acrylonitrile in hydrocarbon solution, in contrast to other such processes involving "live" polymers, does not go to completion, owing to the insolubility of polyacrylonitrile in such media and the passage of the growing chains into a solid phase which cannot be penetrated by the monomer. The present of "trapped" live chains in such reaction mixtures can be detected if the system is homogenised by means of a suitable solvent, in particular dimethylformamide[80]. In dimethylformamide medium the process goes extraordinarily rapidly, complete conversion of the monomer being easily achieved†. It is interesting that the rate of polymerisation is substantially increased even in the presence of catalytic quantities of dimethylformamide. Interaction of the latter with organomagnesium halides at −75°C produces coordination complexes, which are less subject to deactivation by interaction with acrylonitrile, and ensure the formation of a larger number (in comparison with RMgX) of active centres[77,78]. This constitutes one of the main reasons for the activating effect of dimethylformamide at $[\mathrm{HCON(CH_3)_2}]/[\mathrm{RMgX}]$ ratios of about unity. Catalytic quantities of dimethyl sulphoxide[78] and hexamethylphosphoramide[82] exert an analogous influence on polymerisation in acrylonitrile–organomagnesium halide–toluene systems. Krasnosel'skaya and Erusalimskii[82] have shown that the acceleration of polymerisation in the presence of complexing agents has various causes. Thus catalytic quantities of hexamethylphosphoramide produce only an increase in the number of active centres: a substantial increase in the yield of polymer is not accompanied in this case by change in molecular weight, compared with results obtained under the same conditions in the absence of hexamethylphosphoramide. Dimethyl sulphoxide and dimethylformamide cause an increase in yield and in the molecular weight of the polymer: both the growth rate constant and the number of active centres increase here (Table 4).

Table 4. Polymerisation in systems comprising 1.5 M acrylonitrile + 0.01 M tributyldimagnesium iodide + a complexing agent in toluene[82] at −75°C for 1 min.

Complexing agent	Conversion, %	Mol. wt., $10^{-3}M$	Efficiency of initiation, %
–	11	73	1.3
Hexamethylphosphoramide	65	73	7.7
Dimethylsulphoxide	60	200	2.5
Dimethylformamide	45	160	2.3

Several other papers have discussed the polymerisation of acrylonitrile and methacrylonitrile initiated by organomagnesium compounds as involving the intermediate formation of complexes. Such a conclusion was drawn, for example, by Dawans and Smets[83], who investigated the copolymerisation of acrylonitrile and methacrylonitrile with other monomers under the influence of phenylmagnesium bromide‡, and also by Natta et al.[86], who regard these processes as cases of anionic coordination.

Several papers describe the synthesis of stereoregular polymers of acrylonitrile[87] and methacrylonitrile[86,88-91] under the influence of organomagnesium compounds. In most cases the degree of stereoregularity is estimated from the crystallinity and the solubility of the polymers, but hardly any data are given on their detailed microstructure. This does not apply to work[92-94] in which nuclear magnetic resonance was used to investigate the structure of methacrylonitrile polymers obtained in the presence of various organometallic initiators. The most stereospecific initiators proved to be organomagnesium compounds,

† At −75°C and concentrations of 1.5 M acrylonitrile and 0.005 M butylmagnesium chloride in dimethylformamide medium, polymerisation is complete in a fraction of a minute. In toluene the initial stage of the process (up to 5% conversion) goes at a rate of around 1% min^{-1}.[78,80]

‡ Data on the copolymerisation of acrylonitrile with various monomers in the presence of organomagnesium initiators have been given also in other papers[84,85].

which yielded predominantly isotactic polymers§. According to Natta[86] the stereospecificity of the polymerisation of unsaturated nitriles in the presence of alkylmagnesium halides is due to orientation of the monomer at the stage of coordination of an active centre with the monomer at the nitrogen atom.

Table 5. Polymerisation of α-alkylacrylonitriles and β-alkyl-αγ-dimethyleneglutaronitriles.

Monomer	R	Catalyst	Solvent	Temp., °C	Duration of polymerisation, h	Conversion, %

The polymerisation of α-alkylacrylonitriles and of β-alkyl-αγ-dimethyleneglutaronitriles under the influence of organomagnesium compounds has been described by Covács and Marvel (Table 5).[96] Furukawa et al.[97] have used phenylmagnesium bromide to initiate the polymerisation of *cis*- and *trans*-crotononitrile.

4. Vinylpyridines

The polymerisation of vinylpyridines in the presence of organomagnesium compounds, studied mainly by Natta[98-102], is interesting in connection with the role of various factors in producing the chain structure. In the polymerisation of 2-vinylpyridine in hydrocarbon medium by various metal alkyls, only the magnesium derivatives (RMgX, R_2Mg, R_2NMgX) exhibit high stereospecificity. Nuclear magnetic resonance data indicate that the polymers have an isotactic structure[103-105]. Views on the mechanism of stereoregulation are based on the considerations formulated in discussing the polymerisation of unsaturated nitriles[86] (see subsection 3). In the present case it is postulated that the heteroatom and the double bond of the monomer take part simultaneously in acts of complex formation. This is consistent with differences in the behaviour of 2- and 4-vinylpyridines: stereoregular polymers are formed only in the former case. In Natta's opinion, considerable remoteness of the nitrogen atom from the vinyl group eliminates the possibility that complexes of the growing chain can be formed by means of both donor positions in the monomer, and thereby excludes its rigid orientation in acts of growth. The role of complex formation as a factor determining the microstructure of the polymer is clearly exhibited in the polymerisation of 2-vinylpyridine in the presence of catalytic quantities of Lewis bases, which either hinder or eliminate (depending on their relative basic strength) the stage of complex formation between the growing chain and the monomer (Table 6).

Data are lacking on the kinetics of polymerisation in these systems. The papers cited above indicate only the total conversion of the monomer achieved after a standard time. As Fontanille and Sigwalt[15] remark, polymerisation in the 2-vinylpyridine–biphenyl–magnesium–hexametapol system involves "live" chains and is characterised by a high growth rate constant.

Table 6. Polymerisation of 2-vinylpyridine in anionic systems in toluene at 45°C.[102].

Initiator	Complexing agent (CA)		Yield of polymer in 5 h, %	Crystalline fraction

* Determined in dimethylformamide at 30°C.

** Polymer contains 65% of a fraction insoluble in boiling acetone and characterised by low crystallinity.

Some idea of the rate of polymerisation of 2-vinylpyridine with organomagnesium initiators is given by Erusalimskii and Ovsyannikov's results[106] for tributyldimagnesium iodide. At monomer and initiator concentrations of 2.0 M and 0.1 M respectively, quantitative conversion in toluene is reached at −20°C in 10 min. It is shown that effective polymerisation is possible at −50°C. The same paper reports that in hydrocarbon medium 2-methyl-5-vinylpyridine undergoes polymerisation at room temperature.

5. Chlorine-containing Monomers

Organomagnesium compounds have been used for the polymerisation of chlorine-containing monomers—vinyl chloride[107-111], vinylidene chloride[112], chloroprene[14,113-115], and 2,3-dichlorobutadiene[116]—in several researches. Deactivation plays an especially important part with most of these monomers, this being due not only to the great tendency of chlorine atoms to enter into side-reactions with metal alkyls. The low relative activity of these monomers in anionic polymerisation eliminates the possibility of conducting the process at low temperatures; even at room temperature they do not polymerise very rapidly in anionic systems. This makes it impossible to suppress side-reactions by substantially lowering the temperature¶.

§ No data are yet available on the structure of polyacrylonitrile formed in systems involving organomagnesium compounds. A stereoblock isosyndiotactic structure (1 : 1) has been established[95] for the polymer produced in the acrylonitrile–butyl-lithium–toluene system at −78°C.

¶ For example, effective polymerisation can be accomplished in the butyl-lithium–methyl methacrylate system only because the monomer is sufficiently active in the growth reaction at low temperatures. Even at −30°C polymerisation is effectively suppressed by reactions at the carbonyl group.

The polymerisation of vinyl chloride, vinylidene chloride, and chloroprene initiated by organomagnesium compounds is characterised by low consumption of the initiator in forming active centres and cessation of the process at a low degree of conversion. The latter feature, which is shown also by polymerisation of the same monomers in the presence of lithium alkyls[115,117,118], is due to the extension of deactivating reactions to the growing chains. The mechanism of these reactions probably consists in detachment of chlorine from the end of the growing chain by a gegenion:

$$\sim CHCl-CH_2^- \quad MgX \rightarrow \sim CH=CH_2 + MgClX$$

This is supported by the data of Guyot and Pham Quang Tho[108-111], who detected vinyl groups in the polymer formed in the vinyl chloride–t-butylmagnesium chloride–tetrahydrofuran system. These workers established the slowness of initiation, which under their conditions lasted for practically the whole time of polymerisation[111], and also the incomplete consumption of the initiator by the initiation reaction: ~ 75% of the initial quantity of initiator was deactivated[110,111]. Polymerisation in this system was found to be formally similar to radical polymerisation (microwave resonance of the polymers constant with time, steady-state occurrence of the reaction). Nevertheless, in view of all the experimental results obtained, the authors do not doubt the anionic character of the polymerisation they were studying.

The occurrence of secondary reactions between the organomagnesium initiator and the chlorine-containing monomer is shown by Erusalimskii and Krasnosel'skaya's investigation[114,115] of polymerisation in the chloroprene–tributyldimagnesium iodide–heptane system. Data on the kinetics of polymerisation, the consumption of the initiator, and the variation in the total concentration of organomagnesium compounds indicate the rapid occurrence of the following parallel reactions

$$M + In \begin{cases} \rightarrow \text{initiation} & < 1\% & (4) \\ \rightarrow \text{elimination of Cl (formation of MgClX)} & 8\% & (5) \\ \rightarrow \text{formation of inactive organomagnesium compounds} & \sim 91\% . & (6) \end{cases}$$

Polymerisation in this system is of the first order with respect to monomer and initiator, and is described by the general equation

$$\frac{[M]_0 - [M]}{[M]_0} = 1 - e^{-k_2/k_3[M^*]_0 (1-e^{-k_3})}\dagger$$

where $[M]_0$ and $[M^*]_0$ are the concentrations of monomer and active centres at zero time, and k_2 and k_3 are the growth and termination rate constants. Values of k_2 and k_3 calculated by means of this equation for 25°C are respectively 0.016 M^{-1} s^{-1} and 1.3×10^{-5} s^{-1}.

A general idea of the effectiveness of the anionic polymerisation of monomers of this type is given by the limiting conversion attainable in several cases (Table 7).

Initiating systems which are considerably more effective towards these monomers are formed by the interaction of certain organomagnesium and organolithium compounds, and have been suggested by Krasnosel'skaya for the polymerisation of chloroprene[112,119-121], vinyl chloride[112,120], and vinylidene chloride[112]. In particular, the interaction of tributyldimagnesium iodide and butyl-lithium in the proportions 1 : 2 in hydrocarbon medium at room temperature yields the heterogeneous system $C_4H_9Li.LiI$ (solid phase)–$2(C_4H_9)_2Mg$ (in solution). The components of the system, which can be easily separated from one another, exhibit enhanced activity towards polymerisation only when present together. Under conditions comparable with those in Table 7 this system brings about up to 90% conversion of chloroprene and up to 50% conversion of vinyl chloride at room temperature. Increased efficiency has been noted also for vinylidene chloride; in this case the limiting conversion was not established. Analogous phenomena are observed when systems formed by the direct interaction of dibutylmagnesium with the complex $C_4H_9Li.LiI$ are used[121]. The hypothetical structure

has been suggested[121] for the active centres.

Table 7. Limiting conversion in the anionic polymerisation of unsaturated chlorine-containing monomers.

Monomer		Initiator		Solvent	Initial rate of polymerisation, % h^{-1}	T, °C	Limiting conversion,		Ref.
compound	concn., M	formula	concn., M				%	reached in, h	
Vinyl chloride	8.0	BuLi	0.09	heptane	3	25	25	15	112
ditto	3.6	Bu^tMgCl $BuMgCl$	0.156	tetrahydrofuran	8	25	~50	25	108, 109
Vinylidene chloride	2.0	Bu_3Mg_2I	0.045	heptane	1	20	18	20	112
		BuLi	0.03	heptane	1	20	4	10	112
ditto	2.0	BuLi	0.10	heptane	1.5	25	7	24	115
Chloroprene	6.0								
ditto	6.0	Bu_3Mg_2I	0.08	heptane	4	40	50	50	115

The mechanism of the process has been examined in greater detail on the closely similar system $C_4H_9Li.LiI$–C_4H_9Li. According to results for the polymerisation of vinyl chloride obtained by Gasan-Zade and Mazurek[112], the enhanced efficiency of the process is due to an increase in the effectiveness of initiation and also a more favourable k_2/k_3 ratio for growth. Both of these constants have lower absolute values than in the polymerisation of vinyl chloride by butyl-lithium.

Dichlorobutadiene differs fundamentally in behaviour from the above monomers. Polymerisation in the $C_4H_4Cl_2$–$(C_4H_9)_3Mg_2I$ system at 20°C takes place at a relatively high rate (around 10% h^{-1} with [M] = 2 M and [In] = 0.025 M), and can be brought to high degrees of conversion[116]. This interesting feature, indicating the exceptionally minor role of termination reactions, can be explained by enhanced reactivity of the monomer (i.e. increase in k_2) or by the absence of labile chlorine atoms (1,2-units) in the polymer chain. In polymers of chloroprene formed by the action of metal alkyls the presence of such units (together with the main structural *trans*-1,4-units) is not excluded[114].

6. Other Monomers and Certain Special Cases

Several other anionic systems involving organomagnesium compounds are worthy of attention. Thus in the

† Reactions (4)–(6) are disregarded here, since they are complete at the very first stage, and the overall rate of polymerisation is low. The value of $[M^*]_0$ is determined from data on the degree of polymerisation, since $\bar{P} = x[M]_0/[M^*]_0$, where x is the conversion.

vinyldiphenylphosphine oxide–organomagnesium halide–toluene system[123] it has been established that termination reactions do not occur (at 25°C). It has been concluded from colorimetric measurements that initiation involves intermediate formation of a monomer–initiator complex, which is then converted into a coloured monomeric anion. An analogous mechanism is assumed for growth (coordination of the phosphine oxide group of the monomer with an active centre).

An interesting case of the use of organomagnesium compounds for synthesising anionic initiators of high molecular weight, suitable for the preparation of graft polymers, has been described by Guber and Egle[124]. Interaction of a styrene–acrylonitrile copolymer with dimethylsilylmethylmagnesium chloride in tetrahydrofuran forms magnesium-substituted imino-groups on the polymer chain:

$$\sim CH_2CH(C_6H_5)-CH_2CH(CN)\sim \xrightarrow{RMgX} \sim CH_2CH(C_6H_5)-CH_2CH(RC{=}NMgX)\sim ,$$

At temperatures of −30°C and below these addition products effectively polymerise acrylonitrile, methyl methacrylate, and 4-vinylpyridine to give the corresponding hybrid polymers.

Grignard reagents have been used by Japanese workers for the migration polymerisation of acrylamide[125–127]. Phenylmagnesium bromide in dioxan showed the highest activity. The peculiar mechanism of this process, leading to the formation of poly-β-alanine, has been studied by Nakayama et al.[126,127]. In particular, when polymerisation is conducted at a high temperature (100°C)‡ in toluene and in pyridine, appreciable differences are observed depending on the nature of the solvent: in pyridine a considerable quantity of dimer is formed, which is barely noticeable in toluene. It has therefore been suggested that polymerisation has a stepwise mechanism in pyridine and a chain mechanism in toluene. The synthesis of block copolymers of acrylamide with acrylonitrile and caprolactam under the influence of alkylmagnesium halides has been reported[128].

Among other monomers which can be polymerised by means of organomagnesium initiators are isopropyl crotonate[129,130], t-butyl crotonate[129–131], methyl atropate[132], isopropenylpyridine[133], and penta-2,4-dienonitrile[134].

III. POLYMERISATION OF CARBONYL DERIVATIVES AND CYCLIC MONOMERS

During recent years organomagnesium compounds have been tested as initiators for the polymerisation of a large number of aldehydes and ketones. Attention has been concentrated mainly on the structure of the polymers formed; in several cases the action of the organomagnesium compounds has been found to be stereospecific (Table 8). Hardly any work has been done specifically on the mechanism of the polymerisation of monomers of this type initiated by organomagnesium compounds. The well known concepts relating to aldehyde–metal alkyl systems, formulated by Natta[136] and by Furukawa[137,138], and generalised by Vogl[154], are entirely applicable to these systems. A case of particular interest is the interaction of but-3-en-2-one and of 3-methylbut-3-en-2-one with butylmagnesium bromide in ethereal solution and in hexane. It was established that polymerisation and secondary reactions—dimerisation of the monomer and formation of butane—take place in parallel[33].

‡ Lowering the temperature for the anionic polymerisation of acrylamide diminishes the role of migration effects. It is possible that polyacrylamide completely free from isomerised units may be synthesised by anionic initiation, but this has not yet been established experimentally.

Most of the papers on the polymerisation of various cyclic monomers by the compounds RMgX and R_2Mg are similarly purely descriptive in character. They are concerned predominantly with ethylene and propylene oxides[155–162], with which the process goes efficiently to form polymers of high molecular weight; the oxides of butadiene[157] and of styrene[157], epichlorohydrin[157], and epoxyalkyl ethers[163] have also been mentioned. In the presence of a Grignard reagent trimethylene sulphide yields a crystalline polymer[164]. Organomagnesium compounds initiate the polymerisation of epoxyorganosilanes[165]. Data have been published on the synthesis of copolymers of oxides with other monomers[166], in particular with phthalic anhydride.

Table 8. Polymerisation of aldehydes, ketones, and dimethylketen.

Monomer	Initiator	Solvent	T, °C	Duration	Yield of polymer %	State of polymer	Ref.
HCHO	EtMgBr	Et_2O	−78	—	—	solid	135
CH_3CHO	RMgX	—	−70	—	—	crystalline	136

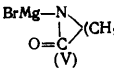
CH_2=CHCHO	RMgBr	Et_2O, ether hexane,	20—50	5—36 h	10—30	mixture of liquid and solid	143
CH_2=CHCHO	n-C_4H_9MgBr	toluene	room	24 h	30	solid	144
But-3-en-2-one, 1-phenylprop-2-enone, 3-methylbut-3-en-2-one	C_6H_5MgBr; Et_2Mg	in bulk	0	—	—	crystalline	145—147
4,4-Dimethylpent-1-en-3-one	RMgX	tetrahydrofuran	—	—	—	amorphous	148
Acetophenone	C_6H_5MgBr	toluene	−78	3 days	90	solid	149
Dimethylketen	R_2MgX; R_2Mg	toluene, tetrahydrofuran, etc	from 20 to 78	—	20	—	150—153

In most cases the processes can be assumed to have a mechanism of anionic coordination. A possible exception is provided by the initiating systems $RMgX–H_2O$, described by Vandenberg[157], which, by analogy with $R_3Al–H_2O$ systems, can be regarded as cationic. The polymerisation of ethylene and propylene oxides under the influence of R_2Mg has been investigated in rather more detail. According to Kagiya et al.[158–161] this process, in which polymers of high molecular weight are formed in good yield, has a termination reaction. The activation energies for the reactions of growth and termination are found to be 15.8 and 29.2 kcal mole^{-1} respectively.

Organomagnesium compounds, free from ether, are able to initiate the polymerisation of caprolactam[167]. The first act—addition of alkylmagnesium halide to the monomer—takes place even at room temperature, with formation of the compound



(V)

The development of polymerisation requires a substantially higher temperature, 240–250°C. According to the patent literature[168,169] caprolactam is effectively polymerised by the action of organomagnesium compounds in the presence

of certain promoters, e.g. *N*-acetylcaprolactam and *N*-phenylsuccinimide. These agents probably add to the product (V) to form centres which are more active for polymerisation. According to Vofsi et al.[170] the rate constants of reactions of this type are several orders of magnitude larger for substituted than for unsubstituted lactams (Table 9).

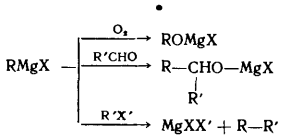
Table 9. Interaction of pyrrolidones with pyrrolidonylmagnesium bromide in tetrahydrofuran at 25°C.[170]

Lactam	Addition rate constant, 10^2 M^{-1} s^{-1}
Pyrrolidone	$3 \cdot 10^{-7}$
N-Methylpyrrolidone	$5 \cdot 10^{-2}$
N-Acetylpyrrolidone	2.8
N-Benzoylpyrrolidone	9.5

Promoter–RMgX systems are used also for initiating the copolymerisation of caprolactam with pyrrolidone[171] and with acrylamide[172]. β-Propiolactone also polymerises in the presence of organomagnesium initiators[173].

IV. CATIONIC POLYMERISATION

Organomagnesium halides, which are Lewis acids, can in principle be regarded as cationic agents. Their ability to initiate cationic polymerisation was discovered with vinyl ethers; here there is no doubt about the mechanism of the process, in view of the inertness of these monomers towards anionic initiators. The first observations in this field were made by Cray[174], who established that various vinyl ethers underwent polymerisation in bulk and in solution in the presence of butylmagnesium bromide at 80°C. It has been assumed that polymerisation is effected by MgX^+, RMg^+, or Mg^{2+} ions, with the monomer acting as cocatalyst. By analogy with other cationic systems it is more probable that catalytic complexes are formed, and produce carbonium ions (if the monomer does actually function as a cocatalyst). However, the concept of the cocatalytic action of vinyl ethers in cationic polymerisation, which was generally accepted until quite recently, requires re-examination in view of results obtained by Eley and Johnson[175], who established that hept-1-en-3-one is inert towards boron trifluoride in hydrocarbon medium provided that the system has been carefully freed from traces of moisture. There is no direct evidence of this kind for organomagnesium initiators, but Iwasaki et al.[176] consider that the presence of an independent cocatalyst is essential in vinyl ether–organomagnesium halide systems. They include among such agents oxygen, aldehydes, metal oxides, and halogenated hydrocarbons. In their opinion reactive compounds can result from the reactions



The cocatalytic action of these agents is confirmed by the results[176]. A positive effect due to oxygen has been noted also by Bruce and Farren[177], but the suggested interpretation of these phenomena cannot be regarded as reliable. In particular, formation of catalytic complexes of the type $R^+[RMgX_2]^-$ cannot be excluded in the presence of alkyl halides. Furthermore, Iwasaki et al.[176] distinguished between use of the $RMgX-O_2$ system and that of alkoxides ROMgX for initiating the polymerisation of vinyl ethers. Only in the former case are polymers of high molecular weight produced. Consequently the active centres which appear when both RMgX and oxygen are present are more complicated in character. As with most other cationic systems, results obtained with maximum exclusion of traces of water would probably be of great interest.

V. ZIEGLER–NATTA INITIATING SYSTEMS

Ziegler's early patents[11] already included the use of organomagnesium compounds among other organometallic components for synthesising new complex catalysts. These compounds have since been used in systems of similar type for the polymerisation of alkenes[13,178–185], acetylene and phenylacetylene[186,187], styrene[13,188–190], and dienes[13,185,191–201]. These systems have not found wide application, obviously owing to their being less stereospecific than catalysts based on aluminium derivatives. In the polymerisation of propene under the influence of $RM-TiCl_3$ catalytic systems, according to Natta[202], organomagnesium compounds result in the formation of polymers having a rather lower isotactic fraction (up to 85%) than do organoaluminium and organoberyllium compounds (90% and 96% respectively). In the polymerisation of diene hydrocarbons a highly stereospecific process is achieved with $RMgX-TiCl_4$(or $TiBr_4$) systems only when certain third components—alkyl iodides[203], hydrogen iodide[204], lithium iodide[205], and others[206–208]—are also present. Under these conditions polybutadiene containing up to 98% of *cis*-1,4-units can be synthesised. In the absence of such additional agents, the greatest homogeneity of chain structure in the polymerisation of dienes under the influence of titanium–magnesium complexes has been found in the isoprene–$(C_4H_9)_3Mg_2I$–$TiCl_4$ system. With an initial ratio of Mg/Ti = 1.5, the polyisoprene formed contained 84% of *cis*-1,4-units[13]. *cis*-1,4-Polybutadiene has been obtained in high yield by using the catalytic system $C_6H_5MgX-TiI_4$ (Mg : Ti ≥ 2).[209]

Ziegler–Natta catalysts including magnesium components have been used for the polymerisation of various polar monomers, such as vinyl chloride, acrylonitrile, methyl methacrylate, etc.[11,193,194,210]. The mechanism of the polymerisation of polar monomers initiated by Ziegler–Natta catalysts is a matter of controversy. The most plausible view is the free-radical nature of the process. This was first put forward by Furukawa[211] on the basis of results for the copolymerisation of various pairs of monomers; it has since been confirmed in several kinetic investigations[212,213]§. These conclusions, reached in the study of other systems, can probably be extended to systems involving organomagnesium compounds.

---o0o---

The most interesting aspect of an analysis of the information surveyed in the present Review is to reveal the specific character of organomagnesium compounds distinguishing

§ Milovskaya[214] has discussed a possible mechanism for the generation of free radicals in systems comprising a polar monomer and a Ziegler–Natta catalyst.

them from other organometallic initiators of polymerisation. The data on the polymerisation of isoprene, methacrylonitrile, and 2-vinylpyridine are noteworthy in this connection. In the first case, compounds RMgX and R_2Mg yield polymers constructed almost entirely of 3,4-units (in contrast to the polyisoprene formed by the action of other metal alkyls). In the other two cases a substantially higher stereospecificity of action has been established for these reagents. These characteristics are most probably due to steric factors associated with active centres in the corresponding systems, not to the degree of polarity of the carbon–magnesium bond in the organomagnesium compounds.

Owing to the great sparsity of quantitative data it is difficult to draw rigorous conclusions on the reactivities of different organometallic compounds in polymerisation processes, or to establish the place occupied in this sequence by magnesium derivatives. Nevertheless, there are facts indicating divergence from rules to be expected from general considerations. This applies to differences in the behaviour of lithium and magnesium alkyls towards unsaturated hydrocarbons and halogenated monomers, as is shown especially clearly by a comparison of data on the polymerisation of styrene and of vinyl chloride. Thus the growth rate constants in the polymerisation of styrene in hexane (at 30°C)[215] and of vinyl chloride in heptane (25°C)[117] in the presence of butyl-lithium are respectively 5.0 and 0.0099 $M^{-1}\ s^{-1}$. The reactivity of organomagnesium compounds in these systems is opposite in character: they are inert towards styrene, but cause the polymerisation of vinyl chloride.

Finally, it is worth noting that the lower reactivity in acts of initiation and growth, which is usual for organomagnesium compounds (in comparison with alkali-metal alkyls), is accompanied by a relatively lower tendency to undergo various deactivating reactions. In certain cases this will lead to a relation between the rate constants of the elementary reactions which is more favourable to polymerisation than when alkyl derivatives of the alkali metals are used. This is probably the explanation of the substantially higher conversion limit attainable with organomagnesium initiators, compared with organolithium compounds, in the polymerisation of unsaturated chlorinated monomers.

Dependence of Thermal Stability of Polymers on Their Chemical Structure

V.V.Korshak and S.V.Vinogradova

It is shown, on the basis of a large amount of experimental work, how the thermal stability of polymers depends on the strength of the bonds between the atoms forming the macromolecule, on the structure of the chain unit in the macromolecule, and also on the structure of the polymer molecule itself as a whole. Especially detailed attention is given to the effect on thermal stability of such structural features of the chain unit as the presence of side-chains, halogen atoms, and other elements (boron, silicon, phosphorus, various metals), the positions and number of these substituents, and also groups of aromatic character, including benzene rings and various heterocycles. Those structural features which tend to increase the thermal stability of polymers are elucidated.
An important place in the review is occupied by examining the dependence of thermal stability on such structural aspects of the macromolecule itself as the regularity in the arrangement of monomer units along its chain, the isomerism of substitution in the aromatic ring, the presence of branching and cross-linking, copolymerisation, and also the nature of end-groups, etc. A list of 100 references is given.

I. INTRODUCTION

The most important problem of polymer chemistry is to establish the relation between the properties of polymers and their structure. Only when this is known is it possible to solve consciously and successfully the problems involved in preparing polymers having required properties which have been specified in advance.

Although relatively little experimental work has yet been done on the relations between the structure and the properties of polymers, it is already possible, on the basis of known data, to establish certain relations of this type. The main method for finding links between the structure and the properties of polymers is to study and compare the behaviour of series of polymers of analogous structure[1].

We shall not deal here with one extremely important aspect of this problem—the influence of the physical structure of polymers on their properties—which has been determined by the work of Kargin[2]. He has shown, on the basis of a large number of experimental results, that the physical structure of a polymer affects not only its strength but also several of its chemical reactions.

Without being concerned with the whole problem of the relation between structure and properties, we shall examine only its purely chemical aspect. The aim of the present review is to show quite clearly the relations which have now been elucidated between the chemical structure and the thermal stability of polymers, these being of interest in particular in connection with the problem of producing the heat-resistant materials which are so necessary for modern technology.

Let us first define the concepts of heat-resistance and thermal stability, with which we shall often be dealing. *Heat-resistance* we shall take to mean the limiting temperature at which a given polymer is able to maintain a particular mechanical strength. *Thermal stability* will imply the limiting temperature which a given polymer can withstand without chemical change. Above this temperature the polymer begins to undergo chemical breakdown, in most cases accompanied by loss of mechanical strength.

We shall not be concerned here with problems associated with the thermal breakdown of polymers under the simultaneous influence of high temperatures and chemical reagents such as oxygen, water, etc., i.e. the oxidative thermal degradation and the hydrolytic cleavage of polymers.

Various methods are used to assess the thermal stability of polymers. The most widely used are methods of *dynamic thermogravimetric analysis*, in which loss in weight is determined while the temperature is raised continuously and uniformly. *Isothermal thermogravimetric analysis* is often employed also, this being conducted at a constant temperature. These methods are of value only for the preliminary assessment of polymers under laboratory conditions. A more exact estimate of the thermal stability of polymers necessitates prolonged tests at the required temperatures. Methods of determining thermal stability from the loss in weight of polymers on heating has the disadvantage that they give no information on chemical changes unaccompanied by loss of volatile products. In many cases, however, comparative results of the thermogravimetric analysis of various polymers nevertheless give an idea of their thermal stability.

When discussing the dependence of the thermal stability of polymers on their chemical structure, we understand by the latter both the composition of the polymer and various structural features of its chain unit, the individual macromolecule, and the union of individual linear macromolecules joined by chemical bonds. Only a few experimental data have been published on this question, and attempts have been made at certain generalisations in individual reviews [3-8] and monographs [9,10].

The thermal stability of a polymer depends primarily on the strength of the bonds between the individual atoms and groups forming this macromolecule. The strength of these bonds determines the temperature at which they are ruptured as a result of dissociation or other chemical reactions caused by high temperature or various chemical agents. We shall therefore first examine the dependence of the strength of these bonds on the nature of the atoms constituting the polymer macromolecule, and then elucidate the effect on the thermal stability of the polymer of the chemical structure of the chain units and of the macromolecule as a whole.

II. STRENGTH OF BONDS BETWEEN ATOMS IN THE MACROMOLECULE

The strength of a chemical bond depends on the nature of the atoms between which it is formed, the sequence of bonded atoms, the nature of substituents, and other structural features. The strength of bonds can be characterised by the bond energy, which corresponds to the energy of their dissociation into free radicals (Table 1).

Table 1 shows that the most stable bonds are those between carbon atoms. The strength of a bond between atoms of other elements is considerably less. Therefore only those elements in which the energy of the bonds linking one atom to another is sufficiently large are able to form homochain polymers. If, however, the energies of bonds between atoms of elements are small, the polymers show poor stability; and at bond energies less than 37 kcal mole^{-1} elements are completely unable to form polymeric chains, since the latter would obviously break down as a result of thermal degradation even at ordinary temperatures.

The existence of a large number of carbon-chain polymers is due to the high bond energy between carbon atoms. Thus in this case the effect of strength of bonding on the properties of a polymer is shown quite clearly.

Heterochain polymers, whose macromolecules are formed from different elements, show considerably higher bond energies between the atoms (Table 2), so that a marked increase in their thermal stability is observed. Table 2 shows that the energies of bonds between atoms of different chain-forming elements, which are typical of heterochain polymers, are quite high, in many cases exceeding the bond energies encountered in homochain polymers. The highest energies are exhibited by boron–nitrogen and boron–oxygen bonds, and also by those between aromatic carbon and nitrogen or oxygen. The silicon–oxygen bond is also extremely stable. These are the bonds which occur in polymers having the greatest thermal stability.

Table 1. Energy of bonds (kcal mole^{-1}) between atoms of elements [11,12].

Bond	Energy	Bond	Energy
C_{arom}–C_{arom}	98.0	Te—Te	49.0

B—C_{arom}	100.0	Si—S^{II}	60.9
C_{aliph}—O	93.0	C_{aliph}—As^{III}	54.6
B—C_{aliph}	89.0	N—O	37.0

Table 3. Bond energies (kcal mole^{-1}) of surrounding atoms [11].

Bond	Energy
Si—F	135
C—F	116
C_{aliph}—H	97
Si—Cl	91
C—Cl	80
Si—H	76

However, the strength of the bonds between atoms in the main chain of the macromolecule and atoms or groups attached to this chain is no less important. Table 3 shows that the fluorine–silicon and fluorine–carbon bonds possess the highest energy, which is the reason for the high thermal stability of organofluorine polymers. However, this is valid only when such bonds undergo cleavage by thermal dissociation. If the halogen can be removed in

other ways, e.g. by elimination as a hydrogen halide molecule containing a hydrogen atom from an adjacent carbon atom, the thermal stability of the polymer drops sharply. Thus poly(vinyl fluoride) and poly(vinyl chloride) show poor thermal stability owing to the ready elimination of the hydrogen halide. This applies also to poly(vinylidene chloride), poly(vinyl alcohol), and analogous compounds of general formula $[CH_2-CHX]_n$ as well as to polymers containing halogen in side-chains. Thus the higher thermal stability of pentone (the polymer of 3,3-bischloromethyloxacyclobutane) compared with poly(vinyl chloride) is due to the absence of hydrogen on the carbon atom adjacent to the chloromethyl group, which would be necessary for the formation of hydrogen chloride.

Table 4. Electronegativities of elements in different groups of Periodic System[14].

Group			
III	IV	V	VI
B—2.0	C—2.5	N—3.0	O—3.5
Al—1.5	Si—1.8	P—2.1	S—2.5
	Ge—1.8	As—2.0	Se—2.4
	Ti—1.6	V—1.9	Te—2.1
	Sn—1.7	Sb—2.1	Mo—2.1
	Sr—1.5		W—2.0
	Pb—1.6		

The energies given in Tables 2 and 3 for bonds between atoms of different elements have been calculated for homolytic dissociation of the bonds. However, all these bonds are in some measure polar, and this must always be borne in mind. Application of Pauling's concept of the electronegativity of bonds[14] is especially convenient for this purpose. The electronegativities listed in Table 4 for the most important elements can be used to determine the ionic character of bonds. If the difference in electronegativity is 1.9, such bond is 50% ionic in character; if the difference is still larger, it is more correct to regard such a compound as having an ionic structure; and if the difference is less than 1.9, the bond is covalent.

The polarity of bonds has a fundamental effect on their stability at elevated temperatures, since the more polar a bond, the more marked the decrease in its strength with rise in temperature. Organic carbon-chain compounds of high molecular weight are built up solely by covalent bonds between carbon atoms, whose electronegativity is 2.5.

From a study of polymers containing inorganic chains Andrianov[15] concluded that the stability of a bond El–El′ will be greater the less ionogenic are the bonds forming the main chain, i.e. the closer the mean electronegativity of the two elements forming the bond to that of the carbon atom. As examples of the construction of organoelementary polymers on this principle, he mentions polyorganosiloxanes and polyalumino-organosiloxanes, the chains in which are made up of alternating atoms of electropositive silicon and aluminium and of electronegative oxygen, while the mean electronegativity of bonding of these two elements approaches the electronegativity of carbon. These chains reproduce the skeleton of naturally occurring inorganic polymers—quartz, aluminosilicates—and are thermally and hydrolytically stable.

III. DEPENDENCE OF THERMAL STABILITY ON STRUCTURE OF CHAIN UNIT

The thermal stability of polymers depends both on the structure of the monomeric chain unit and on that of the whole macromolecule, the presence and nature of all intermolecular bonds, and also the presence of various impurities.

Let us first examine how the structure of an individual chain unit affects thermal stability. For this purpose we regard all polymers as derivatives of two main types of macromolecular chains—polymethylene $[CH_2]_n$ and polyphenylene $[C_6H_4]_n$—as well as of various combinations thereof. These main units can also be separated by various heteroatoms or heterocycles.

Fig. 1 illustrates the results of a dynamic thermogravimetric analysis of the two extreme members—polyethylene and polyphenylene—of these classes of polymers. The thermogravimetric curves clearly show a fundamental difference in their thermal stability, which is characteristic of these two classes of substances.

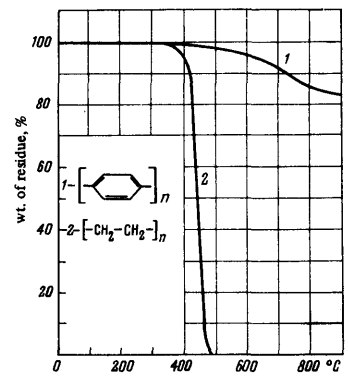

Figure 1. Dynamic thermogravimetric analysis (in vacuum, rate of heating 5 deg min^{-1}) of hydrocarbon polymers: *1*) polyphenylene; *2*) polyethylene.

The general dependence of the thermal stability of polymers on the structural unit can be illustrated by means of the relative thermal stabilities listed in Table 5. The values of the relative thermal stability of polymers (temperatures of half-decomposition T_h, at which 50% loss in weight occurs on heating for 40–45 min) are arranged in increasing order. Table 5 includes only those polymers which in a vacuum lose not less than 80–85% of their weight without the occurrence of stabilisation or cross-linking phenomena[16].

It must be remarked, however, that the half-decomposition temperature is an extremely rough indication of the thermal stability of polymers, since a far more important characteristic in this respect is the temperature of incipient decomposition of the polymer, determined as the point at which appreciable loss in weight of the heated polymer begins. The half-decomposition temperature is not characteristic of this point, but rather shows how rapidly thermal degradation of the polymer is taking place. Moreover,

Table 5. Relative thermal stability (temperature of half-decomposition) of polymers [16,17].

No.	Polymer	Chain unit	°C
1	Polyperfluoroheptene	$-CF_2-CF-$ C_6F_{11}	248
2	Polytetramethyl-*p*-phenylene-ethylene		265

18	Polydivinylbenzene		399
19	Polyethylene	$-CH_2-CH_2-$	468
20	Polybutadiene	$-CH_2-CH=CH-CH_2-$	407
21	Polytrifluoroethylene	$-CF_2-CHF-$	413
22	Polymethylene	$-CH_2-$	415
23	Polybenzyl	$-CH_2-C_6H_4-$	430
24	Poly-*p*-phenylene-ethylene	$-CH_2-C_6H_4-CH_2-$	432
25	Polytetrafluoroethylene	$-CF_2-CF_2-$	509

with aromatic and heterocyclic polymers, which are distinguished by great thermal stability, this constant is altogether unsuitable, since many polymers of this type lose less than 50% of their original weight when heated to high temperatures. Thus many polybenzimidazoles, polyquinoxalines, polyimidazopyrrolones, etc. lose only ~ 30% of their original weight at 900°C, polyphenylene only 18%, and carborane–polyamides only ~ 6%. At the present time we still have very little information on the thermal stability of polymers, so that half-decomposition temperatures, despite their inadequacy, nevertheless give some idea of the relative thermal stability of polymers.

Let us examine the effect of the structure of the chain unit on thermal stability in various classes of polymers. Straight-chain polyalkenes have better thermal stability than have the branched polymers, as can be seen from a comparison of the half-decomposition temperatures of polymethylene (T_h = 415°C) and polyethylene (406°C) with those of polypropylene (387°C), polyisobutylene (348°C), and other polymers. (This question will be discussed in greater detail in Section IV, 3.)

The presence of a double bond in the chain hardly diminishes the thermal stability at all, as can be seen from a comparison of polyethylene with polybutadiene (T_h = 407°C). The thermal stability of *cis*- and *trans*-isomers shows no fundamental difference, as evidenced by natural rubber and gutta-percha, and also by synthetic polyisoprene[18].

Several polymers are characterised by low thermal stability owing to the presence in their chain units of such groups and atoms as OH, Cl, RCO, etc., which are readily eliminated as water, hydrogen chloride, alcohol, ammonia, etc. Examples of such compounds are poly(vinyl alcohol), poly(vinyl acetate), poly(vinyl chloride), etc. The breakdown of poly(vinyl acetate) yields polyvinylene via an intermediate activated complex:

Poly(vinyl alcohol) and poly(vinyl chloride) also decompose:

The formation of double bonds sharply diminishes the stability of adjacent hydroxy-groups, since the latter are in the β-position with respect to the double bond, and are especially easily split off. Therefore poly(vinyl chloride), poly(vinyl alcohol), and various derivatives easily eliminate almost 100% of halogen or hydroxyls, as the hydrogen halide or water, at relatively low temperatures[19,20]. Fig. 2 shows the loss in weight of poly(vinyl alcohol) and polyethoxyethylene compared with polyethylene, and Fig. 3 that of poly(vinyl chloride) and poly(vinylidene chloride), as a result of being heated at various temperatures.

In most cases replacement of hydrogen by fluorine atoms enhances the thermal stability of polymers, this being due to the higher energy of the carbon–fluorine bond compared with the carbon–hydrogen bond (see Table 3). Fig. 4 shows the quantity of volatile products lost by various fluorinated polymers when heated at various temperatures for 2 h.[21,22] The most stable proved to be polytetrafluoroethylene (T_h = 509°C). The other copolymers and polymers in Fig. 4 show lower thermal stability. Partial replacement of hydrogen by fluorine atoms, as e.g. in poly(vinylidene fluoride), or the presence of chlorine atoms in polychlorotrifluoroethylene lowers the thermal stability. Copolymers of trifluoronitrosomethane have the lowest thermal stability, since they contain –N–O– bonds, which are less stable than –C–C– bonds (Tables 1 and 2). On the other hand, –C–O– bonds are stable, and poly(hexafluoropentamethylene adipate) therefore possesses higher thermal stability. Polymers of fluorinated ethylenes and polyethylene are

arranged in the following sequence of diminishing thermal stability (T_h)

$$(-CF_2-CF_2-)_x > (-CH_2-CF_2-)_x > (-CF_2-CHF-)_x > (-CH_2-CH_2-)_x >$$
(T_h=509°) (T_h=445°) (T_h=412°) (T_h=406°)
$$> (-CH_2-CHF-)_x$$
(T_h=388°)

Only poly(vinyl fluoride) is inferior to polyethylene, while the other fluorinated polymers surpass it in thermal stability[22].

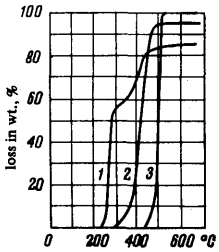

Figure 2. Dynamic thermogravimetric analysis (rate of heating 2 deg min^{-1}) of vinyl polymers[19]:
1) poly(vinyl alcohol); *2*) poly(ethyl vinyl ether); *3*) polyethylene.

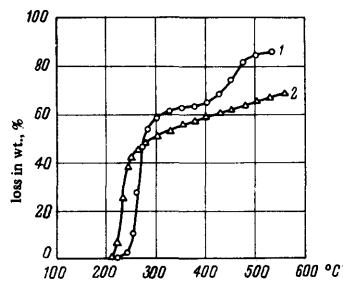

Figure 3. Isothermal thermogravimetric analysis (in atmosphere of nitrogen)[20] of:
1) poly(vinyl chloride); *2*) poly(vinylidene chloride).

A factor of fundamental importance in the relation between thermal stability and structure is the ability of a polymer to decompose on heating with formation of a volatile monomer. All polymers can be divided into two groups according to their behaviour on pyrolysis: polymers in the first group form monomers and other volatile products on thermal decomposition, and either volatilise completely or leave a small non-volatile residue when heated; polymers of the second group do not form volatile monomers, but are converted mainly into non-volatile products. The former group includes vinyl and diene polymers; the second group contains mainly polymers with benzene rings or heterocycles in the main chain.

The presence of benzene rings in the chain enhances the thermal stability of a polymer in comparison with polyethylene (T_h = 406°C), as is evident from the examples of polybenzyl (430°C) and poly-*p*-xylylene (432°C). The effect of position isomerism of the substituents in the aromatic ring must be noted here, as can be seen from Fig. 5, which gives thermogravimetric curves for polymeric *m*- and *p*-xylylenes and their copolymers.

Polymers containing aromatic rings linked together either directly or through various radicals are distinguished by great thermal stability. Table 6 gives values of the relative thermal stability of several polymers containing aromatic rings, determined at the temperature at which the weight of a specimen is halved in 2 h.[17]

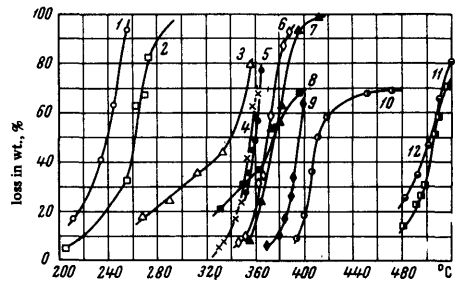

Figure 4. Isothermal thermogravimetric analysis (each point corresponds to a separate specimen heated in a vacuum for 2 h) of various fluorine-containing polymers[22]:
1) copolymer of trifluoronitrosomethane with trifluoroethylene;
2) copolymer of trifluoronitrosomethane with tetrafluoroethylene;
3) poly(hexafluoropentamethylene adipate);
4) polychlorotrifluoroethylene;
5) copolymer of vinylidene fluoride (36%) with chlorotrifluoroethylene (64%);
6) copolymer of vinylidene fluoride (55%) with chlorotrifluoroethylene (45%);
7) copolymer of vinylidene fluoride (77%) with chlorotrifluoroethylene (23%);
8) copolymer of octafluorocyclohexa-1,3-diene with butadiene;
9) copolymer of vinylidene fluoride with hexafluoropropylene;
10) poly(vinylidene fluoride);
11) copolymer of tetrafluoroethylene with hexafluoropropylene;
12) polytetrafluoroethylene.

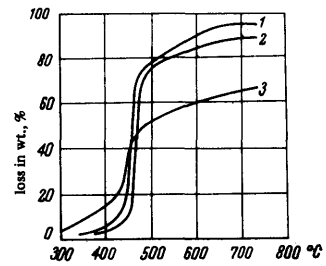

Figure 5. Thermal stability, determined by dynamic thermogravimetric analysis (rate of heating 2.5 deg min^{-1})[22], of polyphenylene-ethylenes:
1) *meta*-isomer; *2*) copolymer of *meta*- and *para*-isomers (1 : 1);
3) *para*-isomer.

The polymers listed in Table 6 can be divided into two types according to their behaviour on heating. The first type includes polymers whose chain unit is made up of such groups as *p*-phenylene (No. 4), *m*-phenylene (5), *pp'*-biphenylylenemethylene (6), tetramethyl-*p*-phenylenemethylene (10), tetramethyl-*p*-phenylene-ethylene (16), *p*-phenyleneimine (7), *pp'*-biphenylylenedi-imineoxalyl (15), naphthylenecarbonyl (18), *p*-phenylenecarbonyl (1), terephthaloylfluorenylidene (2), and also the condensation product of fluorene-2,7-disulphonyl chloride and diphenyl ether (3).

Table 6. Relative thermal stability of polymers (temperature at which the weight of the polymer is halved in 2 h).

No.	Chain unit	Stability, °C	Softening point, °C
1		700	>400
2		640	>400
3		>690	>400
4		<680	>400
5		540	400
6		525	>400
7		485	>400
8		450	>400
9		430	>400
10		430	225—230
11		425	150
12		415	225—230
13		375	215
14		360	>400
15		350	400
16		265	480
17		230	does not soften, but volatilises completely at 350°C
18		<250	>400

The second type includes 2,5-dimethyoxy-1,4-phenylene-ethylene (13), *p*-phenylene-ethylene (9), naphthylene-ethylene (8), anthrylene-ethylene (14), *pp'*-biphenylylenethioureylene (17), *pp'*-biphenylylene-ethylenephenoxy (11), and *p*-phenylene-ethylene-*p*-phenylenesulphonyl (12).

Compounds of the first type are characterised by a rapid loss of part of their weight during the initial stage of heating, after which the residue either undergoes no further change or decomposes slowly.

Polymers of the second type lose weight more slowly on being heated, but these losses are larger than in the first type. They all contain the ethylene group, which is probably readily eliminated. Polymers containing a carbonyl group as linking unit show the greatest thermal stability. An exception is the thermally least stable naphthylenecarbonyl, which already shows appreciable loss in weight at around 250°C, but on further heating to 500°C decomposes only slightly: this is, perhaps, due to contamination with products of low molecular weight.

Fig. 6 shows the loss in weight of a series of polyalkylenephenylenes when heated in a vacuum for 2 h.[24] It includes for comparison the curve for polytetrafluoroethylene.

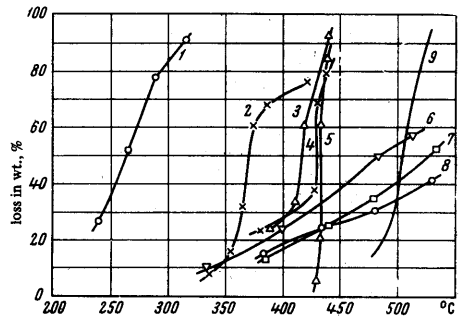

Figure 6. Isothermal thermogravimetric analysis (heating in a vacuum for 2 h) of various polyalkylenephenylenes[24]:
1) polytetramethyl-*p*-phenylene-ethylene; *2*) poly-2,5-dimethoxy-*p*-phenylene-ethylene; *3*) poly-2,5-dimethyl-*p*-phenylenemethylene; *4*) polytetramethyl-*p*-phenylenemethylene; *5*) poly-*p*-phenylene-ethylene; *6*) poly-*pp'*-biphenylylenemethylene; *7*) poly-*m*-phenylene; *8*) poly-*p*-phenylene; *9*) polytetrafluoroethylene.

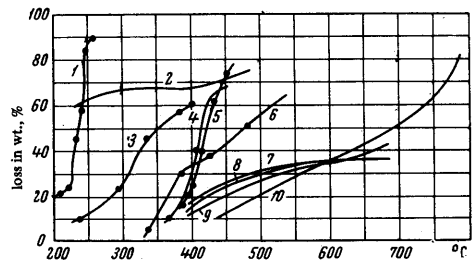

Figure 7. Thermal stability of aryl polymers containing various bridging groups, determined by isothermal thermogravimetric analysis[17] (heating in a vacuum for 2 h):
1) poly-*pp'*-biphenylylenethioureylene; *2*) polynaphthylenecarbonyl; *3*) poly-*pp'*-biphenylylenedi-imineoxalyl; *4*) poly-*p*-phenylene-ethylene-*p'*-phenylenesulphonyl; *5*) poly-*pp'*-biphenylylene-ethylenephenoxy; *6*) *p*-phenyleneimine; *7*) polymer of fluorene-2,7-disulphonyl chloride and diphenyl ether; *8*) polymer of terephthaloyl chloride and naphthalene; *9*) polyphenylenecarbonyl; *10*) polymer of terephthaloyl chloride and fluorene[17].

The nature of the bridging groups joining arylene units in polymers also has a substantial influence on thermal stability, as can be seen from Fig. 7, which gives curves showing the loss in weight of several polymers when heated at various temperatures for 2 h.[17] It can be concluded from these results that the thermal stability of polymers

containing aromatic rings in the chain diminishes according to the nature of the bridging groups in the sequence

The presence of hydroxyl and other substituents in the aromatic ring affects all the properties of the polymer, including its thermal stability. Thus phenol–formaldehyde polymers, which are fairly thermostable substances[25], clearly confirm this principle: the introduction of substituents into the benzene ring results in diminished thermal stability. The thermogravimetric curves for poly-*p*-phenylene and resite, reproduced in Fig. 8, show that the thermal stability of the latter is considerably lower than that of the former, which is explained by the presence of methylene and hydroxyl groups in the benzene rings of resite.

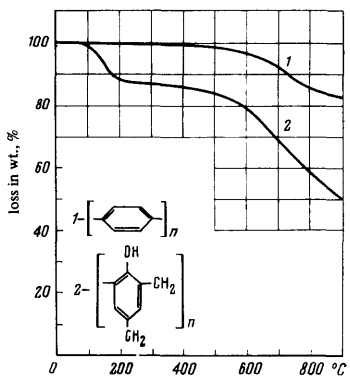

Figure 8. Dynamic thermogravimetric analysis (heating in argon at 15 deg min^{-1}) of:
1) poly-*p*-phenylene; *2*) resite.

Table 7. Amine–formaldehyde polymers[27].

Amine	Loss in wt., %, at 330°C	Loss in wt., %, at 900°C	Temp. of max. gas evolution, °C
Fuchsine	19	35	700
p-Aminophenol	15	47	600
Melamine	36	56	450, 500
Dicyanodiamide	37	62	200, 700
2,6-Diaminopyridine	30	56	600
m-Phenylenediamine	20	57	600
Urea	36	70	300
Aniline	47	81	650

Phenoplasts can operate at 175°C for an indefinite period, but at 200°C for only a few hours; above 200°C their stability drops sharply. As a comparison it may be mentioned that the temperature at which thermal degradation of phenol–formaldehyde polymers begins in an atmosphere of hydrogen is 432°C, as determined by thermoparticulate analysis, whereas the corresponding temperatures for poly(methyl methacrylate) and polystyrene are 310° and 337°C respectively[26].

Many products of the polycondensation of formaldehyde with aromatic amines, which have been prepared by Sergeev et al.[27], are characterised by great thermal stability. When heated to 330°C they lose 15–30% of their weight, but when heated to 900°C they form a non-volatile residue constituting up to 65% of the weight of the original polymer (Table 7). The most thermostable are products of the polycondensation of formaldehyde with *p*-aminophenol.

The introduction of ethereal oxygen into the main chain of a polymer lowers its thermal stability. Thus the thermal stability T_h of polyformaldehyde, poly(ethylene oxide), and isotactic and atactic poly(propylene oxide) (170°, 345°, 312°, and 295°C respectively) is lower than for the corresponding hydrocarbon polymers—polymethylene, polyethylene, and polypropylene (415°, 406°, and 387°C).[16,21] Owing to the polarity of the C–O bond, polyethers show a great tendency to thermal degradation with liberation of the monomer or its conversion products:

As in the case of polyalkenes the presence of lateral substituents lowers the thermal stability. It is interesting that atactic poly(propylene oxide) is thermally less stable than the isotactic isomer. The irregular arrangement of substituents is obviously the cause of structural inhomogeneities facilitating breakdown of the polymer chain.

Aromatic polyethers, in contrast to the aliphatic polymers, are extremely thermostable[28]. Fig. 9 shows thermograms for poly-(2,6-dimethyl-1,4-phenylene oxide) in an atmosphere of nitrogen[29]. It is seen that the poly(phenylene oxide) begins to decompose at 430°C.

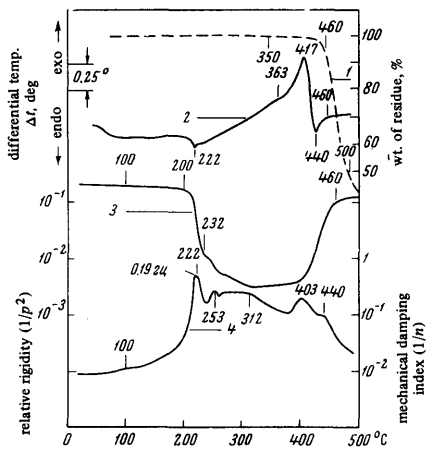

Figure 9. Thermograms of poly-(2,6-dimethyl-*p*-phenylene oxide) determined in an atmosphere of nitrogen[22]:
1) dynamic thermogravimetric analysis (rate of heating 5 deg min^{-1}); *2*) differential thermal analysis (5 deg min^{-1}); *3*) thermomechanical torsion method (2 deg min^{-1}); *4*) thermomechanical torsion method (2 deg min^{-1}).

The thermal stability of polyesters depends on their structure. Table 8 gives Ritchie's measurements[30] of the temperatures at which a series of unsaturated polyesters and their copolymers begin to decompose. It is seen from Table 8 that the temperature at which carbon dioxide is eliminated lies in the range 280–345°C depending on the structure of the polyester. Formation of unsaturated products and aldehydes takes place over practically the same

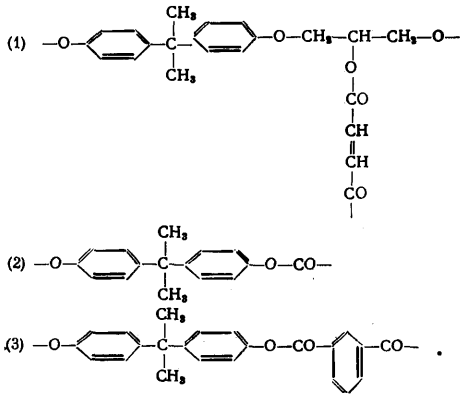
temperature range. It must be noted that a polyester of the saturated succinic acid begins to break down at a higher temperature than is found for polyesters of the unsaturated fumaric acid.

Table 8. Temperatures of start of thermal decomposition of various unsaturated polyesters* and their copolymers[30].

Polyester	Initial temperature, °C			
	evolution of CO_2	formation of unsaturateds	formation of aldehydes	formation of methyl methacrylate
Poly(ethylene fumarate)	295	305	305	—
Poly(neopentyl fumarate)	290	335	290	—
Poly-(*p*-phenylene fumarate)	280	+	+	—
Poly(ethylene succinate)	345	320	330	—
Ethylene fumarate + methacrylate copolymer	305	305	310	265
Neopentyl fumarate + methyl methacrylate copolymer	310	380	310	260
Methyl fumarate + methacrylate copolymer	—	—	—	250
Poly(methyl methacrylate)	—	—	—	240

* Up to 500°C neither ethylene, acetylene, nor aldehyde evolved.

It is seen from the above data that aliphatic polyesters and their copolymers have no great thermal stability. In contrast to them, polyesters of arenediols and aromatic dicarboxylic acids—"polyarylates"—are highly thermostable substances. The curves in Fig. 10 show the relative rates of decomposition of poly-(2,2-di-*p*-phenylenepropane isophthalate) (a polyarylate), a polycarbonate, and an epoxide resin at 400°C. It is seen that the polyarylate considerably surpasses the polycarbonate and the epoxide resin in thermal stability. These three polymers resemble one another in the structure of the principal chain unit, in which a 2,2-diphenylpropane-*pp'*-diol residue is present:



The differences in their thermal stability depend on the structure of the second component of the chain unit. Therefore the thermal stability of polyarylates should be improved by removing the aliphatic part of the chain unit, as also on replacing isophthalic by terephthalic acid. Fig. 11 illustrates the thermal stability of polyarylates of phenolphthalein with isophthalic and terephthalic acids: the extent of decomposition of the former considerably exceeds that of the latter at the same temperatures[32].

The thermal stability of polyarylates is greatly influenced by the nature of substituents in the central dihydric phenol. Polyarylates based on diphenylfluorene-*pp'*-diol are distinguished by especially high thermal stability, as can be seen from Fig. 12. These polyarylates have also a higher photostability[33].

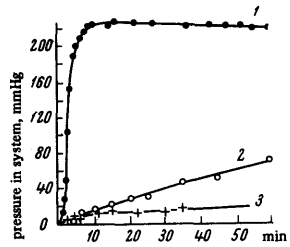


Figure 10. Rate of thermal degradation at 400°C of some polymers based on 2,2-diphenylpropane-*pp'*-diol (dian), determined from pressure of gases evolved[31]:
1) epoxide polymer obtained by hardening the epoxide oligomer ED-6 with maleic anhydride; *2*) poly(dian carbonate); *3*) poly(dian isophthalate) (polyarylate D-2).

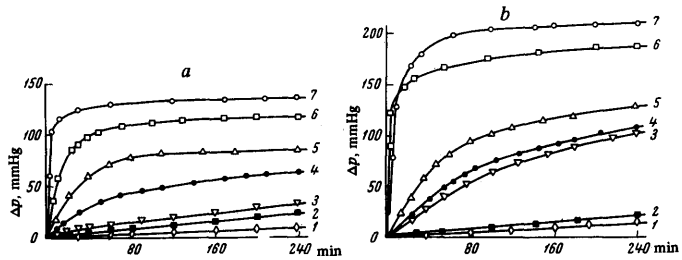

Figure 11. Kinetics of the degradation, determined from the increase in pressure in a closed system[32], of the polyarylates of phenolphthalein and: *a*) terephthalic acid; *b*) isophthalic acid. Temperature (°C): *1*) 350; *2*) 375; *3*) 400; *4*) 425; *5*) 450; *6*) 475; *7*) 500.

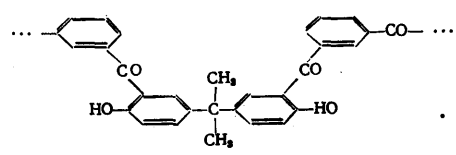
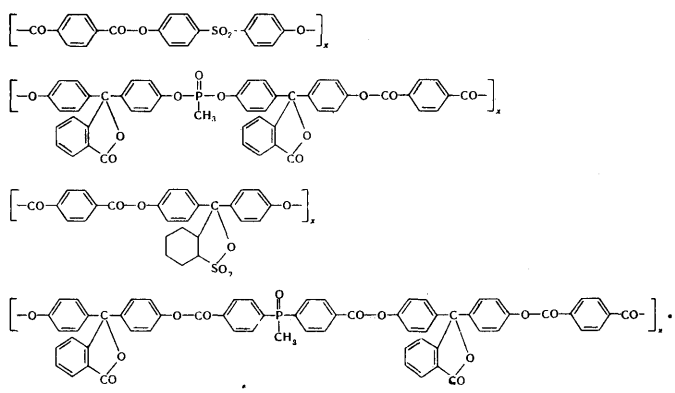
It has been shown with the polyarylates that the incorporation of certain groups may produce "self-protective polymers", which contain various groups and atoms enhancing their stability and protecting them from thermal and chemical breakdown. Self-protective polyarylates have been obtained in several ways[34,37]. Thus the Fries rearrangement or the use of trihydric phenols yields polyarylates containing free phenolic hydroxyls



Such polyarylates have improved thermal stability, and are also more resistant to the action of light and to hydrolysis[34,35].

An equally favourable effect is produced by introducing sulphonyl groups[36] or residues of phosphinic acids[37] into

the polyarylate molecule, as has been shown for the compounds



The introduction of residues of *p*-iodobenzoic acid as end-groups has also proved extremely effective[38]. Such self-protective polyarylates are considerably more resistant to the action of high temperatures.

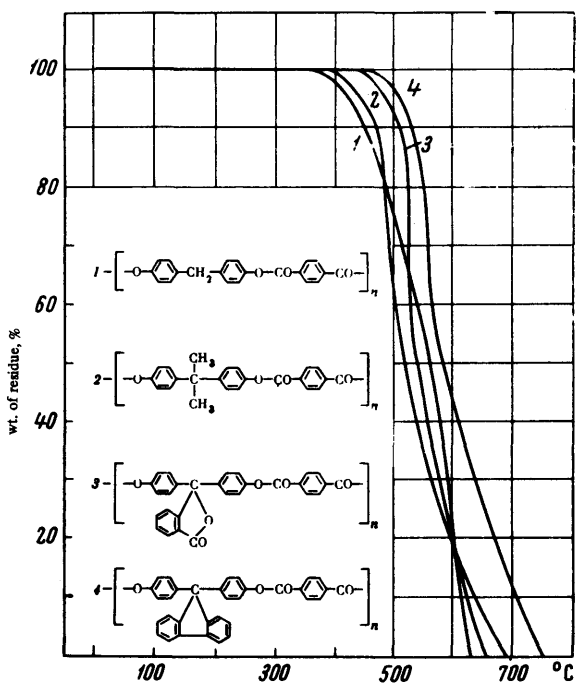


Figure 12. Dynamic thermogravimetric analysis (heating in nitrogen at 4 deg min^{-1})[40] of the polyterephthalates of:
1) diphenylmethane-*pp'*-diol; *2*) 2,2-diphenylpropane-*pp'*-diol; *3*) phenolphthalein; *4*) 9,9-diphenylfluorene-*pp'*-diol.

There are also several extremely thermostable compounds among heterochain polyamides. Aliphatic polyamides have a lower thermal stability than have aromatic polyamides. Thus polyhexano-amide fibre begins to decompose at 400°C, the maximum rate of decomposition occurring over the range 400–436°C.[29,39] Fig. 13 gives thermograms for polyhexano-amide characterising its thermal stability. In general the breakdown of polyamides begins with cleavage of the amide bond. Therefore they start to decompose at temperatures of around 350°C, independently of the structure of the rest of the chain unit, as can be seen from Fig. 14. Nevertheless, aromatic polyamides are more thermostable.

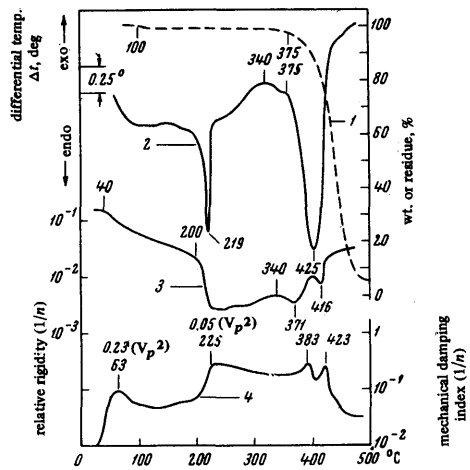

Figure 13. Thermograms of polyhexanoamide[29]:
1) dynamic thermogravimetric analysis (heated in nitrogen at 5 deg min^{-1}); *2*) differential thermal analysis; *3*) thermomechanical torsion method (rate of heating 2 deg min^{-1}); *4*) thermomechanical torsion method.

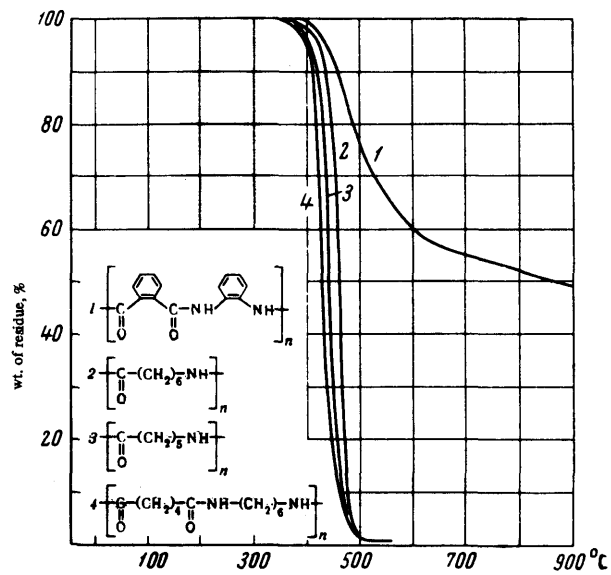

Figure 14. Dynamic thermogravimetric analysis (heated in helium at 5 deg min^{-1}) of polyamides:
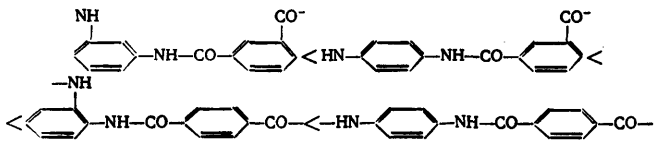
1) poly-*m*-phenyleneisophthalamide; *2*) poly-ω-heptanoamide; *3*) polyhexanoamide; *4*) polyhexamethyleneadipamide.

Aromatic polyamides obtained from phenylenediamines and benzenedicarboxylic acids can be arranged according to increasing thermal stability, in the sequence



i.e. polyamides of isophthalic acid are inferior to those of terephthalic acid, just as polyamides from *p*-phenylenediamine are more stable than those from *m*-phenylenediamine (Fig. 15).[41] Thermogravimetric analysis of the polyamide obtained from anilinephthalein and terephthalic acid has shown that this polymer possesses high thermal stability (Fig. 16).[42]

Ordinary polyurethanes begin to decompose at a temperature above 220°C. The thermal stability of polyurethanes can be increased by replacing the hydrogen atoms of the carbamate group by an alkyl or an acyl group[43], and also by using di-isocyanates, in which the isocyanate groups are separated from an aromatic ring by methylene groups, which hinders intramolecular resonance[44-46].

As we have already seen, replacing aliphatic by aromatic groups in the chain unit produces a sharp increase in the thermal stability of polymers. The same result is achieved also by introducing heterocyclic groups of aromatic character into the chain unit, which yields such polymers as polybenzimidazoles, polybenzoxazoles, polyimides, polybenzothiazoles, pyrrones, polypyrazoles, polythiazoles, polyoxadiazoles, polytriazoles, etc. A large number of polymers of this type have now been prepared, and their properties investigated. The results have been summarised in reviews[3,4,8,48,49].

An important feature of these polymers—"polyheteroarylenes"—is their extremely high thermal stability (Table 9). The results of a thermogravimetric analysis of four polybenzimidazoles are plotted in Fig. 17. Polymers containing an aliphatic residue in the chain unit begin to decompose above 450°C, and those containing phenylene groups above 550°C. Even at 900°C the losses in weight of the last two polymers are only 30%.

Table 9. Thermal stability (temperature at which decomposition begins) of some polymers containing heterocycles in the chain.

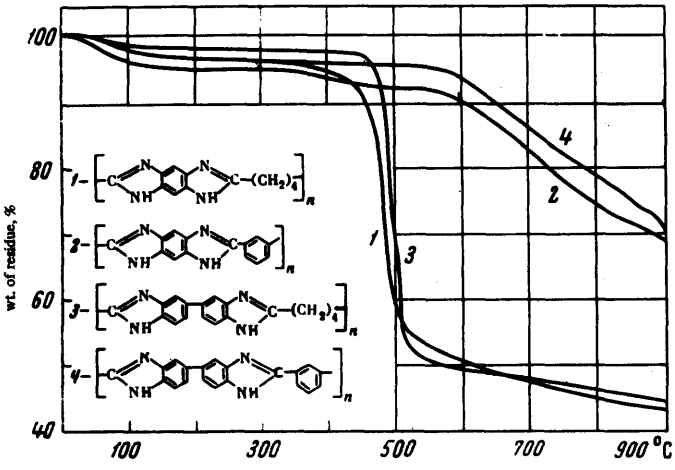

Figure 17. Dynamic thermogravimetric analysis of polybenzimidazoles[50] (heated in nitrogen at 2.5 deg min^{-1}).

The products obtained by the polycondensation of tetraamines with anhydrides of tetracarboxylic acids are more thermostable. Fig. 18 illustrates the results of a thermogravimetric analysis of two polybenzimidazoimides (pyrrones) prepared from pyromellitic anhydride; they have a ladder structure and are distinguished by great thermal stability.

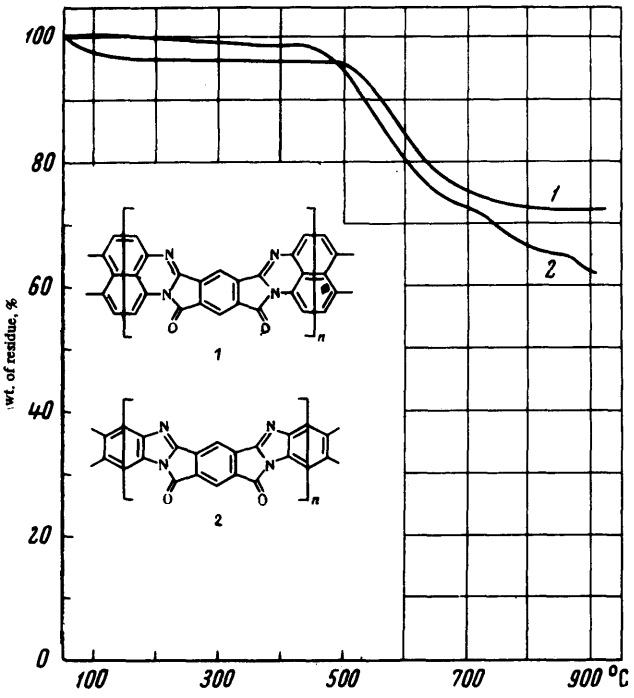

Figure 18. Dynamic thermogravimetric analysis of polybenzimidazoimides[62] (heated in nitrogen at 6 deg min^{-1}).

Polyimides also constitute an extremely thermostable class of polymers. Thus thermogravimetric analysis of four polypyromellitimides shows (Fig. 19) that a polymer containing a biphenylylene group is the most thermostable, polymers containing a *m*-phenylene or a diphenylene oxide group are not quite so good, and the most unstable is the polymer containing a diphenylenemethane group. Soluble polypyromellitimides obtained from anilinephthalein and diaminodiphenylfluorene are extremely thermostable (Fig. 20). Results of a dynamic thermogravimetric analysis of a polyimide and of several vinyl polymers are illustrated in Fig. 21.

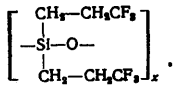
Fig. 22 gives for comparison results of a thermogravimetric analysis of polyquinoxaline, polybenzoxazole, and polyoxadiazole. Curves for polyquinazolinediones—representatives of a new class of thermostable polymers—are given in Fig. 23.

In a large group of thermostable polymers other elements accompany carbon in the chain of the macromolecule. The most interesting are polymers containing silicon, boron, phosphorus, and various metals. The chief factor determining the thermal stability of these polymers is the energy of the bond between atoms in the main chain

and those surrounding it. A characteristic feature of polydiphenylsilanes is their tendency to oxidise when heated in the air to 300°C. As a consequence, the weight of a specimen increases, as shown in Fig. 24.

Fig. 25 gives thermogravimetric curves for a series of organosilicon polymers. The thermal stability of polysiloxanes containing aromatic radicals is higher than that of those containing aliphatic radicals. The introduction of phenylene groups into the main chain produces an especially marked increase in thermal stability, as occurs with silaphenylene polymers.

Polyfluoroalkylsiloxanes are also characterised by enhanced thermal stability, but both this and their hydrolytic stability depend on the position of the fluorine relative to the silicon, as is evident from Table 10.[71] The most thermostable were polyfluoroalkylsiloxanes containing fluorine atoms in the γ-position relative to the C–Si bond, and having the structure



A large number of organoboron polymers are known, containing B–C, B–N, and other bonds[73]. However, very few data are at present available on their thermal stability. Thermogravimetric analysis of a polybenzoborimidazoline and of a polybenzimidazole containing phosphorus shows

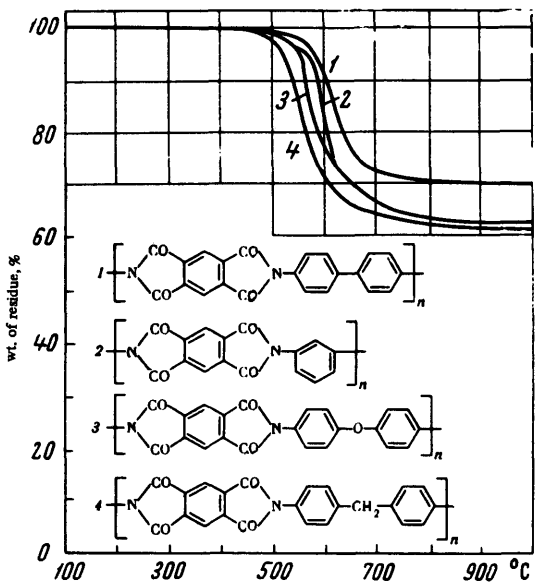


Figure 19. Dynamic thermogravimetric analysis of polypyromellitimides[70] (heated in dry helium at 3 deg min^{-1}).

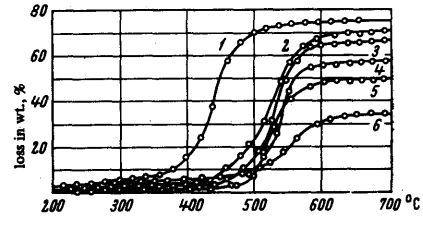

Figure 25. Isothermal thermogravimetric analysis of polysiloxanes[72]:

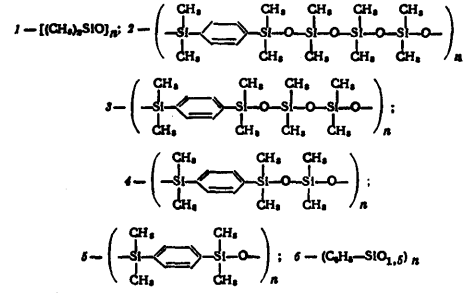
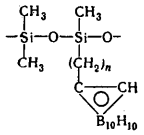


(Fig. 26) that the thermal stability of the benzoborimidazoline ring is lower than that of the imidazole ring.

Polymers containing carborane (barene) residues in the chain unit are extremely interesting[74]. Introduction of a carborane residue into a polymer molecule produces a considerable increase in thermal stability. Thus polyesters, polyamides, and other polymers obtained from dicarboxylic acids containing carborane ring systems are distinguished by exceptionally high thermal stability. The introduction of a carborane system into polysiloxanes produces

polycarboranesiloxanes having the structure



which show considerably better thermal stability than does polydimethylsiloxane[75]. Equally high thermal stability is characteristic of the polycarboranebenzimidazole

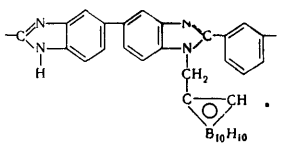


Table 10. Thermochemical and chemical stability of polyfluoroalkylsiloxanes[71].

Chain unit	Thermal stability on heating in sealed tube for 6 h: temp., °C	Thermal stability on heating in sealed tube for 6 h: polymer decomposed, %	Resistance to hydrolysis by 10% aq. NaOH 20°C

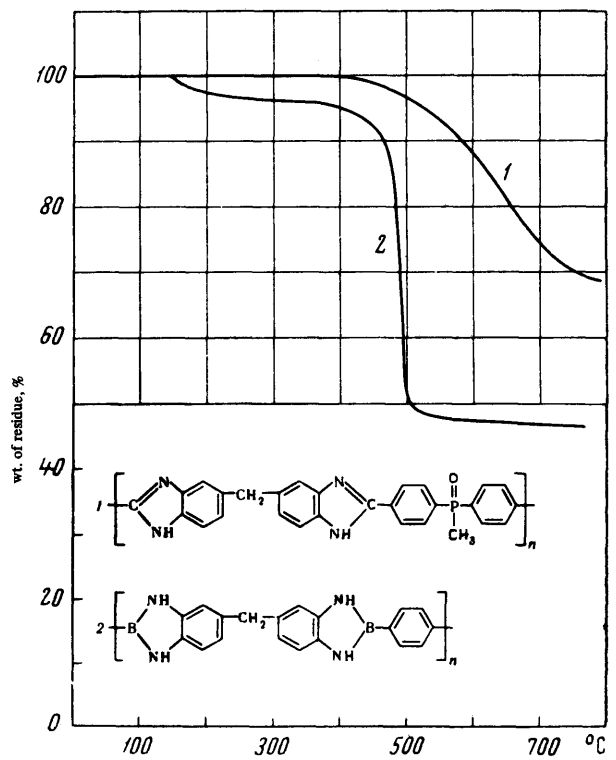

Figure 26. Dynamic thermogravimetric analysis (in nitrogen) of organoelementary polymers containing boron and phosphorus[77].

It surpasses the analogous unsubstituted polybenzimidazole in thermal stability, and when heated in the air to 900°C it loses only 25% of its original weight[76].

Very few phosphorus-containing polymers are characterised by high thermal stability. Among them are poly(phosphonitrile chloride) $[PCl_2=N]_n$ and PON polymers.

1) copper; *2*) zinc; *3*) cobalt; *4*) nickel.

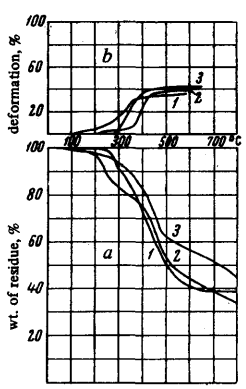

Figure 30. Thermal analysis of chromium polyphosphinates[83]:
a) dynamic thermogravimetric analysis (heated in air at 20 deg min^{-1});
b) thermomechanical analysis (with load of 100 g on tool of diameter 4 mm, heated in air at 70 deg h^{-1}):
1) polydiphenylphosphinate; *2*) poly-2,8-dimethylphenoxaphosphinate;
3) copolymer of equimolecular quantities of the two phosphinates.

Metal-containing polymers, especially inner-complex (chelate) polymers, are distinguished by high thermal stability. Inoy[78] determined the thermal stability of a series of coordination polymers of zinc, copper, nickel, cobalt, and manganese with bis-8-hydroxyquinol-5-ylmethane (Fig. 27). The dependence of the decomposition temperature (thermal stability) of several coordination polymers on the atomic number of the metal is shown in Fig. 28: the thermal stability of these polymers falls in the sequence Mn > Fe > Co > Zn > Ni > Cu. As is evident from Table 11, zinc gives the most thermostable coordination polymers, and copper the least stable[80].

The zinc complexes of salicylideneimines have also been shown to be the most stable[81]. This can be explained by the electronic structure of the bivalent ion of zinc, which possesses only one state of oxidation. Other transition metals can be oxidised to higher valencies, and this may catalyse processes of thermal decomposition.

The replacement of organic ligands by phosphinic acids enables coordination polymers to be obtained having an inorganic main chain. Such polymers are also characterised by high thermal stability, as is shown (Fig. 29) by thermomechanical and thermogravimetric analyses of copper, zinc, cobalt, and nickel polydiphenylphosphinates[82]. The nature of the metal ion plays an important part here. Cobalt polyphosphinate proved to be the most thermostable. The nature of the ligands is also significant, as is seen from Fig. 30, which illustrates the results of a dynamic thermogravimetric analysis of three chromium polyphosphinates[83]. The polydiphenylphosphinates proved to be more thermostable than the poly-2,8-dimethylphenoxaphosphinates.

IV. DEPENDENCE OF THERMAL STABILITY ON STRUCTURE OF MACROMOLECULE

As we have seen from many examples, the structure of the chain unit in the macromolecule plays an immense part in determining the thermal stability of the polymer. However, besides the structure of the monomer unit, various structural features of the macromolecule itself often play a no less fundamental part in determining the thermal stability. Among such factors are regularity of structure of the macromolecule, isomerism of substitution in the ring, the presence of cross-links between macromolecules, and also the molecular weight. Below we shall examine one by one the effect of these structural features on the thermal stability of polymers.

1. Dependence of Thermal Stability on Regularity of Structure of Macromolecule

The chain units in a macromolecule can be arranged in two ways—"head to tail" $-CH_2.CHX.CH_2.CHX-$ or "head to head" $-CH_2.CHX.CHX.CH_2-$.

Vinyl polymers are usually built up in the first way, "head to tail". The content of units arranged in the second way is minute (1–2%). However, even a small number of units joined "head to head" may substantially affect the properties of the polymer, in particular its thermal stability.

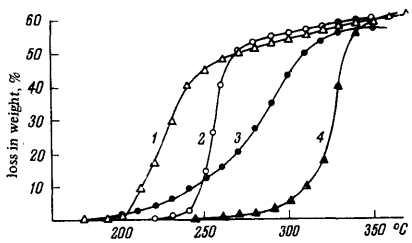

Figure 31. Isothermal thermogravimetric analysis of poly(vinyl chlorides) and poly(vinylidene chlorides) of various types[84].
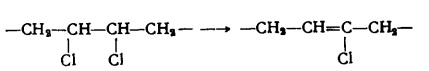
1) poly(vinylidene chloride) of "head to tail" structure; *2*) poly(vinyl chloride) of "head to tail" structure; *3*) poly(vinyl chloride) of "head to head" structure; *4*) poly(vinylidene chloride) of "head to head" structure.

Murayama and Amagi[84] investigated the thermal breakdown of poly(vinyl chloride) and poly(vinylidene chloride) having head-to-head and head-to-tail structures. Fig. 31 shows that polymers having the latter type of arrangement begin to decompose at a great rate, and their decomposition extends as far as complete elimination of hydrogen chloride. In contrast to this, polymers with the head-to-head construction break down at a lower rate. The explanation is that, although the first stage occurs more easily owing to the lower stability of the head-to-head structure, the second stage occurs more slowly owing to formation of a chloroprene-like structure containing halogen attached to double-bonded carbon:



In this case there is no opportunity for a chain dehydrochlorination reaction to develop along the macromolecule.

2. Effect of Isomerism of Substitution in the Aromatic Ring

Polymers containing aromatic or heterocyclic rings in the chain differ substantially in thermal stability according to the relative arrangement of substituents in the ring.

Table 12 shows that polymers containing *para*-substituted rings are the most thermostable. Polymers containing the *meta*-isomers are less stable, as has been established with polyphenylenes, polyamides, and polybenzoxazoles. Derivatives of terephthalic acid surpass the corresponding derivatives of isophthalic acid in thermal stability.

In the case of aromatic heterocycles the relative arrangement of the heteroatoms also plays a significant part. Thus poly-1,2,4-oxadiazoles are less thermostable than are poly-1,3,4-oxadiazoles.

3. Effect of Lateral Groups and Branching

The presence of lateral groups and of branching in a macromolecule always leads to diminished thermal stability of the polymers. This principle is confirmed by comparing the relative thermal stabilities (T_h) of a series of polymers containing these structural features (Table 5).

The thermal stability of polyethylene (19)†, which is a branched-chain variety of polymethylene, is lower than that of the straight-chain polymer (22). The introduction of side-groups into every chain unit in the polymer lowers the thermal stability still more, as can be seen from the examples of polypropylene (16) and polyisobutylene (12). The same situation is observed on comparing poly(methyl acrylate) (10) with poly(methyl methacrylate) (3): the latter is inferior to the former in thermal stability.

A similar variation occurs in the perfluorocarbons, as is seen from the examples of polytetrafluoroethylene (25), polyperfluoropropylene (6), and polyperfluoroheptene (1). In this case the thermal stability also falls in the presence of side-groups, not only their presence but also their nature being significant: the larger the lateral group, the lower the thermal stability. Thus polyperfluoroheptene (T_h = 248°C) is less thermostable than is polyperfluoropropylene (297°C).

Substituents in the macromolecules of polyethers have an analogous effect: poly(propylene oxide) is less thermostable than is poly(ethylene oxide) (295° and 345°C respectively).

The presence of substituents in phenylene groups also lowers the thermal stability of polymers, as has been shown in the case of substituted poly-*p*-phenylene-ethylenes[17]. Thus polytetramethyl-*p*-phenylene-ethylene and poly-2,5-dimethoxy-*p*-phenylene-ethylene (265° and 375°C) are inferior in thermal stability to poly-*p*-phenylene-ethylene (430°C). In this case the number of substituents is also important. Thus the general rule can be formulated that the more substituents are present in a chain unit the lower is the thermal stability of the polymer. In the case of vinyl polymers this is because side-groups weaken the bonds between the chain units in the macromolecule, which facilitates their breakdown with the formation of monomer:

† The parentheses indicate the numbering of the polymers in Table 5.

Table 12. Thermal stability of isomeric polymers containing rings in the chain.

Polymer	Chain unit	Temp., °C	Ref.
Poly-*p*-phenylene		650*	17
Poly-*m*-phenylene		540*	17
Polyaniline-phthaleiniso-phthalamide		420**	85
Polyaniline-phthaleintere-phthalamide		450**	85
Polyaniline-imidophthalein-isophthalamide		420**	85
Polyanilineimido-phthaleintere-phthalamide		440**	85
Poly-*m*-phenyl-eneisophthal-amide***		330**	41
Poly-*m*-phenyl-eneisophthal-amide***		390**	41
Poly-*p*-phenyl-eneterephthal--amide***		410**	41
Poly-2,2′-*m*-phenylene-5,5′--dibenzimida-zolylmethane		490**	86
Poly-2,2′-*p*-phenylene-5,5′-dibenzimida-zolylmethane		500**	86
Poly-3,3′-*pp*′-phenoxyphenyl-ene-5,5′-bi-1,2,4,--oxadiazolyl		300**	87
Poly-2,5-*pp*′-phenoxyphenyl-ene-1,3,4-oxa-diazole		430**	65
Poly-5-*m*-phenyl-ene-1,3,4-oxa-diazol-2-yl-5′--*pp*′-phenoxy-phenylene-1′,3′,,4′-oxadiazol-2′-yl		380**	88
Poly-5-*m*-phenyl-ene-1,3,4-oxa-diazol-2-yl-5′--*p*′*p*″-phenoxy-phenylene-1,′3′,4′-oxadia-zol-2′-yl		430**	88

* Temperature at which a specimen loses half its weight during 2 h.
** Temperature of start of loss in weight on thermogravimetric curve.
*** Some of this information is obviously incorrect (Ed. of Translation).

4. Dependence of Thermal Stability on Degree of Cross-linking of Polymer

All the relations which we have considered hitherto have applied to linear macromolecules. However, there are also other structures, as is evident from Fig. 32. Linear chains may consist of (*a*) rings of spiran structure, or two linear polymer chains may be joined by cross-links, as in the case of (*b*) ladder polymers. Polymer chains joined to two adjacent chains in the same plane form (*c*) parquet structures, and finally chains joined to a large number of macromolecules arranged in all three directions form (*d*) spatially cross-linked three-dimensional structures. For the most part, bond formation between macromolecules leads in all the above cases to an increase in their thermal stability compared with that of the corresponding linear structure. Tessler[89] made a theoretical calculation showing that ladderlike structures form smaller quantities of volatile products during a given time than do analogous simple polymers.

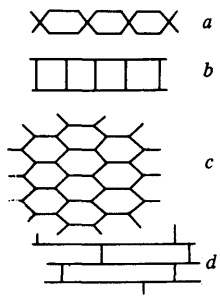


Figure 32. Various forms of macromolecules:
a) spiran; *b*) ladderlike; *c*) parquet; *d*) three-dimensional cross-linked.

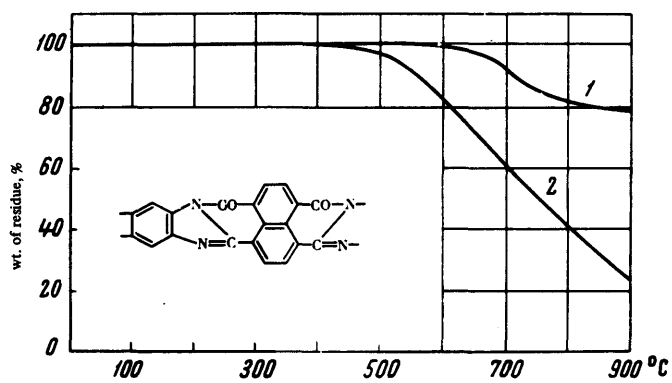

Figure 33. Dynamic thermogravimetric analysis (rate of heating 2.5 deg min^{-1}) of pyrrones[90] in:
1) nitrogen; *2*) air.

A dynamic thermogravimetric analysis of pyrrones shows (Fig. 33) that these ladderlike polymers have extremely high thermal stability. Such parquet structures as graphite, as well as porphyrin polymers, are characterised by exceptionally high thermal stability.

Cross-linked polymers have higher thermal stability because the introduction of cross-links increases the chemical stability of the polymers. A fundamental difference exists between the effect, on the properties of polymers, of interchain forces of interaction (both dipole forces and hydrogen bonds) and valency bridges: the former are strongly dependent on temperature, rapidly becoming weaker as the temperature rises, whereas the latter are independent of variation in temperature over a wide range.

Table 13. Temperature of half-decomposition T_h of styrene copolymers.

Content in copolymer, %			T_h, °C
styrene	divinyl-benzene	trivinyl-benzene	
100	0	0	364
98	2	0	365
75	25	0	373
75	0	25	393
0	100	0	399
44.2	55.8	0	401
0	0	100	462

Table 13 gives values of the thermal stability (T_h) for cross-linked copolymers of styrene with divinylbenzene and trivinylbenzene as a function of the frequency of cross-linking. Thus the cross-linking of chains has a considerable effect in raising the thermal stability, as is evident from the examples of polystyrene, polydivinylbenzene, and polytrivinylbenzene (364°, 399°, and 462°C respectively)[91-93].

This fact is illustrated by the thermogravimetric curves (Fig. 34) for polymers of divinylbenzene and trivinylbenzene and their copolymers with styrene. It is seen that the losses in weight of the trivinylbenzene polymers are smaller than those of the divinylbenzene polymers. The latter losses are in turn smaller than those of polystyrene. Fig. 35 shows comparative curves for the thermal stability of cross-linked polytrivinylbenzene and for several other polymers[92].

The strongly cross-linked polymer of 1,3,5-triacryloylhexahydro-1,3,5-triazine is a thermostable substance, decomposing at ~ 400°C.[94]

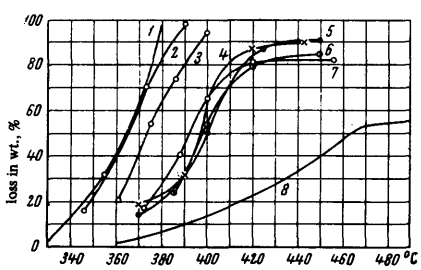

Figure 34. Relative thermal stability of polymers and their copolymers with styrene determined by isothermal thermogravimetric analysis[92,93]:
1) polystyrene; *2*) copolymer of styrene with 2% of divinylbenzene; *3*) copolymer of styrene with 25% of divinylbenzene; *4*) copolymer of styrene with 48% of divinylbenzene; *5*) copolymer of styrene with 55% of divinylbenzene; *6*) polydivinylbenzene; *7*) copolymer of styrene with 25% of trivinylbenzene; *8*) polytrivinylbenzene.

A marked improvement in thermal stability results from the formation of cross-links in polyarylates containing free hydroxyls in their macromolecule. Fig. 36 shows that a more thermostable polymer is formed by cross-linking such a polyarylate by means of maleic anhydride[95].

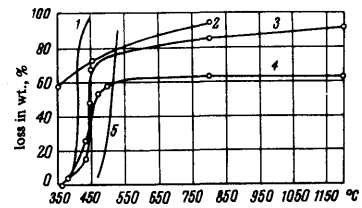

Figure 35. Relative thermal stability of polymers determined by isothermal thermogravimetric analysis[92]:
1) polymethylene; *2*) polyacrylonitrile; *3*) poly(vinylidene fluoride); *4*) polytrivinylbenzene; *5*) polytetrafluoroethylene.

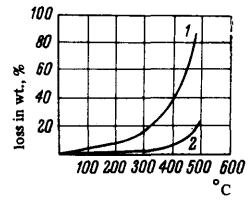

Figure 36. Thermogravimetric curves of polyarylates[95]:
1) original polyarylate D-5; *2*) polyarylate D-5 cross-linked with 15% of maleic anhydride.

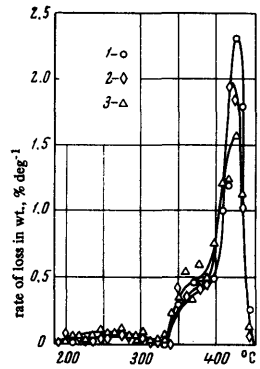

Figure 37. Differential thermogravimetric analysis of polyethylene exposed in air to different doses (Mrad) of radiation[96]:
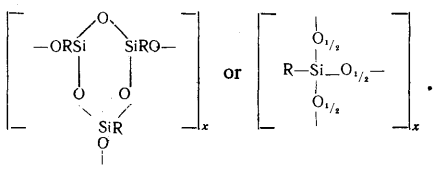
1) 0; *2*) 5.2; *3*) 55.

The irradiation of polymers is a general method for cross-linking them and improving their thermal stability. Fig. 37 shows curves for the differential thermogravimetric analysis of polyethylene exposed in air to different doses of radiation[96]. It is seen that the thermal stability of the polymer increases with increase in the dose.

Andrianov[15] observed a marked increase in thermal stability as a result of the cross-linking of polyorganosiloxanes containing rings or irregular cross-links of the type

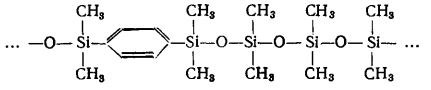


In this case the detachment of a chain unit or a large portion of the polymer molecule involves breaking the latter at three points, since the polymer contains cross-linked molecules. This is associated with the destruction of two or three energetically stable Si–O bonds. In polyorganosiloxanes containing three-dimensional bonds, therefore, no degradation of the molecular chains at a silicon–oxygen bond is observed even at 550°C, independently of the nature of the organic radical.

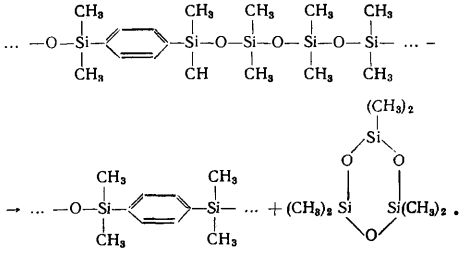
5. Effect of Copolymerisation

Copolymerisation or copolycondensation results in the formation of copolymers containing different types of unit in a chain. The presence of units differing in structure often presents difficulties in the detachment of molecules during thermal degradation.

A clear example of such improvement in thermal stability resulting from copolymerisation is provided by silaphenylene–siloxane copolymers having the structure



When such a polymer undergoes thermal breakdown, six-membered rings are split off:



This process extends along that part of the chain which consists of dimethylsiloxane units. When a silaphenylene group is reached, however, ring formation becomes impossible, and degradation ceases. Therefore the thermal stability of such copolymers is considerably higher than that of polydimethylsiloxanes (temperatures at which breakdown begins 450° and 350°C respectively).

An analogous improvement in thermal stability is observed in copolymers of formaldehyde with cyclic oxides or acetals[97]. Polyformaldehyde itself already decomposes at 170°C, whereas its copolymers are stable up to 200°C.

6. Effect of Other Structural Features on Thermal Stability

Several structural features of polymers, other than those which we have discussed, affect their thermal stability. We must first note the part played by end-groups.

It has been shown in the case of polyformaldehyde that its thermal stability depends on the nature of the terminal groups. Thus ordinary polyformaldehyde, having hydroxyls at the ends of the macromolecules, begins to decompose at about 170°C.[98] Acetylation yields a stabilised polyformaldehyde containing acetyl groups at the ends of the chain. The breakdown of polyformaldehyde takes place by a chain mechanism, beginning at the end-groups:

Acetylation changes the nature of the terminal group, and depolymerisation proceeds according to the equation

The acetyl group, being heavier and less mobile, requires more energy for its transfer, and therefore such acetylated polyformaldehyde decomposes at a higher temperature (200°C). Fig. 38 illustrates the results of a thermogravimetric analysis of polyformaldehyde in a vacuum, showing the higher thermal stability of acetylated polyformaldehyde[99].

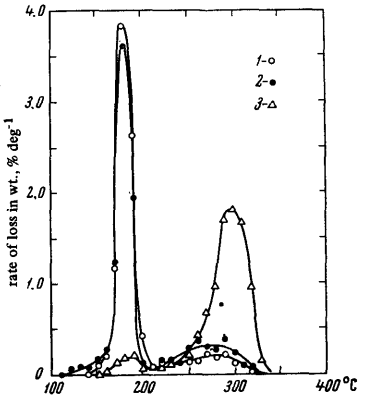


Figure 38. Differential thermogravimetric analysis of polyformaldehyde heated in a vacuum at different rates (deg min^{-1})[99]: *1*) polyformaldehyde (1); *2*) polyformaldehyde (0.5); *3*) acetylated polyformaldehyde (1).

In some cases the glass point and the thermal stability of polymers are also interrelated. If the glass point lies far below the temperature of decomposition, no relationship between them is observed, and the thermal stability is determined by the energies of the interatomic bonds. If, however, the glass point lies above or near the decomposition point, there is a clear relation between them: in these cases thermal breakdown is usually considerably accelerated after transition through the glass point.

---o0o---

The data given above show that we are now aware of several relations linking the thermal stability of polymers with their chemical structure. Among a number of structural features having general significance and producing high thermal stability in polymers the most important are

high interatomic bond energies, the presence of stable aromatic and other groupings in the chain unit, the presence of intermolecular bonds, ladderlike, and other cross-linked structures.

High energy of the bonds between chain units, as also within a unit and with surrounding groups, constitutes an important factor determining the thermal stability of a polymer. It makes difficult the formation of free radicals, by either thermal or thermo-oxidative mechanisms, and prevents the occurrence of chain reactions of thermal and oxidative degradation. An effective way of producing thermostable structures is to introduce aromatic carbocycles and heterocycles, as well as carborane, ferrocene, and other stable groups. Improvement in the thermal stability parallels the increased content of aromatic rings in the chain. Decreasing the content of aliphatic groups, both in the chain and in side-groups, and increasing the content of aromatic rings in the polymer are of fundamental value. The thermal stability is improved in all cases on passing to ladderlike, parquet, and three-dimensional cross-linked structures, this being due to the diminished opportunities for the formation of volatile pyrolysis fragments. One way of improving the thermal stability of vinyl, oxide, and other linear polymers is to diminish their capacity for depolymerisation, this being accomplished by introducing large end-groups and by copolymerisation with monomers giving stable chain units, incapable of easy detachment as monomeric molecules.

An important way of improving thermal stability is to introduce, into the composition of the polymer, groups which are able to increase its resistance to oxidation or pyrolysis, as occurs in the case of "self-protective" polymers. The incorporation of groups which prevent oxidation or pyrolysis by combining with the free radicals formed and thus terminating the chain processes of decomposition considerably enhances the thermal stability of polymers. Such protective groups are sometimes formed in the course of chemical rearrangement of the polymer, but far more often they are introduced as "external" additives (stabilisers, antioxidants, etc.), which is a very widely used technical procedure for improving stability during the processing of polymers.

As is evident from the data which have been discussed, several relations have already been established linking the structure of polymers with their thermal stability. The task for future research is to refine these relations, so that they can be used still more widely for the consciously controlled synthesis of thermostable polymers.

Synthesis of Vinyl Ethers Containing Functional Groups and Heteroatoms

M.F.Shostakovskii, B.A.Trofimov, A.S.Atavin, and V.I.Lavrov

The paper gives a brief analysis of the chief methods for synthesising vinyl ethers containing functional groups and heteroatoms. Published information on the Favorskii-Shostakovskii reaction—the direct vinylation of hydroxylated compounds (alkoxyalkanols, glycols, polyhydric alcohols)—is surveyed, the mechanism of the reaction is discussed, and its application considered to the vinylation of nitrogen-containing alcohols (amino-alcohols and amino- and nitro-phenols), and to alkylthio-alcohols, silicon-containing alcohols, halogenated alcohols, and halogenated phenols. The elimination of hydrogen halides from halogenated ethers and the reaction of vinyl exchange are also reviewed. Methods are discussed based on the reactions of functional groups in substituted vinyl ethers (vinyloxyalkanols and halogenated and nitrogen-containing vinyl ethers), catalytic elimination in functional acetals, and the interaction of halogenated acetals with metals and of alkoxides of functional alcohols with vinyl halides. The fields of application of each of the above methods are assessed. A list of 302 references is included.

I. INTRODUCTION

The increasing amount of research on $\alpha\beta$-unsaturated ethers containing reactive functional groups has long ago made it necessary to summarise and analyse in detail the available experimental information. A monograph[1], review papers[2-6], and numerous theses[7-21] from the Favorskii–Shostakovskii school have covered more or less fully only the vinyl ethers of alcohols containing no functional substituents. The present paper gives a brief analysis of the principal methods for the synthesis of functional vinyl ethers, and an attempt is made as far as possible to assess the field of application of each of them. Alkoxyethylenes containing substituents in the vinyl group, vinyl sulphides, and vinylamines are not discussed.

II. THE FAVORSKII–SHOSTAKOVSKII REACTION

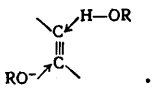
Direct vinylation, i.e. the addition of hydroxylated compounds to acetylene in the presence of basic catalysts (the Favorskii–Shostakovskii reaction[22,23]), is at present the most widely used method for preparing vinyl ethers. The simplicity of the synthesis, its completion in one stage, the availability of the starting material, and the almost quantitative yields of the required products make this a convenient method for industrial application. An obstacle to its wide introduction into industry is the need to use high pressures in individual cases: this, of course, increases the likelihood of explosion of the acetylene[24], but the danger is often greatly exaggerated[25].

The work of the Favorskii–Shostakovskii school[1,23,26-30] had already demonstrated by the end of the 1930s, independently of Reppe's work[31,32], the possibility of accomplishing industrial syntheses based on acetylene under pressure. In contrast to the patents of the IG. Farbenindustrie AG.[33-35], which envisaged dilution of the acetylene with an inert gas, a more intensive technology was developed in the USSR, under conditions of the inevitable dilution of the acetylene with the vapours of the starting material to be vinylated and the vinyl ethers formed, which are reliable stabilisers.

1. Mechanism of the Reaction

In spite of isolated attempts to make the problem a matter of controversy[36,37], the view has become accepted, strengthened by chemical kinetic data[38-40], that the process is a typical case of nucleophilic addition at the triple bond[41,42]. Vinylation has already been cited[43] as a classic example of nucleophilic addition to acetylenic systems. Nevertheless, examples exist[44,45] which do not fit well into such a scheme.

A detailed examination of the mechanism of vinylation has recently been made in a review[41] and in theses[18,21,46]. However, several aspects of the problem have been left untouched. Nucleophilic vinylation can be interpreted most acceptably as a concerted *trans*-addition:



This scheme[47] explains perfectly satisfactorily the main features of vinylation—(*a*) preferential formation of *cis*-adducts[38,41], (*b*) oriented addition to monosubstituted acetylenes, with formation of β-isomers when an acceptor substituent (phenyl[38,42,48], trifluoromethyl[49], diethoxymethyl[50]) is present at the triple bond, and formation of the α-isomer if acetylene containing a donor substituent is involved in the reaction[50], (*c*) the difficulty of reaction when donor substituents are present at the triple bond[51], and (*d*) increase in rate of reaction with increase in the nucleophilic character of the reagent[40,44,52]. In cyclic mechanisms *cis*-addition is assumed, although there has probably not yet been an example of the isolation of *trans*-adducts, which should be formed in this case.

Analysis of the literature in terms of simultaneous nucleophilic addition permits us to explain tentatively several known generalisations and discrepancies associated with vinylation which hitherto have not been entirely clear. Thus the presence of water sharply diminishes the rate of vinylation of aliphatic alcohols[1,4,26], whereas it definitely promotes the vinylation of phenols[40,44,52] and thiols[53,54]. In the absence of solvents or in non-polar media, phenols yield vinyl ethers under considerably more severe conditions than do aliphatic alcohols[37,46]. Yet in the vinylation of phenols in an alcoholic medium, under conditions close to those used for the vinylation of aliphatic alcohols, the corresponding aryl vinyl ethers are formed smoothly[55]. In all these cases a number of acid–base equilibria (alcohol, water, alkali, alkoxide) are superposed and actively interact. In the pair alcohol–water the latter component is a stronger acid than the alcohol, and suppresses dissociation thereof; at the same time the undissociated alcohol molecules act as a base towards the water, displacing the equilibrium towards formation of hydroxide ions. The net result is that the concentration of alkoxide ions and the rate of addition of alcohol to acetylene fall. The accompanying absorption of acetylene which is observed in several cases is probably due to "vinylation" of water[36,40]. Another secondary reaction involving water,

$$HC{\equiv}CH + H_2O + NaOH \rightarrow CH_3COONa + H_2:$$

is known[56]. According to a patent[57] almost pure hydrogen and sodium acetate in 96% yield can be obtained in this way.

Towards phenol water acts as a base and an ionising agent: it intensifies dissociation of the phenol, thereby increasing the concentration of phenoxide ions, which ultimately facilitates vinylation. Alcohols are also capable of filling the function of water as an ionising agent and a proton-acceptor in the vinylation of phenols[40,53-55]. In our view a similar explanation can be put forward for the favourable influence of water and alcohols in the vinylation of thiols[40,53-55,58] and also for the possibility of using t-butyl alcohol as the medium in the vinylation of alcohols[39]. The favourable influence of dioxan and *N*-methylpyrrolidone on vinylation[59] is probably due primarily to their increased ability to dissolve acetylene; however, being strong proton-acceptors, these solvents should further also strengthen the acid–base dissociation of the substrate.

The rate of vinylation falls appreciably on passing from a primary to a tertiary alcohol[10,60,61]. Since the nucleophilic character of alkoxide ions increases in the same sequence, this observation appears at first glance to contradict the mechanism of nucleophilic vinylation. This is seemingly not only a matter of steric hindrance to activation. According to the scheme of concerted addition, the rate of vinylation depends both on the nucleophilic character of the alkoxide ion and on the ability of the medium to donate protons. The latter is known to fall from a primary to a tertiary alcohol.

Although the above mechanism of simultaneous *trans*-addition provides an acceptable explanation for most of the features of nucleophilic vinylation, nevertheless it is probably an extremely crude approximation, and cannot claim to be universally applicable. In particular, it is difficult with its aid to provide any satisfactory explanation of the known dependence of the reaction velocity on the cationic portion of the catalyst[40,45] (though this applies to all other mechanisms of vinylation). It has been suggested[40] that nucleophilic attack at the triple bond is preceded by attack by the cation with formation of an "acetylene–cation" complex compound. In any case, it is now clear that all the variety of modifications and variants of the reaction of vinylation cannot be forced into the framework of any one scheme.

2. Field of Application

In principle the reaction does not extend merely to those functionally substituted alcohols and phenols which contain structural units sensitive to alkalis and to heat. Compounds which have not yet proved susceptible to direct vinylation include in particular unsaturated aliphatic alcohols (the higher unsaturated alcohols possibly constitute an exception[62]). The main reason preventing direct vinylation in unsaturated alcohols may be supposed to be their prototropic isomerisation into the corresponding carbonyl compounds. In a kinetic study[45] of the vinylation of allyl alcohol (together with other alcohols) in the presence of sodium hydroxide as catalyst, the reaction velocity was measured from the absorption of acetylene, but it is not clear whether allyl vinyl ether was isolated in the pure form. The vinylation of the but-2-enyl and allyl monoethers of ethylene glycol[63] is apparently not accompanied by isomerisation of the radical. Tertiary ethylenic alcohols, with which the final stage of isomerisation (conversion into the α-ethylenic alcohol, and then into a carbonyl compound) is excluded, can probably be vinylated under the conditions of the Favorskii–Shostakovskii reaction with preservation of the molecular skeleton. In general, of course, the position of the double bond need not necessarily be maintained here. In this connection patent information[64] on the preparation of the vinyl ether of *p*-menth-1-en-8-ol (together with the vinyl ethers of other mono- and poly-cyclic terpene alcohols) by vapour-phase vinylation over basic catalysts is not without interest. In the case of acetylenic alcohols isomerisation may be supplemented by intramolecular and intermolecular "self-vinylation".

3. Alcohols having Oxygen-containing Functions

(*a*) Alkoxyalkanols. Alcohols containing alkoxy-groups (monoethers of glycols) are smoothly vinylated under ordinary conditions with the formation of alkoxyalkyl vinyl ethers[4,63,65,66]. Monoalkyl ethers of hydrobenzoin have been successfully vinylated[67-69]. Furfuryl vinyl ether has been obtained[70] in 45% yield by the vinylation of furfuryl alcohol in aqueous medium; the reaction is more successful in the absence of solvents (yield of the ether 68.7%[71]). The presence of water proved necessary in the vinylation of guaiacol[72] and other alkoxyphenols[73].

(*b*) Glycols. In the vinylation of 1,2- and 1,3-glycols, cyclic acetals[74,75]—products of the isomerisation[76] of monovinyl ethers—are usually present in the reaction mixture. The vinylation of ethylene glycol is accompanied[23] by the formation of other unsaturated products, boiling at 150–195°C, of undetermined structure. However, this has not been confirmed in later investigations. With propyne[77] ethylene glycol gives exclusively 2,4-dimethyl-1,3-dioxolan under the conditions of vinylation.

A patent stated[78] that vinyl ethers of ethylene glycol could be obtained by passing a mixture of acetylene and the glycol vapour over heated metals (calcium, magnesium, barium, copper, aluminium), peroxides, or salts on carriers. The preparation was reported[33,34] of vinyl ethers of glycols (the monovinyl ether of ethylene glycol and the

divinyl ethers of ethylene, diethylene, and triethylene glycols) by the action of acetylene diluted with an inert gas on the diols in the presence of alkaline catalysts under pressure. Vinylation forms the basis of a process for the manufacture of the divinyl ether of butane-1,4-diol[4,79]. The synthesis of the divinyl ether of triethylene glycol has been described in a thesis[12]. A process which has been patented[80] for the production of monovinyl ethers of ethylene glycol, trimethylene glycol, and diethylene glycol is based on the rapid removal of the resulting ethers from the reaction zone by means of excess of acetylene or an inert gas. Shostakovskii et al.[81] accomplished the synthesis of the monovinyl ethers of ethylene, propylene, tetramethylene, diethylene, and triethylene glycols under pressure. The vinylation of butane-1,4-diol in tetrahydrofuran gives a 52% yield of the monovinyl ether[82]. Monovinyl ethers can be obtained[83] by vinylating glycols in the liquid phase at normal pressure and a temperature of 100°C with simultaneous removal of the reaction products. Some information has been published[45] on the kinetics of the vinylation of butanediol and diethylene glycol. The synthesis of vinyl ethers of diethylene glycol has been discussed also by Zimmerman et al.[84]

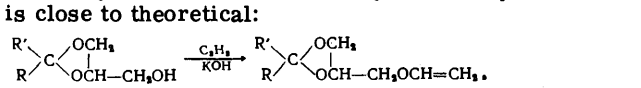
Qualitative assessment indicates that ease of vinylation increases in the sequence from ethylene glycol through diethylene glycol to triethylene glycol[85]. The exhaustive vinylation of triethylene glycol yields as secondary products vinyl ethers of ethylene and diethylene glycols and also 2-methyl-1,3-dioxolan. The vinylation of diethylene glycol is accompanied by the formation of vinyl ethers of ethylene glycol and 2-methyl-1,3-dioxolan. These facts indicate cleavage of the ether bonds during the reaction. Acetylene probably plays an active part in this secondary process. During the vinylation of diethylene glycol partial conversion of the monovinyl ether into an eight-membered cyclic acetal has been noted[86].

A simple apparatus has been developed[87] for the continuous preparation of vinyl ethers of glycols at atmospheric pressure. Continuous synthesis of acetaldehyde is accomplished by subsequent hydrolysis of the vinylation products. This scheme forms the basis of a new industrial method for manufacturing acetaldehyde via the vinyl ethers[88-91]. An interesting and successful attempt has been made to produce vinyl ethers (including those of glycols) by the direct use—instead of free acetylene—of calcium carbide in aqueous medium[92,93] under conditions of alkaline catalysis. A process for preparing the divinyl ethers of quinol, resorcinol, catechol, and trimethylquinol has been investigated[94]. The mono- and di-vinyl ethers of hydrobenzoin and isohydrobenzoin[69,95,96] and of anthraquinol[97] and the divinyl ether of bishydroxyphenylpropane[98] have been obtained.

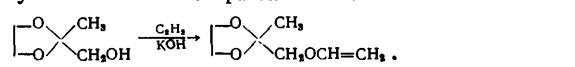
(*c*) Polyhydric alcohols. The early work on the vinylation of glycerol showed[23,75,99] that the yields of mono- and di-vinyl ethers could be controlled by varying the concentration of acetylene, and with excess of the latter exhaustive vinylation could be accomplished. The authors assumed that under these conditions the trivinyl ether of glycerol could be obtained in 90% yield. Subsequent refinement of these investigations by Shostakovskii et al.[20,21,100] has established, however, that a substance which is formed under these conditions in ~ 63% yield is actually 2-methyl-4-vinyloxymethyl-1,3-dioxolan, while the yield of the trivinyl ether of glycerol does not exceed 10%. American workers have reached a similar conclusion[59]. They synthesised the trivinyl ether of glycerol in up to 50% yield by a special method[59] ensuring a considerable excess concentration of acetylene in the reaction zone and brief contact between the reactants, *N*-methylpyrrolidone being used as solvent. The vinylation of glycerol has been accomplished in dioxan with the use of a three- to four-fold excess of acetylene in the presence of potassium butoxide[20,21,100]. Under these conditions 2-methyl-4-vinyloxymethyl-1,3-dioxolan and the trivinyl ether of glycerol were obtained in 43% and 25–28% yields respectively. The mono- and di-vinyl ethers of glycerol could not be isolated. Preparation of a monovinyl ether of glycerol has been reported[4,75], as also that of monoalkenyl ethers of glycerol[101,102].

The first communication on the vinylation of pentaerythritol and trishydroxymethylethane was made by Atavin[103]. In the latter case[104] 5-hydroxymethyl-2,5-dimethyl-1,3-dioxan, 2,5-dimethyl-5-vinyloxymethyl-1,3-dioxan, and 2,2-bisvinyloxymethylpropanol were isolated. Under the same conditions a diacetal and 2-methyl-5,5-bisvinyloxymethyl-1,3-dioxan were obtained from pentaerythritol[105]. A 22% yield of a divinyl ether of pentaerythritol has been synthesised in aqueous medium[106]; further vinylation of the product in the absence of water yielded a tetravinyl ether (60–70%) and 2-methyl-5,5-bisvinyloxymethyl-1,3-dioxan (30–40%). On vinylating pentaerythritol in alcohol, only a tetravinyl ether was isolated[107].

(*d*) Partial ethers of polyhydric alcohols. The vinylation of 1-alkoxypropane-2,3-diols[20,21,108] gives 4-alkoxymethyl-2-methyl-1,3-dioxolans and 1-alkoxy-2,3-divinyloxypropanes. 2,2-Dialkyl-4-hydroxymethyl-1,3-dioxolans are vinylated at a lower temperature (110–120°C) than are monohydric alcohols[109]. The yield of vinyl ethers is close to theoretical:



Several compounds of this type have been reported previously without detailed description[4-6]. Cyclic ketals of acetol are vinylated without complication[110]:



The preparation of mono-, di-, and tri-vinyl ethers of cellulose has been reported[111]. Subsequently only the corresponding acetals could be isolated[112] on vinylation of the same carbohydrate. Recently cellulose has been vinylated in aqueous dioxan[113]. Tetrahydrofuran was used as solvent for the vinylation of starch[114]. Vinylation of mannitol[115] gave only a low yield of its triacetal. A 10 to 15-fold excess of acetylene is necessary in order successfully to suppress isomerisation during the vinylation of polyhydric alcohols[116]. In this way a tetravinyl ether of α-methylglucoside and vinyl ethers of cellulose were obtained in yields of 65–80%. The vinylation of mono- and di-acetyl derivatives of α-glucose, α-galactose, mannitol, sorbitol, and dulcitol has been accomplished. In all cases it was reported that the completely vinylated ethers were isolated[117]. When acetylene reacts with poly(vinyl alcohol)[118] in aqueous alkali, not more than 6 mole % of the hydroxyls are etherified.

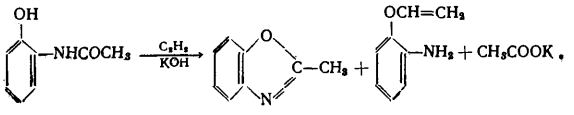
(*e*) Alcohols having other oxygen-containing functions. Very brief mention has been made[4,6] of the production of vinyl ethers of partial acetates of ethylene glycol and glycerol in the presence of salts of organic acids. The yields are not given, the boiling point serving as the only characteristic of the ethers. The reaction is accompanied by active redistribution of acyloxy-groups. Among hydroxy-compounds having other oxygen-containing functions, phenolic ketones have been successfully

vinylated[98]. The reaction conditions are analogous to the synthesis of the vinyl ethers of alkylated and arylated phenols[119,120]. Naphthyleneglycollic acid is converted[121] under conditions of vinylation into a mixture of mono- and di-vinyl ethers, the latter of which has been obtained also directly from acenaphthenequinone.

4. Nitrogen-containing Alcohols

(*a*) Amino-alcohols. Vinyl ethers of hydroxyethylamines have been obtained[31-35] in the presence of basic catalysts at 80–250°C. The conditions for the vinylation of aliphatic alcohols are too severe[122,123] for aminoalkanols. The best results are obtained by conducting the reaction in benzene, with an alkoxide of the corresponding alcohol as catalyst. Complete and partial vinyl ethers of bis- and tris-hydroxyethylamines have been synthesised[124]. An apparatus in which a gas–liquid emulsion is produced by means of a stirrer has been proposed[125] for the preparation of trisvinyloxyethylamine. In such apparatus vinylation can be conducted over a wide range of pressures (2–12 atm). Decrease in pressure and the presence of moisture impair the yields of vinyl ethers. Kinetic investigations (with bis-2-hydroxyethylamine in t-butyl alcohol and an initial acetylene pressure of 19.5 atm)[44] indicate that the order of the reaction with respect to the amino-alcohol varies from the first to zero as the concentration of the latter changes. Methods in the mathematical planning of experiments have been used in the kinetic study of the vinylation of trishydroxyethylamine[126]. The vinylation of phenylaminoethanol in the presence of caustic potash in butanol yields phenylaminoethyl vinyl ether[4]; under similar conditions but in the presence of cadmium acetate[127] *N*-phenyloxazolidine is formed.

(*b*) Aminophenols. Various aminophenols[128-133] and hydroxydiphenylamines[132,134] have been subjected to vinylation, the expected vinyl ethers being obtained in all cases. Vinylation is promoted by the presence of 15–20% of water based on the weight of the aminophenol[128]. The corresponding vinyl ethers have been synthesised by the vinylation of phenolic acetanilides[135], the reaction being effected in dioxan medium in the presence of 20–25% of caustic potash. The vinyl ether of *o*-hydroxyacetanilide was not isolated, owing to cyclisation and saponification of the original phenol:



(*c*) Nitrophenols. The possibility of the direct vinylation of *p*-nitrophenol was probably first shown in a kinetic study[40] of the vinylation of substituted phenols. The preparative vinylation of *o*-, *m*-, and *p*-nitrophenols is accomplished[136,137] in aqueous dioxan in the presence of cadmium acetate. Caustic potash and zinc acetate proved to be less effective catalysts (the yield of ethers did not exceed 2.5–3.5%). The *para*-isomers are most readily vinylated (at 145–150°C), the successful vinylation of *m*- and *o*-nitrophenols requiring temperatures of 175–185°C. Halogenated nitrophenols (2-chloro-4-nitrophenol, 2,6-dichloro- and 2,6-dibromo-nitrophenols) require temperatures of at least 180°C for vinylation, this being due[136] to steric hindrance by the *ortho*-substituents.

5. Mercapto- and Alkylthio-alkanols

Shostakovskii et al.[138] investigated the reaction between acetylene and 2-mercaptoethanol, and obtained a 70–75% yield of 2-vinylthioethanol, which clearly illustrates the greater reactivity of the thiol group than of hydroxyl towards vinylation:

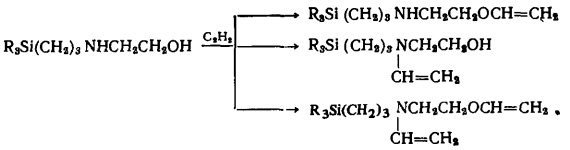
$$HOCH_2CH_2SH + C_2H_2 \xrightarrow[90-105^\circ]{20\%\ KOH} HOCH_2CH_2SCH{=}CH_2.$$

Further vinylation under more severe conditions (120 to 135°C) yields the diether.

The vinylation of 2-ethylthioethanol[139] gave a 40–60% yield of ethylthioethyl vinyl ether. The vinylation of thiodiglycol[140,141] involves complications, and only partly follows the usual scheme: there is a very vigorous competing process, yielding vinyl ethers of 2-mercaptoethanol. Experiments in the absence of acetylene, under otherwise similar conditions, did not yield such ethers. This proves that their formation was not a consequence of dehydration of the thiodiglycol. It is possible that acetylene plays an active part in cleaving the carbon–sulphur bond. It is not excluded that rupture of this bond during vinylation is common to 2-hydroxyalkyl sulphides, although work on the vinylation of 2-ethylthioethanol[139] and 2,2-dialkylthiopropanols, in which only the normal reaction products were isolated[142], would appear not to support this hypothesis. The vinylation of 1-thienylcarbinols in dioxan in the presence of potassium hydroxide yields the corresponding vinyl ethers[143].

6. Silicon-containing Alcohols

γ-Organosilicon alcohols can be vinylated[145] by the Favorskii–Shostakovskii method. The highest yields (65–68%) are obtained[146] at 150–160°C and acetylene pressures of 15–20 atm in the presence of potassium ethoxide. Under these conditions tertiary γ-silicon-containing alcohols are not vinylated[147]. Ethylenic and acetylenic tertiary γ-silicon-containing alcohols are cleaved at the SiC≡C bond during the reaction, with the formation of hexaalkyldisiloxanes. The vinylation of α- and β-silicon-containing alcohols in the presence of potassium hydroxide and alkoxides entails breakdown of the initial compounds[147]. Trialkylvinyloxysilanes can be obtained by vinylating trialkylsilanols[148] in the presence of potassium silanoxide in dioxan medium at 65–70°C. The vinylation of trialkylsilylpropylaminoethanols[149] yields three different products:



In view of the reported[5] unsuccessful attempts at the vinylation of primary and secondary aliphatic amines, the structures of the latter two products perhaps require refinement.

7. Halogenated Alcohols and Phenols

The literature probably contains no example of the direct vinylation of halogenated alcohols: the obstacle is their sensitivity (especially of 1,2- and 1,3-halogenohydrins) to the action of bases. An exception is 2,2,2-trifluoroethanol, which is 90% converted into the vinyl ether

on being vinylated (17% potassium hydroxide at 135–150°C for 10 h) under pressure in an autoclave[150].

Halogenated phenols undergo vinylation without appreciable complication[151,152]. The vinyl ethers of monochloro-(fluoro)-, 2,4-dichloro-, 2,4,6-trichloro-, pentachloro-, and pentafluoro-phenols have been obtained in good yields[153]. Replacement of caustic potash by zinc acetate permitted the synthesis also of the vinyl ethers of 2,4,6-tribromo- and chloronitro-phenols, these phenols being unstable in an alkaline medium. The vinyl ethers of *o*-chloro-, *p*-chloro-, 2,4-dichloro-, 2,4,6-trichloro-, and pentachlorophenols have been prepared[4] by vinylation with acetylene diluted with nitrogen in the presence of zinc and cadmium acetates. The ability of halogenated phenols to undergo vinylation is directly dependent on their acidity[151,152]: fluorophenol is most easily vinylated, and bromo- and chloro-phenols with greater difficulty. These results contradict kinetic data[39,154], and are probably explained by the differing stability of phenols under the conditions of vinylation.

III. ELIMINATION OF THE ELEMENTS OF A HALOGEN HALIDE FROM HALOGENATED ETHERS

In spite of the greater lability of halogen in 1-halogenoethyl ethers (substitution and detachment takes place by a unimolecular mechanism) and the relative accessibility[155,156] of these compounds, they are considerably more rarely used than are 2-halogenoethyl ethers for the synthesis of functional ethers, owing to their instability. The vinyl ethers of allyl and prop-2-ynyl alcohols have been obtained[157] in this way, as also those of mono- and di-methylethynylcarbinols. The effectiveness of the scheme

$$CH_3CH(OR)_2 \xrightarrow{BCl_3} CH_3CHClOR \xrightarrow{(CH_3)_3N} \left[\begin{array}{l} CH_3CHOR \\ \quad | \\ \quad +N(CH_3)_3 \end{array}\right] Cl^- \xrightarrow{100-120^\circ C} CH_3{=}CHOR + N(CH_3)_3 \cdot HCl$$

is due to the use of boron trichloride at the stage of formation of the α-chloro-ether. 2-Chloroethynyl vinyl ether is formed[158] when 1,2′-dichlorodiethyl ether is heated in diethylaniline at 80–85°C. 1-Bromo-2-vinyloxyethylene has been prepared[158] under similar conditions:

$$CH_3CHClCHBrCH_2Br \rightarrow CH_2{=}CHOCH{=}CHBr.$$

α-Silicon-containing vinyl ethers have been obtained[159] by dehydrochlorination of 1-halogenoethyl ethers of the corresponding alcohols:

$$R_3SiCH_2OCHClCH_3 \xrightarrow{-HCl} R_3SiCH_2OCH{=}CH_2.$$

Conditions for the dehydrohalogenation of 2-halogenoethyl ethers have been discussed in detail in a monograph[156]. The reaction goes with considerably greater difficulty than in the cases of 3-halogenoalkyl ethers and alkyl halides. The 2-halogenoethyl ether is usually distilled over excess of solid caustic potash or caustic soda. The peculiar resistance of β-halogeno-ethers to dehydrohalogenation deserves more than mere mention. The process is undoubtedly bimolecular, so that the main factor here is not the lability of the halogen, which has hitherto been stressed[156], but that of the α-hydrogen atom (with respect to the oxygen), which is the primary object of attack by the nucleophile. In view of the polarity of the $O{\leftarrow}C^{\delta+}$ bond, detachment of a proton from the OCH_2 group should apparently be facilitated, whereas actually it is strongly hindered. It may be supposed that there occurs in the $O{-}CH_2$ fragment a special interaction, consisting in partial overlapping between the orbitals of the C–H bonds and those of the lone pairs of electrons of the oxygen atom (*p*–σ conjugation):

$$\left[-O-CH_2 \leftrightarrow -O^+{=}C- \leftrightarrow -O^+{=}C-\right]$$

(H⁻ on the C–H bond; H on the C–H bond; H⁻ on the terminal CH₂)

2-Chloroethyl vinyl ether is obtained by the dehydrochlorination of bis-2-chloroethyl ether (Chlorex)[160–162], dioxan and small amounts of divinyl ether and acetaldehyde being formed as byproducts[163]. The production of 2-chloroethyl vinyl ether by the pyrolysis of 2-chloroethoxyethyl acetate has been reported[164]. The complete dehydrochlorination of Chlorex provides a convenient route for obtaining divinyl ether itself[165–167]. 2-Bromoethyl vinyl ether has been prepared from bis-2-boromethyl ether[168]. Examples are known of the preparation of an allyl vinyl ether via allyl 2-bromoethyl ether[169,170]. α-Substituted alkyl vinyl ethers have been prepared[171,172] by means of the scheme

$$CH_2{=}CHOR \xrightarrow{Br_2} CH_2BrCHBrOR \xrightarrow{R'MgX} CH_2BrCH(R')OR \xrightarrow[KOH]{-HBr} CH_2{=}C(R')OR\ (80\%).$$

Vinyl ethers of β-silicon-containing alcohols have been synthesised by dehydrochlorination[173]:

$$R_3SiH + CH_2{=}CHOCH_2CH_2Cl \rightarrow R_3SiCH_2CH_2OCH_2CH_2Cl \xrightarrow[350-400^\circ]{KOH} \rightarrow R_3SiCH_2CH_2OCH{=}CH_2\ (75\%).$$

The vinyl ether of glycidol has been prepared by dehydrochlorinating the corresponding 2-chloroethyl ether[174]:

$$ClCH_2CH_2OCH_2CH(O)CH_2 \xrightarrow[200^\circ]{NaOH} CH_2{=}CHOCH_2CH(O)CH_2.$$

Aryl 2-halogenoethyl ethers are considerably more easily dehydrohalogenated[72,153,175]. This can be explained in terms of the above considerations by the part played by the lone electron pairs of the oxygen atom in conjugation with the benzene ring, so that the effect of *p*–σ conjugation with the α-C–H bonds is weakened.

Certain fluorinated vinyl ethers can be synthesised as follows[176]:

$$CH_2(O)CH_2 + ROH \rightarrow HOCH_2CH_2OR \rightarrow ClCH_2CH_2OR \xrightarrow{-HCl} CH_2{=}CHOR,$$

where R = CH_2CHFCl, CH_2CF_3, $CH_2C_2F_5$, $CH_2C_3F_7$. Fluorinated alkenes have been used for the same purpose[177]:

$$HOCH_2CH_2OH + F_2C{=}CFCl \xrightarrow{Na} HOCH_2CH_2OCF_2CHFCl \xrightarrow[I_2]{P} \rightarrow ICH_2CH_2OCF_2CHFCl \xrightarrow[CaO]{NaOH} CH_2{=}CHOCF_2CHFCl.$$

The series of reactions

$$ROH + COF_2 \xrightarrow{100-120^\circ} ROCOF \xrightarrow{SF_4} ROCF_3 \xrightarrow[C_2H_5OH]{KOH} CH_2{=}CHOCF_3,$$

where R = $ClCH_2CH_2$, $BrCH_2CH_2$, has been proposed[178] for the preparation of trifluoromethyl vinyl ether. The same route has been used to synthesise[178] dichlorovinyl trifluoromethyl ether $CCl_2{:}CHOCF_3$ from trichloroethanol.

Divinyl ethers of *gem*-diols (divinyl acetals) have been obtained by dehydrochlorination of the corresponding 2-chloroethyl acetals[179–181]. Unsymmetrical alkyl 2-chloroethyl acetals have similarly been used[179,180] for the synthesis of α-alkoxylated vinyl ethers (alkyl vinyl acetals) $CH_3CH(OR)OCH{:}CH_2$. Formaldehyde alkyl 2-halogenoethyl acetals $ROCH_2OCH_2CH_2X$ (where X = Cl, Br) treated with potassium hydroxide at 350–400°C yield[182] alkoxymethyl vinyl ethers $CH_2{:}CHOCH_2OR$.

In the case of chloroacetaldehyde bis-2-chloroethyl acetal all three possible vinyl ethers can be isolated[183]. Elimination occurs with greatest difficulty in the aldehyde

part of the molecule, where, according to the ideas discussed above, the single β-hydrogen atom (relative to the halogen) under attack by bases is able to interact by means of its σ-bond with the *p*-electrons of the two oxygen atoms at once. As a consequence its proton mobility is considerably restricted.

Dehydrochlorination has been applied also to cyclic acetals of glycerol chlorohydrin[184]. Chloroacetaldehyde acetals of glycols, glycerol, glycerol chlorohydrin, diethylene glycol, pentaerythritol, mannitol, and sorbitol do not split off hydrogen chloride on treatment with caustic potash in butanol, but form the corresponding acetals of butoxyacetaldehyde[185]. Dehydrochlorination takes place only in the presence of potassium t-butoxide.

IV. VINYL EXCHANGE

Vinyl ethers[186-192] and esters[193-197] are able to exchange their vinyl groups with alcohols in the presence of mercury salts:

$$ROCH{=}CH_2 + R'OH \xrightarrow{Hg^{2+}} ROH + R'OCH{=}CH_2$$

where R = alkyl or acyl. The reaction makes it possible to obtain vinyl ethers containing functional groups which are unstable in the presence of bases. The catalyst is usually mercury acetate or sulphate, while the vinylating agent is an alkyl vinyl ether[186-191], phenyl vinyl ether[192], or vinyl acetate[193-195,197].

The mechanism of exchange is complicated and has not been finally elucidated. The concept of π-complexes explains activation of the vinyl ether, but not the actual act of vinyl migration. It appears paradoxical that a vinyl ether and an organic acid (or alcohol) can coexist in the presence of mercury salts, which are among the most active catalysts of electrophilic addition. It is probable that the hydroxy-component which is formed combines with excess of the vinylating agent to produce the corresponding acetal or acylal.

Vinyl exchange involving vinyl acetate has been explained[197] by dissociation to yield a mercury–acetylene complex and acetic acid:

$$CH_2{=}CHOCOCH_3 \overset{Hg^{2+}}{\rightleftharpoons} [C_2H_2 \cdot Hg^{2+}] + CH_3COOH.$$

According to Watanabe and Conlon[189], vinyl ethers first add the catalyst at the multiple bond:

$$Hg(OAc)_2 \rightleftarrows HgOAc^+ + AcO^-$$

$$HgOAc^+ + ROCH{=}CH_2 + R'OH \rightleftarrows \begin{matrix} RO \\ R'O \end{matrix}\!\!>\!CHCH_2HgOAc + H^+$$

$$\begin{matrix} RO \\ R'O \end{matrix}\!\!>\!CHCH_2HgOAc + ROCH{=}CH_2 + R'OH$$

$$\downarrow\uparrow$$

$$\left[\begin{matrix} RO \\ R'O \end{matrix}\!\!>\!CHCH_2-\right]_2 Hg + HOAc$$

$$\downarrow\uparrow$$

$$\begin{matrix} RO \\ R'O \end{matrix}\!\!>\!CHCH_2HgOAc + R'OCH{=}CH_2 + ROH$$

However, kinetic investigations using isotopes[198] indicate that vinyl exchange catalysed by mercury salts does not involve the intermediate formation of mercury–acetylene complexes or intermediate acetoxymercuration, and therefore a mechanism of direct substitution has been suggested[198].

Vinyl transetherification is widely used for the preparation of functional alkoxyethylenes. Vinyl ethers of several diols have been obtained[187,191,197]. The vinylation of the methyl ester of glycollic acid has been reported[197]. Various vinyl ethers have been used[189,190] for the vinylation of ethylcellulose, allyl, methylallyl, and chloroallyl alcohols, ethylene chlorohydrin, ethylene cyanohydrin, 2-nitropropanol, and 4-hydroxypentan-2-one. Boiling divinylcarbinol in excess of ethyl or isobutyl vinyl ether with mercury acetate and sodium acetate yields[199] the vinyl ether $(CH_2:CH)_2CHOCH:CH_2$. Phenyl vinyl ether has been successfully used[192] for vinylating 2-naphthol, *p*-phenylphenol, and quinol with mercury acetate as catalyst. American workers[200] have obtained the vinyl ethers of phenol, *p*-cresol, and 2,6-dichlorophenol in yields of 80–100%, using divinylmercury as vinylating agent. Polyfluorinated vinyl ethers have been synthesised[201] by the transetherification of vinyl acetate with fluorinated alcohols. The vinyl transetherification of the methyl and ethyl ethers of hydrobenzoin with butyl vinyl ether has been investigated[69,202]. When salicylic acid is treated with vinyl acetate in the presence of mercury acetate, only a cyclic acylal (2-methyl-4-oxobenzo-1,3-dioxan) can be isolated[203].

V. SYNTHESES OF VINYL ETHERS BASED ON THE REACTIONS OF FUNCTIONAL GROUPS IN SUBSTITUTED VINYL ETHERS

The chief obstacles in the way of accomplishing such reactions are the difficult accessibility of functional vinyl ethers capable of further modification involving the functional substituent and the great reactivity of the vinyloxy-group itself. Mild conditions are usually required, and *electrophilic* reagents are then usually unsuitable. Nevertheless, these methods possess great synthetic possibilities.

1. Monovinyl Ethers of Glycols

Until quite recently only a few isolated examples were known of the synthesis of functional ethers from monovinyl ethers of glycols[76,204-208]. After a technically practicable route had been found for synthesising 2-vinyloxyethanol at atmospheric pressure, in the course of the development and industrial exploitation of a mercury-free technology for producing acetaldehyde via vinyl ethers of glycols[21,91], the widespread use of this compound in organic synthesis actually became possible.

Researches carried out during recent years[209] have enabled certain general rules to be formulated for the selective modification of functional fragments of a vinyl ether, and have shown that hydroxylated vinyl ethers may become a new, readily available source of polyfunctional monomers.

New unsaturated diethers were obtained by treating the sodium derivatives of monovinyl ethers of glycols with prop-2-ynyl bromide[210,211]:

$$CH_2{=}CHORONa + BrCH_2C{\equiv}CH \rightarrow CH_2{=}CHOROCH_2C{\equiv}CH.$$

Vinyloxyalkoxyalkynols have been synthesised[212,213] by the reaction

$$CH_2{=}CHOROCH_2C{\equiv}CH + R'R''C{=}O \rightarrow CH_2{=}CHOROCH_2C{\equiv}CCR'R''OH.$$

This reaction has since been applied to other examples[214]. Dehydration of the products[213] yields vinyl ethers containing

an enyne bond system in the alkoxy-radical. Propynyloxyalkyl vinyl ethers react[215,216] with trimethylchlorosilane, both as its sodium and as its magnesium bromide derivative, to form trimethylsilylpropynyloxyalkyl vinyl ethers:

$$CH_2{=}CHOROCH_2C{\equiv}C\,(Na)\,MgBr + ClSi(CH_3)_3 \rightarrow CH_2{=}CHOROCH_2C{\equiv}CSi\,(CH_3)_3.$$

The corresponding reaction with triethyltin chloride yields triethylstannylpropynyloxyalkyl vinyl ethers[217]. Trialkylstannylalkynyl vinyl ethers are obtained by the reaction of alkynyl vinyl ethers containing a terminal acetylenic group with hexa-alkyldistannoxanes and trialkylstannyloxyalkanes[218].

The behaviour of propynyloxyalkyl vinyl ethers under the conditions of the Mannich condensation has been studied[219,220], and dialkylaminobutynyloxyalkyl vinyl ethers have been synthesised:

$$CH_2{=}CHOROCH_2C{\equiv}CH + CH_2O + HNR'_2 \rightarrow CH_2{=}CHOROCH_2C{\equiv}CCH_2NR'_2.$$

The same scheme has been since used[221] to synthesise the ether $CH_2:CHOCH_2CH_2C:CCH_2N(C_2H_5)_2$. Potassium t-butoxide in t-butyl alcohol converts propynyloxyalkyl vinyl ethers into the corresponding allenes[222] $CH_2:CHOROCH:C:CH_2$. Successive treatment of vinyloxyethyne with lithamide in liquid ammonia and with butyl bromide[158] converts it into 1-vinyloxyhexyne in 60% yield.

The cyanoethylation of monovinyl ethers of glycols is accompanied[223-225] by the formation of β-vinyloxyalkoxypropionitriles $CH_2:CHOROCH_2CH_2CN$. When these compounds are reduced with lithium tetrahydroaluminate[226], the expected aminoalkyl vinyl ethers are not formed, but the initial molecule undergoes almost quantitative cleavage at the carbon–oxygen bond in the cyanoethoxy-group:

$$CH_2{=}CHOROCH_2CH_2CN \xrightarrow{LiAlH_4} CH_2{=}CHOROH + CH_3CH_2CH_2NH_2.$$

A similar cleavage is observed when the cyanoethoxyalkyl vinyl ethers react with sodium in alcohol[226]. An attempt has been made[227] to prepare the corresponding ketones from these ethers by the Grignard synthesis, but the main reaction products were vinyloxyalkanols and polymeric materials:

$$CH_2{=}CHOROCH_2CH_2CN + R'MgX \rightarrow CH_2{=}CHOROMgX + \text{polymer}.$$

Secondary amines together with paraformaldehyde smoothly aminomethylate monovinyl ethers of glycols, provided that the water evolved is removed azeotropically[225,228,229]. When dialkylaminomethoxyalkyl vinyl ethers interact with alcohols and with thiols[230], the expected addition of the reagents at the vinyl group is not observed, but the carbon–oxygen bond in the aminomethoxy-group undergoes cleavage with formation of the monovinyl ether of the glycol and the corresponding amine.

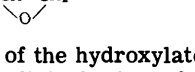
The monovinyl ethers of mono-, di-, and tri-ethylene glycols react with trimethylchlorosilane to give the corresponding silyl vinyl ethers of the glycols[225,231]. The sodium derivatives of hydroxylated vinyl ethers give with triethyltin chloride almost theoretical yields of triethylstannyloxyalkyl vinyl ethers[225,232,233]. Several vinyl ethers containing an ester group have been synthesised[234] by the interaction of acyl halides with vinyloxyalkanols in the presence of triethylamine. Chlorides of phosphorous acids form with monovinyl ethers of glycols[235,236] or their sulphur analogues[237] a new series of reactive trialkyl phosphites $(AlkO)_2POR$, where $R = CH_2:CHO[CH_2]_2$, $CH_2:CHO[CH_2]_2S[CH_2]_2O$, $CH_2:CHS[CH_2]_2$, etc.

Arbuzov rearrangement of 4,5-dimethyl-2-vinyloxyethoxy-1,3,2-dioxaphospholan in the presence of ethyl iodide yields 2-iodoethyl vinyl ether[238]:

A quantitative yield of dialkyl vinyloxyalkyl phosphorothionates has been obtained[239] by the reaction

$$CH_2{=}CHOCH_2CH_2OP(OC_2H_5)_2 \xrightarrow{S} CH_2{=}CHOCH_2CH_2O(S)P(OC_2H_5)_2.$$

A detailed investigation has been made[240] of the reaction of monovinyl ethers of glycols with epichlorohydrin, and a series of glycidyloxyalkyl vinyl ethers



have been synthesised. Excess of the hydroxylated component favours the formation of a divinyl ether of the structure

$$CH_2{=}CHOROCH_2CH(OH)CH_2OROCH{=}CH_2$$

by a secondary reaction involving the glycidyl fragment. Subsequent cleavage of the oxide ring by means of thiols, amines, metal derivatives of acetylenes, and organochlorosilanes provides a ready method for obtaining the corresponding substituted vinyl ethers[241,242].

2. Halogenated Vinyl Ethers

Halogenoalkyl vinyl ethers possess no less potentialities for the synthesis of functionally substituted alkoxyethylenes, although 2-chloroethyl vinyl ether still remains the only one which is available. Before the start of systematic investigations on vinyl ethers of halogenated alcohols[243,244] there were a few examples of the use of 2-chloroethyl vinyl ether for the preparation of vinyl ethers containing functional substituents (the reactions with alkoxides[245], benzonitrile[246], *N*-substituted 2-trifluoromethylphenothiazines[247], and trialkyl phosphites[248]). It would be of great interest for organic synthesis to obtain a Grignard reagent from halogenoalkyl vinyl ethers. However, the only known attempt in this direction[168], based on 2-bromoethyl vinyl ether, was unsuccessful, this ether being found to decompose into acetylene and ethylene on treatment with magnesium. Similar breakdown was observed[168] on interaction with metallic sodium.

Investigations of nucleophilic substitution of the chlorine atom in 2-chloroethyl vinyl ether[244] have confirmed that, in alcoholic solutions of alkoxides, the latter forms around 30% yields of 2-alkoxyethyl or 2-aryloxyethyl vinyl ethers. The course of the reaction is similar in liquid ammonia with but-3-ynol[249], obtained directly in the reaction medium from ethylene oxide and sodium acetylide. Alk-1-ynes, in the form of their sodium derivatives, are alkylated by 2-chloroethyl vinyl ether in liquid ammonia[250], but the rate of the reaction is fairly low. Replacement by an alkylthio- or arylthio-group takes place considerably more easily[244,251], and treatment with sodium sulphide yields the divinyl ether of thiodiglycol[244]. The reaction of 2-chloroethyl vinyl ether with secondary amines has been used[252] as a basis for a convenient method of synthesising 2-dialkyl(aryl)aminoethyl vinyl ethers of diverse structure. Treatment of 2-chloroethyl vinyl ether with sodium iodide in acetone resulted in replacement of the chlorine atom by iodine[244]. 2-Iodoethyl vinyl ether alkylates tertiary

amines with formation of the corresponding vinyloxyethyltrialkylammonium salts[244], and on treatment with potassium fluoride in diethylene glycol[253] is converted into 2-fluoroethyl vinyl ether. It has been proposed[254] to use vinyl ethers of halogenated phenols for the synthesis of aryl vinyl ethers containing alkyl and alkoxyl groups.

3. Nitrogen-containing Vinyl Ethers

Use of the divinyl ether of bishydroxyethylamine for the aminomethylation of acetylene[255], alcohols[255,256], and thiols[256] opens up a simple path to various classes of nitrogen compounds containing a vinyloxy-group—$R_2C{:}CH$, $RC{:}CR$, $RC{:}CCH_2OH$, $RSCH_2CH{:}CH_2$, etc., where R = $CH_2N(CH_2CH_2OCH{:}CH_2)_2$.

On treatment with vinyl acetate the vinyl ether of aminoethanol and the divinyl ether of bishydroxyethylamine form[257] the corresponding *N*-acetyl derivatives. With methyl chloroacetate the divinyl ether of bishydroxyethylamine gives methyl *NN*-bisvinyloxyethylaminoacetate $(CH_2{:}CHOCH_2CH_2)_2NCH_2COOCH_3$.[258] Methyl *β-NN*-bisvinyloxyethylaminopropionate[258] has been prepared from the divinyl ether of bishydroxyethylamine and methyl acrylate:

$$(CH_2{=}CHOCH_2CH_2)_2NH + CH_2{=}CHCOOCH_3 \xrightarrow{100^\circ} \rightarrow (CH_2{=}CHOCH_2CH_2)_2NCH_2CH_2COOCH_3 .$$

The addition of the vinyl ether of aminoethanol to methyl methacrylate has also been reported[259].

In the course of a study of the cycloaddition of dialkylketens to vinyl ethers[260] it was noted that initially the vinyl ether of aminoethanol undergoes vigorous acylation at the amino-group.

Vinyloxyalkylcyanamides[261,262] are formed by reaction between aminoalkyl vinyl ethers and a cyanogen halide:

$$CH_2{=}CHOCH_2CH_2N(R)H + NCHal \rightarrow CH_2{=}CHOCH_2CH_2N(R)CN,$$

where R represents methyl, allyl, or cyclohexyl. The resulting ethers react with dicyandiamide to form[262] *N*-methyl-*N'*-vinyloxyethylmelamines. Treatment of aminoalkyl vinyl ethers with potassium cyanate[263] in acidified water (pH > 6.8) yields vinyl ethers of hydroxyalkylated ureas. Analogous compounds have been synthesised by reaction between urea and aminoalkyl vinyl ethers. Treatment of isocyanatoalkyl vinyl ethers with aqueous ammonia and with aziridine[264,265] also yields the corresponding vinyl ethers containing a ureido-group:

$$CH_2{=}CHOCH(CH_3)CH(CH_3)N{=}C{=}O \xrightarrow[HN]{NH_3} \begin{cases} \rightarrow CH_2{=}CHOCH(CH_3)CH(CH_3)NHCONH_2 \\ \rightarrow CH_2{=}CHOCH(CH_3)CH(CH_3)NHCON \end{cases}$$

Acylation of aminophenyl vinyl ethers with acid chlorides has been used[266] to synthesise vinyloxyanilides of various acids, as well as bis-*p*-vinyloxyphenylurea and isopropyl *m*- and *p*-vinyloxyphenylcarbamates. Reaction between ammonium dialkyl phosphorodithioates and *p*-chloroacetamidophenyl vinyl ether yields[266] *OO'*-diethyl *S*-*p*-vinyloxyphenylcarbamoylmethyl phosphorothiolothionate $p\text{-}CH_2{:}CHOC_6H_4NHCOCH_2SPS(OC_2H_5)_2$.

The acylation of vinyl ethers of aminophenols by means of anhydrides of organic acids have also been described[135,267]. Interation of vinyl ethers of aminophenols with acrylaldehyde and with furfuraldehyde forms the basis of proposed methods for the preparation of vinyl ethers of alkenyl- and furyl-aldiminophenols[268,269].

Whereas dialkyl phosphorodithioates add readily at the double bond in aryl vinyl ethers containing no substituents of basic character in the ring[266,270], aminophenyl vinyl ethers form salts $[CH_2{:}CHOC_6H_4NH_3]^+[(RO)_2PSS]^-$ in the analogous reaction[271]. Reduction of vinyl ethers of nitrophenols in alkaline medium yields divinyl ethers of azo- and azoxy-phenols[272,273].

4. Divinyl Ethers

The addition of hydrogen chloride to divinyl ether itself takes place in stages, and ultimately 1-chloroethyl vinyl ether can be isolated in yields up to 60%.[158,165] When divinyl ether interacts with carbon tetrachloride[274] it is difficult to retard the reaction in any way substantially at the first stage, the yield of tetrachloropropyl vinyl ether being only 17%. Divinyl ether undergoes the Diels–Alder reaction with hexachlorocyclopentadiene[275,276] and with anthracene[277]. Two adducts are formed, the yields of which depend on the proportions of the components and the temperature of the reaction. Some divinyl ethers of glycols have been subjected to hydroxylation[278,279], but monoadducts have not been isolated.

Hemiacetals (1-hydroxyalkyl vinyl ethers) $RCH(OH)OCH{:}CH_2$ have been obtained[280] by interaction between divinylpropanals and mercuric oxide in the presence of mercury acetate in aqueous–alcoholic medium.

Promising routes for the synthesis of functionally substituted vinyl ethers from divinyl ethers will probably be opened up by the investigation of reactions of homolytic addition occurring preferentially at one of the vinyloxy-groups.

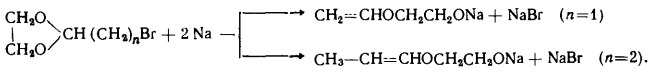
VI. CATALYTIC ELIMINATION IN A SERIES OF FUNCTIONAL ACETALS

The preparation of vinyl ethers containing functional substituents by eliminating one alcohol molecule from an appropriate acetal has not yet become widely used. The initial functional acetals are in general difficultly accessible compounds, being in several cases most easily obtained actually from vinyl ethers. Another reason lies in the conditions of the reaction[281–285], which are often either severe or altogether inapplicable with certain functional groups. The method is used mainly for the preparation of 2-substituted vinyl ethers[283,286–288] of the type $AlkCH{:}CHOAlk$ which cannot be obtained by direct vinylation. Nevertheless, the literature contains several examples of the use of this method for obtaining vinyl ethers of functional alcohols (allyl vinyl ether[289,290], ethyl vinyl ether of ethylene glycol[282], a polyfluorinated vinyl ether $CH_2{:}CHOCH_2CF_3$,[291,292] alkynyl vinyl ethers[293,294]). When unsymmetrical alkynyl ethyl acetals undergo cleavage[214], the relative proportions of ethyl vinyl and alkynyl vinyl ethers depend on the structure of the radical, the yield of acetylenic ether increasing in the sequence $CH_2C{:}CH$ (5%) < $CH_2CH_2C{:}CH$ < $CH(CH_3)CH_2C{:}CH$ (70%). From this we conclude that the acid-catalysed pyrolysis of unsymmetrical acetals takes place predominantly with elimination of the most electronegative radical and formation of the more stable carbonium ion $[CH_3CHOR]^+$.

VII. OTHER METHODS

1. Interaction of Acetals of α-Halogenoaldehydes with Metals

This method[295] is seldom used in practice, and then mainly for the preparation merely of vinyl ethers of monohydric alcohols[286,296,297]. Among functional vinyl ethers it is probable that only hydroxylated αβ-unsaturated ethers are obtained in this way[76,298,299]:



Feugeas and Normant[300] reported that the action of metallic magnesium in ether on the cyclic acetal of α-chloroacetone (2-chloromethyl-2-methyl-1,3-dioxolan) gave not an organomagnesium compound but the 1-methylvinyl monoether of ethylene glycol. The same reaction with cyclic acetals of β-halogeno-ketones yields not a vinyl ether but an ether of cyclopropanol:

Cyclic acetals of αγδξ-halogeno-ketones react similarly with metallic magnesium, forming 2-hydroxyethyl ethers of the corresponding cyclic alcohols. Apparently Hill and Pidgeon[298] were dealing not with 2-methyl- and 2-ethylvinyl ethers of ethylene glycol but with the corresponding cyclopropanol derivatives ,  .

2. Reaction of Alkoxides of Functional Alcohols with Vinyl Halides

The possibility of extending the Butlerov reaction[301] to functional alcohols has been demonstrated by the synthesis of vinyl ethers of ethylene glycol by heating (to 80–90°C) vinyl chloride with sodium glycolates under pressure[302]. It is not excluded that the process may be only formally a case of nucleophilic substitution, the reaction actually involving an intermediate stage in which free acetylene is formed[6].

Synthesis of Ion-exchange Membranes

O.D.Savenko, F.T.Shostak, and B.N.Laskorin

Extensive research has been conducted during recent years on the synthesis, properties, and applications of ion-exchange membranes. On the basis of the periodical and patent literature the paper gives a systematic account of membranes and methods for their production, the various ways of synthesising them, and brief information on their application and the laws of membrane processes. Classification is based on various criteria, primarily the homogeneity, the nature of the skeleton and the character of functional groups, electrochemical properties, etc.
Numerous methods of synthesising and producing polymerisation and polycondensation membranes, activated films, and heterogeneous membranes are described and critically examined. The main reactions are given. From an analysis of the literature, patents, and other sources the prospects are given for possible future developments in the synthesis of ion-exchange membranes. A list of 367 references is included.

I. INTRODUCTION

Ion-exchange polymers are used in many fields of science and technology. Depending on the character of the process, the exchangers are employed in the form of particles varying in geometrical shape and size. They are most widely used as granules and sheets (membranes). Methods for the synthesis of ion-exchange resins of the former type are well known and have been widely described [1,2]. Methods which have hitherto been proposed for the synthesis of ion-exchange membranes have been reported almost exclusively in the patent literature and in a few review papers [3-14], which contain a brief list of processes for obtaining membranes, published over a definite period of time.

The first specimens of membranes (heterogeneous), based on industrial exchangers, were obtained in 1950 by Wyllie and Patnode [15]. The synthesis of homogeneous membranes was first described by Manecke [16] and by Sollner and Neihof [17] in 1951, and later Gregor and his co-workers [18,19] synthesised interpolymer membranes.

With expansion in the possible fields of application of membrane processes, the demands made on membranes have risen, and consequently new types of membranes and methods for synthesising them have appeared.

The applications of ion-exchange membranes show great variety. Particularly important uses are the desalination of salt-water and of brackish waters, the preparation of high-purity metals, and recently the production of fuel cells. Membrane methods of desalination—electrodialysis [20-31,33,34], ion-osmosis [32], and hyperfiltration [35-37]—have aroused great interest. Promising uses of ion-exchange membranes are the preparation of pure metals, the isolation of certain metals from their mixtures with others, the separation of elements of closely similar properties, etc. [26,38-45].

Fuel cells provide a new field for the application of ion-exchange membranes [46-52], whose use has such advantages as decreasing the weight of the fuel cells, the absence of a liquid electrolyte, and the possibility of obtaining pure water when hydrogen and oxygen are employed. The prospects for the use of membrane processes are very promising.

II. CLASSIFICATION OF MEMBRANES

The literature on ion exchange contains no papers specially devoted to the classification of membranes. This question is sometimes touched on in review papers and monographs. Laskorin et al. [45], Morgan [53], Lyubman and Shostak [14], and Hasenberg [54] discuss ion-exchange membranes mainly from the point of view of structure. There is as yet no rigorous scientific classification of membranes and methods of synthesis, based on a single common criterion. It is difficult to make such a classification.

An attempt is made in the present paper to give a practical classification, based on various criteria, of the membranes which have been described in the periodical and the patent literature. A distinction must be made between films and ion-exchange membranes: films consist of inert, uncharged polymers, whereas ion-exchange membranes are insoluble polyelectrolytes, containing positively or negatively charged groups, in the form of sheets, plates, discs, rods, etc. The term "diaphragms" is applied in most cases to inorganic membranes [55-57].

Ion-exchange membranes are of either natural or synthetic origin. Each type is divided according to its chemical character into organic and inorganic [55-65]. Examples of organic natural membranes are proteins, the skin of frogs, and ox bladder; while inorganic natural membranes include insoluble minerals containing calcium, several zeolites, and clays.

Depending on their type of selectivity, membranes are either (1) permeable to ions having charges of one sign and impermeable to oppositely charged ions and water, or (2) permeable to water but impermeable to ions. The former type are used in electrodialysis, mainly for demineralising water [66-77] and separating metals [38-40,78-83]; while the latter are still in the research stage, and may find application predominantly in hyperfiltration processes for the demineralisation of water [35,84-121].

Membranes are divided into ionogenic, complexing, and redox membranes according to the character of the fixed groups. Ion-exchange membranes contain acidic or basic functional groups. In complex-forming membranes the functional groups are able to form complexes with various

elements[122-126]. Such membranes have been obtained, for example, from a copolymer of di-isobutyl vinylphosphonate and acrylic acid[122], the resin Dowex A-1 and poly(vinyl chloride)[124], etc. These membranes have not yet found sufficiently wide application. Redox membranes contain oxidation–reduction groups instead of ionogenic groups.

According to the acid–base function of the ionogenic groups we can distinguish cation-exchange, anion-exchange, and amphoteric membranes. Cation-exchange membranes containing the strongly dissociated sulpho-group are said to be strongly acidic[127-169], while groups of moderate or low degree of dissociation (phosphoric, carboxylic) are said to be weakly acidic[170-173]. On this criterion anion-exchange membranes are in turn divided into strongly basic, containing the strongly dissociated pyridinium, quaternary ammonium, or rarely phosphonium or sulphonium groups[174-190], and weakly basic, having tertiary, secondary, or primary nitrogen atoms[191-199]. Amphoteric membranes contain both negatively charged and positively charged ionogenic groups[200-203]. These membranes play an important part in the vital activity of living cells. They are mostly membranes of animal (mainly proteins) or vegetable (mainly lignin) origin. Depending on the pH of the surrounding medium, protein membranes function as inert at a hydrogen-ion concentration corresponding to the isoelectric point, as anion exchangers at lower pH values, and as cation-exchange membranes at higher pH. It has been proposed to synthesise amphoteric membranes, containing quaternary ammonium and carboxyl groups, by the copolymerisation of a homogeneous solution of a 5-ethyl-1-methyl-2-vinylpyridinium salt, methacrylic acid, styrene, and divinylbenzene in the presence of a plasticiser[201]. In another case a copolymer of methacrylic acid and 2-diethylaminoethyl methacrylate is used as the active component[200]. The main theoretical principles of membrane processes, worked out by Meyer and Sievers[204] and by others (see below) extend also to membranes of this type.

Depending on their structure, membranes are subdivided into heterogeneous, homogeneous, interpolymer, isoporous (synthesised by the Reviewers), bipolar, mosaic, and coated with an inert polymer film.

Heterogeneous membranes are two-phase systems, the ion-exchange resin being distributed in an inert binder[159-164,205-223]. Since a continuous phase of the ion-exchange component is not present in this case, transport of ions takes place as a consequence of contact between the resin particles or through solution present between them, the process often being governed by both factors.

Homogeneous membranes consist solely of the ion-exchange component, forming one continuous phase[127-154,224-298]. In most cases they are transparent and uniform for visible wavelengths ($\sim$ 4000 Å). Homogeneous membranes are now finding preferential dissemination in connection with their successful use in electrodialysis. According to their mode of production these membranes can be divided into condensation[133-139] and polymerisation[228-238] membranes, together with those based on inert polymer films[240-298]. This last group are divided in turn into sheet[141,142], graft[240-274], and film[275-298] membranes.

Interpolymer membranes, obtained by the molecular blending of two polymers, are similar in properties and structure to homogeneous membranes[74,76,299-338]. In membranes of this type molecular chains of the two components are closely interlinked, and the polyelectrolyte forms one phase, although chemical bonds are not usually present between the two polymers. This has a good effect on the properties of the membranes, in particular their mechanical stability, since on swelling in water no great stresses are produced in the membrane, owing to the mobility of one polymer molecule relative to another. Two types of interpolymer membranes—dynel[299-305] and those based on inert polymer films[306-315,330-336]—can be distinguished.

Membranes exist in which one surface is a cation exchanger, while the other is an anion exchanger. These are bipolar membranes[339-343]. Their most important feature is their selectivity towards hydrogen. A Japanese patent[343] proposes the synthesis of a bipolar membrane from a polyethylene film, styrene, and 4-vinylpyridine by the use of γ-radiation. A bipolar membrane can be obtained by sticking together sheets of cation-exchange and anion-exchange membranes prepared from the appropriate resins and a solution of poly(vinyl chloride) in cyclohexanol by a method of pouring[342]. The use of bipolar membranes has not become widespread.

Little is known about mosaic membranes[292,344]. They consist of sharply divided regions, one of which is permeable to cations, while the other is permeable to anions. A synthesis of mosaic membranes has been described[292]: polyethylene film is treated with sulphuryl chloride or a mixture of sulphur dioxide and chlorine, after which individual portions are treated with tetraethylenepenta-amine.

According to the state of aggregation membranes are divided into ordinary and liquid[345,346], and according to their physical structure into porous[347,348] and those having limited swelling (gel membranes). A further distinction is made between reinforced and unreinforced membranes. The reinforcement—unilateral, bilateral, or between the sheets—confers great mechanical strength on the membranes, but at the same time lowers their exchange capacity and their electrochemical parameters, while considerably increasing the cost[349].

Reference is made in the literature to the possibility of using as reinforcing material glass fibres[79,129,138], Saran[136,137,192], Teviron[299], and Vinyon[136] fabrics, nylon[163], capron[186], poly(vinyl chloride) and poly(vinylidene chloride) fibres[175], polyacrylonitrile[163,181,206], linear polyesters and polyamides[163,206], paper[208], etc. Glass cloth, poly(vinyl chloride), and other rigid materials are less suitable as reinforcements owing to their hydrophobic character and differences in the variation in their linear dimensions compared with the membrane material on contact with polar solvents and water. Use of an unsuitable reinforcing cloth encourages the appearance of microcracks and other chemical defects as a result of differences in the coefficients of expansion and also internal stresses. Investigations on the effects of reinforcements on the electrochemical properties of heterogeneous membranes of Ankalit A-7, synthesised from the anion-exchange resin AT-1 and low-density polyethylene, have established[349] that bilateral reinforcement greatly increases the mechanical strength and permits the amount of the ion-exchange component to be increased at the expense of the binder; the electrical conductivity of the membrane is almost doubled. Capron, Saran, and Vinyon provide the most suitable reinforcement for this type of membranes. The improved adhesion of the resin to such fibres is explained by the presence of identical groups (e.g. amino) in the two structures.

Membranes can be distinguished from one another also by the location of the functional groups: an ionogenic group may be situated in the main chain[66,67,128,130] or in a side-chain[193] of the polymer.

Finally, the ion-exchange membranes can be subdivided according to the nature of the starting material, which may be a monomer[69,72], a monomer containing an

ionogenic group[131,145], a polymer containing an ionogenic group[159-164,205-223] or none[229,230], a copolymer[130,228], or various polymer films[287-298].

Neither in the Soviet nor in the foreign literature does there exist a unified chemical terminology for membranes, and arbitrary names, given by individual authors or firms, have become widely used. In the USA, for example, Amberplex, Nepton, Permutit, Nalfilm, Amfion, Jonac, etc. brands of membranes are marketed; in England, Permaplex, Zerolit, etc.; in Japan, Selemion, Scrion, Neozeplan, Neozepta, etc.; and in the USSR, MK-40, MA-40, MA-41, MK-100, MA-100 Ankalit, etc.

III. PROPERTIES OF ION-EXCHANGE MEMBRANES

An ideal ion-selectively permeable membrane allows ions of only one sign to pass through on application of an electric potential gradient, independently of the concentration of the external solution. Ion-selective permeability should be combined with high electrical conductivity, mechanical strength, elasticity, and thermal and chemical stability. Some of these properties are completely incompatible, and therefore ideal membranes cannot be obtained. The electrochemical properties of membranes are independent of their geometrical shape: membrane potentials, among the most important of properties, are identical for discs, rods, and strips provided that these are of the same composition[350].

The founders of the theory of selectively permeable membranes and their electrochemical properties were Teorell[351] and Meyer and Sievers[204]. According to this theory the selective permeability of ion-exchange membranes can be explained by the presence of mobile charged ions and counter ions in the membrane phase.

A considerable contribution to the study of the electrochemical properties of ion-exchange membranes has been made by Soviet scientists. The theoretical foundations of the process of electrodialysis were established by I.I. Zhukov[352], and his pupils Laskorin, Smirnova[353,354], Nikol'skii, Materova, Stefanova[355], Belinskaya[218], and others have made detailed investigations of the properties of various ion-exchange membranes. Some of the results of these investigations have been used in the book by Laskorin et al.[45].

IV. METHODS OF SYNTHESISING ION-EXCHANGE MEMBRANES

1. HETEROGENEOUS MEMBRANES

All the methods which have been proposed for producing heterogeneous membranes are based on combining a finely divided ion-exchange resin with an inert binder and then forming the mass into a film. These methods are distinguished by the technology of preparation, the state of aggregation of the binder, or its chemical nature. The properties of the membranes depend in considerable measure on the quantity and the degree of subdivision of the initial exchanger. The content of active component in the membrane usually varies over the range 60–80%. Increase in its content is accompanied by a considerable decrease in mechanical strength as well as the increases in electrical conductivity and in exchange capacity of the membrane. The proportions of ion-exchange resin and of binder must therefore by selected so that the membrane does not deform or disintegrate during use.

A fraction of particle size not exceeding 100 μm is usually taken. Thermoplastic substances—polyethylene, polystyrene, poly(vinyl chloride), phenolic resins, polymethacrylic ester, synthetic and natural rubber, etc.—are especially widely used as binders. Inert materials are employed in the form of granules, powder, film, viscous mass, or solution.

A heterogeneous membrane can be obtained from practically any ion-exchange resin. It has been proposed[214,356] to compress the finely divided exchanger into sheets, which are then impregnated with a monomeric liquid, the latter being polymerised on further treatment.

In some cases the ion-exchange resin is introduced into the semi-liquid binder. Such a state is achieved either by adding a plasticiser or by keeping at an elevated temperature. After careful stirring the viscous mass is passed between rollers or pressed into sheets. If a plasticiser has been used, it is usually removed[75,187,215]. Membranes of this type possess improved mechanical strength. However, the use of high temperatures in the process of synthesis often impairs the properties of the exchangers, and it is therefore best to mix the resin and the binder at lower temperatures. A rubber latex can conveniently be used as the inert component[210,213].

A very interesting and effective way of modifying and improving heterogeneous membranes has been suggested by Laskorin et al.[222,357], who use a method of cross-linking with surface-active substances. Introduction of the latter enables a stable bond to be produced between the poorly compatible hydrophilic ion-exchange resin and the hydrophobic polymeric binder, with consequent decrease in the electrical resistance and increase in mechanical strength. The absence of reinforcement in cross-linked heterogeneous membranes considerably lowers their cost, and hence the cost of the demineralised water.

The following bands of heterogeneous ion-exchange membranes—Amberplex C-1 and A-1 (USA), Permaplex C-10, C-20, A-10, and A-20, Zerolit C-20 and A-20 (England), MK-40, MA-40 (USSR), etc.—are widely known at the present time.

Heterogeneous membranes possess several important defects—low electrical conductivity, high permeability to water, low resistance to the diffusion of electrolyte, and the possible formation of deposits inside the membrane—their high mechanical strength being due to reinforcement.

2. HOMOGENEOUS MEMBRANES

Because of the unsatisfactory electrochemical properties of heterogeneous membranes, extensive research has been undertaken during recent years on the synthesis of homogeneous membranes. The foundations of their synthesis are the reactions of polycondensation, polymerisation, and the chemical activation of inert films.

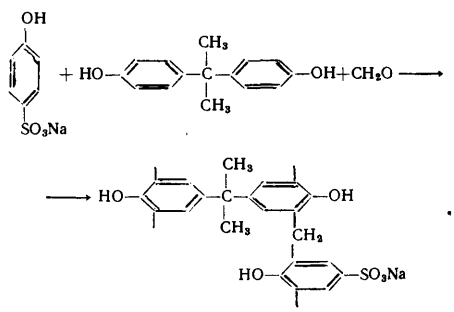
(*a*) Polycondensation Membranes

The starting materials most often used for this type of membranes are monohydric or polyhydric phenols, aromatic and aliphatic amines, urea and its derivatives, certain hydrocarbons, and other products. Choice of monomer is guided primarily by its chemical structure: the more reactive groups the initial compound contains the higher usually are the chemical stability of the final product and the three-dimensional interlocking of the individual chain units[358].

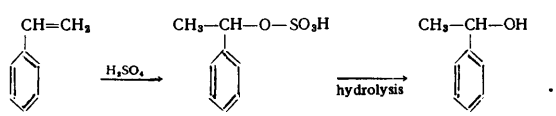
Ways of synthesising polycondensation membranes differ according to the medium in which the reaction is conducted, the nature of the initial monomers, and the process conditions. The first membranes were obtained from acidic aqueous mixtures containing hydroxybenzenesulphonic acid, melamine, or other similar monomer, formaldehyde, and a catalyst. It has been proposed to conduct polycondensation in an organic medium, e.g. methanol [138]. Morgan [53] refers to the production of polycondensation membranes by pouring the solutions on to the surface of mercury in a closed vessel. The more uniform and improved structure of the product is explained by the high thermal conductivity of mercury preventing the occurrence of local overheating.

Methods for the synthesis of polycondensation membranes have been most widely developed on the basis of hydroxybenzenesulphonic acid and formaldehyde [128,147]. The reaction can be conducted either in acid or in alkaline medium. The hydroxybenzenesulphonic acid can be replaced by the viscous product of the initial condensation of phenol with formaldehyde in the presence of acid or alkaline catalysts, followed by sulphonation of the resulting polymer [129]. In neither case do the membranes obtained possess adequate mechanical strength.

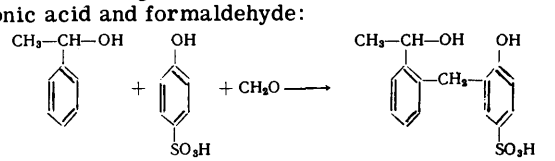
Improved membranes are obtained by condensing sodium hydroxybenzenesulphonate with phenol and formaldehyde [133,154]. Replacement of phenol by 2,2-diphenylpropane-*pp'*-diol yields specimens of enhanced stability, e.g. in solutions containing oxidising agents at 40°C [227]. The increased stability of the polymer is probably explained by the chemical nature of tne diol:



An interesting method has been suggested by Japanese chemists [143]. They took a mixture of phenol, styrene, and 98% sulphuric acid, preheated at 100–110°C, for cocondensation with formaldehyde and paraformaldehyde. Under these conditions sulphuric acid adds to the styrene at the vinyl bond, and the resulting partial sulphuric ester is hydrolysed:



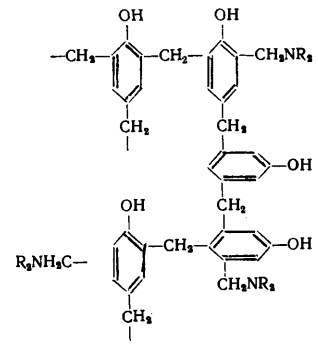
The product undergoes cocondensation with hydroxybenzenesulphonic acid and formaldehyde:



The use of styrene in the synthesis of polycondensation membranes apparently enables stronger specimens to be obtained, possessing diminished electrical resistance (in the present case 4 ohms cm^{-2}).

It has been proposed [153] to synthesise anion-exchange membranes by the polycondensation of tetraethylenepentaamine, ammonium sulphate, phenol, and formaldehyde in the presence of sulphuric and acetic acids. Replacement of the penta-amine by *o*-dimethylaminomethylphenol confers greater chemical resistance on the membrane, e.g. to the action of oxidants [193].

Japanese authors [198] suggest an original process for the industrial manufacture of anion-exchange membranes having a long service life. They use a resin in which the nitrogen atom constituting the central atom of the exchange base is not involved in the network structure of the resin:



For this purpose a compound of phenolic type containing a tertiary amino-group (e.g. $HOC_6H_4CH_2NR_2$) or a quaternary ammonium group is condensed with phenol and formaldehyde. The viscous resol resin is then formed into a film, and the gel ripened by heating. A membrane of this type is probably less suitable for use in electrodialysis, owing to its polyfunctionality.

Because of poor stability and low selectivity, especially in relatively concentrated solutions of electrolytes, polycondensation membranes have limited application.

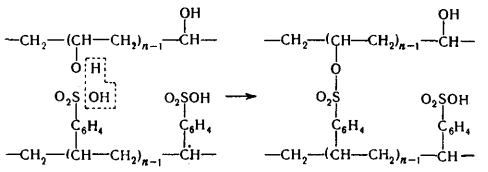
(*b*) Polymerisation Membranes

Membranes of this type are synthesised by the polymerisation or copolymerisation of unsaturated compounds, one of which should contain an ionogenic group or a group capable of transformation into such. Compounds containing vinyl groups are used, among them the aromatic compounds styrene, styrenesulphonic acid, and vinylpyridine, and the aliphatic vinylsulphonic, acrylic, and methacrylic acids, as well as salts, esters, and other derivatives of these compounds. The bridge-forming agents used are polyfunctional vinyl compounds—di- and tri-vinylbenzene, ethylene dimethacrylate, allyl acrylate, bismethylallyl ether, and other dienes and polyenes.

The above monomers are known to exhibit differing tendencies to polymerise, this constituting the main factor determining choice of the initial monomer in the synthesis. For example, cation-exchange membranes could have been more conveniently synthesised from styrenesulphonic acid, since sulphonation goes more easily with monomeric than with polymeric styrene; furthermore, polystyrene films on treatment with sulphonating agents undergo partial loss of their mechanical strength, and are deformed. But since styrenesulphonic acid is difficult to polymerise, in most cases polymerisation or copolymerisation of monomeric styrene with subsequent sulphonation is used.

Membranes possessing satisfactory electrical conductivity together with high mechanical strength are obtained from styrene and vinylsulphonic acid [145,152,182].

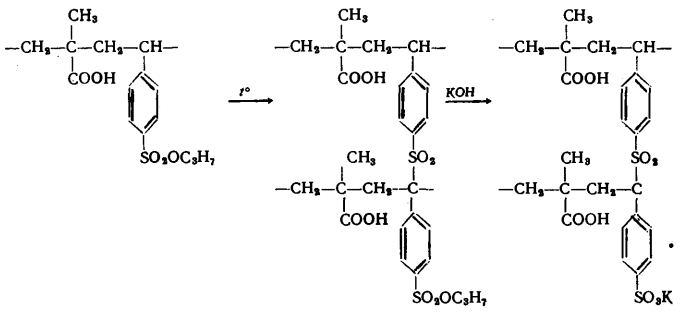
Synthesis is sometimes accomplished by using together styrene and styrenesulphonic acid [72] or styrenesulphonic acid with poly(vinyl alcohol) [134,232]. It has been suggested [314] that the combination of poly(vinyl alcohol) with poly(styrenesulphonic acid) occurs in conformity with the equation



To avoid the aqueous solubility of such a membrane and to ensure good electrochemical properties, the synthesis has been suggested of poly(styrenesulphonic acid) having a maximum content of sulpho-groups. An increase in the content of the acid in the copolymer from 20% to 60% is accompanied by an increase in the exchange capacity of the membrane from 1.1 to 2.8 mg-equiv. g^{-1}, while the electrical resistivity is halved. Even in the best specimens, however, the latter exceeds 500 ohm cm.

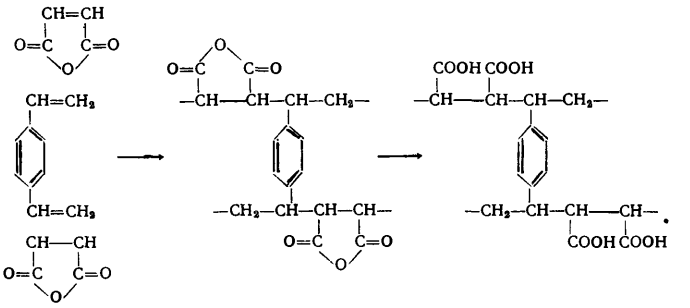
More promising is the use of styrenesulphonic esters mixed with other monomers. These esters polymerise more easily than does the acid itself, and are better combined with vinyl monomers (styrene, divinylbenzene, vinyl acetate, etc.).

Trostyanskaya et al. [131] synthesised cation-exchange membranes by the copolymerisation on various fabrics of toluene-*p*-sulphonic ester and divinylbenzene with subsequent sulphonation. The membranes possessed a high electrical resistance [131]. Sigodina et al. [66] obtained a cation-exchange membrane of low electrical resistance, but of poor mechanical strength, on the basis of copolymers of propyl styrenesulphonate and vinyl acetate. These workers [66] suggested the preparation of polyfunctional membranes based on copolymers of propyl styrenesulphonate and methacrylic acid, the membrane being vulcanised at 100°C for 5 h and then saponified. The process can be represented by the scheme



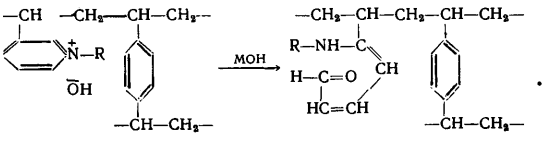
These membranes have greater mechanical strength than have monofunctional membranes. However, such membranes can hardly be used in electrodialytic desalination apparatus.

A carboxylated membrane of capacity 2.1 mg-equiv. g^{-1} has been synthesised by the copolymerisation of maleic anhydride with divinylbenzene in the presence of azoisobutyronitrile [231]. The reaction is conducted on the reinforcing fabric between two glass plates, the anhydride group then being hydrolysed [231]:



A Dutch patent [230] proposes the use of a complicated mixture—(1) a monomer (styrene, methacrylic or acrylic acid, methyl methacrylate), (2) its polymer, (3) a cross-linking agent (divinylbenzene or a mixture thereof with butadiene), and (4) a plasticiser not involved in the reaction—as starting materials for the synthesis of strongly and weakly acidic cation-exchange and anion-exchange membranes. Polymerisation is conducted in two stages, with partial (~25%) conversion of the monomer, addition of the remaining components, and completion of polymerisation. Ionogenic groups are introduced in the usual way. The final membranes are claimed to possess increased mechanical strength. Such membranes probably constitute a variety of ion exchangers of isoporous structure; the improved mechanical strength may therefore be assumed to be due to a more ordered polymer structure.

It has been proposed to synthesise most anion-exchange polymerisation membranes from vinylpyridine or its derivatives mixed with other components—polyepoxide compounds [78], quinol, styrene, butadiene [180], etc.—the vinyl-pyridine being alkylated during the synthesis with the formation of a pyridinium base. Membranes based on pyridinium compounds possess strongly basic properties, and are unstable in alkaline media [359]:

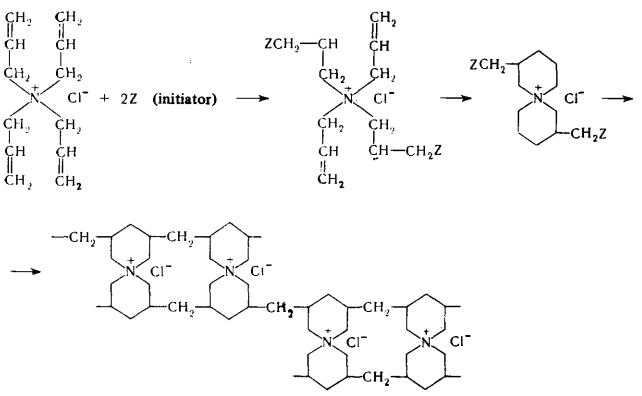


Tevlina et al. [238] first synthesised a water-soluble polymeric base (by the chloromethylation of polystyrene and polyvinyltoluene followed by amination), and then combined it with poly(vinyl alcohol). The resulting films were heated at 120–140°C for 20 h in order to cross-link them. The authors [238] suggest a scheme for formation of the water-soluble polymeric base, but give no mechanism by which the three-dimensional structure is produced. The poly(vinyl alcohol) probably undergoes cross-linking by the formation of ether bonds [360]. It is hardly possible in this case that a cross-linked membrane of homogeneous type could be obtained by interaction of unchanged chlorine in the chloromethyl group with the poly(vinyl alcohol). This is supported also by the fact that the polyelectrolyte is gradually eluted from the membrane [238]. The membranes possess quite low electrical resistance (1–2 ohm cm^{-2}) and an exchange capacity of around 1–2 mg-equiv. g^{-1}. The swelling is greatly dependent on the amount of polyelectrolyte introduced, which usually varied over the range 25–75%.

The swelling in water, and especially in alkaline solutions, was found to increase at polyelectrolyte contents of 50% and above. When it was increased to 75%, the capacity of the membranes dropped sharply after the first regeneration (owing to elution of the water-soluble polymeric base).

Syntheses of anion-exchange membranes have also been suggested from but-3-en-2-one, styrene, and divinylbenzene[312], styrene, divinylbenzene, and butadiene[230], etc.

An interesting synthesis of anion-exchange membranes is based on poly(tetra-allylammonium chloride). The polymer is obtained in aqueous solution in the presence of ammonium persulphate at 50°C, and is treated with triallylamine hydrochloride[197]. The work of Butler et al.[361,362] established that tri- and tetra-allyl derivatives form insoluble three-dimensional structures on polymerisation. They suggest that the mechanism of polymerisation involves radical formation from the initial monomer, intra- and inter-molecular chain transfer, and formation of a three-dimensional polymer from alternating piperidine rings and methylene groups. It is probable that synthesis of the membranes[197] involves also formation of stable six-membered rings, which then undergo cross-linking:



Many polymerisation membranes have not found wide industrial use owing to their low mechanical strength and the difficulty of obtaining large sheets. The following membranes are manufactured by industry—Nepton CR-51, CR-61, and AR-111, Permutit C-1373 and A-1374 (USA); Zerolit C-60, DK-1, A-60, and DA-1 (England); Serion C-100 and A-100 (Japan); MK-100 and MA-100 (USSR); etc.

(c) Activated Films

The chemical modification of inert polymer films is the most convenient way of synthesising ion-exchange membranes, since it is considerably simpler to obtain films from an inert thermoplastic polymer than from a polymer containing ionogenic groups. Furthermore, this method enables very thin membranes to be obtained.

Matrix membranes. The way in which membranes of this type are synthesised is in effect to obtain a film from a copolymer (mostly a styrene–divinylbenzene or a styrene–butadiene copolymer), and then to introduce ionogenic groups into the film.

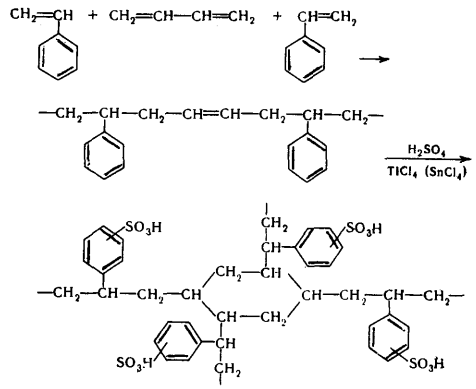
An example is the method proposed by the Japanese chemists Tsunoda and Seko[141], who used a copolymer of styrene, divinylbenzene, and ethylbenzene to form the matrix. The partly polymerised copolymer was dissolved in monomeric styrene, and the reaction completed by heating the mixture in a closed vessel at 100°C for 50 h. The copolymer was sulphonated.

Several analogous membranes have been obtained based on a styrene–divinylbenzene copolymer[142,195].

A ready prepared rubber latex can be used for film formation. The technique of this process is usually to impregnate a reinforcing cloth with a butadiene–styrene latex, dry, and treat with sulphonating or aminating agents. In an example described in a Japanese patent[149], a latex consisting of 29% of styrene and 71% of butadiene is applied to glass fibre, and the dried film is sulphonated with 96% sulphuric acid. Other membranes are obtained similarly[70,130]. The properties of this type of membranes depend on the film thickness, the proportions of styrene and butadiene, the concentration of sulphuric acid, and the time of treatment. The optimum concentration of sulphuric acid is 96%, and the styrene content 40–50%.

Nishihara[79] suggests a synthesis of a cation-exchange membrane which is selective with respect to individual cations. A matrix consisting of glass fibre and a styrene–butadiene latex (1 : 1) is placed in a 25% aqueous solution of resorcinol at 30°C for 20 min, and then in an aqueous solution containing hydrogen chloride (20%) and formaldehyde (15%) at 30°C. After half an hour the membrane is washed with water and 0.5 *N* sodium chloride. The presence of a three-dimensional structure helps to increase selectivity and improve other properties of the membrane[79].

Cyclisation is often used to form a cross-linked structure. Reactions of this type can be accomplished in the presence of such reagents as titanium and tin tetrachlorides. The former is the more effective catalyst, polymers having a greater degree of cross-linking being obtained in its presence, while the membranes are characterised by better electrochemical characteristics. Japanese chemists[189,239] suggest the synthesis of cation- and anion-exchange membranes based on a styrene–butadiene copolymer, cross-linking being effected by cyclisation. An advantage of this method is the simultaneous occurrence of the reactions in a single stage. The mechanism of formation of a cross-linked sulphonated polymer can probably be represented by the scheme



To obtain a strongly basic anion-exchange membrane a film of a copolymer of butadiene with 2-methyl-5-vinylpyridine is treated with methyl iodide. A disadvantage of such membranes is[185] that they can be used only in solutions of pH < 6.

Methods of synthesising matrix membranes have the advantage that a ready made copolymer is usually used, and films of large dimensions are fairly simply obtained. In

most cases, however, the membranes do not possess sufficient mechanical strength for their practical utilisation.

Graft membranes. Membranes having comparatively good electrochemical properties and mechanical strength can be synthesised on the basis of graft polymers formed by attacking the main chain of the polymer with reaction-initiating radicals. In practice initiation by ultraviolet radiation or by a cobalt-60 source is most often employed. The production of radicals by means of peroxide initiators is also widely used. In the synthesis of graft membranes based on polymer matrices and obtained by radiation grafting the source most often used is cobalt-60 [246-259].

Polyethylene, poly(vinyl chloride), polytetrafluoroethylene, etc. films are used as base for radiation grafting. The monomers which are grafted on are styrene [240,245-254], vinylpyridine and its derivatives, methyl acrylate, acrylonitrile [255,265], vinyltoluene, vinylnaphthalene [258], etc.

Ballantine et al. [363] studied the initiation by γ-rays of the formation of graft copolymers from polyethylene films and styrene. Ion-exchange membranes obtained by grafting styrene (20–30%) to polyethylene at a radiation dose of 1.06 Mrad possess the following characteristics [364]: thickness of damp membranes ~ 0.15 mm, exchange capacity 1.2 mg-equiv. g^{-1}, surface electrical resistance in 0.6 N potassium chloride solution 30 ohms cm^{-2}, selectivity 91.0, resistance to tearing in damp state 2.32 kg cm^{-2}, tensile strength in damp state 147.7 kg cm^{-2}, and elongation 190% [364].

Carbon–halogen bonds are more susceptible to attack by a radical and to the reaction of chain transfer than are carbon–hydrogen bonds. Therefore a membrane based on poly(vinyl chloride) is more easily obtained than one based on polyethylene.

In the synthesis of graft polymers, including those used for membranes, various changes produced by the action of radiation—formation of chemical bonds, degradation, oxidation, evolution of gas—are often observed, and these affect the properties of the final products [365].

An interesting generalisation applying to the action of radiation on vinyl polymers, which are usually employed in the synthesis of ion-exchange membranes, was made by Wall [366]: on irradiation in the absence of oxygen, cross-linking processes predominate in polymers having a fairly high heat of polymerisation, whereas degradative processes predominate in polymers possessing a lower heat of polymerisation. The heat of polymerisation is small for stressed molecules (poly-α-methylstyrene) and high for systems having sterically unstressed molecules (polystyrene, polypropylene, polyethylene). This is probably the reason why compounds of the latter type have been suggested almost exclusively for the synthesis of membranes.

Kargin, Cherneva, and their coworkers [71,266] among others have described the preparation of homogeneous graft membranes by initiation with ultraviolet radiation.

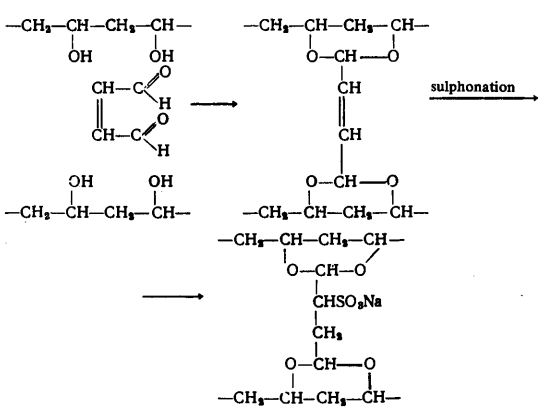
Zenftman [132] proposes the preparation of a graft ion-exchange membrane based on a styrene–polyethylene copolymer. Grafting is conducted in the presence of benzoyl peroxide in an inert gas (nitrogen). Treatment of the matrix with chlorosulphuric acid at 52°C for 30 min yields a cation-exchange membrane having a resistance of 37.7 ohms cm^2 and a selectivity of 0.97.

From a technical point of view the use of radiation polymerisation gives several advantages in comparison with well known methods of polymerisation. In particular, it becomes possible to avoid severe conditions for polymerisation, and unnecessary to employ expensive catalysts, traces of which cannot now contaminate the polymer. Opportunities for controlling the polymerisation process are considerably improved [367]. However, a disadvantage of radiation-grafted membranes is the difficulty of obtaining them under industrial conditions: this method has hitherto been still at the stage of laboratory research. The greatest interest attaches to chemical methods, since they enable graft polymers of desired composition and structure to be obtained in a pure form.

Film membranes. Ready made polymer films—hydrophilic or hydrophobic—are taken in all the proposed methods of synthesising film membranes. An inert film is transformed into an ion-exchange membrane in a single stage. Active groups are introduced by treatment with sulphonating agents, or else by chloromethylation followed by amination. Membranes based on either hydrophilic or hydrophobic films often have diminished mechanical strength.

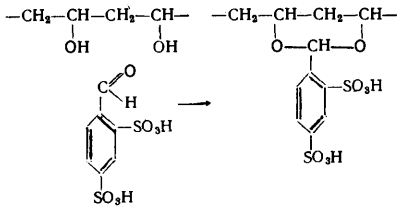
Membranes based on hydrophilic films. A cellulosic material—parchment, cotton cloth, cellulose acetate or regenerated cellulose sheets—or poly(vinyl alcohol) is used as the base. Polyisocyanates, bishydroxymethyladipamide, xanthates, etc. can be used as bridging agents. The use of parchment paper as starting material in the industrial production of large membranes is due mainly to its cheapness and availability. The ability of membranes based on parchment paper to withstand the stresses arising during heat-treatment and on subsequent immersion in water is attributed to the fibrous structure of the cellulosic base. The high water content of membranes of this type leads to low selectivity in relatively concentrated electrolyte solutions; the electrical resistance of such membranes is not large. In spite of the widespread use of membranes of this type, they have several important defects—poor chemical stability, cumbersome mode of production in most cases, etc.

Hydrophilic films of poly(vinyl alcohol) and cellulose can be modified in various ways, the most suitable being acetalisation or etherification of the hydroxyls with compounds containing ionogenic groups [158,173,176,275-286]. Cation-exchange membranes based on poly(vinyl alcohol) are obtained by treatment of the film under mild conditions with malealdehyde followed by addition of sodium hydrogen sulphite [158]:



The strength of the specimens obtained exceeds that of viscose rayon fibres, but the exchange capacity is around 0.2–0.25 mg-equiv. g^{-1} [158]. A greater effect is achieved

by using 4-formylbenzene-1,3-disulphonic acid:



Treatment with formaldehyde makes the membranes insoluble in water. The exchange capacity reaches 0.5–1.0 mg-equiv. g^{-1} [158].

Weakly acid membranes are obtained by heating a high-viscosity poly(vinyl alcohol) in a current of oxygen at 175°C for 5–15 min. Degradation is accompanied by an increase in crystallinity, cleavage of the chains, cross-linking, and oxidation to ketonic and carboxylic groups. Membranes obtained by the thermo-oxidative degradation of poly(vinyl alcohol) under milder conditions are less selective [173].

Weakly acid membranes are obtained by treating sheets of cellulose with an aqueous solution of phosphates of poly(vinyl alcohol) and then heating without a catalyst at 150°C for 15 min [176]. Treatment of poly(vinyl alcohol) films with various aliphatic, aromatic, and heterocyclic amines yields anion-exchange membranes [150,177,194]. The action of pyridine on a dry poly(vinyl alcohol) film at 100°C for 2 h gives a membrane having a low resistance. Insolubility in water (cross-linking) is effected by treating the final product with an organic polyisocyanate [177].

Membranes based on hydrophobic matrices. In this case industrial films of polystyrene, polyethylene, poly(vinyl chloride), polychlorotrifluoroethylene, and several others serve as base for the membranes. Ionogenic groups are introduced by direct sulphonation or amination of the film. The reagents usually employed in these reactions are hydrophilic in character and it is difficult to combine them with a hydrophobic film of compact structure. A further series of difficulties arise in the preparation of such membranes. For example, if the initial hydrophobic films are more than 0.07–0.08 mm thick, a very long time (usually exceeding 24 h) is required for complete swelling of the film. Thinner films are easily deformed, and the membranes obtained have poor mechanical strength. These difficulties, which usually occur in the chemical treatment of hydrophobic sheet material, can probably be overcome by using agents which promote swelling, or plasticisers, the presence of which facilitates sulphonation and has a favourable effect on the mechanical properties of the membranes. Phthalates are most often used as the plasticisers.

Cation-exchange membranes are obtained predominantly by sulphonation, more rarely by phosphorylation. Anion-exchange membranes are produced by chloromethylation of aromatic rings followed by amination or, in the case of halogenated polymer films, by direct amination.

Polystyrene films is the most convenient from the point of view of reprocessing and the chemical stability of the resulting membranes. Westermark [140] prepared a cation-exchange membrane by treating sheet polystyrene with sulphuric acid mixed with an organic solvent. The action of a strong sulphonating agent (e.g. chlorosulphuric acid) effects cross-linking through sulphonyl bridges. A disadvantage of these membranes is their poor mechanical strength.

Abrams and Adrian [178] obtained anion-exchange membranes from sheet polystyrene by the action of a mixture of formaldehyde, a polar organic liquid containing oxygen, and a halogenated sulphonic acid. This mixture forms a complex capable of cross-linking a linear polystyrene matrix. At the same time active groups are included in the polymer structure, and these can be subsequently transformed into quaternary bases by treatment with the appropriate amines. A negative aspect of this method is that the complex of the halogenated sulphonic acid with formaldehyde gradually ages.

Polyethylene [168,287–292] and poly(vinyl chloride) [77,293–297] films are most often used as the hydrophobic base. In view of the chemical resistance of these films to the action of sulphuric acid, sulphonation is accomplished predominantly with strongly acting agents (chlorosulphuric acid, oleum, sulphuryl chloride).

Vasil'ev et al. [289] prepared homogeneous membranes by sulphonating polymer films, and investigated the possibility of their use in electrochemical processes. Films of high-pressure polyethylene were sulphonated with sulphuric acid, oleum, or chlorosulphuric acid at 30°C; the resistance of the membrane was 20 ohm cm^{-2} in 10 *N* potassium hydroxide solution, and its exchange capacity 1.5 mg-equiv. g^{-1}. At 40°C chlorosulphuric acid destroys the film. Low-pressure polyethylene is broken down by chlorosulphuric acid above 50°C, but at 45–50°C sulphonation yields a membrane having an exchange capacity of 4 mg-equiv. g^{-1}. The crystallinity of polyethylene is preserved during sulphonation for 2 h, but is completely destroyed at 50°C after 4 h. Transition of the crystalline into an amorphous structure probably accompanies sulphonation throughout the thickness of the films, as is proved by the sharp increase in the electrical conductivity of the membranes. Degradation of the polyethylene is also possible, of course. The investigations made it clear that the homogeneous membranes obtained could have no practical application owing to their inadequate mechanical strength, chemical stability, and electrical conductivity.

Improvement in mechanical and chemical stability is achieved when the matrix of the membrane consists of polymeric chlorotrifluoroethylene or tetrafluoroethylene, but these membranes exhibit a tendency to intermembrane deposits.

Membranes based on poly(vinylidene fluoride) have been described. Direct sulphonation of a film of the latter takes place mainly on the surface owing to the difficulty of access by the sulphonating agent to the interior of the polymer. Sulphonation of a previously swollen film of the same material takes place throughout the film. In the latter case the rate of sulphonation is increased, and a membrane of relatively low electrical resistance is obtained [254].

The synthesis of ion-exchange membranes based on hydrophobic films has not become widespread. This is because the introduction of ionogenic groups into inert films takes place under severe conditions (high temperature, strong sulphonating agents, etc.) and causes degradation of the polymer. Owing to the difference in chemical nature between the film and the reagent introducing the active groups, the distribution of the latter in the membrane is non-uniform. This has an unfavourable effect on the electrochemical properties of the resulting membranes, which in most cases have a high resistance and low selectivity.

3. INTERPOLYMER MEMBRANES

Increasing attention has been paid during recent years to this type of membranes, because of their interesting combination of properties. Several of them possess

excellent electrochemical characteristics together with satisfactory mechanical strength. Interpolymer membranes are closely similar to homogeneous membranes in properties and structure, since the macromolecules of polyelectrolyte and inert polymer are closely interlinked and appear to form one phase, although chemical bonds are not usually formed. The interlinking of the active component of the membrane with the inert component should hinder and practically exclude its elution during operation. However, the absence of cross-linking bridges may be a reason for gradual partial elution of the active component.

Dynel Membranes

These membranes obtained their name from the original product "dynel" (a copolymer of vinyl chloride and acrylonitrile)[70,76,169]. Poly(styrenesulphonic acid), poly(acrylic acid), a copolymer of maleic acid and methyl vinyl ether, polyvinylimidazole, polyamines, etc. are used as the polyelectrolyte. A mixture of the two polymers is dissolved in a solvent for both hydrophilic polyelectrolytes and hydrophobic inert polymers, this requirement being met by dimethylformamide, dimethyl sulphoxide, and γ-butyrolactone.

Dynel membranes were first synthesised by Gregor and his coworkers[18,19]. A cation-exchange membrane was synthesised by dissolving poly(styrenesulphonic acid) (23%) and dynel (77%) in a mixture of cyclohexanone and methanol, and then pouring the film at 50°C and removing the solvent. For the synthesis of an anion-exchange membrane it is proposed to dissolve a linear poly(vinylbenzyltrimethylammonium chloride) (27%) with dynel in the same solvents. Such a membrane possesses an electrical resistivity of 200–300 ohm cm in 0.1 *N* sodium chloride and a selectivity of around 99%.

The difficulty of producing dynel membranes of large dimensions, the consumption of large quantities of solvents, the complexity of obtaining pure polyelectrolytes, and the relatively low electrical conductivity of the synthesised specimens create obstacles to their industrial utilisation.

Lyubman, Shostak, and their coworkers[316-329] suggested original syntheses of the interpolymer membranes Ankalit K-1 and K-2. The former are obtained by blending polystyrene and polyethylene on rolls in the presence of a hydrocarbon–formaldehyde resin, which functions as both cross-linking agent and plasticiser, lowering the melting points of both polymers. The electrical resistivity of the membrane does not exceed 130 ohm cm[316]. The K-2 membranes were synthesised by dissolving poly(vinyl chloride) and styrene–formaldehyde resin in a common solvent and then pouring the film. Introduction of ionogenic groups (sulphonation) takes place at the same time as cross-linking. The cross-linking–sulphonating reaction takes place at low temperatures of 0–20°C[320]. Introduction of a sulphogroup into the polymer at high temperatures (80–100°C) has an adverse effect on the strength of the membranes. Ankalit K-2 membranes are noteworthy in this respect, their synthesis involving rapid cross-linking at temperatures close to 0°C.

Activated Interpolymer Membranes

These membranes have been acquiring increasing importance during recent years. Combining a ready made inert polymeric film with a monomer which is activated by further treatment may yield mechanically strong membranes possessing adequate electrochemical characteristics.

Polystyrene[74,309,311], a copolymer thereof with divinylbenzene[306,308,310,313,315] or with butadiene[184,185], or a copolymer of styrene, divinylbenzene, and but-3-en-2-one[312] is usually taken as the polymer into which ionogenic groups are introduced. Polyethylene[306-310,316,317], poly(vinyl chloride)[311,315,332], polypropylene[303], and poly(vinylidene chloride)[313,314] are used in the form of films.

The synthesis of interpolymer membranes by the activation of a ready made thermoplastic film is accomplished by impregnating the initial polymer in a monomer or a mixture of monomers, polymerising (or copolymerising) the latter within the film in the presence of an initiator, and introducing ionogenic groups by the usual methods.

Activated interpolymer membranes will probably be given the principal role in electrodialysis processes, although at the present time most of them possess insufficiently low electrical resistance (~ 150–300 ohm cm). The above methods do not ensure good electrochemical characteristics, and moreover membranes of great mechanical strength are rarely obtained.

---o0o---

In spite of the great scope of the investigations, the problem of synthesising ion-exchange membranes remains unsolved. The effective life of even the best of them does not exceed 3–5 years, whereas for a granular exchanger it sometimes reaches 15 years. No practical methods have been developed for synthesising membranes possessing selective properties towards individual ions of the same sign. Theoretical investigations on membrane processes considerably outstrip corresponding researches on the synthesis of membranes. An urgent problem is also the production of biologically active membranes, which might fulfil the functions of membranes in animal and vegetable organisms.

Sulphur-containing Organic Compounds of Boron

B.M.Mikhailov

This article gives the present state of the chemistry of the organic compounds of boron which include sulphur in their composition. Methods of preparation and the chemical properties of the ortho- and meta-thioborates, esters of halogenothioboric acids, esters of organothioboric acids, alkylthio-1,3,2-dioxaborolanes, 1,2-thiaborolanes, *B*-alkylthio-derivatives of borazole, alkylthioboranes, and dialkylamino(alkylthio)boranes are examined. The sulphur-containing boron compounds exhibit high reactivity and many types of compounds with B–S bonds which are now readily available are used successfully for the synthesis of the most diverse classes of organoboron compounds, including various boron–nitrogen heterocyclic systems and boron-containing polymers. The esters of thioboric and organothioboric acids also find application for the synthesis of organosulphur compounds. There is a bibliography of 124 references.

I. INTRODUCTION

The first mention of sulphur-containing organic compounds of boron dates from 1878, when Councler[1] obtained from tri-isobutyl borate and phosphorus(V) sulphide a compound which was taken to be tri-isobutyl thioborate. From 1908 [2] for half a century the investigations in this field were carried out sporadically and only became systematic in 1959. This division of boron chemistry can now be regarded as comparatively well studied. There are simple and preparatively convenient methods for the synthesis of the main types of compound with B–S bonds, such as thioborates, esters of organothioboric acids, alkylthioboranes, compounds with mixed functions, and sulphur-containing heterocyclic boron compounds of various types. The chemical properties of sulphur-containing organoboron compounds have been rather widely studied.

The problems of the chemistry of sulphur-containing boron compounds has been partly covered in a review article[3] and in Gerrard's book[4]. Compounds with B–S bonds but not containing B–C bonds were examined in Steinberg's book[5] published in 1964.

II. ORTHO- AND META-THIOBORATES

As a result of the reaction of tri-isobutyl borate with phosphorus(V) sulphide a yellow substance was obtained, which was assumed to be slightly impure tri-isobutyl thioborate[1]. It is very doubtful, however, whether this substance was a thioborate, since it decomposed in a vacuum, whereas alkyl thioborates distil without decomposition. The first representative of the esters of thioboric acid—trimethyl thioborate—was made in 1952 by the action of silver or lead hydrogen sulphide on boron tribromide[6].

A. METHODS OF PREPARATION

1. Synthesis of Thioborates from Boron Trihalides

The most convenient and economic method for obtaining thioborates consists in the action of thiols on boron trichloride:

$$BCl_3 + 3\,RSH \rightarrow B(SR)_3 + 3\,HCl\,.$$

Despite the apparent simplicity of this reaction, the first attempts to use it for the synthesis of thioborates were unsuccessful. Thus as a result of the reaction of boron trichloride and methanethiol, methylthioboron dichloride was obtained as the dimer $(CH_3SBCl_2)_2$, which does not react further with the thiol[6]. The reaction with thiophenol also does not go to completion[7]. As was shown later, all the chlorine atoms can be replaced by alkylthio-groups under more severe conditions. On mixing boron trichloride and thiols in the cold, crystalline complexes

$$Cl_3B \cdot S\begin{matrix}R\\H\end{matrix},$$

are formed, which lose a molecule of hydrogen chloride at 0–40°C. On carrying out the reaction with higher thiols, which have a rather high boiling point, subsequent heating of the reaction mass at 80–150°C gave alkylthioborates[8]. Propyl thioborate (30%) and butyl thioborate (67%) were obtained by this method. Pentyl thioborate was obtained in 57% yield by boiling a decane solution of boron trichloride and pentanethiol[9].

The reaction of boron trichloride with thiols in the presence of tertiary amines or pyridine proceeds more smoothly. When the reaction is carried out without heating, the yields of thioborates under these conditions are moderate. Thus, in the care of boron trichloride and methanethiol in pentane at 0°C in the presence of trimethylamine the yield of trimethyl thioborate was only 34%.[9] However, on boiling an ethereal solution of a mixture of methanethiol, boron trichloride, and triethylamine for 2 h trimethyl thioborate could be obtained in 80% yield. The reaction with other thiols also proceeds smoothly (yields of 70–90%)[8]:

$$BCl_3 + 3\,RSH + 3\,R'_3N \rightarrow B(SR)_3 + 3R'_3NHCl\,.$$

The reactions of boron tribromide with thiols were also investigated. With methanethiol BBr_3 forms a monosubstituted compound—the dimer of methylthioboron dibromide[6,10]; reaction with pentane-1-thiol in the presence of pyridine leads to pentyl thioborate in 27% yield[9]; with thiophenol, triphenyl thioborate is obtained[7,11].

Thioborates can be obtained by the action of metal mercaptides on boron trihalides. Trimethyl thioborate is synthesised by boiling a benzene solution of boron trichloride and silver or lead hydrogen sulphide (but not potassium hydrogen sulphide)[6] or by heating BBr_3 with sodium hydrogen sulphide without a solvent[12].

By starting from boron tribromide with silver thiocyanate, boron thiocyanate was synthesised[2], which was subsequently assigned the isothiocyanate structure[13].

2. Synthesis of Thioborates on the Basis of Diborane

The trimers of the alkylthioboranes (1,3,5-cyclotriborathianes) obtained by the action of thiols on diborane react at 100–120°C with thiols to form alkyl thioborates[14]:

$$(RSBH_2)_3 + 6\,RSH \xrightarrow{100-120^\circ} 3\,B(SR)_3 + 6\,H_2\,.$$

Alkyl thioborates can also be obtained by heating di(alkylthio)boranes[15,16] or trialkylamine–boranes[17,18] with thiols:

$$(RS)_2BH + RSH \xrightarrow{60-150^\circ} B(SR)_3 + H_2$$

$$H_3B \leftarrow NR_3 + 3\,RSH \xrightarrow{60-100^\circ} B(SR)_3 + NR_3 + 3\,H_2\,.$$

3. Various Reactions in Which Orthiothioborates, Their Derivatives, and Metathioborates Are Formed

A series of reactions are known, mostly not of preparative value, as a result of which thioborates are formed.

The reaction of methanethiol, hexanethiol, or phenylmethanethiol and hydrogen chloride with tris(dialkylamino)-boron gave the corresponding thioborates[9,19].

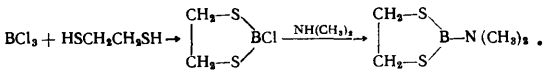
Ethyl thioborate was obtained by the action of hydrogen sulphide on ethylthioboron dibromide[20]:

$$3\,C_2H_5SBBr_2 + 3\,H_2S \rightarrow B(SC_2H_5)_3 + B_2S_3 + 6\,HBr\,.$$

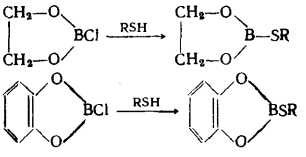
The polymer of methylthioborane undergoes disproportionation into methyl thioborate and diborane at 140°C;[12] trimethylamine–methylthioborane[12] and the methyl esters of methyl- and dimethyl-thioboric acids[21] also disproportionate (145°C) to methyl thioborate. Triphenyl thioborate was obtained by the reaction of potassium tetrafluoroborate and tris(phenylthio)aluminium[22]:

$$KBF_4 + Al(SC_6H_5)_3 \xrightarrow{240^\circ} B(SC_6H_5)_3 + AlF_3 + KF\,.$$

The action of ethane-1,2-dithiol on boron trichloride gave 2-chloro-1,3,2-dithiaborolane, which was converted into the dimethylamino-derivative[23]:

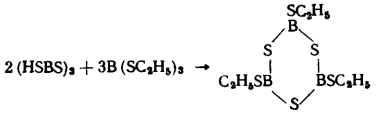


2-Alkylthio-1,3,2-dioxaborolanes are obtained from the corresponding chloro-derivatives and thiols[24–26]:



where R = n-C_4H_9 or n-C_8H_{17}.

Prolonged boiling of a carbon disulphide solution of metaboric acid[27,28] and triethyl borate gives a trimer of an ester of metaboric acid[29]:



which is converted on distillation into the dimer $(C_2H_5SBS)_2$.

B. PROPERTIES

Trialkyl thioborates are liquids with a very unpleasant odour; triphenyl thioborate is a solid melting over a wide range.

The ^{11}B chemical shift in tributyl thioborate is –47.9 p.p.m. in relation to trimethyl borate[17]. Thioborate exhibits an intense absorption band in the 10–11 μm range and a weaker one in the 13.25–13.50 μm range.

1. Hydrolysis and Alcoholysis

Thioborates are readily hydrolysed by water with the formation of boric acid and thiols[12,17]; with alcohols they give alkyl borates and thiols[6]:

$$B(SR)_3 + 3\,ROH \rightarrow B(OR)_3 + 3\,RSH\,.$$

2. Reactions with Amines

Trimethyl thioborate and pyridine form a 1 : 1 adduct[8]; triethyl thioborate gives an unstable complex with pyridine, which decomposes on heating into the initial components[30].

As the example of triethyl thioborate showed, the reaction of thioborates with primary or secondary amines proceeds by successive replacement of alkylthio-groups by the corresponding alkylamino-groups and as a result, depending on the ratio of the reagents, the products[30] are *N*-substituted bis(alkylthio)aminoborane, an alkylthiodiaminoborane, or triaminoborane, unchanged on distillation:

$$B(SC_2H_5)_3 + RR'NH \rightarrow RR'NB(SC_2H_5)_2 + C_2H_5SH\,,$$
$$B(SC_2H_5)_3 + 2\,RR'NH \rightarrow (RR'N)_2BSC_2H_5 + 2\,C_2H_5CH\,,$$
$$B(SC_2H_5)_3 + 3\,RR'NH \rightarrow (RR'N)_3B + 3\,C_2H_5SH\,,$$

where R = H or Alk.

Bis(ethylthio)phenylaminoborane, obtained by the action of 1 mole aniline on triethyl thioborate, is symmetrised at room temperature into tris(phenylamino)boron and triethyl thioborate.

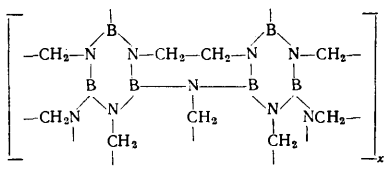
The compound $[(CH_3)_2NBS]_3$ which is a trimer of the anhydride of dimethylaminothioboric acid, is synthesised by the action of tris(dimethylamino)boron on metathioboric acid[31,32] or the anhydride of bromothioboric acid[32] and also from metathioboric acid and $Al[N(CH_3)_2]_3$:[33]

$$(HSBS)_3 + B[N(CH_3)_2]_3 \rightarrow [(CH_3)_2NBS]_3 + B(SH)_3\,,$$
$$(BrBS)_3 + B[N(CH_3)_2]_3 \rightarrow [(CH_3)_2NBS]_3 + BBr_3\,.$$

$(CH_3NHBS)_3$ was also obtained by the action of methylamine on $(BrBS)_3$:[20]

$$(BrBS)_3 + 3NH_2CH_3 \rightarrow (CH_3NHBS)_3 + 3HBr\,.$$

The action of ethylenediamine on triethyl thioborate (1 : 1) gives a polymer which does not contain ethylthio-groups and to which is ascribed the structure[30]:



3. Exchange Reactions with Boron Compounds

Trialkyl thioborates undergo exchange reactions with esters of organoboron acids[34-36] or boron trialkyls[21,34,37], as a result of which esters of organothioboron acids are formed. These conversions are a method for the synthesis of the last class of compound, considered in Section III, A, 3.

4. Reactions with Carbonyl Compounds and Vinyl Esters

The high reactivity of thioborates appears in their reactions with various organic compounds, such as aldehydes, ketones, amides of acids, and vinyl esters.

Trialkyl thioborates react with aldehydes and ketones to form thioacetals or thioketals and boron sesquioxide[38]. The reaction between triethyl thioborate and benzaldehyde in benzene solution is exothermic and yields boron sesquioxide and the bis(ethylthio) acetal of benzaldehyde in 91% yield:

$$3C_6H_5CHO + 2B(SC_2H_5)_3 \rightarrow 3C_6H_5CH(SC_2H_5)_2 + B_2O_3\,.$$

On heating a benzene solution of acetone and tributyl thioborate, the bis-(n-butylthio) ketal of acetone is formed in 90% yield:

$$3CH_3COCH_3 + 2B(SC_4H_9)_3 \rightarrow 3(CH_3)_2C(SC_4H_9)_2 + B_2O_3\,.$$

Under similar conditions triethyl thioborate and acetophonone give acetophenone diethylthio ketal smoothly.

The process evidently proceeds by the addition of thioborate at the carbonyl group:

$$R_2CO + B(SR)_3 \rightarrow R_2C\begin{matrix}OB(SR)_2\\SR\end{matrix}$$

and further conversion of the addition product by the scheme:

$$R_2C\begin{matrix}OB(SR)_2\\SR\end{matrix} + B(SR)_3 \rightarrow R_2C(SR)_2 + (RS)_2BOB(SR)_2\,.$$
$$\downarrow B(SR)_3 + B_2O_3$$

Dimethylformamide reacts like aldehydes and ketones with thioborates[39]:

$$3(CH_3)_2NCHO + 2B(SC_4H_9)_3 \rightarrow (CH_3)_2NCH(SC_4H_9)_2 + B_2O_3\,.$$

The comparatively high yield (66%) of bis(butylthio)-dimethylaminomethane shows the possibility of using this reaction for the preparation of amidomercaptals.

On heating thioborates with vinyl esters, alkyl vinyl sulphides and alkyl borates are obtained[39]:

$$3CH_2{=}CHOR + B(SR)_3 \xrightarrow{100-150^\circ} CH_2{=}CHSR + B(OR)_3$$

Butyl vinyl sulphide was obtained in 71% yield from tributyl thioborate and butyl vinyl ether by this method. Tripropyl thioborate and butyl vinyl ether react similarly, as do tributyl thioborate and ethyl vinyl ether.

It must be assumed that the thioborate adds at the double bond of the vinyl ether and the addition product then undergoes β-decomposition with the elimination of an alkyl vinyl sulphide:

$$CH_2{=}CHOR + B(SR)_3 \rightarrow (RS)_2BCH_2CH\begin{matrix}OR\\SR\end{matrix} \rightarrow$$
$$\rightarrow (RS)_2B\begin{matrix}O-CH-SR\\|\\CH_2\end{matrix} \rightarrow (RS)_2BOR + CH_2{=}CHSR\,.$$
$$\downarrow B(OR)_3 + B(SR)_3$$

This mechanism for the reaction agrees well with the tendency of β-alkoxy-derivatives of alkylboron acids to eliminate ethylene[40].

III. ESTERS OF ORGANOTHIOBORIC ACIDS

Like thioborates, esters of organothioboric acids have attracted attention only in recent years. The first representatives of this class of compounds—the dodecyl and

octyl esters of 2-chlorovinylthioboric acid—were obtained[41] in 1946. Several other representatives of this class of compound were described subsequently but systematic study of the esters of organothioboric acids only began in 1959. Preparative methods for their synthesis are based on the use of organoboron halides, boron trialkyls, and esters of organoboron acids. The esters of organothioboric acids are, like the thioborates, very reactive substances, and are used successfully for the synthesis of various classes of boron compounds.

A. METHODS OF PREPARATION

1. Synthesis of Esters of Organothioboric acids from Organoboron Halides

One of the general methods of synthesis of esters of organothioboric acids consists in the action of thiols or metal mercaptides on organoboron halides. This method allows esters of organothioboric acids of the aliphatic and aromatic series to be obtained.

Octyl (2-chlorovinyl)chlorothioborate was first obtained by this method from octanethiol and 2-chlorovinylboron dichloride[41]. It was found subsequently that the replacement of one or both halogen atoms in alkylboron dihalides by an alkylthio-group depends on the ratio of the reagents, the temperature, and the duration of heating.

On boiling a mixture of an alkylboron dichloride or alkylboron dibromide with an excess of butane-1-thiol for 10–15 h, n-butyl alkylthioborates are formed smoothly[42]:

$$RBX_2 + 2n\text{-}C_4H_9SH \rightarrow RB(SC_4H_9\text{-}n)_2 + 2HX.$$

n-Butyl phenylthioborate is obtained similarly from phenylboron dichloride[42].

On heating mixtures of alkylboron dichlorides with an excess of ethanethiol, in addition to the diethyl esters of the alkylthioboric acids, products of the incomplete replacement of chlorine atoms are also formed—ethyl esters of (alkylthio)chloroboric acids[43].

$$RBCl_2 \xrightarrow{C_2H_5SH} RB(SC_2H_5)_2 + RBCl(SC_2H_5).$$

Esters of (alkythio)chlorothioboric acids undergo partial symmetrisation into esters of alkylthioboric acids and alkylboron dichlorides when distilled in a vacuum so that esters of alkylchlorothioboric acids cannot be obtained in high yields even in experiments with an equimolecular ratio of the reagents.

Ethyl esters of alkylbromothioboric acids are obtained in 65–75% yields by the reaction of alkylboron dibromides with ethanethiol in 1 : 1 ratio[43]:

$$RBBr_2 + C_2H_5SH \rightarrow RBBr(SC_2H_5) + HBr.$$

Bromothio-esters have a much greater thermal stability than chlorothio-esters and can be distilled in a vacuum without decomposition. Phenylboron dibromide undergoes a similar reaction with ethanethiol[43].

The preparation of esters of alkylchlorothioboric acids can also be effected by an exchange reaction between alkylboron dichlorides and the esters of alkylthioboric acids[43]. Thus, when an equimolecular mixture of n-propylboron dichloride and diethyl n-propylthioborate is left at room temperature for 20 h then by distilling the reaction mixture the ethyl chloro(propyl)thioborate can be isolated in 50% yield.

$$n\text{-}C_3H_7BCl_2 + n\text{-}C_3H_7B(SC_2H_5)_2 \rightarrow 2n\text{-}C_3H_7B(SC_2H_5)Cl.$$

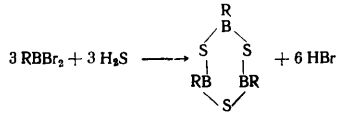
The difference in stability of the esters of the organo-(halogeno)thioboric acids and their oxygen analogues merits attention. Among the compounds of the latter class the tendency to disproportionation is observed only in the esters of organofluoroboric acids[44], whereas the esters of chloro- and bromo-organic acids distil unchanged[45,46].

Yet another method for obtaining esters of alkyl(halogeno)organothioboric acids must be mentioned, consisting in the action of boron halides on the esters of alkylthioboric acids at room temperature[43]. Thus n-butyl isopentylthioborate and boron tribromide gave n-butyl isopentylbromothioborate [bromo(butylthio)isopentylborane]:

$$3iso\text{-}C_5H_{11}B(SC_4H_9\text{-}n)_2 + BBr_3 \xrightarrow[80\%]{} 3iso\text{-}C_5H_9B(SC_4H_9\text{-}n)Br + B(SC_4H_9\text{-}n)_3.$$

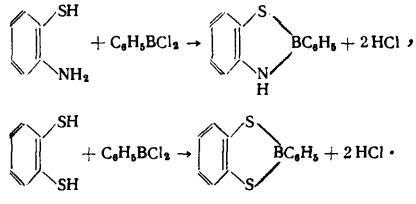
Dialkylboron halides[21,47] and diarylboron halides[42] are converted into the esters of dialkyl- and diaryl-thioboric acids respectively on heating with thiols. In this method various metal mercaptides can be used instead of thiols. Thus the di-n-pentyl ester of phenylthioboric acid [phenyldi(pentylthio)borane] was synthesised by the reaction of phenylboron dichloride with methylthiosodium[48].

When heated with hydrogen sulphide in an inert solvent (benzene, carbon disulphide), phenylboron dibromide[49] and alkylboron dibromides[20] are converted respectively into the anhydrides of phenyl- or alkyl-thioboric acids, which exist as cyclic trimers:



where R = n-C_4H_9, iso-C_4H_9, or C_6H_5.

Cyclic esters of organothioboric acids are formed in the reaction of organoboron dihalides with *ortho*-thio-derivatives of benzene. Thus phenylboron dichloride and 2-aminothiophenol or dithiocatechol gave 2-phenylbenzo-1,3,2-thiazaborolane and 2-phenylbenzo-1,3,2-dithiaborolane respectively[50]:



2. Synthesis of Esters of Organothioboric Acids from Boron Trialkyls

a. Use of thiols. A simple method of obtaining esters of dialkylthioboric acids is the reaction between boron trialkyls and thiols[51,53]. The reaction starts at room temperature and is accompanied by evolution of heat; additional heating of the reaction mass at 110–160°C is necessary to complete the process:

$$BR_3 + R'SH \rightarrow R_2BSR' + RH.$$

A detailed study of this reaction disclosed that it is initiated by peroxide compounds in ultraviolet light[54]. Only freshly distilled boron trialkyls, which almost always contain traces of peroxy-compounds >BOOR, start to react with thiols at room temperature. Furthermore, boron trialkyls freed from peroxides (by heating at 100°C for a few

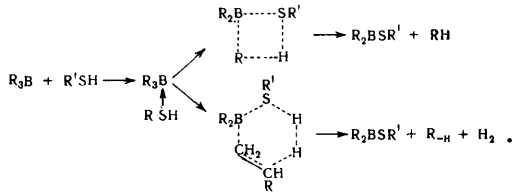
hours or by keeping at room temperature for a few months) do not react with thiols below 150°C. When a little (2–10 ml) air or pieces of porcelain or diatomaceous brick is introduced into a mixture of such "deactivated" boron trialkyls and a thiol a reaction starts, accompanied by the formation of a thioester R_2BSR and an alkane. Reaction takes place at a still greater rate on adding drops of hydrogen peroxide or an alkyl hydroperoxide to the mixture.

The peculiarities of the behaviour of thiols in relation to boron trialkyls, sharply distinguishing them from other nucleophilic reagents, such as water, alcohols, and amines, with which boron trialkyls react at 150–200°C,[51] are explained evidently by the ability of thiols to participate in radical processes brought about by organoboron peroxides.

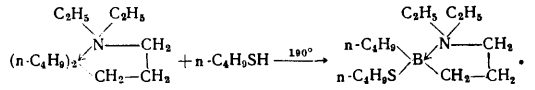
Unlike thiols, thiophenol[51,52] reacts with boron trialkyls on heating and in addition to saturated hydrocarbons the products include alkenes and hydrogen, as when other nucleophilic reagents are used[52]:

$$BR_3 \xrightarrow[150-170^\circ]{C_6H_5SH} R_2BSC_6H_5 + RH + R_{-H} + H_2 .$$

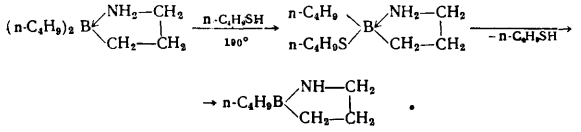
Evidently the formation of saturated hydrocarbons in this reaction occurs through a four-centre transition state, whereas the alkene and hydrogen are obtained by a six-centre mechanism:



It is interesting that mercaptans are capable of reacting with inner complexes of boron trialkyls, but only at a high temperature (190°C). Thus in the action of butane-1-thiol on 3-(diethylamino)propyldibutylboron butyl butyl-3-(diethylamino)propylborate is obtain in 55% yield:



3-Aminopropyldibutylboron also reacts with thiols at high temperature, but the ester of 3-aminopropylbutylthioboric acid formed as an intermediate is immediately converted with loss of a thiol into 2-n-butyl-1,2-azaborolidine[55]:



An increased ability to exchange a radical by an alkylthio-group is exhibited by triallylboron[56,57], which reacts with ethanethiol at temperatures between −10° and −15°C; at an equimolecular ratio of the reagents ethyl diallylthioborate and propene are formed. In the action of 2 moles ethanethiol on 1 mole triallylboron the main reaction product is diethyl allylthioborate but in addition ethyl diallylthioborate and ethyl 3-ethylthiopropylthioborate are obtained:

$$B(CH_2CH=CH_2)_3 + 2\,C_2H_5SH \rightarrow CH_2=CHCH_2B(SC_2H_5)_2 + 2\,C_3H_6$$
$$\downarrow C_2H_5SH$$
$$C_2H_5-S-CH_2-CH_2CH_2B(SC_2H_5)_2 .$$

Diethyl 3-ethylthiopropylthioborate can be obtained by the direct action of ethanethiol on diethyl allylthioborate.

The high reactivity of triallylboron in relation to thiols and also to other nucleophilic reagents[58–61] is evidently connected with an allyl rearrangement in these compounds. As investigation by proton magnetic resonance showed[62], the allyl rearrangement in triallylboron:

$$(C_3H_5)_2\overset{\bullet}{B}CH_2CH=CH_2 \rightleftarrows \overset{\text{transition state}}{\rightleftarrows} (C_3H_5)_2BCH_2CH=\overset{\bullet}{C}H_2$$

proceeds with a velocity from 4.7 Hz at −25°C to 3.3 kHz at 88°C, that is, the average life time of each state varies in this temperature range from 2×10^{-1} to 3×10^{-4} s.

b. Use of Sulphur. One of the features of boron trialkyls is their ability to react with oxygen to form esters of dialkyl- or alkyl-boric acids, depending on the condition. It seemed that sulphur is also capable of reacting with boron trialkyls on heating with formation of esters of dialkylthioboric acids[63,64]:

$$BR_3 + S \xrightarrow{140^\circ} R_2BSR .$$

c. Use of thioborates. At elevated temperatures boron trialkyls enter into an exchange reaction with thioborates to form esters of organothioboric acids. Methyl dimethylthioborate was obtained by this method on prolonged heating of methyl thioborate with trimethylboron in the presence of traces of diborane[21]:

$$2\,B(CH_3)_3 + B(SCH_3)_3 \rightleftarrows 3\,(CH_3)_2BSCH_3 .$$

By heating a 1 : 2 mixture of boron trialkyls and ethyl thioborate for 30–35 h at 250°C ethyl alkylthioborates were obtained in 65–75% yields[37]:

$$BR_3 + 2\,B(SC_2H_5)_3 \xrightarrow{250^\circ} 3\,RB(SC_2H_5)_2 .$$

The reaction of boron trialkyls with butyl thioborate under similar conditions proceeds less smoothly.

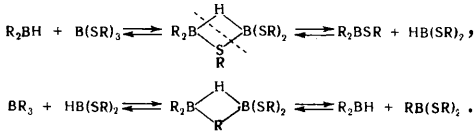
In the reaction products there is a certain amount (10–15%) of an ester of a dialkylthioboric acid and also the initial compounds, which is explained by the reversibility of the reactions:

$$BR_3 + B(SR')_3 \rightleftarrows R_2BSR' + RB(SR')_2 ,$$
$$R_2BSR' + B(SR)_3 \rightleftarrows 2\,RB(SR')_2 .$$

In the reaction with triethyl borate the equilibrium is shifted to the right to a greater extent than in that with tributyl thioborate.

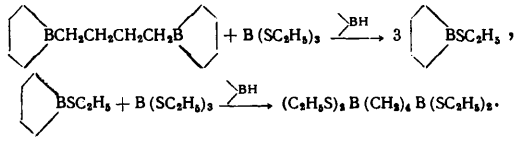
The use of tetra-alkyldiborane as a catalyst allows a much lower temperature and a shorter reaction time to be used in the reaction of tributylboron with tributyl thioborate. The yield of dibutyl butylthioborate was 73%.[34]

The catalytic action of tetra-alkylboranes and also other compounds with B–H bonds, just as in exchange reactions between boron trialkyls and orthoborates[34,65–67], explains their ability to form dimeric intermediate compounds with three-centre B–H–B bonds, for example:



In the presence of compounds with B–H bonds 1,4-di-(1-boracyclopentyl)butane is smoothly converted by ethyl

thioborate into 1-ethylthioboracyclopentane, and the latter into an ester of butane-1,4-dithioboric acid[68]:



3. Synthesis of Esters of Organothioboric Acids from Esters of Organoboric Acids

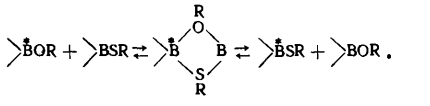
A universal and preparatively very simple method for the synthesis of esters of organothioboric acids is an exchange reaction between esters of organoboric acids and thioborates or esters of organothioboric acids.

Whereas in organoboron compounds the exchange of an alkyl radical for an alkoxy- or alkylthio-radical is effected smoothly only in the presence of compounds with B–H bonds the exchange of alkoxy- and alkylthio-groups in organic compounds of boron can be effected without a catalyst[35,36]:

$$3RB(OR')_2 + 2B(SR'')_3 \rightleftarrows 3RB(SR'')_2 + 2B(OR')_3,$$
$$3R_2BOR' + B(SR'')_3 \rightleftarrows 3R_2BSR'' + B(OR')_3,$$
$$RB(OR')_2 + R''B(SR''')_2 \rightleftarrows RB(SR''')_2 + R''B(OR')_2,$$
$$RB(OR')_2 + 2R''_2B(SR''') \rightleftarrows RB(SR''')_2 + R''_2BOR',$$
$$R_2BOR' + R''_2BSR''' \rightleftarrows R_2BSR''' + R''_2BOR'.$$

These reactions are reversible and the equilibrium can be displaced by the removal of the most volatile component in a vacuum with the reaction mass at 80–150°C. Under these conditions even after 2–3 h the equilibrium is almost completely displaced in favour of a low-boiling compound and the yields of the compounds sought is usually ◁ 90%. On using esters with radicals of different molecular weight exchange reactions of the types mentioned could be effected in any direction. This is an extremely valuable procedure for the production of esters of low molecular weight from esters of higher molecular weight. For example, with ethyl thioborate butyl propylthioborate or dibutylthioborate gave the corresponding ethyl esters in 87–97% yields.

The reaction mechanism leads to the formation of intermediate dimeric compounds and their subsequent decomposition in an energetically favourable direction:



This method of synthesis of esters of organothioboric acids was used with success for a series of alkanediboric and triboric compounds. Thus tetramethyl propane-1,3-diborate is converted into tetramethyl propane-1,3-dithioborate on heating with methyl thioborate[68]:

$$3(CH_3O)_2B(CH_2)_3B(OCH_3)_2 + 4B(SCH_3)_3 \rightarrow (CH_3S)_2B(CH_2)_3B(SCH_3)_2 + 4B(OCH_3)_3.$$

Tetraethyl butane-1,4-dithioborate was obtained from tetramethyl butane-1,4-diborate and triethylthioborate[70]:

$$3(CH_3O)_2B(CH_2)_4B(OCH_3)_2 + 4B(SC_2H_5)_3 \rightarrow$$
$$\rightarrow (C_2H_5S)_2B(CH_2)_4B(SC_2H_5)_2 + 4B(OCH_3)_3.$$

The corresponding 1,1,5,9,9-penta-alkylthio-1,5,9-triboranononanes were synthesised from 1,1,5,9,9-pentamethoxy-1,5,9-triboranonane and trimethyl thioborate or triethyl thioborate[71]:

$$3(CH_3O)_2B(CH_2)_3\underset{\displaystyle OCH_3}{B}(CH_2)_3B(OCH_3)_2 + 5B(SR)_3 \rightarrow$$
$$\rightarrow 3(RS)_2B(CH_2)_3\underset{\displaystyle SR}{B}(CH_2)_3B(SR)_2 + 5B(OCH_3)_3$$

where R = CH_3 or C_2H_5.

When the polymers which are formed in the hydroboronation of dimethyl allylthioborate are heated with methyl thioborate in the presence of tetrapropyl diborane they give tetramethyl propane-1,3-dithioborate[72].

4. Synthesis of Esters of Organothioboric Acids from Alkylthioboranes and Unsaturated Hydrocarbons

Di(butylthio)borane reacts with hex-1-ene or oct-1-ene to form the esters of the corresponding organothioboric acids[73]:

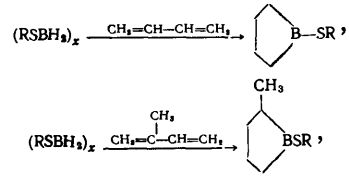
$$(n\text{-}C_4H_9S)_2BH + CH_2{=}CHR \rightarrow RCH_2CH_2B(SC_4H_{9}\text{-}n)_2.$$

The reaction with propene or 2-methylpropene is complex, leading to mixtures of butyl alkylthioborates, dialkylthioborates, and tributyl thioborate. The reaction of polymeric butylthioborane with ethylene or propene is also complex but with hex-1-ene an ester of dihexylthioboric acid is obtained in 60% yield[74]:

$$(n\text{-}C_4H_9SBH_2)_x + 2x\,CH_2{=}CHC_4H_9 \rightarrow x(C_6H_{13})_2BSC_4H_{9}\text{-}n.$$

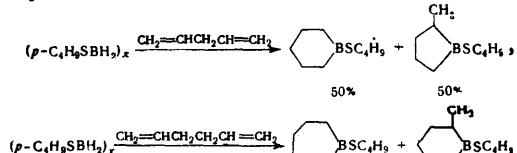
Methyl esters of diethylthioboric, dihexylthioboric, and dicyclohexylthioboric acids were obtained from methylthioborane polymer and ethylene, hex-1-ene, and cyclohexene[74].

1-Alkylthioboracycloalkanes can be synthesised from polymers of alkylthioboranes and diene hydrocarbons. Thus the reaction of polymers of methylthioborane or butylthioborane with dienes (buta-1,3-diene or isoprene) in ethereal medium gave 1-methylthioboracyclopentane[74], 1-butylthioboracyclopentane[75,76], 3-methyl-1-methylthioboracyclopentane[74], and 3-methyl-1-butylthioboracyclopentane[76]:



where R = CH_3 or n-C_4H_9.

The reaction of the polymer of butylthioborane with penta-1,4-diene or hexa-1,5-diene gives a mixture of alkylthioboracyclanes[76]:



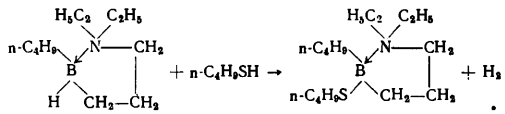
5. Synthesis of Esters of Organothioboric Acids from Alkyldiboranes or Aminoalkyl(aryl)boranes

Esters of organodialkylthioboric acids are formed by the action of thiols on tetra-alkyldiboranes[12,77]:

$$R_4B_2H_2 + 2RSH \rightarrow 2R_2BSR + 2H_2 .$$

The reactions are complicated by the formation of small amounts of side-products, owing to the symmetrisation of the initial compounds.

Butyl-(3-diethylaminopropyl)borane reacts with a thiol at 190°C to form an ester of butyl-(3-diethylaminopropyl)-thioboric acid[55]:



Esters of alkylthioboric acids are formed on heating trimethylamine–alkylboranes with thiols[17,78]:

$$RBH_2 \cdot N(CH_3)_3 + 2RSH \xrightarrow{60-100^\circ} BB(SR')_2 + 2H_2 + N(CH_3)_3 .$$

Esters of dialkylaminoarylboric acids are obtained by the action of thiols on dialkylaminoarylboranes[79].

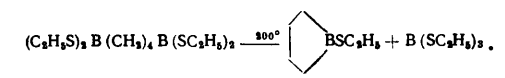
B. PROPERTIES

1. Thermal Conversions

Esters of organothioboric acids are compounds of rather high thermal stability. Thus propyl dipropylthioborate is unchanged after heating for 4 h at 160°C.[64] However, long heating at a high temperature leads to disproportionation of thioesters. After 34 days at 84°C dimethyl methylthioborate is 10% symmetrised into methylthioborate and methyl dimethylthioborate[21], and dibutyl isobutylthioborate after 10 h at 240–250°C was 30% converted into butyl thioborate and butyl di-isobutylthioborate[37]:

$$\text{iso-}C_4H_9B(SC_4H_9\text{-}n)_2 \rightleftarrows (\text{iso-}C_4H_9)_2BSC_4H_9\text{-}n + B(SC_4H_9\text{-}n)_3 .$$

On heating, esters of butane-1,4-dithioboric acid are converted into thioborate and 1-alkylthioboracyclopentane[70]:



2. Hydrolysis and Alcoholysis

Esters of organothioboric acids are readily hydrolysed by water with the formation of organoboric acids and thiols:

$$R_2BSR + H_2O \rightarrow R_2BOH + RSH .$$

Under the action of alcohols esters of organothioboric acids are also readily converted into esters of organoboric acids[64]. With alcohols, alkylthio-derivatives of boracycloalkanes give 1-alkoxyboracycloalkanes[75].

Smooth and rapid reaction of thioesters with alcohols allows esters of dialkylboric acids to be synthesised from boron trialkyls under mild conditions including the difficultly accessible methyl esters by using a catalytic quantity of thiol in the reaction[80]:

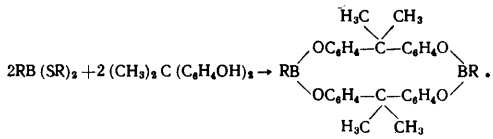
$$BR_3 + CH_3OH \xrightarrow[65-70^\circ]{RSH} R_2BOCH_3 + RH .$$

The thiol and the boron trialkyl form esters of dialkylthioboric acids and thiol, which again reacts with the boron trialkyl. In this way tris-(3-dimethoxyborylpropyl)boron is smoothly converted into 1,1,5,9,9-pentamethoxy-1,5,9-triboranonane and dimethyl propylborate[81]:

$$B[CH_2CH_2CH_2B(OCH_3)_2]_3 + CH_3OH \xrightarrow{C_2H_5SH,\ 100^\circ} \rightarrow (CH_3O)_2B(CH_2)_3B(CH_2)_3B(OCH_3)_2 + n\text{-}C_3H_7B(OCH_3)_2 .$$

Under the action of alcohols, esters of alkylthioboric acids give dialkyl alkylborates.

Dialkyl esters of organoalkylthioboric acids and organoarylthioboric acids form heterocyclic compounds with 2,2-bis-(4-hydroxyphenyl)propane[82] [Bisphenol A]:



3. Reactions with Ammonia and Amines

Esters of dialkylthioboric acids give dialkylboramines with ammonia[63,80,83]. On introducing ammonia into a cooled ester of organothioboric acid an adduct is formed, which decomposes at ~20°C with loss of thiol into dialkylboramines with almost quantitative yield:

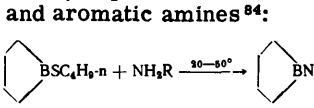
$$R_2BSR' + NH_3 \rightarrow R_2BSR' \cdot NH_3 \rightarrow R_2BNH_2 + R'SH .$$

Dialkylboramines can be obtained starting directly from boron trialkyls and ammonia by using a little thiol, which plays the part of a catalyst of the reaction[80,83]. The thioester formed in the first stage of the reaction between the boron trialkyl and the thiol reacts with the ammonia to regenerate the thiol, which again reacts with the boron trialkyls, and the process is repeated until the boron trialkyl is completely consumed. Esters of diarylthioboric acids also react smoothly in the cold with ammonia to form diarylboramines[42].

With amines the esters of dialkylthioboric acids form *N*-substituted dialkylboramines[63,64,83]:

$$R_2BSR' + NH_2R'' \rightarrow R_2BNHR'' + R'SH .$$

Just as in the synthesis of dialkylboramines, the production of their *N*-substituted derivatives is possible directly from boron trialkyls and amines in the presence of trace amounts of thiols[80,83]. Esters of diarylthioboric acids and 1-alkylthioboracyclopentane[76,85] react similarly with aliphatic[42] and aromatic amines[84]:



With hexamethylenediamine the esters of dialkylthioboric acids form *NN'*-di(dialkylboryl)-1,6-diaminohexanes:

$$2R_2BSR' + H_2N(CH_2)_6NH_2 \xrightarrow[85\%]{160-180^\circ} R_2BNH(CH_2)_6NHBR_2 + 2R'SH;$$

with hydrazine they give 1,2-bis(dialkylboryl)hydrazines

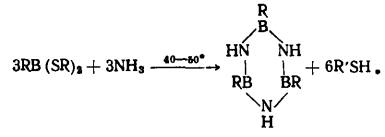
$$2R_2BSR' + NH_2-NH_2 \xrightarrow[80\%]{150-180^\circ} R_2BNH-NHBR_2 + 2R'SH;$$

and with phenylhydrazine they are converted into 2-(dialkylboryl)-1-phenylhydrazines[63]:

$$R_2BSR' + NH_2NHC_6H_5 \xrightarrow[70\%]{160-200^\circ} R_2BNH-NHC_6H_5 + R'SH .$$

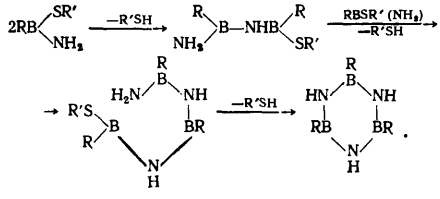
The reactions of esters of alkylthioboric and arylthioboric acids with ammonia and amines leads to a different nitrogen-containing compound of boron.

Ammonia with dialkyl esters of organothioboric acids gives *B*-trialkylborazoles smoothly[42,86]



The mechanism of the reaction leads to the formation of an amino-ester in the first stage:

which then is apparently condensed by the following scheme:



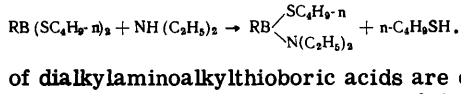
This is an effective method for the synthesis of *B*-trisubstituted borazoles, which is also applicable for the production of *B*-triallylborazole[57].

Unlike the reactions with ammonia, with 2 moles of primary aliphatic amines both alkylthio-groups in esters of alkylthioboric acids are replaced by alkylamino-groups to form *N*-alkyl-substituted alkylborondiamines[87]:

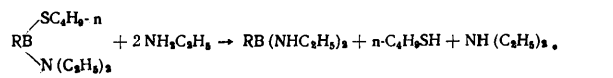
The reaction of equimolecular amounts of reagents gives a mixture of an *N*-alkyl-substituted alkylboron diamine, an aminothioester, and the initial thioester.

Diethyl allylthioborate and butylamine form allyldibutylaminoboron[57].

Esters of alkylthioboric acids behave quite differently with secondary aliphatic amines (for example, diethylamine). Here only one alkylthio-group is replaced by an alkylamino-residue with formation of esters of dialkylamino-acids[87]:



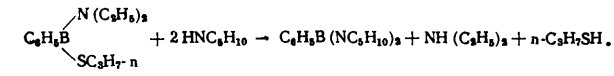
Esters of dialkylaminoalkylthioboric acids are capable of reacting with ethylamine; when an excess of the amine is used both the alkylthio- and the diethylamino-groups are replaced by the ethylamino-group and *N*-ethyl derivatives of alkylborondiamine are obtained[87]:



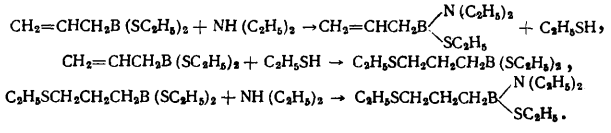
The difference in the behaviour of the esters of diethylaminoalkylthioboric acids towards ethylamine and diethylamine is evidently due to the latter's lower ability to form complexes.

Esters of dialkylaminoaryl thioboric acids behave in relation to primary amines similarly to compounds of the alkyl series, with both alkylthio- and dialkylamino-groups being replace by alkylamino-groups to form *N*-alkyl-substituted arylborondiamines[79].

The esters of dialkylaminoarylthioboric acids are more stable towards secondary amines. When a secondary amine with a high boiling point is used and the thiol and low-boiling secondary amine produced are distilled off from the reaction mass, bis(dialkylamino)arylboron can be obtained[48]:



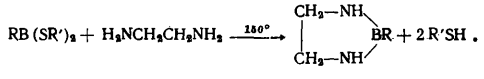
The reaction of diethyl allylthioborate with diethylamine is unique[57]. Approximately equal amounts of ethyl diethylaminoallylthioborate and ethyl diethylamino-3-ethylthiopropylthioborate are obtained. In the first stage of the reaction the ethylthio-group is replaced by diethylamino-, then the ethylthiol thus obtained adds to the initial ester and the ester of 3-ethylthiopropylthioboric acid formed exchanges an alkylthio-group for a diethylamino-group:



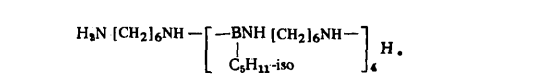
The replacement of an ethylthio-group by diethylamino- in mixed esters does not take place, as for the esters of alkylthioboric acids[87].

Dibutyl phenylthioborate and diethylamine react to form butyl diethylamino(phenyl)borate[79].

The reactions of esters of alkylthioboric acids with diamines proceed differently, depending on the nature of the latter. With ethylenediamine, 2-alkyl-1,3,2-diazoborolidines are obtained[42]:

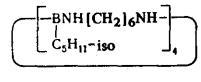


Gentle heating of dibutyl isopentylthioborate with two moles of hexamethylenediamine followed by removal of butylthiol and the unreacted diamine in a vacuum yields a benzene-soluble resinous linear polymer (I) of molecular weight 900, which includes in its structure four $RBNH[CH_2]_6NH-$ chains and an $NH_2[CH_2]_6NH$ terminal group[82]:



(I)

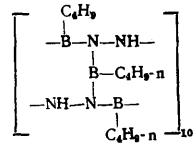
The reaction with equimolecular amounts of the reagents gives the cyclic polymer (II): structure:



(II)

A similar polymer is obtained in the reaction of hexamethylenediamine and dibutyl butylthioborate.

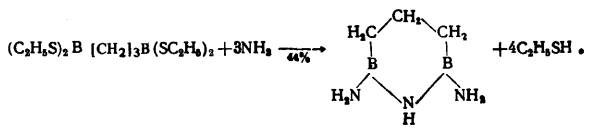
With hydrazine, the esters of alkylthioboric acids give polymers[82] probably having a reticular cyclic structure (III) in which each link contains three RB< groups and two >N–NH– groups, and the number of links is shown by molecular weight determinations to be 10.



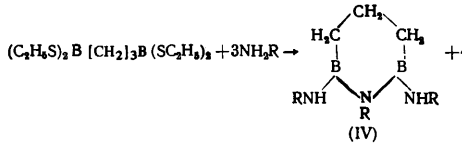
(III)

The reaction of hydrazine with an ester of phenylthioboric acid proceeds differently, leading to the formation of 3,6-diphenyl-3,6-dibora-1,2,4,5-tetrazine[82]:

The action of ammonia on tetraethyl propane-1,3-dithioborate yields 2,5-diamino-1-aza-2,5-diboracyclohexane[88]:

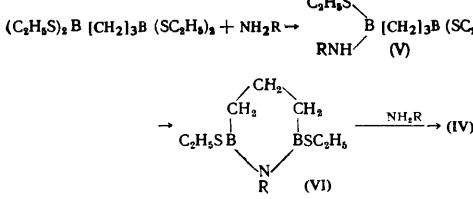


With primary amines (methylamine or ethylamine), cyclic compounds (IV) are also obtained—1-alkyl-2,5-di-(alkylamino)-1-aza-2,5-diboracyclohexanes:



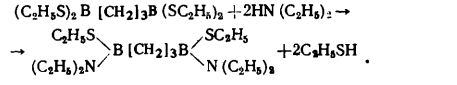
(IV)

In the first stage of the reaction one of the alkylthio-groups in the thio-ester is replaced by an alkylamino-group and the compound (V) which results is cyclised with loss of a thiol into compound (VI), which subsequently exchanges an alkylthio-group, being converted into a compound of type (IV):

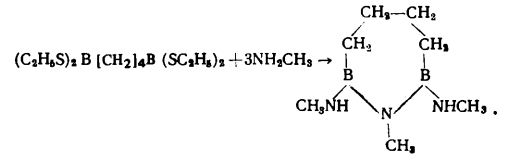


The reaction of tetraethyl propane-1,3-dithioborate with dimethylamine leads to 1,3-bis-[di(dimethylamino)bora]-propane[88].

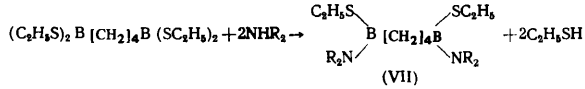
With diethylamine, esters of propane-1,3-dithioboric acid give, like esters of alkylthioboric acids, mixed (alkylamino)alkylthio-derivatives[88]:



The esters of butane-1,4-dithioboric acid react with amines similarly to the esters of propane-1,3-dithioboric acid[70]. The action of an excess of methylamine gives smoothly a seven-membered heterocyclic compound—1-methyl-2,7-bis(methylamino)-1-aza-2,7-diboracycloheptane:



In the reaction with secondary amines the replacement of two alkylthio-groups takes place very readily with the formation of 1,4-bis(dialkylaminoethylthiobora)butane (VII)[70]:



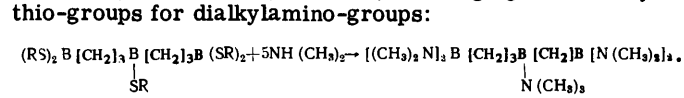
(VII)

The further replacement of alkylthio-groups is effected by the use of a large excess of the dialkylamine, heating (80–100°C), and periodically distilling off in a vacuum the thiol formed in the reaction:

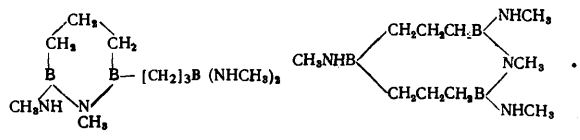
(VIII)

The reverse reaction—the replacement of the dimethylamino-group in compound (VIII) by ethylthio-groups—also proceeds with difficulty, only two of them being replaced, with formation of the compound (VII; R = CH_3).

1,1,5,9,9-Penta-alkylthio-1,5,9-triboranonanes react vigorously with dimethylamine[71], exchanging all the alkylthio-groups for dialkylamino-groups:

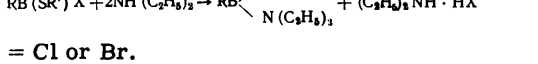


With methylamine a substance with structure (IX) or (X) is formed:



(IX) (X)

The action of diethylamine on esters of halogenoalkylthioboric acids causes halogen atom replacement by an alkylamino-group, with formation of esters of (diethylamino)alkylthioboric acids[43] resistant to further action by diethylamine:



where X = Cl or Br.

4. Reactions with Thiols, Hydrogen Sulphide, and Hydrogen Cyanide

Esters of dialkylthioboric acids are readily re-esterified by higher thiols on heating[52]:

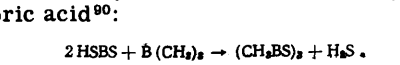
The equilibrium can be displaced completely to the right by removal of the low-boiling thiol.

Diethyl allylthioborate adds ethanethiol to form an ester of 3-ethylthiopropylthioborate[56,57].

When treated with hydrogen sulphide and heated to 140–180°C esters of organodialkylthioboric acids form dialkylthioboric acids and a thiol[89]:

Organothioboric acids withstand vacuum distillation. Prolonged heating of dibutylthioboric acid at 180–250°C decomposes it into hydrogen sulphide, hydrogen, butene, butane, and uninvestigated sulphur-containing organoboron compounds.

The reaction of esters of organoalkylthioboric acids with hydrogen sulphide, as a result of which anhydrides of alkylthioboric acids could be obtained, has not been investigated. One of the representatives of this class of compound—the trimer of the anhydride of methylthioboric acid—was obtained by the reaction of trimethylboron and metathioboric acid[90]:



The trimer is stable only in the solid state; in solutions a greater association of the anhydride is observed.

In solution the polymeric anhydride of metathioboric acid is oxidised by oxygen into $(CH_3OBS)_3$,[90] which can also be obtained by the action of trimethyl borate on metathioboric acid[31] or $(BrBS)_3$:[91]

$$(HSBS)_3 \xrightarrow[-B(SH)_3]{B(OCH_3)_3} (CH_3OBS)_3 \xleftarrow[-BBr_3]{B(OCH_3)_3} (BrBS)_3 .$$

Butyl dialkylthioborates react with hydrogen cyanide in the cold or on gentle heating to form dialkylcyanoborons[89]:

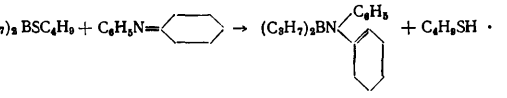
$$R_2BSC_4H_9\text{-}n + HCN \rightarrow [R_2BSC_4H_9\text{-}n \cdot HCN] \rightarrow R_2BCN + n\text{-}C_4H_9SH .$$

5. Reactions with Vinyl Esters, Cyclohexylideneaniline, and Nitriles

Esters of dialkylthioboric acids are capable of reacting with various classes of unsaturated organic compounds. Like thioborates they react with alkyl vinyl ethers, as a result of which alkyl vinyl sulphides and esters of dialkylboric acids are formed[39]. Evidently, as for thioborates the process proceeds by addition of the thioester at the multiple bond followed by β decomposition:

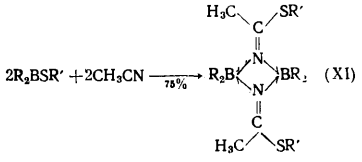
$$R_2BSC_4H_9 + CH_2=CHOC_4H_9 \rightarrow \left[R_2BCH_2CH\begin{matrix}OR\\SC_4H_9\end{matrix}\right] \rightarrow CH_2=CHSC_4H_9 + R_2BOR.$$

On heating an ester of dipropylthioboric acid with cyclohexanone anil, (cyclohexenylyl)phenylaminodipropylboron and a thiol are formed[39]:



Evidently the anil reacts in the tautomeric form as an enamine.

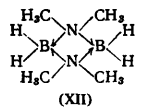
Esters of dialkyl and diaryl-thioboric acids are capable of adding at room temperature to acetonitrile with formation of 1,3-di-(1-alkylthioethylidene)-2,2,4,4-tetra-alkylcyclodiborazones (XI):[92]



where R′ = C_2H_5, or n-C_4H_9.

Infrared spectroscopy showed that in the first stage of the reaction the addition product $R_2BN{=}CCH_3(SR)$ is formed, which then dimerises into compound (XI). This is unchanged in air and is not decomposed at room temperature by alcohol, water, or even hydrochloric acid.

Concerning the nature of the chemical bond in derivatives of cyclodiborazane (XI), in these compounds, as in the dimers of aminoboranes (cyclodiborazanes), the trimers of aminoboranes (cyclotriborazanes), and other such compounds (trimers of phosphinoboranes, alkylthioboranes), all the bonds of the boron atom with a heteroatom (N, P, S) are equivalent. The equivalence of the chemical bonds in this type of compound, for example, in 1,1,3,3-tetramethylcyclodiborazane (XII)



(XII)

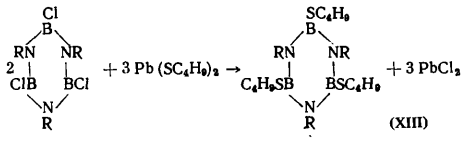
is attained by the formation of a special type of coordinate bond between the boron atom and the heteroatom. In this coordination interaction, each boron atom allows one tetrahedral orbital (sp^3) and one electron for covalent bonds with hydrogen atoms and one sp^3-orbital and $\frac{1}{2}$ electron for bonds with each neighbouring nitrogen atom. On the other hand, each nitrogen atom supplies an sp^3-orbital and one electron for its bonds with each carbon atom and one sp^3-orbital and 1.5 electrons for bonds with each neighbouring boron atom. It is desirable to call this type of bond semicoordinate and to represent it with a half-arrow.

In cyclodiborazanes of type (XI) the bond between the boron and nitrogen atoms also has a semicoordinate nature, the only difference being that each nitrogen atom in a $tr^2trtr\pi$ valence state provides for the double bond with the carbon atom one trigonal orbital (sp^2, or in another notation tr) and one π orbital whereas for the bond with each neighbouring boron atom one trigonal orbital (tr). The semicoordinate bonds formed by the trigonal orbitals of the nitrogen atom are stronger than those with tetrahedral orbitals.

IV. *B*-ALKYLTHIOBORAZOLES

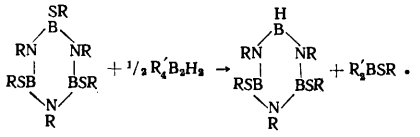
A. METHODS OF PRODUCTION

B-Trialkylthioborazoles (XIII) were synthesised by heating *B*-trichloroborazoles with lead mercaptides in benzene, the yields being 70–90%:[93]



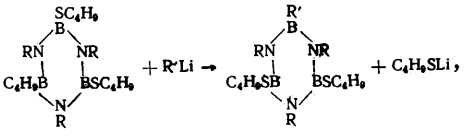
where R = H, CH_3, C_2H_5.

B-Trialkylthioborazoles served as starting materials for the synthesis of unsymmetrical *B*-dialkylthioborazoles. The latter were obtained by heating *B*-trialkylthioborazoles with tetrapropyldiborane[94]:



B-Dialkylthio-derivatives of borazole can also be obtained by the action of tetra-alkyldiborane on *B*-trichloroborazoles with subsequent treatment of the reaction products with lead mercaptide.

In the reaction of organomagnesium compounds with *B*-trialkylthioborazoles small yields of *B*-alkyl-*B*-dialkylthioborazoles are obtained[95]. With organolithium compounds the stepwise replacement of alkylthio-groups by alkyl radicals proceeds more smoothly and from *B*-trialkylthio-*N*-trialkylborazoles it was possible to obtain by this method *B*-alkyl-*B*-dialkylthio-*N*-trialkylborazoles in 62–65% yields:



where R = CH_3, C_2H_5, R′ = C_2H_5, n-C_4H_9.

B. PROPERTIES

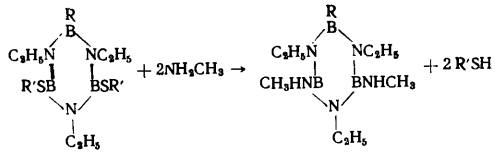
B-Trialkylthioborazoles are, like esters of organothioboric acids, highly reactive. With alcohols they exchange alkylthio-groups for alkoxyl groups in the cold to give *B*-trialkoxyborazoles.[95]

B-Tributylthioborazoles react in the cold with primary or secondary amines, forming the corresponding *B*-alkylamino-derivatives[93]. Thus *B*-tributylthioborazole and dimethylamine gave *B*-tri(dimethylamino)borazole (yield 97%) and the action of aniline on *B*-tributylthioborazole or *B*-tributylthio-*N*-triethylborazole gave respectively *B*-triphenylaminoborazole and *B*-triphenylamino-*N*-triethylborazole.

On introducing ammonia into a benzene solution of *B*-trialkylthioborazoles, *B*-triamino-substituted borazoles are obtained[93]. Like the esters of organothioboric acids, *B*-trialkylthioborazoles are capable of re-esterification on heating with higher thiols[96].

The synthesis of various unsymmetric derivatives of borazole has been effected from *B*-alkyl-*B*-dialkylthio-*N*-trialkylborazoles[95]. *B*-Butyl-*B*-dimethoxy-*N*-triethylborazole was obtained by treatment of *B*-butyl-*B*-dibutylthio-*N*-triethylborazole with methanol.

The reactions with primary or secondary amines take place with high yields:

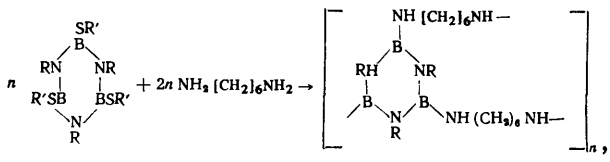


where R = C_2H_5, n-C_4H_9, R′ = n-C_4H_9.

B-Dialkylthio-*N*-trialkylborazoles undergo analogous exchange reactions with amines[96].

Starting from *B*-alkylthio-derivatives of borazole, three-dimensional and linear polymers can be obtained[97]. Polycondensation with participation of *B*-alkylthio-derivatives of borazole takes place under mild conditions ensuring retention of the borazole ring and the regularity of the repeating units.

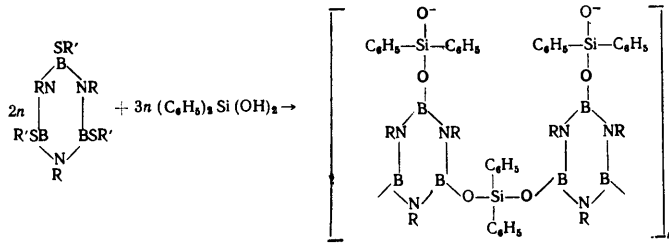
The condensation of the *B*-tributylthio-*N*-trialkylborazoles with hexamethylenediamine in *o*-xylene at 125°C gave polymers (XIV) which were thermostable powders, insoluble in ordinary organic solvents, hydrolysing in air:



(XIV)

where R = CH_3, C_2H_5.

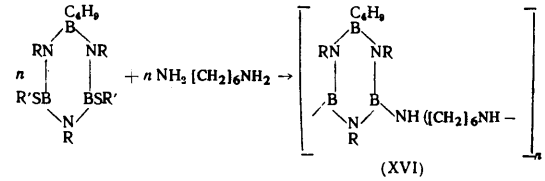
B-Tributylthio-*N*-trimethylborazole with diphenylsilandiol (1 : 1.5) in ethereal medium gives a powdered thermostable polymer (XV) not hydrolysed in air, soluble in tetrahydrofuran or dioxan:



(XV)

where R = CH_3.

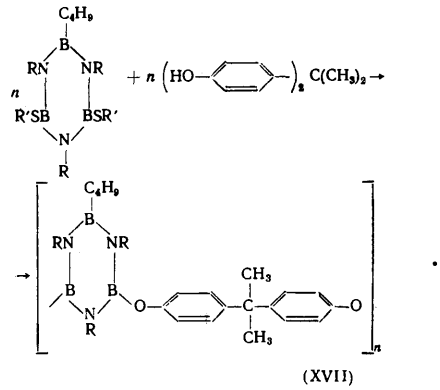
The condensation of *B*-butyl-*B*-dibutylthio-*N*-trialkylborazoles with hexamethylenediamine (1 : 1) in benzene gave linear polymers (XVI) which are brittle substances, less hydrolysed in air than three-dimensional polymers and more stable thermally (decomposition temperature > 400°C)[97]:



(XVI)

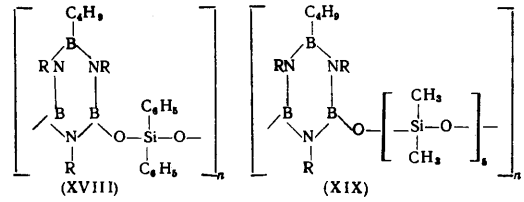
where R = CH_3, C_2H_5.

Linear polymers from *B*-butyl-*B*-dibutylthio-*N*-trialkylborazoles and 2,2-bis-(4-hydroxyphenyl)propane (XVII) are comparatively low-melting but more resistant to hydrolysis than polymers from hexamethylenediamine:



(XVII)

The reaction of *B*-butyl-*B*-dibutylthio-*N*-trimethylborazole and diphenylsilandiol[97] in boiling ethereal solution gives a viscous liquid of molecular weight ~ 1200, which corresponds with a cyclic trimer (XVIII; $n = 3$). Heating in a vacuum at 200°C converts the trimer into a brittle solid polymer (XVIII):



(XVIII) (XIX)

The condensation of *B*-butyl-*B*-dibutylthio-*N*-trimethylborazole with decamethyl-1,9-dihydroxypentasiloxane[97] in ethereal solution leads to a liquid with molecular weight ~ 1100, evidently possessing a cyclic structure (XIX; $n = 2$). On heating in a vacuum the dimer is converted into an elastic polymer (XIX) m.p. 146–149°C, which is not hydrolysed in air.

V. 1,2-THIABOROLANES

A. METHODS OF PREPARATION

1,2-Thiaborolanes are obtained by the addition of 1,2-dialkyl or 1,2-diaryl diboranes to allylthiol[98,99]:

$$^1/_2(RBH_2)_2 + CH_2{=}CHCH_2SH \rightarrow RB\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix} + H_2 ,$$

where R = n-C_4H_9, iso-C_4H_9, or C_6H_5.

2-Alkyl-1,2-thiaborolanes can be synthesised by heating mixtures of a boron trialkyl, trialkylamine–borane, and allenethiol[98]:

$$R_3B + 2\,H_3B\cdot N(C_2H_5)_3 + 3\,CH_2{=}CHCH_2SH \xrightarrow{110^\circ} 3\,RB\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix}.$$

B. PROPERTIES

Unlike the 2-alkyl-1,2-azaborolidines, which tend to dimerise[100], 1,2-thiaborolanes exist in a monomeric form. A feature of the cyclic structure of the 1,2-thiaborolanes appears in the definite ability to form complexes with amines which sharply distinguishes them from the related esters of dialkylthioboric acids R_2BSR.

An increase in the complex-forming ability of 1,2-thiaborolanes (and other such compounds: 1,2-azaborolidines, 1,2-oxaborolanes) is explained by the smaller reorganisation energy of the molecule compared with the acyclic compounds, when the boron atom changes from a trigonal to a tetrahedral valence state. The losses in reorganisation energy add up to the difference between the promotion energies of the boron atom from the ground state into tetrahedral and trigonal, 2.1 eV [101] and the decrease in the boron–element (C, S, N, O) bonds with decrease in the *s*-character of the boron orbitals.

In cyclic boron compounds, in which the angle of the C–B–X bonds in the ring (X = C, S, N, O) approaches the tetrahedral angle, during complex formation there is a weakening of only one (acyclic) boron–element bond, and not three, as occurs in compounds of the type BX_3, which is due to a decrease in the reorganisation energy. Strictly speaking, the energy of the outer B–X bond in the cyclic compound decreases to a larger extent in complex formation than in the compounds of the type BX_3, so that the *s*-character of the boron orbitals in this bond is greater than 0.33, but evidently the energetic losses occurring during this are less than in the change of two B_{tr}–X bonds into B_{te}–X bonds. The gain in reorganisation energy during complex formation in cyclic boron compounds in comparison with the acyclic analogues is adequate equal to more than adequate to compensate for the strain energy in the ring.

2-Butyl-1,2-thiaborolane forms a stable liquid complex with pyridine capable vacuum distillation without decomposition. Like other coordination compounds of boron this complex has a high dipole moment (5.2 D), whereas the dipole moment of the original thiaborolane is only 1.5 D.

Alkylthiaborolanes also form stable complexes with secondary and primary amines or ammonia (XX) which distil in vacuum without decomposition:

$$RB\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix} + L \rightarrow \begin{matrix}R\\ L\end{matrix}\!\!>\!B\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix} \quad (XX)$$

where R = n-C_4H_9, iso-C_4H_9; L = NH_3, $NH_2C_2H_5$, $NH(C_2H_5)_2$, NHn-C_4H_9, $NH(n\text{-}C_4H_9)_2$, HNC_5H_{10}.

In the infrared spectra of the compounds (XX; L = NHR_2) there are absorption bands in the region 3050–3300 cm^{-1} corresponding to the stretching vibrations of the N–H bonds and the absence of S–H bands. In the infrared spectrum of the compound (XX; L = NH_2R) there is an intense band with a maximum at 1582 cm^{-1} due to the deformation vibrations of the NH_2 groups.

Less stable complexes are given by alkylthiaborolanes with sterically hindered amines. Thus 2-butyl-1,5-thiaborolane forms a complex, with evolution of heat, with t-butylamine; however, on heating, the complex decomposes into the initial substances.

Unlike the primary and secondary amines, when alcohols act on 2-alkyl-1,2-thiaborolanes there is breaking of the B–S bond with formation of esters of (3-mercaptopropyl)alkylboric acids (XXI):

$$RB\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix} + R'OH \rightarrow \begin{matrix}R\\ R'O\end{matrix}\!\!>\!B{-}CH_2CH_2CH_2SH . \quad (XXI)$$

2-Butylthiaborolane reacts with 2-aminoethanol similarly to give crystalline 2-aminoethyl (3-mercaptopropyl)-butylborate:

$$n\text{-}C_4H_9B\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix} + HOCH_2CH_2NH_2 \rightarrow \begin{matrix}n\text{-}C_4H_9\\ HSCH_2CH_2CH_2\end{matrix}\!\!>\!B\begin{matrix}NH_2{-}CH_2\\ |\\ O{-}CH_2\end{matrix}.$$

The infrared spectra of compounds (XXI) have an absorption band in the 2580 cm^{-1} range (S–H); there is also strong absorption in the range for the B–O bond but OH absorption is absent. The fact that this reaction does not stop at the complex formation stage and nucleophilic substitution occurs at the boron atom can be explained by the weaker complex-forming ability of alcohols in comparison with amines and the higher energy of the B–O bond in comparison with the B–N bond.

In the reaction of butanol with the pyridine complex of 2-butyl-1,2-thiaborolane breaking of the B–S bond also occurs and pyridine and butyl (3-mercaptopropyl)butylborate are formed:

$$\begin{matrix}n\text{-}C_4H_9\\ C_5H_5N\end{matrix}\!\!>\!B\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix} + n\text{-}C_4H_9OH \rightarrow \begin{matrix}n\text{-}C_4H_9\\ n\text{-}C_4H_9O\end{matrix}\!\!>\!B{-}CH_2CH_2CH_2SH + C_5H_5N.$$

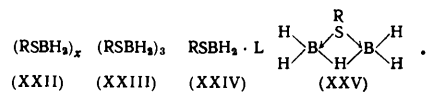
With piperidine the latter loses a molecule of alcohol, forming a piperidine complex of alkylthiaborolane:

$$\begin{matrix}n\text{-}C_4H_9\\ n\text{-}C_4H_9O\end{matrix}\!\!>\!BCH_2CH_2CH_2SH + C_5H_{11}N \rightarrow \begin{matrix}n\text{-}C_4H_9\\ C_5H_{11}N\end{matrix}\!\!>\!B\begin{matrix}S{-}CH_2\\ |\\ CH_2{-}CH_2\end{matrix} + n\text{-}C_4H_9OH.$$

VI. ALKYLTHIOBORANES

Various types of compound with alkylthio-groups and hydrogen atoms at the boron atom are known. These compounds, which differ in structure and properties, are classified together under the common name of "alkylthioboranes", since they contain the groupings $RSBH_2$ and

$(RS)_2BH$, with different modes of mutual coordination. Alkylthioboranes $RSBH_2$ are unknown in the monomeric form. They exist in the form of polymers (XXII), trimers (XXIII), and complexes with secondary or tertiary amines (XXIV):

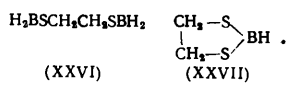


(XXII) (XXIII) (XXIV) (XXV)

A single representative of a fourth type of compound with an $RSBH_2$ grouping has been described, formed by coordination of methylthioborane with borane (XXV).

Of the $(RS)_2BH$ type of compounds di-t-butylthioborane, which exists in monomeric form, is stable. Other known dialkylthioboranes are associated to a certain extent and show a significant tendency to disproportionation.

1,2-Di(borylthio)ethane (XXVI) and 1,3,2-dithiaborolane (XXVII) have been obtained in associated form:



(XXVI) (XXVII)

1. Methods of Preparation

The reaction between diborane and thiols was first investigated by Burg and Wagner[12] for the example of methanethiol. On mixing the reagents at −78°C and holding the reaction mixture at that temperature for a few days a solid polymer of methylthioborane was obtained:

$$x/2\ B_2H_6 + x\ CH_3SH \rightarrow (CH_3S\ B\ H_2)_x + x\ H_2\ .$$

Treatment of the partly depolymerised reaction product with trimethylamine led to trimethylamine–methyl thioborane, $CH_3SBH_2.N(CH_3)_3$.

The action of diborane on a polymer of methylthioborane or trimethylamine–methylthioborane gave the thermally unstable methylthiodiborane, which rapidly decomposes at room temperature into diborane and the polymer $(CH_3SBH_2)_x$:

$$(CH_3SBH_2)_x + x/2\ B_2H_6 \rightarrow x\ CH_3SB_2H_5\ ,$$
$$CH_3SBH_2 \cdot N(CH_3)_3 + B_2H_6 \rightarrow CH_3SB_2H_5 + H_3B \cdot N(CH_3)_3 .$$

Subsequently the reactions between diborane and thiols were carried out in ethereal medium using the ordinary laboratory techniques, which allowed experiments to be performed on a large scale and the properties of the compounds thus formed to be widely investigated.

On introducing 1 mole diborane into an ethereal solution of 2 moles thiol a steady evolution of hydrogen was observed. After the reaction had ceased and the solvent had been removed in a vacuum the residue contained a solid polymer (when methanethiol or 2-methylpropane-2-thiol were used) or a syrupy product (for ethanethiol, propane-1-thiol, or butane-1-thiol)[14,102]:

$$x/2\ B_2H_6 + x\ RSH \rightarrow (RSBH_2)_x + x\ H_2\ .$$

The polymers of ethyl-, propyl-, and butyl-thioborane are converted on standing into trimers of alkylthioboranes (1,3,5-trialkylcyclotriborathianes); the polymers of methyl- and t-butyl-thioboranes are converted into trimers in tetrahydrofuran solution[14,102]:

$$(RSBH_2)_x \rightarrow x/3\ (RSBH_2)_3\ .$$

The trimers of alkylthioboranes, with the exception of the trimer of t-butyl thioborane (m.p. 105–107°C) are liquids which distil without decomposition in a vacuum.

When pentane-1-thiol, phenylmethanethiol, or thiophenol react with diborane (2 : 1) in tetrahydrofuran or Diglyme 2 moles hydrogen are rapidly liberated. The RS-substituted boranes thus formed are not isolated from the solutions and are identified solely by their infrared and NMR spectra[103,104].

Polymeric 1,2-di(borylthio)ethane is obtained from diborane and 1,2-dithioethyleneglycol[105]:

$$B_2H_6 + HSCH_2CH_2SH \rightarrow H_2BSCH_2CH_2SBH_2 + 2\ H_2\ .$$

Dipropylthioborane and dibutylthioborane are obtained by passing diborane into ethereal solutions of the corresponding thiols (1 : 4) and subsequent distillation of the reaction products[15,16]:

$$B_2H_6 + 4\ RSH \rightarrow 2\ (RSH)_2BH + 2\ H_2\ .$$

The general method for obtaining dialkylthioboranes is the reduction of alkylthioborates with lithium tetrahydroaluminate in ethereal medium[106]:

$$4\ B\ (SR)_3 + LiAlH_4 \rightarrow 4\ (RS)_2BH + LiSR + 2\ Al(SR)_3\ .$$

Dialkylthioboranes can be obtained from the trimers of alkylthioboranes and thioborates in the distillation of mixtures of these substances in the ratio 1 : 3.

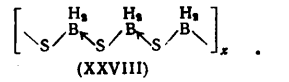
$$(RSBH_2)_3 + 3\ (RS)_3B \rightarrow 6\ (RS)_2BH\ .$$

The synthesis of di-t-dodecylthioborane from aminoborane and t-dodecanethiol[49] has also been described[49]. Associated 1,3,2-dithiaborolane is obtained by the reaction of diborane and dithioethylene glycol[105]:

In the reaction of diborane and triphenylthioborate (1 : 4) in tetrahydrofuran, diphenylthioborane is formed[104], which was not isolated in a pure state and was identified solely by its NMR spectrum (doublet at −24 p.p.m., J = 140 Hz).

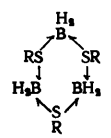
2. Physical Properties

The polymers of the alkylthioboranes are solids or syrupy substances and most of them swell in ether, are insoluble in benzene, but soluble in tetrahydrofuran. The association of the molecules of alkylthioboranes is effected by donor–acceptor bonds between the boron and sulphur atoms (XXVIII):



(XXVIII)

The trimers of alkylthioboranes are liquids with a cyclic structure (XXIX) with semicoordinate bonds between the boron and sulphur atoms, similar to the semicoordinate B–N bonds (see p. 944).



(XXIX)

The dipole moment of 1,3,5-triethylcyclotriborathiane is 2.90 D, and that of 1,3,5-tributylcyclotriborathiane, 3.16 D.

The infrared spectra of 1,3,5-trialkylcyclotriborathianes have two intense absorption bands in the range 2412–2420 cm^{-1} and 2465–2470 cm^{-1}, corresponding to the stretching vibrations of the B–H bonds.

In the ^{11}B NMR spectra of 1,3,5-triethylcyclotriborathiane at 25°C there is a broad peak (chemical shift +31 p.p.m. relative to trimethyl borate). At 90°C the broad peak is converted into a triplet with a 1 : 2 : 1 ratio of intensities[107].

In the proton magnetic resonance spectrum of 1,3,5-trimethyl cyclotriborathiane (internal standard tetramethylsilane, $\delta = 0$) there is a singlet from the protons of the methyl groups at $\delta = 2.14 \pm 0.03$ p.p.m. and a quadruplet from the protons connected with the boron, centred at $\delta = 2.35 \pm 0.02$ p.p.m., $J_{BH} = 115 \pm 5$ Hz.

The properties of the dialkylthioboranes are determined by the nature of the alkyl groups. The infrared spectrum of monomeric di-t-butylthioborane has an absorption band at 2545 cm^{-1} corresponding to the B–H stretching vibrations. The ^{11}B NMR spectrum at room temperature is a weakly resolved doublet with chemical shift −40.7 p.p.m. relative to $B(OCH_3)_3$. Other dialkylthioboranes tend to disproportionate and even in freshly distilled specimens the presence of ~ 20% thioborate and alkylthioboranes of a different degree of association is observed spectroscopically. During the disproportionation of the methyl and ethyl derivatives equilibrium is reached when the mixture contains ~ 20% dialkylthioborane:

$$2(RS)_2BH \rightleftarrows (RS)_3B + RSBH_2 .$$

On standing, di-isopropylthio- and dibutylthio-boranes are completely symmetrised[108]. 1,3,2-Dithiaborolane exists in the gas phase as a monomer[105]. The frequency of the B–H vibrations drops from 2595 cm^{-1} in the vapour to 2435 cm^{-1} in the solid state.

3. Chemical Properties

a. Thermal Changes. Most of the known polymers of the alkylthioboranes are slowly and spontaneously converted into trimers at room temperature[14,102]. The solid polymers of methylthioborane and t-butylthioborane are exceptions; they are converted into trimers on dissolution in tetrahydrofuran.

The trimers of alkylthioboranes (1,3,5-trialkylcyclotroborathianes) are more stable thermally and can be distilled in a vacuum, with the exception of the trimer of n-butylthioborane, which undergoes partial decomposition on distillation. Other trimers also decompose above 100°C. Thus the trimer of ethylthioborane distils from a small fractionating column without decomposition but in distillation with an efficient column the trimer decomposes, the products obtained being readily volatile substances and a very viscous distillate which ultimate analysis shows to have the composition $[(C_2H_5S)_3B_2H_3]_x$.

The results[107] suggesting that the polymeric product of composition $[(C_2H_5S)_3B_2H_3]_x$ is formed in the reaction of diborane with ethanethiol in the ratio 1 : 3 is erroneous. In reality at this ratio the reagents replace two of the hydrogen atoms in BH_3 by ethylthio-groups to only a slight extent and on distillation of the reaction products the trimer of ethylthioborane $(C_2H_5SBH)_3$ is obtained in high yield (up to 80%)[108].

b. Oxidation and Protonolysis. The trimers of the alkylthioboranes (1,3,5-trialkylcyclotriborathianes) are stable in relation to oxidants. They are almost unchanged in air and are completely unoxidised even on boiling with hydrogen peroxide in alkaline solution[14].

The polymers and trimers of the alkylthioboranes exhibit different stability towards hydrolysis. The polymers are readily hydrolysed at room temperature, whereas the trimers are only slowly hydrolysed on heating in water.

With alcohols the polymers of the alkylthioboranes readily react in the cold; alcoholysis of the trimers at room temperature proceeds very slowly, but on boiling with the alcohols they are completely decomposed, being converted into the corresponding borates, with liberation of hydrogen[14]:

$$(RSBH_2)_3 + 9\,R'OH \rightarrow 3\,B(OR')_3 + 6\,H_2 + 3\,RSH .$$

With thiols the trimers react at 100–120°C to form alkyl thioborates[14]:

$$(RSBH_2)_3 + 6\,RSH \rightarrow 3\,B(SR)_3 + 6\,H_2 .$$

Dialkylthioboranes are quantitatively hydrolysed by water in the cold to boric acid; with alcohols they give alkyl borates. The replacement of hydrogen by the alkylthio-group in dialkylthioboranes starts only at 50–60°C and proceeds rather vigorously at ~ 100°C.[15,16]

c. Reactions with amines. The trimers of the alkylthioboranes react at room temperature with secondary and tertiary amines. The reactions take place with breaking of the ring and lead to the formation of amine complexes of alkylthioboranes[109,110]:

$$(RSBH_2)_3 + 3\,R'_2R''N \rightarrow 3\,RSBH_2 \cdot NR'_2R'' ,$$

where R″ = H or alkyl.

The polymers of alkylthioboranes also give aminoalkylthioboranes with amines.

Amine complexes of the alkylthioboranes are formed by the reaction of diborane with aliphatic sulphenylamines[111]:

$$^1/_2\,B_2H_6 + CH_3SNR_2 \rightarrow CH_3SNR_2 \cdot BH_3 \rightarrow CH_3SBH_2 \cdot NHR_2 .$$

The complexes of the alkylthioboranes with tertiary amines are non-associated liquids, stable at room temperature but partly decomposing on heating[110].

The complexes of the alkylthioboranes with secondary amines undergo further changes on heating with formation both of products of the replacement of the alkylthio-groups (dialkylaminoboranes) and products with replacement of hydrogen—dialkylamino(alkylthio)boranes[110,111]:

$$RSBH_2 \cdot NHR'_2 \rightarrow \begin{cases} \rightarrow R'_2NBH_2 + RSH \\ \rightarrow R'_2N\diagdown\!\!\diagup BH + H_2 \end{cases} .$$

The reactions of amine complexes of alkylthioboranes with hydrogen chloride and with halogen derivatives of hydrocarbons have been studied[109,112]. The complexes of alkylthioboranes with dimethylamine are converted into the corresponding boronium salts with these reagents:

$$2\,RSBH_2 \cdot NH(CH_3)_2 + HCl \rightarrow \{H_2B[NH(CH_3)_2]_2\}Cl + 1/3\,(RSBH_2)_3 + RSH$$
$$2\,RSBH_2 \cdot NH(CH_3)_2 + R'X \rightarrow \{H_2B[NH(CH_3)_2]_2\}X + 1/3(RSBH_2)_3 + RSR .$$

Trialkylamine–alkylthioboranes are split by hydrogen chloride, regenerating the orginal trimer. They undergo exchange reactions with the halogen derivatives of hydrocarbons, as a result of which amine complexes of halogenoboranes and dialkyl sulphides are obtained:

$$RSBH_2 \cdot NR'_3 + R''X \rightarrow XBH_2 \cdot NR'_3 + RSR'' .$$

The complexes of alkylthioboranes with pyridine behave uniquely in relation to the halogen derivatives of hydrocarbons. With carbon tetrachloride they are converted into bis(pyridine)boronium chloride:

$$RSBH_2 \cdot NC_5H_5 + CCl_4 \rightarrow [H_2B(NC_5H_5)_2]Cl$$

and with alkyl halides they exchange an alkylthio-group for halogen:

$$RSBH_2 \cdot NC_5H_5 + R'X \rightarrow XBH_2 \cdot NC_5H_5 + RSR' .$$

There is a very interesting reaction between dimethylamine–ethylthioborane and dimethylammonium chloride, leading to the formation of bis(dimethylamino)boronium chloride:

$$RSBH_2 \cdot NH(CH_3)_2 + (CH_3)_2NH_2Cl \rightarrow \{H_2B[NH(CH_3)_2]_2\}Cl + RSH .$$

1,3,5-trialkylcyclotriborathiane also reacts readily with primary amines but the reaction is different from that with secondary and tertiary amines[113]. When methylamine or ethylamine react with the trimers of the alkylthioboranes, irrespective of the ratio of the reagents, boronium salts are obtained–mercaptides of bis(methylamino)boronium or bis(ethylamino)boronium, respectively:

$$(RSBH_2)_3 + 6\,R'NH_2 \rightarrow 3\,[H_2B(NH_2R')_2]SR .$$

The mercaptide ion of bis(alkylamino)boronium mercaptides is replaced by the chloride ion when they are treated with an ethereal solution of hydrogen chloride:

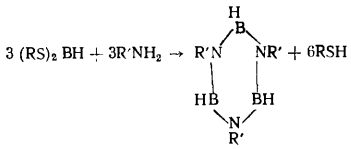
$$[H_2B(NH_2R')_2SR + HCl \rightarrow [H_2B(NH_2R')_2]Cl + RSH .$$

A similar exchange takes place on reaction with benzyl chloride.

Bis(alkylamino)boronium chlorides can be obtained directly from the trimers of alkylthioboranes with primary amines in the presence of benzyl chloride:

$$(RSBH_2)_3 + 6\,NH_2R' + 3\,C_6H_5CH_2Cl \rightarrow 3\,[H_2B(NH_2R')_2]Cl + 3\,C_6H_5CH_2SR .$$

Dialkylthioboranes react with amines at room temperature. With primary amines, dialkylthioboranes give *N*-trialkylborazoles[16]:



where R′ = C_2H_5, n-C_4H_9.

With secondary amines, depending on the nature of the reagents dialkylamino(alkylthio)boranes RS(R_2N)BH or bis(dialkylamino)boranes are obtained[114]:

$$(RS)_2BH + 2R'_2NH \rightarrow (R'_2N)_2BH + 2RSH .$$

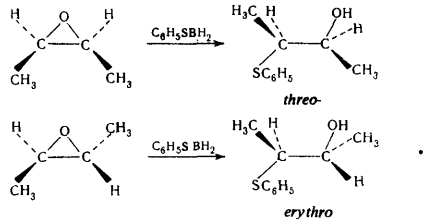
The reactions of dialkylthioboranes with tertiary amines lead to the formation of $(RS)_2BH$.amine complexes. 1,3,2-Dithiaborolane forms complexes with trimethylamine and trimethylphosphine[105].

d. Reactions with Ethers, Oxides, and Carbonyl Compounds. Phenylthioborane, pentylthioborane, and benzylthioborane are split into ethers at room temperature[103,104]:

$$RSBH_2 + R'{-}O{-}R' \rightarrow RSR + H_2BOR'' .$$

For example, in 1,2-dimethoxyethane at 25°C phenylthioborane is 79% converted after 20 h into thioanisole, and in tetrahydrofuran it gives 4-(phenylthio)butan-1-ol in 45% yield after 3 h.

Oxides of unsaturated hydrocarbons react with phenylthioborane and alkylthioboranes (pentylthio- and benzylthio-derivatives) with breaking of the oxide ring[104,115] The stereochemical direction of these reactions depends on the nature of the oxides[115]. In the reaction of phenylthioborane with *cis*- and *trans*-2,3-epoxybutane trans-opening of the epoxide ring occurs, since as a result only the *threo*- and only the *erythro*-3-phenylthiobutan-2-ols respectively are formed:



The reaction of phenylthioborane with cyclohexene is just as selective, leading to the trans-2-phenylthiocyclohexanol. The stereochemical course of these reactions is inconsistent both with a four-centre mechanism[103] and a mechanism with participation of carbonium ion intermediates. The mechanism of the trans-opening of the oxide ring in this reaction remains uncertain.

The reaction of phenylthiol with *trans*-αα′-epoxybibenzyl is complicated, and with diglyme as a solvent only 6% *threo*- and 6%-*erythro*-1,2-diphenyl-2-phenylthioethanol are obtained, the main product (45%) being 1,2-diphenylethanol.

Phenylthioboranes obtained from thiophenol and diborane in tetrahydrofuran, react with optically active L-(−)-styrene oxide with the formation of only L-(−)-2-phenyl-2-phenylthioethanol.

Phenylthioborane reduces carbonyl compounds and acids (benzaldehyde, acetophenone, benzoic acid, ethyl benzoate) in alcohols but does not react with benzyl chloride[104].

d. Reactions with alkenes. The polymers of alkylthioboranes react with alkenes in ethereal medium, and the course of the process depends on the nature of the reagents[74]. A polymer of methylthioborane in the form of a gelatinous mass containing only a little solid polymer adds to ethylene, hex-1-ene, or cyclohexene with gentle heating (1.5 h at 50°C) with the formation of the corresponding esters of dialkylthioboric acids:

$$(CH_3SBH_2)_x + \text{olefin} \rightarrow R_2BSCH_3 .$$

The hydroboronation of ethylene or propene by the polymer of butylthioborane is accompanied by symmetrisation in which, as well as the butyl dialkylborate, appreciable amounts of borontrialkyl and dibutylthioborane are obtained. The reaction with hex-1-ene is smoother, leading to a satisfactory yield of an ester of dihexylthioboric acid.

In the hydroboronation of hex-1-ene by phenylthioborane in tetrahydrofuran solution (25°C, 1–1.5 h) and subsequent methanolysis of the reaction products methyl dihexylborate (45%) and dimethyl hexylborate (21%) are formed. The reaction of phenylthioborane with styrene is similar. Oxidation of the hydroboronation products gives 2-phenylethanol and 1-phenylethanol in 91 : 9 ratio[104].

The reaction of polymers of alkylthioboranes with diene hydrocarbons leads to the boron-containing heterocyclic compounds (see Section III. A. 4.).

The trimers of alkylthioboranes do not react with unsaturated compounds at room temperature. When the reaction is carried out in boiling ether a complex mixture of substances is obtained. Thus in the reaction of the trimer of ethylthioborane (erroneously taken to be triethylthiodiborane) and oct-1-ene triethyl borate (10%), diethyl octylthioborate (20%), and ethyl dioctylthioborate (15%) are formed[116].

Dialkylthioboranes are less active hydroboronation agents than the polymers of alkylthioboranes. The reaction of dibutylthioborane with hex-1-ene, oct-1-ene, or cyclohexene takes place at room temperature and more rapidly on heating, and butyl esters of the corresponding alkylthioboric acids are obtained[73].

In the reaction of diphenylthioborane with styrene in tetrahydrofuran and the subsequent oxidation of the reaction products, 2-phenylethanol and 1-phenylethanol were isolated in 95 : 5 ratio with a yield of 77%.[104]

VI. DIALKYLAMINO(ALKYLTHIO)BORANES

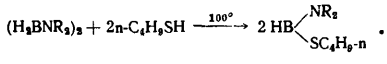
An unusual class of mixed sulphur-containing compounds of boron is the dialkylamino(alkylthio)boranes (XXX):

(XXX)

A. METHODS OF PREPARATION

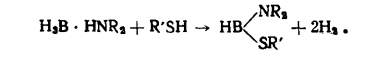
1. Synthesis of Dialkylamino(alkylthio)boranes from Dimers of Dialkylaminoboranes

Dialkylamino(alkylthio)boranes are obtained on heating dimers of dialkylaminoboranes with thiols[117,118]:

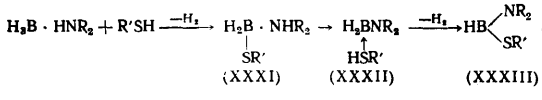


2. Synthesis of Dialkylamino(alkylthio)boranes from Dialkylamine–Boranes

It is preparatively more convenient to obtain dialkyl amino(alkylthio)boranes by heating dialkylamine–boranes with thiols[117,119]. Reaction with liberation of hydrogen starts 70–80°C, proceeds vigorously at 100°C, and ends on briefly raising the temperature to 120–130°C

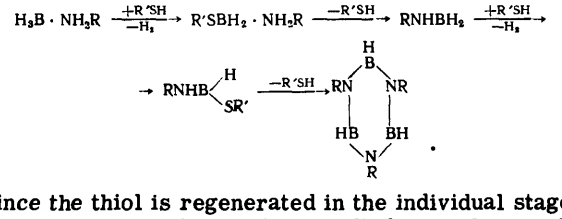


In the first stage of the reaction a complex of dialkylamine with alkylthio boranes (XXXI) is formed with liberation of hydrogen and is then converted into a complex of a dialkylaminoborane with a thiol (XXXII). The latter loses hydrogen to give the final product (XXXIII):



(XXXI) (XXXII) (XXXIII)

It should be noted that when heated with a thiol the complexes of borane with primary amines are converted into *N*-trialkylborazoles in high yield[120]



Since the thiol is regenerated in the individual stages of the reaction the synthesis of *N*-trialkylborazoles can be carried out using a catalytic amount of the thiol.

3. Synthesis of Dialkylamino(alkylthio)boranes from Dialkylamine–Alkylthioboranes

Complexes of the alkylthioboranes give, on heating with secondary amines, dialkylamino(alkylthio)boranes in 60–88% yield[110]:

The processes are complicated by side-reactions, as a result of which a thiol and a bis(dialkylamino)borane are formed.

4. Synthesis of Dialkylamino(alkylthio)boranes from Dialkylthioboranes and Amines

Dialkylamino(alkylthio)boranes are obtained by the reaction of dialkylthioboranes and secondary amines[114]:

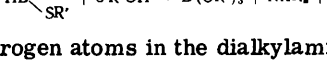
The reaction starts at room temperature and requires brief heating to complete it.

B. PROPERTIES

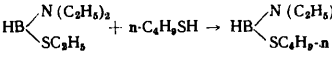
Dialkylamino(alkylthio)boranes are colourless mobile liquids with an extremely unpleasant odour, rather rapidly hydrolysed and oxidised in air. They are miscible with organic solvents in any proportions; they are not decomposed nor symmetrised at ~ 200°C. In the infrared spectra there are absorption bands in the range 2485–2500 cm^{-1}, corresponding to the B–H vibrations.

1. Reactions with Alcohols and Thiols

Dialkylamino(alkylthio)boranes react vigorously with alcohols at room temperature with liberation of hydrogen; initially the R_2N–and RS groups are replaced and then the dialkoxyboranes already formed are converted into borates[121]:

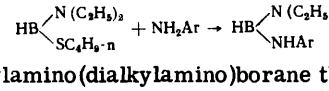


The hydrogen atoms in the dialkylamino(alkylthio)-boranes are not replaced by alkylthio-groups on heating with thiols, even up to 200°C. On using higher thiols re-esterification[12] occurs, like that which takes place in the esters of dialkylthioboric acids[52]:



2. Reactions with Amines

Dialkylamino(alkylthio)boranes with aromatic amines under mild conditions exchange an alkylthio-group for an arylamino-group[121]:



The arylamino(dialkylamino)borane thus formed reacts in its turn with an aromatic amine at 60–80°C, with the

arylamino-group replacing not hydrogen but the dialkylamino-group, as a result of which a bis(arylamino)borane is obtained:

$$HB\begin{matrix}N(C_2H_5)_2\\NHAr\end{matrix} + NH_2Ar \rightarrow HB(NHAr)_2 + NH(C_2H_5)_2 .$$

Similarly, under the action of primary aliphatic amines, bis(arylamino)boranes are obtained[118]:

$$HB\begin{matrix}N(CH_3)_2\\SR'\end{matrix} + 2NH_2R \rightarrow HB(NHR)_2 + NH(CH_3)_2 + R'SH .$$

The reaction of dialkylamino(alkylthio)boranes with secondary amines is peculiar[121,122]. When diethylamino-(butylthio)borane is heated with diethylamine the equilibrium:

$$HB\begin{matrix}N(C_2H_5)_2\\SC_4H_9\text{-}n\end{matrix} + NH(C_2H_5)_2 \rightleftarrows HB[N(C_2H_5)_2]_2 + n\text{-}C_4H_9SH$$

is established.

Heating bis(dimethylamino)borane with butylthiol leads to the same equilibrium mixture. In this last instance a dialkylamino-group at the boron atom is replaced by an alkylthio-group, whereas the reverse process—the replacement of the RS group by the R_2N group—usually occurs, as in the action of amines on esters of organothioboric acids[63,87]. The above equilibrium can be displaced completely to the right if the amine used boils at a higher temperature than the thiol product, which can then be distilled from the reaction mixture:

$$HB\begin{matrix}N(C_5H_{11}\text{-iso})_2\\SC_3H_7\text{-}n\end{matrix} + NH(C_5H_{11}\text{-iso})_2 \rightarrow HBN(C_5H_{11}\text{-iso})_2 + n\text{-}C_3H_7SH .$$

Under the action of an equimolecular amount of methylaniline on diethylamino(butylthio)borane both the RS–and R_2N–groups are replaced, and half the original organoboron compound remains. At a reagent ratio of 1 : 2, bis-(*N*-methyl-*N*-phenylamino)borane is obtained in 83% yield[122].

The low mobility of the hydrogen atom in dialkylamino-(alkylthio)boranes also appears in their inability to add to alkenes even under comparatively severe conditions in which the dimer of diethylaminoborane hydroborates but-1-ene and oct-1-ene[117]. Hence the ease of nucleophilic replacement of various groups at the boron atom in dialkylamino(alkylthio)boranes decreases in the following series: RS > NR_2 > H.

---o0o---

As the above shows, sulphur-containing organic compounds of boron exhibit increased reactivity in comparison with their oxygen analogues, expressed in their tendency to form complexes and exchange RS groups for other groupings. This is explained, on the one hand, by the lower ionisation potential[123] of the unshared pair at the sulphur atom (13.64 eV) in comparison with oxygen (18.70 eV), and on the other by the relatively low value of the energy of the B–S bond ($\sim$ 70 kcal mole^{-1})[5] compared with that of the B–O bond (110–115 kcal mole^{-1}) and at the same time there is the similarity in the energies of the N–H (85 kcal mole^{-1}), B–N (80 kcal mole^{-1}), and S–H (87 kcal mole^{-1}) bonds[124]. Because of this, reactions with breaking of B–S bonds, leading to the formation of bonds between the boron and other elements (N, O), seem energetically favourable.

Readily accessible alkylthioborates which are smoothly obtained from boron trichloride and thiols in the presence of tertiary amines seemed suitable for the synthesis of various classes of sulphur-containing esters of organothioboric acids. In turn these esters can be used with success in the synthesis of various other types of organoboron compounds.

A feature of the methods of synthesis developed is that Grignard reagents are not used. The starting compounds are boron trialkyls, obtainable from diborane and alkenes, which by a combination of new synthetic procedures are readily converted into reactive sulphur-containing organoboron compounds, which can then be used for further syntheses. A second source of organoboron compounds is the "alkylthioboranes" obtainable from diborane and thiols, which are of independent theoretical interest in the chemistry of boron.

Electron Transfer as an Elementary Act of Organic Reactions

K.A.Bilevich and O.Yu.Okhlobystin

Many heterolytic reactions are often accompanied by radical processes and contrariwise the reactions of radicals in many instances lead to the formation of ions. The simultaneous occurrence of homolytic and heterolytic processes cannot be explained from the viewpoint of the now generally accepted theory of organic reactions. These contradictions can be easily resolved if it is assumed that the formation of a new bond is preceded by the transfer of an electron from one reacting entity to another.

In the present work on the basis of voluminous literature material the conclusion is drawn that electron transfer processes actually play an important part in many organic reactions (reactions with free metals, some substitutions, etc.).

The influence of various factors on electron transfer processes is examined. Assumptions concerning the relative role of these processes in the formation and reactions of organometallic compounds are advanced. There is a bilbiography of 242 references.

I. INTRODUCTION

Many of the concepts of contemporary theoretical chemistry built up in the first half of the XXth century and which are indisputably of use in chemistry need not now be regarded as absolute. This relates, for example, to attempts to positively divide reactions which really proceed according to a cyclic transfer scheme into electrophilic and nucleophilic[1,2]. Frequently on the basis of such a division one of the reacting species is essentially regarded arbitrarily as the "reagent" and the other as the "substrate". Dessy and Paulik[2] recently criticised the expediency of such a categoric classification for examples of a multicentre mechanism.

The same uncertainty arises also in attempts to divide strictly reactions into homolytic and heterolytic. Usually the problem of the homolytic or heterolytic nature of a process becomes unnecessary ultimately. In most instances only the fact of the formation of radical products in ionic reactions (or, contrariwise, the production of ions in free radical reactions) is stated but these processes are regarded as side-reactions which proceed in parallel with the main reaction.

Apparently such a contradiction can be resolved if it is assumed that the formation of a new bond is preceded by the transfer of electrons from one reacting species to another (by virtue of a difference in electron affinity and the greater mobility of the electron cloud in comparison with the nuclei or entire fragments of the molecules). Assumptions of this type are sometimes regarded as one of the possible approaches to the classification of organic reactions[3], but really these considerations have until recently not been taken into account in examining particular mechanisms.

In examining different electrochemical processes, Semenov[4] noted that "... strictly speaking, in a single act one electron is transferred, since the simultaneous transfer of two electrons is a much less probable event". Despite the considerable differences between chemical changes and electrode processes, this position, it seems to us, must be taken into account in studying organic reactions when the sources of electrons are metals, ions, or neutral molecules.

Heterolytic breaking of a non-ionic bonds with not too pronounced solvation effects is energetically less favourable than homolytic breaking, since in the first instance additional energy is needed for the preliminary polarisation of the bond[5,6]. More and more information is becoming available showing that the so-called homolytic dissociation is usually a minimum bimolecular process[7,8] and one of the reagents can also serve to localise an electron[9].

Electron transfer is a widely distributed phenomenon in inorganic redox reactions and various photochemical and radiation-chemical processes[10,11].

Finally, extensive although insufficiently systematised material about organic reactions of electron transfer is being accumulated and the tempo of the increase in new facts in this region is so high that the idea naturally arises that reactions of this type actually permeate the whole of organic chemistry including the field of "classical" heterolytic reactions.

This article is an attempt to generalise and systematise these facts, although it is hardly possible to deal with them exhaustively within the framework of the present review.

II. FORMATION OF STABLE RADICAL-IONS

The most typical electron transfer reactions, where the very fact of the transfer of just one electron is unquestioned, are reactions for the formation of radical-ions (RI). Since in this instance the electron transfer is usually not complicated by side-processes and the RI itself is readily identified by EPR methods and ultraviolet spectroscopy, these reactions are an extremely convenient model for studying electron transfer in organic reactions. Some typical examples of monoelectron transfer reactions are given in Table 1.

Table 1. Types of electron transfer.

Reaction	Electron donors	Electron acceptors (EA)
Reduction by metals	M = alkali or alkaline earth metals or its amalgam	aromatic and heterocyclic compounds, arylalkyl and diaryl ketones, imines of diaryl ketones, nitro-compounds, some organoelemental compounds
Electrochemical reduction	cathode	ditto
Electrochemical oxidation	aromatic hydrocarbons, amines	anode
Reduction by anions	organometallic compounds of active metals, alkoxides, iodide ion	aromatic compounds, diaryl ketones, aromatic diazo-compounds, tetracyanoethylene, nitro-compounds
Reduction by Lewis bases	aromatic hydrocarbons, amines, alkenes	nitro-compounds, tetracyanoethylene, stable radicals, carbonium ions
Oxidation	aromatic hydrocarbons, amines, metallocenes, free radicals	conc. H_2SO_4, $AlCl_3 + CH_3NO_2$, $SbCl_5$, tetracyanoethylene, heavy metal cations, nitro-compounds

A large number of organic compounds of different classes exhibit the capability to receive one electron with the formation of anionic radicals (AR).[12] This relates to aromatic[13-16] and heterocyclic[11-20] systems and also to systems which contain conjugated bonds[21-23] and electron-withdrawing groups[24,25]. Initial reports of the production of AR of cyclopropane, adamantane, hexamethylenetetramine, spiropentane, and 1-methyladamantane proved erroneous[26].

Reports recently appeared about the production of a series of organoelemental AR, containing boron[27,28], silicon[29,30], germanium[30], nitrogen[31,32], phosphorus[33-35], and transition metals[36].

Under the action of oxidants, aromatic[37] and heterocyclic[38] compounds and also some amines[39-40] can give up one electron to form cationic radicals (CR).

1. Reduction by Metals

Historically the first and therefore now the most developed method of production of stable AR are reactions with free metals. The ease of formation of AR depends on a series of factors, the most important of which are the affinity of the acceptor for an electron, the solvating capability of the medium, and the donor ability of the electron source. In a series of aromatic hydrocarbons the capability for reduction rises on going from benzene to condensed aromatic hydrocarbons: benzene < biphenyl < < naphthalene < anthracene < tetracene[41,42]. The introduction of electron-withdrawing substituents also acts in the same direction. The ease of transfer of an electron to the molecule of the acceptor from a metal is determined by the donor capability of the latter. However, the quantitative evaluation of this capability encounters considerable difficulties: in particular it is impossible to use standard electrode potentials in water, the photochemical work function, etc. In most instances alkali or alkaline earth metals or their amalgams[12] are used for reduction, but when the acceptor molecule has a sufficiently high electron affinity heavy metals can also act as reductant. For example, tetracyanoethylene forms an AR on reduction with copper powder[43]:

$$(CN)_2C{=}C(CN)_2 + Cu \rightarrow [(CN)_2C{=}C(CN)_2^{\cdot-}Cu^+ .$$

In the alkali metal series lithium seems the best reductant for most instances. In dimethoxyethane the reaction of biphenyl with sodium is equilibrium ($K \simeq 10^{-2}$),[44] whereas a dianion is formed with lithium under these conditions[45]:

$$C_{12}H_{10} + Na \underset{}{\overset{DME}{\rightleftharpoons}} C_{12}H_{10}^{\cdot-} + Na^+$$

$$C_{12}H_{10} + Li \xrightarrow{DME} C_{12}H_{10}^{2-} + 2Li^+ .$$

This can be explained by the greater solvation of the lithium cation compared with the cations of its analogues in the Group[46], which appears, in particular, in the fact that lithium, unlike sodium, is soluble in tetrahydrofuran[47]. In the general case the ease of formation of similar AR in various ethers changes symbathically with the solubility in these ethers of alkali metals or of K/Na alloy[47-53]. Probably, in the formation of the AR the solvent plays the part of a carrier of an electron from the metal to the molecule of the acceptor†. Hexamethyltriamidophosphate exhibits the greatest dissolving ability in relation to alkali metals (up to 1 M),[53,54] however, unfortunately the influence of this solvent on the formation of AR has not yet been studied. The important and sometimes also the decisive part of the medium in the formation of AR can be illustrated by a series of examples. Thus whereas in DME naphthalene is reduced by sodium to an AR,[57] in liquid ammonia a dianion is formed[58]. Similarly magnesium does not reduce naphthalene in ethers, whereas in liquid ammonia naphthalenemagnesium is formed[59]; trimesitylboronsodium, which exists in benzene solution as a diamagnetic dimer, dissociates on the addition of tetrahydrofuran[27].

2. Electrochemical Reactions

A review was recently published about the mechanism of electrochemical reactions[60], therefore we will consider here only certain examples dealing with the formation of RI in electrode processes. AR of naphthalene[61], anthracene, biphenyl, chrysene, fluoranthene[62], azulene[63], substituted benzenes[63], benzophenone[64], and fluorenone[65] were obtained by electrochemical reduction.

In many instances electrochemical methods have definite advantages over other methods of generating AR.[40,66]

† It is known, however, that potassium also reacts with aromatic compounds in a hydrocarbon medium[55,56].

Carrying out the electrolysis in the microwave cavity of an EPR spectrometer allowed extremely unstable IR to be identified, the experimental detection of which by other methods would be extremely complicated. This relates, for example, to the production of the AR of butadiene[21] and certain organoelemental compounds[36], and the CR of *p*-phenylenediamine[66] and triethylenediamine[40]. The use of electrochemical methods allowed the effect of various solvents (including protic solvents) on the distribution of unpaired electron density in various AR to be investigated[68,69]. In several instances EPR spectra with a high degree of resolution were obtained[70].

Interesting results have been obtained in investigating the polarographic reduction of halogenonitrobenzenes[71]. It was found that with iodonitrobenzenes only the spectrum of the AR of nitrobenzene is observed, whereas the formation of an AR precedes the loss of an iodide ion. With the bromonitrobenzenes a bromide anion is detached only from the *ortho*-position; chloronitrobenzenes form stable AR. In drawing attention to the undoubted similarity between electrochemical reduction and reactions with free metals it can be suggested that the first act in the reduction of halogen derivatives by metals is also the transfer of an electron and the formation of AR (see p. 962).

3. Anions as Donors of an Electron

A large number of examples are known when the donors of an unpaired electron are diamagnetic anions: carbanions[72-77], dihydro-derivatives of aromatic compounds in the presence of bases[78,79], alkoxide ions[80,81], the hydroxide ion[82,83], and the iodide ion[84].

An acceptor of an unpaired electron can be neutral molecules (A)

$$B^- + A \rightarrow B^{\cdot} + A^{\cdot -}$$
$$B^{2-} + A \rightarrow B^{\cdot -} + A^{\cdot -};$$

free radicals formed with sufficient electron affinity:

$$B^- + R^{\cdot} \rightarrow B^{\cdot} + R^-$$
$$B^{2-} + R^{\cdot} \rightarrow B^{\cdot -} + R^-;$$

ions:

$$B^- + R^+ \rightarrow B^{\cdot} + R^{\cdot}$$
$$B^- + B^{1-} \rightarrow B^{\cdot} + B$$

etc.

The potential carbanion of active organometallic compounds can also play the part of anions B^-, that is, in other words, a polar metal–carbon bond:

Apparently the first established instance of the transfer of a single electron from an anion to a neutral organic molecule is a reaction studied by Schlenk and coworkers[85,86], that between triphenylmethylsodium and diaryl ketones, leading (after hydrolysis and oxidation by atmospheric oxygen) to triphenylmethyl peroxide and pinacones:

$$(C_6H_5)_3C^- + Ar_2CO \rightarrow (C_6H_5)_3C^{\cdot} + Ar_2\dot{C}-\bar{O}.$$

Triphenylmethylmagnesium bromide reacts similarly[87].

The suggestion made by Arbuzov and Arbuzova about the free radical nature of the reaction of cyclohexylmagnesium bromide with benzophenone[88] is essentially equivalent to an assumption concerning the possibility of single-electron transfer in the reaction of Grignard reagents with ketones:

Indirect arguments in support of the stepwise nature of such reactions were found in subsequent years. The intermediate formation of ketyl was recently proved by the EPR method by the example of the reaction of a series of substituted benzophenones with ethylmagnesium iodide and phenylmagnesium bromide[76].

A single-electron transfer was observed in the reaction of triphenyltinlithium with benzophenone, carbon dioxide, and sulphur dioxide[74]. Streitwieser and Lawler noted the formation of AR of anthracene in investigating deuterio-exchange, which can be catalysed by lithium cyclohexylamide[89].

Organolithium compounds reduce certain aromatic hydrocarbons (for example, anthracene[77]) with the formation of the corresponding AR:

$$RLi + ArH \rightarrow R^{\cdot} + Li^+ + ArH^{\cdot -}.$$

The ability of organolithium compounds to transfer a single electron changes symbatically with their ease of oxidation[90], evidently by virtue of the similarity in the mechanisms of these reactions. For example, in going from primary to secondary, and further to tertiary radicals R, the rate of oxidation and the ease of electron transfer increase. According to Russell, this is connected with the decrease in the stability of the carbanion and the increase in the stability of the corresponding radical in this series. It is characteristic that the AR of tolane could be observed in the action of t-butyl-lithium on tolane but not of n- or s-butyl-lithium[91].

Table 2. Decomposition potentials of Grignard reagents in 1 M ethereal solution.

R in RMgX	Decomposition potential, V	R in RMgX	Decomposition potential, V
C_6H_5	2.17	$C_6H_5(CH_3)CH$	1.24
CH_3	1.84	$(CH_3)_2CH$	1.07
C_3H_7	1.42	$(CH_3)_3C$	0.97
C_4H_9	1.32	$CH_2=CHCH_2$	0.86
C_2H_5	1.28		

A searching quantitative appraisal of the donor ability of organometallic compounds can evidently be obtained by using their electrochemical oxidation potential, but information on this question is scanty[92-94]. Evans[92,93] determined the decomposition potentials of ethereal solutions of alkylmagnesium halides (Table 2). If it is assumed that in a series of corresponding organo lithium compounds an analogous picture will be obtained, then it can be expected that depending on the type of radical the donating ability of the alkyl-lithiums will increase in the order: CH_3 < higher alkyls < allyl < benzyl. Actually, the rate of formation of the AR increases in the order CH_3Li, $C_6H_5Li \ll C_4H_9Li < C_6H_5CH_2Li$.[73]

The transfer of an unpaired electron from an organometallic compound is greatly increased under ultraviolet irradiation, Thus on irradiating the C_6H_5Li–ArH system the rate of formation of the AR $ArH^{\cdot -}$ is increased by a factor of 10^5.[75]

An important condition for the single-electron transfer from an anion to a neutral molecule is a sufficiently great difference between the values of the electron affinity of the donor and the acceptor. As noted above, organolithium

compounds reduce aromatic hydrocarbons[77], and organomagnesium compounds reduce diaryl ketones[76,95]. Although apparently weaker reductants than organometallic compounds of the active metals, nevertheless alkoxide ions are capable of reducing aromatic ketones and nitro-compounds[80,95].

The reduction of diaryl ketones and nitro-compounds by alkoxides is also accelerated by irradiation, and the concentration of the AR formed is determined by the intensity of the irradiation[96]:

$$ArNO_2 + RO^- \xrightarrow{h\nu} ArNO_2^{\cdot -} + RO^{\cdot}$$

$$Ar_2CO + RO^- \xrightarrow{h\nu} Ar_2CO^{\cdot -} + RO^{\cdot}.$$

Tetracyanoethylene[43] and tetracyanoquinodimethane[98], which exhibit a very high electron affinity, are readily oxidised by even the iodide ion:

$$I^- + (CN)_2C{=}C(CN)_2 \rightarrow {}^1/_2 I_2 + [(CN)_2C{=}C(CN)_2]^{\cdot -}$$

$$I^- + (CN)_2C{=}\langle\rangle{=}C(CN)_2 \rightarrow {}^1/_2 I_2 + \left[(CN)_2C{=}\langle\rangle{=}C(CN)_2\right]^{\cdot -}.$$

The hydroxide ion reacts similarly, also reducing *p*-quinone, chloroanil, and duroquinone[82,83,97,99].

Many acetylenic compounds are also rather strong acceptors in relation to the anions I^-, CN^-, and SCN^- in dimethylformamide medium[100]:

$$A^- + RC{\equiv}CR' \rightarrow [RC{\equiv}CR']^{\cdot -} + A^{\cdot}$$

where A = I, CN, or SCN.

It was noted above that in the dissolution of aromatic nitro-compounds in alcohol–dimethylsulphoxide mixture in the presence of alkali metal alkoxide the EPR signal of the corresponding AR is observed, but the degree of electron transfer‡ is relatively low (~ 0.1%). Since under these conditions many conjugated acids are converted into anions this allowed us to evaluate the relative donating ability of a series of anions[95] (Table 3). The data in Table 3, however, allow only an approximate estimation of the relative donor ability of the various sources of an unpaired electron, since these values are greatly dependent upon the degree of ionisation of the initial compound under the action of an alkoxide:

$$BH + RO^- \rightarrow B^- + ROH,$$

and also of the side-reactions, the importance of which depends upon the nature of the donor. The nature of the acceptor is also far from being unimportant. Thus in relation to nitrobenzene, cyclopentadienes are arranged in the order: cyclopentadiene < fluorene < indene, whereas in relation to azobenzene the order is different: cyclopentadiene < indene < fluorene[95]. Whereas organolithium compounds are frequently better reductants than the corresponding organomagnesium compounds the observable degree of electron transfer in benzofurazane and benzo[*c*]indolene is significantly greater for alkylmagnesium halides.

The restrictions associated with side-processes which accompany the transfer of an electron from an anion to an acceptor molecule are reduced to a minimum in studying electron transfer reactions between dianions and the corresponding hydrocarbons[42,101,102]:

$$B^{2-} + B \rightarrow 2B^{\cdot -}.$$

In many instances instead of dianions it is possible to use the corresponding dihydro-derivatives in the presence of strong bases[78,103–108]. Exceptions are the 1,4-dihydronaphthalene–naphthalene and 1,4-cyclohexadiene–benzene systems in which the AR were not observed. This departure is evidently explained by the fact that under these reaction conditions ionisation of the 1,4-dihydronaphthalene and 1,4-cyclopentadiene does not take place.

‡ The degree of electron transfer = [AR] × 100/[acceptor] %.

Table 3. Degree of electron transfer* from anions to aromatic nitro-compounds.

Donors[a]	Acceptor[b], degree of electron transfer, % (5 min)	
	nitrobenzene[c]	m-dinitrobenzene[d]
Pure solvent	0.1 (10 min)	0.1 (20 min)
Fluorene	13	40.80 (2 min)
Indene	36	—
Cyclopentadiene	0.8	2.6
Acetophenone	0.8	2.7
Propiophenone	91	4
Benzoin	100[f]	—
Bluoren-9-ol	100[f]	—
1,4-Hydroquinone	40[f]	100[f]
Thiophenol	0.2 (30 min)	0.6
3,4-Dimercaptotoluene	11	58
Nitroethane	0.6	2
N-Hydroxybenzenesulphamide	92	10[e] (10 min)
Hydrazobenzene	2 (40 min)	7.5[e] (2 min)
Benzophenone ketyl[h]	100	6.8 (3 min)
n-Butyl-lithium[i]	6	

* See note

a) Concentration of donor 0.025 M, concentration of base 0.05 M;
b) Concentration of acceptor 0.005 M.
c) Dimethyl sulphoxide (20%)–t-butyl alcohol (80%).
d) In ethanol (EPR spectrum does not correspond with the AR of the acceptor
e) [Not given in Russian (Ed. of Translation)].
f) EPR spectrum of the AR of the donor predominates.
g) Spectra of both AR are observed.
h) Obtained in the dissociation of saturated solution of benzpinacone.
i) 1 M solution in a mixture of tetrahydrofuran (75%) and hexane (25%).

Stable radicals are effective electron acceptors but reactions of this type have hardly been studied at all. From the broadening of the hyperfine structure lines of the EPR spectrum Weissmans and coworkers[109] found the presence of electron exchange between the tris-(*p*-nitrophenyl)methyl radical and the corresponding anion:

$$(p\text{-}NO_2C_6H_4)_3C^{\cdot} + (p\text{-}NO_2C_6H_4)_3C^- \rightleftarrows (p\text{-}NO_2C_6H_4)_3C^- + (p\text{-}NO_2C_6H_4)_3C^{\cdot}.$$

Depending on the solvent the rate constant varies within the limits 10^7–10^9 litre mole^{-1} s^{-1} and the activation energy from 0.9 to 2.3 kcal mole^{-1}.

4. Neutral Molecules as Donors of an Electron

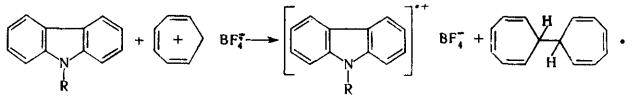
A large number of aromatic and heterocyclic compounds, and also compounds which contain a hetero-atom, have an unshared pair of electrons (many, a nitrogen atom) capable of acting as a donor of an electron in relation to a strong oxidant, forming a CR.

For example, triphenylamine is readily oxidised by iodine in the presence of silver perchlorate with the formation of a coloured paramagnetic solution of triphenyliminium perchlorate $(C_6H_5)_3NH^{\cdot +}ClO_4^-$.[110] Other aromatic amines behave similarly[111,112]. CR of *p*-phenylenediamine[66,67] and its alkyl-substituted derivatives[39,113], triethylenediamine[40], tetrakis(dimethylamino)ethylene[114], and several other amines were obtained by electrochemical oxidation.

Electron transfer was observed for the reaction between aliphatic amines and trinitrobenzene[113,115], tetracyanoethylene, and tetracyanoquinodimethane[116]. Many complexes of aromatic amines are paramagnetic even in the solid state. The complexes of tetramethyl-*p*-phenylenediamine with benzoquinones and tetracyanoquinodimethane dissociate in solvating solvents, forming the corresponding CR and AR.[78,117,118] The complexes of tetracyanoethylene[43,66] behave similarly. Tetramethyltetrazene is oxidised by tetranitromethane into the corresponding CR:[119]

$$(CH_3)_2NN{=}NN(CH_3)_2 + C(NO_2)_4 \rightarrow [(CH_3)_2NN{=}NN(CH_3)_2]^{\cdot+} + [C(NO_2)_4]^{\cdot-}.$$

Carbonium ions can act as the electron acceptor. Thus tropylium tetrafluoroborate oxidises carbazole and *N*-methylcarbazole to the corresponding CR:[120]

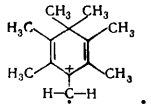


The CR themselves can act as oxidants in relation to other amines having less electron affinity than amines corresponding to the given CR. Thus the CR of *NN'*-tetramethylbenzidine is reduced by *p*-phenylenediamine and its *NN'*-tetramethyl derivative[121]:

$$[(CH_3)_2NC_6H_4C_6H_4N(CH_3)_2]^{\cdot+} + (CH_3)_2NC_6H_4N(CH_3)_2 \rightarrow (CH_3)_2NC_6H_4C_6H_4N(CH_3)_2 + [(CH_3)_2NC_6H_4N(CH_3)_2]^{\cdot+}.$$

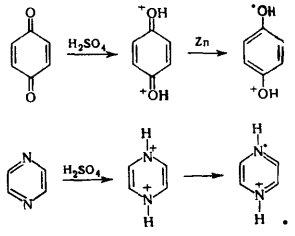
The oxidation of aromatic and heterocyclic compounds can be brought about both electrochemically and by chemical means[122-125].

The oxidants used are: 98% sulphuric acid[126,127], alkyl- or aryl-sulphonic acids[128], antimony(V) chloride[129,130], and aluminium chloride in nitromethane solution[131]. Sulphuric acid is a relatively weak oxidant, therefore the CR concentration is usually low. Thus with anthracene only 1% of the total amount of hydrocarbon introduced is oxidised. With $SbCl_5$ the oxidation is almost complete. In the action of $SbCl_5$ on an excess of anthracene in methylene chloride an adduct of CR with the neutral molecule is formed $(C_{10}H_{12})_2^{\cdot+}SbCl_4^-$.[130] When sulphuric acid acts on hexamethylbenzene a CR related to the heptamethylbenzonium cation is formed[132]:



The same CR is formed in the reaction of iodine and antimony(V) chloride.

The CR of the semiquinone type are formed in the reduction of dicarbonyl compounds and of related nitrogen heterocycles in an acid medium[133]. For example, for *p*-benzoquinone and piperazine:



Analogous CR are obtained from 1,4-naphthoquinone, anthraquinone, phenazine, 4,4'-bipyridyl, and certain α-diketones[134-136].

Strong π-acids of the tetracyanoethylene (TCNE) and tetracyanoquinodimethane (TCQ) type react with aromatic hydrocarbons to form the corresponding AR and CR:[43,98]

$$ArH + TCNE \rightarrow ArH^{\cdot+} + TCNE^{\cdot-}$$

With tetracyanoquinodimethane, complexes of the composition $ArH^+(TCNQ)^-$ (TCNQ) are also formed[98].

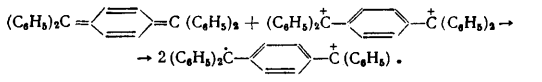
The biscyclopentadienyls of cobalt and iron are oxidised by TCNE and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone to the corresponding metallocinium cations[107,137]:

$$(C_5H_5)_2M + TCNE \rightarrow (C_5H_5)_2M^+ + TCNE^{\cdot-}$$

where M = Fe, Co. The position of the equilibrium depends greatly on the solvent[137].

The formation of paramagnetic products, probably the result of electron transfer, was noted in the reaction of tetranitromethane with 2,3-dimethylbutadiene, cyclohexadiene, and isoprene[138].

One of the reliably established examples of the donor capability of a conjugated system of double bonds is the single-electron transfer from tetraphenylquinodimethane to a dicarbonium ion from tetraphenyl-*p*-xylene[139]:

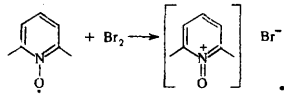


5. Radicals as Donors of an Electron

Free radicals, which exhibit high electron affinity usually emerge as vigorous oxidants. However, the available experimental data suggest that free radicals in the accepted sense are amphoteric, that is, capable both of capture of an electron not supplied to the carbanion and of the supply of an unpaired electron to a sufficiently strong acceptor with the formation of a corresponding cation. The best known example of the donor ability of free radicals is the reduction of heavy metal salts by the triphenylmethyl radical[140]:

$$Ph_3C^{\cdot} + AgClO_4 \rightarrow Ph_3C^+ClO_4^- + Ag.$$

Stable *N*-oxide radicals are readily oxidised by bromine to form immonium cations[141]:



Bulê and Norman[142], in investigating the reaction of formaldehyde and acetaldehyde with hydroxyl radicals, found that with an excess of the aldehyde the EPR spectrum of the AR of the corresponding aldehyde is observed. On adding nitrobenzene to the reaction mixture the EPR spectrum of a nitrobenzene AR was observed. These results formed a basis for the hypothesis that a hydrated form of a primary radical, produced in the removal of a hydrogen atom from a molecule of the aldehyde, is capable of reducing a neutral molecule of the aldehyde or nitrobenzene:

$$RCH(OH)_2 + \cdot OH \rightarrow RC(OH)_2,$$
$$R\dot{C}(OH)_2 + RCHO \rightarrow RCO_2H_2^+ + R\dot{C}HO \rightleftarrows RCOOH + R\dot{C}HOH,$$

or

$$R\dot{C}(OH)_2 + C_6H_5NO_2 \rightarrow RCO_2H_2^+ + C_6H_5NO_2^{\cdot-}.$$

III. REACTIONS OF RADICAL-IONS

The reactions of RI, the high chemical activity of which is due to the presence of an unpaired electron, can be divided into two groups. The first type comprises the reactions in which RI participate only as donors (or acceptors) of an electron (reactions with organic halides, the initiation of polymerisation, exchange reactions, etc.). During the course of these reactions the skeleton of the RI molecule does not undergo any changes. The second class of reaction includes a large number of conversions of RI which lead to a fundamental reconstruction of the initial molecule (hydrolysis, alkylation, decomposition of the RI, etc.).

1. Radical-ions as Donors and Acceptors of an Electron

Typical representatives of this type of reaction are the exchange reactions of RI with neutral molecules[121,143-145]:

$$ArH + ArH^{\cdot-} \rightleftarrows ArH^{\cdot-} + ArH,$$
$$ArH^{\cdot+} + ArH \rightleftarrows ArH + ArH^{\cdot+}.$$

Weissmann and coworkers[143] first showed that exchange by an electron appears in a broadening of the hyperfine structure lines of the EPR signal, the increase in breadth depending significantly on the concentration of the neutral compound. The changes in the EPR spectra were used to calculate the rate constants of the exchange[144,145]. Exchange reactions between stable AR and various acceptors[40,41,122] of the type:

$$ArH^{\cdot-} + Ar'H \rightleftarrows ArH + Ar'H^{\cdot-}$$

were also studied and it was shown that the position of the equilibrium depends on the difference in potentials of the polarographic reduction of the two partners[121].

Reactions of AR with organic halides have been studied in the greatest detail. In these reactions the AR act as an effective donor of an electron. The primary act of the reaction is the transfer of an electron from the AR to the halide molecule with the formation (probably through the intermediate formation of an AR of the halogen derivative) of a hydrocarbon radical and a halide ion[146-149]:

$$ArH^{\cdot-}M^+ + RX \rightarrow ArH + [RX^{\cdot-}M^+] \rightarrow R^{\cdot} + X^- + M^+.$$

The subsequent fate of radical R is determined by its structure and the conditions under which the process is carried out. In carrying out the reaction of the AR of naphthalene with an equimolecular mixture of two alkyl halides, RX and R'X, a mixture of the hydrocarbons RR, RR', and R'R' is formed in the ratio 1 : 2 : 1, together with appreciable quantities of RH and R_{-H}.[147] The ratio of the products of dimerisation (R–R) and of the products of the reaction of the radical with the solvent depends greatly on the nature of the halogen atom. Thus in the system $n\text{-}C_5H_4X + C_{10}H_8^{\cdot-}Na^+$, on going from n-pentyl chloride to the iodide the quantity of n-pentane decreases from 43.9 to 17.3% and the yield of n-decane increases from zero to 55.7%. The reaction of hexenyl halides with naphthalenesodium is accompanied by a rearrangement of the hexenyl radical formed into the cyclopentylmethyl radical[149]. With certain aromatic and aliphatic-aromatic halides the reaction with the AR leads to products of a Wurtz reaction with rather high yields (bibenzyl 30, bibenzhydryl 71, bi-2-naphthyl 71, biphenyl 90%)[148]; the initial aromatic hydrocarbon can be used in catalytic amounts.

Spectrophotometric investigation of the reactions of AR with various alkyl halides showed that the reaction is second order overall, first with respect to each of the reagents[150-152].

Since during the course of the reaction the organically bound halogen is converted into a halide ion, this method could be used for the quantitative determination of halogen in organic compounds[153,154].

Alkyl tosylates are split by the naphthalene AR with formation of the corresponding alkoxides and salts of toluene sulphinic acid. The yield of alcohols (after hydrolysis) is almost quantitative. Under the action of an excess of AR the sulphinic acid is reduced to toluene[155]:

$$p\text{-}CH_3C_6H_4SO_3OR + C_{10}H_8^{\cdot-}Na^+ \rightarrow p\text{-}CH_3C_6H_4SO_2^-Na^+ + RONa \xrightarrow{\text{excess } C_{10}H_8^{\cdot-}Na^+} CH_3C_6H_5.$$

Under the action of inorganic oxidants the AR also very readily give a surplus electron. In oxidation by atmospheric oxygen the original hydrocarbon and the alkali metal peroxide are formed, for example[156]

$$2C_{10}H_8^{\cdot-}Na^+ + O_2 \rightarrow 2C_{10}H_8 + Na_2O_2.$$

Under these conditions cobalt(II) chloride is reduced with the formation of colloidal cobalt, which ignites in air[157]. The reducing action of AR finds application for obtaining highly reactive manganese, used for making manganese carbonyl[158].

2. Reaction of Radical-ions Accompanied by a Change in the Structure of the Initial Molecule

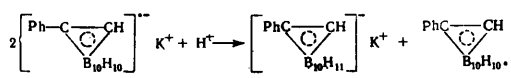
The overwhelming majority of AR are stable only in aprotic media. The addition of protic solvents causes a rapid disappearance of a characteristic signal in the EPR spectrum. With the AR of aromatic hydrocarbons the main products are the corresponding dihydro-derivative and the initial hydrocarbon (mixture ~ 1 : 1):[156,159]

$$ArH^{\cdot-} + H^+ \rightarrow ArH_2^{\cdot},$$
$$ArH_2^{\cdot} + ArH^{\cdot-} \rightarrow ArH_2^- + ArH,$$
$$ArH_2^- + H^+ \rightarrow ArH_3.$$

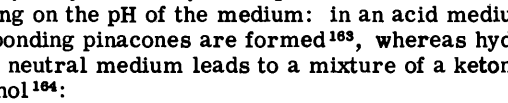
In the addition of a proton to the AR of an aromatic hydrocarbon the $ArH_2^{\cdot}$ radical is formed, which exhibits a greater electron affinity than the molecule of the initial hydrocarbon[160], which is subsequently reduced further by the excess of AR to the corresponding anion. If the anion formed is sufficiently stable (as it is, for example, in the alcoholysis of triphenylboronsodium) the reaction stops at this stage[161]:

$$2Ph_3B^{\cdot-}Na^+ + CH_3OH \rightarrow [Ph_3BH]\,Na + [Ph_3BOCH_3]\,Na.$$

The hydrolysis of the AR of phenylbarene proceeds analogously[162]:



The hydrolysis of ketyls can proceed in two directions, depending on the pH of the medium: in an acid medium the corresponding pinacones are formed[163], whereas hydrolysis in a neutral medium leads to a mixture of a ketone and an alcohol[164]:



The hydrolysis of dianions of aromatic hydrocarbons which are formed during the subsequent reduction of the

AR leads to the same products as the hydrolysis of the AR:[165,166]

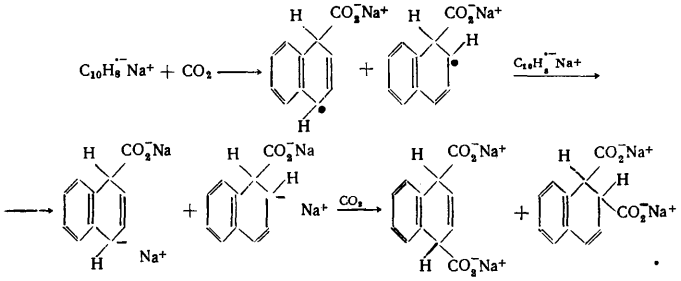
$$ArH^{2-} + H^+ \rightarrow ArH_2^-,$$
$$ArH_2^- + H^+ \rightarrow ArH_3.$$

The mono-anions which are formed in the addition of a proton to a dianion are identical with anions formed in the hydrolysis of the AR. Depending on the nature of the initial hydrocarbon these monoanions disproportionate in solution by one of the following schemes:

$$2ArH_2^- \rightarrow ArH_3 + ArH^{2-},$$
$$2ArH_2^- \rightarrow ArH_3^- + ArH^-.$$

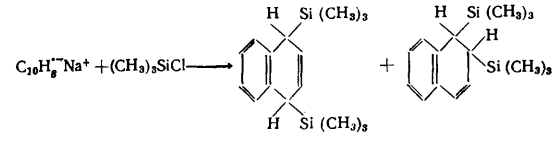
The stable AR can also detach a proton from extremely weak acids, entering into the role of effective metallating agents[67,167,173]. Thus Normant and Angelo[67] used naphthalenesodium for the metallation of carboxylic acids and their salts. The yields of the corresponding malonic acids (after carboxylation) reached 80%.

The carboxylation of AR, like hydrolysis, leads to the formation of dihydro-derivatives of the initial aromatic hydrocarbons[168,169]. For example, a mixture of 1,2- and 1,4-dihydronaphthalenedicarboxylic acids is obtained from the AR of naphthalene:



Unlike the reactions of aromatic AR with alkyl halides considered in the previous section, the reaction of dimethyl sulphate with the AR of biphenyl leads to the formation of a dimethylated product[170]:

Chlorotrimethylsilane reacts similarly with the AR of naphthalene[171]:



1,2- and 1,4-isomers are formed in the approximate ratio of 1 : 2.

Evidently, the formation of bis-3,6-(trimethylsilyl)-cyclohexa-1,4-diene in the reaction of benzene with chlorotrimethylsilane in the presence of metallic lithium[172] must be classified among reactions of this type:

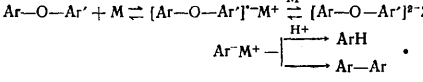
The reactions with toluene and anisole proceed similarly.

IV. REACTIONS WHICH PROCEED THROUGH THE INTERMEDIATE FORMATION OF RADICAL-IONS

The development of physicochemical methods of investigation, and above all of EPR, gave the possibility of tracing the formation, and in some instances also the kinetics, of the accumulation and decomposition of short-lived AR during chemical reactions. The results obtained are undoubtedly of considerable interest in themselves but in addition they clearly show the large part which electron transfer processes play in various chemical changes.

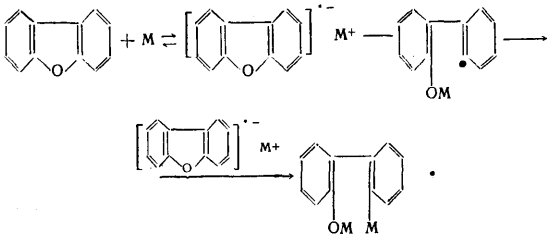
1. Cleavage of Carbon–Element Bonds

The cleavage of diaryl and alkyl aryl ethers by alkali metals has long been known[174] and in some instances finds synthetic application for the production of compounds containing a free hydroxyl group, but the mechanism of this process has still not been established. Recently, Eargle[175] and Strojny[176] showed that the first act of the reaction is the transfer of an electron from the alkali metal atom to the ether molecule with the formation of an AR; the latter takes a second electron, forming a dianion, the decomposition of which also leads to the products of the reaction:



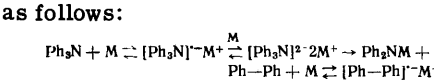
The direction of the splitting of the dianion into different Ar and Ar′ depends on the nature of the aromatic radical[176]. For example, with biphenylyl phenyl ether, phenol and biphenyl are formed:

It is interesting to note that dinitrodiphenyl ether does not cleave under the conditions of the experiment[175]. This is evidently due to the delocalisation of an unpaired electron on the nitrogen atoms of the nitro-groups, which leads to the decrease in the electron density on the oxygen atom. The splitting of the C–O bond in dibenzofuran takes place at the AR stage. The radical formed as a result of the breaking of the bond is rapidly reduced by another molecule of AR into the corresponding anion[177]:



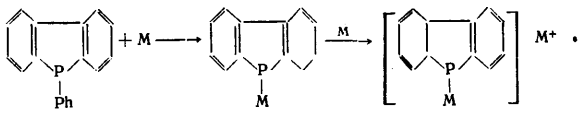
The kinetics of the decomposition of the AR was measured from the change in the intensity of the EPR signal. The activation energy depends slightly on the nature of the metal (19.0 kcal mole^{-1}). Splitting with alkali metals and other heterocyclic compounds evidently proceeds in a similar manner.

In investigating the splitting of compounds of the type Ar_3E (where E = N or P) by alkali metals the formation of a primary AR of the type $[Ar_3E]^-M^+$ has not yet been established (see Eliseeva and coworkers[35]). Thus with triphenylamine the only identifiable paramagnetic product is the AR of biphenyl[178]. The probable scheme of the decomposition, as for the diaryl ethers, can be represented as follows:



The splitting of triphenylphosphine[33] stops at the first stage with the formation of Ph_2PM, which is reduced by an excess of the metal to the dianion radical $[Ph_2PM]^{\cdot-}M^+$.

Biphenylylene(phenyl)phosphine [9-phenyl-9-phosphafluorene] reacts similarly with alkali metals[34]:



The metallation of aromatic hydrocarbons containing "acid" hydrogen atoms also proceeds through the stage of formation of AR.[179-181] It has been shown, by the example of indene and fluorene, that the AR formed can either decompose with the loss of a hydrogen atom, or detach a proton from a neutral molecule:

$$ArH + M \rightleftarrows ArH^{\cdot-}M^{+}$$

$$ArH^{\cdot-}M^{+} \rightarrow ArM + H^{\cdot}$$

$$ArH^{\cdot-}M^{+} + ArH \rightarrow ArM + ArH_{\text{a}}^{\cdot} .$$

Which direction predominates depends on the nature of the initial hydrocarbon and the alkali metal. A unimolecular decomposition is catalysed by iron(II) salts[180].

Evidently, just the same happens in the breaking of the N–H bond. Thus, in the action of metallic potassium on carbazole in a medium of dimethoxyethane at low temperature the formation of an AR was established[182]; it was converted on heating into carbazylpotassium with the liberation of hydrogen. Solutions of the alkali metals in amines also slowly liberate hydrogen, forming the corresponding amides. It is interesting to note, that as for the AR of fluorene, this decomposition is accelerated by iron(II) ions.

Summarising all that has been said above, the general conclusion can be drawn that reactions with free metals start with the transfer of an unpaired electron to a molecule of another reagent with the formation of an AR, the subsequent conversion of which also determines the occurrence of the process as a whole.

This general position can, we consider, be extended also to one of the main reactions of organometallic chemistry—the reaction of metals with halogen derivatives, leading to the formation of a metal–carbon bond. Although this reaction was discovered more than a century ago, the mechanism of the process cannot be considered to be explained. Each of the suggested approaches to the solution of this problem is confirmed by the indirect evidence, but in not one instance is the reasoning conclusive.

Any scheme which pretends to give a rather complete explanation of the nature of this reaction should successfully explain not only the very fact of the formation of a metal–carbon bond but also the nature of the side processes, the effect of the solvent, stereochemical features of the synthesis, etc.

All the points of view on this subject can be roughly divided into two large groups, depending on which of the two species—the radical $R^{\cdot}$ or the carbanion R^{-}—is ascribed the part of "actual start" in the intermediate stage of the reaction.

Suggestions about the free radical nature of the reaction are based mainly on the studies of Polyani and coworkers[183,184], completed as long ago as 1930. The authors studied the reaction of sodium vapour with methyl halides. A kinetically bimolecular reaction leads to the formation of free methyl radicals identified by their reaction with iodine vapour:

$$CH_3X + Na \rightarrow Na^{+}X^{-} + {}^{\cdot}CH_3 .$$

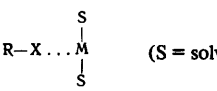
The activation energies fall sharply with decrease in the strength of C–X in the order F $\gg$ Cl > Br > I.

It is claimed that in a transition state of type $\geq C \ldots X \ldots M$ transfer of an electron takes place from a metal atom to a chlorine atom, which leads to the production of an ion pair $M^{+}X^{-}$ which is removed from the free radical formed simultaneously.

On the other hand, even from the work of Paneth it is well known that free radicals are readily "seated" on the free valencies of the metal with the formation of organometallic compounds[185,186]. Even a simple comparison of these two factors leads to the hypothesis of the free radical nature of the whole process: in the adsorbed layer on the metal surface (according to Polyani's scheme) free radicals are generated, which, by reacting with this surface, also form metal–carbon bonds. In this instance when the chemisorption is insufficient the possibility appears of the escape of the free radicals into the solution with all the consequences that follow: recombination (dimeric products, R–R), disproportionation (mixture of hydrocarbons RH and R_{-H}), interaction with the medium (hydrocarbons RH). On the basis of the extremely approximate kinetic results about the reaction of magnesium with alkyl halides[187,188] even the assumption about a radical-chain mechanism was advanced, which agrees with the existence of an induction period, the acceleration of certain reactions when irradiated, etc.

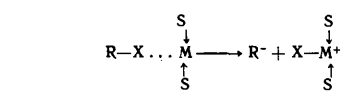
Another viewpoint mainly being developed by the French school (Prevost[189], Normant[190], and others) is that during the course of organometallic synthesis a carbonion R^{-} is formed as the active species.

In this instance the reaction of an alkyl halide with a metal is regarded as the nucleophilic attack of the metal due to the unshared electron pairs of the halogen. In Prevost's opinion[189], such interaction cannot by itself lead to the formation of a carbanion without the participation of an outside donor of electrons, which is the solvent. The common attack of the halogen and solvent leads to the removal of a metal atom from the lattice and the formation of a hypothetical species of the type:



(S = solvent, M = divalent metal)

which then undergoes intramolecular electron transfer:



The carbanion which is formed either adds to a positively charged metal atom (normal reaction), or participates in the formation of side products:

$$R^{-} + RX \rightarrow R{-}R + X^{-}$$

$$R^{-} + RX \rightarrow RH + R_{-H} + X^{-} .$$

It would appear that a single answer about the validity of one or another of the schemes given above can be given by a study of the stereochemistry of the replacement of a halogen connected to an asymmetric carbon atom by a metal. However, the available results on this seem contradictory. Moreover, the interpretation of any stereochemical results is hindered in this instance by the impossibility of the unambiguous assignment of this reaction to any of the accepted types of substitution. The stereochemistry of redox substitutions has not yet been studied systematically and a basis for the prediction of the stereochemical results of such reactions is still impossible.

The available facts lead to the following results. The stereoisomeric *cis-trans*-halides of the propenyl and stilbenyl types react with lithium, almost completely retaining

the configuration of the sp^2-carbon atom, which is also retained in subsequent reactions for the transfer of an unsaturated radical[191,192].

The stereochemical "purity" of the reaction of *trans*-β-bromostyrene with magnesium depends somewhat on the solvent[193]; however, here also it is possible to speak about retention of configuration.

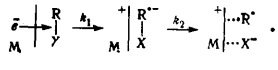
The substitution of a metal for a halogen connected to a saturated sp^3-carbon atom is less stereospecific on the whole. Optically active organo-magnesium[195] and -lithium[194] compounds are obtained from (+)-(*S*)-1-halogeno-1-methyl-2,2-diphenylcyclopropane; however, most optically active halides of the type RR'R"CX,[196] for example, (−)-3,3-dimethylcyclohexyl chloride[197], form racemic organometallic compounds.

In the reaction of a series of optically active halides with metallic sodium (Wurtz reaction) the optical activity is partly retained[198].

Strictly speaking, all these results do not prove and do not rule out any of the proposed schemes. In particular the retention of the configuration can result both from the formation of "intimate radical pairs" of the

type, where there is no free rotation[194] and from the similarly constructed ion pairs formed by the carbanion and metal ion which are produced.

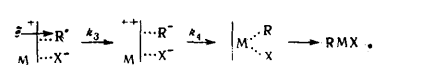
It should be borne in mind that the two main approaches to understanding the mechanism of the RX + M reactions are not mutually exclusive. In any case the first act of this redox reaction taking place on the metal surface must be considered the transfer of "dead" electrons of the metal lattice to the adsorbed molecule of halogen and the formation of the corresponding AR§, $RX^{\cdot -}$,[199] after which there is the breaking of the C–Hal bond and the formation of an organic radical and a halide anion adsorbed on the metal surface:



Depending on the nature of the metal, the organic halide, and the solvent, the breaking of the C–Hal bond can also proceed synchronously with the electron transfer ($k_2 > k_1$). In the last instance the elementary act can be regarded as the nucleophilic attack on the halide adsorbed on the metal surface by an electron (type S_N2)

$$\bar{e} + RX \longrightarrow \bar{e} \ldots R^{\delta+} \ldots X^{\delta-} \longrightarrow R^{\cdot} + X^{-}.$$

The radical which has been formed takes a second electron, being converted into a carbanion, and simultaneously the metal cation enters the solution:



The medium has an enormous influence on the occurrence of all the stages of this process. Firstly, the solvent facilitates the transfer of the electron both on account of the solvation of the cationic centres on the metal and also owing to its own affinity for an electron, which makes possible the transfer of an electron from the metal to the halogen through the solvent¶. Secondly, donor solvents facilitate the stabilisation of AR, $RX^{\cdot -}$, and finally they facilitate, owing to the solvation, the escape of a metal cation into the solution. Catalytic additions evidently usually act similarly.

As regards the mechanism of formation of the side-products (R–R, RH, R_{-H}), two completely different processes must be distinguished: the formation of side-products during the synthesis of an organometallic compound and their formation due to secondary reactions of the metal alkyl already formed. The second type of reaction will be considered in the section dealing with substitutions.

If the rate of conversion of a radical R' into a carbanion is low in comparison with its rate of formation (k_1 and $k_2 > k_3$), there is some probability of its recombination with another of the same radicals on the metal surface (formation of R–R hydrocarbon) or of its escape into the solution (hydrocarbons RH and R_{-H}). A certain amount of side-products can arise due to the reaction of the described carbonium ion R^- with the solvent or form an excess of unreacted halogen derivative:

$$R^- + H^+ \quad \text{(from solvent)} \longrightarrow RH$$
$$R^- + RX \longrightarrow R{-}R + RH + R_{-H} + X^-.$$

If the rate of addition of the second electron is greater than the rate of splitting of the C–Hal–($k_3 > k_2$), the carbanion formed should retain the geometric configuration of the initial halogen derivative. Naturally, this condition can be fulfilled for the more active metals and halogen derivatives, the molecules of which contain atoms and groups of atoms capable of delocalisation of the unpaired electron in RX^-. Actually, optically active organometallic compounds of lithium and magnesium could be obtained only from (+)-(*S*)-1-halogeno-1-methyl-2,2-diphenylcyclopropane, and in the formation of the organomagnesium compound the degree of racemisation is significantly greater[194,195].

If the metal taking part in the reaction is incapable of forming a normal organometallic compound the process stops at the stage of formation of a radical which subsequently either dimerises or disproportionates. Such a direction of the reaction is brought about by the reaction of halogen derivatives with metal derivatives[200].

2. Substitutions

The ability of the anions to act as active electron donors suggests that in many instances the reaction of anions proceeds in stages, the first stage being the transfer of an electron from the anion to the acceptor. Indirect confirmation of this hypothesis is the linear relation between the rate of reaction of the anion (nucleophilic nature) and the half-wave oxidation potential[201–203].

Let us consider, for example, the reaction of anion A^- and cation B^+. Because of the difference in electron affinity of A^- and B^+ (which is completely natural on taking into account that in many reactions the anions act as donors and the cations as acceptors of electrons), the first act is the transfer of an electron from anion to cation with the formation of two radicals, the recombination of which leads to a product corresponding to the normal heterolytic process:

$$A^- + B^+ \xrightarrow{k_1} A^{\cdot} + B^{\cdot} \xrightarrow{k_2} A{-}B.$$

The recombination and disproportionation of like radicals and their interaction with the medium leads to the formation of side-products. Since the recombination of radicals (k_2) usually proceeds at an extremely high rate the observation of valence-unsaturated intermediate species is

§ For the principal possibility of the existence of AR of this type, see p.956.

¶ This assumption is based on the solubility of a series of active metals in amines, esters, and other aprotic solvents[49–54].

possible only when there is a rather large difference in the electron affinities of the initial reagents, that is, when the rate of electron transfer is rather high and is not the rate-limiting stage of the process ($k_1 > k_2$).

In some instances only one of the radicals can be observed (A˙ or B˙) which exhibits relative stability, when the second radical similarly simultaneously participates in some side-process. Finally, there can be the example when the radicals formed are incapable of further changes, that is, the reaction stops at the stage of electron transfer.

Similar discussions can also be held for the reactions of anions (and cations) with neutral molecules (reactions of the ion–dipole type) and for reactions between neutral molecules (reactions of the dipole–dipole type). In the last example the complete transfer of an electron evidently takes place relatively rarely in media of high solvating ability. In many instances some displacement of the electron density takes place with formation of a charge-transfer complex (CTC)†.

Evidently the first experimental confirmation of the formation of radical species in reactions between neutral molecules was obtained in 1958 [7] in an EPR study of the reaction of chlorotriphenylmethane with ethyl-lithium. The concentration of the triphenylmethyl radical under the conditions of the experiment considerably exceeded the equilibrium value which was convincing proof of its primary nature:

$$Ph_3CCl + EtLi \longrightarrow Ph_3C^{\cdot} + LiCl + Et^{\cdot},$$
$$2\,Ph_3C^{\cdot} \longrightarrow Ph_3CCPh_3\ .$$

In addition the results obtained did not solve the problem of the participation of the triphenyl radical in the normal substitution since the reaction products were not studied.

In investigating the reaction of benzophenone with various alkyl- and aryl-magnesium halides the formation of benzophenone ketyl was observed[76]. However, in this instance the results obtained did not permit a definite conclusion to be drawn about the role of electron transfer in normal additions.

In studying the reactions of *p*-nitrobenzyl chloride and *p*-nitrocumyl chloride with various anions (the anion of 2-nitropropane, 2-ethoxycarbonylcoumaran-3-one, the thiophenolate ion), Kornblum and coworkers[205–208] noted the formation of paramagnetic species, which, in their opinion, are the AR of *p*-nitrobenzyl chloride or *p*-nitrocumyl chloride. However, since the authors did not obtain a resolved EPR spectrum, this assumption also cannot be considered completely proved.

Nevertheless, this assumption is indirectly confirmed by the fact that the substitution is retarded by *p*-dinitrobenzene and molecular oxygen.

The present authors with Bubnov recently showed that the alcoholysis of triphenylmethyl chloride and perchlorate with potassium t-butoxide proceeds through a stage of electron transfer[209]. On mixing solutions of triphenylmethyl chloride (or triphenylmethyl perchlorate) with a solution of potassium t-butoxide in the microwave cavity of an EPR spectrometer a well resolved signal of the triphenylmethyl radical was observed, the concentration of which passes through a maximum during the course of the reaction. If potassium 2,4,6-tri-t-butylphenoxide is taken instead of potassium t-butoxide, the reaction stops at the stage of single-electron transfer, since the triphenylmethyl and 2,4,6-tri-t-butylphenoxyl radicals which are formed do not recombine with one another. Measurement of the concentration of phenoxyl radical shows that this process takes place quantitatively. These results show that the classical, as it were, S_N1 reaction is in reality at least a two-stage process: electron transfer and the subsequent recombination of two radicals.

Electron transfer processes evidently also play an important part in nucleophilic substitutions in the aromatic series. It was shown recently[210] that the reaction of esters of *p*-nitrophenol with alkoxides take place through the formation of the corresponding AR.

Despite the fact that electron transfer in substitutions has at present been proved only in isolated instances we consider that this process is extremely general and the lack of direct experimental confirmation is determined by technical difficulties.

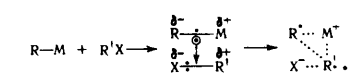
One of the main reactions of organometallic chemistry approaches very closely to the reactions considered: the reaction of organometallic compounds with halogen derivatives. This reaction usually proceeds ambiguously and leads to a complex mixture of products. At least two main directions can be distinguished for this process: double decomposition leading to the formation of a new organo-elemental compound and a halogen derivative.

$$RM + R'X \rightarrow R'M + RX$$

and the Wurtz reaction:

$$RM + R'X \rightarrow R{-}R' + MX\ .$$

The latter is usually complicated by a series of side processes leading to the formation of hydrocarbons of the type RR, R′R′, RH, R_{-H}, R′H, and R'_{-H}. If the Wurtz reaction can be considered as a heterolytic substitution, the exchange reaction cannot be classified as any single type of reaction in accordance with the classification accepted in organic chemistry. Formally, during the course of the reaction there is a conversion of the "carbanion" of the organometallic compound into a "carbonium ion" of the halogen derivative and respectively the "carbonium ion" of the initial halogen derivative into the corresponding "carbanion". Hence it is quite evident that here we are dealing with a redox process. Since in this pair of reagents the donor properties should naturally be exhibited by organometallic compounds (RM), the first act of the reaction should be the transfer of an electron by the metal–carbon bond to the molecule of the halogen derivative:



In the complex which is formed two main directions of the process are subsequently possible: the transfer of a second electron with the formation of a carbanion R′⁻ (exchange reaction) and recombination of the radicals R˙ and R′˙, leading to the products of the Wurtz reaction. As well as these normal processes there is a certain probability of escape of radicals into the solution, which should lead to the formation of side-products—hydrocarbons of the type RH and R_{-H}. Since as a result of the exchange reaction both organometallic compounds (initial and that formed from the added halogen derivative) are always present in the reaction mixture, their reactions with the halides leads to the formation of the so-called "doubled" radicals—RR and R′R′. The ratio of the reaction products in each particular instance depends chiefly on the polarity of the C–M bond, the relative electron affinity of R˙ and R′˙, and the solvating ability of the medium. The higher the polarity of the C–M bond, the easier the electron transfer and the easier the normal reactions (compare the

† See Kosover[204] for the role of CTC in organic reactions.

organolithium and organomagnesium compounds). An increase in the difference in electron affinity of R and R′ facilitates the exchange reaction[211] and simultaneously can lead to a decrease in the yield of the product of the normal Wurtz reaction, if the organometallic compound formed reacts more readily with the initial halogen derivatives[212]. The role of the medium appears, on the one hand, in a change in polarity of the C–M bond and on the other in the solvation of the intermediate reaction complex. The stabilisation of this complex in solvating solvents should lead to an increase in the normal Wurtz and exchange reactions. Actually, many examples[212–214] have shown that a solvating solvent greatly facilitates a Wurtz reaction, whereas homolytic processes predominate in non-solvating media[215,216]. An increase in the solvating ability of the medium leads to a sharp increase in the exchange rate in the series of organolithium[218] and organomagnesium[219] compounds.

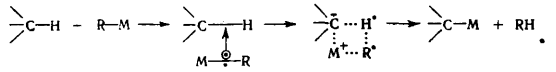
The problem of the catalytic activity of transition metal salts in this reaction is closely connected with the problem under consideration[220]. The role of these catalysts is that they serve as electron transporters, acting as an electron acceptor in relation to the potential carbanion of the organometallic compound. The reduced form of the catalyst then gives the excess electron to a molecule of the organic halide, and evidently such a stepwise electron transfer is hypothetical.

The first stage of this process is effected in the oxidative dimerisation of monosubstituted acetylenes by copper(II) ions in the presence of bases[217]:

$$RC{\equiv}C^- + Cu^{2+} \rightarrow RC{\equiv}C^{\cdot} + Cu^+$$
$$2\,RC{\equiv}C^{\cdot} \rightarrow RC{\equiv}C{-}C{\equiv}CR\,.$$

Depending on the nature of the initial reagents and catalyst this transfer can be effected either in a molecular complex[221,222] or both stages can proceed separately, so that the interaction of unlike radicals is hindered or completely impossible, as, for example, occurs in the reaction of alkylmagnesium halides with aryl halides[220]. In this connection it is not surprising that this reaction is catalysed also by certain other electron acceptors, for example, azobenzene[223].

General considerations concerning the mechanism of the RM + RX′ reaction can also be applied to the reactions in the metallation of aromatic hydrocarbons containing "acid" hydrogen atoms. In the reaction complex formed as a result of electron transfer the loss of a hydrogen atom takes place owing to its recombination with a radical from the organometallic compound:

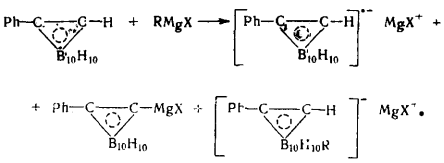


If the AR formed is relatively stable the radical from the organometallic compound can be attached to the aromatic system with formation of the corresponding alkyl derivatives. Actually, in several instances the alkylation of aromatic hydrocarbons under the action of organometallic compounds was observed. Thus in the metallation of perylene, in addition to perylenecarboxylic acid (after carboxylation) 13% 1-butylperylene and a little 3-butylperylene were isolated[224].

Dixon and coworkers[225,226] found that the ease of alkylation increases in the order toluene < benzene < biphenyl < < naphthalene, phenanthrene, but the electron affinity and ability to form AR increase in the same order[41,42]. The ease of alkylation of various organolithium compounds increases in the order n-BuLi < s-BuLi < t-BuLi and as already mentioned above, the ability of the RLi to transfer an electron increases in the same order[91].

A comparison of different RLi by their metallating ability in relation to triphenylmethane[227] and by their donor activity[73] leads to the same sequence: benzyl > allyl > > n-butyl > phenyl > methyl.

The formation of AR, alkylation, and metallation was observed in the reaction of phenylbarene with alkylmagnesium halides[228]:



Of course, it is impossible to regard the examples given as proof of the general scheme of metallation suggested, but the good qualitative agreement with the results of the experiments is indirect evidence in support of the above approach to the mechanism of metallation.

3. Other Reactions

First of all among the electron transfer reactions should be put the oxidation of organic compounds, but the number of experimental studies confirming this viewpoint are extremely few.

Russel and coworkers[229], in studying the oxidation of carbanions by oxygen, concluded that this reaction best agrees with the electron transfer scheme:

$$R^- + O_2 \rightarrow R^{\cdot} + O_2^{\cdot-}.$$

Several articles by Dewar and coworkers[230–232] on the oxidation of various aromatic esters by manganese(III) acetate appeared recently. The kinetic results suggest that in the systems studied the oxidation proceeds through a reversible stage of an single-electron transfer. Analogous results were obtained in investigating the kinetics of the oxidation of a series of the simplest amines by chlorine dioxide[233].

Direct experimental confirmation of electron transfer during oxidation was obtained by Smentowski[234], who observed the formation of AR by nitrobenzene in the oxidation of thiophenoxides by nitrobenzene:

$$ArS^- + PhNO \rightarrow \underset{\downarrow}{ArS^{\cdot}} + PhNO^{\cdot-} \rightarrow \text{reduction products}\,.$$
$$ArSSAr$$

Maruyama[235] noted the formation of diphenylnitrogen oxide in the reaction of phenylmagnesium bromide with nitrobenzene. Evidently in the reaction the diphenylhydroxylaminium anion formed is oxidised by the excess of nitrobenzene:

$$PhNO + PhMgX \rightarrow Ph_2NOMgX \xrightarrow{PhNO} Ph_2N{-}O^{\cdot} + PhNO^{\cdot-}.$$

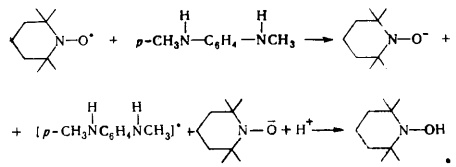
Similarly, the formation of di-t-butyl-[236] and t-butylphenylnitrogen oxide[237] probably occurs in the reaction of t-nitrobutane with t-butylmagnesium chloride and phenylmagnesium bromide.

The formation of the CR of tetramethylhydrazine was noted in the reaction of tetramethyltetrazine with various anhydrides of carboxylic acids[238]:

$$(CH_3)_2NN{=}NN(CH_3)_2 \xrightarrow[0^\circ]{Ac_2O} N_2 + [(CH_3)_2NN(CH_3)_2]^{\cdot+}.$$

Interesting results were obtained in investigating the reaction of stable nitrosyl radicals with aromatic amines.

It was found that the formation of hydroxylamine is a two-stage process: electron transfer from the aromatic amine and addition of a proton from the solvent[239]. In this the aromatic amine is converted into the corresponding CR:



Finally, there are results on the important role of electron transfer reactions in the isomerisation of tetraphenylbutadiene[240], Friedel–Crafts alkylation[241], the diene synthesis[242], and several other processes.

---o0o---

The subject under discussion is extremely general in character since it evidently touches all the fields of organic chemistry to some extent. Therefore an exhaustive treatment of single-electron transfer reactions would scarcely be possible within the framework of a single review.

Nevertheless the material presented shows that electron transfer reactions play an important part in the elementary acts of many organic reactions. The transference ideas about the electron, both about the kinetic particle widely distributed in inorganic and radiation chemistry, into organic chemistry allows the mechanism of organic reactions which do not fit within the framework of classical theory to be explained in many instances (for example, it allows the simultaneous occurrence of homolytic and heterolytic processes to be explained from a single standpoint).

The fruitfulness of such an approach is also confirmed by the fact that the number of publications devoted to electron transfer reactions in organic chemistry has grown sharply recently. The further accumulation of experimental results in this field will undoubtedly lead to an extension of our knowledge about the nature of chemical changes.

Stereospecific Catalysis in the Field of Optically Active Polymers

E.I.Klabunovskii

The present review examines a new field of polymerisation catalysis—the catalytic synthesis of optically active polymers of various classes: (1) poly-α-alkenes under the influence of dissymmetric catalysts, acting as anionic or cationic catalysts, and (2) poly-oxides and poly-imines under the influence of both heterogeneous and homogeneous coordination catalysts. The stereospecific polymerisation of optically active alkenes and the stereoselective polymerisation of racemic alkenes using optically active catalysts are examined. The bibliography contains 127 references.

I. INTRODUCTION

Progress in stereospecific catalysis has been particularly extensive in the field of optically active polymer synthesis. In recent years, fundamentally new stereoselective and stereo-elective processes have been carried out, and the advantages of the use of optically active compounds in the study of the mechanism of stereospecific catalysis have been demonstrated. Work has also begun on the directed synthesis of optically active polymers with required structure for use as dissymmetric adsorbents and catalyst components[1,2].

The present review is restricted to an examination of the conditions of the catalytic synthesis of optically active polymers, the part played by heterogeneous dissymmetric catalysts in the stereospecific polymerisation of α-alkenes, propene oxide, and imines, and the catalytic stereo-elective polymerisation of propene oxide and poly-α-alkenes.

The large amount of experimental material examined in the present review has been obtained chiefly by Natta, Furukawa, Tsuruta, and their schools, and demonstrates convincingly the part played by asymmetric adsorption and complex formation in asymmetric polymerisation catalysis; this is of considerable interest for an understanding of the mechanism of heterogeneous and homogeneous dissymmetric catalyst action.

II. THE ROLE OF HETEROGENEOUS CATALYSTS IN STEREOSPECIFIC POLYMERISATION

The presence of the surface of a heterogeneous catalyst in a reacting system decreases the number of symmetry elements compared with a homogeneous reaction, so that we should expect the production of greater stereoregularity in the polymerisation products in the presence of heterogeneous catalysts. Stereoregular polymers may also be formed, however, in homogeneous radical polymerisation under certain conditions.

Heterogeneity of the catalytic system, which is essential for the preparation of stereoregular poly-α-alkenes, apparently becomes superfluous in the polymerisation of other monomers (aldehydes, dienes, and acrylates). According to Schildknecht[3], stereoregular poly(vinyl isobutyl ether) may also be formed in the absence of a solid surface with soluble catalysts[4]. In this instance, however, the structure of the monomer and the conditions of polymerisation are of particular importance. The monomers should contain not less than two functional groups interacting electronically with one another, the reaction must be carried out at low temperatures to reduce the freedom of rotation of the chains, and the presence of large bulky groups in the monomer leads to rigidity of the chains and high stereoregularity[5]. Since stereospecificity is determined by the atomic configuration surrounding the ends of the chain and situated not more than 20 Å from it, and since this corresponds to the dimensions of large complexes, the production of stereospecificity, according to Szwarc and Smid[6], requires the presence of a macroscopic surface. Thus isotactic polystyrene can also be obtained in homogeneous solution with $n\text{-}C_4H_9Li$ as initiator at −30°C. The solvent also has a considerable influence: in toluene, methyl methacrylate gives an isotactic polymer with a fluorenyllithium catalyst, but a syndiotactic polymer in dimethoxyethane. If we ignore particular instances, however, heterogeneity of the system remains a necessary condition (particularly in the polymerisation of α-alkenes) for the production of stereoregular polymers. With heterogeneous catalysts, stereospecificity depends to a significant extent on the stage involving adsorption of the monomers at the active centre on the solid catalyst surface. Stereoregular polymers are obtained on catalysts acting by an ion-coordination mechanism (anionic and cationic). These contain metals capable of coordinating molecules of the monomer before the stage corresponding to their introduction into the growing chain. A specific action is shown by metals with small ionic radius (Al, Be, and Li) and compounds of the transition metals. The steric effect of bulky groups in the coordinating monomer is also significant. This factor cannot be decisive in stereospecific polymerisation, however, and it can lead only to stereoregularity of the syndiotactic type.

Different authors have different views on the mechanism of Ziegler–Natta catalyst action (see Tsuruta's monograph[7]), but in one respect they agree: the structure of the macromolecule is determined by the stage in which the monomer is adsorbed on the surface of the heterogeneous catalyst. The active centre on the surface may contain metal alkyls adsorbed on $TiCl_3$ or $TiCl_2$ (Friedlander), and the mechanism of chain growth is a form of matrix polymerisation, when both ends of the chain are attached to the surface. According to Nenitzescu, the organotitanium compounds, which undergo splitting to form radicals, act as the catalyst. Natta considers that in coordination anionic polymerisation, adsorption of AlR_3 takes place on the surface of the $TiCl_3$ crystals with the formation of active centres, the number of which can be determined, for example, by using AlR_3 labelled with ^{14}C.

Asymmetric centres are formed with the participation of aluminium atoms and the spatial configuration of the chain is determined by the way in which the monomer molecule approaches between Al and R. Since two approaches are possible, the resulting polymer (isotactic) consists of a mixture of DDD- and LLL-structures.

When two of the coordinating groups are of different chemical character, enantiomorphic structures are possible in the surface complexes. High stereospecificity in such a catalyst should be produced when it is joined to a growing chain (Natta[4]).

The problem of the nature of the active centres has been the subject of detailed discussion. According to the data of Carrick and coworkers[8], and contrary to Natta's opinion, growth takes place at transition metal active centres without direct participation of the reducing agent (AlR_3). Cossee[9] suggests that polymerisation takes place at a titanium ion on the surface of the $TiCl_3$ (or $TiCl_2$) lattice, in which one of the chlorine atoms has been replaced by an alkyl group R, and beside which there is a vacant site on which adsorption of the monomer molecule takes place. After this stage, the Ti–Al bond and the vacant site are preserved in the active centre, and only their positions change.

Polymerisation by the anionic mechanism is influenced considerably by steric factors, because of the small radius of the coordinating metal cation. The stereoregulating power of these catalysts is greater than that in cationic polymerisation, and steric factors are decisive. It is considered that the monomer molecule being attached should be orientated beforehand, but the essential features of the transition state have not yet been determined.

According to Cossee[9], the active centre of heterogeneous Ziegler–Natta catalysts is a transition metal ion with octahedral configuration. When the α-alkene molecule is adsorbed on the surface, its position is such that it forms a π-bond with the titanium ion and occupies the vacant site in such a way that the CH_3 group (in the case of propene) is directed away from the surface, and the CH_2 group is directed towards the surface of the catalyst.

This orientation of the monomer molecule explains the "head-to-tail" addition. The action of AlR_3 reduces to alkylation of the catalyst surface. This scheme explains the formation of isotactic polymers and the fact that alkenes with a non-terminal double bond and with a large R group do not undergo polymerisation at all. Moreover, compounds such as acetylene, water, and CO act as poisons, since they are firmly bound to the catalyst on the vacant sites.

Cram[10] explains stereospecific polymerisation on the basis of steric repulsion between the substituents in the monomer and the penultimate link in the chain. The growing chain takes its origin from the edge of the catalyst crystal. The monomer entering the chain will react with least steric hindrance when R is on the same side as H— on an asymmetric carbon atom.

It is evident that we should expect a much greater part in this process to be played by a dissymmetric catalyst capable of forming surface diastereoisomers on asymmetric adsorption. Cossee's scheme readily explains the formation of these "diastereoisomers".

These ideas were used by Krylov and Livshits[11-13] to explain the asymmetrising action which they observed for the heterogeneous catalyst magnesium d-tartrate in the polymerisation of propene oxide.

Ideas about the existence of asymmetric centres on the catalyst surface were put forward in general form by Hartung and coworkers[14]. They examined various types of centre on the surface of a catalyst on the basis of Ogston's "three-point adsorption"[15] and Balandin's multiplet theory of catalysis[16].

If two enantiomorphic centres are present in different quantities, stereospecificity is not observed. In the examination of this problem, however, Hartung and coworkers[14] reached an incorrect conclusion by assuming that in the hydrogenation of, for example, (–)-α-oximinopropiophenone the optically active product is formed as a result of the action of only one type of centre[17], whereas this result is due to purely steric interaction as a consequence of asymmetric synthesis under the influence of the original asymmetric centre in the molecule.

To investigate the problem of the properties of the enantiomorphic complexes formed between the dissymmetric centres of the catalyst and the monomer molecule, it is convenient to use the approach proposed by Pajaro, Corradini, and coworkers[18,19], who studied diastereoisomeric complexes of alkenes with optically active complex compounds.

An alkene with unsymmetrical structure can be coordinated by means of a $\sigma\pi$-bond to a transition metal complex with the formation of two enantiomorphs. If the transition metal compound contains an optically active ligand, the diastereoisomers formed with the alkene may be separated. The complexes $PtCl_2$[(–)-(*S*)-α-phenylethylamine]X, where X = styrene, propene, *trans*-but-2-ene, or *cis*-but-2-ene, have in fact been prepared and separated. The following values of $[M]_D^{18}$ were obtained for the first three diastereoisomers: $+1200° \pm 150°$, $-300° \pm 50°$, and $-280° \pm 20°$ As expected, the complex with *cis*-but-2-ene did not give diastereoisomers, because of the symmetry of the molecule.

Asymmetric induction arises on coordination of an alkene to the surface of a heterogeneous catalyst in which asymmetric centres have been produced beforehand.

III. DISSYMMETRIC POLYMERISATION CATALYSTS

1. The Catalytic Asymmetric Synthesis of Poly-α-alkenes

The polymerisation of α-alkenes is the most widely studied field of stereospecific vinyl polymerisation. Isotactic poly-α-alkenes have been prepared only using heterogeneous catalysts, and high stereospecificity has been observed when the organometallic component has been deposited (according to Natta) on the carrier—crystalline modifications of $TiCl_3$, with a layer lattice. The use of other carriers, for example, β-$TiCl_3$, which has a different lattice, or metal oxides, gives polymers with low regularity.

We should expect a greater structural regularity in optically active polymers than in the corresponding polymers formed from their racemic monomers, since the presence of the asymmetric centres in the monomer, as a result of their steric influence, will facilitate the predominant formation of one chain configuration.

An incorrect understanding of the role of the asymmetry of the atoms in the polymer chain has led to attempts to prepare optically active vinyl poly-α-alkenes.

Murahashi and coworkers [20] polymerised styrene under the influence of a catalyst consisting of $TiCl_3$ + tri-(2-methylbutyl)aluminium at 70°C and obtained polystyrene which was identical with the polymer obtained with a racemic catalyst. The polymerisation of styrene with optically active 2-methylbutylsodium also gave an inactive polymer. Braun and Kern [21] found, however, that polystyrene obtained using the optically active 2-methylbutylsodium (optical purity 85%) exhibited slight rotation (up to 0.120°; $[\alpha]_D^{20}$ + 0.60°). Calculation of the contribution of the terminal groups to the polymer chain showed that the optical activity of the polymer does not exceed the values due to the formation of $C_5H_{11}-CH_2CH(C_6H_5)-$ groups at the ends of the chain. This contribution is greater for the amorphous fractions with low molecular weight, where the macromolecule contains one 2-methylbutyl group (0.120° for M = 5400) and is smaller for the isotactic fractions (0.011° for M = 28 800). The use of rotatory dispersion enabled larger rotations to be observed for amorphous polymers.

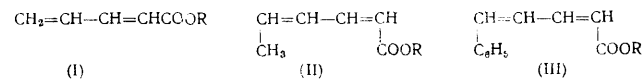
Thus, although in this example of heterogeneous catalysis we might expect steric control of the monomer orientation in the initiation stage at the catalyst surface, these results indicate that polymerisation begins with the alkyl anion of the catalyst.

Fray and Robinson [22] hoped to prove the presence of optical activity in polypropene obtained using (+)-tri(2-methylpentyl)aluminium (optical purity 38%), by subjecting the polymer to pyrolysis. It was expected that optical activity would appear in the chain fragments with low molecular weight, both as a result of the presence of asymmetric atoms and as a result of "spiralisation" of the chain. The results were negative, however.

It has been known for a long time (pp. 109 and 186 of Ref. 1) that an optically active solvent may have an asymmetrising action in the synthesis and separation of racemates. Theoretical examination of this problem by Amaya [23] showed that the probability of formation of optically active polymers under the influence of an optically active solvent increases with decrease in temperature and concentration. An attempt to induce "spiralisation" of the chain by polymerising propene using (+)-tri(2-methylpentyl)aluminium under the asymmetrising influence of (+)-pinane as solvent was unsuccessful, however [20].

Studies in the field of optically active poly-α-alkenes are associated chiefly with the names of Natta and Pino. Natta and coworkers [24] carried out the asymmetric catalytic synthesis of tritactic polymers from optically inactive monomers using dissymmetric catalysts. The dissymmetric catalyst 2-methylbutyl-lithium with methyl *trans-trans*-sorbate gave polymethyl sorbate [25] with $[\alpha]_D$ equal to −3.1° (α_D = −0.235°, *c* = 2.55, *l* = 3); $[M]_D$ = 3.9°; and $[M]_{375}$ = −13.5°. The original *trans-trans*-sorbate gives only *erythro*-di-iso-*trans*-tactic polymethyl sorbate. The other possibilities (*trans-threo*, *cis-threo*, and *cis-erythro*) are not realised. Its optical activity is much greater than that which might have been expected from the contribution of the terminal groups to the rotation and is close to the value for the model compound. It was proved by chemical methods [25,26] and by using ^{14}C that terminal groups from the catalyst are not present in the polymer. The comparatively low value of α indicates that there is no spiralisation of the chain, as was suggested for poly-α-alkenes, and is due entirely to the asymmetric atoms in the main chain.

Highly crystalline 1,4-*erythro*-di-iso-*trans*-tactic polymers exhibiting optical activity have been prepared from esters of vinylacrylic (I), sorbic (II), and styrylacrylic (III) acids:



(I) (II) (III)

Table 1 gives data on the optical rotation of polymers obtained by polymerisation of these esters with a catalyst containing an optically active group [(+)-2-methylbutyl-lithium] and also using the complex of butyl-lithium with the asymmetric Lewis base, (−)-menthyl ethyl ether.

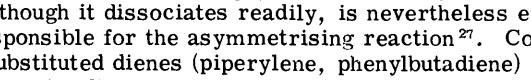
Table 1.

Monomer	Catalyst	Optical rotation of polymer in chloroform		$[M]_D$
		α_D, deg	$[\alpha]_D$, deg	
Methyl sorbate	(*R*)-2-methylbutyl-lithium	−0.70	−7.95	−10.0
Butyl sorbate		+0.36	+3.3	+5.5
Butyl β-styrylacrylate		+0.31	+2.0	+4.6
Methyl β-vinylacrylate	butyl-lithium-(−)-ethyl-menthyl ether		+7.2	
Methyl sorbate		0.27	+6.4	+3.0
Butyl sorbate		0.57	+8.4	+14.1
Butyl β-styrylacrylate		0.42	+3.7	+8.5

The mechanism of action of the first catalyst—the optically active organometallic compound R*Li—apparently involves the introduction of R* into the first monomeric unit, with subsequent transfer along the growing chain.

The second type of catalyst induces asymmetry in the first unit without the formation of a σ-bond between the dissymmetric agent in the catalyst and the chain.

When the catalyst $C_5H_{11}Li$ is used, the polymer contains one alkyl group for every 150–250 monomeric units, so that the optical activity cannot be due to their contribution to the total rotation (the value of $[\alpha]_D$ due to the terminal groups is smaller by a factor of 100 than the observed value of the rotation). Thus the optical rotation is due entirely to the asymmetric atoms in the chain. The same is true of the complex catalyst C_4H_9Li–menthyl ethyl ether, which, although it dissociates readily, is nevertheless entirely responsible for the asymmetrising reaction [27]. Conjugated substituted dienes (piperylene, phenylbutadiene) polymerise with dissymmetric catalysts to form optically active polymers with asymmetric centres in the main chain:



Starting from piperylene, Natta and coworkers [28] prepared *cis*-1,4-polypentadiene in which isotactic chains predominated. They used $AlR_3-Ti(OR)_4$ catalysts; in the system with R = (+)-2-methylbutyl and R = n-butyl, the polymer with high molecular weight did not show optical activity, and only the fraction with low molecular weight gave α_D = 0.03° ($[\alpha]_D$ = 1.76°), possibly due to the introduction of the terminal group from the catalyst.

The action of (+)-$Al(C_5H_{11})_3-VCl_3.(C_2H_5)_2O$ on *trans*-penta-1,3-diene [29] gives 1,3-*trans*-isotactic polypentadiene

with $[\alpha]_D = -1.05°$ ($\alpha_D^{18} = 0.11°$). The optical activity decreases with increase in molecular weight, indicating the occurrence of asymmetric induction in the initial stage of chain growth.

For the $Al(C_2H_5)_3$–(−)-tetra(menthoxy)titanium system, optically active *cis*-1,4-isotactic polypentadienes with maximal specific rotation of −22.8° and $[\eta] = 6.8$ (78% *cis*-chains) have been obtained.

This example is interesting since as well as optical activity due to the asymmetric atoms in the chain possibly there are also conformational factors: α increases with increase in the proportion of isotactic *cis*-1,4-structures. Moreover, the fact that an asymmetrising action is shown by a catalyst containing the asymmetric menthyl group joined to a titanium atom indicates that the transition metal is included in the active centre in the coordinating catalyst. The monomer is coordinated to this centre, and growth takes place on the surface of the heterogeneous catalyst.

Similarly, *trans*-pentadiene under the influence of the catalytic complex [VCl_3–(+)-tri-(2-methylbutyl)aluminium] gives optically active *trans*-1,4-isotactic polypentadiene[29].

Aliev[30,31] studied the asymmetric polymerisation of *trans*-1-phenylbuta-1,3-diene with (+)-2-methylbutyl-lithium and reported slight optical activity ($\alpha_D^{25} = 0.014$–$0.018°$ for $l = 1.55$), but this lies within the limits of experimental error. The use of rotatory dispersion did not permit a convincing demonstration of asymmetric synthesis, since although the value of $[\alpha]$ for $\lambda = 390$ nm increased by a factor of 2.5–3 compared with that for $\lambda = 589$ nm, the errors in the measurements showed a simultaneous increase, and this was not analysed.

Table 2.

Monomer/lithium ratio	Polyphenylbutadiene [η]	[α]390, deg	[α]390 M	Solvent	Monomer/lithium ratio	Polyphenylbutadiene [η]	[α]390, deg	[α]390 M	Solvent
37.6	0.075	+0.982	42.2	toluene	54	0.195	0.838	88.0	heptane
54	0.23	0.524	49.8	heptane	37.6	0.095	1.272	63.6	toluene
27	0.18	1.022	74.6	ditto	27	0.124	1.595	104	heptane

The polymerisation of phenylbutadiene on the complex catalyst butyl-lithium–(−)-menthyl ethyl ether at 0° and 15°C in heptane and toluene gave polymers with considerable activity and low characteristic viscosity (Table 2).

The highest optical activity in the polymers was observed at a ratio ether : butyl-lithium = 2. Decrease in the reaction temperature and increase in the solvent polarity lead to a decrease in the optical activity of the polymer. The optical rotation of the polymer specimens is independent of molecular weight, suggesting a mechanism of asymmetric growth, in which the asymmetric synthesis takes place as a result of the configurational orientation of the monomer on coordination to the lithium atom, through interaction with the asymmetric ligand—ethyl menthyl ether.

2. Asymmetric Cationic Polymerisation

In the polymerisation of cyclic monomers (benzofuran[32]), use is made of cationic catalysts, which form a complex with the optically active counter-ion, whose configuration determines, together with the growing chain, the spatial configuration of the first unit, and exercises steric control over chain growth. To intensify the stereospecificity of the action[23], the reaction is carried out between −75° and −100°C in toluene under the influence of, for example, the complex catalyst $C_2H_5AlCl_2$–(−)-β-phenylalanine (Table 3).

In each monomeric unit there are two asymmetric atoms; the polymer does not contain terminal groups from the catalyst, as proved by using phenylalanine labelled with ^{14}C.[33–36]

Table 3. Polymerisation of benzofuran on cationic catalysts.

Catalyst	Asymmetric co-catalyst	Polymer, $[\alpha]_D$, deg (benz.)	$[M]_D$, deg (diox.)	α_D
$AlCl_2 \cdot C_2H_5$	(−)-β-phenylalanine	−33.1	−39.1	−2.65
$AlCl_2 \cdot C_2H_5$	(+)-β-phenylalanine	+13.1	+15.5	
$AlCl_2 \cdot C_2H_5$	(+)-camphor-10-sulphonic acid	−3.8	−4.5	−0.68
$AlCl_2 \cdot C_2H_5$	(+)-tetramethylammonium camphor-10-sulphonate	−2.4	−2.8	
$AlCl_2 \cdot C_2H_5$	(−)-brucine	+2.8	+3.3	0.47
$AlCl_3$	(−)-phenylalanine	−28.5		

The polymer has a high conformational stability: it does not undergo racemisation even when heated in decalin at 200°C for several hours. This is also confirmed by the low temperature coefficient of optical rotation: $+0.04° \pm 0.01° \text{ deg}^{-1}$.

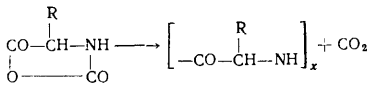
Although the optical activity is associated with the stereoregularity of the three-dimensional structure of the polymer chain, it does not necessarily lead to a tendency for the polymer to crystallise. Thus isotactic or di-isotactic polymers (for example, polybenzofuran) are obtained in amorphous form, although they are optically active. Sterically regular but amorphous polymers, for example, isotactic polymers, can be crystallised in the form of their derivatives, in which they retain their steric configuration: it is probable that, as for example in polybenzofuran, the steric conformation of the polybenzofuran chain is such that it does not permit regular packing of the chains in the crystal lattice[5,32]. It has been suggested that polybenzofuran is partly isotactic, since the optical activity in the main chain cannot be associated with a syndiotactic structure because of internal compensation. The optical activity of polybenzofuran remains constant with time. The rotatory dispersion curve shows a maximum at 303 nm: $[M]_{303} = -800°$.

The asymmetric synthesis is due to the orientating influence of the negative counter-ion situated on the growing end of the polymer chain. The efficiency of this asymmetric synthesis (calculated for unit linkage) is much greater than that for compounds with low molecular weight and approaches that of enzymatic asymmetric syntheses[33]. The mechanism, unlike that of the catalytic synthesis, evidently involves the transfer of asymmetric induction along the chain by means of the asymmetric counter-ion, the monomers being attached predominantly in one configuration. This mechanism is confirmed by the fact that the optical activity is independent of the molecular weight of the polymer[37,38].

Farina, Natta, and Bressan[38] established that the asymmetric polymerisation of benzofuran is autocatalytic. The optical activity depends to a marked extent on the monomer concentration, and from an initial value of 25–30° it passes

through a maximum in the course of the polymerisation, to a constant final value. If, at the start of the reaction, small quantities of previously formed or added polymer are already present, the value of $[\alpha]$ for the polybenzofuran formed is equal to the constant terminal value from the start of the reaction: $[\alpha]_D = 85-90°$. This suggests an autocatalytic reaction under the influence of the polymer formed. Three stages are observed in the polymerisation: (1) the formation of a polymer with low molecular weight and low value of $[\alpha]$, (2) increase in molecular weight and $[\alpha]$, and (3) new formation of fractions with low molecular weight. The second stage is autocatalytic[39]. In actual fact, the introduction of prepared polymer into the reaction sphere decreases the rate of the process by a factor of 5 to 10, but increases the asymmetrising effect, which is independent of both the sign and the magnitude of the rotation of the added polymer, and depends only on the asymmetry of the catalyst—the (+)-polymer is obtained using (+)-β-phenylalanine. The polymer formed probably intensifies the steric influence of the catalyst $AlCl_3$.(β-phenylalanine). Polybenzofuran, because of the presence of its oxygen atoms, can itself act as a Lewis base and modify the structure of the counter-ion. In the catalytic complex at a ratio $AlCl_3$: phenylalanine $\simeq$ 3, one mole of $AlCl_3$ is apparently held much less strongly, and the polymer formed produces a complex with $AlCl_3$, leading to modification of the catalyst. A polymer with high value of $[\alpha]$ is then formed under the influence of this catalyst. Thus as suggested by Natta and coworkers[38] the autocatalytic action is not steric but chemical in character.

This asymmetric autocatalysis shows a close analogy with enzymatic asymmetric syntheses in nature. A similar picture is also observed, for example, in the polymerisation of Leuch's anhydrides[40].



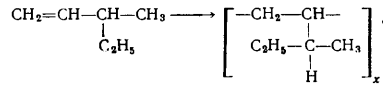
The kinetics of this reaction show a number of characteristic features: the rapid initiation stage is accompanied by chain growth processes which are at first slow (formation of a polypeptide with low molecular weight) and then rapid (conversion into a polypeptide with high molecular weight). According to Doty, a coil (β-peptide) is formed in the first stage, whereas in the second stage an α-spiral, which grows much more rapidly, is formed. If the reaction is initiated by an α-peptide, the first stage is not observed at all, but if the reaction is carried out in dimethylformamide, in which spirals are not formed, the second stage disappears. This mechanism is confirmed by study of the kinetics of the polymerisation of optically pure isomers of Leuch's anhydride and mixtures of the isomers. The homogeneous α-spiral is stable: the introduction of residues with opposite configuration decreases its stability. Thus the racemic mixture polymerises much more slowly than the optical isomer. The decrease in the rate of polymerisation of the latter when the antipode is added, however, is much greater than that when each isomer is polymerised separately. This is attributed to the fact that the polymerisation of, for example, the *d*-isomer, initiated by α-peptides obtained from the *l*-isomer, takes place slowly at first, and rapid polymerisation begins only when a sufficient number of *d*-units for the formation of a spiral are attached to the initiator. The role of the *d*-units (or other rigid conformations) can be seen from the fact that, for example, the addition of only 5% of the *d*-isomer to the *l*-anhydride is sufficient to decrease the rate constant by a factor of 3. The rate of polymerisation of the racemate is slower than that of the optical isomers by a factor of 17. Thus the polymerisation of the L-*N*-carboxyanhydride of γ-benzyl-L-glutamic acid takes place at a high rate when the polymer of γ-benzyl-L-glutamic acid is added as initiator. The reaction rate for the racemate of the anhydride is smaller by a factor of 2. In the system formed by the D-anhydride with L-polymer as initiator, the D-units are first introduced into the right-hand spiral of the L-polymer without altering its shape, but as the D-units accumulate, inversion of $[\alpha]$ is observed with an increase in rate as a result of the conversion of the α-spiral of the L-polymer into the left-hand spiral of the D-polymer.

Comparison of the relative rates of attachment of the D- and L-isomers to the right-hand α-spiral of the L-polymer showed that the L-anhydride is almost five times more active than the D-antipode[40].

IV. THE STEREOSELECTIVE POLYMERISATION OF OPTICALLY ACTIVE α-ALKENES

In the polymerisation of α-alkenes using an organometallic catalyst containing optically active alkyl groups[5] it was found that the active alkyl groups to some extent enter the polymer chain, and if the proportion of these groups is sufficiently large, optical rotation is observed in the low-molecular weight fractions. If optically active monomers are used as starting materials, however, the use of the same optically active catalyst leads to the formation of a polymer whose rotation may be 5–30 times greater than the optical rotation of the model compound, that is, a molecule with the structure of a unit in the polymer chain.

Bailey and Yates[41] at an American Chemical Society conference (1960) described a study of the effect of asymmetric atoms in the side groups of a poly-α-alkene on its crystallinity. The polymerisation of (+)-3-methylpentene ($[\alpha]_D^{25} = +33.49°$) with $TiCl_4$–$Al(n\text{-}C_4H_9)_3$ in xylene at 120–132°C for 7 days gave two polymer fractions: an atactic fraction with $[\alpha]_D^{23} = +94.9°$, and an isotactic fraction with $[\alpha]_D^{23} = -257°$ and m.p. 271–278°C, soluble only in 1,1-ditolylethane. (+)-3-Methylpentene with 4-methylpentene gave a copolymer with $[\alpha]_D^{26} = +112.4°$ and m.p. = 190°C, containing the monomers in the ratio 60 : 40. These authors attributed the marked increase in optical rotation in the polymer compared with the monomer to spiralisation of the chain



The polymer from *dl*-3-methylpentene had m.p. = 229–237°C, dissolved in 1,1-diphenylethane, and consisted of equal quantities of amorphous and crystalline phases.

An extensive series of papers on the polymerisation of optically active α-alkenes has been published by Pino and coworkers[42-55]. From optically active monomers they prepared optically active poly-α-alkenes with asymmetric centres in the side-chain. These reactions were carried out with ordinary Ziegler–Natta catalysts, and also with optically active organometallic catalysts. The latter were used to carry out stereo-elective polymerisation—selective polymerisation of one of the optical antipodes in a racemic monomer.

The polymerisation of α-alkenes on heterogeneous complex catalysts of the type $TiCl_4$–R_3Al gives polymers with a high degree of stereoregularity. A number of their characteristic properties led Pino and Natta to suggest that in the polymers, secondary structures of a spiral type,

similar to the α-spirals in proteins and polypeptides, are formed. The possibility that spiral structures are present in vinyl polymers was pointed out by Natta as early as 1954, but proof of their existence in solutions and in melts has not yet been obtained. The detailed studies of Pino have been of considerable assistance in the elucidation of the nature of the secondary structures of poly-α-alkenes. Evidence in support of the suggestion that spiral structures are present is provided by the high degree of stereoregularity, the high melting points, and the increased values of $[\alpha]_D$, which exceed the values for the monomers and model compounds by a factor of 5–30. The magnitude of $[\alpha]$ depends to a marked extent on the stereoregularity of the polymers and tends towards a limiting value[53] with increase in stereoregularity. For stereoregular specimens, the optical rotation is less sensitive to change in the regularity of the structure[53]. The absolute value of $[\alpha]_D$ for polymer solutions decreases with temperature, and the isotactic fractions show an unusually high temperature coefficient, close to the values found for solutions of proteins and polypeptides (for example, 0.30 for silk fibroin). The magnitude of $[\alpha]_D$ depends on the structure of the side-chain of the polymer, and there is an optimal distance (n = 1) between the asymmetric centre in the side group and the main chain:

Pino regards all these facts as confirmation of the existence of secondary formations analogous to the α-spirals of proteins or polypeptides[56] in solutions of poly-α-alkenes, in melts, and in the solid state.

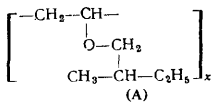
Since the contribution of the spiral structures to the total rotation increases the total rotation, decrease in $[\alpha]$ may serve as an indication of a decrease in the stereoregularity of the main chain of the polymer structure; this is also indicated by a marked negative temperature coefficient $\Delta[\alpha]/\Delta t$, characterising the reversible disappearance of regular spiral segments in the macromolecular chain with increase in temperature.

Calculation by Brewster's semiempirical method[57] established that monomers with the (*R*)-configuration form isotactic polymers in which right-hand spirals predominate.

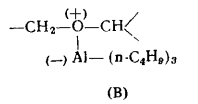
Despite the fruitfulness of this interpretation of the characteristic features of the structure of poly-α-alkenes, however, increasing doubt has recently been cast on the correctness of this interpretation[58] and it has been suggested that hindered conformations, and not spirals, are present.

Experimental data obtained by Pino and coworkers on optically active poly-α-alkenes and vinyl ethers in the presence of dissymmetric catalysts are given below.

The existence of rigid conformations, possibly of a spiral type, was suggested by Pino and coworkers[46] for the polymerisation of (*S*)-2-methylbutyl vinyl ether ($[\alpha]_D^{20}$ = +6.68°). In toluene solution, the polymer had a low rotation ($[M]_D^{25}$ = +1.1°), which was independent of the stereoregularity (infrared spectra and X-ray diffraction data) of the polyether and changed little with temperature ($\Delta[M]/\Delta t$ = +0.02). This behaviour was attributed to the presence of the ether oxygen between the asymmetric group and the main chain, weakening the steric interaction (A):



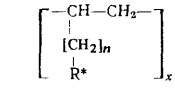
(A)



(B)

As a result, according to Pino[47], formation of a secondary structure takes place in the chain. If, however, the effect of the ether oxygen is eliminated by binding the group in a complex with $Al(n\text{-}C_4H_9)_3$, the polymer shows a sharp increase in $[M]_D$, and the temperature coefficient acquires a negative sign and a high value (up to −0.37), close to the values found for poly-α-alkenes (for example, 0.28 for poly-[*S*]-5-methylheptene). Moreover, a clearly defined dependence of $[M]_D$ on the stereoregularity of the structure is observed. All this suggested that in the "complexed" polymer one of the spiral structures predominates, as a result of the restriction of the free rotation about the C–O–C bonds in the complex (B).

A large amount of experimental material[40,59] has accumulated on the catalytic synthesis of optically active polyalkenes of general formula:



Usually, optically active monomers were employed as starting materials, and complex catalysts $Al(n\text{-}C_4H_9)_3$–$TiCl_3$ were used. The polymers were fractionated and the relationship between the optical rotation and stereoregularity was studied.

Table 4. Optical rotation of solutions of poly-α-alkenes.

	$[\alpha]_D$ monomer	Polymers					
		α_D, deg	$[\alpha]_D$, deg	$[M]_D^{20}$, deg	$\frac{\Delta[\alpha]}{\Delta t}$	$\frac{\Delta[M]}{\Delta t}$	$[\eta]$
Poly-(*S*)-3-methylpentene	(*S*) + 34.2		35.5	104	−0.10	−0.23	0.08
				163		−0.36	0.8
(*S*)-2,3-Dimethylpentane			−14.4	−11.4			
Poly-(*S*)-4-methylhexene	(*S*) − 2.5		28.6	+153	0.66	−0.42	1.3
				+288		−0.68	5.15
				+21.3			
				+9.9			
Poly-(*S*)-5-methylheptene	(*S*) + 9.8	0.95	56.5	58.1	−0.25	−0.34	5.80
Ditto, melt		0.96	—		−0.30		
Ditto, cryst.		1.02	59.6		−0.01		
(*S*)-2,5-Dimethylheptane				11.7			
(*S*)-3-Methylheptane				11.4			
Poly-(*S*)-6-methyloctene				+20.4	—	−0.09	3.78

Table 4 gives data on the optical rotation of the poly-α-alkenes obtained, the monomers, and the corresponding model compounds. Sometimes, for example, for poly-(*S*)-3-methylpentene, $[\alpha]$ for the model with low molecular weight and the same absolute configuration of the asymmetric atom in the side-chain is not only smaller in magnitude, but even of opposite sign. On polymerisation, the sign of the rotation of the polymers coincides with that of the monomer, and inversion of the configuration does not take place. Inversion of the configuration is observed only for poly-(*S*)-4-methylhexene, just when there is optimal asymmetrisation of the polymer chain ($[M]_D$ = +286°).

Comparison of $[M]_D$ for model compounds (the corresponding alkanes) given in Table 4 with $[M]_D$ for the atactic fractions of poly-α-alkenes with low molecular weight shows that their rotations are of the same order of magnitude, whereas for the isotactic fractions $[M]_D$ is greater by one order of magnitude; the temperature coefficient of molecular rotation of the latter is also much greater (0.2–0.7) than that for fractions with lower stereoregularity.

The firm of Montecatini has obtained patents[48-50] on the preparation of optically active poly-α-alkenes from the corresponding monomeric (*S*)-(+)-3-methylpentene, (*S*)-(−)-4-methylhexene, (+)-3-phenylpentene, and (+)-5-methylheptene, or their antipodes, under the influence of a $TiCl_4$–$Al(n\text{-}C_4H_9)_3$ catalyst.

Pino and coworkers[44] suggest that the high optical rotation of poly-α-alkenes results from the algebraic summation of the relatively weak influences of the asymmetric atoms in the side groups and the much greater influence of the spiral structure of sections of the main chain which have identical rotation and are present in solutions.

This view appears to be confirmed by the marked dependence of the rotation on the stereoregularity of the polymers. The presence of atactic sections of chain in the polymer should decrease considerably the proportion of spirals of one sign, and hence $[\alpha]_D$. In this instance, the structure of the side group acquires considerable importance. Even when the asymmetric carbon atom is in the α-position relative to the main chain, as, for example, for poly-*R*-(−)-3,7-dimethyloctene (I), a decrease in $[M]_D$ is observed relative to the value of $[M]$ for poly-3-methylpentene (II):[51]

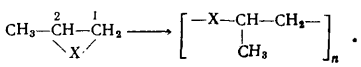
(I)  (II) 
Fractionation of the poly-3,7-dimethyloctene fraction with $[\eta] = 6.52$ and $[M] = 144°$ at various temperatures (34–80°C) increased the rotation only to $[M]_D = 154°$ ($[\eta] = 6.93$).

Comparison of the properties of two groups of poly-α-alkenes, obtained by two methods: (a) by catalytic asymmetric synthesis, and (b) from the optically active monomers, shows that in the latter there is a marked increase in optical rotation as a result of the conformational contribution from the main chain, whereas the polymers obtained by asymmetric synthesis owe their optical activity to the configuration of the asymmetric atoms in the main chain.

V. STEREOSPECIFIC CATALYSIS IN THE POLYMERISATION OF PROPENE OXIDE AND IMINES

A number of problems of the detailed mechanism of polymerisation can be solved by studying the reactions of optical isomers instead of the racemates usually employed. Of particular interest are problems related to the determination of the part played by a heterogeneous catalyst in a stereoselective or stereo-elective process, the determination of the influence of the asymmetrising stages of polymerisation on the properties of the polymer produced, and the determination of the nature of the active centres of a stereospecific catalyst by comparison of the rates of polymerisation of the optical isomers and the racemate. In this connection, some success has been achieved with propene oxide—the simplest monomer capable of existing in an optically active state.

The overall polymerisation scheme assumes rupture of the epoxide ring (X = O) at the C_1–O or C_2–O bond;



If the rupture of the bonds is equally probable, as, for example, in the polymerisation of D-(+)-2,3-epoxybutane, the action of, for example, the catalytic system $Al(n\text{-}C_4H_9)_3$–H_2O in heptane gives an inactive polymer with the *meso*-diisotactic structure, with properties identical with those of the polymer from the racemic monomer[60]. Treatment of *cis*-2,3-epoxybutene with an optically active catalyst obtained from $(C_2H_5)_3Al$, acetylacetone, and *l*-menthol, however, gives a diisotactic polymer with $[\alpha]_D^{25} = +1.1° \pm 0.3°$. Inversion of the configuration of the monomer takes place in the reaction[61]. In the discussion of papers on the polymerisation of propene oxide, mention must be made of the erroneous assignment of (+)-propene oxide to the L-series[62,63]. It is more correct to relate (+)- and (−)-propene oxides to the D- and L-series respectively[64,67]. In this instance it would probably be more appropriate to use the nomenclature system of Terent'ev and coworkers[68].

The polymerisation of an optical isomer of propene oxide was first attempted by Levene and Walti[64]; the action of KOH solution gave a cyclic trimer with $[\alpha]_D^{20} = -43.0$ and a tetramer with $[\alpha]_D^{20} = -49.19$. By the action of powdered potassium hydroxide at 25°C on the D-isomer with $[\alpha] = +14.75°$, Price and Osgan[69] (1956) obtained a crystalline polymer ($\eta_{sp}/c = 0.13$; $[\alpha]_D^{25} = +25 \pm 5°$ chl., m.p. 56°C), whereas the racemic monomer gave a viscous polymer whose molecular weight, however, was similar (3000–5000), indicating a chain reaction mechanism

The use of the Pruitt–Baggett catalyst[70] ($FeCl_3$ + propene oxide) on (−)-propene oxide also gives a crystalline polymer (m.p. 72°C) with the same value of $[\alpha]_D$ as that obtained using KOH, but in addition, an amorphous fraction is always produced (from both the *l*-isomer and the racemate). Water acts as a co-catalyst, and the proportion of crystalline fraction increases in its presence. This interesting observation was subsequently applied to produce new asymmetric catalytic systems[66]. According to Price, the formation of a completely crystalline polymer from the *l*-monomer on KOH and the formation of a partly crystalline polymer on the $FeCl_3$ catalyst indicates preservation of the configuration in the first instance and partial racemisation in the second instance.

For catalysis on the $FeCl_3$ catalytic system, it was found that the rate of polymerisation is independent of the monomer concentration, but proportional to that of the catalyst, and that the degree of depolymerisation is inversely proportional to the catalyst concentration and increases with increase in the degree of conversion. This indicates that the polymerisation is heterogeneous[69], that the crystalline polymer is formed on the catalyst surface, and that the amorphous fraction is formed in solution in the presence of dissolved catalyst. This scheme presupposes asymmetric adsorption of the substrate, and this was later proved.

According to Price, the reaction mechanism involves "coordinative growth of the chain" as a result of coordination in the transition state to give a five-membered ring. The influence of water on the crystallinity of the polymer is due to its reaction with the catalyst and the creation of considerable steric hindrance in the reaction. The attachment of the first molecule of monomer takes place with preservation of the configuration of the asymmetric atom. The next molecule forms a coordinate bond with the iron atom, and this bond is formed preferentially by molecules with the same configuration. (The various reaction schemes are examined by Gaylord and Mark[71].) Other views on the mechanism of this reaction are given in a review by Bakalo and Krentsel'.[72]

Ziegler–Natta catalysts can also be used for the reaction; this gives a polymer with the same melting point as Price's polymer, indicating that the racemic polymer contains monomer chains with a single configuration[71,73].

Racemic isotactic polypropene oxide can be separated, albeit only slightly, into optically active fractions by chromatography on saccharose and on the complex formed by diethylzinc with *l*-menthol or borneol[74].

On the basis of a large amount of experimental data it is assumed that stereospecific polymerisation is facilitated by the orientating influence of the surface of a heterogeneous (or microheterogeneous) catalyst, although data have recently been published on the preparation of isotactic and syndiotactic polymers under conditions of homogeneous polymerisation by the methods of not only ionic polymerisation but also radical polymerisation[75–77]. At the same time it is known that soluble catalytic systems are less active, and the polymers obtained show a lower degree of stereoregularity[71]. This is confirmed by the data of Price and coworkers on the polymerisation of propene oxide. The fact that these microheterogeneous systems may be visually homogeneous[72] does not prove the absence of heterogeneous formations[78]. Moreover, heterogeneity may be produced in situ[71] as a result of the reduction of metal salts in the catalytic complex. The existence of active, purely heterogeneous, catalysts for the polymerisation of propene oxide also confirms this view.

Krylov and Livshits[11–13] showed that it is possible to use magnesium oxide, oxalate, and tartrate and a number of other heterogeneous catalysts for the polymerisation of propene oxide, and that the activities of Be, Ca, and Mg oxalates are comparable with that of the most effective of Price's catalysts.

A number of important problems of stereospecific catalysis have been studied for the example of the heterogeneous polymerisation of the optical isomers of propene oxide. In polymerisation on a heterogeneous catalyst, three examples of stereochemical correlation are possible: (1) the active centres of the catalyst are stereochemically indistinguishable for adsorption of the (+)- and (−)-isomers of the monomer; the probability of growth and the rate of polymerisation of the (+)-monomer are then double those for the racemate; (2) the catalyst contains equal quantities of enantiomorphic centres; the rates of polymerisation of the isomer and racemate will be equal, since replacement of the racemate by the (+)-isomer decreases the number of available centres by a factor of two but increases by a factor of two the probability of growth of the *ddd*-chains; (3) the catalyst contains centres with the same sign; the rate for one isomer will be greater than the rates of polymerisation of the other isomer and the racemate. Livshits, Krylov, and Klabunovskii[2,79,80] studied the kinetics of the polymerisation of (+)-, (−)-, and (±)-propene oxide on the heterogeneous catalyst magnesium oxalate and found that the probability of chain growth from the optical isomer [(+)- or (−)-propene oxide] is twice that for the racemate (the ratio of the first-order rate constants was ~ 2).

The results obtained (Table 5) indicate that the first situation is realised, that is, the active centres on the catalyst are indistinguishable with respect to the (+)- or (−)-isomers, and the number of accessible centres is the same for the antipode and the racemate.

In this section we must also consider the polymerisation of imines—the nitrogen analogues of propene oxide. Propeneimine isomers with $[\alpha]_D = -12.8°$ and $+12.4°$ have been polymerised in the presence of a number of catalysts [including $BF_3.(C_2H_5)_2O$] with the formation of solid polymers with $[\alpha]_D = +190.27°$ or $-101.46°$ and m.p. = 83° or 73°C respectively. Inversion of the sign of rotation takes place on polymerisation, as with propene oxide. The racemate under the same conditions gave a polymer with m.p. 17°C, although their molecular weights were similar[81].

The polymerisation of oxides and imines probably involves a succession of S_N2 reactions, in which first hydroxide ions and then alkoxide ions function as nucleophilic reagents[82]:

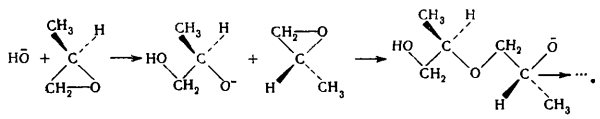


Table 5. The polymerisation of D-(+)- and L-(−)-propene oxide on magnesium oxalate and the properties of the polymers obtained.

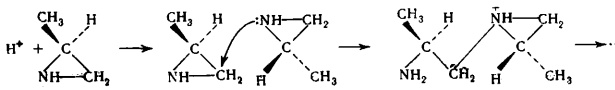
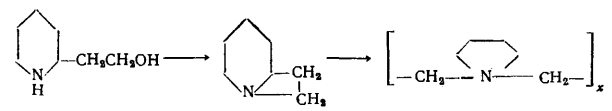
$[\alpha]_D^{20}$ for monomer, deg	Temp. of experiment, °C	Weight of MgC_2O_4, g	Duration of reaction, h	Degree of conversion, %	Polymer		Ratio of rate constants
					$[\alpha]_D$ (benz.), deg	$[\eta]$	
+9.50	83.9	0.15	33.5	74.2	−24.2	0.12	—
9.50	89.4	0.208	11.5	59.8	−23.1	0.12	1.9
9.50	93.4	0.207	14.0	54.5	−31.9	0.06	2.2
−6.95	89.4	0.242	13.5	41.1	+12.8	0.18	2.1

In the polymerisation of propeneimine we must also assume an S_N2 mechanism initiated by a proton:



Similarly, isobutylethyleneimine with $[\alpha] = -24.6°$ ($-15.4°$ [83]) gave a polymer with m.p. 56°C and $[\alpha]_D^{20} = +66.7°$ or 68° (benz.).[84] The polymer was used successfully as catalyst in an asymmetric cyanohydrin synthesis[84].

Polyconidine, prepared by Toy and Price[85], is of equal interest in connection with the use of polymers as models of enzymatic asymmetric systems. If the polymerisation is carried out in the presence of BF_3, the catalyst enters the polymer chain; the resulting polyconidine has $[\alpha]_D = +12.7°$. The action of the ether addition compound of BF_3 at room temperature gives a crystalline polymer, whose sign of rotation is the opposite of that of the monomer:



$[\alpha]_D + 11°$ $[\alpha]_D + 71°$ $[\alpha]_D - 140.8°$ m.p. 94°C

(+)-Polyconidine was obtained analogously. The racemic polymer obtained by dissolving equal quantities of (+)- and (−)-polyconidine had the same melting point as the optical isomers.

VI. THE STEREO-ELECTIVE POLYMERISATION OF DL-PROPENE OXIDE UNDER THE INFLUENCE OF DISSYMMETRIC CATALYSTS

Price and Osgan[69] found that prolonged contact between racemic propene oxide and a Pruitt–Baggett catalyst prepared using (−)-propene oxide gives a polymer containing

a crystalline fraction. This showed that under certain conditions the action of this dissymmetric catalyst may lead to a stereo-elective process, that is, the selective extraction of one of the optical antipodes of the racemate in the polymerisation. This was verified in work by Chu and Price[86]. Various catalytic systems for the polymerisation of (+)-propene oxide were studied: $Al(OC_3H_7)_3$, $ZnCl_2$, $Zn(C_2H_5)_2.H_2O$, and $FeCl_3.C_3H_6O$. All the catalysts gave crystalline polymers with similar rotations, with $[\alpha]_D$ about $-25°$, but the melting point for $Zn(C_2H_5)_2$ was much lower than that for the other catalysts, indicating a polymer with low tacticity. The polymer from the DL-monomer was even less stereoregular, however. An attempt to carry out a stereo-elective process in this way was unsuccessful.

The preparation of the catalysts involved production of the complex by the reaction of a small quantity of D-propene oxide with $FeCl_3$, after which the main bulk of the DL-monomer was added. Optically inactive products were also obtained using other dissymmetric catalytic systems: (−)-propene oxide + $Zn(C_2H_5)_2$ + H_2O; (−)-aluminium–propene glycol complex + $ZnCl_2$; and $(n\text{-}C_4H_9)_3Al$ + (−)-1-methoxypropan-2-ol.

The systems studied give less soluble and hence more stereoregular polymers from L-propene oxide than from the DL-monomer. Asymmetrisation of the catalyst by the introduction of a "seed" of the L-polymer did not give the catalyst stereo-elective properties.

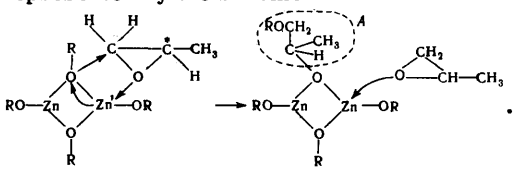
The optical activity in polypropene oxide obtained on an optically active Pruitt–Baggett catalyst was preserved only in the first hours of polymerisation at 80°C and, as shown by calculation, could be attributed entirely to the inclusion of active propene oxide from the catalyst.

The effective stereo-elective polymerisation of DL-propene oxide was carried out using a catalyst based on $Zn(C_2H_5)_2$. Polymerisation with this catalyst takes place effectively in the presence of water or alcohols. Dimeric or trimeric zinc alkoxides, whose presence was proved spectroscopically[87], are formed:

$$Zn(C_2H_5)_2 + ROH \rightarrow ROZnC_2H_5 \xrightarrow{ROH} RO{-}Zn{-}OR\,.$$

When an optically active alcohol is introduced into the system instead of water, we should expect this dissymmetric catalyst to have a stereospecific action and lead to the formation of an optically active polymer.

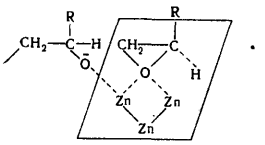
The catalytic properties of the complex are due to the presence of free coordination centres, and the zinc atom is of primary importance. For the dimer, the reaction can be represented by the scheme:



Since in the experiments the radical R was the optically active (+)-bornyl group, the introduction of each monomer molecule into the reaction sphere is sterically controlled not only by the preceding unit introduced into the chain (denoted *A* in the scheme) but also by the influence of the asymmetric centres of the bornyl group of the catalyst.

Furukawa[88] considers the polymerisation of oxides in terms of a multi-centre coordination mechanism, according to which there are two coordination centres, and the propene oxide molecule is joined through oxygen to two zinc atoms. One of the bonds is an ordinary ionic bond and involves the counter-ion.

In this coordination-anionic polymerisation, the attachment takes place at the α-carbon atom of the monomer, which contains the key atom. The stereoregulating action is brought about by the reaction of the R group in the monomer with the ligand of the catalyst or with the R group in the polymer chain. The monomer, coordinating to two catalyst centres, preserves a definite position in space relative to the end of the polymer chain and to the catalyst. The attachment of the next monomer takes place in the same configuration, with the formation of an isotactic structure. The appropriateness of this approach followed from papers by Price (1959) and the experiments of Furukawa (1962),[89] and was confirmed in work by Tsuruta and coworkers[90,91]. Asymmetric induction takes place by the stereoregular control of the reaction of the OR alkoxy-group of the optically active alcohol joined to the complex catalyst (Inoue, Tsuruta, and Furukawa[92]):



The dissymmetric catalyst was obtained, for example, by adding 0.05 M HOR[(+)-borneol, (−)-menthol] to 0.025 M $Zn(C_2H_5)_2$. At 80°C the degree of conversion in the polymerisation of DL-propene oxide amounts to 17–30%.

The crystalline polymer obtained exhibited optical activity. The conditions of the stereo-elective polymerisation, and the constants of the polymer, are given in Table 6.

Table 6. Stereo-elective polymerisation of DL-propene oxide on $Zn(C_2H_5)_2$ + co-catalyst.

Co-catalyst	Medium	% conversion	Crystalline polymer					Amorphous polymer	
				in benzene		in chloroform			
			η/c	α obs., deg	$[\alpha]_D$, deg	α obs.,, deg	$[\alpha]_D$, deg	η_{sp}/c	α obs., deg
(+)-borneol	toluene	27.6	5.63	−0.07	−5.9	+0.26	+7.4	—	—
ditto	hexane	25.0	3.30	−0.06	−4.6	+0.19	+6.1	1.48	±0.01
ditto	benzene	30.0	3.65	−0.06	−3.7	+0.04	+2.5	1.70	±0.01
(−)-menthol	ditto	17.3	0.59	−0.02	−3.6	+0.07	+2.2	—	—

A noteworthy feature is the very low values of the rotation, which lie, for example when the (−)-menthol co-catalyst is used, at the limits of error of the measurement (−0.02°). In chloroform, however, the magnitude of the rotation increases and its sign changes, confirming the presence of an optically active polymer. The amorphous fraction of the polymer did not exhibit optical activity. The molecular weights of the polymers were sufficiently large to exclude the influence of terminal groups on the total rotation, and the sign of the rotation was opposite to that of the bornyl or menthyl ether, confirming that the fragments of the optically active alcohol had almost no influence on the rotation of the polymer, although the introduction of terminal groups from the catalyst into the polymer was subsequently proved. It was also confirmed using the catalyst 9,10-di(hydroxymethyl)anthracene–dibutylzinc. The polymer obtained contained alkoxy-groups, which were identified from their ultraviolet fluorescence.

The observed inversion of the optical rotation of poly(propene oxide) from negative in benzene to positive in

chloroform is a characteristic feature, which was also observed by Price for the (−)-polymer. The curves for the dispersion of the rotation, recorded in these solvents, are completely symmetrical. It may be assumed that this sensitivity of the optical rotation to the nature of the solvent is due to the contribution of the molecular asymmetric structures of the polymer to the total rotation[92].

The magnitude and sign of the rotation are influenced considerably not only by the solvent but also by the concentration of the polymer in chloroform. This is possibly due to the formation of hydrogen bonds between the oxygen atom in the polymer and the chloroform[13]. The point of inversion lies at about 2.2 g in 100 g solution; the negative rotation increases with increase in the concentration of polymer in chloroform.

As expected, the unreacted propene oxide isolated after polymerisation acquires optical activity. Thus when the diethylzinc–(+)-borneol system was used, the monomer remaining had $[\alpha]_D^{20} = -0.98° \pm 0.05°$ so that the (+)-isomer in the racemate reacted more rapidly, enriching the monomer in the (−)-isomer[93].

If k_i and k_p are the rate constants for the initiation and propagation of the chain, it follows that if the catalyst centres are equivalent $k_{il} = k_{id}$, a mixture of *d*- and *l*-polymer chains in equal proportions is formed. On a dissymmetric catalyst, containing, for example, (+)-borneol, $k_{id} > k_{il}$ and the polymer contains more D-units than L-units. Thus more of the D-(+)-isomer is withdrawn from the racemate during polymerisation.

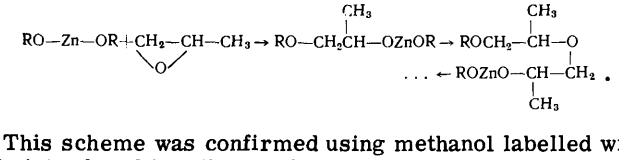
Analysis of the material balance from the optical rotation of the polymer and the activated monomer indicated that in the amorphous fraction of the polymer the influence exerted on the rotation by the bornyl group entering the polymer as terminal group cannot be neglected, since the molecular weight of this fraction is low. For the crystalline polymer, on the other hand, this influence can be neglected, in view of the high molecular weight.

The calculation is based on the formula[62,94]:

$$A\alpha_M = KP_x[\alpha_x],$$

$$K = \frac{[\alpha_{ML}]}{[\alpha_{pL}]} \cdot \left(1 + \frac{P_S[\alpha_S] + P_A[\alpha_A]}{P_x[\alpha_x]}\right),$$

where $[\alpha_{ML}]$ and $[\alpha_{pL}]$ are the specific rotations of the pure L-monomer and the polymer, A the ratio of the returned monomer to the original monomer, P_x, P_S, P_A and $[\alpha_x]$, $[\alpha_S]$, $[\alpha_A]$ the yields in per cent and the specific rotations of the crystalline, semi-crystalline, and amorphous fractions of the polymer; and $[\alpha_M]$ the specific rotation of the returned monomer. Calculation on the basis of the experimental data[62,94] showed that the plot of $P_x[\alpha_x]$ against $M[\alpha_M]$ is a straight line, indicating that K in the equation is constant, and hence that the optical activity of the polymer appears as a result of the polymerisation of the (+)-isomer in the racemate. The fact that the (+)-bornyl group can enter the fraction with low molecular weight in the polymerisation process follows from the mechanism of the initiation:



This scheme was confirmed using methanol labelled with ^{14}C, introduced into the catalytic system.

The radioactivity was found chiefly in the fraction with low molecular weight ($\bar{M}_n$ = 6100) and to a slight extent in the fraction with high molecular weight ($\bar{M}_n$ = 50000). Thus the alcohol radical enters chiefly the amorphous fraction of the polymer. Its optical activity is due to the introduction of the bornyl group, whose rotation in chloroform is positive, like that of bornyl alkyl ethers.

Experimental data[90] obtained with the $Zn(C_2H_5)_2$–(+)-borneol catalytic system show that the optical activity of the monomer increases with time as far as 70 h, and then decreases, like the proportion of crystalline fraction. The optical activity of the polymer, however, increases slightly with duration of polymerisation, and the value of $[\eta]$ does not show a definite pattern, although it changes in the same sense as the change in the specific rotation of the polymer.

Livshits and Krylov[11–13], following Price, tried to initiate the stereo-elective polymerisation of DL-propene oxide by modifying magnesium oxalate with the (−)-isomer of propene oxide or the (−)-polymer.

The influence of added polymer on the rate of polymerisation was examined above; this is also observed in the polymerisation of benzofuran[32,95], but the effect can evidently also be expected when stereoregular structures with sufficiently high molecular weight are formed in polymerisation. In this instance there is in fact an intensification of the stereospecificity of the action of the catalytic system when the optically active polymer is introduced during polymerisation.

In the example studied[11–13], the addition of polymer to the catalyst did not lead to asymmetric polymerisation, but it nevertheless facilitated the formation of a crystalline stereoregular structure in the optically inactive polymer.

Magnesium oxide and iron oxide modified with D-tartaric acid polymerised DL-propene oxide in 18% yield with the formation of a crystalline fraction of polymer with low optical activity: $[\alpha]_D^{20} = 1.4° \pm 0.3°$ and $[\eta] = 0.57$. Magnesium oxalate was modified with D- and L-propene oxide and used in the polymerisation of the racemic epichlorohydrin. This did not lead to a stereo-elective process; the polymerisation of each monomer was kinetically independent. Only magnesium tartrate proved to be an effective catalyst (Table 7).

Table 7. Stereo-elective polymerisation of DL-propene oxide on magnesium tartrate[11–13].

Magnesium tartrate, g	*dl*-Propene oxide, g	Degree of conversion, %	Polymer	
			$[\alpha]_D$, deg	$[\eta]$
0.223	4.352	10.3	−9.2	0.03
0.153	4.472	4.32	−15.6	0.24
0.690	8.368	1.67	−27.4	0.11
0.816	6.764	2.08	16.1	0.53

In the first stages of the reaction, the polymer obtained is optically pure, but its optical purity subsequently decreases. An analogous phenomenon was also observed in the polymerisation of benzofuran[96], and this can be attributed to the stage of asymmetric initiation, and not asymmetric growth. Attempts to carry out the stereo-elective polymerisation of DL-propene oxide on iron tartrate and magnesium glutamate were unsuccessful. Magnesium tartrate proved to be an effective dissymmetric catalyst, capable of bringing about not only the polymerisation of optical isomers, but also the stereo-elective polymerisation

of racemate with the formation of polymers with a high degree of optical purity (Table 7). (The specimen obtained by Price[86], with $[\alpha]_D = -28.6°$, was taken as the optically pure polymer.) In the series of catalysts magnesium oxide–magnesium oxalate–magnesium tartrate, the specific catalytic activity decreases (30 : 20 : 1), due to the increasing degree of screening of the magnesium ion, which is regarded as the active centre[11], by the organic anion. A coordination reaction mechanism, involving chemisorption of the monomer molecule and the formation of a bond between the oxygen of the ring and the coordinatively unsaturated metal ion on the catalyst surface, is assumed. Because of steric hindrance, coordination and growth are possible only when anion vacancies are present. In the oxalate these vacancies are symmetric, whereas in the D-tartrate the vacancies are dissymmetric, and this is responsible for the stereo-elective character of the polymerisation of propene oxide. The importance of anion vacancies is also emphasised in the examination of the mechanism of action of Ziegler–Natta catalysts[9,97]. This view differs essentially from earlier views[98], according to which the stereospecificity of heterogeneous polymerisation catalysts is associated with a regular crystal lattice, and lattice defects can have only a negative influence on the stereospecificity of the catalyst.

Japanese workers were able to obtain reproducible results in the stereo-elective polymerisation of DL-propene oxide on a diethylzinc–borneol catalytic system, and this enabled them to undertake a detailed study of the mechanism of stereospecific catalysis and an investigation of the part played by asymmetric adsorption.

Tsuruta and coworkers[63] studied the "copolymerisation" of the D- and L-isomers using a stereo-elective catalytic system and, for comparison, using the non-specific catalyst KOH. Neither KOH nor $Zn(C_2H_5)_2$–CH_3OH exhibit stereoselectivity, and in the polymerisation of (+)-propene oxide the original monomer and the returned monomer have the same specific rotation. The plot of $[\alpha]_D$ for the non-fractionated polymer against $[\alpha]_D$ for the original monomer is a straight line for both catalysts, and if racemisation takes place in the reaction, it does so to an equal extent on KOH and $Zn(C_2H_5)_2$–CH_3OH.

When $FeCl_3.C_3H_6O$ was used as catalyst, the monomer with $[\alpha]_D = +15°$ gives a polymer with $[\alpha]_D^{20} = +17°$ (chloroform), that is, with a higher degree of racemisation than that in the example studied[63]. If the polymer is fractionated, the more crystalline fraction has a higher specific rotation than the amorphous fraction, so that the quantity of D-isomer entering the crystalline polymer is greater than that corresponding to the D/L ratio in the original monomer.

This is due to the fact that for a ratio D/L > 1 in the monomer, the rate of formation of a bond between the D-molecule and the active centre D* will be greater than the rate of formation of a bond between the L-molecule and this centre, so that $k_{DD}* > k_{LD}*$, despite the fact that the numbers of D*- and L*-centres on the non-specific catalyst [KOH or $Zn(C_2H_5)_2$–CH_3OH] are equal[63]. As a result, the ratio D/L in the polymer is greater than that in the monomer. Thus on a non-stereospecific catalyst $k_{DD}*k_{LD}* = k_{LL}*k_{DL}*$, whereas on a specific catalyst this equality is not observed, and the distribution of the D*- and L*-centres will be unsymmetrical.

Not only alcohols, but also ethers and amines[99], can be used as optically active modifying co-catalysts for carrying out "asymmetrically selective polymerisation".[66]

Stereo-elective power is also shown by a catalyst consisting of the reaction mixture of the partial hydrolysis of the $FeCl_3$–C_3H_6O catalyst, carried out in the presence of *d*-bornyl ethyl ether (*d*-BEE). This system was found to be highly effective and led to optical activation of the unreacted propene oxide with the formation of a crystalline polymer which, to the surprise of the authors, was found to be optically inactive. This phenomenon is so interesting that it is worth considering in more detail.

The catalyst was prepared by the Pruitt–Baggett and Price methods[69], after which *d*-BEE and water were added. The optimum Fe : H_2O : BEE ratio was found to be 1 : 1.5 : 0.5 (the returned monomer in this instance had $[\alpha]^{13} = +1.94°$, but the crystalline and amorphous fractions of the polymer were optically inactive). The rotation of the monomer increased with time, from +0.22° (1.4% activation) to 1.19° (7.9% activation).

Thus the (−)-isomer polymerises more rapidly, but the numbers of units with the *d*- and *l*-configurations in the polymer are equal and the polymer does not show optical activity.

The discovery by Furukawa and coworkers[66] of asymmetric adsorption on the catalytic system studied is of extreme importance. When DL-propene oxide was added to the system at −20°C, the excess distilled off in a vacuum, and the adsorbed quantity displaced by the addition of triethylamine, the propene oxide fractions obtained had optical rotations with different sign: $[\alpha]'_D = +0.084°$ and $[\alpha]''_D = -0.42°$.

It can thus be seen that the concentration of (−)-isomer on the surface of the complex is greater than that of the (+)-isomer, and the sign of rotation corresponds to the antipode which is polymerised at a greater rate by the given catalytic system. Thus asymmetric adsorption is one of the chief factors determining the reactions of *d*- and *l*-isomers. Kinetic treatment of the results showed that the ratio of the rates of polymerisation is close to the ratio of the isomers adsorbed on the catalyst.

The reaction takes place by a coordination-anionic mechanism, in which the monomer is first coordinated to the active centre (activated by adsorption), after which opening of the epoxide ring takes place. This can be represented by the scheme:

$$D \overset{K_D}{\rightleftarrows} D_{ad} \xrightarrow{k_D} \text{polymer}$$

$$L \overset{K_L}{\rightleftarrows} L_{ad} \xrightarrow{k_L} \text{polymer}$$

where K_D and K_L are the constants for the adsorption equilibrium, and k_D and k_L the rate constants for opening of the ring.

The rate of polymerisation is proportional to the concentration of adsorbed monomer, that is

$$\frac{dD}{dL} = \frac{k_D[D_{ad}]}{k_L[L_{ad}]} = \frac{k_D K_D[D]}{k_L K_L[L]},$$

or

$$\ln\frac{D}{D_0} = \frac{k_D K_D}{k_L K_L}\ln\frac{L}{L_0} = r\ln\frac{L}{L_0},$$

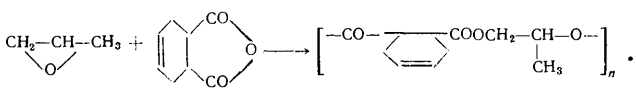
$$r_0 = \frac{k_D K_D}{k_L K_L},$$

where D_0 and L_0 are the initial concentrations of the isomers of the monomer, and r the selectivity index of the process. The inequality of the rates of polymerisation of the *d*- and *l*-isomers is controlled chiefly at the coordination (adsorption) stage. The selectivity index of the process depends essentially on the composition of the catalyst. The optimum Fe : H_2O : *d*-BEE ratio is 1 : 1.5 : 0.5, at which $r = 1.71$. The selectivity of the catalyst r increases with

increase in the water concentration and decreases with increase in the concentration of $FeCl_3$ and *d*-BEE. A second interesting observation made by Furukawa and coworkers[66] was the absence of optical activity in the polymer. Since there can be two forms of adsorption: (1) selective adsorption, when there are unequal quantities of D- and L-centres on the catalyst surface, and (2) non-selective adsorption, when the entire surface of the catalyst is equally accessible to the D- and L-molecules of the adsorbate, four states are possible, depending on whether the quantities of adsorbed D- and L-molecules are equal or unequal (non-equilibrium). Moreover, at the stage of ring opening there are four possibilities: (1) preservation of the configuration, (2) inversion of the configuration, (3) racemisation and stereospecific growth of the chain, and (4) racemisation and non-stereospecific growth of the chain. ("Racemisation" here denotes not conversion of an isomer of the monomer into the racemic monomer, but the formation of equal quantities of *d*- and *l*-units in the chain from the *d*- or *l*-monomers.) Path (3) gives equal quantities of the *d*- and *l*-polymers, whereas path (4) gives a stereoregular polymer consisting of equal quantities of *d*- and *l*-units.

In the diethylzinc–(+)-borneol and diethylzinc–water–(+)-BEE systems, processes of selective non-equilibrium coordination take place with preservation of the configuration (the formation of optically active monomer and polymer with regular structure) and racemisation with non-stereospecific growth of the chain (the formation of optically active monomer and inactive and non-regular polymer).[109]

Since propene oxide readily undergoes asymmetric selective polymerisation, it may be expected that asymmetric copolymerisation of propene oxide with another monomer having an asymmetric carbon atom will take place successfully[101]. Thus DL-propene oxide and 3-phenyl-Δ^4-tetrahydrophthalic anhydride copolymerise under the influence of 2% diethylzinc–(+)-borneol catalyst in toluene at 80°C. The copolymer (yield 49.9%) had $[\alpha]_D^{25} = +2.9°$ for a duration of reaction equal to 108 h. The rotation of the polymer, and its viscosity, increase with duration of the reaction.



The unreacted propene oxide and the propene glycol obtained by hydrolysis of the polymer were optically inactive, whereas the unchanged anhydride (isolated as the monomethyl ester) had a rotation between +1.4° and +1.7°. The dicarboxylic acid obtained by hydrolysis of the polymer was also optically active (between −0.4° and −0.5°). This unexpected result is most readily explained by assuming that the asymmetric centres of the catalyst directly activate the anhydride, which displaces the propene oxide from the D- and L-centres by adsorption.

Tsuruta and coworkers[102–105] extended stereo-elective polymerisation to the synthesis of optically active polyalanine from *N*-carboxy-DL-alanine anhydride (I), which polymerises under the influence of compounds containing active hydrogen, to form a water-soluble polypeptide. Organometallic compounds were recently used for the polymerisation of L-(I) to give a high polymer[106]. It was found that the use of even one component of the catalytic systems studied, for example, (+)-borneol or (−)-menthol as catalyst made it possible to obtain, from DL-(I), a macromolecular optically active polyalanine, which was (+) in dichloroacetic acid (DCAA) and (−) in a chloroform–DCAA mixture; the water-insoluble fraction had a high rotation (+1.3° and −1.0°).

The use of the triethylaluminium–(+)-borneol (in the ratio 1 : 2) system gave the same results: a water-insoluble fraction with $[\alpha]_D = +1.2°$ (DCAA) and $[\alpha]_D = -0.4°$ (chloroform–DCAA) was obtained in 29.5% yield.

VII. THE STEREO-ELECTIVE POLYMERISATION OF DL-α-ALKENES

Stereo-elective polymerisation has also been used successfully in the field of poly-α-alkenes. Here, two mechanisms are possible: (1) the "selection" of one of the enantiomorphs of the monomer is regulated by the asymmetric group of the chain—the alkyl group of the catalyst or the first monomeric unit, and (2) the difference in the rates for the enantiomorphs is due to the asymmetry of the active centre of the catalyst, produced as a result of appropriate arrangement of the surface atoms or by inclusion of asymmetric organic groups in the active centre.

The first possibility might be verified by comparing the optical activity of polymers from racemic 4-methylhexene and propene on an optically active catalyst. In actual fact, using a $TiCl_3$-[(+)-(*S*)-2-methylbutyl]$_3$Al.O$(C_2H_5)_2$ catalyst (optical purity 91%), Pino and coworkers[52] were able to detect optical activity in polypropene and polystyrene. Although the values found for the rotation of polypropene and polystyrene are very small, they are slightly greater than the values given by Braun and Kern[21]: +0.1 ± 0.003° for isotactic polystyrene and 0.12° for amorphous polystyrene. It should be noted that earlier, Murahashi and coworkers[20] had not detected rotation under these conditions, and Fray and Robinson[22] had not observed rotation for polypropene, either in the polymer or in the fragments obtained by pyrolysis of the polymer. Pino[52] attributed the discovery of slight activity in polypropene and polystyrene to the high optical purity of the 2-methylbutyl group in the catalyst which he used, and to the more successful selection of polymerisation conditions. In experiments at atmospheric pressure, the polypropene fractions with low molecular weight had $\alpha_D = +0.025°$ (*l*1) and $[\alpha]_D = +3.9°$, whereas the corresponding values at 10 atm were $\alpha_D = +0.05°$ (*l*1) and $[\alpha]_D = +0.90°$. For polystyrene with (*R*)-2-methylbutyl-lithium/tris(acetylacetonato)chromium catalyst the values $\alpha_D = +0.105°$ (*l*2) and $[\alpha]_D = +0.6°$ were obtained for the fraction with low molecular weight.

The stereo-elective polymerisation of racemic 4-methylhexene on a $(C_5H_{11})_3Al$–$TiCl_3$ catalyst gave an optically active polymer whose $[\alpha]_D$ value did not depend on the stereoregularity, but only on the monomer: $(C_5H_{11})_3Al$ ratio (the best result was obtained at a ratio 1 : 4) and on the molecular weight: $[\alpha] = 1.1°$ at $[\eta] = 0.15$ and falls to zero with increase in $[\eta]$ to 2.05. The highest rotation was found in the amorphous fraction, soluble in acetone: $\alpha_D = +0.095°$, $[\alpha]_D = +7.1°$.

Since one antipode entered the racemate preferentially during polymerisation, activation of the unreacted monomer due to the excess of the antipode remaining might have been expected. It was found, however, that the monomer remained inactive. Other dissymmetric catalysts were studied: [(*R*)-2-methylbutyl]Li–$TiCl_4$, [(*S*)-2-methylbutyl]$_2$Zn–$TiCl_4$, and [(*S*)-4-methylhexyl]$_3$Al–$TiCl_4$. The specific rotation of the poly-4-methylhexene fraction soluble in acetone had the values +0.7°, 13.6°, and 4.6° respectively.

Fractionation of the polymer obtained using the [(*S*)-C_5H_{11}]$_2$Zn–$TiCl_4$ catalyst gave an amorphous fraction with

$\alpha_D = +1.385°$ (*l*1) and $[\alpha]_D = +15.2°$, and a fraction with high molecular weight, with $\alpha_D = +0.030°$ and $[\alpha]_D = +1.7°$. The unreacted monomer had $\alpha_{350} = +0.045°$.

Examination of these results shows that the optical activity in polypropene and polystyrene can arise only from the introduction of terminal groups from the catalyst. At a high catalyst: monomer ratio, optical activity may appear not only in the amorphous fractions but also in the isotactic fractions. Thus the optical activity in the polymers depends not on the stereoregularity, but chiefly on the molecular weight of the fractions.

The fact that the poly-(4-methylhexene) obtained by stereo-elective polymerisation from the racemic monomer had a value of $[\alpha]_D$ comparable with the values for polypropene and polystyrene, and smaller by a factor of 10–100 than the value for poly-(*S*)-4-methylhexene obtained from the optically active monomer, and also the absence of rotation in the unreacted monomer, evidently indicate that the reaction rate is the same for both antipodes and that the catalyst groups are introduced as alkyl terminal groups into the polymer chain. Moreover, for the experiments using $TiCl_4$–$Zn(C_5H_{11})_2$ catalyst, when the greatest rotation of the polymer was observed, it may be assumed that the terminal groups themselves also have an influence by asymmetric induction, which according to calculation by Brewster's method[57] should be considerable. Despite its low efficiency, a method for the stereo-elective polymerisation of poly-α-alkenes has been patented[48–50].

The polymerisation of racemic 3,7-dimethyloctene and 3-methylpentene on a $(C_5H_{11})_2Zn$–$TiCl_4$ catalyst is stereo-elective, and the unreacted monomer remaining shows appreciable optical activity[54]. The optical activity of the polymer fractions increases with increase in stereoregularity, in contrast with cases where the activity decreases and is due to terminal groups.

Table 8. Stereo-elective polymerisation of racemic 3-methylheptene and 3,7-dimethyloctene on a $TiCl_4$-di-(+)-2-methylbutylzinc catalyst.

Monomer	Unreacted monomer		Polymerised monomer			Optical purity of polymer, %
	α_D^{25}	$[\alpha]_D^{25}$	(*S*)	(*R*)	(*S*)/(*R*)	
3-Methylheptene	—0.07 (*l* 2)	—0.75	0.15	0.10	1.5	5.5
3,7-Dimethyloctene	—0.20	—0.28	0.20	0.16	1.25	9.97
	—0.36	—0.52	0.46	0.37	1.24	1.6

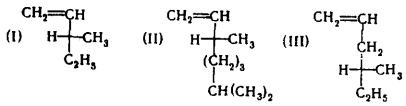
The sign of rotation of the monomer indicated that the polymerisation involves the (*S*) antipode, which has the same absolute configuration as the optically active (*S*)-2-methylbutyl group in the catalyst, whereas the excess of monomer remaining has the (*R*) configuration (see Table 8).

The (*S*)/(*R*) ratio characterises the rates of polymerisation of the antipodes in the racemate. Fractionation of poly-(3,7-dimethyloctene) gave a polymer insoluble in diisopropyl ether and soluble in cyclohexane, with $[\eta] = 0.91$ and $\alpha_D = 0.11°$ ($[\alpha]_D = +18.0$). After the fractionation of poly-(3-methylpentene), the most stereoregular fraction had $\alpha_D = 0.17°$ and $[\alpha]_D = +13.4$, whereas the fractions with low molecular weight had high rotation (+16.9°).

It was previously found that the stereo-elective polymerisation of racemic poly-(4-methylhexene) gives a polymer from which fractionation gives fractions whose optical activity decreases with increase in stereoregularity.

Stereo-elective polymerisation was achieved by Goodman and coworkers[107] using a catalyst obtained by the action of $LiAlH_4$ on *R*(−)-3,7-dimethyloctene (formation of the compound $LiAlR_4$) in its compound with $TiCl_4$. The action of this catalyst on racemic 3,7-dimethyloctene led to selective polymerisation, which depended on the value of $[\alpha]$ (between −8.3° and −11.74°) of the monomer in the catalyst, and the monomer/catalyst ratio (from 7.6 to 84.0). The specific rotation of the polymer increased from −49.6° to −83.3°.

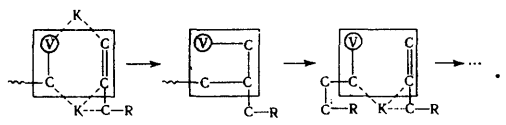
These results show that the structure of the monomer plays an important part in stereo-elective polymerisation. The catalyst is able to selectively remove one antipode from the racemate if the asymmetric atom is in the α-position to the double bond, for example, in 3-methylpentene (I) and 3,7-dimethyloctene (II); asymmetric stereo-elective polymerisation does not take place if the asymmetric atom in the side-chain is in the β-position, as in 4-methylhexene (III):



The problem of the detailed mechanism of asymmetrisation in stereo-elective polymerisation can be resolved by accumulating sufficient experimental data, but it can already be assumed that of the two mechanisms: (1) that in which the (*S*)-C_5H_{11}-group in the catalyst takes direct part in the asymmetric initiation of the polymer chain, and (2) that in which the (*S*)-C_5H_{11}-group modifies the active centre of the catalyst on which the preferential adsorption of one antipode of the monomer takes place on the transition metal, the latter is to be preferred[55], since this does not require the introduction of the concept of highly efficient 1,3-asymmetric induction with transfer along the chain of 1,3-carbon atoms. This is necessary, however, if we adopt the first scheme, which is similar to Cram's model of 1,3-asymmetric induction[108].

In actual fact, vinyl polymerisation gives 1,3-pseudo-asymmetric atoms in the chain; a polymer formed by a mechanism of 1,3-asymmetric induction will show the sequence $(ddd\ldots)_n(lll\ldots)_m$, whereas for induction due to the asymmetry of the catalytic asymmetric centre the sequence $(ddd\ldots)_n l(ddd\ldots)_m$ should predominate, that is there should be a much higher probability (p) of formation of sequences with the same configuration ($p_{dd} \gg p_{dl}$ or $p_{ll} \gg p_{ld}$), and with stereo-isomeric centres in the catalyst $p_{dd} \neq p_{ll}$.[109]

If we accept Cossee's ideas[9] regarding the part played by vacancies in polymerisation catalysis, we can picture the following mechanism, using the multiplet theory of catalysis:



Ⓥ - represents a vacancy

For α-alkenes, the adsorption of the C of the asymmetric centre outside the index is small, and the polymer is formed with preservation of the configuration[110].

Propene oxide, as a result of the strong adsorption of a carbon atom on a centre close to a vacancy, undergoes inversion of configuration (always observed for alkylpropene oxide and polypropeneimine) and the efficiency of the stereo-elective process should be slightly greater.

The concept of modification of the active centres of the catalyst by the asymmetric component is apparently more correct. This is confirmed, for example, by the stereo-elective polymerisation of racemic propene oxide when previously prepared active poly(propene oxide) is introduced on to the catalyst, as indicated above. "Autocatalysis" with benzofuran is also apparently due to some extent to this modification. The stereo-elective copolymerisation of racemic (*R*)(*S*)-3,7-dimethyloctene and (*R*)-(+)-methylpentene† can probably also be attributed to this morphological catalysis. In this connection, mention should be made of the production of asymmetrising properties in Raney nickel catalyst after modification with optically active compounds[111-113].

In conclusion, it should be noted that the high efficiency of stereoselective and stereo-elective polymerisation and the chromatographic separation of racemic polymers on other optically active polymers under conditions in which compounds with low molecular weight did not give these effects, apparently confirms Pasynskii and Pavlovskaya's view[114] that in nature, asymmetry has developed not by the formation of optically active compounds with low molecular weight, which then act as monomers, but initially by a process in which stereospecific polymerisation has led to the formation of stereoregular and then dissymmetric catalysts, on whose basis the optical asymmetry of compounds with low molecular weight began to develop, so that the origins of the latter are secondary.

---o0o---

Since the present manuscript was submitted for publication, a number of new papers on asymmetric catalysis in the field of optically active polymers, including a number of particular interest[122-127], have been published[115-121].

Macromolecular Complexes as Chemical Reaction Catalysts

S.L.Davydova, N.A.Plate, and V.A.Kargin

The wide potential applications of catalysis by macromolecular compounds have aroused universal interest in this relatively new branch of chemical science: the number of publications devoted to this problem has been growing continuously since the 1950's. Thus, many papers have dealt with the use of sulphonic acid resins as catalysts for hydrolysis and esterification, hydration and dehydration, alkylation, and also various condensations (see review by Polyanskii[1], recent Japanese work[2], etc.). A substantial fund of knowledge has accumulated also on the use of macromolecular catalysts and initiators in polymerisation reactions. For example, the above sulphonic acid resins have been used as polymerisation catalysts for isopentene, butene, dienes[1] and vinyl alkyl esters[3]. Macromolecular radicals obtained by chain transfer reactions[4], illumination, mechanical methods[5], or by chemical changes of reactive groups[6] are already used extensively in the synthesis of graft or block copolymers. These and other polymer systems can be synthesised also on macromolecular anions obtained as macromolecular Ziegler-Natta catalysts[7], macromolecular anion-radicals, or dianions[8], on macromolecular organometallic compounds of the polylithiumpolystyrene[9] or polylithiumpolyethylene[10] type, etc.
Papers on the catalysis of reactions by macromolecular complexes relate to the same field of research. The present review, without attempting to be fully comprehensive, deals with the most important papers (published up to 1968) on the catalysis of organic and of inorganic reactions by macromolecular complexes. For comparison, low-molecular-weight complexes are considered in a number of instances. 84 references.

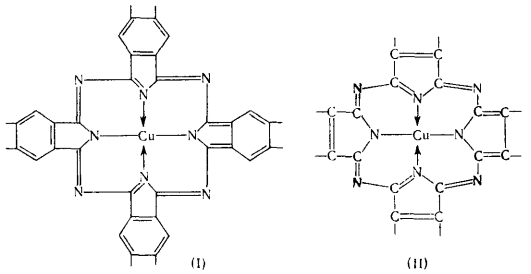
1. REDOX REACTIONS AND DECOMPOSITIONS

Since the earliest days of the study of catalysis by macromolecular complexes, the catalytic action of these materials towards various oxidation–reduction reactions has attracted most attention†. Among the first papers to be published in this field were those of Roginskii and coworkers[11,12], who studied the catalytic properties of macromolecular chelates with a system of conjugated bonds.

Thus, Roginskii and coworkers[11] investigated the activity of a series of poly(copper phthalocyanines) having different electrophysical properties towards the decomposition of H_2O_2. The greatest catalytic activity was found in the polyphthalocyanine which had the highest electrical conductivity at room temperature and the lowest activation energy for electrical conduction. The lowest activity was observed with the polymers of lowest electrical conductivity and highest E_{act}. The authors attempted to correlate the electrophysical properties and the catalytic activity of these polyphthalocyanines. They also attempted a correlation in their study of the oxidation of alkylaromatic and cyclic hydrocarbons on macromolecular phthalocyanines[12].

These workers compared the rates of oxidation of various hydrocarbons on copper phthalocyanines of type (I), and also the catalytic activity of polymeric and monomeric copper phthalocyanines towards the oxidation of cumene to the hydroperoxide, with the activity of polymeric complexes of tetracyanoethylene and copper, which are presumably macrocyclic azoporphyrin structures of type (II):



(I) (II)

It was found that the polyphthalocyanines are more active than their monomeric analogues and that the tetracyanoethylene polymers are more active than the polyphthalocyanines: the underlying reasons were not discussed. Manecke and coworkers[13] also examined polychelates of this type, prepared from metal acetylacetonates and tetracyanothiophen (or tetracyanofuran), *p*-phenylenedimalononitrile, or *o*-phthalodinitrile.

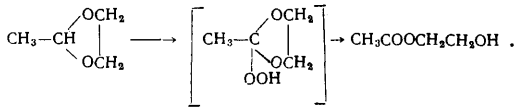
To explain the mechanism of the catalytic action of macromolecular complexes with conjugated bonds, Berlin and coworkers[14] suggest that the presence of acetylacetonate residues in the azoporphyrin structures (II) causes initiation of a chain decomposition of the polymer with formation of peroxide radicals. These workers conclude that in the oxidation of, for example, cumene, in the presence of poly(copper phthalocyanine), oxygen must be present as

† Data on the catalytic properties of low-molecular-weight complexes have long been available: for convenience in presentation we shall discuss them and compare them with the catalytic properties of macromolecular complexes of similar structure;

undissociated molecules or as radical-ions on the catalyst surface.

The catalytic activity of mixed Cu, Fe polyphthalocyanines in the heterogeneous oxidation of aldehyde acetals by oxygen was recently discussed in some interesting papers by Inoue and coworkers[15,16].

Assuming that the main product of the oxidation of acetaldehyde ethylene acetal [2-methyl-1,3-dioxolane (Ed. of Translation)] is 2-hydroxyethyl acetate (as well as acetic acid, acetaldehyde, ethylene glycol, and water), the authors propose the following reaction scheme:



The catalytic activity of this polymeric complex towards the oxidation of other acetals or of cumene is considerably lower (see Fig. 1).

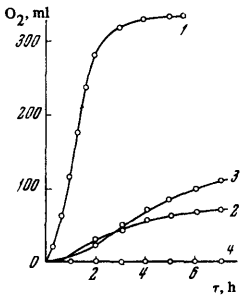


Figure 1. Rate of absorption of O_2 in the presence of Cu, Fe-polyphthalocyanine in the following oxidation reactions:
1) acetaldehyde ethylene acetal [2-methyl-1,3-dioxolane (Ed. of Translation)]; *2*) benzaldehyde ethylene acetal [2-phenyl-1,3-dioxolane (Ed. of Translation)]; *3*) cumene; *4*) acetaldehyde dimethyl and diethyl acetals.

The catalytic activity is strongly dependent on the ratio of the metals (Cu–Fe or Mo–Fe), and on the activation energy for electrical conduction of the polyphthalocyanine. It has been pointed out that these polymers are highly selective and show a synergic effect due to the interaction of two redox metal atoms through a system of conjugated bonds, since the reaction is catalysed neither by Cu-, Fe-, or Mo-polyphthalocyanines, nor by their mixtures[16].

The oxidation of hydrocarbons in the presence of low-molecular-weight chelates was known in the 1950's, and acetylacetonates as well as other chelate compounds are now used industrially for this purpose.

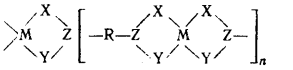
The acetylacetonates of Cu and Co are used, for example, in the liquid-phase oxidation of toluene and ethylbenzene by oxygen or air to the corresponding aldehydes and acids; the rate of the reaction is periodically increased by adding inorganic adsorbents of the Al_2O_3 or kieselguhr type[17].

Cobalt isovalerylacetonate is used industrially as a catalyst for the oxidation of primary and secondary (but not tertiary) alkylbenzenes to the corresponding acids[18]. Salcamine (bis-salicylaldiminatocobalt) is widely used in industry to deodorise petroleum (by oxidising mercaptans to disulphides with atmospheric oxygen[19]) or to remove oxygen-containing impurities dissolved in hydrocarbons[20].

Turning now to oxidation–reduction reactions on macromolecular complexes, we note that the Du Pont company[21] reported in 1962 an investigation of the catalysis of a large number of reactions in the presence of polychelates. These included the oxidation of isovaleraldehyde, metacrolein‡, furfural, and cinnamaldehyde to the corresponding acids, and the oxidation of ascorbic acid to dehydroascorbic acid; the reduction of nitrobenzene to aniline and of nitrocyclohexane to nitrosocyclohexane (cyclohexanone oxime); the reduction of metal ions (Ag, Hg, Fe) to a lower valency, etc. The structure and properties of the polychelates are not quoted: it is stated only that the macromolecular ligands used include salicyl- or resorcinol–formaldehyde resins, polythiosemicarbazides, polyoximes, polyaminostyrene-*NN*-diacetic acids, and other polyfunctional polymers.

The choice of a polymeric ligand to prepare macromolecular chelates for the catalysis of the stated oxidation–reduction reactions is mainly dictated, according to the authors, by the stability of the resulting chelate (though stability or formation constants are not quoted), whereas the metal suitable for complex formation is chosen on the grounds of its redox potential. Both these factors are known to affect the rates of reactions catalysed by low-molecular-weight complexes. Thus, Sn^{II}-polyformaldehyde salicylate reduces silver ions to metallic silver almost instantaneously, whilst Sn^{II}-polyaminostyrene-*NN*-diacetate reduces them in 10–15 min. Nitrocyclohexane is reduced quantitatively to cyclohexanone oxime in the presence of the above polychelates of Fe^{II}, Cu^{I}, and Sn^{II} in times of 24–36, 4, and 1 h respectively[21].

The reactivity of polymeric chelates of transition metals with linear or cross-linked structures (III)



(III)

and of their monomeric analogues was investigated by Boreskov and coworkers[22–25] for a number of reactions; the rates of decomposition were found to be strongly influenced both by the nature of the metal and by the structure of the organic ligand.

No correlation was found when the electrical conductivities of the polychelates were compared with their catalytic activities[22]. Thus, the Zn- and Cu-polychelates of the type 2(S, N)§ thiocarbamate have an electrical conductivity of $10^{-9}\ \Omega^{-1}\ cm^{-1}$, and the corresponding Ni-polychelates have a conductivity of the order of $10^{-13}\ \Omega^{-1}\ cm^{-1}$, and yet the catalytic activity of the Cu and Ni polychelates is high, whereas the Zn polychelates are catalytically inactive. This is probably due to the fact that chemisorption and catalysis are determined not so much by the semiconducting properties of the polymer as a whole as by the electronic state of the metal in the chelate group: the latter criterion is responsible for the strong influence of the environment of the metal in the coordination centre on the catalytic properties of the polymer.

Keier and coworkers[27–30] have shown that studies of X-ray absorption spectra are valuable in establishing the state of the metal in the coordination centres of chelate compounds. In this way, they were able to evaluate and compare the effective charges concentrated on the copper

‡ It is uncertain whether metacrolein $(C_3H_4O)_3$, or methacrolein (methacrylaldehyde, 2-methylprop-2-enal) $CH_2{=}C(CH_3)CHO$, is intended (Ed. of Translation).

§ Complexes can have a variety of coordination centres. According to Calvin and Martell's classification[26], adopted here, these can be designated 2(O,O), 2(O,N), 2(N,N), 2(S,N), 2(O,S), etc. (for bidentate ligands).

atom in the molecules of various chelate compounds, and to establish a correlation between these values and the reactivity of the polymeric chelates. They were also able to identify the direction of changes in the charge on the metal atom accompanying changes in the structure of the ligand. Thus, a direct experimental study of the interaction of polychelates of the Cu–2(S, N) type with the reactants was possible.

For example, in the decomposition of N_2H_4 the effective charge η_π^{eff} remains practically constant during the first hour, and changes by approximately $0.15e$ during the following 15 h. In the oxidation of isopropylbenzene, a change of approximately $0.2e$ (and of the opposite sign) was noted in the charge on the copper atom. Thus, the change in the charge on the central atom of the polychelate is evidence for direct interaction between the reactants and the polymer. In particular, in the decomposition of N_2H_4 partial reduction of the copper during the course of the reaction is indicated by the direction of the shift of the K absorption edge of the copper in the polychelate and by the sign of the change in the charge on the copper atom[27–30]. The X-ray K absorption spectra of copper in polychelates of the type 2(S, N) were used to evaluate η_π^{eff} as a function of molecular weight (between 600 and 3100). On increasing the degree of polymerisation, η_π^{eff} decreases non-uniformly, and on changing from the monomer to a polymer with $M = 1790$ this quantity is hardly affected (but the reactivity of the polychelate is approximately 5–6 times higher than that of the monomer). With further increase in molecular weight η_π^{eff} begins to increase, reaching $0.2e$ for a polychelate with $M = 2560$ (whose reactivity is higher than that of the monomer by a factor of 35).[29]

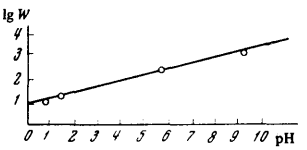


Figure 2. Variation of the rate of decomposition of H_2O_2 on the Cu polychelate of dinitrosoresorcinol with pH at 60°C (W in $cm^3\ m^{-2}\ min^{-1}$).

Because of the lack of solubility, polychelates are difficult to study by physical methods, and the authors were compelled to use much less active monomeric analogues (for example, those prepared from thiopicolineanilides).

Anufrienko and coworkers[31] showed by the ESR method that the M–X,Y bonds in compound (III) have a mainly covalent character, and Zeif and coworkers[32] determined the structure of the complexes as a whole by ultraviolet and infrared spectroscopic studies. Using an approximate quantum-mechanical method of calculation, the nature of the change in effective charge (η_π^{eff}) of the metal ions in the chelate group on varying the structure of the organic ligand was characterised from experimental ultraviolet spectra; in this way, the relationship between the rate of decomposition of hydrazine and the change in effective charge was investigated for a series of chelate complexes. We should note that the application of all these methods has revealed a substantial change in the copper chelate during the decomposition of N_2H_4, which obviously points to chemical (as distinct from catalytic) decomposition of hydrazine under the conditions used in this work[25,33].

According to the same authors[34], the catalytic activity of the polychelates is higher than that of their low-molecular-weight analogues by at least an order of magnitude. They conclude that the higher activity of the polychelates is associated with disorder and distortion in the structure of their chelate groups. Furthermore, the catalytic activity can be influenced by the presence of uncomplexed metal ions at chain ends, which is itself very sensitive to the conditions of preparation of the polymers.

Boreskov and coworkers consider[34] that their observations on the reactions catalysed by macromolecular chelates show a similarity to the characteristic features of the catalytic properties of enzymes, and that chelate polymers are a type of heterogeneous catalyst occupying an intermediate position between inorganic catalysts and enzymes. In this connection, they examined the catalytic activity of synthetic polymeric chelates towards the liquid-phase decomposition of hydrogen peroxide, one of the simplest organometallic enzyme reactions[35]. Kinetic isotherms for this reaction on polychelates of the 2(o, o) type with different metal atoms were obtained; on raising the pH the rate of the reaction increased by almost two orders, evidently as a result of the greater degree of dissociation of the hydrogen peroxide. The reaction rate varies linearly with pH over a wide range of pH values (Fig. 2). The authors believe that the rate of the heterogeneous decomposition of H_2O_2 on each surface centre of the copper polychelate is close to the value found for the enzyme catalase[35].

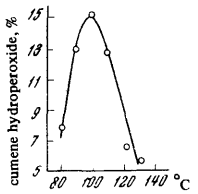

Figure 3. Concentration of cumene hydroperoxide in the oxidised material as a function of temperature of the oxidation in the presence of a 2(S,N) Cu polychelate.

Keier and coworkers[36] studied the catalytic properties of Cu- and Ni-polychelates of the 2(S, N) type based on the bis-thioamides of quinaldine towards various reactions, including the oxidation of isopropylbenzene (cumene) to the hydroperoxide by atmospheric oxygen (Fig. 3). Although in this instance the catalytic activity (which is greatest for the Cu polychelates) and selectivity are determined by the metal ion, the structure of the ligand also plays a role. By introducing electron-donor groups (CH_3, OCH_3) into the biphenyl unit of the polymer chain, and thus raising the electron density on the central metal atom, the rate of the secondary reaction of cumene hydroperoxide is increased, leading to a faster rate of formation of 2-phenylpropan-2-ol:

$$ROOH \rightarrow RO^{\cdot} + OH^{\cdot};\ RO^{\cdot} + RH \rightarrow ROH + R^{\cdot}.$$

A multi-step mechanism has been reported also for the liquid-phase oxidation of isopropylbenzene and ethylbenzene in the presence of heterogeneous catalysts prepared by

depositing 8 wt. % of a Cu polychelate based on 4,4′-bis-(α-thiopicolinamido)biphenyl upon Al_2O_3.[37,38] The catalytic decomposition of the primary oxidation products (the hydroperoxides of ethylbenzene and isopropylbenzene) on the same polychelates is of zero order with respect to hydroperoxide and of first order with respect to the heterogeneous catalyst. E_{act} for the decomposition into radicals is 10.7 kcal mole^{-1} for ethylbenzene and 10.0 kcal mole^{-1} for isopropylbenzene[37].

Time-changes in the activity of the polychelate catalyst towards the formation of radicals from the hydroperoxide were examined by measuring initial rates (W_0) of consumption of 1-naphthol (an inhibitor for the resulting radicals) as a function of the time of operation of the catalyst. The rate of formation of radicals is high on a fresh catalyst, but falls off sharply after 20 min, and after 30 min it levels off at 25% of its initial value (Fig. 4). A comparison of the rates of formation of free radicals by thermal and by catalytic decomposition has shown that at 110°C the former (10^{-6} mole min^{-1}) is lower than the latter by a factor of $\sim 10^4$.[37]

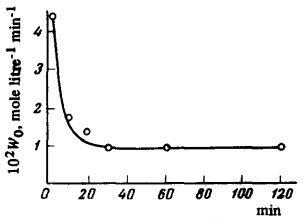

Figure 4. Change of W_0 with time at 90°C; [ROOH] = 3.26 wt. %, c_{cat} = 2.66 mg ml^{-1}.

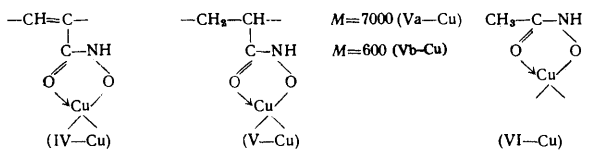
From their study of the catalytic action of polychelates towards the liquid-phase oxidation of hydrocarbons the authors conclude that free radicals are formed mainly by the catalytic decomposition of the hydroperoxide, and the overall oxidation process is a classical non-branching chain reaction[39].

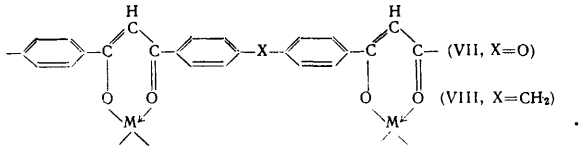
In 1966 a group of Japanese workers[40] prepared some new polychelates (hydroxamic acid derivatives) and studied their catalytic activity towards the decomposition of H_2O_2 in aqueous solutions. Thus, the following copper chelates of polyhydroxamic acid, with (IV) or without (V) a system of conjugated bonds (and Cl residues) in the main chain:



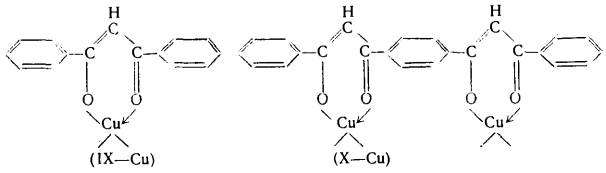
were compared for catalytic activity with the low-molecular-weight Cu chelate of methylhydroxamic acid (VI).

The catalytic activity of these chelates was found to increase in the sequence VI-Cu < Vb-Cu < Va-Cu < IV-Cu, in other words, it was found to be higher in the macromolecular chelates than in their low-molecular-weight analogue. The authors ascribe this behaviour to differences in the polarity of the copper–ligand bond[41].

The same workers[42] studied the catalytic activity of chelates of the poly-(β-diketone) type, which were prepared independently also by Soviet workers[43]:

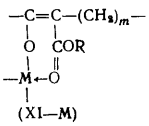


The catalytic activity of the polychelates VII-Cu and VIII-Cu for the decomposition of H_2O_2 is higher than that of their low-molecular-weight analogues IX-Cu and X-Cu



The rate of the decomposition reaction follows a first-order equation with respect to peroxide concentration; the catalytic activity of the chelates is fully reproducible on adding fresh portions of hydrogen peroxide. However, in respect of the catalytic activity of copper chelates of the β-diketone type towards the oxidation of L-ascorbic acid, the activity of the macromolecular chelates is higher than that of their low-molecular-weight analogues but the rate of oxidation shows a zero-order dependence on the concentration of ascorbic acid[42].

The present writers and coworkers[44] have examined the oxidase and catalase activity of a large number of transition metal complexes with macromolecular ligands of the poly-(β-ketoester) type first prepared by the ester polycondensation of dicarboxylic acid diesters[43,45]:



where m = 6, 7, 9; R = C_2H_5; M = Cu, Ni, Fe, Co, Mn.

The catalytic activity of these macromolecular chelates of poly-(β-ketoesters) towards the oxidation of ascorbic acid decreases in the order Cu > Ni ≫ Fe, Mn, Co (Fig. 5), whereas the opposite sequence of catalytic activity is observed in the decomposition of hydrogen peroxide by these complexes: Co > Mn > Fe ≫ Ni, Cu (Fig. 6). This inversion is ascribed to the mechanism of the interaction of the complexes with the substrates. Since the rate-limiting step in the decomposition of H_2O_2 under the influence of complexes is known[46] to be the addition of atomic oxygen, it is to be expected that complexes which are active in this step (and shift the equilibrium to the right) will have low activity in the O_2 absorption reaction which proceeds from right to left, as in the oxidation of ascorbic acid. We note that the catalytic activity of the complex XI-Co (m = 6) is increased very significantly by raising the pH to 10 (Fig. 6, curve *6*), as in the case of the decomposition of H_2O_2 in the presence of polycoordination complexes of type (III) (p.). The catalytic activity of macromolecular chelates of the poly-(β-ketoester) type (XI-M) is strongly dependent on the metal content, for example, copper (in the oxidation of ascorbic acid) or cobalt (in the decomposition of hydrogen peroxide), that is, on the degree of complex formation by the coordination centres (in both instances). As for the polycoordination compounds of

type (III) (p. 985), the catalytic activity of complexes with macromolecular ligands is very sensitive not only to the nature of the metal but also to the nature of the macromolecular ligand, for example, on the length of the polymethylene chain [m in the compound (XI-M)].[44]

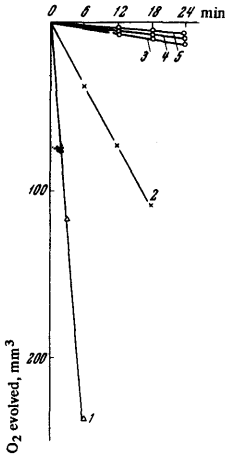


Figure 5. Kinetics of the oxidation of ascorbic acid in the presence of poly-(β-ketoester) complexes (XI)-M, m = 6: *1*) Cu, *2*) Ni, *3*) Mn, *4*) Co, *5*) Fe.

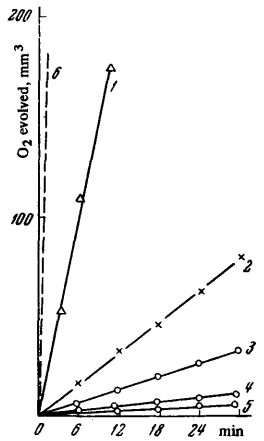

Figure 6. Kinetics of the decomposition of H_2O_2 in the presence of poly-(β-ketoester) complexes (XI)-M, m = 6: *1*) Co, *2*) Mn, *3*) Fe, *4*) Ni, *5*) Cu, *6*) decomposition in the presence of (XI)-Co at pH 10.

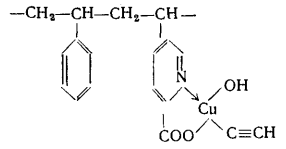
In our view, a quantitative comparison of the catalytic activity of macromolecular complexes with that of their low-molecular-weight analogues (such as the benzoyl- and acetyl-acetonates of the transition metals for VII-M, VIII-M, and IX-M), as Japanese workers[40,42], among others, have attempted, is complicated by the fact that these reactions proceed in a homogeneous medium in the presence of the low-molecular-weight complexes and in a heterogeneous medium in the presence of macromolecular chelates. This difficulty is apparent also with polymeric complexes of a different type—those of polymeric picolinic acid with copper (XII-Cu)—studied by Stepanov and Zosim[47] also in connection with the decomposition of hydrogen peroxide: under conditions of heterogeneous decomposition at room temperature the catalytic activity, expressed in mg-equiv. H_2O_2 per mg-equiv. Cu, is 204, whilst under homogeneous decomposition conditions it is 1540. We note, incidentally, that polymeric complexes of the same type were examined as catalysts for the synthesis of 1,4-butynediol from acetylene and formaldehyde. The copolymer of styrene and vinylpicolinic acid forms polymeric acetylide structures



(XII—Cu)

showing catalytic activity; the Cu complex of polypyridineethanol is practically unreactive towards acetylene under the same conditions. On the other hand the copper complex of the styrene–maleic acid copolymer, in which the copper atom is bound to the macromolecule by ionic forces only, catalyses the formation of butynediol on passing acetylene through a suspension of paraformaldehyde and of the polymeric acetylide[47].

A paper by Gregor and Liu[48] describes a study of catalysis on macromolecular zinc complexes obtained from poly-(*N*-vinylbenzimidazole). These workers investigated the decomposition of carbonic acid, and found that the "coefficient of catalytic activity" for this reaction (λ) is 400 ± 12 for both the Zn^{II} complex of poly-(*N*-vinylimidazole) and for poly-(*N*-vinylimidazole) itself, whereas for the monomeric imidazole λ is 1.5. Thus, the catalytic activity of the polymeric catalysts is significantly higher even for reactions of this type.

2. POLYMERISATION AND COPOLYMERISATION

Before beginning our discussion of the catalytic activity of the macromolecular chelates of transition metals towards the polymerisation of vinyl monomers, we shall dwell on a few examples of the use of low-molecular-weight chelates for the same purpose.

The earliest reports of the use of Co, Ni, and Fe acetylacetonates for the polymerisation and copolymerisation of unsaturated compounds appear in British patents of 1946;[49] subsequently, the use of ethylenediaminetetra-acetic acid complexes in emulsion polymerisation processes was also patented[50]. Later, Strubell[51] used a metal-containing oxidation–reduction system based on the propionylacetonate, benzoin, and benzoyl peroxide to initiate the polymerisation of methyl methacrylate. Fig. 7 shows curves for the increase of viscosity with time of the reaction mixture as a function of the metal in the propionylacetonate. The rate of polymerisation is directly proportional to the amount of added propionylacetonate with the exception of copper propionylacetonate, which activates the reaction strongly whatever amount is added, and of the nickel complex, which has no effect on the rate of polymerisation[51]. Indictor and Linder[52] have recently used a similar system (t-butyl hydroperoxide–acetylacetonate) to study the polymerisation of styrene at 50°C. They found that the initial rate of polymerisation is increased by adding $(1-2) \times 10^{-4}$

mole litre^{-1} of Co^{III}, Cr^{III}, Fe^{III}, or Cu^{II} acetylacetonate to the hydroperoxide, but begins to decrease at higher concentrations of these additives, possibly as a result of the formation of atomic oxygen. According to the authors, the acetylacetonates of other metals are inactive in this particular reaction.

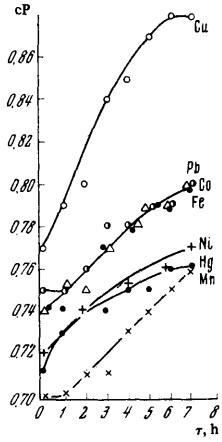


Figure 7. Viscosity of poly(methyl methacrylate) as a function of time of polymerisation in a benzoyl peroxide (1.210 g), benzoin (1.060 g), propionylacetonate (0.60 g) system.

Arnett and Mendelson[53] studied the polymerisation kinetics of styrene in the presence of a large number of acetylacetonates with and without benzoyl peroxide at 110°C, and obtained the following activity series for the metal acetylacetonates:

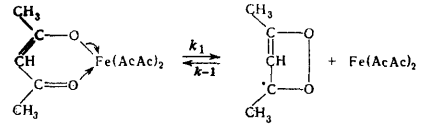
With peroxide: $Co^{III} \simeq Ce^{IV} > Mn^{III} > Fe^{III} > Al^{III} \simeq Cr^{III} \simeq$ without initiator $> V^{III}$.

Without peroxide: $Mn^{III} > Ce^{III} > Co^{III} > Fe^{III} > Al^{III} \simeq Cr^{III} \simeq$ without initiator $> V^{III}$.

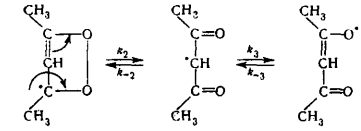
It is interesting to note that these catalytic activity sequences of the acetylacetonates for polymerisation are opposite to the thermal stability sequence obtained by Von Hoene and coworkers[54]:

$$Na^{I} > Cr^{III} > Al^{III} > Ni^{II} > Cu^{II} > Fe^{III} > Co^{II} > Co^{III} > Mn^{III}.$$

The last members of this series begin to decompose in an inert atmosphere at temperatures as low as 150°C, giving acetylacetone as the main decomposition product. Arnett and Mendelson were the first to try to explain the mechanism of formation of radicals on heating the acetylacetonates. Homolytic breaking of the chelate ring (for example, with Fe^{III}) takes place, with formation of Fe^{II} acetylacetonate and a free radical:



which can exist either in the C or in the O form and can initiate the polymerisation of styrene:



Bamford and coworkers[55] also made a study of the initiation of the polymerisation of vinyl monomers by low-molecular-weight metal chelates; they examined, in particular, systems containing the acetylacetonates of Cu^{II} and Co^{II}, and they pointed out that without suitable additives these systems are ineffective for the polymerisation of methyl methacrylate. In conjunction with halogenated compounds of the type CCl_4, CBr_4, CCl_3Br, CCl_3CN, $CCl_3.COONH_4$, and in particular with the last of these the copper chelate is fairly active at a concentration of 1.9×10^{-3} M at 80°C. The authors believe that at low concentrations of CCl_3COONH_4 ($< 6 \times 10^{-4}$ M) the initiating radical is formed by the decomposition of a 1:1 chelate–salt complex, whereas at high concentrations of CCl_3COONH_4 (2.5×10^{-2} M) the initiating radical is formed simply by the interaction of the chelate with the primary decomposition products of the salt[56].

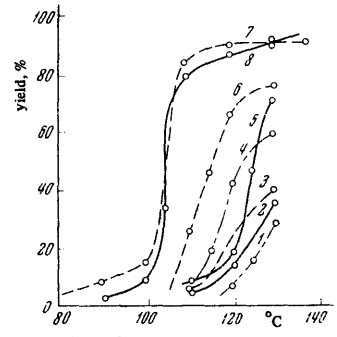


Figure 8. Polymerisation of styrene in the presence of acetylacetonates (concentration 0.5 wt. %, time 1 h):
1) Pd^{II}, *2*) Mn^{II}, *3*) Pt^{IV}, *4*) Ni^{II}, *5*) Rh^{IV}, *6*) Co^{III}, *7*) R_2O_2, *8*) Mn^{III}.

Kastning and coworkers[57] (see also the patents[58,59]) made a detailed study of the efficiency of initiation of the polymerisation of styrene by chelate complexes as a function of the nature of the central metal atom and of the structure of the ligand. It is evident from Fig. 8 that the highest yields of polystyrene are obtained by using the acetylacetonates of metals from Groups VII and VIII of the Periodic Table, and that the rates of polymerisation in the presence of the Mn^{III} chelate or of the peroxide are approximately equal. When the metal can exist in several valency states, the most effective initiators are those in which the metal exhibits the highest valency. The activity of chelates of 1,3-dicarbonyl compounds increases in the order dibenzoylmethane < benzoylacetone < acetylacetone < ethyl acetoacetate (Fig. 9).

Calvin and Wilson[60] showed that the stability constants (K_{st}) of Cu^{II} chelates increase in the same order.

One drawback of the acetylacetonates is the need to use relatively high polymerisation temperatures: these initiators were therefore activated by irradiation or by additives. Both in the presence and in the absence of activators the rate of polymerisation was proportional to the square root of the concentration of initiator[57].

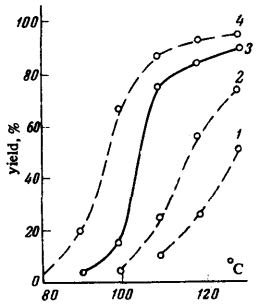

Figure 9. Polymerisation of styrene in the presence of Mn^{II} chelates (concentration 0.5 wt. %, time 1 h): *1*) dibenzoylmethane, *2*) benzoylacetone, *3*) acetylacetone, *4*) ethyl acetoacetate.

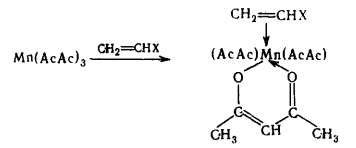
Chelate initiators can be used also for the polymerisation of acrylate and methacrylate esters, ethylene, butadiene, and for the copolymerisation of these monomers. Polymerisation of butadiene and isoprene under the influence of these chelates in solution yields high-molecular-weight polymers containing up to 60% of *cis*-1,4- and up to 10% of 1,2-vinyl units. A recent paper by Riches[61] on the polymerisation kinetics of dienes on Co^{III} acetylacetonate should be mentioned here: the reaction was found to be of one-half order with respect to the initiator and of first order with respect to the monomer (E_{act} = 13 and 20 kcal mole^{-1} for isoprene and butadiene respectively).

The results of Kastning and coworkers[57] on the copolymerisation of vinyl monomers which do not react under the influence of peroxides are particularly interesting. Thus, the polymerisation of a (1 : 1) mixture of styrene and vinyl acetate in the presence of Mn^{III} acetylacetonate at 80°C produces a copolymer containing 28 wt. % of vinyl acetate. (It is well known that for this pair of monomers r_1 = 55 and r_2 = 0.01.) At a higher temperature (100 to 150°C) and 1000–1600 atm pressure styrene and ethylene can be copolymerised with the same initiator. Simple vinyl ethers, which do not polymerise in the presence of chelates, can be made to copolymerise with ethylene to give up to 30% of vinyl ether units in the copolymer.

The authors do not put forward a mechanism for polymerisation in the presence of metal chelate initiators of the type examined, but some of their results are consistent with a free-radical mechanism. They were unable to observe any change in the valency of the central metal atom during polymerisation under the influence of chelates; valency changes took place only for reaction temperatures higher than the decomposition temperature of the chelate[57].

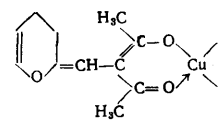
By using tracer atoms and infrared spectroscopy it was shown that the ligand is attached to the growing polymer chain; hence the authors concluded that the polymerisation can be initiated by free radicals formed from the chelate ligands. The microstructure of the resulting polymers does not depend on the nature of the ligand or of the activating additives, which affect only the rate of initiation, and the configuration of the chain is determined only by the nature of the central metal atom.

A group of Japanese workers[62] has measured the copolymerisation constants of vinyl monomers in the presence of metal acetylacetonates (Mn, Co, Fe). Thus, for the styrene–methyl methacrylate system they found r_1 = 0.53 ± 0.08 and r_2 = 0.52 ± 0.05, and for the styrene–methacrylate system r_1 = 0.89 ± 0.02 and r_2 = 0.17 ± 0.02. The authors believe that the first step in the polymerisation is decomposition by monomer attack¶, for example:



Nikolaev and coworkers have shown, in a very recent investigation[63], that their values for the copolymerisation constants of vinyl acetate and styrene (r_1 = 0.01 ± 0.1 and r_2 = 3.9 ± 0.8) suggest a change in the activity of the monomers and the radicals in the presence of $Mn(AcAc)_3$ as compared with copolymerisation in the presence of the usual radical initiators. The valency of manganese changes during the copolymerisation ($Mn^{III} \rightarrow Mn^{II}$), and the rate of the reaction decreases at the same time.

Whereas the above workers found copper acetylacetonate (without appropriate additives) to be inactive towards the polymerisation of vinyl monomers, Uehara and coworkers[64,65] have shown that unsaturated substituents in the pseudo-aromatic ring of Cu^{II} acetylacetonate enable it to initiate the polymerisation of styrene and methyl methacrylate (but not of vinyl acetate) at 0.5% concentration and 70°C. The polymerisation is inhibited by benzoquinone and is accelerated by ammonia and methanol. The reaction order is 0.5 with respect to the initiator and 1.8 with respect to the monomer; the overall activation energy is 20.1 kcal mole^{-1}. The infrared spectra suggest that the ligand becomes part of the polymer chain, as in the examples considered above. Initiators of this type (for example, XIII-Cu) have been used also to prepare a styrene–maleic anhydride (1 : 1) copolymer at room temperature:

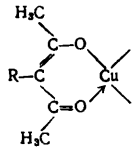


(XIII—Cu) .

We may assume that K_{st} for the (XIII-Cu) chelate, which is not quoted by the authors, is lower than K_{st} for the unsubstituted acetylacetonate, because of conjugation of the chelate ring with the π-system of the dihydropyran ring: we may ascribe the catalytic activity to this effect. The same workers[65,66] have demonstrated the influence of other substituents with double bonds on the activity of substituted copper acetylacetonates in polymerisations. They condensed acetylacetone with propionaldehyde, butyraldehyde,

¶ Subsequently, the reaction proceeds by the schemes shown on p.989.

isobutyraldehyde, and dimethacrolein, and obtained (XIV-Cu)



(XIV—Cu)

where R = CH= (*a*); CH=CH—CH_3 (*b*); CH=CH—CH_2CH_3 (*c*); $CH=C(CH_3)_2$ (*d*); or its hydrogenation products $CH_2CH_2CH_3$ (*e*); $CH_2CH_2CH_2CH_3$ (*f*).

The following activity sequences are given for the XIV-Cu chelates: $a > b > c > f > d > e \simeq 0$ for styrene; $a > c > b > d > e > f \simeq 0$ for methyl methacrylate.

In 1965 Bamford and Lind[67] published the results of a study of the initiation of polymerisation with acetylacetonates without any additives. In contrast to Kastning's results[57], obtained for the polymerisation of styrene at 100°C, these authors (who studied the polymerisation of methyl methacrylate at 80°C) arranged the acetylacetonates examined in their work in the following order: $Mn^{III} > Ni^{II} > V^{III} > Cr^{III} \gg Co^{III} > TiO^{II} > Pb^{II}$. Neither addition of CCl_3COONH_4 (2.77×10^{-4} M) up to a chelate concentration of 2.7×10^{-3} M, nor addition of equimolecular amounts of CCl_4 up to a chelate concentration of 2.8×10^{-2} M, produced any increase in the reaction rate. A more detailed kinetic analysis of a system containing Mn^{III} acetylacetonate (curve *3* of Fig. 10) showed that the rate of polymerisation is proportional to the concentration of chelate raised to the power 1/2:

$$\omega = 1.0 \cdot 10^{-2} [Mn(AcAc)_3]^{1/2} \text{ mole litre}^{-1} \text{ s}^{-1} \text{ (at 80°C)},$$
$$\omega = 0.05 \cdot 10^{-2} [Mn(AcAc)_3]^{1/2} \text{ mole litre}^{-1} \text{ s}^{-1} \text{ (at 70°C)}.$$

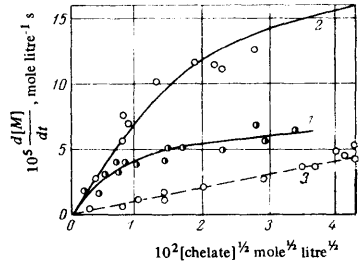


Figure 10. Polymerisation of methyl methacrylate at 80°C on: *1*) Mn^{III}-*p,p'*-dichlorodibenzoylmethane; *2*) Mn^{III} acetylacetonate without additives; *3*) ditto, with CCl_4.

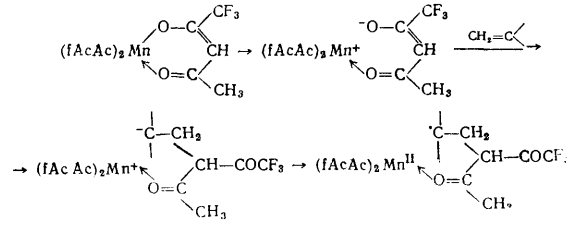
The product $k_p k_t^{-1/2}$ (rate constants for chain propagation and chain termination respectively) is close to the known value for the free-radical polymerisation of methyl methacrylate (0.17 $\text{mole}^{-1/2}$ $\text{litre}^{-1/2}$ $\text{s}^{1/2}$). Hence the authors conclude that polymerisation occurs by a free-radical mechanism in the present system under the influence of radicals formed by the decomposition of the chelate. A similar hypothesis had been put forward by Arnett and Mendelson[53] (see p. 989).

The rates of polymerisation on Mn^{III}-dibenzoylmethane and its *p,p'*-dichloro-derivative (Fig. 10) are proportional to the concentration of the chelate to the power 1/2 for low chelate concentrations ($< 10^{-4}$ M for curve *1* and $< 0.4 \times 10^{-4}$ M for curve *2*). At higher chelate concentrations ($> 10^{-3}$ M) this relationship no longer applies and the product $k_p k_t^{-1/2}$ takes abnormally low values (0.14 and 0.13 $\text{mole}^{-1/2}$ $\text{litre}^{-1/2}$ $\text{s}^{1/2}$ respectively), pointing to some unexplained type of inhibition. Another paper by Bamford and Lind[68], devoted to the selective initiation of free-radical polymerisation in fluorinated derivatives of acetylacetonates, is particularly interesting. In the case of the fluorinated derivative of Mn^{III} acetylacetonate the rate of polymerisation of methyl methacrylate at 80°C is higher by a factor of 7 than the rate corresponding to the non-fluorinated analogue. On the other hand, the polymerisation of styrene is substantially inhibited in the presence of this system: for a given concentration of the fluorinated and the non-fluorinated acetylacetonate (2.5×10^{-4} M), the rates of formation of the polymer are 1.6 and 34 mole litre^{-1} s^{-1} respectively. This inhibition is explained by the fast interaction of the styrene radicals with Mn ions (positively charged) induced by the CF_3 group. The ratio of the rates of polymerisation initiated by benzoyl peroxide in the presence (W) and in the absence (W_0) of the chelate is given by the equation

$$W/W_0 = (Ik_t)^{1/2}/b[C] + a/b \quad (k'/I)^{1/2},$$

where C is the chelate concentration, I is the rate of polymerisation initiated by benzoyl peroxide, a and b are constants which characterise the rates of initiation and of inhibition of the reaction by the chelate. Comparison of the data on the polymerisation of methyl methacrylate and of styrene shows that the action of the fluorinated acetylacetonate of Mn^{III} is highly selective: it induces most effectively the polymerisation of monomers having a strongly polarised double bond. In particular, the rate of polymerisation of acrylonitrile is 70 times higher in the presence of this compound than in the presence of the corresponding acetylacetonate. This is ascribed to the ready attachment of a monomer with relatively high electron-accepting properties to the anion formed by the cleavage of the Mn—O bond. This anion subsequently decomposes with formation of a radical and of the Mn^{II} chelate. The proposed initiation mechanism is consistent with the extremely low (2×10^6 litre mole^{-1} s^{-1}) frequency factor observed in the polymerisation of methyl methacrylate in the presence of the fluorinated chelate:



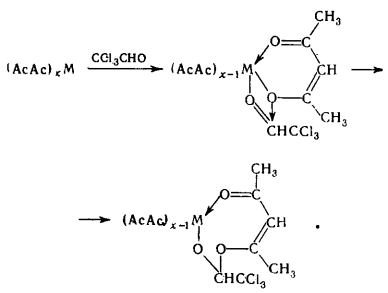
where

We note that the strong inductive effect of the CF_3 group in $CF_3COCH_2COCH_3$ is responsible for the much lower value of K_{st} of its chelate as compared with the acetylacetonates[26] (see p. 990).

The work of Bamford and Lind[68] provides one of the few examples of selective radical (or, more strictly, radical-ionic) polymerisation processes. We may conclude from this work that a correct choice of the structure of the low-molecular-weight or macromolecular ligand allows the free-radical nature of the process to be retained whilst

adopting some features of the ionic mechanism, thus giving rise to a polymerisation which is intermediate between radical and ionic polymerisation. Thus, under conditions of radical polymerisation it becomes possible to vary the reactivity both of the monomer and of the resulting radical. It may be suggested that the use of chelate complexes is the most efficient way of influencing the reactivity of the radical both in the initiation and in the chain propagation step. In this sense, both the low-molecular-weight and the macromolecular chelates offer interesting possibilities because of the ease of electron transfer in the ligand and of the change in electron density on the metal in the coordination centre.

An interesting example of selective initiation of polymerisation by acetylacetonates of the transition metals Mn^{II} and Mn^{III}, Co^{II} and Co^{III}, was reported by Otsu and coworkers[69]. The polymerisation of chloral, according to these authors, follows a coordination-anionic mechanism according to the scheme



The authors have shown that acetylacetonates of this type can initiate the polymerisation not only of chloral but also of acetaldehyde and of styrene oxide. (The polymerisation of formaldehyde by acetylacetonates had already been disclosed in the patent literature[70].)

In contrast to the views of Kastning[57] and of Bamford[67] (see p. 991), Otsu and coworkers[69] believe that acetylacetonates of metals in both the upper and the lower valency state of the metal can initiate the polymerisation of methyl methacrylate as well as of chloral.

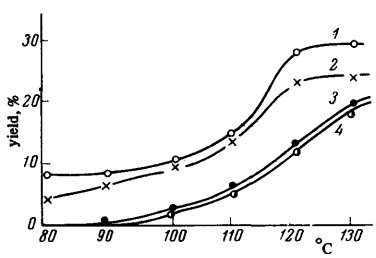


Figure 11. Temperature dependence of the yield of polymerisation products of styrene on poly-(β-ketoester) complexes, (XI)-M, $m = 6$. Time 1 h, concentration of complex 1 wt.%:
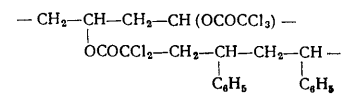
1) Co, *2*) Mn, *3*) Ni, *4*) no complex.

The macromolecular chelates of the poly-(β-keto-ester) type XI-M described by the present writers[43-45,71] were found to initiate the polymerisation of vinyl monomers, such as styrene, methyl methacrylate, etc. Fig. 11 shows the temperature dependence of the degree of conversion of styrene in the presence of various macromolecular chelates of this type. Only the Co and Mn macromolecular chelates are catalytically active under the stated conditions; the degree of conversion in the presence of the Ni chelate is practically the same as in the absence of the chelate. We note that according to Kastning and coworkers[57] the low-molecular-weight chelates of Co and Mn are also the most active in the initiation of the polymerisation of styrene. The rate of block polymerisation of styrene at 80°C in the presence of the manganese chelate (XI-Mn) depends linearly on the concentration of the chelate; addition of benzoquinone (0.2 g litre^{-1}) destroys the polymerisation effect. It was shown that as well as initiation of the reaction, grafting of polystyrene units to the macromolecular initiator (XI-Mn) takes place. The resulting graft copolymers lose their metal atoms as a result of treatment with dilute mineral acids, and become soluble in organic solvents (possibly through the collapse of the three-dimensional network of the initiator macromolecule), whilst retaining the chemical bond between the grafted chain and the macromolecular ligand. When the polymerisation of butadiene was initiated by the poly-(β-diketone) chelates (XI-Mn) and (XI-Co), a significant increase in the yield of polymers can be demonstrated (as compared with initiation by the appropriate acetylacetonates); the product consists of a graft copolymer of butadiene and the poly-(β-ketoester). The degree of grafting of polybutadiene to the macromolecular chelate is 0.80–0.93; the structure of the polybutadiene chains, which contain 20, 34, and 46% of 1,2-, 1,4-*cis*-, and 1,4-*trans*- respectively, is characteristic of polybutadiene prepared by radical initiation.

It is interesting to note that graft (or block) copolymers were obtained by Bamford and coworkers[72] by a different method, namely, by the polymerisation of styrene under the influence of metal carbonyls or acetylacetonates in the presence (as activating additives, see p. 989) of high-molecular-weight halogen compounds, such as poly(vinyl trichloroacetate):



To conclude this Section we note that the catalytic properties of polycoordination polymers (of the quinizarine type) towards the polymerisation of styrene were reported as early as in 1963,[73] but neither the reaction nor the polymerisation products were investigated.

3. CATALYTIC ACTIVITY AND STRUCTURE OF MACROMOLECULAR CHELATES

Whereas the relationship between catalytic activity and structure of low-molecular-weight chelates has been adequately discussed in the literature (see review by Schrauzer et al.[74]), relatively little has been published on this problem regarding macromolecular chelate compounds. Roginskii and his coworkers studied the catalytic activity of semiconductors (for example, polyphthalocyanines) in decompositions and oxidations, and they concluded that the catalytic activity of semiconductors is determined by collective electrical properties[75]. The importance of the collective electrical properties of the system was stressed also by Inoue and coworkers[15,16], who studied the catalysis of the oxidation of the ethyleneacetal of acetaldehyde on mixed polyphthalocyanine semiconductors.

Min'kov and Keier[76] specially pointed out the change in the activity of the catalyst during the reaction in their study of the mechanism of the liquid-phase oxidation of isopropylbenzene on low-molecular-weight copper phthalocyanine chelates. They concluded that initiation in the case of copper phthalocyanine does not involve the activation of oxygen but rather the catalytic decomposition of the reaction products of α-cumyl hydroperoxide into free radicals, which proceeds unimolecularly with specific rate constant $k_{sp} = 1.5 \times 10^3 \exp(-13\,200/RT)$ s^{-1} at 40–70°C and bimolecularly with $k_{sp} = 3.6 \times 10^{10} \exp(-24\,600/RT)$ litre $mole^{-1}$ s^{-1} at 90–100°C. Thus, the decomposition of the hydroperoxide occurs by different mechanisms, depending on the temperature. The activity of the catalyst in this reaction varies with time: at 101°C the rate of decomposition of the hydroperoxide decreases by a factor of 2.5 during the first two hours, and then remains constant, but at 60°C the rate of decomposition of the hydroperoxide has not reached a steady value even after 8.5 h (see Fig. 12).

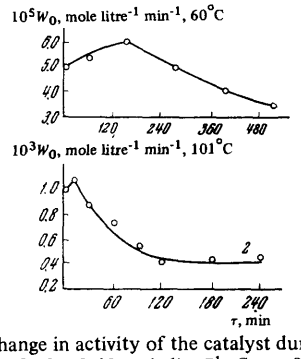


Figure 12. Change in activity of the catalyst during the reaction: *1*) at 60°C, [ROOH] = 0.40 mole litre^{-1}, C_{cat} = 0.66 mg ml^{-1}; *2*) ditto, at 101°C.

On the basis of X-ray diffraction, ESR spectra, and infrared spectra it has been shown that the change in activity of Cu phthalocyanine is associated with a change in the crystal structure of the material (transformation from the α- to the β-modification). As regards the nature of the interaction between the hydroperoxide and the phthalocyanine, the data show that there is no direct interaction between the hydroperoxide and the copper ion: the interaction is with the whole of the π-electron system of the ligand. However, the phthalocyanine itself (metal-free) is inactive towards this reaction. The copper ion exerts a strong polarising effect on the ligand, increasing the π-electron density on the nearest nitrogen atoms and decreasing it on the nitrogen atoms remote from the metal. It is the lower density of π-electrons on the nitrogen atoms not involved in the chelate ring which favours complex formation with the hydroperoxide and activates it in reactions involving its decomposition into free radicals, which finally bring about the oxidation of cumene[77].

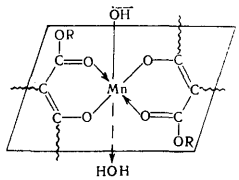
Keier and coworkers[25,35] tried to explain the change in rate of a reaction (for example, the decomposition of hydrazine) on low-molecular-weight complexes of different purity, obtained by recrystallisation. By studying ESR spectra they concluded that crystallisation increases the degree of order of the crystal structure. Polymeric chelates with a more ordered structure also showed a lower reactivity towards the reaction under study. For example, a polychelate with a highly ordered structure which was almost free from defects and planar was similar to its low-molecular analogues in reactivity. This material, prepared in a nitrogen atmosphere, was characterised by a narrow ESR line and by well developed anisotropy[39]. ESR spectral studies before and after vacuum annealing showed that polychelates with a regular structure are not formed under the preparative conditions used. Ordering of the polymer structure takes place during the heat treatment, involving completion of the complex formation and molecular redistribution, and also exchange interaction between the copper ions resulting from the increased conjugation in the polymer. The tetrahedrally distorted structure of the chelate centre becomes planar, and the molecular weight of the polychelate increases. Mutual interconversion of various modifications of the polymer is also possible. All these factors tend to lower the reactivity of the polychelate[39].

The surface of the polychelates plays a well known role in determining their catalytic activity. Thus, the catalytic activity per unit weight of polymer increases by almost two orders of magnitude on increasing the surface area of copper polychelates based on α-thiopicolinamidobiphenyl[34]. In an investigation of the catalytic activity of polychelates towards the decomposition of N_2H_4 it was shown that the chelate suffers fully or partly irreversible changes. Measurements of the decrease in intensity of the ESR signal at the beginning of the reaction give almost quantitative agreement between the number of copper chelate centres which have reacted and the number of decomposed N_2H_4 molecules. The first step of the reaction may consist in the attachment of the reactant to the metal of the chelate centre, accompanied by an electron transfer which alters the charge on the metal and thus weakens the metal–ligand bond[25].

Elimination of the ligand can then take place, with simultaneous attachment of hydrogen atoms at the broken bonds and evolution of NH_3 and H_2 molecules into the gas phase. However, the breakdown of the chelation centre is complete when the copper is reduced to Cu^0, with further increase in the rate of decomposition of the substrate. (The rate of decomposition after 21 h increases to 3 cm^3 h^{-1} as compared with 0.1 cm^3 h^{-1} during the first hour.) In the oxidation of isopropylbenzene (p. 986) the polychelates also react with the substrate and undergo irreversible changes, however (and in contrast to the previous reaction) the deactivation of the catalyst is much slower. Thus, polymeric chelates take part in the formation of free radicals as true heterogeneous catalysts[36].

In order to identify the type of metal–polymer bond and the valency state of the metal in the chelates with macromolecular ligands (XI-M) prepared by the present writers, their magnetic moments μ_{eff} were measured[78]. The μ_{eff} values (in Bohr magnetons) were 3.83 and 4.87 respectively for different samples of XI-Mn, which corresponds to three and four unpaired d-electrons. Thus, the samples were spin-free and contained Mn^{IV} and Mn^{III} ions. It is not easy to envisage a coordination of three (or four) macromolecular ligands around the central manganese atom, as the Stewart–Briglebb molecular model clearly shows. Hence we may imagine that the manganese atom is surrounded by six oxygen atoms, four of which belong to polymeric ligands and the other two to two hydroxyls (for Mn^{IV}) or to one

hydroxyl and one solvent water molecule (for Mn^{III}), which thus complete the coordination octahedron:



Some of the centres may be coordinated to one macromolecular ligand and two solvent water molecules[71].

In this instance, as with the macromolecular chelates of type (III),[34] the high catalytic activity can be ascribed[78,79] to the formation of disordered, incompletely saturated coordination centres in the polymer chain, with a distorted geometrical configuration.

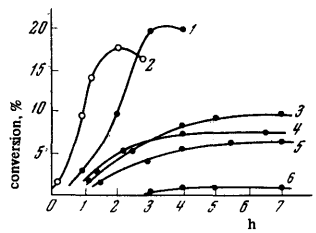


Figure 13. Liquid-phase oxidation of acrolein in the presence of the following acetylacetonates:
1) Mn, *2*) Co, *3*) Fe, *4*) Cu, *5*) Ni, *6*) acetylacetone; concentration 1×10^{-3} mole litre^{-1}.

Japanese workers have put forward[80] some interesting ideas on the changes in the coordination centre of the catalyst in the course of the catalytic reaction. The activity of acetylacetonates decreases in the series Co > Mn ≫ Fe ≃ Cu > Ni (Fig. 13) for the liquid-phase oxidation of acrolein to acrylic and peracrylic acid, and acrylic acid polymers. (The solvent used for the oxidation determines the relative yield of these products.) The authors believe that the reaction occurs by a radical mechanism, and that the initial and the final products (including polymeric products) enter into the coordination centre of the catalyst (for example, Co^{III} acetylacetonate) as they are formed.

The most important thermodynamic characteristic of complexes in general (and macromolecular complexes in particular) is their so-called stability (or instability) constant. Thus, according to Kenney[81], K_{st} of polycoordination polymers (that is, the equilibrium constant of the reaction $M^{m+} + mA^- \rightleftharpoons [MA_m]$) is a measure of the free energy change attending complex formation. The values of this constant for bivalent metals increase in the series Mg < Mn < Fe < Co < Ni < Cu < Zn.[81] Thus, it is particularly relevant to establish the dependence of the activity of macromolecular chelates upon their stability—for example, for the complexes of the 2(O, O) type considered here. The Japanese workers already mentioned[40,42] observed a correlation between the catalytic activity series of the poly-(β-diketone) copper chelates (see p. 987), VII-Cu > VIII-Cu > IX-Cu > X-Cu, and the shifts of the absorption maxima in the visible region of the spectrum towards longer waves (λ_{max} 388, 375, 370, 368 mμm respectively). This is evidence that the energy of the electronic transitions in the macromolecular ligands and their chelates decreases in the stated order, and therefore the strength of the bond between the macromolecular ligand and the metal must also decrease in the same order.

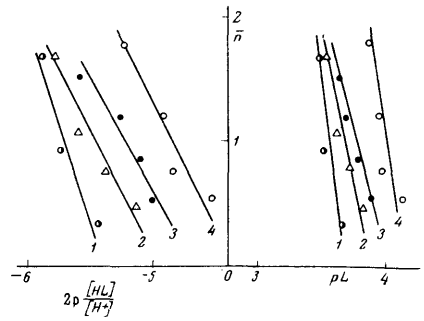

Figure 14. Curves for the formation of poly-(β-ketoester) complexes, (XI)-M, $m = 6$:
1) Mn, *2*) Co, *3*) Ni, *4*) Cu.

The present writers and their coworkers[82] have measured the acid–base dissociation constants of the macromolecular ligands of the poly-(β-ketoester) type XI and the formation (or stability) constants of their complexes with transition metal cations. The acid–base dissociation constant K_a of the macromolecular ligand (XI, $m = 6$) was found to be $10^{-6.4}$ (that is, $pK_a = 6.4$). This value was obtained from the Henderson–Hasselbach equation $pH = pK_a - n\lg[(1 - \alpha)/\alpha]$, where α is the degree of neutralisation, and n is a constant independent of the extent of polymerisation whose value varies between 1 and 2 and increases with dilution of the solution. The formation constants (or stability constants) of the macromolecular chelates XI-M decrease in the series Cu > Ni > Co > Mn (Fig. 14). We note that the same sequence also describes the increase in catalytic activity of the poly-(β-ketoester) complexes XI-M for the decomposition of hydrogen peroxide, and the decrease in the activity of these complexes for the oxidation of ascorbic acid (see Figs. 6 and 5 respectively, and p. 987).

---o0o---

Published data show that the field of macromolecular complexes is an interesting one from many viewpoints. Leaving aside the problem of preparing thermally stable polychelates[83], it is obvious that macromolecular complexes are vitally important as catalytic systems which are active towards a wide range of reactions including the polymerisation of vinyl monomers.

These systems are interesting also from the standpoint of structural studies, since their structure allows mutual interaction of coordination centres through the polymer chain.

Macromolecular complexes containing metals can be treated as model compounds for the substances which take part in a number of biochemical processes, such as the assimilation of metal ions (Cu, Fe), the blocking of functional groups (Mn), redox reactions of the cell (Cu, Fe, Co), and others[84].

Each of the two main classes of macromolecular complexes, prepared either by polycoordination of multivalent ions with multidentate low-molecular-weight ligands or from previously synthesised macromolecular ligands, has some advantages as a catalytic system: the former because of the presence of a conjugated system and of the concomitant synergic effect (that is, the collective electronic property of the macromolecule), the latter because of the presence of a macromolecule which is not destroyed by the removal or replacement of some metal atoms by others, and also because of the solubility of the initial macromolecular ligand.

The Inhomogeneity of Copolymers with Respect to Composition

V.A.Myagchenkov and S.Ya.Frenkel'

The inhomogeneity of composition (i.c.) which arises in copolymerisation not only influences the physical and physicochemical properties of the copolymers formed but also, when it is correctly assessed, makes it possible to arrive at certain conclusions concerning the copolymerisation mechanism. The review deals mainly with binary statistical copolymerisation. A critical analysis is given of the "classical" Mayo-Lewis concept, according to which the copolymerisation constants remain unchanged throughout the process. Regarding such systems as "normal" or standard, the authors have derived expressions for their distribution functions with respect to composition. Further it is noted that the case where r_1 and r_2 are constant is more likely to be an exception rather than the rule and possible causes of the departure from such constancy are indicated. The principles of the derivation of the integral and differential distribution functions with respect to composition for copolymerising systems are discussed in detail. Analytical expressions are proposed for numerical estimates of inhomogeneity with respect to composition. In their statistical significance the expressions obtained resemble equations of different degrees governing the molecular weight ratios in homopolymerisation. The deviations from the "norm" in the copolymerisation of ionogenic monomers in aqueous solution are considered as an example of the application of these expressions. In this case the copolymerisation constants depend on the conversion due to the changes in the degree of ionisation of the "bound" monomers compared with the free monomers and due to the overall change in ionic strength. In conclusion a critical analysis is given of the existing experimental methods for the determination of inhomogeneity of composition and the prospects for the further development of the statistical theory of copolymerisation are discussed. The bibliography includes 111 references.

I. INTRODUCTION

The polydispersity of copolymers is not restricted to differences in chain length. Individual macromolecules can differ also in their chemical composition (inhomogeneity of composition) or in their shape (molecular polymorphism)[1,2]. All three types of polydispersity are a consequence of certain processes occurring in copolymerisation. Their analysis may provide valuable information about the kinetics and mechanism of copolymerisation—by analogy with the detailed information about the homopolymerisation mechanism derived from the analysis of molecular weight distribution (m.w.d.). In addition, inhomogeneity of composition and molecular polymorphism have a

significant effect on the macroscopic properties of copolymeric materials—to a greater extent than the molecular weight distribution.

Nevertheless in the extensive literature devoted to the problems of copolymerisation the number of papers dealing with different types of polydispersity, in particular inhomogeneity of composition, is relatively small[3]. To a large extent this is because as a rule all three types of polydispersity in copolymers are present at the same time and molecular polymorphism is usually a consequence of inhomogeneity of composition[2], which has different effects at the level of macromolecular (in solutions) and supermolecular (in the solid) structures. Not only are there no generally accepted "specific" methods "designed" for a particular type of polydispersity, but also there exists no adequate statistical theory which would describe inhomogeneity of composition, or molecular polymorphism, with the aid of distribution functions or their moments, by analogy with molecular weight distribution[2,4]. Therefore the relatively reliable individual items of evidence concerning inhomogeneity of composition and molecular weight distribution have been obtained only for certain model copolymeric systems.

To avoid the above difficulties, the great majority of investigators have confined themselves to the calculation of the apparent copolymerisation constants r_1 and r_2,[5-10] assuming *a priori* that the system obeys the Mayo–Lewis equation[11-13]. However, as will be shown below, this equation describes the actual copolymerisation process only to a first approximation and is by no means applicable to any system. There exist many "unusual" systems (systems which do not obey the Mayo–Lewis equation), the mechanism and kinetics of the copolymerisation of which cannot be characterised solely by the information concerning the average composition of the copolymer $\bar{\alpha}$ (see below) for certain fixed conversions ψ and compositions of the initial monomer mixture (substrate). In order to characterise such systems, it is essential to have detailed information about their inhomogeneity with respect to composition.

The present review deals with modern hypotheses concerning the causes of inhomogeneity of composition and rational quantitative methods for the statistical description of this inhomogeneity are discussed as well as special experimental methods and principles "designed" specifically for inhomogeneity of composition. The review is concerned mainly with two-component statistical copolymers, since this class of systems has been most thoroughly investigated. However, with some stipulations, the postulates developed below may be extended also to heteropolymers (block and graft polymers) and to multicomponent systems.

II. THE CAUSES OF INHOMOGENEITY OF COMPOSITION

In the estimation of inhomogeneity of composition one should always bear in mind that it is in general due to two fundamentally different processes. Firstly, inhomogeneity of composition is a consequence of the statistical nature of the copolymerisation process itself. We shall call this type of inhomogeneity "instantaneous" inhomogeneity of composition (i.i.c.). The second type of inhomogeneity (we shall call this the "conversion" inhomogeneity of composition, c.i.c.) is caused by macroscopic changes in the parameters of the reaction medium during copolymerisation. In the simplest case conversion inhomogeneity is due to the changes in the composition of the substrate during copolymerisation. Henceforth in the discussion of the inhomogeneity of the composition of copolymers it will be understood that instantaneous and conversion inhomogeneity are present. We shall discuss in greater detail the causes of both types of inhomogeneity.

1. "Instantaneous" Inhomogeneity of Composition

The macroscopic copolymerisation process is a consequence of the superposition of a multiplicity of elementary reactions, such as the initiation and propagation of the kinetic chain, different types of chain transfer, termination of the kinetic chain (by recombination and disproportionation mechanisms), etc.[1,2]. Individual elementary processes in the formation of copolymer macromolecules are also of a statistical character and therefore at each given instant the entire homogeneous system exhibits microheterogeneity due to local fluctuations in the concentrations of the reactants. This is ultimately responsible for "instantaneous" inhomogeneity of copolymers both with respect to molecular weight and composition. Distribution functions with respect to molecular weight and composition α have been obtained in an analytical form for two-component copolymeric systems—by Simha and Branson[14] in a simplified form and more rigorously by Stockmayer[15]. Let $w_{n,\alpha}$ be the weight fraction of macroradicals with a degree of polymerisation n and the composition $\alpha = [A]/([B] + [A])$, where [A] and [B] are the molar concentrations of components A and B in the macroradical (their concentrations in the substrate are denoted respectively by [a] and [b]), and $\alpha = \alpha_0 + \Delta\alpha$, where $\alpha_0 = \sum_{i=1}^{k} N_i\alpha_i / \sum_{i=1}^{k} N_i$ is the arithmetical mean composition of the statistical ensemble of k macroradical fractions and N_i is the number of macroradicals with the composition α_i.

If [a] = const., [b] = const., and $n \gg 1$, then under quasi-steady-state conditions

$$w_{n,\alpha} = A\, n^{1/2} e^{-n(\Delta\alpha)^2/D} e^{-n/B}. \qquad (1)$$

Here $B = \sum_{p=1}^{m} N_p n_p / \sum_{p=1}^{m} N_p$ is the arithmetical mean (number average) degree of polymerisation of macroradicals,

$$A = \frac{\sum_{p=1}^{m} N_p}{\sum_{p=1}^{m} N_p n_p^2} \left[\frac{r_A [a]^2 + 2[a][b] + r_B [b]^2}{2\pi\alpha_0 (1-\alpha_0)(r_A [a]^2 + 2r_A r_B [a][b] + r_B [b]^2)} \right]^{1/2},$$

$$D = 2\alpha(1-\alpha_0) \frac{r_A [a]^2 + 2r_A r_B [a][b] + r_B [b]^2}{r_A [a]^2 + 2[a][b] + r_B [b]^2},$$

and r_A and r_B are copolymerisation constants.

As was to be expected from the very formulation of the problem, the distribution function with respect to composition depends significantly on the molecular weight distribution of the macroradicals. To establish an unambiguous relation with n (or α), Eqn. (1) must be integrated with respect to all the α (or n). Integration yields

$$w_\alpha = \frac{3}{4} \left(\frac{B}{D} \right)^{1/2} \left[1 + \frac{B}{D} (\Delta\alpha)^2 \right]^{-5/2} \qquad (2a)$$

and

$$w_n = \frac{n \sum_{p=1}^{m} N_p n_p^2}{\sum_{p=1}^{m} N_p} e^{-n/B}. \qquad (2b)$$

It is easy to show that Eqn. (2b) can be reduced to the "most probable" [2] distribution function with respect to molecular weight for homopolymeric systems [16].

We may note that an expression analogous to Eqn. (1) can be obtained also when a different aspect of the copolymerisation process is examined. The macroradicals formed may be regarded as chain fragments which arise from a finite number of breaks in a quasi-infinite Kuhn chain [2,17], which is ordered with respect to composition. One should remember that all the distribution functions considered [Eqns. (1), (2a), and (2b)] were derived for "instantaneous" values of [a] and [b], time not entering into them, and therefore it is impossible to obtain $w_{n,\alpha}$ in an explicit form by means of Eqns. (1), (2a), and (2b) for finite values of ψ. Eqns. (1), (2a), and (2b) were obtained for the condition $n \to \infty$, and become significantly more complex when they are modified to describe the instantaneous inhomogeneity of composition in real systems [18]. Thus if Eqn. (1) is valid also for finite n under the condition that the termination of kinetic chains takes place only by a disproportionation mechanism, then, with the probability f of recombination termination steps, Eqn. (1) becomes

$$\omega_{n,\alpha} = A\left(1 - f + \frac{nf}{B}\right) n^{1/6} e^{-n/B} e^{-n(\Delta\alpha)^2/D} . \qquad (3)$$

Experimental tests of Eqns. (1), (2a), (2b), and (3) require a precision in the estimation of the composition of the copolymer which is not a present attainable. However, the contribution of instantaneous inhomogeneity to the total inhomogeneity of composition should not be overestimated —for copolymers with $n > 500$ the broadening of the curve for inhomogeneity of composition due to instantaneous inhomogeneity is relatively slight and decreases with increasing n.

Instantaneous inhomogeneity of composition can also be a consequence of the microheterogeneity of the system in the following cases.

1. The formation around the macroradicals of a "microsubstrate" with the composition [a]′/[b]′ which differs from the macroscopic value [a]/[b] and depends on n [2].

2. The dependence of the reactivity of the co-monomers on n arises from the possible dependence of the diffusion coefficients of the monomers on microviscosity in the bulk of the macroradicals. A change in the conformation of the macroradicals during copolymerisation (i.e. the occurrence of molecular polymorphism) should favour the appearance of additional instantaneous inhomogeneity of composition.

3. A change in the nature of the selective interactions between the co-monomers and the individual components in the copolymerising system [19].

The effect of each component of instantaneous inhomogeneity of composition can be taken into account only by means of appropriate model experiments and it is necessary to attain a very high accuracy in the determination of α.

2. Conversion Inhomogeneity of Composition

Systems which obey the Mayo–Lewis rule. The Mayo–Lewis equation was derived on the following assumptions:

(1) [a] = const. and [b] = const.;
(2) $r_A \neq r_A(t)$ and $r_B \neq r_B(t)$.

It is assumed that the reactivity of the monomer is independent of the alternation of the preceding units up to the terminal radical.

(3) $r_A \neq r_A(n)$ and $r_B \neq r_B(n)$;
(4) $r_A \neq r_A([a]/[b])$ and $r_B \neq r_B([a]/[b])$;
(5) the reaction system is fully homogeneous;
(6) the chain propagation reactions are completely irreversible.
Then

$$\frac{[A]}{[B]} = \frac{[a]}{[b]}\left\{\frac{r_A[a]+[b]}{r_B[b]+[a]}\right\} . \qquad (4)$$

It is possible to modify this expression. We introduce the weight concentrations (g cm^{-3}) of the substrate components C_A and C_B defined by the equations

$$[a] = \frac{C_A/M_A}{C_A/M_A + C_B/M_B} \text{ and } [b] = \frac{C_B/M_B}{C_A/M_A + C_B/M_B},$$

where M_A and M_B are the molecular weights of the components A and B. Eqn. (4) can then be written in the more convenient form:

$$\frac{M_A}{M_B}\frac{\beta^2}{\gamma} r_B - r_A = \beta\left(\frac{M_A}{M_B} - \frac{1}{\gamma}\right), \qquad (5)$$

where $\gamma = dC_B/dC_A$ and $\beta = C_B/C_A$.

For high conversions ψ, the Mayo–Lewis equation can be written in an integral form as follows [1,3]:

$$\log([a]|_t/[a]_{t=0}) = \frac{r_A}{1-r_A}\log\left(\frac{[a]}{[b]}\right)\Big|_{t=0} \times \left(\frac{[b]}{[a]}\right)\Big|_t - \frac{1-r_A r_B}{(1-r_A)(1-r_B)}\log\frac{(r_B-1)\left(\frac{[b]}{[a]}\right)\Big|_t - r_A + 1}{(r_B-1)\left(\frac{[b]}{[a]}\right)\Big|_{t=0} - r_A + 1} . \qquad (6)$$

In the derivation of Eqn. (6) it was assumed that r_A = const. and r_B = const. Bearing in mind that $[a]/[b] = F(t)$, one may conclude that the composition of the copolymer varies with increasing ψ and that in the general case ($r_A \neq r_B$) inhomogeneity of composition appears in the specimen due to the variation of [a]/[b] in the copolymerisation process.

When data are available for the composition of the copolymer and the substrate at fixed ψ, it is possible to determine the copolymerisation constants either from Eqns. (4) and (5) for $\psi < 0.05$ or from Eqn. (6) for $\psi > 0.1$. However, the experimenter is frequently faced with a different problem—it is necessary to obtain information about inhomogeneity of composition for various ψ_t from known values of $[a]_t$, $[b]_t$, $[A]_t$, $[B]_t$, r_A and r_B. This problem has been solved in the most general form by Skeist [20].

We introduce the notation

$$f_A = \frac{[a]}{[a]+[b]}, \quad f_B = \frac{[b]}{[a]+[b]},$$
$$F_A = \frac{[A]}{[A]+[B]}, \quad F_B = \frac{[B]}{[A]+[B]} .$$

From the condition of the constancy of the total content of the monomeric units A in the substrate and the copolymer during copolymerisation, it follows that

$$f_A\{[a]+[b]\} + F_A\{d[a]+d[b]\} = \{[a]+d[a]+[b]+d[b]\}(f_A + df_A) \qquad (7)$$

and after integration

$$\log\frac{[a]+[b]}{[a]|_{t=0}+[b]|_{t=0}} = \int_{f_A|_{t=0}}^{f_A} \frac{df_A}{F_A - f_A} , \qquad (8)$$

where

$$f_A|_{t=0} = \frac{[a]|_{t=0}}{[a]|_{t=0} + [b]|_{t=0}} .$$

F_A can be determined from known values of f_A, r_A, and r_B by Eqn. (4) and then the composition and the weight fractions of the individual copolymer fractions can be found by Eqn. (8).[21]

b. "Unusual" systems. In his latest review[22] Mayo notes that one should not expect Eqns. (4)–(6) to apply to all copolymerising systems. In the literature there are no clearly formulated criteria of the applicability of the Mayo–Lewis equations to the system under consideration, although this process is frequently of decisive importance in the study of copolymerisation. At the same time a knowledge of the variation of the average composition of the copolymer with $([a]/[b])|_{t=0}$ is as a rule insufficient to determine unambiguously whether or not the system obeys Eqns. (4)–(6), because (1) there is a considerable relative indeterminacy in the positions of the points in [A]/[B]–[a]/[b] or dC_A/dC_B–C_A/C_B diagrams, since the accuracy in the determination of $\alpha_A \leq 1\%$, while

$$0 \leq dC_A/(dC_A + dC_B) \leq 1$$

and $0 \leq \alpha_A \leq 1$, and (2) even in the simplest cases of copolymerisation two parameters (r_A and r_B) are unknown and, when account is taken of the experimental error, the positions of the experimental points in the dC_A/dC_B–C_A/C_B diagram can be described by several combinations of r_A and r_B.[23–25]

In order to assess the characteristic features of the copolymerisation process, we believe it more correct to investigate the variation of $\beta(M_A/M_B - 1/\gamma)$ with β^2/γ [Eqn. (5)] for different substrate compositions and varying ψ rather than analyse [A]/[B] – [a]/[b] diagrams with a subsequent attempt to describe the copolymerisation process with the aid of combinations of r_A and r_B. For "classical" systems, the relation between $\beta(M_A/M_B - 1/\gamma)$ and β^2/γ is linear, the intercept on the ordinate axis being $-r_A$ and the slope $(M_A/M_B)r_B$. The non-linearity of the relation between $\beta(M_A/M_B - 1/\gamma)$ and β^2/γ under the condition $[A]/[B] = ([A]/[B])(t)$ $([a]/[b])|_{t=0} = \text{const.}$ is evidence that the relative reactivity of the co-monomers varies with ψ, while the non-linearity of this relation for different $([a]/[b])|_{t=0}$ indicates that the reactivity of the co-monomers varies with the composition of the substrate.

Fig. 1 shows the variation of $\beta(M_A/M_B - 1/\gamma)$ with β^2/γ for the "unusual" system acrylamide (Aa)–maleic acid (Ma),[26] the non-linearity of the relation between $\beta(M_A/M_B - 1/\gamma)$ and β^2/γ for the system Aa–Ma being due to changes in ψ and $([a]/[b])|_{t=0}$.

The inapplicability of the Mayo–Lewis equations to the system may be due to the failure of even only one of the six conditions formulated above in the derivation of Eqns. (4)–(6). Conditions (2), (4), and (6) are particularly important; for some systems, the fulfilment of condition (5) is not obligatory[27], and condition (3) is fulfilled automatically in the synthesis of high polymers[1,3,5].

In the general case of copolymerisation

$$r_A = r_A\{([a]/[b])|_{t=0},\ t\}$$

and $r_B = r_B\{([a]/[b])|_{t=0},\ t\}$ and one cannot expect that Eqns. (4)–(6) would then apply. A number of possible reasons for the departure of the polymerisation process from the Mayo–Lewis rule have been given in the literature.

1. The variation of the reactivity of the copolymers with the nature of the units preceding the terminal unit[28–31]. We may recall that, since "experimental errors are frequently associated with discrepancies of similar order of magnitude, a fairly marked effect of the penultimate unit has been established only in systems readily susceptible to analysis and usually for only one of the two types of radical considered".[22]

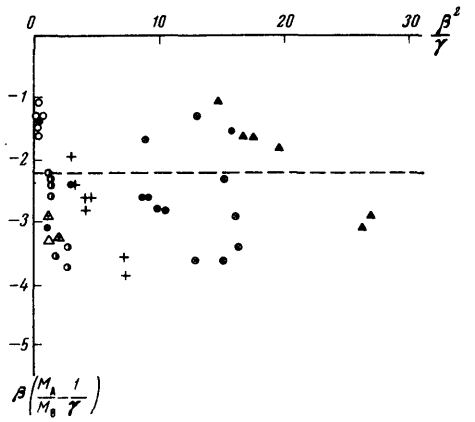

Figure 1. Variation of $\beta(M_A/M_B - 1/\gamma)$ with β^2/γ for the system acrylamide (Aa)–maleic acid (Ma). Copolymerisation in 5% aqueous solution at 70°C; the experimental points correspond to different Ψ and $([a]/[b])|_{t=0}$.

2. The appearance of phase heterogeneity in the system (precipitation of the copolymer, copolymerisation in emulsions and suspensions)[2,32,33].

3. The occurrence of a depolymerisation process in the system[34–38].

4. The occurrence in the system of chain-transfer reactions accompanied by chain rupture[39–41].

5. The dependence of the relative reactivity of co-monomers with ionogenic groups on the ionic strength of the solution[19,42–46]. This is in fact what happens in the system acrylamide–maleic acid; this system will be examined in detail below as a very clear example of "anomalous" copolymerisation.

III. INTEGRAL AND DIFFERENTIAL CURVES FOR DISTRIBUTION WITH RESPECT TO COMPOSITION

Important information about the copolymerisation process can be obtained from the analysis of integral and differential curves for distribution with respect to composition (ICDC and DCDC) when ψ and $([a]/[b])|_{t=0}$ are varied. The role of ICDC and DCDC increases markedly in the analysis of "unusual" systems where, apart from a quantitative description of inhomogeneity of composition, it is necessary to assess the causes of the "anomaly". In view of the importance of the problem and insufficient information about it in the literature[3], we shall consider in detail the method of plotting experimental and theoretical ICDC and DCDC. Here and henceforth n will be regarded as fairly large and therefore in the calculation of theoretical ICDC only the contribution due to conversion inhomogeneity of composition will be taken into account (neglecting

the instantaneous inhomogeneity). DCDC may be constructed on the basis of Eqn. (8) and, by evaluating the corresponding integral in an explicit form (as is done by Meyer and Lowry[47]) or by graphical interpolation, molar DCDC may be obtained. As an example, Fig. 2 presents the DCDC for a number of model systems (the calculation was performed by Izyumnikov and Vyrskii[48]). It is interesting to note that the DCDC is concave upwards for the case $r_A < 0.5$ (r_B can have any value) or $r_A < 0.5$ (r_A can have any value), but if $r_A > 0.5$ and $r_B > 0.5$, then the DCDC passes through the origin of coordinates[21,50]. Fig. 2 shows that the difference in the DCDC for two models, "terminal" and "preterminal", is fairly considerable and therefore by plotting the experimental DCDC one can show which model is correct.

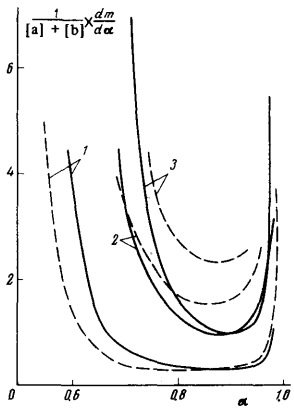

Figure 2. Differential distribution curves with respect to composition for "terminal" (dashed curves) and "preterminal" (continuous curves) models:
1) styrene–maleic anhydride; $r_A = 0.023$ and $r_B = 0.29$,[49] and also $r_A = 0.17$, $r'_A = 0.063$; and $r_B = r'_B = 0$;[48] *2*) styrene–citraconic anhydride; $r_A = 0.135$ and $r_B = 0.015$, and also $r_A = 0.07$, $r'_A = 0.25$, and $r_B = r'_B = 0.015$;[48] *3*) styrene–fumaronitrile; $r_A = 0.2$ and $r_B = 0$,[49] and also $r_A = 0.072$, $r'_A = 1.0$, and $r_B = r'_B = 0$.[48]

In order to obtain weight distribution functions with respect to composition, it is convenient to employ Eqn. (5), and, by analogy with the foregoing, to plot the DCDC. Frequently the following procedure for the plotting of ICDC and DCDC is the most convenient (one of the advantages is that initially the ICDC is plotted and then the DCDC is obtained, whereas the reverse process, the derivation of the ICDC from the DCDC, is more complex). Suppose that in the general case the equation for copolymerisation of an "unusual" system is of the form

$$dC_B = f_1(C_A|_{t=0},\ C_B|_{t=0},\ dC_A, r_A, r_B, r'_A, r'_B, r''_A, r''_B, \ldots) \qquad (9)$$

or in terms of molar concentrations

$$[B] = f_2([a]|_{t=0},\ [b]|_{t=0},\ [A],\ r_A, r_B, r'_A, r'_B, r''_A, r''_B, \ldots). \qquad (10)$$

By specifying definite values of dC_A or [b], dC_B or [B] are calculated from Eqns. (9) and (10) and then the average composition of the copolymer and the weight fraction ($dC_A + dC_B$) or the number of moles of the polymerisation increment are evaluated. After arranging the fractions in an ascending order of $\left(\frac{dC_A}{dC_A + dC_B}\right)\Big|_{\Psi - d\Psi}^{\Psi}$ or $\left(\frac{[A]}{[A]+[B]}\right)\Big|_{\Psi_1 - d\Psi_1}^{\Psi_1}$ we introduce the integral weight fraction

$$y_i = \sum_{k=1}^{i} (dC_A + dC_B)_k / (C_A + C_B)|_{t=0}$$

or

$$y'_i = \sum_{k=1}^{i} d([a] + d[b])_k / ([a] + [b])|_{t=0},$$

and $y_p = 1$ and $y'_{p'} = 1$ (p and p' are the numbers of fractions). Then the ICDC are plotted in terms of the coordinates

$$y_i - \left(\frac{dC_A}{dC_A + dC_B}\right)_i \text{ or } y'_i - \left(\frac{[A]}{[A]+[B]}\right).$$

Adequate precision in the plotting of ICDC is achieved when

$$\frac{(dC_A + dC_B)_k}{(C_A + C_B)|_{\psi=0}} \leqslant 0.001$$

with $\Psi \leqslant 0.8$, but, when the differences between r_A and r_B are not too great, the required precision in the construction of the ICDC is attained also under the condition

$$\frac{(dC_A + dC_B)_k}{(C_A + C_B)|_{\psi=0}} \leqslant 0.01.$$

Figs. 2 and 4*b* present a number of ICDC for a "classical" system corresponding to several values of Ψ, r_A, and r_B, the curves having been plotted according to the scheme described above.

Experimental ICDC can be plotted by two methods. In the first case the ICDC are obtained directly from the analysis of the copolymerisation kinetics and in the second case the required data are obtained from the analysis of the composition of the fractions. In the first variant the C_A–t and C_B–t curves are divided into 30–50 sections and the integral weight fraction and the composition of the copolymers are calculated for each section[50,51]. Figs. 3 and 4 present experimental kinetic curves and distribution curves with respect to composition constructed from these data.

In the plotting of the ICDC on the basis of fractionation data, it is desirable to have about 20 and more fractions. The fractions are arranged in terms of the ascending content of one of the components, their integral weight fractions are evaluated, and the ICDC and DCDC are plotted[26,52–55]. Experimental ICDC and DCDC obtained for the copolymers of methyl methacrylate and methacrylic acid for low values of Ψ have been plotted[56–59]; in some cases an ionising solvent—dimethylformamide—was added to the system to alter the activity of the acid units.

In the fractionation of copolymers it is very important to choose correctly the solvent–precipitant system, since in the general case the fractionation process takes place both with respect to molecular weight and composition[52–55,60]. In some cases the use of two- and even three-component solvents as precipitants proved to be the most effective[52,57]. The main theoretical principles of copolymer fractionation have been developed by Fuchs, Litmanovich, Kudryavtseva, Topchiev, and Shtern[53–55,61]. According to Kudryavtseva and Litmanovich[61], the volume

fractions of macromolecules with a degree of polymerisation n and a composition $\alpha = [A]/([A] + [B])$ in solution $(v_{n,\alpha})$ and in the precipitate $(v'_{n,\alpha})$ are related as follows:

$$\frac{v'_{n,\alpha}}{v_{n,\alpha}} = \exp[n(\sigma - \lambda\alpha)] \qquad (11)$$

where σ and λ are constants which depend on the energy and entropy parameters of the interaction in the system polymer–solvent–precipitant.

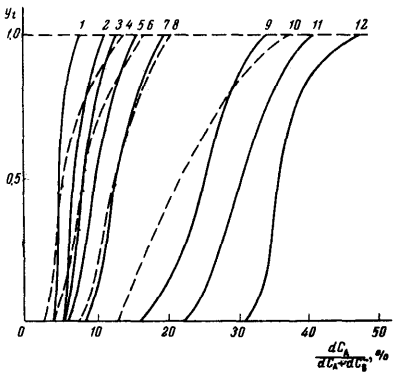

Figure 3. Integral distribution curves with respect to composition[26]. Substrate composition: acrylamide–sodium maleate: *1*) 4:1, $\Psi = 0.44$; *4*) 4:1, $\Psi = 0.82$; acrylamide–maleic acid: *2*) 9:1, $\Psi = 0.59$; *3*) 4:1, $\Psi = 0.74$; *5*) 3:1, $\Psi = 0.40$; *6*) 4:1, $\Psi = 0.85$; *7*) 3:2, $\Psi = 0.36$; *8*) 3:2, $\Psi = 0.71$; *9*) 1:1, $\Psi = 0.35$; *10*) 1:1, $\Psi = 0.43$; *11*) 2:3, $\Psi = 0.34$; *12*) 3:7, $\Psi = 0.28$; Ψ = conversion with respect to acrylamide.

Using Eqn. (11), it is possible to obtain the distribution functions with respect to composition and molecular weight for the kth fraction:

$$w_{n,\alpha}^{(k)} = w'^{(k-1)}_{n,\alpha} \frac{1}{1+P} \qquad (12)$$

$$w_n^{(k)} = \int_0^1 w_{n,\alpha}^{(k)} d\alpha = \int_0^1 w'^{(k-1)}_{n,\alpha} \frac{d\alpha}{1+P} \qquad (13)$$

$$w_\alpha^{(k)} = \int_0^\infty w_{n,\alpha}^{(k)} dn = \int_0^\infty w'^{(k-1)}_{n,\alpha} \frac{dn}{1+P} \qquad (14)$$

$$P = \frac{1}{R_k} \exp[-n(\sigma_k + \lambda_k\alpha)]$$

Here $w'^{(k-1)}_{n,\alpha}$ is the distribution function with respect to n and α of the copolymer remaining in solution after the isolation of the $(k-1)$th fraction.

The parameters σ_k, λ_k, and R_k are found from the system of equations

$$\left.\begin{aligned} w^{(k)} &= \int_0^\infty w_n^{(k)} dn = \int_0^\infty dn \int_0^1 w'^{(k-1)}_{n,\alpha} \frac{d\alpha}{1+P}, \\ \bar{n}_B^{(k)} &= \frac{1}{w^{(k)}} \int_0^\infty n dn \int_0^1 w'^{(k-1)}_{n,\alpha} \frac{d\alpha}{1+P}, \\ \bar{\alpha}^{(k)} &= \frac{1}{w^{(k)}} \int_0^1 \alpha d\alpha \int_0^\infty w'^{(k-1)}_{n,\alpha} \frac{dn}{1+P}. \end{aligned}\right\} \qquad (15)$$

Here $w^{(k)}$, $\bar{n}_B^{(k)}$, and $\bar{\alpha}^{(k)}$ are the weight, the weight-average degree of polymerisation, and the average composition of the kth fraction, all of which can be determined experimentally. Thus, knowing the distribution functions with respect to n and α in the initial specimen, it is possible to evaluate the distribution functions with respect to n and α for the fractions by determining $w^{(k)}$, $\bar{n}_B^{(k)}$, and $\bar{\alpha}^{(k)}$. Assuming that the distributions with respect to n and α in the initial specimen are independent, i.e.

$$w_{n,\alpha}^0 = w_n^0 \; w_\alpha^0 \qquad (16)$$

and that $r_A = 0.52$, $r_B = 0.46$, $\bar{n} = 10^3$, and $\Psi = 1$, Kudryavtseva and Litmanovich[61] estimated the possibility of consecutive, cross, and step-wise fractionation of copolymers[62]. The specimen was divided mathematically into 16 fractions according to the following scheme: initially four fractions of identical weight were obtained (*a*, *b*, *c*, *d*) and then each was in turn subdivided into four fractions of equal weight. Assuming that $R_k = 10^{-3}$ and $\lambda_k = 0.02$, $w_n^{(k)}$ and $w_\alpha^{(k)}$ were calculated on an M-20 computer,

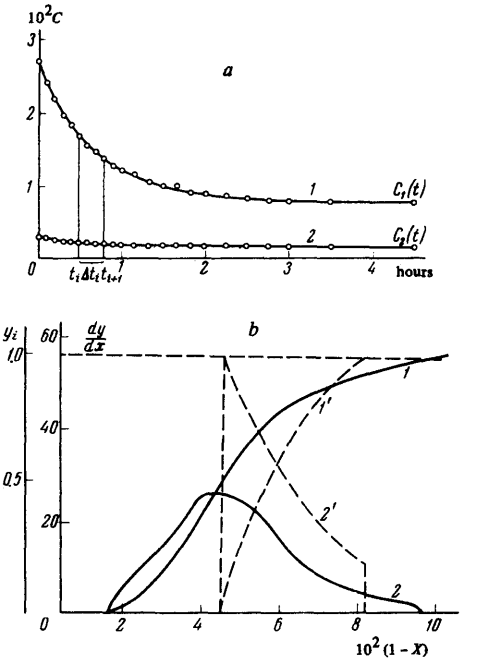

Figure 4. *a*) Curves representing the consumption of the co-monomers in 3% aqueous solution of acrylamide (curve *1*) and maleic acid (curve *2*) (9:1) at 70°C; integral (curve *1*) and differential (curve *2*) curves describing inhomogeneity of composition for $\Psi = 0.67$; *1'*) and *2*) calculated curves obtained by Skeist's method for $r_A = 2.2$ and $r_B = 0$; x = weight concentration of acrylamide in the copolymer.

assuming that Eqn. (16) applies. Fig. 5 presents the calculated distribution curves with respect to composition for all 16 fractions. It is interesting to note the overlapping of the DCDC and the at first sight paradoxical finding that the inhomogeneity with respect to composition in certain fractions (*3d*, *4a*, *4b*, *4c*, *4d*) is greater than in the initial specimen. Fig. 6 shows the differential distributions with respect to composition for two cases of fractionation. On the basis of these data, Litmanovich and Kudryavtseva conclude that cross fractionation is preferred to consecutive and stepwise fractionation.

With increasing differences in the physicochemical parameters (polarity, chemical composition, microstructure, etc.) of the homopolymeric components, the efficiency of fractionation increases. In the case of the random copolymers of methyl methacrylate and methacrylic acid, in which there is a marked difference between the properties of the homopolymeric components, good results are obtained also by consecutive fractionation[56-59]. With increasing number of fractions and stages in stepwise fractionation, the efficiency of fractionation also increases[62].

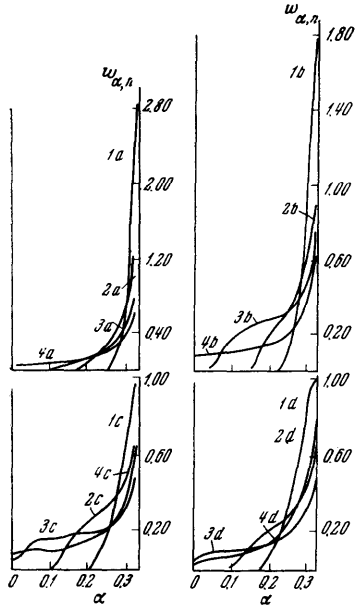

Figure 5. Inhomogeneity of the copolymer fractions with respect to composition.

Fig. 3 shows the ICDC for the acrylamide–maleic acid copolymers. The number of fractions analysed for each specimen was not less than 38.[26] Here sufficiently effective fractionation was attained partially also because the conformational and thermodynamic stability of the macromolecules in solution depends significantly on the concentration of the inorganic acid groups in the macromolecule (we emphasise that a polyelectrolyte system was fractionated). In this connection it is of interest to estimate the effectiveness of fractionation with respect to composition as a function of the ionic strength of the solution, but the amount of experimental data of this kind is much too small for final conclusions.

It has already been stated that the copolymerisation of "unusual" systems can be most conveniently analysed with the aid of ICDC or DCDC. We shall consider in somewhat greater detail concrete "anomalous" systems. When the relative reactivity is influenced by the nature of one, two, and three terminal units of the growing chain, it is necessary to introduce respectively two, four, and eight probabilities of the addition of units A and B. It has been shown[63] that the study of the average composition of copolymers does not show unambiguously whether the penultimate units have an effect or not. At the same time, as already mentioned by Vyrskii and Izyunikov[48], it has been shown that ICDC and DCDC are fairly sensitive characteristics which can be used to decide which model (terminal or preterminal) is to be preferred.

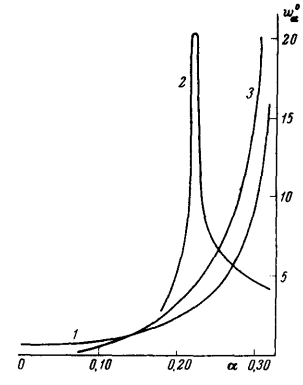

Figure 6. Differential distribution curves with respect to composition for the initial copolymer: specified curve (curve *1*) and curve plotted on the basis of branched (curve *2*) and cross (curve *3*) fractionation.

Fig. 7 presents the ICDC for the copolymer of acrylamide and maleic acid and the total inconsistency between the experimental and theoretical ICDC, going far beyond the possible experimental errors, is evidence that the Mayo–Lewis equation does not apply to this system[64].

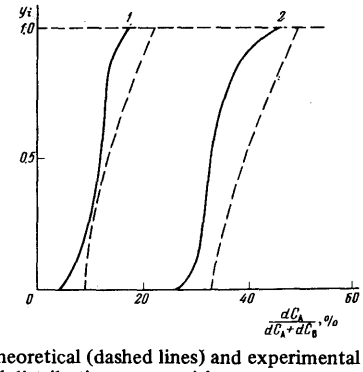

Figure 7. Theoretical (dashed lines) and experimental (continuous lines) integral distribution curves with respect to composition. Substrate composition for the acrylamide–maleic acid system: *1*) 4:1, $\Psi_A = 0.56$; *2*) 2:3, $\Psi_A = 0.04$; Ψ_A = conversion with respect to acrylamide.

This can be explained by the non-isoionic nature of the copolymerisation process, since the ionic strength is different for different substrate compositions and furthermore the effective dissociation constant of maleic acid can vary in the copolymerisation process[65-67]. To illustrate the effect of the ionic strength of the solution on the nature of the ICDC Figs. 8 and 9 present the curves for the system at different pH and concentrations of co-monomers. These

data confirm the conclusion that the effective dissociation constant of maleic acid influences the relative reactivity in its addition to the macroradical with a terminal acrylamide unit. As in the studies of a number of investigators[26,48,64], when an "anomaly" appears in a copolymerising system, a relative increase in inhomogeneity of composition compared with "classical" systems is to be expected. Considerable spreading of the ICDC and DCDC may be expected also when account is taken of instantaneous inhomogeneity of composition whose contribution to the total inhomogeneity should increase as the molecular weight of the copolymers falls[53]. In principle, instantaneous inhomogeneity of composition may be estimated by analysing the ICDC for fixed values of [a]/[b] and Ψ by varying n (in the simplest case by varying the concentration of the initiator in the copolymerising system), but an approach of this kind requires a degree of precision in the plotting of the ICDC higher than can be attained at the present time.

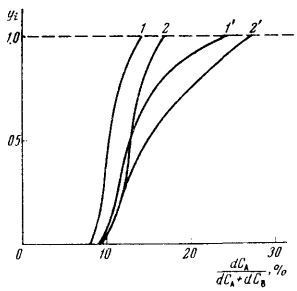

Figure 8. Integral distribution curves with respect to composition in the presence and absence of added phosphoric acid[26]. Substrate composition for the acrylamide–maleic acid system: *1*) 7:3, $\Psi = 0.60$; *1'*) 7:3, $\Psi = 0.56$; *2*) 1:1, $\Psi = 0.50$; *2'*) 1:1, $\Psi = 0.39$; curves *1* and *2* were obtained with added phosphoric acid at pH 1.4 and curves *1'* and *2'* were obtained without added phosphoric acid [*1'*) pH 1.64; *2'*) pH 1.50].

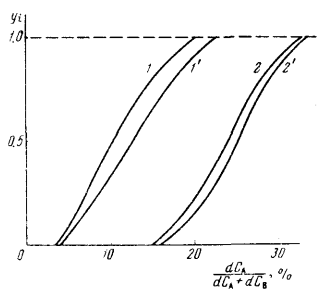

Figure 9. Integral distribution curves with respect to composition for 5% solutions at pH 1.58 (curves *1* and *1'*) and 10% solutions at pH 1.42 (curves *2* and *2'*)[26]; Composition of substrate-acrylamide: maleic acid = 65:35; polarographic data: *1*) $\Psi = 0.60$; *2*) $\Psi = 0.33$; fractionation data: *1'*) $\Psi = 0.71$; *2'*) $\Psi = 0.71$.

The instantaneous inhomogeneity can also be estimated from the analysis of the structure of the macromolecules obtained by the "dose" method[68–71].

IV. ANALYSIS OF THE CHEMICAL STRUCTURE OF COPOLYMERS

Using the principle of reversibility[2], it can be shown that the necessary information about the process can be obtained not only from a comparison of the copolymerisation parameters but also from the analysis of the "formed" macromolecules. The scope of the study of the chemical structure of copolymers is analysed in Kantov's review[72]. We are interested in problems concerning the relation between instantaneous inhomogeneity of composition and the chemical structure of the macromolecule. The chemical structure may be regarded as known if the probabilities of different sequences of monomeric units A and B have been determined, without taking into account the differences in the stereochemical configurations within the sequences. According to the literature[73,74],

$$w_{AA} = \frac{r_A [a]}{r_A [a] + [b]} \text{ and } w_{BB} = \frac{r_B [b]}{r_B [b] + [a]},$$

whence the probability of the formation of blocks of n units of monomer A is

$$P_A(n) = w_{AA}^{n-1}(1 - w_{AA})$$

and the fraction of the units A in blocks consisting of n units is

$$F_A(n) = \frac{nP_1(n)}{\sum_{n=1}^{\infty} nP_1(n)} = \frac{nw_{AA}^{(n-1)}}{\sum_{n=1}^{\infty} nw_{AA}^{(n-1)}}. \quad (17)$$

After simple transformation, we have

$$F_A(n) = n(1 - w_{AA})^2 w_{AA}^{(n-1)}. \quad (18)$$

Similarly,

$$F_B(n) = n(1 - w_{BB})^2 w_{BB}^{(n-1)}, \quad (19)$$

and from the normalisation condition we obtain

$$\sum_{n=1}^{\infty} F_A(n) = \sum_{n=1}^{\infty} F_B(n) = 1.$$

By estimating the probabilities of the formation of different triads, it can be shown that

$$\left.\begin{aligned} &F_{AAA} = w_{AA}^2;\ F_{BBB} = w_{BB}^2;\ F_{AAB} + F_{BAB} = 2w_{AA}(1 - w_{AA}),\\ &F_{BBA} + F_{AAB} = 2w_{BB}(1 - w_{BB});\ F_{ABA} = (1 - w_{BB})^2,\\ &F_{BAB} = (1 - w_{AA})^2;\ F_{AAA} + F_{BAA} + F_{AAB} + F_{BAB} = 1. \end{aligned}\right\} \quad (20)$$

Similarly it is possible to calculate the probability of more complex combinations of units A and B.

In order to obtain direct information about the chemical structure of the macromolecules of the copolymers, it is possible to use a number of spectroscopic or radiospectroscopic (nuclear magnetic resonance) techniques and also chemical methods—see the reviews in the literature[75–77]. However, the application of even the best of these methods, for example nuclear magnetic resonance, does not as yet ensure the necessary accuracy for reliable estimates of instantaneous and conversion inhomogeneity of composition[78–80].

There are fundamental reasons why methods such as X-ray diffraction structure analysis, differential thermal analysis[81], and electrical and mechanical methods for the investigation of polymers in the solid state[82] are unsuitable for the determination of inhomogeneity of composition. The point is that these methods are "sensitive" to the behaviour of relatively large sections of the chains; therefore they can, for example, distinguish block or graft copolymers from random copolymers (if the blocks or

branches are sufficiently large), but, as regards random polymers, they can "detect" to some degree only the *average* composition.

This applies equally to optical methods, which can determine any one characteristic—for example optical density[83], refractive index, etc.

The situation changes significantly, however, if measurements of this kind can be combined with the second ("fractionating" [2]) parameter and (or) one of the components of the copolymers is "masked". The "masking" principle was first applied in the light scattering method. The principal theoretical postulates and the available experimental results obtained by this method are described in the reviews of Benoit[84] and Eskin[85].

It has been shown[86-88] that the molecular weight of the copolymer M_{app} obtained by the usual extrapolations is a function of the true weight-average molecular weight $\overline{M}_B$ and the statistical parameters P and Q, which characterise the polydispersity and the inhomogeneity of the copolymeric specimens with respect to composition:

$$M_{app} = \overline{M}_B + \frac{(2\nu_A - \nu_B)}{\nu} P + \left(\frac{\nu_A - \nu_B}{\nu}\right)^2 Q. \qquad (21)$$

Here

$$P = \sum_i \sum_j \gamma_{ij} M_{ij} \delta x_{ij} = \frac{1}{2}[(1-\bar{x})(\overline{M}_B - \overline{M}_B^A) - \bar{x}(\overline{M}_B - \overline{M}_B^B)], \qquad (22)$$

$$Q = \sum_i \sum_j \gamma_{ij} M_{ij} \delta x_{ij}^2 = \bar{x}(1-\bar{x})(\overline{M}_B^A + \overline{M}_B^B - \overline{M}_B), \qquad (23)$$

where γ_{ij} is the relative fraction of macromolecules with $\delta x_{ij} = x_{ij} - \bar{x}$, $\overline{M}_B^A$ and $\overline{M}_B^B$ are the true weight-average molecular weights of the hypothetical sequences or blocks (in block copolymers) of components A and B the refractive increments for which are respectively ν_A and ν_B, and $\bar{x}$ is the weight-average content of component A in the copolymer.

The summation in Eqns. (22) and (23) is carried out with respect to two parameters, taking into account the fact that in the general case differences in composition are assumed within *ensembles* of macromolecules with the same molecular weight and differences in molecular weight within macromolecules with the same chemical composition. It can be shown that

$$-\bar{x}\overline{M}_B \leqslant P \leqslant (1-\bar{x})\overline{M}_B,$$
$$0 \leqslant Q \leqslant [1-\bar{x}(1-\bar{x})]\overline{M}_B.$$

Of course, P and Q have maximum values for a mixture of homopolymers. The parameter P characterises the change in the composition of the copolymeric system with the molecular weight and Q characterises the dispersion of the specimen with respect to composition and depends on the molecular weight distribution within the specimen.

Theoretical relations (21)–(23) have been tested[89-95] on a series of model systems (statistical, block copolymers, graft copolymers, mixtures of homopolymers) and it has been established that the $\overline{M}_B$, $\overline{M}_B^A$, and $\overline{M}_B^B$ data obtained by light scattering measurements are quite reliable and theoretically justified. Fairly convincing data are obtained for block copolymers by the light scattering method and from determinations based on root mean square radii of inertia of the macromolecule and components A and B.[96] At the same time details and even merely true information about the inhomogeneity of copolymers with respect to composition cannot, be obtained, in principle, for all copolymeric systems and the reliability of such data is in many cases low.

There are several reasons for this: (1) the light scattering method yields reliable results for systems with $\overline{M}_B > 10^4$; (2) in order to obtain P and Q data, it is necessary to have at least three solvents with significantly differing (by not less than 0.05) refractive indices; the solvents must all dissolve the homopolymeric components; this essential condition significantly complicates the analysis of copolymers and makes it almost impossible to obtain (by the light scattering method) data on inhomogeneity of composition in systems where one of the components is hydrophobic and the other hydrophilic; (3) the difference in the refractive indices of the homopolymeric components must be more than 0.05; (4) the parameters P and Q depend on the molecular weight distribution within the specimens and therefore are not unambiguous characteristic of the inhomogeneity; (5) the P and Q data can be obtained only for copolymers of definite composition ([A]/[B] < 10 when [A] > [B] and [A]/[B] > 0.1 when [A] < [B]); (6) the accuracy of the determination of P and Q is inadequate for many systems and this is mainly responsible for the anomalously high value of Q in certain systems. Thus, according to the data of Baranovskaya et al.[97] for statistical styrene–methyl methacrylate copolymers ($r_A = 0.46$ and $r_B = 0.52$), we have $Q/Q_{max} \simeq 0.4$ for [a]/[b] $\simeq \frac{1}{3}\Psi = 0.7$, which is more than ten times greater than the values of Q/Q_{max} calculated by Skeist's method. It was assumed that $Q_{max} = [1 - X(1-X)]\overline{M}_B$, i.e. the extremal value characteristic of a mixture of homopolymers. Such marked inconsistency between the calculated and experimental values of Q/Q_{max} cannot be attributed to instantaneous inhomogeneity of composition, since the system investigated by the authors had a fairly high molecular weight. In somewhat later studies for a similar copolymeric styrene–butyl methacrylate system Eskin et al.[98] obtained $Q/Q_{max} \simeq 0.1$, which is also higher than the calculated values of Q/Q_{max} but in this case the calculated and experimental quantities are of the same order of magnitude. The application of the light scattering method in the analysis of azeotropic styrene–methyl methacrylate copolymers[99] showed that the sensitivity of the method is insufficient to assess the conversion inhomogeneity of composition when the inhomogeneity is low. The authors' conclusion concerning the "anomaly" of one of the ten specimens were not confirmed by data derived by other methods.

In the authors' view the data on inhomogeneity of composition obtained by studying light scattering in copolymer solutions in different solvents must be compared with data obtained by direct estimates of the inhomogeneity; in particular, such combined estimates are essential in the study of statistical copolymers.

We have already emphasised that in this case $\overline{M}_w^A$ and $\overline{M}_w^B$ are *fictitious* quantities which correspond to *hypothetical* sequences of A and B units in each molecule of the *ensemble* investigated. However, even the *optical* properties of this "equivalent" copolymer can differ from those of the statistical copolymer; the interaction of adjacent units of different types may influence the refractive index increments, the average root mean square fluctuation of the refractive index may alter, etc.

It is far from being our desire to "invalidate" the light-scattering method as applied to the analysis of inhomogeneity of composition; we merely wish to stress that, apart from the purely experimental difficulties enumerated above, the method also has certain fundamental limitations, which have not yet been overcome for statistical copolymers.

The scope of the method of sedimentation in a density gradient for the estimate of inhomogeneity of composition is discussed in the review of Hermans and Ende[100]. Un-

fortunately the authors do not consider the problem of the effect of selective solvation on the spreading and displacement of the constant-density curve[2], although this is one of the urgent problems in the study of copolymeric systems[2,4]. Using the sedimentation data, Hermans and Ende[101] made an approximate estimate of inhomogeneity of molecular weight and composition. They chose for investigation the statistical copolymer of styrene and iodostyrene. The weight content of iodine in the fractions varied from 20 to 27% (the average content of iodine in the specimen was 24.15%), i.e. the specimens investigated showed appreciable inhomogeneity of composition. A significant difference in the apparent densities of the homopolymeric components favoured an effective estimate of inhomogeneity of composition. Equilibrium sedimentation in a density gradient was studied at 12°C, i.e. virtually at the θ-point[4]; as a precaution, the concentration effect was excluded by extrapolation to $C = 0$. It was shown that the method employed makes it possible to estimate the width of the distribution with respect to composition with an accuracy of about 20%.

It is noteworthy that one of the most difficult problems in the study of the sedimentation equilibria of copolymers is the separation of the effective broadening of the constant-density line due to inhomogeneity of composition and of molecular weight.

In Baldwin and Schooter's method[102] account is taken of the different inertia in the rearrangement of the constant-density lines in a variable acceleration field for macromolecules with different chemical compositions and different molecular weights. It should be borne in mind that in all cases of analysis of sedimentation data it is extremely difficult to convert them into functions which give a quantitative description of inhomogeneity of composition. As a rule, it is necessary to resort to not altogether justifiable assumptions and much preliminary information about the system is required[2]. Furthermore, sedimentation analysis itself cannot be applied to all systems—it is essential to have adequate differences between the densities and refractive indices of the dissolved species and solvent molecules.

We believe that significant progress may be expected in the study of equilibrium sedimentation for two types of system.

1. A system which is almost homogeneous with respect to molecular weight but is significantly polydisperse with respect to composition. This case is realised most simply by controlled polymerisation-like reactions involving the functional groups of the macromolecules[71,103,104]. With increase of the differences in the densities of the homopolymeric components, analysis of inhomogeneity of composition is facilitated.

2. A system which is almost homogeneous with respect to composition (for example in the case where $r_A = r_B = 0$ strict alternation of A and B units may be expected in the macromolecules regardless of the composition of the substrate when $n \gg 1$), but the fractions differ in their molecular weight. Then the usual[2] quantitative estimate of polydispersity with respect to molecular weight is possible for copolymeric systems where the macromolecules are almost homogeneous with respect to chemical composition.

A combination of the "masking" and high-speed sedimentation methods, which permits in principle the determination of the ICDC and DCDC, shows promise for the description of inhomogeneity of composition. Additional possibilities in the estimation of polydispersity with respect to composition and with respect to molecular weight may be expected when sedimentation and polarographic analyses are combined[106]. In this case it is possible in principle to derive information about the ICDC and the molecular weight distribution in the copolymerising system for different values of ψ.

Klenin et al.[107] showed that in certain specific cases the inhomogeneity of copolymers with respect to composition can be estimated with the aid of a polarisation diffusiometer. The scope of the method has been illustrated using as an example styrene–methyl methacrylate graft copolymers. The authors note that the method is applicable to systems where the variation of the molecular weight of the fractions is related to the variation of their chemical composition. It may be noted that the estimation of inhomogeneity of composition in statistical copolymers with a large set of fractions having different compositions (in particular in the estimation of conversion inhomogeneity) involves enormous difficulties and is scarcely suitable for determinations with a polarisation diffusiometer.

V. QUANTITATIVE ESTIMATION OF THE INHOMOGENEITY OF COPOLYMERS WITH RESPECT TO COMPOSITION

The ICDC and DCDC are the most complete characteristics of the inhomogeneity of copolymers with respect to composition[2,3] and in certain cases it is possible to obtain information about the characteristic features of the copolymerisation reaction from ICDC and DCDC data; in the first place this applies to "anomalous" systems. While noting the great promise of the method involving the comparison of the ICDC, the specific difficulties in the quantitative estimates of inhomogeneity of composition from ICDC data, which are caused in the first place by the different shapes of the curves, must be emphasised. Therefore it is quite justifiable to employ for the quantitative estimate of inhomogeneity of composition, statistical characteristics which represent the ratios of various moments of the distribution with respect to composition[108]. These characteristics are similar to parameters of the Schulz type[109], which are used to describe polydispersity with respect to molecular weight.

Let us consider again a two-component (A and B) copolymeric system; there are no residual monomers. The molecular weight distribution within the specimen may be of any kind, but, in order to exclude random fluctuations with respect to composition, it is assumed that oligomer molecules are absent from the specimen. Let the specimen contain "K" fractions differing in composition and let each fraction consist of macromolecules of the same composition. If $x_1, x_2, x_3, \ldots, x_i, \ldots, x_k$ are the weight contents of component A in the fractions and $\omega_1, \omega_2, \omega_3, \ldots, \omega_i, \ldots, \omega_k$ are the weight concentrations of the fractions in the specimen ($\sum_{i=1}^{k} \omega_i = 1$), then it is possible to calculate the parameters characterising the average composition of the specimen (it is assumed that ω_i and x_i are known for all the fractions). In the general case, by analogy with q, the average molecular weights[2], it is possible to introduce, on the basis of the weight average, a "P-average" composition defined as the ratio of the distribution moments with respect to composition of orders P and $P - l$:

$$x_p = \frac{\bar{x}_p}{\bar{x}_{p-1}} = \frac{\int_0^1 x^p \omega(x)\,dx}{\int_0^1 x^{p-1}\omega(x)\,dx} \cong \frac{\sum_{i=1}^{k} x_i^p \omega_i(x)}{\sum_{i=1}^{k} x_i^{p-1}\omega_i(x)} \qquad (24)$$

and

$$\int_0^1 \omega(x)\,dx = \sum \omega_i = 1 \ .$$

Parameters of the form $f = x_p/x_q - 1$ ($f > 0$ when $P > q$), for example,

$$f_1 = \sum_{i=1}^{k} \omega_i x_i \sum_{i=1}^{k} \frac{\omega_i}{x_i} - 1 \ , \tag{25}$$

$$f_2 = \frac{\sum_{i=1}^{k} \omega_i x_i^2 \sum_{i=1}^{k} \frac{\omega_i}{x_i}}{\sum_{i=1}^{k} \omega_i x_i} - 1 \ , \tag{26}$$

etc, characterise quantitatively the inhomogeneity of composition but the use of the parameter f and its analogues for the estimation of the inhomogeneity is not possible in all cases. In the first place this is because the values of f_1, f_2, and f_3 depend significantly on $\bar{x}_p$ and furthermore the condition $f(A) = f(B)$ or $f(x) = f(1 - x)$ must hold, i.e. the parameter of inhomogeneity of composition should not depend on the nature of the components of the copolymeric system. It is reasonable to assume that the inhomogeneity is determined solely by the shape and width of the ICDC and DCDC and is independent of x_p, i.e. in the general case the following condition should hold:

$$f(x_1, x_2, x_3, \ldots x_i, \ldots x_k) = f(x_1 + x_0, x_2 + x_0, x_3 + x_0, \ldots x_i + x_0, \ldots x_k + x_0), \tag{27}$$

where $x_0 = \text{const}$.

Furthermore the required function of inhomogeneity of composition must have finite values also when $x = 0$ and $x = 1$, which is not the case for f_1 and f_2. Kantov's parameters[72] do not satisfy completely the requirements formulated [in particular the requirement defined by Eqn. (27)]. In terms of the present notation, this parameter is

$$f_3(A) = \frac{\sum_{i=1}^{k} P_i^{(+)}(A)\,\Delta\alpha_i^{(+)}\cdot(A)}{\sum_{i=1}^{k} P_i^{(+)}(A)} + \frac{\sum_{i=1}^{k} P_i^{(-)}(A)\,\Delta\alpha_i^{(-)}(A)}{\sum_{i=1}^{k} P_i^{(-)}(A)} = U^{(+)}(A) + U^{(-)}(A), \tag{28}$$

$$f_4(A) = \frac{U^{(+)}(A)}{U^{(-)}(A)} \ .$$

Here $P_i^{(+)}(A)$ is the weight content of the fractions in the specimen with $\alpha_i(A) = \bar{\alpha}_B(A) + \Delta\alpha_i(A)$ and $\bar{\alpha}_B < \alpha_i(A)$ $P_i^{(-)}$ —the weight content of the fractions in the specimen with $\Delta\alpha_i(A) = \bar{\alpha}_B(A) - \alpha_i(A) > 0$. It can be shown that the above requirements are satisfied by the parameter

$$f_5 = (\bar{x}_z - \bar{x}_B)\,x_B \tag{29}$$

where

$$\bar{x}_z = \frac{\sum_{i=1}^{k} \omega_i x_i^2}{\sum_{i=1}^{k} \omega_i x_i} \quad \text{and} \quad \bar{x}_B = \sum_{i=1}^{k} \omega_i x_i \ .$$

To illustrate the scope of the analysis of inhomogeneity of composition on the basis of ICDC and DCDC, we shall employ experimental data obtained for the system acrylamide (Aa)–maleic acid (Ma) by polarographic analysis[26]. Since maleic acid is incapable of homopolymerisation, $r_B = 0$ for this system. Analogous conclusions can be arrived at when other reasonable values of r_B in the range $0 < r_B \leq 0.05$ are used instead of $r_B = 0$. To calculate f_5, the ICDC were divided into 20–30 sections and the composition and weight fraction of each polymer fraction was calculated for each section.

To compare the relative extents of inhomogeneity of composition, it is most convenient to employ the parameter

$$y = \frac{f_5'}{f_5''} - 1 \tag{30}$$

where f_5' and f_5'' are the experimental and theoretical values of f_5 calculated for the same substrate composition.

Fig. 10 presents data on the variation of y with substrate composition. Analogous results are obtained also when other fixed values of r_A and r_B are used. Fig. 10 shows that $y > 0$ for all γ, which is evidence of the "anomalous" nature of the copolymerisation in the acrylamide–maleic acid system (for an "ideal" system $y \simeq 0$).

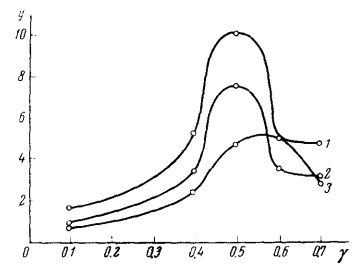

Figure 10. Variation of y with γ (γ is the weight content of maleic acid in the substrate) for certain values of r_A and r_B: *1*) $r_A = 2.2, r_B = 0$; *2*) $r_A = 1.0$, $r_B = 0$; *3*) $r_A = 3.0, r_B = 0$.

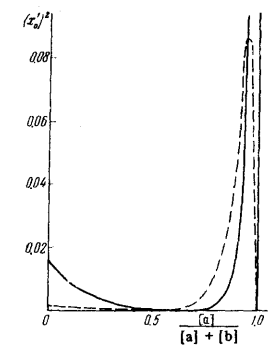

Figure 11. Variation of $(x_0')^2$ with α_A for "terminal" (dashed curve) and "preterminal" (continuous curve) models of the styrene–fumaronitrile system for $\alpha_A = 0.99$ and $(x_0')^2 = 3.7$; $(x_0')^2$ = variance with respect to composition.

This is in fact understandable—the copolymerisation of the acrylamide–maleic acid system is non-isoionic and cannot be described with the aid of fixed values of r_A and r_B, since the reactivities of the co-monomers vary during the copolymerisation process and depend on substrate composition.

In the study already quoted[48] the variance of the distribution with respect to composition σ^2 (for the number average) for the "terminal" and "preterminal" model systems (ψ small) was calculated. Fig. 11 presents the

variation (determined by Izyumnikov and Vyrskii) of $(\varkappa_0')^2 = 12\sigma^2\psi^2$ for various substrate compositions. The data show that the quantitative estimate of inhomogeneity of composition may help determine which model ("terminal" or "preterminal") gives the best description of the real copolymerisation process. We may recall that this cannot be done on the basis of data on the average composition[63].

There is no doubt about the existence of an unambiguous relation between inhomogeneity of composition and the inhomogeneity of the distribution of sequences within the copolymer macromolecule, but so far these relations have not been obtained in an analytical form. Nevertheless the study of the distribution of sequences within the macromolecule can already yield some information about the inhomogeneity of the composition of the copolymeric specimen[72]. It can be shown that the number-average $[\bar{n}(A)]$ and weight-average $[\bar{n}_B(A)]$ lengths of the real sequences of A units are related to the copolymerisation constant r_A:

$$\bar{n}(A) = 1 + r_A\frac{[A]}{[B]}, \qquad (31)$$

$$\bar{n}_B(A) = 1 + 2r_A\frac{[A]}{[B]}. \qquad (32)$$

To characterise the differential inhomogeneity of the sequences, it is convenient to introduce the parameter

$$\lambda(A) = \frac{\bar{n}_B(A)}{\bar{n}(A)} - 1 = \frac{r_A[A]}{r_A[A] + [B]}. \qquad (33)$$

After integration of the function $\lambda(A)$ over all ψ, it is possible to obtain the integral inhomogeneity of composition. It should be noted that, in view of the inadequate sensitivity of the experimental methods, the experimental value of $\lambda(A)$ cannot be compared with the theoretical value [based on Eqn. (33)].

Thus by estimating the inhomogeneity with respect to composition in the system with the aid of parameters of the type of y, it is possible to obtain definite information also about the copolymerisation process itself: namely, the greater is the deviation of y from zero the more anomalous is the system. Having established this fact, it is now possible to seek the reasons for this anomaly in accordance with the principle of "preliminary" analysis described by Frenkel'[2].

---o0o---

In the extensive scientific literature on the problems of copolymerisation, there are very few papers on the analysis of the polydispersity of copolymers with respect to composition despite the fact that it is precisely by plotting the ICDC or on the basis of quantitative estimates of inhomogeneity of composition that one can arrive at direct conclusions concerning the characteristic features of the copolymerisation process itself. At the same time the widely employed data on the average composition of copolymers (for fixed values of ψ) as a rule do not allow the correct interpretation of the copolymerisation mechanism. For the assessment of the "anomalous" systems, ICDC and DCDC are just as necessary as information about the molecular weight distribution of the polymers in the analysis of the mechanism and in the estimation of the kinetic parameters of homopolymerisation[2]. In this connection it is now essential to develop studies where the section "discussion of the results" in the relevant paper involves the comparison of the experimental and theoretical ICDC for concrete copolymerisation mechanisms; at the same time studies on the quantitative estimation of inhomogeneity of composition for various substrate compositions are bound to be of interest. Experimental investigations dealing with the estimation of the contribution of instantaneous inhomogeneity of composition to the overall inhomogeneity are likewise necessary. At the present time maximum caution must be exercised in the classification of concrete copolymerising systems as "classical" or "anomalous". For example, the attempts to apply the Mayo–Lewis equations to describe "unusual" systems is known to be incorrect on *a priori* grounds.

Completely new and interesting evidence has been obtained in studies[110,111] on the copolymerisation of acrylic acid with maleic and fumaric anhydrides. According to the authors of these investigations, in order to describe the copolymerisation process, it is necessary to derive a reaction mechanism taking into account the formation of active complexes and the copolymerisation reaction itself may be classified as "unusual" ("anomalous").

The likelihood of the erroneous interpretation of the characteristic features of copolymerisation is greatly reduced if, instead of data on the average composition of copolymers, ICDC and DCDC are employed. In this sense the problem which we attempted to describe is quite similar to the *combined* kinetic and statistical analysis of homopolymerisation mechanisms[2].

The Dependence of the Mechanism of the Hydrolysis, Trans-esterification, and Trans-etherification of α,β-Alkenyl Ethers and Esters on Their Structure

A.F.Rekasheva

New experimental data obtained in the study of the mechanism of the hydrolysis of ethers and esters formed by enols and the related trans-esterification and trans-etherification of these compounds are collected in the present review.
Recent studies have confirmed the early views that the hydrolysis of the ethers formed by enols passes through a stage involving hydration of the ethylene bond, have made it possible to describe this reaction scheme in considerable detail, and have shown that an analogous mechanism can be extended to the hydrolysis of the esters formed by enols, in the discussion of which, until recently, schemes involving nucleophilic substitution at the carbonyl group were used.
The large amount of data on the alkaline hydrolysis of enol acylates indicates that the mechanism of this reaction is similar to, but not identical with that of the alkaline hydrolysis of alkyl esters.

1. INTRODUCTION

Modern theories of equilibrium and the kinetics of chemical reactions are based on the classical studies of Menshutkin, carried out in the eighteen-hundreds. The object of these studies was the formation and hydrolysis of esters. Fifty years later, Polanyi and Szabo, using ^{18}O, determined the point of fission of the bonds in the hydrolysis of esters of carboxylic acids. This work became a classical example of the use of tracers to investigate reaction mechanisms. Since that time, a large number of workers, including a number of outstanding chemists of the present time, have taken part in the study of the details of the mechanism of esterification and etherification and the hydrolysis of ethers and esters. It is therefore not surprising that the hydrolysis, trans-esterification, and formation of esters are among the processes which have been studied most fully and in greatest detail, in both preparative and theoretical aspects.

The foregoing is only partly true of ethers and esters with characteristic structure in which the ether oxygen atom is next to an ethylenic bond. These are the $\alpha\beta$-alkenyl ethers and esters, which are often also called enol ethers and enol acylates or carboxylates. Studies of the chemistry of this group of ethers and esters have been chiefly of a practical nature, and the mechanism of their transformations has been little studied. Until recently, there was very little published information on the kinetics of the hydrolysis of vinyl ethers and esters, and no direct data on the point of fission of the bonds. In the discussion of the mechanism of the hydrolysis of these compounds, the authors restricted themselves to the analogy with the well-studied processes involving the corresponding alkyl ethers and esters[1-3].

Interest in the mechanism of the transformation of $\alpha\beta$-alkenyl ethers and esters began to increase in the late nineteen-fifties, when the intensive development of the theory of polymerisation brought to the forefront the problem of the dependence of the reactivity of monomers on their structure. The study of the mechanism of hydrolysis of vinyl ethers and esters from this viewpoint has extended in the last ten years to such an extent that the main regular features have now been outlined. It can therefore be regarded an appropriate time to summarise the results. A summary on this basis is also of interest in connection with the theory of the other reactions of these compounds.

The chemical properties of $\alpha\beta$-alkenyl ethers and esters, which have been studied in detail and described in reviews and monographs[1-7], show a similarity in the behaviour of ethers and esters of this type in reactions with acidic reagents, and demonstrate the high reactivity of their ethylenic bond in electrophilic addition, which obeys Markovnikov's rule.

The activation of the double bond can be attributed to conjugation of the π-electrons with the unshared pairs of electrons of the ether oxygen atom:

$$CH_2=CH-\ddot{O}-R\,.$$

According to Wheland's calculations[8], the conjugation energy in methyl vinyl ether is 3.6 kcal mole^{-1}. In accordance with this, the signal of the β-hydrogen atoms of the vinyl group in the proton magnetic resonance (PMR) spectra of enol ethers is displaced towards higher fields compared with the signal of the hydrogen atoms of the ethylene group in simple alkenes[9], and the frequency of the out-of-plane bending vibrations of the $=CH_2$ group† in the infrared spectrum of enol ethers is lower than that for alkenes[10].

In enol acylates, the conjugation of the vinyl group with the ether oxygen should be weakened by the influence of the electron-accepting carbonyl group. The extent to which this decreases the polarisation of the ethylenic bond can be estimated from spectroscopic data (Table 1), which indicate that in alkenyl carboxylates the C=C bond is less extensively polarised than that in methyl vinyl ether, but more extensively polarised than that in propene. Thus conjugation of the ether oxygen with the ethylenic bond still plays an important part.

Table 1. Spectroscopic data characterising the polarisation of the double bond.

Compound	Chemical shift δ of the β-hydrogen atoms in the PMR spectrum	References	Frequencies of the out-of-plane bending vibrations of the CH_2 group in the infrared spectra, cm^{-1} (Ref.10)
Ethylene	5.33	14	—
Propene	4.96	14	912
Methyl vinyl ether	4.05	9	811
Vinyl acetate	4.67	12	870
Isopropenyl acetate	4.62	13	
Vinyl benzoate	4.75	13	870
Methyl vinyl ketone	6.09	14	955

Enol ethers are stable in alkaline media, but are readily hydrolysed in weakly acidic and even neutral aqueous solutions, and this distinguishes them sharply from dialkyl ethers. For example, the rate of the acid hydrolysis of ethyl vinyl ether is greater than that of diethyl ether by a factor of $10^{13.15}$[15] The increase in the rate of hydrolysis of ethers when an ethylene bond is introduced in the α-position relative to the oxygen has been attributed to hydration of the C=C group, preceding the splitting of the bonds in the ether, as shown in the scheme:

$$CH_2=CH-OR+\overset{+}{H_3O}\rightarrow CH_3CH\begin{matrix}OR\\ \diagup\\ \diagdown\\ \underset{+}{OH_2}\end{matrix}\rightarrow ROH+CH_3CH=\overset{+}{O}H\,. \qquad (1)$$

The hydrolysis of αβ-alkenyl acylates, like the hydrolysis of the esters of saturated alcohols, is catalysed by both acids and alkalis. The rates of the acid and alkaline hydrolysis of alkenyl and alkyl acylates differ by not more than two orders of magnitude. The outward similarity in the stoichiometry of the reaction, which for the hydrolysis of vinyl esters can be represented by the equation

$$CH_2=CH-OCOR+H_2O\rightarrow CH_3=CH-OH+RCOOH \qquad (2)$$

† The change in this quantity can give information on the change in the π-charge on the carbon atom[11].

together with their identical catalytic behaviour, suggest that in the hydrolysis of acylates the introduction of the ethylenic group in the α-position to the ester oxygen atom does not alter the reaction mechanism[1-3]. This justifiable assumption probably also explains why almost no experimental studies were made of the mechanism of the hydrolysis of αβ-alkenyl esters until recently.

The molecule of an alkenyl carboxylate, however, contains two reactive centres—the carbonyl group and the vinyl group. The latter, as shown above, is activated by its proximity to the oxygen, so that the hydrolysis of enol acylates can take place in at least two ways: by electrophilic addition to the C=C bond or by nucleophilic addition to the C=O bond. The actual mechanism will depend to a considerable extent on the reaction conditions, in particular the acidity of the medium. In an alkaline medium, in which enol ethers are inactive, primary attack by hydroxide ions at the carboxyl group is most probable. In acidic solutions, attack by protons at the nucleophilic vinyl group becomes equally probable.

αβ-Alkenyl ethers and esters in anhydrous media readily undergo trans-etherification (3) and trans-esterification (4), which in this instance are also described as vinyl exchange:

$$CH_2=CH-OR+XOH\rightleftarrows CH_2=CH-OX+ROH\,, \qquad (3)$$

$$CH_2=CH-OCOR+XOH\rightleftarrows CH_2=CH-OX+RCOOH\,, \qquad (4)$$

where XOH is a compound with a labile hydrogen atom.

Reactions (3) and (4) undergo specific catalysis by the mercury salts of strong acids, whereas in the presence of mineral acids the addition of the reagent XOH takes place chiefly at the ethylenic bond. The mechanism of these reactions will be examined later; here it is important to note the following: (1) catalysis by mercury salts makes it possible to exclude the carbonyl group from consideration as an active centre of the molecule in reaction (4); (2) if the reagent XOH is water, the products of the trans-etherification or trans-esterification are identical with the hydrolysis products, as can be seen from the equation

$$CH_2=CH-OR+HOH\rightarrow ROH+CH_2=CH-OH\rightarrow CH_3CHO \qquad (5)$$

and (3) catalysts for vinyl exchange have also been found to be active in the hydrolysis of vinyl ethers and esters[16-18].

All this leads to the conclusion that in acid hydrolysis and possibly in aqueous hydrolysis the analogy between enol ethers and esters is as valid as that between the esters of enols and the esters of saturated alcohols.

The results of the study of the mechanism of hydrolysis of αβ-alkenyl ethers and esters, given below, have confirmed and refined existing theories of the mechanism of hydrolysis of enol ethers and have shown that existing theories of the mechanism of hydrolysis of enol esters are erroneous.

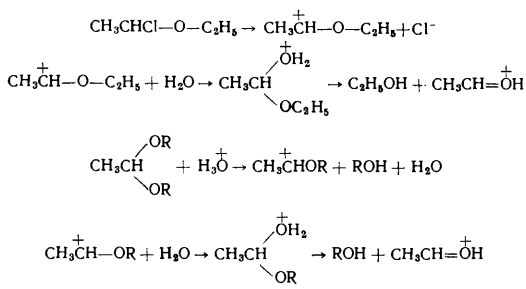
To avoid repetition, we begin with data on the point of fission of the bonds, since this information is necessary in a discussion of any mechanism of hydrolysis of ethers and esters.

2. POINT OF FISSION OF THE BONDS IN HYDROLYSIS

The hydrolysis of ethyl vinyl, n-butyl vinyl, isopropyl vinyl, allyl vinyl, and phenyl vinyl ethers[16], and also 3-ethoxy-2-cyclohexenone[19], in aqueous solutions of sulphuric acid enriched in $H_2{}^{18}O$, gave alcohols which did not contain ^{18}O. "Unlabelled" alcohols were also obtained in the hydrolysis of isopropyl vinyl and α-chlorodiethyl vinyl ethers in neutral solutions, in the hydrolysis of α-chlorodiethyl

ether by sodium carbonate solution[16], and in the acid hydrolysis of acetals[20]. The same result was obtained in the hydrolysis of isopropyl vinyl and n-butyl vinyl ethers, catalysed by mercury sulphate[16]. Thus in the hydrolysis of these alkenyl ethers, bond rupture takes place only between the unsaturated group and oxygen.

On the basis of independent data, the mechanism illustrated by schemes (6) and (7) has been established for the solvolysis of α-halogenoethers[21] and acetals[22]:



(6)

(7)

with the intermediate formation of hemiacetals and their decomposition into carbonyl compounds and alcohols. Data obtained using ^{18}O show that the decomposition of the hemiacetals involves the removal of alkoxy-groups, which during the reaction do not lose their bonds with their oxygen.

Thus the formation of alcohols which do not contain oxygen from the medium, observed in the hydrolysis of vinyl ethers, confirms scheme (1), which assumes the intermediate formation of hemiacetals.

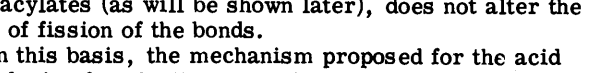
The fact that identical results were obtained regarding the point of fission of the bonds in the hydrolysis of vinyl ethers containing alcohol residues with different structures, such as the ethyl, allyl, and phenyl groups, indicates that the established features are general. This is also indicated by data on the mechanism of the formation of methyl α-naphthyl ether from [^{18}O]methanol and 1-naphthol, catalysed by sulphuric acid, in which the ether contains oxygen only from the methanol[23]. From this it follows that the back reaction in the acid decomposition of this ether should take place with fission of the bond between the unsaturated naphthyl group and oxygen, that is, like the hydrolysis of vinyl ethers.

Study of the acid hydrolysis of enol carboxylates in $H_2{}^{18}O$ showed that in this instance also the reaction involves vinyl–oxygen fission. This was established for the hydrolysis of the following esters: vinyl acetate in acidic and initially neutral media[17,24], vinyl formate, propionate, butyrate, pelargonate, adipate[25], and *p*-methoxybenzoate, isopropenyl acetate and benzoate, α-acetoxystyrene[26], and α-methoxyvinyl benzoate[27]. The same is true of the hydrolysis of vinyl acetate and benzoate[24] and the *p*-methoxy- and *p*-nitro-derivatives of the latter[18] with catalysis by mercury sulphate.

It can be seen from these data that neither the replacement of the alkyl residue by an acyl residue nor the introduction of substituents in the α-position of the vinyl group alters the point of fission of the vinyl group in acid hydrolysis. The point of fission of the bonds is apparently determined primarily by the presence of the ethylenic bond next to the ether oxygen atom.

Fission of the bond between the vinyl group and oxygen in the hydrolysis of enol acylates agrees with the idea that in the presence of electrophilic reagents the active reaction centre is not the carbonyl group but the vinyl group[17,24,27], since solvolytic processes at the carbonyl group are characterised by acyl–oxygen splitting[28,29]. This conclusion is also confirmed by the fact that mercury sulphate—a specific catalyst for electrophilic addition to multiple carbon–carbon bonds—although accelerating the hydrolysis of enol acylates (as will be shown later), does not alter the point of fission of the bonds.

On this basis, the mechanism proposed for the acid hydrolysis of enol esters was the same as that for the hydrolysis of alkenyl ethers[17,24] [see scheme (1)], that is, a mechanism involving hydration of the ethylenic bond [scheme (8)], later confirmed by kinetic data:



(8)

Preliminary addition at the ethylenic bond was also confirmed for the reaction of 1-methoxyvinyl benzoate with $C_6H_5C^{18}O^{18}OH$ without the addition of mineral acid. The ^{18}O is equally distributed between the two reaction products —methyl acetate and benzoic anhydride[30]. Vinyl–oxygen bond fission was also established in the exchange of acetate groups between vinyl acetate and acetic acid in the presence of mercury sulphate[31].

As noted above, enol ethers are stable in the presence of bases, but the ethers of nitrophenols undergo hydrolysis and trans-etherification fairly readily in concentrated alkali solutions. For the example of the alkaline hydrolysis of 2,4-dinitrophenetol, labelled with ^{18}O in the ether group, and the reaction of 2,4-dinitroanisole with $C_2H_5{}^{18}OH$ it was established that during the reaction the alkyl radicals do not lose their bonds with their oxygen atom, that is, only the bond between the aryl group and oxygen is broken[32].

Table 2. Relative* concentration of ^{18}O in the carboxyl group of the acid formed in the alkaline hydrolysis of vinyl esters in the systems: *I*) unlabelled ester + $H_2{}^{18}O$; *II*) ester labelled with ^{18}O in both oxygen atoms + H_2O; *III*) ester labelled with ^{18}O at the oxygen of the C–O–C group + H_2O**.

Vinyl ester	System			Theoretical concentration of ^{18}O for rupture of the bond					
				acyl–oxygen			vinyl–oxygen		
	I	II	III	I	II	III	I	II	III
Acetate	0.32—0.36	0.49—0.50	0.30						
Benzoate	0.39—0.42	0.49	0.34						
Anisate	0.48—0.52	—	0.25	0.50	0.50	0.00	0.00	1.00	1.00
p-Chlorobenzoate	—	—	0.18						
p-Nitrobenzoate	0.45	—	0.28						

* The concentration of ^{18}O in the original labelled compound was taken as unity.

** These esters were prepared by the action of the corresponding acyl chlorides on chloromercuracetaldehyde-^{18}O. It was confirmed for the example of vinyl acetate that the tracer is present only in the ether oxygen atom[35].

In the alkaline hydrolysis of vinyl esters, only part of the ether oxygen appears in the resulting salts of carboxylic acids (Table 2)[17,18,33,34]. At the same time the esters isolated from the reaction mixture after incomplete hydrolysis retain their original isotopic composition. This indicates that isotopic exchange between the ester and the medium does not take place during the reaction, and the results obtained must be attributed to a mixed hydrolysis

mechanism, with fission of the bonds formed by the oxygen atom with both the acyl group and the vinyl group.

The mechanism of the alkaline hydrolysis of enol acylates will be examined in more detail later, in connection with kinetic data. Here we would merely point out that the mechanism of the alkaline hydrolysis of vinyl acetate and vinyl benzoate differs significantly from the mechanism of the alkaline hydrolysis of the ethyl esters of the same acids, since in the hydrolysis of the latter, only acyl–oxygen bond splitting is observed[29].

3. ACIDIC HYDROLYSIS OF ETHERS

After the first systematic studies, which were carried out in Skrabal's laboratory[36–39] with the aim of obtaining quantitative data on the rates of hydrolysis of ethers with the most varied structures, the study of the kinetics of hydrolysis of $\alpha\beta$-alkenyl ethers developed along three directions: (1) investigation of the nature of the catalysis (specific or general acid catalysis); (2) determination of the kinetic isotopic effect of the solvent; and (3) determination of the dependence of the kinetic parameters of the reaction on the structure of the substrate.

With catalysis by mineral acids, the hydrolysis of $\alpha\beta$-alkenyl ethers is described by a first-order equation with rate constants proportional to the concentration of catalyst[40–46]. An exception is the hydrolysis of furan and 2,5-dimethylfuran, for which the kinetic equation contains the acidity function H_0.[47] It should be noted that in the experiments with cyclic ethers the acid concentration amounted to several moles per litre, whereas in the experiments with ethers with linear structure the acid concentration did not exceed 1×10^{-2} N, that is, it was below the limit at which the difference between C_{H^+} and H_0 becomes perceptible. The reaction rate depends to a marked extent on the composition of the solvent, and decreases when dioxan[40] or ethanol[47] are added to the aqueous solutions. The change in the rate of hydrolysis of isopropyl vinyl and n-butyl vinyl ethers with change in the concentration of water in aqueous dioxan solutions from 3 M to 22 M[44] is given by a curve with a minimum in the region of 10 M H_2O, characteristic of changes in H_0 with change in the composition of the medium[48].

The temperature dependence of the rate constants corresponds to the Arrhenius equation[40,43–45]. The activation parameters found from these data are given in Table 3. The values of $\Delta S^{\neq}$ (Table 3) vary from +4 e.u. to −28 e.u., and are linearly related to the activation energy values (only isopropenyl methyl ether does not show this regular feature). This compensation effect is observed if the reaction of the substrate with the solvent makes a significant contribution to the activation parameters of the reaction[49]. With this condition, changes in the value of $\Delta S^{\neq}$ cannot provide a criterion of change in the mechanism of acid catalysis.

The hydrolysis of ethyl vinyl ether[44], isopropenyl methyl ether[43], and 2-ethoxycyclopentene-1-carboxylic acid (ECA)[46] in buffer mixtures with varying concentrations of undissociated acids showed that this concentration appears in the kinetic equation for the reaction, that is, that the hydrolysis of enol ethers undergoes general acid catalysis. The catalytic constants for the proton donors studied are given in Table 4.

The values of k_{HA} given in Table 4 satisfy Brønsted's equation with $\alpha = 0.45$ for ethyl vinyl ether[44] and $\alpha = 0.50$ for isopropenyl methyl ether and isopropyl vinyl ether[43].

General acid catalysis was not observed by Skrabal and coworkers, since they altered the concentration of only one of the components of the buffer mixture, and the increase in the concentration of undissociated acetic acid was proportional to the increase in the H_3O^+ concentration. Recalculation of Skrabal's data[43,44] led to good agreement in the values of $k_{H_3O^+}$ in aqueous solutions, obtained by different authors (Table 4).

* The rate of hydrolysis of ethyl vinyl ether in 80% aqueous dioxan or in aqueous solution was taken as unity. $k_{rel.}$ values in aqueous solution are given in parentheses.

** The rate constant is too high by a factor of at least 100, since no allowance was made for the catalytic action of the undissociated acetic acid[43].

The general acid catalysis in the hydrolysis of enol ethers indicates unambiguously that the rate-determining stage is the transfer of a proton from the catalyst to the substrate[43], in agreement with the marked decrease in reaction rate in D_2O (Table 3).

In this connection it should be noted that re-examination of the theory of the isotopic effect of the solvent, completed in the early nineteen-sixties, showed that neither the value of $k_{H_2O} : k_{D_2O}$ nor the form of the dependence of the reaction rate on the atomic fraction of deuterium in the solvent

can serve, as was previously supposed, as an unambiguous criterion of the mechanism of acid–base catalysis[50–52]. With independent data on the kinetic role of the stage involving proton transfer, however, the results of the determination of the reaction rate in D_2O and its mixtures with H_2O under certain conditions, in particular for $k_{H_3O} : k_{D_2O} \geq 2$, nevertheless give information on the structure of the intermediate complex and the movement of the proton relative to the reaction coordinate[51,53]. The maximal value of the isotopic effect for reactions with slow proton movement from H_3O^+ is equal to 3.6; this value is reached when in the transition state the proton reacts equally strongly with the water molecule which it is leaving and with the nucleophilic centre of the substrate[53]. This structure of the transition state also corresponds to a value of the parameter α equal to 0.5 in Brønsted's equation[54]. This same parameter can be found from the form of the dependence of the reaction rate on the atomic fraction of deuterium in the solvent using the equation[43,44,55]

$$\frac{k_n}{k_H} = \frac{(1 - n + nl^{1+\alpha})^3 \cdot (1 - n + l^{1+2\alpha} n\, k_D : k_H)}{(1 - n + nl)^3} \qquad (9)$$

where n is the atomic fraction of deuterium and l the exchange coefficient of the ion L_3O^+‡, equal to 0.67.[55] The values of the parameter α found in this way for the hydrolysis of ethyl vinyl ether[44] and 2-chloroethyl vinyl ether[43] were 0.6 and 0.5 respectively, in good agreement with the value found from Brønsted's equation.

Table 4. Catalytic constants for various proton donors in aqueous solution at 25°C.

Substrate	H^+ donor	k_{HA}, litre mole^{-1} s^{-1}	Refs.

* Recalculated from Skrabal's data[43].

For proton transfer from formic acid to ethyl vinyl ether, $k_{HCOOH} : k_{HCOOD} = 6.8$, compared with 2.95 for catalysis by hydroxonium ions[44]. For the hydrolysis of ECA, the isotopic effect increases from 2.9 for catalysis by H_3O^+ to 8.0 for catalysis by the protons of the carboxyl group of the substrate itself[46]. The explanation of these facts according to modern theories is that the observed influence of the replacement of H by D in solution is made up of two isotopic effects operating in opposite directions: a primary effect leading to a decrease in the reaction rate in D_2O, and a secondary effect leading to an increase in the rate of the process. The secondary isotopic effect is absent if the proton donor contains only one labile H atom[53,56,57].

‡ Where L represents either H or D (Ed. of Translation).

The general acid catalysis in the hydrolysis of enol ethers provides evidence against primary attack by H^+ on the oxygen atom, since this is characterised by rapid attainment of prototropic equilibrium and specific catalysis. Examples of reactions of this type are provided by the hydrolysis of acetals[58] and the alkyl esters of carboxylic acids[29].

Further confirmation of primary attack by the protons on the unsaturated group is provided by the structural dependence of the reactivity of enol ethers in acid hydrolysis. The available kinetic data (Table 3) show that electron-donating substituents attached to the oxygen atom increase the reaction rate (ethers 1–9 in Table 3), whereas the same substituents attached to the β-carbon atom of the vinyl group decrease the reaction rate (ethers 15–18 in Table 3). In both instances, the changes in the hydrolysis rate constants with change in the structure of the substrate are described by the Hammett–Taft equation in the form[42] $\lg(k/k_0) = \sigma^*\rho^*$. An equation of this form indicates that the influence of polar factors predominates. For substituents attached to the oxygen atom, $\rho^* = -2.8$, and for substituents attached to the β-carbon atom of the vinyl group, $\rho^* = +1.5$.

The above data cannot be explained if primary attack by the protons on the oxygen atom is assumed, since in this instance the direction of the influence of the substituents would be independent of their position in the molecule. The influence of substituents indicates that, among the factors determining the reactivity of enol ethers in electrophilic media, the most important part is played by the conjugation of the p-electrons of the oxygen atom with the π-electrons of the double bond. Electron-donating substituents attached to oxygen facilitate this conjugation and increase the reaction rate, but in the β-position of the vinyl group they hinder conjugation and decrease the rate of hydrolysis

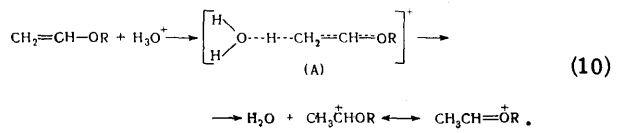
The decrease in the rate of hydrolysis of divinyl ether relative to that of ethyl vinyl ether, which surprised Skrabal, becomes understandable from this viewpoint. Each vinyl group of divinyl ether acts as an electron-accepting substituent relative to the other and weakens its conjugation with oxygen. Comparison of the hydrolysis rate constants for ethyl vinyl ether and divinyl ether, and also for ethyl vinyl ether and vinyl formate, shows that the retarding action of the vinyl group is stronger than that of the carbonyl group, the reaction rate being decreased by a factor of 240 in the first instance and only 80 in the second. Allyl and benzyl groups also show a retarding action, but this is much weaker than that of the vinyl group. The reaction of vinyl ethyl ether is about ten times more rapid than that of 2-chloroethyl ether, but 700 times more rapid than that of β-chlorovinyl ethyl ether. In the first instance the inductive effect of chlorine on the ethylenic bond is shown, whereas in the second instance the effect of conjugation of the free pairs of electrons of the chlorine with the π-electronic system becomes more marked. The chlorine acts as electron donor and hinders the conjugation of the electrons of the oxygen with the double bond.

Not only kinetic data, but also other physicochemical data indicate that electrophilic reagents attack the double bond, and not oxygen. Thus the results of a study of the dielectric constants of solutions of tin(IV) chloride in inert solvents indicate the formation of complexes of two different types on the addition of furan, 2-methylfuran, and thiophen, or the saturated analogues of these compounds[59]. In the first instance, complexes involving the C=C group are

formed, whereas in the second instance complexes involving the oxygen or sulphur atoms are formed. This conclusion was confirmed by spectroscopic data[60] for the example of the complexes of thiophen with tin(IV) chloride.

The analogous study using vinyl ethers was unsuccessful, since these compounds polymerised rapidly in the presence of tin(IV) chloride[59]. Polymerisation itself, however, indicates activation of the double bond, that is, reaction of the complex-forming species with this reactive centre.

The above data provide convincing justification for the mechanism accepted at present for the acid hydrolysis of $\alpha\beta$-unsaturated ethers, according to which the first, rate-determining stage of the reaction involves the transfer of protons from the catalyst to the β-carbon atom of the vinyl group with the formation of carbonium ions[41-47], scheme (10):

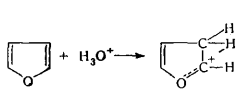


(10)

In the transition complex (A) the proton occupies a central position between the molecules of water and the substrate.

The partial oxonium character of the ions formed, that is, their stabilisation by interaction of the p-electrons of the oxygen with the positive centre, explains the important part played by conjugation and the high reactivity of enol ethers in the presence of electrophilic reagents. In the original state, conjugation of the π-electrons of the multiple bond with the p-electrons of the oxygen leads to localisation of the negative charge on the β-carbon atom of the vinyl group. The corresponding increase in the energy of the original state was recently confirmed experimentally in a determination of the thermodynamic characteristics of the original and final states in the acid hydrolysis of ethyl vinyl ether[61]. The results of this work made it possible to construct the energy profile of the reaction. The presence of the negative charge on the carbon of the vinyl group facilitates attack by protons and the formation of a transition state with structure approaching that of a σ-complex, and not a π-complex. On the other hand, the possibility of displacement of the electrons of the oxygen to the vacant p-orbitals of the neighbouring carbon atom of the carbonium ions leads to delocalisation of the positive charge, and this increases the stability of the ions and makes this reaction path energetically favourable.

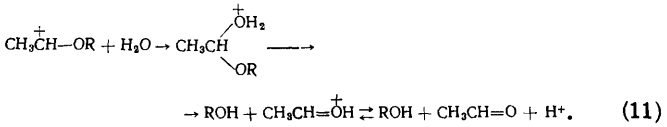
In derivatives of the cyclic vinyl ether furan, the conjugation of the unshared pair of electrons of the oxygen with the π-electrons of the ring does not lead to localisation of the negative charge and an increase in the energy of the original state as a result of the aromaticity of the system produced. The formation of the carbonium ions



is accompanied by loss of aromaticity and a decrease in the conjugation energy. These factors explain the increased stability of furan derivatives in acid hydrolysis, compared with other vinyl ethers, including 2,3-dihydropyran[43]. On the other hand, the increased reactivity of isopropenyl ethers relative to vinyl ethers can be attributed to the increased stability of the carbonium ions with increase in the degree of branching of the carbon chain attached to the positive centre. Carbonium ions with structures similar to those formed in the hydrolysis of enol ethers are formed in the hydrolysis of acetals[58]. In agreement with this, a linear relationship was found between the rate constants for the two reactions with analogous structural changes in the substrate[43].

Kinetic data cannot give information on the subsequent course of the reaction, since the rate-determining stage is the first stage. This gap can be partly filled by using isotopes.

In the hydrolysis of ethyl vinyl ether in D_2O, the acetaldehyde formed contained only one deuterium atom, indicating that the proton transfer is irreversible[44] and that the subsequent transformation undergone by the carbonium ions is more rapid than the isotopic exchange of hydrogen in these ions§. The analogy with the hydrolysis of acetals, and also the results of a study of the mechanism of the acid hydration of alkenes[65], styrene[66], acetylenic ethers, and sulphides[67-69]¶ indicate that the carbonium ions are subjected to nucleophilic attack by water and are converted into the protonated forms of the hemiacetals, which decompose to give the aldehyde and alcohol. The formation of alcohols which do not contain oxygen from the medium in the hydrolysis of both alkenyl ethers and acetals confirms the scheme:



(11)

An interesting feature is that even for allyl vinyl ether, stabilisation of the carbonium ion by attachment of water is more favourable than rupture of the allyl–oxygen bond with the formation of the aldehyde retaining the oxygen of the substrate. This indicates that the $CH_3\overset{+}{C}H-O-CH_2CH=CH_2$ ion is more stable than the allyl cation.

Schemes (10) and (11), based on the results of kinetic and isotopic studies, confirm and give the details of views on the mechanism of the hydrolysis of enol ethers developed on the basis of chemical intuition more than thirty years ago. This now represents one of the few examples where it has been possible to characterise reliably and in sufficient detail the structure of the intermediate complex in the rate-determining stage of the reaction.

4. ACID HYDROLYSIS OF ESTERS

Kinetic data have been published on the acid hydrolysis of esters of four structural types: the vinyl and isopropenyl esters of aliphatic and benzoic acids. It was shown above that change in the structure of enol acylates does not lead to a change in the point of fission of the bonds, which corresponds to the replacement of the anion of the carboxylic acid by hydroxide.

As with the ethers, the acid hydrolysis of enol esters is described by a first-order equation, but it takes place under slightly more severe conditions[25,26,45,70]. The rate constants for the hydrolysis of the alkenyl esters of aliphatic acids in aqueous dioxan solutions are linearly dependent on the analytical concentration of mineral acid. The kinetic equation for the hydrolysis of vinyl and isopropenyl benzoates contains the acidity function H_0 instead of C_{H^+}.[26,45] The problem of whether the acid catalysis is

§ The rapid exchange of the hydrogen of the C–H bonds in carbonium ions is dealt with in papers by Setkina and Kursanov[62,64].

¶ For all these reactions it has been proved that the rate-determining stage is the transfer of H^+ from the catalyst to the substrate with the intermediate formation of carbonium ions.

specific or general has not been studied. The fact that the observed rate constants remain constant with time, that is, as the carboxylic acid accumulates in the reaction system, can be attributed either to the absence of general catalysis or to low values for the catalytic constants of the acids formed, compared with $k_{H_3O^+}$.

The temperature dependence of the rate constants in all instances obeys the Arrhenius equation. The kinetic characteristics of the hydrolysis of the compounds studied are given in Tables 5 and 6.

Table 5. Kinetic characteristics of the hydrolysis of αβ-alkenyl esters of aliphatic acids in aqueous dioxan solutions.

Substrate	Catalyst, solvent	$10^3 k_{80°}$, litre mole^{-1} s^{-1}	$k^*_{rel.}$	$E^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	k_{H_2O}/k_{D_2O}	Refs.

* The rate of hydrolysis of vinyl acetate in 99% aqueous dioxan was taken as unity.

As in the hydrolysis of enol ethers, a compensation effect is observed in the changes in the energy and entropy of activation. The experimental points on the plot of $\Delta S = f(E)$ for vinyl benzoates, the esters of aliphatic acids, and isopropenyl benzoates lie on three parallel straight lines arranged one above the other in the order indicated. Only vinyl formate and isopropenyl acetate do not fit into the general scheme.

In the series of vinyl and isopropenyl benzoates, electron-donating substituents in the *para*- and *meta*-positions of the benzene ring increase the reaction rate, whereas electron-accepting substituents decrease the reaction rate. An exception is vinyl *p*-nitrobenzoate, which reacts more rapidly than vinyl anisate by a factor of several tens. In this example, a departure from simple kinetic orders with respect to substrate and catalyst is also observed. The deviation of vinyl *p*-nitrobenzoate from the general relationship was attributed to a change in reaction mechanism. It is not excluded that the kinetic complications in this instance represent a manifestation of the catalytic activity of the comparatively strong *p*-nitrobenzoic acid.

The logarithms of the hydrolysis rate constants for the benzoates show a correlation with the Hammett constants σ. For the vinyl esters, ρ in the equation $\lg(k/k_0) = \sigma\rho$ is equal to -1.30,[45] whereas for the isopropenyl esters $\rho = 1.1$.[26]

These correlations indicate that the rate of the acid hydrolysis of αβ-alkenyl benzoates is determined chiefly by polar factors. The nature of the influence of substituents is the same as that in the acid hydrolysis of enol ethers, and opposite to that observed in the acid hydrolysis of alkyl benzoates[71].

Table 6. Kinetic characteristics of the hydrolysis of vinyl and isopropenyl benzoates in 99% dioxan at 80°C with catalysis by sulphuric acid.

Substrate,	$10^3 k$, litre mole^{-1} s^{-1}	$k^*_{rel.}$	$E^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	$\frac{k_{H_2O}}{k_{D_2O}}$	Refs.

* The rate constant for the hydrolysis of vinyl benzoate in 99% dioxan was taken as unity.

** In 90% dioxan, $k_{H_2O}/k_{D_2O} = 1.80$.

In the series of αβ-alkenyl esters of aliphatic acids, the rate of acid hydrolysis decreases with increase in the length of the hydrocarbon chain of the acid component and with increase in its degree of branching (Table 5). The fact that the decrease in reaction rate is almost the same on going from vinyl acetate to vinyl propionate and vinyl monochloroacetate, in which the acyl residues differ considerably in polarity but have very similar dimensions, and the marked decrease in reaction rate on going to vinyl trimethylacetate[70] indicate that in the acid hydrolysis of these compounds, as in that of the ethyl esters of aliphatic acids, the chief part is played not by polar factors, but by steric factors[25,71].

In accordance with the foregoing, the introduction of a methyl group into the α-position of the vinyl group produces different effects on reaction rate in the benzoates and the esters of aliphatic acids. The change from vinyl acetate to isopropenyl acetate is accompanied by a slight decrease in the rate of hydrolysis, but the corresponding change in structure in the benzoate series leads to an increase in reaction rate by a factor of 40–70. The influence of substituents in the benzene ring is weakened slightly, as can be seen from the decrease in the absolute magnitude of ρ from 1.30 to 1.10.[26]

The esters of aliphatic and benzoic acids also show different behaviour when the H_2O medium is replaced by D_2O. In the first instance, the sign of the isotopic effect of the solvent depends on the concentration of water in the solution. At relatively high concentrations of water (10–20 wt. % in dioxan) the reaction rate in D_2O increases by a factor of 1.2–1.4. Decrease in the water concentration to 1.0–2.0% leads either to the disappearance of the isotopic effect or to a slight decrease in reaction rate in D_2O. The rate of hydrolysis of vinyl and isopropenyl benzoates in heavy

water decreases by a factor of 1.5–2.0, and the retarding influence of D_2O is apparently independent of the concentration of water in the solution[26].

These data show that the kinetic features of the acid hydrolysis of $\alpha\beta$-alkenyl benzoates and ethers are extremely similar and differ significantly from the kinetic features of the hydrolysis of the alkenyl esters of aliphatic acids (influence of substituents, acidity of the medium, and isotopic effect of the solvent). On this basis, the mechanism proposed for the hydrolysis of alkenyl benzoates is the same as that for the hydrolysis of enol ethers[26], with rate-determining transfer of protons from the catalyst to the substrate.

The predominance of not the polar influence but the steric influence of the substituents, the increase in reaction rate in D_2O, and the linear dependence of the rate on the analytical concentration of mineral acid in the hydrolysis of the esters of aliphatic acids can be explained by assuming the A-2 mechanism of acid catalysis, represented by the scheme[26]

$$CH_2{=}CH{-}OCOR + H_3O^+ \rightleftarrows H^+ \cdots CH_2{=}CH{-}OCOR + H_2O$$

$$H^+ \cdots CH_2{=}CH{-}OCOR + H_2O \xrightarrow{\text{slow}} \left[H^+ \cdots CH_2{=}CH{-}OCOR\right]^+ \longrightarrow \quad (12)$$

$$\longrightarrow CH_3CH(OH_2)(OCOR) \longrightarrow CH_3CH{=}\overset{+}{O}H + RCOOH\,.$$

Although the increase in reaction rate in heavy water does not provide unambiguous proof of rapid reversible protonation in the first stage of the reaction, in the present instance evidence in support of scheme (12) is provided by the fact that the isotopic effect of the solvent (Table 5) has the same magnitude as that in other reactions in which the pre-equilibrium stage has been established independently (these values have been summarised[72]). Moreover, the values of $k_{H_2O}:k_{D_2O}$ for the hydrolysis of the esters of aliphatic acids agree with the results of a calculation[72] carried out on the basis of theories regarding a change in the reaction rate constants for acid catalysis in D_2O following the A-2 mechanism[52].

The decrease in the reaction rate in D_2O at low concentrations of water in the solution was attributed[45] to conversion of the open form of the activated complex into the ring form. The marked decrease in the energy and entropy of activation under these conditions (Table 5) agrees with this explanation. It may be assumed that at water concentrations equal to or slightly greater than the concentration of mineral acid, all the water molecules are bound in the solvate sheaths of the protons. This creates stereochemical conditions for the formation of an intermediate complex with a cyclic structure, since it ensures approach of the electrophilic and nucleophilic reagents, joined by hydrogen bonds, from the same direction towards the substrate molecule.

Thus in the acid hydrolysis of enol ethers and enol benzoates, the reaction rate is limited by the first electrophilic stage, leading to the formation of carbonium ions. For this mechanism, steric factors should not influence the reaction kinetics, as was found in the hydrolysis of vinyl and isopropenyl benzoates. The decrease in reaction rate on going from the ethers to the benzoates is in accordance with the weakening of the conjugation of the p-electrons of the C=C bond and the ether oxygen atom under the influence of the carbonyl group. It might have been expected that a carbonyl group situated next to the ether oxygen would make hydrolysis of the enol ethers through carbonium ions energetically unfavourable, since the stabilisation of the carbonium ions as a result of displacement of the p-electrons of the oxygen to the carbonium centre would have led to an improbable structure with two neighbouring electron-deficient atoms.

$$CH_3C(H){=}\overset{\delta+}{O}{-}\overset{\delta+}{C}(=O){-}R \qquad (a)$$

If, however, R is a benzene ring, the positive charge on the carbonyl carbon atom is reduced considerably as a result of the interaction with the π-electrons of the aromatic system. Data confirming the high stability of the benzoyl cations $C_6H_5\overset{+}{C}{=}O$, compared with acetyl and propionyl cations, were obtained in a study of the infrared spectra and NMR spectra of complexes of the corresponding fluorides with Lewis acids[73].

For the alkenyl esters of aliphatic acids, a decrease in the positive charge on the carbonyl carbon atom can take place only as a result of the relatively weak inductive effect and hyperconjugation, and the formation of ions of type (a) becomes unfavourable, and the nucleophilic character of the β-carbon atom of the vinyl group in the original state is decreased. As a result, the electrophilic attack of the protons in the first stage of the reaction does not proceed as far as the formation of a new covalent C–H bond. This process becomes possible only after or at the same time as nucleophilic attack by the water molecules on the α-carbon atom of the vinyl group. Thus the second, nucleophilic stage becomes the rate-determining stage, and this, as indicated above, should be sensitive to steric factors, since it requires movement out of the plane of the bulky acyl and other groups joined to the α-carbon atom, as confirmed experimentally.

Summarising the discussion of the experimental data at present available on the acid hydrolysis of enol ethers and esters leads to the conclusion that a donor–acceptor scheme is applicable in all instances for the mechanism of hydration of the ethylenic bond.

Other conditions being equal, the nature of the limiting stage is related to the structure of the substrate as follows: when structural factors facilitate the stabilisation of carbonium ions, rupture of the double bond and formation of a new C–H bond take place in the first electrophilic stage, which thus determines the rate of the process. Here the chief part is played by factors favouring conjugation of the p-electrons of the ether oxygen and the ethylenic bond. If this conjugation is suppressed, the fission of the old bonds and the formation of new bonds takes place under the simultaneous influence of both the electron acceptor and the electron donor, and the nucleophilic stage of the reaction becomes the limiting stage.

The extension of these ideas to other reactions involving electrophilic addition across the ethylenic bond of vinyl ethers and esters shows that the structure of the latter is not the only factor determining the composition of the intermediate complex and the nature of the limiting stage. Thus the addition of ethanol to butyl vinyl ether and also to vinyl acetate, catalysed by p-toluenesulphonic acid, is described by a second-order equation, in which the concentration of the nucleophile does not appear[74]; this is in accordance with slow transfer of the proton in both instances and is confirmed by the decrease in reaction rate on replacement of C_2H_5OH by C_2H_5OD.

The addition of acetic acid to the same ether and ester is described by a third-order equation, including the concentrations of substrate, catalyst, and acetic acid[74,75].

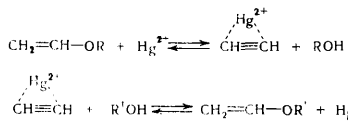
These data, together with the marked isotopic effect for the addition of CH_3COOD, indicate that the reaction mechanism is termolecular.

5. TRANS-ESTERIFICATION AND TRANS-ETHERIFICATION OF VINYL ESTERS AND ETHERS (TRANS-VINYLATION)

The trans-esterification of vinyl esters or the trans-etherification of vinyl ethers formally consists of the transfer of a vinyl group from one alcoholic or acid residue to another—see Eqns. (3) and (4). These reactions are therefore also described as vinyl exchange or trans-vinylation.

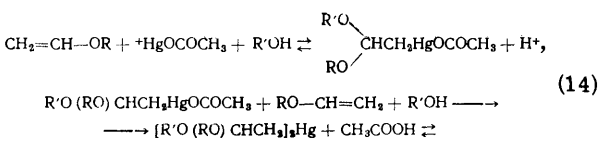
This reaction was first described in the patent literature[1]. Adelman[76] studied vinyl exchange in detail and showed that the mercury salts of strong acids, and also the addition to the reaction mixture of mercury(II) oxide and boron trifluoride, which catalyse the addition of alcohols and carboxylic acids to vinyl ethers and esters, under milder conditions act as specific catalysts for vinyl exchange. It was subsequently established that not only alcohols and acids, but also other organic compounds with a labile hydrogen atom, can take part in this reaction, that the reaction is an equilibrium reaction, and that side-reactions involving addition and polymerisation can be reduced to a minimum if equimolar mixtures of mercury acetate and sulphuric acid are used as catalyst.

For the mechanism of vinyl exchange, Adelman proposed the scheme



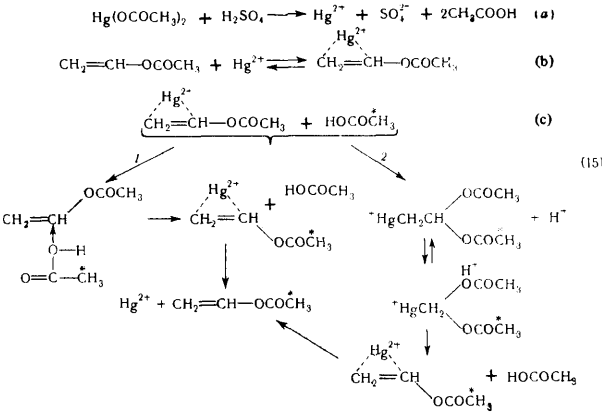
(13)

In 1962 it was established that acid solutions of palladium(II) chloride and salts of other platinum group metals can also catalyse the exchange of acyl residues between vinyl acetate and carboxylic acids and increase the rate of hydrolysis of vinyl acylates[77]. Without giving details of the proposed mechanism, the authors cited suggested that these reactions involve attack on the vinyl ester–metal ion complex by carboxylate ions or water molecules. On prolonged heating, vinyl ethers exchange their alcohol groups for the alkoxy-groups of any alcohols present under the influence of small quantities of mercury acetate in neutral anhydrous media[78]. Good yields of the exchange products could be obtained by removing them by distillation as they were formed. To confirm the suggestion that the reaction involves an organomercury compound, the authors cited showed that the latter catalyse the exchange in the same way as mercury acetate, and proposed the scheme:



(14)

Study of the reaction of vinyl acetate with the two isotopic forms of deuterio-acetic acid CD_3COOH and CH_3COOD at 25°C in the presence of Adelman's catalyst showed that in the reaction with CH_3COOD, deuterium does not enter the vinyl acetate molecule within the time required for the attainment of isotopic equilibrium between vinyl acetate and CD_3COOH.[30] Thus the hydrogen atoms of the vinyl group remain bound to their carbon atoms in the reaction, contrary to scheme (13). This conclusion was also confirmed in a PMR study of the formation of vinyl benzoate from deuterio-vinyl acetate and benzoic acid, catalysed by mercury acetate and BF_3.[12]



(15)

These data unambiguously refute Adelman's mechanism, and also prove that intermediate formation of acylals does not take place in the reactions studied.

Thus for the trans-vinylation of alcohols and carboxylic acids under the influence of the mercury salts of strong acids there remain two possible mechanisms: reversible addition of the cation of the mercury salt and the RO^- or $RCOO^-$ anion across the ethylenic bond, that is, an oxydeoxymercuration mechanism (scheme *15*, *2*) and a mechanism involving direct replacement of one ester group by another in ester molecules activated by coordination to mercury ions, analogous to that proposed by Smidt and coworkers[77] (scheme *15*, *1*).

Both mechanisms assume the formation of ionic complexes of mercury with the vinyl esters (stage *b*) and exchange of ester groups as a result of attack on these complexes by nucleophiles, and both mechanisms show agreement with vinyl–oxygen splitting of the bonds in the ester, confirmed experimentally (see section *2*). According to mechanism (*15*, *2*), the nucleophilic attack is complete with the formation of an organomercury compound. Mechanism (*15*, *1*) makes it possible to avoid this stage. The reaction path is apparently determined by the relative stability of the organomercury compounds and the mercury complexes in each specific instance.

Study of the kinetics of exchange between vinyl acetate and deuterio-acetic acid CD_3COOH under the influence of Adelman's catalyst[79] and the kinetics of the formation of vinyl benzoate from vinyl acetate and benzoic acid with catalysis by mercury acetate and BF_3 [80] showed that the overall order of the reaction with respect to the catalyst depends on the relative concentrations of the mercury salt and the acid. Subsequently, it was found[79] that there is a linear relationship between the reaction rate and the acetic acid concentration (1–10 M) but the initial rate of formation of vinyl benzoate increased more slowly than the benzoic acid concentration (0.3–1.0 M). The reaction with benzoic acid was found to be of first order with respect to vinyl acetate, whereas the exchange with deuterio-acetic acid was found to be of zero order with respect to vinyl acetate. The values found for the Arrhenius activation energy were 9.4 kcal $mole^{-1}$ and 11.0 kcal $mole^{-1}$ respectively.

The kinetic data on the exchange of vinyl acetate with acetic and benzoic acids were obtained under conditions which are not strictly comparable. Firstly, in the works

cited the solvents and acidic reagents used were not identical; secondly, for the exchange with acetic acid the data given were obtained after steady-state conditions had been established, whereas for the exchange with benzoic acid the initial rates of the process were given. Moreover, the ranges of change in the original concentrations in the works cited are narrow and do not always coincide with one another.

The kinetic data on the exchange between vinyl acetate and deuterio-acetic acid were interpreted on the basis of a direct replacement mechanism[78] (scheme *15*, *1*). The chief evidence in support of this scheme was provided by the dependence of the reaction rate on the ratio of the quantities of mercury acetate and sulphuric acid taken; this dependence was incompatible with an oxy-deoxymercuration mechanism. Application of the principle of steady-state concentrations to the corresponding kinetic scheme shows that the reaction rate in this instance would be independent of the acidity of the medium. If, however, the acetoxymercury derivative were formed in concentrations comparable with the concentration of mercury acetate, we would expect the rate to be linearly dependent on the acidity of the medium. The experimental data do not correspond to either situation.

The facts that the reaction rate is independent of the vinyl acetate concentration and that the reaction is of first order with respect to acetic acid do not contradict either of the mechanisms being considered. The linear dependence of the reaction rate on the acetic acid concentration was attributed[79] to rate-determining attack by this reagent on vinyl acetate molecules coordinated to mercury ions. The concentration of the activated substrate, in view of the large excess of substrate relative to the mercury salt, depends only on the latter, so that the concentration of ester does not appear in the kinetic equation.

According to the views of Flid and Temkin[81], the catalytic activity of mercury ions in the reactions of unsaturated compounds is due to the formation of termolecular complexes containing both reagents and the catalyst. From this viewpoint, the slow stage of the process may be the introduction of the reagent with the smaller affinity for the metal ion into its coordination sphere. The dependence of the rate of formation of vinyl benzoate from vinyl acetate and benzoic acid[80] agrees with these views. From published data[80] it can be seen that the initial reaction rate is related to the sum of the concentrations of acetic and benzoic acids†, as would be expected if the slow stage of the reaction is the displacement of one of the molecules of the unsaturated ester from the coordination sphere of the mercury ions by a carboxylic acid molecule.

The difference in the dependence of the reaction rate on the vinyl acetate concentration in the reactions with acetic and benzoic acids can apparently be attributed to the displacement of the equilibrium for complex formation by vinyl acetate with mercury ions towards the starting materials as a result of the lower concentrations of ester and the higher reaction temperature.

Thus although the available kinetic data are insufficient for a final choice to be made between mechanisms (*15*, *1*) and (*15*, *2*), they apparently show better agreement with the first mechanism.

Slinckx and Smets[80] adopted a reaction scheme including the formation of the acetoxy-mercury derivative (*b*) $CH_3COOHgCH_2CH(OCOCH_3)_2$, and they consider that the replacement of the acetate group by the benzoate group takes place in (*b*) as bimolecular substitution at the tertiary carbon atom. As justification for this improbable scheme, which is contrary to extensive experimental material on the behaviour of oxymercury derivatives in acid media[82-84], the authors cited give a kinetic equation of the form:

$$v = k[\text{ester}][C_6H_5COOH][BF_3][(CH_3COO)_2Hg],$$

which does not correspond to their own experimental data, and also the replacement of the acetate group in (*b*) by a benzoate group in the presence of BF_3.[12] This last fact merely confirms again the reversible nature of the deoxymercuration, and cannot serve as proof of the proposed mechanism.

In conclusion it should be emphasised that if the formation of oxymercury derivatives or coordination complexes as active intermediate species in vinyl exchange is determined by the relative stability of these compounds, the second version of the mechanism is more probable for the exchange between vinyl acylates and carboxylic acids, since the stability of organomercury compounds decreases considerably on going from the alkoxy- to the acyloxy-derivatives.

It is not excluded that in the exchange between enol ethers and alcohols the predominating mechanism is that involving the formation of organomercury compounds, as found for vinyl exchange in media not containing a strong acid[78], and also in the hydrolysis of vinyl ethers and esters in the presence of mercury salts, as will be shown below.

6. HYDROLYSIS OF ETHERS AND ESTERS, CATALYSED BY MERCURY SALTS

It was stated above that the addition of a mercury salt increases the rate of hydrolysis of vinyl ethers and esters without altering the point of cleavage of the bonds. Study of the hydrolysis of vinyl acetate and n-butyl vinyl ether in D_2O in the presence of mercury sulphate showed that the acetaldehyde formed contains only one D atom[29], as in the acid hydrolysis of ethyl vinyl ether[43]. The kinetic features of the reaction, which are the same for the hydrolysis of butyl vinyl ether and vinyl acetate[85,86], and also apparently for vinyl benzoates[87], differ significantly from those observed in both acid hydrolysis and vinyl exchange. It was established by a potentiometric method for the example of vinyl acetate and butyl vinyl ether that the addition of mercury perchlorate solution to an aqueous dioxan solution of the ether or ester leads to the formation of acid in quantities equivalent to the mercury salt content[85,86]; this corresponds to quantitative conversion of the mercury salt into an organomercury compound:

$$CH_2{=}CH{-}OR + HgX_2 + HOH \rightarrow XHgCH_2{-}CH\begin{matrix}OR\\OH\end{matrix} + HX$$

or

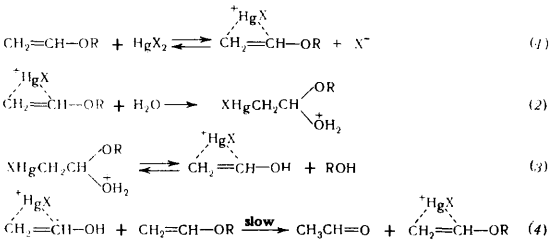
$$CH_2{=}CH{-}OR + HgX_2 + HOH \rightarrow X^- + XHgCH_2CH\begin{matrix}OR\\{}^+OH_2\end{matrix} \rightarrow XHgCH_2CH{=}O + ROH + HX.$$

The rate of hydrolysis increases linearly with increase in the concentration of mineral acid and is independent of the ionic strength of the solution[85,86]. The order of the reaction with respect to the substrate and the mercury salt is fractional and changes with change in the pH of the medium. The ethers and esters can be arranged in the following order of reaction rates at 20°C (the relative rates

† The acetic acid was introduced into the reaction mixture with the mercury acetate solution. The relationship indicated was not noticed by the authors cited[80].

under comparable conditions are given in parentheses): n-butyl vinyl ether (~ 10^2) > vinyl acetate (1.0) > vinyl anisate (0.39) > vinyl benzoate (0.17) > vinyl *p*-chlorobenzoate (0.13) > vinyl *p*-nitrobenzoate (0.10). This order corresponds to an increase in reaction rate with increase in the electron-donating power of the substituent attached to the ether oxygen atom, and is the opposite of that which might have been expected if the reaction rate were determined by the deoxymercuration stage, since organomercury compounds containing acyl groups undergo solvolysis much more readily than their alkoxy-analogues[83,84].

The available experimental data have been explained using scheme (16),[85,86] which is the same for the hydrolysis of vinyl ethers and esters.



(16)

According to scheme (16), the coordination complexes of the ether or ester with mercury ions undergo rapid nucleophilic attack by water and are converted into the oxymercury derivatives. Acid hydrolysis of the oxymercury derivatives does not lead to liberation of the mercury ion catalyst, since the mercury ions remain bound in ionic complexes with the reaction product—the enol form of acetaldehyde. The slow stage of the process is the transfer of mercury ions from the product to the substrate, as shown by stage (4). The transfer of catalyst from the product to new molecules of ether or ester is more rapid, the more nucleophilic their ethylenic bond, in agreement with the observed dependence of the rate of hydrolysis on the structure of the substrate.

Scheme (16), on the one hand, is a detailed form of scheme (*15*, *2*) for aqueous solutions. On the other hand, it corresponds to scheme (*12*) for the acid hydrolysis of the alkenyl esters of aliphatic acids, since the splitting of the double bond takes place under the joint influence of electrophilic and nucleophilic reagents. The difference is that the mercury ions, unlike the protons in acid catalysis, are not regenerated at the end of the catalytic cycle. The greater catalytic activity of mercury ions compared with protons in the hydrolysis of vinyl ethers and esters agrees with the idea that the C=C bond is weakened by dative interaction when the unsaturated ether or ester is introduced into the coordination sphere of mercury ions[88,89].

7. ALKALINE HYDROLYSIS OF ESTERS

The first kinetic study of the alkaline hydrolysis of enol acylates was made in 1927, when Skrabal and Zachorka[90] established that vinyl acetate in alkaline aqueous solutions is hydrolysed much more rapidly than ethyl acetate. They showed that the reaction is described by an equation of second order and of first order with respect to ester and alkali, that is, it is analogous to the hydrolysis of ethyl acetate. The second-order rate constant was found to be 620 litre mole^{-1} min^{-1} at 25°C, which corresponds to an increase in reaction rate by a factor of 100 on going from ethyl acetate to vinyl acetate. The same authors determined the first-order rate constant for the "aqueous" hydrolysis of vinyl acetate, which is equal to 7.4×10^{-6} min^{-1} and is greater than the analogous constant for ethyl acetate by a factor of 1000. According to their data, the maximal stability of vinyl acetate corresponds to pH 4.44.

The vinyl esters of aliphatic acids can be arranged in the following order of rates of hydrolysis at 25°C in a 0.05 *N* solution of sodium hydroxide in 95.5% ethanol[91], analogous to the order for the ethyl and methyl esters[21] (the relative rates of hydrolysis are given in parentheses): monochloroacetate (600) > formate (350) > acetate (1) > butyrate (0.22) > isobutyrate (0.12) > isovalerate (0.085) > crotonate (0.078).

An interesting feature is that under these conditions the rates of hydrolysis of ethyl and vinyl acetates were found to be the same, whereas in the hydrolysis of vinyl acetate in aqueous alkali solution an increase in the reaction rate by more than two orders of magnitude was observed, which is much greater than the increase in the water concentration.

The rates of hydrolysis of the divinyl esters of saturated dibasic acids in aqueous ethanol solutions differ little from that for vinyl acetate. Increase in the length of the hydrocarbon chain leads to a decrease in the reaction rate and an increase in the activation energy[92].

Table 7. Comparison of the kinetic characteristics of the alkaline hydrolysis of vinyl and ethyl carboxylates at 25°C*.

Ester	10^5k, litre mole^{-1} s^{-1}	$E^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.
Vinyl anisate	23.0	18.0	−16.7
Ethyl anisate	11.5	18.6	−15.9
Vinyl benzoate	114	16.9	−17.3
Ethyl benzoate	55.0	17.7	−15.9
Vinyl *p*-chlorobenzoate	371	15.2	−18.5
Ethyl *p*-chlorobenzoate	237	16.8	−16.1
Vinyl *p*-nitrobenzoate	9.25	15.8	−12.3
Ethyl *p*-nitrobenzoate	5.67	14.5	−16.5
Vinyl acetate	1.31	13.0	−26.2
Ethyl acetate	621	14.2	−23.0

* The data on the kinetics of hydrolysis of ethyl benzoate in 85% aqueous ethanol solutions are taken from Ingold and Nathan[93], and the data on the kinetics of the alkaline hydrolysis of ethyl acetate in a solvent with the same composition are taken from Evans and coworkers[94].

The identical influence of substituents in the acyl group of vinyl and ethyl acylates is also confirmed by data on the alkaline hydrolysis of vinyl benzoates with substituents in the *para*-position of the benzene ring in 77% aqueous ethanol solutions[17,34] (Table 7), which show that the similarity in the values of the rate constants for the hydrolysis of vinyl and ethyl benzoates is due to the similarity in the values of the energy and entropy of activation.

The changes in reaction rate in the series of ethyl benzoates, however, is due entirely to change in the activation energy at constant value of the entropy of activation, whereas in the vinyl benzoate series there is an appreciable change in the values of $\Delta S^{\neq}$, which partly compensates the influence of the change in activation energy.

The similarity in the kinetic characteristics of the alkaline hydrolysis of vinyl and ethyl esters (Table 7) apparently is not of great importance from the viewpoint of reaction mechanism, since the results were obtained under

conditions of different water concentration. The marked influence of this factor on the rate of hydrolysis of vinyl acetate was noted above. In the concentration range 5 to 20 M the rate of hydrolysis of vinyl acetate (and vinyl benzoates) is linearly dependent on the water concentration[34], but the influence of the composition of the solvent on the values of $E^{\neq}$ and $\Delta S^{\neq}$ has not been elucidated. Thus the similarity in the values of these parameters for the hydrolysis of vinyl and ethyl esters is possibly due to accidental coincidence. In aqueous solution, the values of $\Delta S^{\neq}$ for the alkaline hydrolysis of $\alpha\beta$-alkenyl and alkyl acetates in some instances differ considerably, although the activation energies are similar (Table 8). For vinyl and ethyl acetates the difference amounts to 17 e.u. The increase in reaction rate by a factor of 30 on going from cyclopentyl acetate to cyclopentenyl acetate is due chiefly to the increase in the entropy of activation.

Table 8. Kinetic parameters of the alkaline hydrolysis of various enol and alkyl acetates in aqueous solution at 20°C.[95]

Acetates	k, litre mole^{-1} s^{-1}	$E^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.	Acetates	k, litre mole^{-1} s^{-1}	$E^{\neq}$, kcal mole^{-1}	$\Delta S^{\neq}$, e.u.
Vinyl	3.28	12.8	−12.7	Ethyl	0.006	11.0	−31.0
Isopropenyl	0.31	11.6	−21.2	Cyclopropyl	0.18	12.1	−20.8
Cyclopentenyl	0.85	10.5	−24.8	n-Butyl	0.06	10.6	−27.7

* At 21°C.

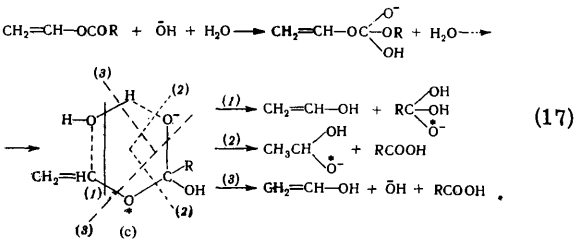
The dependence of the rate constant for alkaline hydrolysis in aqueous ethanol solutions on the structure of the acyl residue satisfies the Taft equation $\lg(k/k_0) = \rho^*\sigma^* + E_S + \psi$ for the vinyl esters of aliphatic acids and the Hammett equation $\lg(k/k_0) = \rho\sigma$ for the benzoates. The values $\rho^* = +2.67$ and $\rho = +2.48$ almost coincide with those established for the alkaline hydrolysis of ethyl carboxylates[17,34].

Change in the structure of the alkenyl radical has a fairly marked influence on the rate of alkaline hydrolysis of enol acylates (Table 8), the effect being apparently stronger than that of analogous changes in the structure of saturated alcohol radicals.

The reaction rate for isopropenyl acetate is smaller by a factor of 10 than that for vinyl acetate, whereas the rate of hydrolysis of isopropyl acetate is smaller than that of ethyl acetate by a factor of only 3.7–4.0;[22,94] according to data obtained by the same authors, the same difference in rates was observed for the hydrolysis of the acetates of primary and secondary butyl alcohols.

The available experimental data are contradictory, since, on the one hand, they indicate a similarity in the mechanism of the alkaline hydrolysis of enol esters and their analogues with a saturated alcoholic group (the stability of the enol ethers in alkaline media and the rapid hydrolysis of the esters, the similarity in the values of ρ in the Hammett–Taft equation for ethyl and vinyl acylates, and the marked similarity in the kinetic parameters for the hydrolysis of ethyl and vinyl benzoates in alcoholic solutions). On the other hand, the partial transfer of the ether oxygen to the carboxyl group in the absence of exchange between the esters and the medium during the reaction, the change in $\Delta S^{\neq}$ when substituents are introduced into the benzene ring of vinyl benzoates, the marked decrease in the reaction rate on going from aqueous to aqueous-alcoholic media, and the more marked influence of the structure of the alcohol component on the reaction rate indicate that the mechanisms of the alkaline hydrolysis of alkenyl and alkyl carboxylates are not the same.

An attempt was made to reconcile the accumulated data by the suggestion that the rate-determining reaction involves attack by hydroxide ions on the carbonyl group with the formation of a cyclic intermediate complex (*c*),[34] similar to that previously proposed by Hinshelwood[96] and by Syrkin and Moiseev[28] for the alkyl esters, scheme (*17*):



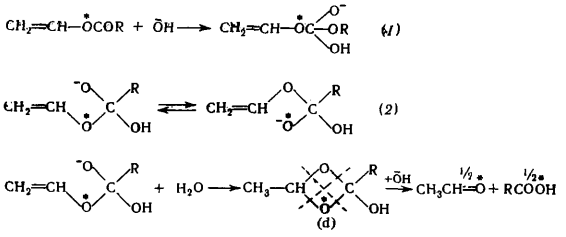
(17)

The authors cited based the proposed scheme on the following considerations: the slow addition of hydroxide ions to the carbonyl carbon atom corresponds to the observed values of ρ and the absence of exchange with the medium during the reaction; the formation of the complexes (*c*) for vinyl esters is facilitated by polarisation of the C=C bond; and decomposition of complex (*c*) in various directions, as shown in the scheme, can lead to the same reaction products with different isotopic compositions. In particular, decomposition in directions *1* and *2* or *3* and *2* at commensurate rates explains the partial transfer of the ether oxygen atom to the carboxyl group of the salt of the carboxylic acid formed.

To this it may be added that the attachment of the oxygen of water to the α-carbon atom of the vinyl group in the transition state agrees with the stronger influence of the structure of the alkenyl group, compared with the alkyl group, on the rate of hydrolysis.

Another possible interpretation of the experimental data appeared recently, since it was established that the hydrolysis of substituted benzhydryl benzoates, in which alkyl–oxygen splitting of the bonds takes place, is accompanied by intramolecular redistribution of ^{18}O between the ether and carbonyl oxygen atoms[97,98]. This was attributed to reversible breakdown of the ester molecule to form ion pairs, whose lifetime in the solvent cell is so great that extensive intramolecular isotopic exchange of oxygen can take place. This reaction path is possible if the structure of the alcohol radical ensures stability of the alkyl cations in the ion pairs.

The structure of the unsubstituted vinyl group does not satisfy this condition, but on the other hand it makes possible exchange between the ester and carbonyl oxygens without the formation of ion pairs, as can be seen from the schemes:

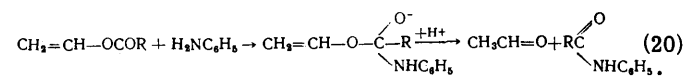


(18)
(19)

In the present instance, this reaction mechanism can be favoured by polarisation of the ethylenic bond. After the formation of the *ortho*-form of the ester, the polarisation

of the double bond should be intensified, and the polarisation is possibly no less than that in the molecules of vinyl ethers.

Evidence in support of schemes (*18*) and (*19*) is provided by the fact that in the acylation of aniline in anhydrous solution by vinyl acetate and benzoate labelled only in the ether oxygen atom, ~ 20% of the tracer was found in the anilides[35]. The following mechanism has been proposed for the acylation of amines by vinyl carboxylates[99]:



(20)

Since the yield of amides is quantitative[99], it is difficult to explain the partial transfer of ether oxygen to the anilide except by using a scheme analogous to scheme (*18*).

For hydrolysis according to scheme (*19*) in a medium enriched in $H_2{}^{18}O$, the concentration of ^{18}O in the anion of the acid formed would be half that in the medium, whereas in the hydrolysis of an ester labelled only in the ether oxygen the concentration would be half that in the original ester, and one-quarter of that in the vinyloxy-group. These relationships were found for the hydrolysis of vinyl anisate (Table 2). It may be assumed that the electron-donating methoxy-group in the *para*-position of the benzene ring facilitates the formation of the cyclic acylal (*d*), since it increases the negative charge on the carbonyl oxygen atom and intensifies the polarisation of the ethylenic bond in the required direction.

All that has been said above regarding the distribution of the tracer in the products of hydrolysis according to scheme (*19*) also applies to scheme (*18*) with the condition that the equilibrium in stage *2* can be established before the decomposition of the *ortho*-form of the ester into the reaction products.

It can be seen from scheme (*18*) that the intramolecular exchange of oxygen may also involve a third oxygen atom of the *ortho*-form. This may explain the data on the isotopic composition of acetic, benzoic, and *p*-chlorobenzoic acids, given in Table 2, particularly if slight exchange between the ester and the medium, which might remain unobserved, is assumed.

We do not yet have sufficient information to enable us to give preference to one of the above schemes. Any interpretation of the mechanism of the hydrolytic decomposition of vinyl esters in alkaline media, however, should take account of the fact that the rupture of the bonds between the vinyl group and oxygen plays a significant part.
