$$RCH_2C{\equiv}CH \xrightarrow{\overset{(+)}{P}Cl_4} [RCH_2{-}\overset{(+)}{C}{=}CHPCl_4] \rightleftarrows RCH{=}C{=}CHPCl_4 + H^{(+)} \rightleftarrows$$

$$\rightleftarrows [RCH{=}\overset{(+)}{C}{-}CH_2PCl_4] \rightarrow RCH{=}CCl{-}\overset{(+)}{C}H_2PCl_3.$$

The new hypothesis which has been developed concerning the mechanism of the reactions of phosphorus pentachloride with unsaturated compounds permit certain conclusions about the reactivity of unsaturated hydrocarbons in these reactions. With increase of acidity in a series of unsaturated hydrocarbons, their phosphorylation with phosphorus pentachloride should be facilitated, and this is indeed observed.

2. Reactions of Phosphorus Pentachloride with Hydrocarbons Containing a Conjugated System of Double and Triple Bonds

The first information about the reaction of phosphorus pentachloride with the simplest hydrocarbon containing a conjugated system of double bonds (divinyl) was published by Kosolapoff[141] in 1946. The complex formed in the reaction was treated with alcohol and the resulting chlorobutenylphosphonic esters were dehydrochlorinated to butadienylphosphonic esters. According to Kosolapoff's data, a mixture of diethylbuta-dien-1-yl- and diethylbutadien-2-yl-phosphonates was obtained. On this basis, it was suggested that the initial addition of phosphorus pentachloride took place in positions 1, 2 and 1, 4. In the subsequent studies by Short[142,143] and also by Anisimov and Kolobova[144-146] it was asserted that the addition of phosphorus pentachloride to divinyl takes place in position 1, 2. It has been shown[147] that these data are erroneous. It has been demonstrated by infrared spectroscopy and by syntheses that the decomposition of the complex of phosphorus pentachloride and divinyl with sulphur dioxide yields the dichloride of 4-chlorobut-2-enylphosphonic acid:

$$2PCl_5 + CH_2{=}CH{-}CH{=}CH_2 \rightarrow CH_2Cl{-}CH{=}CH{-}CH_2PCl_4 \cdot PCl_5 \xrightarrow{2SO_2}$$

$$\rightarrow CH_2Cl{-}CH{=}CH{-}\overset{O}{\overset{\|}{C}}H_2PCl_2 + POCl_3 + 2SOCl_2 .$$

The dialkyl esters of 4-chlorobut-2-enylphosphonic acid proved to be identical to those obtained in the reaction of 1,4-dichlorobut-2-ene with trialkyl phosphites:

$$ClCH_2{-}CH{=}CH{-}CH_2Cl + P(OC_2H_5)_3 \rightarrow ClCH_2{-}CH{=}CH{-}CH_2\overset{O}{\overset{\|}{P}}(OC_2H_5)_2.$$

$$ClCH_2{-}CH{=}CH{-}CH_2PCl_2 + 2C_2H_5OH \rightarrow ClCH_2{-}CH{=}CH{-}CH_2\overset{O}{\overset{\|}{P}}(OC_2H_5)_2.$$

Their oxidation with potassium permanganate gave chloroacetic acid. The 1,2-addition products could be present in the reaction mixture only as an impurity. The decomposition of the complex with hydrogen sulphide leads to the chloride of 4-chlorobut-2-enyl phosphonothionic acid. Butadienylphosphonic esters are very reactive compounds, which readily combine with nucleophilic reagents, enter into the diene synthesis reaction, and are capable of polymerisation and copolymerisation[148]. Isoprene[146,147] and 4-methylpenta-1,3-diene[148,149] react with phosphorus pentachloride to form 1,2-addition products. In the reaction of phosphorus pentachloride with phenylbutadiene in proportions of 1 : 3 and of phenyl- and styryl-tetrachlorophosphoranes with phenylbutadiene in proportions of 1 : 1, diphenylbutadienyltrichlorophosphorane, phenylbutadienyltrichlorophosphorane, and styrylbutadienyltrichlorophosphorane

are formed[150]. Vinylacetylene[151] and other hydrocarbons of this series, vinylethylacetylene[152], isopropenylacetylene[151,153], and ethynylcyclohexene[154], react with phosphorus pentachloride under mild conditions. The intermediate complexes were not isolated. They were immediately decomposed with sulphur dioxide. The dichloride of β-vinyl-β-chlorovinylphosphonic acid was obtained from vinylacetylene, the dichloride of β-cyclohexenyl-β-chlorovinylphosphonic acid was obtained from ethynylcyclohexene, and the dichloride of β-vinyl-β-chloro-α-ethylvinylphosphonic acid was obtained from vinylethylacetylene. It follows from these results that phosphorus pentachloride reacts with hydrocarbons of the vinylacetylene series to form products resulting from addition to the triple bond. Interesting results were obtained with isopropenylacetylene[153]. The final reaction product was the dichloride of 2-chloro-3-chloromethylbutadienylphosphonic acid together with 1,2,3,4-tetrachloro-3-methylbut-1-ene.

3. Reactions of the Chlorides of Phosphorus(V) Acids with Vinyl Ethers

This reaction, first described by Anisimov and Nesmeyanov[155], has attracted the attention of a large number of investigators in recent years. In a series of investigations Anisimov and Nesmeyanov showed that the reaction of phosphorus pentachloride with vinyl ethers yields complex compounds. The decomposition of these complexes with sulphur dioxide or with acetic acid results in the formation of the dichlorides of β-alkoxyvinylphosphonic acids[155-158].

$$RO{-}CH{=}CH_2 + 2\,PCl_5 \rightarrow RO{-}CHCl{-}CH_2PCl_4 \cdot PCl_5$$

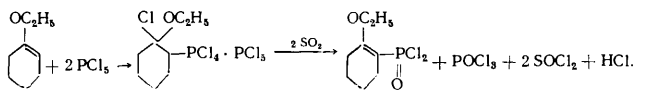
$$\xrightarrow{2\,CH_3COOH} ROCH{=}CHPCl_2 + POCl_3 + 2\,CH_3CCl + 3\,HCl$$

$$\xrightarrow{2\,SO_2} ROCH{=}CHPCl_2 + HCl + POCl_3 + 2\,SOCl_2.$$

A wide variety of alkyl vinyl ethers[144,155,156,158], monoalkyl vinyl ethers of ethylene glycol[157], and aryl vinyl ethers[144,159] were used in these reactions. β-Chloroethyl vinyl[160] and alkyl β-bromovinyl[161], ethers and vinyl sulphides[162] react similarly with phosphorus pentachloride. When the complexes are decomposed with hydrogen sulphide, the dichlorides of β-alkoxyvinylphosphonothionic acids are formed:

$$ROCHCl{-}CH_2PCl_4 \cdot PCl_5 + 2\,H_2S \rightarrow RO{-}CH{=}CH{-}\overset{S}{\overset{\|}{P}}Cl_2 + PSCl_3 + 5\,HCl.$$

Alkoxyvinylphosphonic and alkoxyvinylphosphonothionic esters, compounds which are very difficult to obtain by other methods, can be prepared in good yields by the esterification with alcohols of the dichlorides of β-alkoxyvinylphosphonic and β-alkoxyvinylphosphonothionic acids. When the ratio of the alkyl vinyl ethers to phosphorus pentachloride is 4 : 1, the chlorides of bis(β-alkoxyvinyl)phosphinic acid are obtained ultimately[163]. Arbuzov and coworkers carried out the reaction with phosphorus pentachloride of α-substituted vinyl ethers[164] and cyclic vinyl ethers with a double bond in the ring[165,166]. In these cases too the reactions take place in accordance with the general mechanism:



Apart from the decomposition of the complexes by various reagents, their reduction[167,168] and thermal decomposition[160] were investigated. When the complexes were treated with white phosphorus in the presence of iodine, β-alkoxyvinyldichlorophosphines were obtained, and the products of thermal decomposition were alkoxy-αβ-dichloroethyl vinyl ethers.

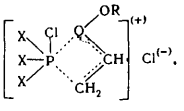
A number of studies have been made on phenyl- and alkyl-tetrachlorophosphoranes. Anisimov and Kolobova[169] studied the reaction of phenyltetrachlorophosphorane with ethyl vinyl ether. When the complex was treated with sulphur dioxide, the chloride of β-ethoxyvinylphenylphosphinic acid was formed, while treatment with white phosphorus in the presence of iodine gave β-ethoxyvinylphenylchlorophosphine. Similar results were obtained by Tsivunin et al.[170]. Thermal decomposition of the complex of phenyltetrachlorophosphine with n-butyl vinyl ether gives the chloride of β-chlorovinylphenylphosphinic acid[171]. In the thermal decomposition of the complex of ethyltetrachlorophosphorane with vinyl ethers[170,172], the same substance, the chloride of β-chlorovinylethylphosphinic acid, is formed regardless of the structure of the alkoxy-group:

$$CH_2{=}CH{-}OR + C_2H_5PCl_4 \xrightarrow{\Delta} C_2H_5\overset{O}{\overset{\|}{P}}(Cl){-}CH{=}CHCl + RCl + HCl.$$

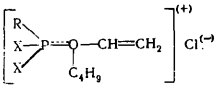
The reactions with diethyl and diphenyl-trichlorophosphoranes take place in an interesting way. Diethyltrichlorophosphorane forms with n-butyl vinyl ether a complex which has the structure of diethyl-α-chloroethoxydichlorophosphorane[173]:

$$(C_2H_5)_2PCl_3 + CH_2{=}CH{-}OC_4H_9 \rightarrow (C_2H_5)_2\overset{Cl}{\overset{|}{P}}(Cl){-}O{-}\overset{Cl}{\overset{|}{C}}H{-}CH_3 + (C_4H_9)_n.$$

Thermal decomposition of this complex leads to the chloride of diethylphosphinic acid. In the reactions of diphenyltrichlorophosphorane and triphenyldichlorophosphorane with n-butyl vinyl ether, diphenyl-α-chloroethoxydichlorophosphorane and triphenyl-α-chloroethoxychlorophosphorane were obtained respectively. It is suggested[173] that in these reactions the vinyl ether molecule forms with the phosphorus chloride a many-centre system due to the presence of the free *d*-orbitals of phosphorus and the conjugated system of $p\pi$-electrons (π-complex):



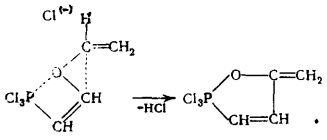
Compared with phosphorus pentachloride, the population of the $d\pi$-orbitals of phosphorus and chlorides of the type $RPCl_4$, R_2PCl_3, and R_3PCl_2 gradually decreases. This leads to an increase in the stability of the π-complexes:



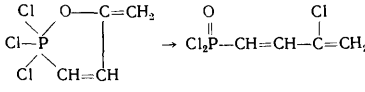
where X may be R or Cl. Their thermal decomposition leads to the formation of a large amount of the chlorides of alkylphosphonic or dialkylphosphinic acids.

The σ-stabilisation of the complexes is due to the formation of β-alkoxyvinylalkylchlorophosphoranes. These postulates were also used to account for the mechanism of the reaction of phosphorus pentachloride with divinyl ether[174,175]. The decomposition of the complex with hydrogen sulphide

leads to a crystalline product, the formation of which can be represented by the mechanism



When the product is heated, the dichloride of γ-chlorobutadienylphosphonic acid is formed:

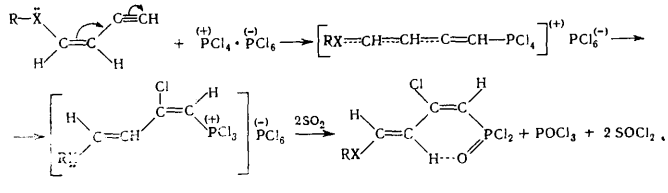


The structure of the cyclic product is consistent with PMR and NMR spectra.

Shostakovskii and coworkers[176-178], who investigated the reactions of phosphorus pentachloride with alkyl ethynylvinyl ethers and alkyl ethynylvinylsulphides, initially suggested that they take place at the double bond with formation (after decomposition of the complexes with sulphur dioxide) of products with the structure

$$ROCH{=}C(POCl_2){-}CCl{=}CH_2 \text{ and } RSCH{=}C(POCl_2){-}CCl{=}CH_2.$$

Subsequently they showed that their initial hypotheses were erroneous[179]; the reaction takes place at the triple bond in accordance with the mechanism:



where X = O or S. The products are the dichlorides of 4-alkoxy(alkylthio)-2-chlorobuta-1,3-dienylphosphonic acids.

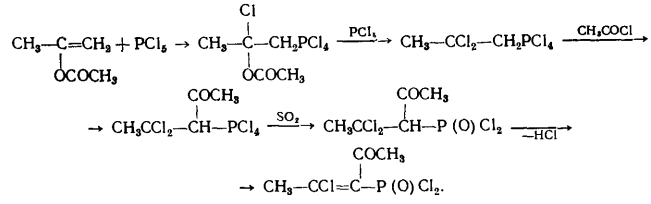
A very convenient method for the synthesis of the dichlorides of alkoxyvinylphosphonic acids or β-alkoxy-α-alkylvinylphosphonic acids has been recently developed by Petrov et al.[180] It is suggested that phosphorus pentachloride be allowed to react with ethers, which, after chlorination, are dehydrochlorinated and converted into vinyl ethers:

$$ROCH_2{-}CH_2R' + PCl_5 \xrightarrow{-HCl} ROCHCl{-}CH_2R' \xrightarrow{-HCl} RO{-}CH{=}CHR'.$$

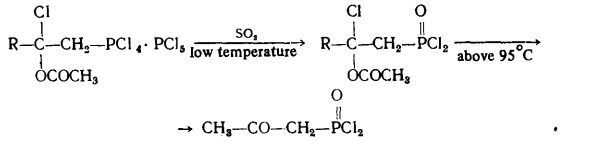
Subsequently the reaction takes place by the usual mechanism. When the complex is treated with hydrogen sulphide, the dichlorides of β-alkoxy-α-alkylvinylphosphonothionic acids are formed in yields up to 80%. This simple reaction makes it possible to obtain a number of interesting organophosphorus compounds.

4. Reactions of Phosphorus Pentachloride with Enol Esters

Lutsenko and Kirilov, who were the first to investigate reactions of this type, suggested that in the first stage the usual mechanism obtains; the addition product formed is then chlorinated by phosphorus pentachloride this being followed by reaction with acetyl chloride[181]: Treatment of the complexes with sulphur dioxide should yield the dichlorides of α-acetyl-ββ-dichloroalkylphosphonic acids:

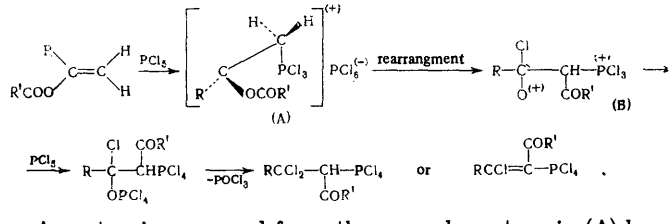


The authors isolated the initial complex at a low temperature. Its treatment with sulphur dioxide yields the dichlorides of β-acetoxy-β-chloroalkylphosphonic acids[182-184]. On heating, acetyl chloride is given off and the complex is converted into the dichloride of acetonylphosphonic acid:

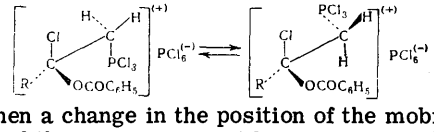


With the benzoate ester, evolution of hydrogen chloride from the complex and the ultimate formation of an unsaturated acid chloride were observed[185]:

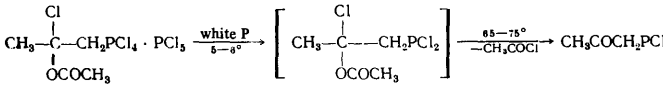
Subsequently, in order to explain the mechanism of the reaction of phosphorus pentachloride with enol esters, the authors suggested a new mechanism involving the intramolecular rearrangement of the complex formed initially[185-187]:



A proton is removed from the α-carbon atom in (A) by the anion $PCl_6^{(-)}$. The resulting dipolar ion (B) reacts with phosphorus pentachloride and is converted into the intermediate (C), which then breaks down the formation of the final products. When account is taken of the conformation of the intermediate complex (A), this mechanism can explain, for example , the unusual behaviour of isopropenyl benzoate in the reaction with phosphorus pentachloride. Because of the large size of the benzoyloxy- and PCl_3 groups, their *cis*-disposition in the complex is difficult; the conformation involving the *trans*-disposition of the groups is more favourable:



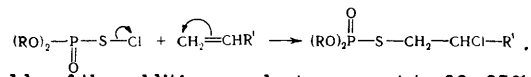
There is then a change in the position of the mobile hydrogen atom and the rearrangement becomes more difficult—the *trans*-elimination of hydrogen chloride becomes more probable. When the complexes (A) are reduced with white phosphorus at a low temperature (5-6°C), i.e. under conditions excluding the possibility of rearrangement, β-oxoalkyldichlorophosphine is formed[167]:



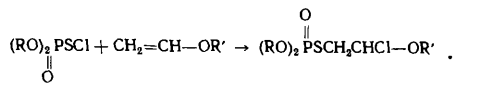
At a higher temperature (10–12°C), the reaction takes place in two ways–reduction and rearrangement. The products are then acetonyldichlorophosphine and the dichloride of α-acetyl-β-chloropropenylphosphonic acid.

5. Addition of Dialkoxyphosphinothiolic and Dialkoxyphosphinoselenolic Chlorides to Unsaturated Compounds

Dialkoxyphosphinothiolic and dialkoxyphosphinoselenolic chlorides contain a very mobile halogen atom which ensures the ready addition of these compounds to a multiple carbon–carbon bond. Dialkoxyphosphinothiolic chlorides have been obtained by the action of chlorine or sulphuryl chloride on dialkyl phosphorothioates, trialkyl phosphorothionates, and bis(dialkoxyphosphinyl) disulphides. Diethoxyphosphinoselenolic chloride was obtained by the action of sulphuryl chloride on triethyl phosphoroselenoate[188]. Michalski and coworkers, who were the first to obtain compounds of this type, achieved their addition to a number of symmetrical and asymmetric hydrocarbons of the ethylene series: ethylene[189–192], propene[193], isobutene[194], tetramethylethylene[189], cyclohexene[188], styrene, and stilbene[195]. The reactions take place very readily when the gaseous hydrocarbons are passed through and liquid hydrocarbons are slowly added to the dialkoxyphosphinothiolic and dialkoxyphosphinoselenolic chlorides at room or a lower temperature, usually in benzene solution. With asymmetric olefins, the mode of addition of the reagents is determined by their polarisation:



The yields of the addition products amount to 60–95%. Dialkoxyphosphinothiolic and dialkoxyphosphinoselenolic chlorides also add very readily to vinyl ethers[188,196,197] and vinyl sulphides[198]. In these reactions too the mode of addition is determined by the nucleophilic properties of the double bond with electron-donor alkoxy- or alkylthio-substituents:



Of the compounds with a conjugated system of double bonds, only divinyl has been used in the reaction with diethoxyphosphinothiolic chloride[199]. The 1,2-addition product is formed:

The Concept of Electronegativity. Conclusions and Prospects†

S.S. Batsanov

The principal methods for the determination of the electronegativity (EO) of the elements and radicals are examined—thermochemical, structural, spectroscopic, quantum-chemical, and a method based on ionisation potential. Particular attention is drawn to the necessity of taking into account the characteristic features of the chemical bond—its multiplicity and degree of hybridisation. The problems of the dimensions of the electronegativity of the elements are discussed. A compilation of the recommended electronegativities of atoms, radicals, and ions is given.
The principal applications of the concept of electronegativity are discussed: the determination of the atomic charges in molecules and crystals (good agreement between experimental and theoretical values is demonstrated); an estimate of the multiplicity of chemical bonds in inorganic ions and compounds, which agrees with the determination from the geometrical or spectroscopic characteristics of these substances; the principal physicochemical properties and the behaviour of inorganic substances as a function of the ionic character of their bonds and the difference between the electronegativities of the constituent atoms have been examined (semiconductor and molecular-physical characteristics, acid-base relations, specific features of the trans-effect of atoms in the inner sphere of platinum compounds, the possibility of the synthesis of new inorganic substances). The controversial questions of the nature and limits of applicability of the concept of electronegativity in general chemistry are briefly discussed.

CONTENTS

I. Introduction 332
II. Methods for the determination of electronegativity 333
III. The scope of the application of the concept of electronegativity 338

I. INTRODUCTION

More than one hundred years ago Berzelius[1] put forward the brilliant hypothesis concerning the electrical nature of chemical forces and divided all atoms into electropositive and electronegative. Lewis's theory gave rise to a concrete concept of polarity—regarded as the result of the displacement of the centre of gravity of the electron cloud of the bond towards one of the atoms, which is in fact electronegative in the given molecule.

More intensive experimental studies on polar molecules by various physical methods created the conditions for a new important scientific theory, whose author was Pauling[3]. The latter introduced into chemistry the concept of electronegativity (EO) defined as the capacity of the atom in a molecule (or in general in a compound) to attract valence electrons, and indicated an experimental method for its quantitative determination. This study gave rise to many other attempts to determine empirically the electronegativities of elements with the aid of geometrical, spectroscopic, and energy characteristics of atoms in molecules.

However, towards the beginning of the 1950's it became clear that the electronegativity of the element is not in most cases a constant property of the latter, but depends on the valence and degree of hybridisation of the bonds. Therefore special experimental and quantum-chemical investigations were begun in order to determine the electronegativity of atoms in various valence states and to find the electronegativities of whole groups of atoms (radicals).

The history of the development of the concept of electronegativity (up till 1961) is described in the present author's monograph[4] and the present review therefore considers mainly recent studies, which have made the greatest contributions to the theory and practical application of electronegativity in chemistry. Here too the principal conclusions following from the controversy on the meaning and limits of applicability of the concepts of electronegativity, which took place in recent years in the Soviet Union and to some extent abroad, will be described.

† In publishing this article, the Editorial Board consider it necessary to inform the readers that, although they do not agree with some of the author's views, the publication of the review is useful, since it will enable a wide circle of chemists to become familiar with the present state of the problem.

II. METHODS FOR THE DETERMINATION OF ELECTRONEGATIVITY

Any empirical method for the determination of electronegativity can be used also for the solution of the converse problem, i.e. the calculation of the corresponding physicochemical characteristic of the substance. Therefore particular attention is given here to quantitative methods for the determination and interpretation of electronegativity.

1. The Use of Thermochemical Data

Pauling[3] represented the difference between the energies of the real and purely covalent bonds between atoms A and B in the form of two terms—the electronegativities of the two species involved in the bond:

$$X_A - X_B = 0.208\{E(A-B) - {}^1/_2[E(A-A) + E(B-B)]\}^{1/2}, \quad (1)$$

where X denotes the electronegativity. Bearing in mind that the expression in braces in Eqn. (1) is equal to the heat of reaction Q, Eqn. (1) may be written in the more compact form

$$\Delta X_{AB} = 0.208Q\,. \quad (2)$$

Both these equations assume an arithmetical mean method for the calculation of covalent bond energies. In view of the correlation between bond strength and the product of the atomic wave functions, Pauling suggested that geometric means be used for the calculation of covalent bond energies, i.e. he replaced $\frac{1}{2}[E(A-A) + E(B-B)]$ by $[E(A-A) \times E(B-B)]^{1/2}$. Apart from being theoretically correct, such replacement made it possible to eliminate the disadvantage that in a number of cases (for example in alkali metal hydrides) the energy difference between $E(A-B)$ and half the sum of $E(A-A)$ and $E(B-B)$ were less than zero. By postulating that the electronegativity of hydrogen is 2.1, Pauling was able to calculate the absolute electronegativity of a large number of elements in the Periodic System. The most accurate and most complete data on the "thermochemical" electronegativities are given by Allred[5].

Comparison of Allred's system with Pauling's initial table reveals in a number of cases deviations in the electronegativities exceeding the effect of the experimental error in the determination of the bond energies. They are due to the use in the calculations of a large number of new thermochemical data for various bonds of the same element. If this entails not only a change in the polarity but also in the degree of hybridisation of the bonds, Eqn. (1) automatically reflects all the effects as changes in electronegativity.

At the present time there are unfortunately no general methods for an *a priori* determination of the type and degree of hybridisation, except for the thoroughly investigated case of carbon. Nevertheless the importance of this factor in the calculation of electronegativity is obvious and was recently again demonstrated by Dobrotin[6,7] for rare-earth compounds. Therefore, in relation to the concept of electronegativity, the problem is solved by a purely empirical procedure, by determining the electronegativities of whole groups of atoms (radicals) thereby taking into account the immediate environment of the given atom. This method was first used in 1955 by Pritchard and Skinner[8] and then by Finemann[9,10].

The latter author suggested that the thermochemical electronegativities of radicals be calculated from Pauling's Equation (1), with the atom B replaced by the radical R. It is then necessary to bear in mind that the energy of one of the covalent bonds must also be included in the calculation in the form $E(R-R)$. In some studies this was disregarded and incorrect values were obtained as a result.

The electronegativities of polyvalent atoms or free radicals, for example of the type AB, where A is a di- or tri-valent metal and B a halogen, can be calculated by the thermochemical method. Such calculations were recently performed by the present author[11] with the aid of the formula

$$\Delta X^s_{A^\bullet-B} = \Delta X^s_{A-B} + 0.433[(E_{A^\bullet-B} - E_{A-B}) + {}^1/_2(E_{A-A} - E_{A^\bullet-A^\bullet})]\,, \quad (3)$$

which can be readily derived from Pauling's basic equation for a normal molecule and a free radical. The results of the calculations are presented in Table 1, which includes for comparison the electronegativities of metals in the covalent state used in the calculation. Table 1 shows that the difference between the electronegativities of the metals decreases on formation of free radicals. The physical reason for this consists in the effect of free electrons on bond energies. Thus the presence of a free electron pair lowers the electronegativity of the atom in consequence of the repulsion between this pair and the valence electrons (in Group III elements); an isolated electron has a dual effect —on the one hand it repels the valence electrons and therefore lowers the electronegativity and on the other hand it increases the contribution to bond energy due to electron pairing. Evidently the repulsion effect of the free electron will predominate in small atoms (beryllium) and will gradually decrease with increasing interatomic distances (magnesium etc.); the spin–spin interaction does not depend on bond length and therefore begins to predominate in large atoms (calcium, strontium, and barium).

Table 1. Electronegativities of metals in free radicals.

Atom	$X_{A^\bullet}$	X_A	Atom	$X_{A^\bullet}$	X_A
Be	1.3	1.5	B	1.6	2.0
Mg	1.2	1.2	Al	1.3	1.5
Ca	1.2	1.0	Ga	1.2	1.6
Sr	1.2	1.0	In	1.2	1.7
Ba	1.2	0.9			
Zn	1.5	1.6			
Cd	1.5	1.7			

In concluding the description of the results derived by classical thermochemical methods for the determination of electronegativities, data will be presented on the effect of bond multiplicity using the carbon atom as an example. Approximate calculations showed[4] that the electronegativity of carbon decreases in the direction of the multiple bond ($X_{C=} = 2.1$, $X_{C\equiv} = 2.0$), increasing in the opposite direction ($X_{=C-} = 2.9$, $X_{\equiv C-} = 3.6$). Calculation of the average electronegativity of the carbon atom yields $X = 2.5$ for ethylenic carbon and $X = 2.4$ for acetylenic carbon. Thus, on formation of a multiple bond, the capacity of the atom to attract valence electrons changes.

The thermochemical method is the first and fairly accurate procedure for the determination of the electronegativities of the elements and is therefore frequently used as a comparison scale for other methods of calculation of atomic electronegativity. However, it should be recalled that it is not free from disadvantages. Apart from the considerations described above, one other factor

must be pointed out. In Pauling's equation it is postulated that the energy of a polar bond consists of the constant energy of the covalent bond and an additional "ionic" energy, although it is evident that, with increasing ionisation of the atom, the coulombic component of the bond energy will increase and the covalent component will fall. Energetic methods for estimating atomic charges, which will be examined below, have been developed on this basis.

Although the basic equation is formally incorrect, in practice the energy of the covalent bond varies within a small range, as can be readily shown by calculating, for example, the overlap integrals for purely covalent and purely ionic bonds of the same atoms at fixed distances. Furthermore the energy of the covalent bond is significantly lower than the electrostatic energy of the interaction between the same atoms over the same distance and therefore even a large relative error in the covalent components of the energy introduces a small absolute error into the final result.

Recently McDaniel and Yingst[12] proposed a new thermochemical procedure for the calculation of the electronegativities of atoms and radicals. By considering the thermochemical cycle for the dissociation of an acid and its oxidation in aqueous solution, the authors arrived at the following expression after a number of simplifications (and reasonable assumptions):

$$0.059\,\mathrm{pK}\,\Omega - E^0 = (X_A - X_H)^2\,, \qquad (4)$$

where E^0 is the electromotive force of the half-cell in the oxidation of the acid residue A^- and $pK\Omega$ was determined for the acid HA at 25°C. It is significant that it proved possible to calculate by means of this equation the electronegativities not only of elements but also of a number of molecular radicals.

The "thermochemical" electronegativities will be used by the present author subsequently in the compilation of a table of electronegativities.

2. The Use of Geometrical Characteristics

The electronegativity of an atom is evidently determined by the force of attraction of its valence electrons by the effective charge of the nucleus. Therefore it is quite reasonable to employ the geometrical characteristics of atoms and molecules for the calculation of electronegativity.

The concept of electronegativity was first applied in the calculation of interatomic distances by Schomaker and Stevenson[13], who suggested that the bond length be calculated from the formula

$$r_{AB} = r_A + r_B - 0.09\Delta X_{AB}\,, \qquad (5)$$

where r_A and r_B are covalent radii. The Schomaker–Stevenson formula was subsequently justified quantum-chemically and found numerous applications[14–18]; it led to the possibility of the solution of the converse problem—the calculation of electronegativities from atomic radii. The general form of the corresponding equations is

$$X = a\frac{Z^*}{r^n} + b\,, \qquad (6)$$

where $n = 1$ in Gordy's formula[19] and $n = 2$ in Allred and Rochow's equation[20]. The principal result of the application of these expressions is that, for atoms having the inert gas electronic structure, the "geometrical" electronegativities are close to the thermochemical values, but, for atoms containing d- and f-electrons in the outer or penultimate shell, the "geometrical" electronegativities are significantly smaller than the generally accepted values. For example, the thermochemical electronegativities for the copper and zinc subgroups are[5]:

Cu	Ag	Au	Zn	Cd	Hg
1.90	1.93	2.54	1.65	1.69	2.00 .

while the values obtained by Gordy and by Allred and Rochow are respectively:

0.96	0.91	0.92	1.21	1.13	1.12
1.75	1.42	—	1.66	1.46	—

The reason for this difference lies in the inadequacy of Slater's rules, which were used to calculate the effective nuclear charge. The more accurate system of Z^* values put forward recently[21] made it possible to bring the geometrical and thermochemical electronegativities much closer together, the difference between the two series of values remaining virtually the same throughout the Periodic System. For example, the average geometrical electronegativities for metals in copper and zinc subgroups are[22]:

Cu	Ag	Au	Zn	Cd	Hg
1.74	1.66	1.97	1.76	1.68	1.80 .

A disadvantage of the geometrical method for the calculation of electronegativities in some cases is the indeterminate valence state of the element in a number of simple compounds from which the interatomic distances were taken. However, in most cases there is no doubt about the valence of the atoms for which the geometrical electronegativity is calculated, and therefore the latter may be used in the compilation of the electronegativities of the elements.

Using the geometrical method, it is possible to determine the electronegativities of carbon atoms involved in multiple bonds. These calculations were performed between 1960 and 1964 [4,22,23] and their results are in good agreement with the data derived by the thermochemical method. When account is taken of the fact that the effective nuclear charge of the carbon atom also depends somewhat on the state of hybridisation and when appropriate ionisation potentials are used to calculate Z^*, then, on the basis of $Z^* = 3.25$ adopted for sp^3-hybridisation, it is easy to show that in the direction of the multiple bond $Z^*_C = 3.09$, $Z^* = 3.39$, for sp^2-hybridisation, and $Z^* = 3.64$ for sp-hybridisation. Hence, using the Allred–Rochow equation and the Gordy–Batsanov formula and also the geometrical characteristics of the multiple bonds taken from the literature[4,22], we arrive at the following electronegativities: 2.5 for sp^3-hybridisation, 2.7 for sp^2-hybridisation, 3.1 for sp-hybridisation, 2.2 for the double bond, and 2.1 for the triple bond.

Thus, if on formation of a multiple bond the electronegativity of the atom decreases in the direction of the bond, the effective charge of the atomic nucleus and its electronegativity become saturated as a result of the enhanced attraction of electrons from the opposite side of the atom. The geometrical method has also been applied in the calculation of the electronegativities of radicals. The first attempt was made by Wilmshurst[24], but, although the results were acceptable in practice, they were nevertheless incorrect from a formal standpoint[4]. A more successful attempt was made by Yan[25], who calculated the electronegativities of radicals with the aid of the equation

$$X = a\frac{n^*}{r^*} + b\,, \qquad (7)$$

where r^* is the effective radius of the central atom of the radical and n^* the number of effective valence electrons

(i.e. actually Z^*) calculated by Sanderson's method (see below).

Somewhat isolated from the trend discussed here is a whole series of studies by Sanderson[26-28], who observed that the average electron density of atoms varies in parallel with their electronegativity. By expressing the electron density of the element as a fraction of the electron density of the corresponding inert gas, Sanderson obtained quantities which he called "stability ratios" (SR) and which are tabulated in the present author's monograph[4] and will not be quoted here. The stability ratios and Pauling's electronegativities are simply related:

$$X^{\frac{1}{2}} = 0.21 \quad \mathrm{SR} + 0.77 \ . \tag{8}$$

We shall return to these studies later.

3. The Use of Spectroscopic Data

The first paper describing the relation between electronegativity and spectroscopic characteristics was published by Gordy[29], who established the following empirical relation:

$$k_{AB} = aN \left(\frac{X_A X_B}{r^2}\right)^{0.75} + b \ , \tag{9}$$

where r is the atomic distance, N the bond multiplicity, a and b are constants, and k is the force constant of the bond. Gordy's "spectroscopic" electronegativities are in good agreement with the thermochemical and geometrical values. However, the use in calculations of electronegativity of dynamic proportionality coefficients reduces the value of Gordy's method, because the determination of bond force constants frequently constitutes a difficult independent problem. Therefore subsequent development of the spectroscopic determination of the electronegativities of atoms and radicals involved the establishment of a direct relation between electronegativities and characteristic vibration frequencies. Without dwelling on the history of the problem, only the general form of functions used will be indicated[30-33]:

$$\nu = a + bX \ . \tag{10}$$

Such a linear relation is at first sight incomprehensible, but if the force constant of a polar bond is put in the simplest form:

$$k \simeq c \frac{Z_1^* Z_2^*}{r^3} \tag{11}$$

and the formula for a harmonic oscillator is then used, it is readily seen that

$$\nu \propto \frac{Z^*}{r^{1.5}} \ . \tag{12}$$

Comparison of Eqns. (6) and (12) shows that the exponent of the atomic radius in Eqn. (12) is the average of the values of n from Gordy's and Allred and Rochow's formulae, i.e. Eqn. (12) is essentially identical with Eqn. (10). Since the latter equation does not involve the mass of the vibrating atoms, in the calculation of electronegativities one usually compares the frequencies of the same A–B bond in molecules of the type ABC_n, where C_n is a variable atom or radical. However, comparison of the data of various workers shows that there is a considerable scatter in their results, which can be explained by the fact that bond frequencies cannot strictly be regarded as isolated, being influenced by the geometry of the molecule in addition to the nature of the chemical bond.

Like the thermochemical and the geometrical procedures, the spectroscopic method shows that the electronegativity of the atom increases in the direction opposite to that of the multiple bond and to a greater extent the larger is the multiplicity of the bond. In the direction of the multiple bond itself, the atomic electronegativity of carbon falls, as follows from the application of Gordy's formula to this case[23]: if it is assumed that $X_C = 2.5$, we have 2.3 and 2.2 respectively for C= and C≡ and similarly for nitrogen we have $X_{N=} = 3.0$ and $X_{N\equiv} = 2.8$.

The calculation of electronegativities from electronic spectroscopic data (optical electronegativities) is very interesting. Here mass does not play a significant role and therefore it is possible in principle to obtain more accurate values. Jörgensen and coworkers[34-36] showed that the wave number of the electronic transition for complexes of the type $MHal_n$ is proportional to the difference between the electronegativities of the central atom and the halogen. On the basis of the generally accepted electronegativities of the halogens, the authors obtained a number of electronegativity values for complex-forming metals.

This development in the calculation of atomic electronegativities is very promising; calculations of this kind can probably detect effects such as the trans-effect and other forms of interatomic interaction in the inner sphere of complex compounds.

Apart from the relation between electronegativities and vibration spectra, definite relations between the electronegativities of atoms and radicals on the one hand and spectroscopic characteristics on the other have been observed also in the radiowave part of the spectrum. This field was pioneered by Dailey and Shoolery[37], who established that the chemical shift (CS) of the nuclear magnetic resonance frequency of the hydrogen atom in alkyl derivatives is linearly related to the electronegativities of the radicals linked to the carbon atom:

$$X = 0.01158\delta + 1.71 \ , \tag{13}$$

where δ is the internal chemical shift in the ethyl group between α- and β-protons. Since these measurements were made in benzene solution and the latter exhibits an anomalous dilution effect, Cavanaugh and Dailey[38] later repeated the measurements in carbon tetrachloride solution and obtained more reliable data, which are described by the equation

$$X = 0.0114\delta + 1.78 \ . \tag{14}$$

The electronegativities of oxygen-containing radicals[39], Group IV elements[40], and Group IIb metals[41] have been calculated from similar equations.

Comparison of "radiowave" electronegativities with the "optical" values shows that in most cases the agreement is satisfactory. However, the electronegativities of certain radicals and in particular of CN, are significantly smaller than the generally accepted values. The reason for this lies in the inadequacy of the method of calculation of electronegativity from an equation of the type of Eqn. (14). Heel and Zeil[42,43] showed that, to a first approximation, the chemical shift measured experimentally consists additively of a term which depends on the chemical bond and terms characterising the geometry of the molecule only:

$$\delta = a + b + c + d \ , \tag{15}$$

where a is determined by the chemical difference between the protons, b is a diamagnetic correction which depends on the trial form adopted, c depends on the intermolecular interaction, and d characterises the magnetic anisotropy of the atoms and radicals within the molecule. The low value

of the "radiowave" electronegativity is due to the neglect of the factor d by Dailey and Shoolery[37].

To avoid errors, Heel and Zeil suggest that the comparative method be used to establish the relation between the chemical shift and electronegativity. With the available data on the magnetic resonance of two protons in α- and β-positions, it is possible to derive a difference equation in which the factors b and c vanish. Having chosen an appropriate pair of compounds, it is also possible to write yet another difference equation, the combination of which with the previous equation yields a double difference expression, involving only the relation between the factor a and the electronegativity.

A similar idea was developed by Thompson and Davis[44], who suggest that in compounds of the type AB_3, where B is a halogen or an organic radical, the chemical shift depends only on bond polarity and not on the presence of multiple bonds. Therefore the equation for calculations is of the form

$$\delta = a + bX + c\delta_\pi , \qquad (16)$$

where the bond multiplicity δ_π is determined independently. As a result, it is necessary to subtract the term $1.79\delta_\pi$ in order to obtain the polar component of the chemical shift from the measured value of δ.

Very interesting results have been obtained by Muller and Pritchard[45], who established a relation between the quadrupole bond constant in substituted hydrocarbons (CH_3A) as a function of the electronegativity of A and the interatomic distance r_{C-A}:

$$\chi_{C-H} = 22.6X + 40.1r_{C-A} + 5.5 , \qquad (17)$$

The data presented in this section do not exhaust all the results obtained by the application of spectroscopic methods for the determination of the electronegativities of atoms and radicals, but the principal studies carried out in recent years have been examined.

4. The Use of Ionisation Potentials in Quantum-chemical Calculations

Immediately after the development of the thermochemical method for the determination of the electronegativities, Mulliken[46] suggested that atomic ionisation potentials be used to calculate the electronegativity values. According to Mulliken, the arithmetical mean of the ionisation potential and the electron affinity of the atom in the given valence state is a measure of its electronegativity:

$$X \simeq {}^1/_2(I + E) . \qquad (18)$$

In order to convert Mulliken's values into Pauling's electronegativities, it is necessary to divide the former by a constant (for example 3.27, according to Pilcher and Skinner[47]).

Mulliken's method has been justified quantum-chemically both by Mulliken himself[48] and in Moffit's work[49,50]. Having written the wave function for the bond A–B in the form of a superposition of the wave functions for the purely ionic and purely covalent bonds between the same atoms, Moffit varied the coefficients of these terms in a way which ensured that the condition for formation of a non-polar bond is maintained. Assuming further that the energy of the atomic orbital is approximately equal to the ionisation potential of the corresponding electron and that the difference between the energy of the orbital and the coulombic integral is equal to the electron affinity, he arrived at Eqn. (18) as a measure of the electronegativities of atoms A and B.

The most interesting feature of Mulliken's method is the possibility of calculating the electronegativities of atoms in various valence states and for various degrees of hybridisation. In fact both the ionisation potential and the electron affinity depend significantly on the orbital where the relevant electron is located. Hence it is possible to solve also the converse problem—to determine the degree of hybridisation of the atom in a given compound from the known electronegativity (for example, the thermochemical value) and the known electronegativity values for various orbitals.

Skinner and Summer[51] found by Mulliken's method that the electronegativity of copper is 1.36 in the s-state and 3.32 in the d-state. Using the thermochemical electronegativity of copper, they calculated that in the given case copper is present to the extent of 23% in the d-state. Similar calculations have also been made for nickel.

Later Pilcher and Skinner[47] calculated the Mulliken electronegativities for atoms of the Second Period of Mendeleev's Table in various hybridisation states, which are in good agreement with the electronegativities for single and multiple bonds derived by other procedures. Table 2 presents the corresponding data converted into Pauling electronegativities.

Table 2. Effect of hybridisation on atomic electronegativities.

Element	Orbitals				
	p	sp^3	sp^2	sp	s
Be	—	—	—	1.43	—
B	—	—	1.91	—	—
C	—	2.50	2.74	3.20	—
N	2.46	3.51	3.74	4.40	—
O	3.32	4.66	—	—	2.19

A significant advance in the development of an ionisation method for the determination of electronegativities was made by Iczkowski and Margrave[52], who drew attention to the fact that the ionisation energy of the atom can be represented as a function of the charge:

$$I(q) = aq + bq^2 + cq^3 + \ldots , \qquad (19)$$

where a, b, c, ... are coefficients and q is the number of electrons in the valence shell. However, in practice only the first two terms need be retained in Eqn. (19). Differentiation of this equation with respect to q leads to the formula

$$\frac{\partial I}{\partial q} = a + 2bq . \qquad (20)$$

After substituting $q = 1$ and $q = 2$ in Eqn. (20), one obtains (see Iczkowski and Margrave[52] and Klopman[53])

$$\left(\frac{\partial I}{\partial q}\right)_{q=1} = \frac{I_v + E_v}{2} . \qquad (18a)$$

Thus Iczkowski and Margrave's hypothesis that the electronegativity is a derivative of the energy with respect to charge leads to Mulliken's formula.

Iczkowski's paper was followed by a series of papers by Hinze and Jaffe[54–56], in which the electronegativities were also determined as $\partial I/\partial q$ and the ionisation energies themselves were calculated for the given valence state quantum-chemically using the experimental or interpolated ionisation potentials for the ground state. A significant feature

of these studies is the fundamental approach to the concept of electronegativity not as a property of an abstract atom but as a property of its concrete electronic orbitals in the given chemical compound. The authors introduce the concept of "orbital electronegativity" (OEO) which characterises the capacity of an atom in a molecule to attract an electron to the given orbital. Hence it is clear that orbital electronegativity is a derivative of the energy of the atom and depends on the number of electrons in the orbital.

It is readily seen that this definition is based on two assumptions: (1) that the number of electrons in the orbital can be arbitrary in the range 0–2, including non-integral values; (2) that the energy is a continuous and differentiable (with respect to q) function. To justify both assumptions, one may refer to the experimentally determined distribution of electrons among the bonds joining atoms in molecules and crystals which leads to fractional charges on the atoms in the case of polar bonds. Another test of these assumptions can be provided by the similarity of the electronegativities calculated in this way to the values determined by independent methods.

Table 3. Group electronegativities according to Hinze and Jaffe.

Group R	R (–R)	R (–F)	R (–H)	Group R	R (–R)	R (–F)	R (–H)
CH_3	2.30	1.93	2.33	NH_2	2.82	2.61	2.96
CH_2Cl	2.47	2.13	2.55	PH_2	2.06	1.76	2.04
$CHCl_2$	2.63	2.32	2.77	OH	3.53	3.45	3.82
CCl_3	2.79	2.50	2.98	SH	2.35	2.11	2.38

The possibility of the determination of group electronegativities by the Hinze–Jaffe method is also very important[55]. These values are calculated on the assumption of a certain degree of hybridisation and polarity of the bond in radicals. Hence it follows immediately that the group electronegativity will depend to a high degree on the atom or radical with which the given group is linked. To characterise this effect, Table 3 lists the group electronegativities for covalent radicals (i.e. for radicals linked to groups of precisely the same kind) and for radicals combined with hydrogen and fluorine. Table 3 shows that the trend in the changes of the electronegativity values for radicals remains constant in all three cases but, if one includes, for example, hydrogen ($X = 2.20$) in this series of radicals, then it is readily seen that its relative position will differ appreciably depending on the atom with which it is combined. We shall return to this problem later.

The use of ionisation potentials for the calculation of electronegativities appears to be a very attractive procedure and this is in fact widely done by various investigators. Of the work of Soviet investigators, one should mention the studies of Nekrasov[57] and Povarennykh[58] and concerning the work of non-Soviet scientists one may refer to Chang's study[59], wherein an extensive calculation was made of the electronegativities of atoms in various states of hybridisation from formulae genetically related to Mulliken's equation. It must, however, be pointed out that ionisation potentials have to be used very cautiously, taking into account the peculiarities of this property. Thus, in an attempt to calculate the ionisation electronegativities of radicals, Pritchard and Skinner[8] used the values of I and E for the ground state and the same conversion factor as for the atomic ionisation potentials in the valence state. According to the data of Hinze and Jaffe, the equation relating the Mulliken electronegativities to Pauling's values is of the form

$$X_P = 0.336(X_M - 0.615) \quad (21)$$

On the other hand, if the ionisation potentials for the ground state are used, the formula is somewhat different:

$$X_P = 0.4(X_M - 0.5) \quad (22)$$

However, even the use of Eqn. (22) does not save the situation. The reason is that the ionisation potential and the electron affinity of a radical are essentially determined for different components, i.e. different atoms. As a simplification, one can of course postulate that the first ionisation potential of the radical corresponds to the removal of an electron from the negatively charged component. Similarly the electron affinity of the radical corresponds to the addition of an electron to the positively charged component. Consequently we are not justified in combining the ionisation potential determined for the radical with its electron affinity. Eqn. (18) can be used only when we can determine for the same atom in the radical both the ionisation potential and the electron affinity.

So far Mulliken's method can be applied to covalent molecules of the type A_2, where the above indeterminacy does not exist. The present author believes that the best way of applying Mulliken's method to molecular problems consists in comparing the sum of ionisation potentials and electron affinities for the molecules and the isolated atoms and then introducing corrections to the standard electronegativity on the basis of this comparison[60,61]. It has been shown[4] that the electronegativity of an isolated A atom is higher by 20% than the value in the molecule A_2. The reason for the increase of electronegativity on going from a covalently linked atom to a free atom consists precisely in the presence of the free valence, which leads to an additional energy gain on formation of the bond due to the electron pairing energy.

Similarly it proved possible to determine also atomic electronegativities for aqueous solutions[62] (Table 4). It is interesting that the electronegativities of metals are sharply reduced as a result of the hydration of the cations in aqueous solutions (Table 4).

Using the ionisation potentials and electron affinities of the carbon atom in various states of hybridisation, it proved possible to show[4] that $X_{C=} = 2.0$, $X_{=C-} = 2.8$, and $X_{\equiv C-} = 3.1$, i.e. to obtain a result similar to that derived by all other methods for the determination of electronegativities.

5. Compilation of Electronegativities

The above data show that the electronegativity of an atom depends on its valence, state and degree of hybridisation of its bonds, and even on the medium in which the given molecule is located. However, this is a characteristic feature of many concepts in structural chemistry. For example, the concept of the atomic radius was initially formulated by Bragg as a constant for a given element. Then the radii were differentiated into ionic and covalent, metallic and van der Waals. Within each Group relations were subsequently established between the radii and the valence of the atom, its coordination number, or bond multiplicity; molecular radii for ions in aqueous solutions have been derived.

Table 4. Electronegativities of the elements in aqueous solutions.

Group / Period	1a	2a	3a	4a	7a	8a	1b	2b	3b	4b	6b	7b
I	H 0.32											
II	Li 0	Be 0.13										F 3.87
III	Na 0.11	Mg 0.17							Al 0.18		S 2.28	Cl 3.15
IV	K 0.06	Ca 0.09	Sc 0.14	Ti 3+ 0.16	Mn 2+ 0.18	Fe 2+ 0.28 3+ 0.35 Co 2+0.28 Ni 2+0.34	Cu 1+ 0.32	Zn 0.38	Ga 0.25			Br 2.71
V	Rb 0.04	Sr 0.08	Y 0.07				Ag 0.55	Cd 0.46	In 0.31	Sn 2+ 0.44		I 2.34
VI	Cs 0.02	Ba 0.06	La 0.06					Hg 0.56	Tl 0.44	Pb 2+ 0.41		
VII		Ra 0.09										

Although this procedure increases our information about the structure of matter, this type of development of a concept reflects the fact that a molecule or a crystal is regarded as approximately a collection of interacting atoms. In a more rigorous approach, where the molecule or a crystal is regarded as a single system, a collection of nuclei and electrons, all the additive concepts of structural chemistry vanish altogether. Therefore a rigorous solution of the many-electron problem is impossible: in practice investigators use the "atoms in the molecule" method and then all that has been said above is valid.

The methods for the determination of electronegativities discussed in Sections 1–4 yield values characterised by different dimensions, which is undesirable for a physical concept. This disturbs some investigators (see, for example, Iczkowski and Margrave[52]) and can lead to misunderstanding of the role and position of the concept of electronegativity in the treatment of the nature of the chemical bond. The point, however, is that the concept of electronegativity is chemical in nature, reflecting one of the aspects of the chemical bond and therefore it cannot be characterised, in principle, by only one physical dimension. Chemical combination of atoms leads to a change in size, energy, and spectroscopic, magnetic, electrical, and other properties of the elements and can be adequately expressed in terms of these properties. However, it is evident that none of the properties enumerated above can exhaustively describe all the specific features of the reaction, the entire chemistry of the phenomenon. One can assert that a wide variety of dimensions of the concept is encountered not only with electronegativities but also with any other chemical concept. This can be demonstrated by examining the possible quantitative characteristics of the dimensions of such concepts as "metal", "hydrogen bond", "acid", "reactivity", etc.

Table 5‡ presents a compilation of the electronegativities of the elements, which can be recommended at the present time on the basis of the results obtained by different methods. Table 6 lists examples of the effect of bond multiplicity on atomic electronegativities.

‡ For hydrogen, antimony, and the actinides, the upper rows correspond to the lower-oxide state, and the lower rows to the higher-oxide state.

The same values can be used for an approximate calculation of the electronegativities of other atoms with multiple bonds, as can be seen in Table 7, where the electronegativities of molecular radicals are compiled. These are the electronegativities of the atoms in the radicals which are combined with the remainder of the molecule, for example, oxygen in NO_3 or nitrogen in NO_2. In compiling Table 7, the data of Ettinger[63] and Huheey[64] were used in addition to those quoted earlier.

In conclusion of this Section, we can consider briefly the problem of the electronegativities of the inert gas atoms. The problem of the calculation of these quantities arose after the publication of work on the fluorides and oxides of the inert gases and therefore the first electronegativities of inert gases were calculated (by Mulliken's method) as late as 1963 by Neiding[65] and Rundle[66]. The data of Sanderson[28] and Fung[67], obtained by means of different methods, are more correct. These values are in fact used in Table 5. Sanderson made the significant remark that the electronegativities of the inert gases must be understood not as the oxidising capacity of the elements but as the capacity of the atoms to resist the removal of their electrons on formation of a polar bond.

III. THE SCOPE OF THE APPLICATION OF THE CONCEPT OF ELECTRONEGATIVITY

As already stated above, any of the methods of calculation can be used to apply electronegativities. In this section we shall examine the use of the concept of electronegativity in the treatment of chemical properties only of substances (mainly inorganic) and various manifestations of the nature of the chemical bond in molecules and crystals. However, before presenting the factual data, several preliminary comments must be made.

The concept of electronegativity is not a theory in the sense that it does not explain experimental findings on the basis of some new hypotheses. It permits only the estimate or measurement of the asymmetry of the electron cloud of the bond, i.e. it makes it possible to say which of the species involved in the bond has a negative and which a positive charge and what is the approximate magnitude of these charges. Having obtained such information, the investigator can set up (on the basis of a familiar theory or

Table 5. Electronegativities of the elements.

relation) a hypothesis concerning the law governing the variation of the chosen physicochemical property of the substance as a function of the polarity of its bond. Thus, for a successful application of the concept of electronegativity, it is necessary to know how the ionic character of the chemical bond influences a given characteristic and only then introduce quantitative criteria.

The above limitations do not diminish the scope of the concept of electronegativity, since millions of molecules and crystals have structures involving polar bonds and the total number representatives of extreme types of bonds in nature amounts to only several hundred. Therefore the study of polar bonds is of great theoretical and practical importance.

1. Atomic Charges in Molecules and Crystals

Even simple comparison of the electronegativities of two atoms makes it possible to say which of them will behave as an electron donor or acceptor on formation of the bond. However, additional theoretical and experimental data must be used to establish a quantitative relation.

The first functional relation between the ionic bond and the difference between atomic electronegativities was established by Pauling[68] in 1939. Having adopted as the reference points the effective atomic charges in hydrogen halide molecules, calculated from the simple formula

$$i = \frac{\text{dipole moment}}{\text{bond length}} \qquad (23)$$

and the thermochemical electronegativities, he obtained a smooth curve, which fits the following equation:

$$i = 1 - e^{-0.25\Delta X^2}. \qquad (24)$$

After the dipole moment of hydrogen fluoride had been corrected, Pauling modified Eqn. (24):

$$i = 1 - e^{-0.18\Delta X^2}. \qquad (25)$$

Table 8 lists the values calculated by this formula.

The validity of Eqn. (25) has been confirmed theoretically by many investigators (see the present author's monograph[4] for a more detailed description), who obtained by independent methods similar values for the ionic character of hydrogen halide molecules and certain other simple cases. It is significant that even the most accurate atomic charges obtained by Barinskii and Nadzhakov[70] by X-ray spectroscopy are also in fairly good agreement with Pauling's data. The experimental percentages of the ionic character of the bonds§ are listed below (first row) together with the theoretical values (second row) obtained from a comparison of the data in Tables 5 and 8.

0	2	5	20	5	20	32 .

§ Calculated from the atomic charges.

Chronologically the next important study on the use of electronegativities for the calculation of the ionic character of bonds in molecules is that of Sanderson[26-28]. According to Sanderson, the stability ratio (i.e. the electronegativity in his terminology) of any atom in a molecule is equal to the stability ratios of all the remaining atoms, i.e. on formation of the bond the stability ratios of the atoms become equalised. This postulate is almost self-evident, since it is clear that in a stable molecule or bond the electron pair will be located at such a distance from each species involved that the attraction which it exerts is balanced out and this means that the stability ratios are equalised. Sanderson suggests that in practice the geometrical mean stability ratio be calculated as the value for the molecule AB:

$$SR_{AB} = \sqrt{SR_A \times SR_B}\,. \qquad (26)$$

Table 8. Dependence of the ionic character of the bond in molecules on electronegativity.

ΔX	i	ΔX	i	ΔX	i	ΔX	i	ΔX	i	ΔX	i
0.0	0	0.5	7	1.0	20	1.5	35	2.0	51	3.0	80
0.1	1	0.6	9	1.1	23	1.6	38	2.2	58	3.2	84
0.2	2	0.7	11	1.2	26	1.7	41	2.4	64	3.4	88
0.3	3	0.8	14	1.3	29	1.8	44	2.6	70	3.6	91
0.4	5	0.9	17	1.4	32	1.9	47	2.8	75	3.8	93

Having further postulated that the ionic character of the bond in the sodium fluoride molecule amounts to 75%, Sanderson was able to calculate the ionic electronegativities of the sodium and fluorine atoms and then of all the remaining elements in the Periodic System. When the set of covalent and ionic stability ratios is available, it is easy to calculate the ionic character of the bond from the equation

$$i = \frac{SR_{AB} - SR_{A^0}}{SR_{A^+} - SR_{A^0}}\,. \qquad (27)$$

Comparison of the values of the ionic character of the bond obtained by Sanderson's and Pauling's methods shows that the average statistical discrepancy amounts to 10%.

However, extension of Sanderson's method to more complex compounds (including complexes) leads to incorrect results[71]. This is reasonable, since, for example, in potassium sulphate there are two independent (to a first approximation) bond systems, K–O and S–O, and there is no need for the requirements that the stability ratios of the potassium and sulphur atoms should be equalised on formation of this compound.

The present author proposed a modification of Sanderson's method, based on the postulate that the electronegativity of an atom is a characteristic of one valence state[72] (see also Iczkowski and Margrave's definition of electronegativity). Therefore the method of calculating the stability ratio for a compound was modified so that under the root sign the stability ratios of the species involved in the bond were each raised to a power equal to the product of the valence of the atom and the number of such atoms in the given molecule:

$$SR_{A_nB_m} = \sqrt[np+mk]{SR_A^{np} \times SR_B^{mk}}\,, \qquad (28)$$

where p is the valence of atom A, k the valence of atom B, and n and m are the numbers of atoms A and B in the molecule respectively. Since in neutral molecules $np = mk$, Eqn. (28) transforms into

$$SR_{A_nB_m} = \sqrt{SR_A \times SR_B}\,. \qquad (29)$$

Thus on formation of any complex molecule only the stability ratios of linked atoms are equalised and the stability ratio of the molecule must be equal to the geometrical mean of the values for the species involved in the chemical bonds.

The suggested modification of the method makes it possible to avoid the contradictions which arose in the calculation of the stability ratios of molecules containing polyvalent atoms. For example, according to Sanderson the stability ratio of the sodium atom in Na_2O is less than in sodium itself and therefore the ionic character in the first case is lower than in the second, which is incorrect. Sanderson's modified method can also be applied in the calculation of the stability ratios of complex ions, for example the sulphate ion:

$$SR_{SO_4} = \sqrt[7]{SR_S^3 \times SR_O^4}\,. \qquad (30)$$

On comparing the stability ratio of the sulphur atom in the sulphate ion with the values for neutral and positively charged sulphur, it is readily seen that $SR_{SO_4} = 4.48$ corresponds to a charge of +0.15 on the sulphur atom. The stability ratios of a number of oxygen-containing anions, listed in Table 9 together with the charges of their central atoms, were calculated similarly. Comparison of the data in Tables 7 and 9 shows that the sequences of experimental and theoretically calculated electronegativities of radicals are the same.

Table 9. Stability ratios (SR) and charges (Z) of atoms in complex ions.

A procedure for the determination of the ionic character of the bond, similar to Sanderson's method, was developed by Lakatos[73-75], who suggested that, on formation of the molecule AB, the forces which the effective charges of the nuclei of the atoms A and B exert on the valence electrons should be equalised. This hypothesis enabled Lakatos to obtain results differing on average by 7% from the amounts of ionic character calculated by Pauling's method.

Simultaneously with Lakatos, Fereira[76] used the idea of the equalisation of electronegativities on bond formation. He concentrated particularly on the relation between the electronegativity of the atom and its effective charge q.

Having expressed the electronegativity of the real atom by a power series, as suggested by Daudel[77,78]

$$X(q) = X(0) + a\left(\frac{\partial X}{\partial q}\right) + \cdots \quad (31)$$

and having retained only the first and second terms of the expansion, Fereira was able to calculate, on the basis of the postulated equality of $X_A(q)$ and $X_B(q)$ in the A–B bond, the amounts of ionic character in the bonds of hydrogen halides, in good agreement with Pauling's data: 32% for HF, 16% for HCl, 10% for HBr, and 5% for HI.

The equalisation principle has also been used in the method of orbital electronegativities[79-81]. Since in this method the electronegativity of an atom is also represented by a linear function of the charge, the formulae and the results are very similar to those obtained by Fereira.

The data presented show that Sanderson's idea of the equality of the electronegativities of atoms when these form a stable bond has been widely accepted and has given rise to the possibility of calculating the ionic character of the bonds in molecules, the result being in qualitative or even semiquantitative agreement with experiment. It is only fair to mention that Sanderson's postulate originates from the fundamental work of Pauling[68], who established that, when an atom acquires a positive charge, its electronegativity increases (approximately by 0.4 for each +1 unit of charge) and on acquisition of a negative charge it decreases to the same extent. As a result, on formation of a polar bond, the electronegativity of the cationic component of the molecule increases and that of the anionic component falls, i.e. the electronegativities of the two atoms approach one another. The electronegativity increments quoted by Pauling for ± 1 units of charge are, of course, approximate and corrected values will be given below: here it is desired to mention only the fundamental aspect of the problem.

The approach to the determination of the ionic character of bonds in molecules examined above has been criticised by Pearson and Gray[82], who remarked that the equalisation of electronegativities only reduces the mutual electrostatic energy and the change in the overlapping of the wave functions is not taken into account. However, the Coulombic component of the energy of polar bonds is the major component of the total bond energy and therefore the above approximation is in practice quite acceptable. Pritchard[83] took into account the effect of the change in the overlapping of the orbitals for the carbon–nitrogen bond and showed that the electronegativities of the atoms are not then equalised but their values approach one another—after the formation of the bond the difference between the electronegativities of the species in the bond amounts to only 10% of ΔX for these atoms before interaction. This calculation yields a characteristic estimate of the degree of approximation in the "electronegativity equalisation" method.

The ionic character of the bond can be calculated also with the aid of overlap integrals (OI). The latter characterise the electron density of the bond and in a series of similar molecules vary quite steadily, namely the overlap integral decreases with increasing ΔX, i.e. bond polarity. However, for a quantitative solution of the problem, it was necessary to normalise the overlap integrals, i.e. to adjust them to a single scale. For this purpose, the present author suggested[21,84,85] that the overlap integral of a real bond A–B be compared with the overlap integral of a purely covalent bond between the same atoms, the latter being defined as a bond whose length is equal to the sum of the covalent radii and whose polarity is zero (the second condition means that the effective charges quoted for the atoms A and B are equal). Then the ratio of the overlap integrals of the real and purely covalent bonds represents the covalent character of the bond A–B. Calculations showed that the results are close to Pauling's data and are described by the same equation:

$$i = 1 - e^{-0.25\Delta X^2}. \quad (32)$$

We now come to the description of methods in which empirical data are used, the reader being referred to the present author's monograph[4] where other theoretical studies on the calculation of the ionic character of ionic bonds in molecules carried out up to 1960 are described. The first method using experimental data for the calculation of the ionic character is that of dipole moments [see Eqn. (23)]. Later it was shown that the dipole moment is a complex function which depends on the ionic character and hybridisation of bonds and also on the effect of isolated electron pairs.

At the present time these other factors cannot be taken into account although certain advances on those lines have been made[86]. Therefore the employment of dipole moment data can be justified only in those cases where all the factors, except the ionic character of the bond, are low or cancel out. This condition obtains in hydrogen halides.

The application of radiospectroscopic data, for example data on quadrupole interaction, which appeared very promising initially, later failed to justify these hopes, since for an unambiguous determination of the ionic character of the bond it is again necessary to know accurately the degree of hybridisation of the bond. In those cases where the latter characteristic is unknown, certain assumptions are made concerning the type and degree of hybridisation[4] and therefore the final data are of no greater value than the initial assumptions. Data on quadrupole interaction can be used directly only for qualitative purposes in comparing similar or genetically related molecules. Fundamentally important results were obtained recently by Mikhailov[87,88] and Gilson[89], who used orbital electronegativities to establish a relation between the ionic character of the bond and the quadrupole coupling constant χ. Since orbital electronegativities are themselves functions of bond hybridisation, it is possible to establish more unambiguous relations between χ and the ionic character of the bond.

A third method whereby experimental data are used to calculate the degree of ionic character of the bond is based on chemical bond energies. The principal idea of this procedure consists in the representation of the bond energy by a set of ionic and covalent terms (supplemented by a polarisation component or account being taken of bond multiplicity). On minimising such a system by the variation of the relative contributions of both terms or by comparing the calculated and experimental values, it is possible to obtain information about the ionic character of chemical bonds. In an elementary form this idea is contained even in Pauling's basic equation [Eqn. (1)] and subsequently only the calculation of the two terms of bond energy was formulated in a concrete form. In the author's monograph[4] the covalent component of bond energy was calculated with the aid of overlap integrals, while Pearson and Gray[82] used the Coulombic and exchange integrals, for complex molecules the latter being calculated with the aid of empirical data on covalent bond energies and ionisation potentials.

In a series of studies by Fereira[90-92] the ionic character of the bond was calculated by the equation

$$E(A-B) = E_{cov} + E_{coul} + \Delta E_A(q) + \Delta I_B(q), \quad (33)$$

where ΔE and ΔI are the partial electron affinity and partial ionisation potential. These concepts reflect the energies

which must be expended to remove "part of the electron" (in the statistical meaning of this term) or which are evolved on partial addition of the electron to the atom. Subsequently Fereira modified the first two terms of Eqn. (33), namely he established a relation between the covalent energy term and the ionic character of the bond, took account of hybridisation, and varied not only the polarity but also the chemical bond length in order to minimise the energy.

The energy method can be applied, however, only in simple cases—di- or tri-atomic molecules. In more complex molecules it is difficult to take into account the non-valence interatomic interaction and bond hybridisation. This is the reason why it is almost impossible to calculate the ionic character of the bond. Therefore, for fairly complex systems, the only suitable experimental method available at the present time is X-ray spectroscopy. Table 10 compares the results of X-ray spectroscopic studies on the molecules of ferrocene and its analogues[93-95], with the values calculated by the present author[96] using the electronegativity method.

Table 10. Effective atomic charges in π-complexes.

Molecule	X-ray spectrum		EO method	Molecule	X-ray spectrum		EO method
	Refs.93 and 94	Ref.95			Refs.93 and 94	Ref.95	
Fe $(C_5H_5)_2$	0.4	0.73	0.70	Ni $(C_5H_5)_2$	—	0.65	0.55
Fe $(C_5H_5)_2^+$	—	0.68	0.76	Ni $(C_5H_5)_2^+$	1.0	—	0.76
Co $(C_5H_5)_2$	0.4	—	0.70	Mn $(C_5H_5)_2$	1.5	1.6	1.25
Co $(C_5H_5)_2^+$	1.2	0.8	0.94	Cr $(C_6H_6)_2$	1.1	1.5	1.44

It follows from Table 10 that the electronegativity method can be used to describe the distribution of charges in molecules, in good agreement with experiment.

Before concluding the description of the methods of calculating charges in molecules, we must return to the question of taking into account the effect of bond polarities on atomic electronegativities. When a molecule of the type MA_2 formed by the combination of atoms M and A, the latter acquire charges i due to the ionic character of the bond. The appearance of a positive charge i increases the electronegativity while the appearance of a negative charge reduces it. As a result, in order to calculate the ionic character of the second M–A bond it is necessary to compare the electronegativity of the atom A with $X_M + ip$, where p is a constant coefficient equal to the change in X on appearance of an integral charge. Bearing in mind the equivalence of both M–A bonds in MA_2 molecules, the ionic characters of the first and second M–A bonds must be averaged. This is the general scheme of the calculation of the ionic character of the bonds in complex molecules (for other examples, see the monograph[4]).

The coefficient p can be determined using Eqn. (6). For this purpose, a variable value of the atomic radius, varying as a result of ionisation (see the author's monograph[4], p. 176), must be substituted in the formula

$$X = a\frac{Z^*}{r} + 0.54 . \qquad (6)$$

and Z^* must be changed appropriately as a function of i. Calculations for all the electropositive elements of the Periodic System show that $p = 0.4$ for Periods III–VI and $p = 0.8$ for the elements of Period II. For the electronegative elements, $p = 0.4$ (chalcogens) and $p = 0.8$ (halogens). Thus the value $p = 0.4$ postulated by Pauling has been confirmed in general. However, fundamentally different results are obtained for hydrogen. The formula for the calculation of X_H is of the form

$$X = 0.60\frac{Z^*}{r} + 0.54 . \qquad (6)$$

Assuming that the radius of the hydrogen atom varies according to the same law as for divalent cations (see Ref. 97), it is easy to calculate that the electronegativity increases anomalously with increasing charge:

Charge =	0	+0.1	+0.2	+0.3	+0.4	+0.5 ...
X=	2.1	2.5	3.0	3.6	4.4	5.6 .

Hence it follows that, after the formation of a bond, for example C–H, where the hydrogen atom should acquire a charge of +0.06, the electronegativity of hydrogen increases to 2.4, i.e. significantly approaches the electronegativity of the methyl group. If, as a result of the mutual influence of the atoms in substituted hydrocarbons, the ionic character of the C–H bond increases still further, the relative electronegativities of the carbon and hydrogen atoms may be reversed. This may explain the unusual finding that in many hydrocarbons the methyl group frequently behaves as a more powerful electron donor than hydrogen. This anomalous variation of the electronegativity of the hydrogen atom with increasing positive charge can also constitute the basis for explaining the contradictions which occur in the determination of the direction of the moment in the C–H bond.

Coming now to the determination of the ionic character of bonds in solids, the following fundamental characteristics of the coordination crystals of inorganic compounds must be emphasised: namely the valence of the atoms is as a rule less than the coordination number (CN). If, for simplicity, we consider sodium chloride, it is evident that in the crystalline state, where each sodium atom is surrounded by six chlorine atoms, there can exist only one normal NaCl chemical bond because the Na and Cl atoms are univalent, and the interaction between the sodium ion and the remaining five chloride ions can only be of the Coulombic, ion–dipole type. The ionic character of such an electrostatic bond, i.e. the degree of ion–dipole interaction, can be conveniently calculated by a formula similar to that proposed by Nekrasov[57]:

$$i_{\text{el-stat.}} = \frac{I_B - X_A}{I_B + X_A} . \qquad (34)$$

This formula reflects the relative effects of two forces on the electron cloud of the atom B (in the present case Cl)—its attraction by the atom A (in our case Na), characterised by its electronegativity, and the resistance by the atom B to the withdrawal of electrons, characterised by its ionisation potential.

Since in fact all six Na–Cl bonds within the coordination polyhedron are equivalent, the ionic characters of the electrostatic and the normal chemical bonds must be averaged:

$$i_{\text{cryst}} = \frac{i_{\text{mol}} + (\text{CN} - 1)\, i_{\text{el-stat}}}{\text{CN}} . \qquad (35)$$

In the more general case of compounds consisting of polyvalent atoms we have

$$i_{\text{cryst}} = \frac{i_{\text{mol}} + (\text{CN} - Z)\, i_{\text{el-stat}}}{\text{CN}} , \qquad (36)$$

where Z is the valence. In Eqns. (35) and (36) i_{mol} denotes the ionic character of the bond determined from a comparison of the electronegativities of the atoms, i.e. in the same way as for molecules.

The formulae proposed for the calculation of the ionic character are of course approximate, in particular where account of the polarisation ion–dipole interaction is concerned. Their validity may be assessed by comparing the calculated data with experimental results. For the latter, we used the results obtained by Szigeti's method, by X-ray spectroscopic investigation of crystals, and from thermochemical data for crystalline compounds.

Without dwelling on the theory of Szigeti's method, we shall quote at once the final formula whereby it is possible to calculate the effective charge per bond, i.e. the ionic character of the bond expressed in terms of fractions of an electron:

$$(e^*)^2 = \frac{\pi(\varepsilon - n^2)\cdot \mathrm{M}\,\omega_0^2}{\left(\frac{n^2+2}{3}\right)^2 (Ze)^2 N_a}, \qquad (37)$$

where e^* is the effective charge of the atom (divided by the valence Z) in terms of fractions of the electron, n the refractive index, ϵ the dielectric constant, M the reduced mass of the pair of atoms M–A, M the absolute mass of the atoms, N_a the number of molecules (more precisely the number of formula units per cm^3, and ω_0 the frequency of lattice vibrations. In some cases (for crystals of the type MA_n) the present author's data differ from the literature values[98–100] because the reduced mass is expressed throughout in the form

$$\mathrm{M} = \frac{M_A\ M_B}{M_A + M_B}, \qquad (38)$$

as is done in spectroscopy (see also Refs. 101 and 102).

Table 11. Comparison of effective charges determined by Szigeti's method (e^*) and by the electronegativity method (i).

The amounts of ionic character (in fractions of the electron) determined by the electronegativity method were found from Eqn. (36) and from Tables 5 and 8; the values of the ionic character of electrostatic bonds were taken from the present author's monograph[4]. Table 11 shows that the agreement between the theoretical and experimental values of the ionic character of the bond is on average to within 4%.

The next most accurate method for the determination for atomic charges in crystalline compounds is X-ray spectroscopy. Here two different approaches have been formulated. In one of them (see the work of Urusov[103] and Nefedov[104]) the shift of X-ray lines on ionisation of atoms is examined and a relation is established by quantum-chemical methods between the magnitude of the shift and the effective charge. The above workers do not specify to what type of charges their values refer, but it is evident from the considerations developed in their papers and the normalisation employed[105] that the charges obtained are of the same type as those which follow from Szigeti's equation and the amounts of ionic character in fractions of the electron are referred to a single valence. The present author believes[4] that such an atomic charge, which is associated with the loss or acquisition of an integral electrostatic charge or a fraction of the latter, can be usefully called the intrinsic atomic charge; the charge is distributed within the limits of the atomic skeleton, i.e. it operates within a sphere described by a radius extending from the nucleus to the outer closed electronic orbitals. Suchet[106] suggests that the intrinsic charges be also called "physical charges".

Apart from the intrinsic atomic charges, it is necessary to introduce the concept of coordination charges which represent the collection of electrons received by the given atom from the atoms in the first coordination sphere and the positive charges acquired by the given atom as a result of losing its valence to the bonds with other atoms[4]. Suchet suggests that such charges be called "chemical charges"[106] (see also Cochran[107]). These verbal formulations are identical with the equations

$$Z^*_{\mathrm{intr}} = iZ;\ Z^*_{\mathrm{coord}} = iZ - (1-i)\mathrm{CN}. \qquad (39)$$

It is evident from these formulae that the intrinsic charge of the atom will be always positive for cations and negative for anions. The effective coordination charge can be of either sign both for cations and anions and in most cases it is small in absolute magnitude (Pauling's electroneutrality rule[108,109]). It is significant that, when the bond has a large proportion of covalent character and the coordination number is likewise large, Z^*_{coord} for metals in compounds can be negative. This problem will be discussed further below.

Table 12. Intrinsic charges of metal atoms in crystals.

Crystal	$Z^*_{\text{X-ray}}$	Z^*_{EO}	Crystal	$Z^*_{\text{X-ray}}$	Z^*_{EO}
MgF_2	1.25	1.62	FeF_2	1.91	1.46
$MgSO_4$	1.15	1.56	$FeSO_4\cdot 7H_2O$	1.78	1.84
$MgCO_3$	1.10	1.52	$FeCl_2\cdot 4H_2O$	1.63	1.74
MgO	1.00	1.50	FeC_2O_4	1.65	1.32
			FeS	0.69	1.02
Al_2O_3	1.15	1.89	FeF_3	1.72—2.23	1.95
$AlCl_3$	1.45	0.71	$Fe(NO_3)_3\cdot 9H_2O$	1.70	1.83
AlP	0.60	0.72	$Fe_2(SO_4)_3\cdot 9H_2O$	1.71	1.77
SiO_2	1.30—1.50	1.40	Fe_2O_3	1.58	1.65
P_2O_5	0.75	1.30	$FeCl_3$	0.90	1.47

The values of Z^*_{intr} calculated with the aid of electronegativities and determined from X-ray spectroscopic data are compared in Table 12.[103,104] It follows from the Table that the average difference between the effective charges amounts to 0.12 per bond. Here one must mention in addition the calculations of charges in iron(II) salt hydrates. It is known from structural analysis that in the crystal structure of such salts the iron atom is surrounded by six water molecules arranged octahedrally, i.e. here the situation is the same as in aqueous solutions of iron salts. According to crystal chemists[110,111], the interatomic distances and the nature of the interaction between ions in aqueous solutions and in hydrates are the same. Therefore in calculations of the ionic character of such hydrates the electronegativities of atoms in aqueous solutions should be used (Table 4).

The results of the calculations of the effective charges of atoms in crystals by Eqn. (39) using electronegativities and Barinskii's data[70,93,94], which he obtained by the X-ray spectroscopic method, are compared in Table 13. This group of investigations was undertaken to study the behaviour of the X-ray electron within the first coordination sphere. Calculation of the size of the sphere in which the electron moves leads to a value which is intermediate between the ionic and covalent radii of the metal studied by the X-ray spectroscopic method, which demonstrates the dependence of the behaviour of the electron precisely on the effective charge. This finding was mentioned earlier[4] and was again demonstrated recently in the dependence of the position of the edges of the absorption X-ray K-spectra of manganese on the effective and not on the intrinsic atomic charge in crystalline compounds[112].

Table 13. Comparison of the coordination charges of atoms in crystals.

Metal	Compound	$Z^*_{X\text{-ray}}$	i, %	Z^*_{coord}
Cr	$CrSO_4 \cdot 7H_2O$	1.9	95	1.7
	$Cr(NO_3)_2 \cdot n\,H_2O$	1.2	68	1.1
	K_2CrO_4	0.1	29	0.3
Mn	$Mn(NO_3)_2 \cdot 4H_2O$	1.8	95	1.7
	$K_3Mn(CN)_6$	0.9	62	0.7
Fe	$(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$	1.9	93	1.6
	$K_3Fe(CN)_6$	1.0	54	0.2
Co	$Co(NO_3)_3$	1.2	63	0.8
Os	$K_4Os(CN)_6$	1.5	59	−0.5
	OsO_3	0.8	44	0.6
	K_2OsCl_6	0.8	38	0.3
	K_2OsO_4	0.8	38	1.0
	K_2OsNCl_5	0.7	33	0.6
	$KOsO_3N$	1.0	25	1.2

It is evident from the data presented that, with the exception of osmium hexacyanide, the agreement between the calculated and experimental data may be regarded as good: the average discrepancy amounts to $0.3e$ or 5% of the ionic character. On the other hand, in $K_4Os(CN)_6$ there may be a trans-effect, unless one is dealing simply with an experimental error. In fact in the series of hexacyanides of manganese, iron, and osmium there is a systematic increase of the experimental charge on the central atom together with the increase of its electronegativity. If one remembers that the trans-effect should increase in the same series and that this gives rise to an increase in the ionic character of the central atom–ligand bond, one can understand why the charge of the metal atom increases despite the increase of its electronegativity.

The last method for estimating effective atomic charges in crystalline compounds is based on thermochemical data. By representing the energy of the bonds between atoms in the crystal as a sum of ionic and covalent terms, it is possible to estimate the ionic character of the bond, provided that the interatomic distances are known. The difficulty of this method consists in the fact that the covalent component of bond energy decreases with increasing ionic character according to a law which is, strictly speaking, unknown.

The effective atomic charges obtained by the energy method[113–116] are in good agreement with the values of Z^*_{intr} calculated from Eqn. (39). As an illustration, the "thermochemical" [116] values Z^*_{therm} and the theoretical values calculated for a single valence, i.e. the amount of ionic character of the bonds (i), are compared in Table 14. The average discrepancy amounts to $0.08e$ for each valence.

Thus, when account is taken of the structure of the crystals and ion–dipole interaction, the electronegativity method yields values for the ionic character of the bonds between atoms in crystalline compounds which differ from those determined experimentally by the Szigeti, X-ray spectroscopic, and thermochemical methods by amounts in the range 5–12%. Such precision is quite satisfactory for the majority of physicochemical problems.

Before concluding this Section, dealing with the determination of atomic charges, we shall consider briefly yet another parameter of the chemical bond, namely its multiplicity, which can be also calculated by the electronegativity method.

Table 14. Intrinsic charges of metal atoms determined from thermochemical data.

Crystal	Z_{therm}	i	Crystal	Z_{therm}	i	Crystal	Z_{therm}	i
NaF	0.97	0.89	MgO	0.74	0.75	Na_2S	0.62	0.73

KBr	0.96	0.81	ZnS	0.42	0.46	$MgBr_2$	0.70	0.67
KI	0.96	0.81	CdS	0.36	0.44	AlF_3	0.82	0.72
CuCl	0.45	0.64	MnS	0.44	0.50	$AlCl_3$	0.62	0.57
CuBr	0.42	0.60						

There exist two fundamental methods for the experimental determination of bond multiplicity—geometrical and spectroscopic. Both methods are based on a single principle—an increase in bond multiplicity increases its energy and leads to a corresponding decrease of the interatomic distance or an increase of the frequency of bond vibration. The first method was initially proposed by Pauling[68] and then developed by Hanic[16] and the second is due to Siebert[117]. However, in both these methods no account is taken of the effect of the ionic character of the bond on its energy and therefore they yield unambiguous results only for bonds of low polarity. It is of interest to develop an independent method for the determination of the multiplicity of bonds, including significantly polar bonds.

The simplest formulation of the concept of bond multiplicity N is

$$N = \frac{Z}{CN}. \qquad (40)$$

In coordination compounds or crystals $CN > Z$ and the interatomic space contains, apart from the electron cloud of the bond, also electrons withdrawn from the atoms as a result of ion–dipole interaction. Therefore the overall number of electrons per metal atom in coordination crystals is evidently

$$\Sigma = Z + (CN - Z) \cdot (1 - i_{el\text{-}stat}). \qquad (41)$$

Hence we obtain the following formula for the calculation of bond multiplicity in coordination crystals containing univalent anions:

$$N = \frac{\Sigma}{CN}. \qquad (42)$$

In polyvalent anions the overall number of electrons in the interatomic space is

$$\Sigma = Z_{cat.} + (CN \times Z_{an} - Z_{cat.})(1 - i_{el\text{-}stat}), \qquad (43)$$

and bond multiplicity can also be determined from Eqn. (42).

The results of the calculations by Eqns. (41) and (42) are compared in Table 15 with spectroscopic determinations of bond multiplicity in coordination crystals and complex ions.

The application of Eqn. (42) in the calculation of bond multiplicities in coordination crystals of the type AB leads to the following results:

for	$A^{I}B^{VII}N$	varies in the range	0.2—0.5
	$A^{II}B^{VI}$	» » »	0.4—0.7
	$A^{III}B^{V}$	» » »	0.6—0.8 .

It is clear from this equation that an increase in coordination number entails a decrease of N, which implies an increase in bond length. Since on going from a single to a double bond the length usually changes by 0.15–0.24 Å, it can be shown that the changes in N on going from CN = 4 to CN = 6 are consistent with the differences in interatomic distances usually observed in crystal chemistry.

Table 15. Bond multiplicities in hydrides and halides.

Compound	Ref.118	Ref.117	Ion	Ref.118	Ref.117
LiH	0.28	0.38	$(ZnCl_4)^{2-}$	0.61	0 75
NaH	0.27	0.27	$(ZnBr_4)^{2-}$	0.62	0.76
KH	0.26	0.26	$(CbCl_4)^{2-}$	0.62	0.70
CuH	0.42	0.68	$(CdBr_4)^{2-}$	0.62	0.86
BeH_2	0.60	0.69	$(CdI_4)^{2-}$	0.64	0.86
MgH_2	0.41	0.45	$(AlCl_4)^{-}$	0.80	0.99

The results obtained by Eqns. (43) and (42) are compared in Table 16 using oxygen-containing anions as an example. The agreement between the results of different methods can be regarded as satisfactory.

2. Physicochemical Properties and the Behaviour of Inorganic Substances

The knowledge of the ionic character of the bond is important for the understanding and theoretical calculation of many physicochemical properties of chemical compounds.

Table 16. Bond multiplicities in complex ions.

Ion	Ref.118	Ref.16	Ref.117	Ion	Ref.118	Ref.16	Ref.117

* For Cl_2O_7.

Examples of the use of the concept of electronegativity for the calculation of interatomic distances and electronic polarisabilities of inorganic substances were given in the author's monograph[4]. In his paper Lakatos[119] quotes interesting examples of the solution of the converse problem. Without dwelling on these questions, which are quite fully described in the papers quoted and also in Ref. 97, we shall examine certain new aspects of the application of the concept of electronegativity in general chemistry.

The problem of the interpretation of the semiconductor properties of certain crystalline compounds was chosen as the first example. At the present time there exists no textbook on the chemistry of semiconductors in which the relation between the electronegativity and the width of the forbidden gap is not considered[120,121]. This is quite natural, since the transition of an electron from the valence band to the conduction band is inevitably associated with the nature of the chemical bonds and the mobility of electrons in the interatomic space, i.e., in other words, with the ionic and metallic character[122,123]. Bearing in mind that the energy of the forbidden gap itself is a consequence of the overall structure of the solid, its band structure, there is no point in seeking a relation between ΔE and ΔX only, which would undoubtedly be incapable of reflecting the entire set of specific features of the chemical compound. It is much more correct to introduce ΔX into an equation which already contains the ΔE values for the components of the compound determined for a purely covalent state (i.e. for the corresponding elements), so as to allow only for the deviation of the bond character in the given compound from the purely covalent state. The Schomaker–Stevenson equation[13] is a classical example of such an application of electronegativity:

$$r_{AB} = r_A + r_B - 0.09\Delta X_{AB} \quad . \qquad (5)$$

In complete agreement with this principle, the present author has proposed the following relation[124] between ΔE and ΔX:

$$\Delta E_{AB} = \Delta E_A + \Delta E_B + a\Delta X_{AB} - b\bar{n}_{AB} \qquad (44)$$

where ΔE_A and ΔE_B are the widths of the forbidden gap for the elements A and B (determined for the corresponding pure elements), $\bar{n}$ the average value of the principal quantum number, and a and b are constants. Tests of this equation using all the values of ΔE_{AB} known in 1964 showed that the average error is 0.2 eV. The equation of course constitutes the simplest method of taking into account the effects of the ionic and metallic character of the bond on the energy of the forbidden gap and requires further improvement, particularly as regards a more correct determination of the role of the metallic character of the bond. However, the principle of the derivation of the equation itself appears to be correct (see also Hooge[125]). Comparison of the electronegativities ΔX of atoms forming crystals having the same structure with their melting points reveals a distinct relation—the greater is the covalent character of the bond the lower is the melting point[126]. Table 17 presents several pairs of compounds with the same structures (coordination numbers) and similar interatomic distances, but which differ appreciably in their electronegativities. Geologists believe[127] that this relation is responsible for the magmatic crystallisation sequence and processes involving the substitution of cations in crystals. The explanation for this relation is that the energy of the Coulombic interactions is much higher than the energy of the covalent component of the bond, and therefore an increase of ΔX entails an increase in the total bond energy (for further details, see Ref. 4). This finding also plays an important role in the determination of the mode of double decomposition reactions which occur with formation of combinations of the most ionic and the most covalent compounds[128] (however, here one should recall that the electronegativity method can be applied directly only to purely molecular cases and account must be taken of the coordination number, etc., when crystals are considered).

The use of the concept of electronegativity to characterise the acid–base properties of chemical compounds has

proved extremely fruitful. On the basis of the Lewis–Brønsted theory, it is readily seen that an increase of the negative charge of the oxygen atom in an oxide will entail an increase in its basic properties. Therefore it is possible to establish a proportionality between ΔX and the acidity of the medium set up by the given combination of atoms. Such an approach is interesting because one need not consider the specific features of the medium and one can characterise objectively the acid–base properties of substances. Examination of the acid–base properties of silicates from the standpoint of the concept of electronegativity is also useful because classical chemical methods are inapplicable to this case[129]. A new finding is that in the usual substitution of the hydroxy-groups in aluminosilicates by fluorine atoms there is an increase in the acid character of the compound.

Table 17. Dependence of the melting point on bond type.

Crystal	Interatomic distance	CN	ΔX	M.p., °C	Crystal	Interatomic distance	CN	ΔX	M.p., °C
AgCl	2.77	6	1.2	455	CaF_2	2.36	8	3.0	1378

CdF_2	2.34	8	2.3	1100	ZnS	2.35	4	1.0	1850

The electronegativity method makes it possible to understand and to predict the changes in the acid–base properties of organic compounds as a result of changes in their structure or on introduction into the molecular skeleton of definite substituents. The general principle which can be used here is that, in consequence of the higher electronegativity of the carbon combined with the hydroxyl, the oxygen atom of the OH group is forced to saturate the electron affinity on the side of the H atom to a greater extent, as a result of which the latter becomes more polar, i.e. acid. Hence, one may conclude that halogeno-substituted acids will be stronger than the normal acid and that the increase in acid strength will be greater the higher is the electronegativity of the halogen. However, it should be recalled that in comparisons of this kind one must of course select related molecules in which the same number of hydrogen atoms are replaced at the same carbon atom, because otherwise the structural effect may compete with the inductive effect[130]. Thus, the electronegativity method has recently been successful in the interpretation of the ionisation of fluoro-substituted organomercury compounds and the correlations proved to be so precise that it was possible to determine the group electronegativities from the pK data[131].

Since the dissociation of complex ions depends on the relation between the energy of the ligand–central atom bond and the ligand hydration energy, it is clear that the instability constants of complex compounds will be functionally related to the covalent character of the latter and hence to the electronegativities of the atoms. Such relations have been indeed established for numerous examples and have been used successfully in the chemistry of complex compounds (for further details, see Refs. 4 and 132). In general, according to Nyholm[133], the establishment of correlations between bond strengths and the electronegativity of the central atom is extremely promising for the chemistry of complex compounds. In this connection it is of interest to examine Chernyaev's trans-effect rule. The essence of the latter is that, when certain atoms and radicals interact with ligands located in the trans-position with respect to them, they ionise the latter and render them capable of more rapid (and sometimes actually ionic) substitution. A direct relation between the magnitude of the trans-effect and the covalent character of the bond between the given ligand and the central atom is a firmly established fact. It is quite clear that the ionisation of the species in the trans-position leads to a change in energy and in most cases to an increase in the strength of its bond, but the increased effective charge on the ligand results also in a sharp increase of its hydration energy, which facilitates the dissociation of this atom.

On the basis of what has been said above, the parallel variation of the position of the ligands in the trans-effect series and their electronegativities is evident[134] and it is clear why the same ligands, for example thiocyanato- and nitro-groups, can occupy different positions in the trans-effect series depending on the atom via which they are combined with the complex-forming metal.

The most interesting is the case of the combination of the central atom of the complex with a nitro-group and a chlorine atom. The electronegativity of both ligands is 3.2 and, other conditions being equal, their trans-activities should be the same. However, calculation of the effective coordination charge in complexes of di- or tetra-valent platinum by Eqn. (45) shows that in the first case $Z^*_{coord} < 0$ and in the second $Z^*_{coord} > 0$. Since in the N–O bond the positive pole is located at the nitrogen atom and the negative pole at the oxygen atom, it is easy to see that in complexes of divalent platinum with the NO_2 group the N–O bond length will be greater than in similar complexes of tetravalent platinum. These changes in bond length are consistent with the decrease in the multiplicity of the nitrogen–oxygen bond in platinum(II) complexes and its increase in platinum(IV) complexes relative to the normal state of the nitro-group. Since a decrease of the bond multiplicity of a given atom is accompanied by a decrease of its electronegativity on the opposite side, $X_{NO_2}(Pt^{II})$ will be less than X_{Cl} and $X_{NO_2}(Pt^{IV})$ will be greater than X_{Cl}. In accordance with what has been said above, this finding implies that the trans-effect of the nitro-group in platinum(II) compounds will be greater than the trans-effect of chlorine and that the converse relation will obtain in platinum(IV) compounds. It is known[135] that there is indeed a difference between the trans-effects of NO_2 and Cl but the postulated difference between the properties of the nitro-groups in complexes of di- and tetra-valent platinum still requires experimental tests[4,136].

Bearing in mind that in complexes of trivalent cobalt and gold with the nitro-group the central atoms have effective positive coordination charges, as can be readily seen from Tables 5 and 8 and Eqns. (39), the behaviour of the NO_2 group will be the same as in platinum(IV) complexes. On the other hand, in the nitrite complexes of trivalent metals of the platinum group the central atoms have an effective negative coordination charge and therefore the trans-effect of the NO_2 group will be greater than that of chlorine.

If these predictions prove to be valid and considerations based on charges do indeed play an important role in the determination of the trans-effect of the nitro-group, then one may postulate the possibility of a change in the trans-activity of NO_2 even for the same valence of the central atom, for example platinum. Thus in the iodide complexes of tetravalent platinum the nitro-group would exhibit a greater trans-effect than chlorine because here Z^*_{coord} is less than zero, while in fluorine-containing platinum(II) com-

plexes the relations between NO_2 and Cl may become the same as for tetravalent platinum because of the effective positive charge on the central atom of the complex. The variation of the trans-activity of ligands as a function of the composition of the complex can be regarded as a manifestation of the cis-effect in the inner sphere of complex compounds.

Of the entire wide variety of chemical properties and behaviour of simple inorganic compounds, we shall examine in this Section only one example each of the analysis and synthesis of substances, which can be interpreted or predicted from the standpoint of the concept of electronegativity.

The concept of electronegativity was recently successfully applied by Rozen and coworkers[137,138] in the problem of the separation of elements by extraction, or more precisely the problem of selecting optimum organic compounds for use as extractants. These workers showed that the electronegativities of the radicals are an important characteristic of compounds such as substituted tributyl phosphates and the analogous phosphonates. It is significant that the electronegativities found from the extraction of uranyl nitrate also describe satisfactorily the capacity of substances to be extracted by nitric acid, i.e. the relation obtained is of general importance. It has also been shown[138] that the Hammett–Taft equation can be derived from equations involving electronegativities. Therefore the latter can be used successfully also to describe the reactivities of organic compounds.

The findings arrived at with the aid of the electronegativity method proved fruitful also in the synthesis of new compounds. The synthesis of salts with mixed anions of the type MABC ... appears to be very promising, since by varying the anions A, B, and C, it is possible to increase almost without limit the range of chemical compounds of the given metal. Mixed salts are obtained by the combination of homogeneous salts, for example

$$PbF_2 + PbCl_2 = 3PbFCl\,, \qquad (45)$$

or by hydrolytic reactions, for example

$$MoCl_5 + H_2O = MoOCl_3 + 2\,HCl\,, \qquad (46)$$

or by double-decomposition reactions, for example

$$TiBr_4 + Cl_2O = TiOBr_2 + 2\,ClBr\,. \qquad (47)$$

However, it is difficult to expect the formation of substances in new valence states by these reactions. Therefore a very attractive procedure is the preparation of the mixed salts by reactions of the type

$$MA + B = MAB\,, \qquad (48)$$

where B is a halogen or a chalcogen, but there is then a possibility of displacement reactions if the oxidising capacity of the atom B is higher than that of the atom A.

Calculation of the effective coordination charges of variable-valence metals present in crystalline compounds in the lower-valence state showed that in most cases they are negative[4]. This can be understood when the coordination number of the metal is large, and the bonds which it forms with its nearest neighbours are significantly covalent; in other words, when the metal has given up fewer electrons for the formation of the bonds than the number it has received from them. Physically, a negative charge implies that the free electron pairs of the anions interact with the vacant sites of the cations. Finally, we must recall Z^*_{coord} is a concept reflecting the situation in the interatomic space and not within the atomic skeleton and this is in fact an important factor in oxidisation processes.

If we now return to Eqn. (48), we readily see that, when there is a negative charge on the atom M, the effect of the oxidant B should lead not to displacement of A but to an increase of the valence of M, i.e. the formation of a salt with mixed anions. Experiments confirmed this conclusion: with salts of copper, mercury, thallium, tin, chromium, manganese, and platinum, the present author succeeded in obtaining oxidised salts with mixed anions[139-149].

A few words must also be said about the change in the nature of the bond on heating and about the effects of such changes on chemical properties. It is clear from general considerations that the chemical bond can change as the molecule or crystal is heated. On heating, a solid melts and is then converted into a gas. Evidently, these processes are accompanied by a decrease of the ionic character of chemical bonds. One can also arrive at the conclusion that, within the same state of aggregation, heating increases the covalent character of the bond. In fact on heating the material expands due to the increased amplitude of atomic vibrations. The increase in volume may be interpreted in terms of the statistical decrease of the coordination number, which should entail a decrease of the ionic character of the bond. Physically, this has the following meaning: as the vibration amplitude increases, there is an increased frequency of instances when the oppositely charged ions approach one another to a distance so short that one can speak of the formation for a very brief instant of a molecule or molecular complex; the increase in the proportion of the molecular state in the crystal as the latter is heated is in fact consistent with the increased contribution of the covalent component to the chemical bonds of the substance.

The above considerations have found experimental justification. Thus Jones et al.[99] showed by Szigeti's method that, as alkali halide crystals are heated, their effective charges fall, i.e. there is an increase in the covalent component of the bond. Quantitatively this increase amounts on average to $0.02e$ per 100 deg.

Such increase in covalent character may give rise to significant changes in the distribution of the effective charges in the crystal. For example, when MnO is heated to 350°C, the ionic character of the bond decreases by $0.07e$ or from $0.71e$ (see Ref. 4, p. 173) to $0.64e$. Hence the effective coordination charge of the manganese atom in the MnO crystal changes from ± 0.26 to -0.16, i.e. there is a reversal of the sign of the charge. It is interesting that it is precisely at this temperature that the heating curve for MnO in air shows an exothermic maximum corresponding to the oxidation of manganous oxide to Mn_2O_3. This example illustrates the possibility of regarding oxidisation reactions which occur on heating from the standpoint of the system of the effective atomic charges in the substance and the effect of heating on the dynamics of this system. Knowing the ionic character of the bond in the initial state of the substance, it is possible to estimate the temperature ranges in which oxidation processes can begin.

The most pronounced changes in bond polarity are to be expected in coordination or dative bonds formed in the inner sphere of complex compounds, because the latter are formed by virtue of additional atomic orbitals and their energy frequently makes them less stable than the usual chemical bonds. This is why one may expect very considerable changes in chemical behaviour in complex compounds when the latter are heated even slightly.

---oOo---

The above factual and theoretical data show that the concept of electronegativity can be successfully applied in the determination of atomic charges in molecules and crystals; at any rate, at the present time there is no other method for the determination of the ionic character of the bond as universal and simple as the electronegativity method. However, this method shows what the charge should be only if the latter is determined only by the normal valence bonds between atoms; when hydrogen bonds, trans-effects of atoms, or any other additional interaction is present, the atomic charges determined by the electronegativity method may differ from the actual values, but the difference itself can serve as a characteristic of the given type of interaction.

The formulae for and the magnitudes of the electronegativities of atoms permit the calculation of the fundamental properties of matter–bond energies and lengths, ionisation potentials, optical characteristics, and the distribution of electron density. This is why electronegativity will retain for a long time its importance in structural chemistry within the framework of the additive approach to the problems of molecular structure. Therefore, the present author believes that even the discovery of new properties and effects of the chemical bond will not entail the rejection of this concept.

The above view does not of course imply that the concept of electronegativity is free from disadvantages and that it is able to reflect all the features of the atomic and electronic structure of matter known at the present time. In this connection it is useful to consider briefly the controversy concerning the role and limits of applicability of the concept of electronegativity which occurred recently.

The concept of electronegativity, like other methods of theoretical chemistry, has its critics as well as supporters. The former can be divided into two groups—some workers criticise particular schemes for the calculation or application of electronegativity and propose new more successful ones (from their point of view); others see fundamental defects in the concept of electronegativity and suggest that it be completely excluded from the arsenal of theoretical chemistry. The first group is the most numerous and includes many investigators who have been fruitfully developing the concept of electronegativity, but their electronegativity values will not be considered here, particularly since later studies, which incorporate all the constructive postulates put forward in recent years, are quoted in the present review.

The first negative criticism of the concept of electronegativity was made in the paper by Fajans[140], who reviewed Pauling's book. Fajans noted that, by ascribing to each element of the Periodic System a constant electronegativity value, one cannot arrive even at a qualitatively correct understanding of chemical phenomena and the physical properties of substances. For example, in chloroacetylene the chlorine atom has a positive charge, in chloroethylene a zero charge, and in chloroethane a negative charge, while $X_{Cl} > X_C$. We now know that the electronegativity of the carbon atoms varies with the degree of hybridisation of its bonds and can assume values ranging from 2.0 to 3.3 (see Table 6). Comparison of these electronegativities of carbon with the constant electronegativity of chlorine shows that the sign of the charge on the chlorine atom should indeed change on going from chloroacetylene to chloroethane.

The second serious criticism of Pauling's concept was made by Hückel[151], who tested the principle of additivity in calculations of electronegativity and compared the amounts of ionic character calculated from the dipole moments of halogeno-hydrocarbons and interhalogen compounds. In the same paper Hückel formulated for the first time the question of the dimensions of electronegativity and expressed his perplexity concerning the physical significance of the dimension "(energy)$^{1/2}$". Without dwelling on the factual inaccuracies which were pointed out in the present author's review of Hückel's work[152], we may mention that his comparison of the dipole moments of various molecules with the aim of determining the ionic character of the bonds is without foundation, since, on changing the composition, the contributions of the various components of the dipole moment can also change. The large relative errors observed by Hückel in additive calculations involving electronegativity are purely an arithmetical effect, which arises when a constant absolute error (0.1 electronegativity unit) is compared with the small difference $\Delta X = 0.3–0.9$, and has almost no influence on the accuracy of the calculation of chemical bond energies.

The dimensions of the concept of electronegativity were discussed above, and, concerning Pauling's values of X, one can only add that Pauling himself calculated the ionic character of the bonds by Eqns. (24) or (25), which involve ΔX^2. The present author has already pointed out[152] that there is a definite analogy between ΔX and the wave function, bearing in mind that in the latter case it is precisely $|\psi|^2$ that is physically significant.

In the critical article of Lakatos[86] the arguments of Fajans and Hückel are quoted and it is emphasised that electronegativity is not a constant, since it must have a certain range of values depending on the valence state, the ionic character of the bond, hybridisation, etc. Lakatos also points out that the amounts of ionic character of bonds are determined from various atomic properties and therefore it is frequently difficult to make them consistent.

Iczkowski and Margrave[52] again draw attention to the differences in the dimensions of electronegativities determined by different methods and believe that the most correct representation of electronegativity is in the form of a potential. Together with Hückel, these authors believe that the main reason for the successful application of electronegativity in chemistry is that this quantity reflects the periodic variation of properties in Mendeleev's system.

In 1962 Syrkin[153] published a critical paper on the concept of electronegativity. Noting that in the early stage of development this concept constituted an advance, he now concluded that at the present time it can no longer be used for a satisfactory interpretation of experimental facts and even less so for their prediction. This paper is unfortunately not free from factual inaccuracies and Syrkin does not employ the most accurate system of electronegativities, as pointed out in the present author's review[154], but fundamentally his formulation of the problem is valid. The facts which have accumulated at the present time no longer fit within the Procrustean bed of constant electronegativities and require successive corrections for ionic character, multiplicity, and other characteristics of the chemical bond which are frequently unknown *a priori*. The question arises whether the numerous corrections and additions are justified by the results which can be gained with the aid of electronegativity. Syrkin gives a negative answer. The data presented above suggest that the answer is yes.

Finally in recent years Spiridonov and Tatevskii[155] published a series of papers in which they repeated the concrete objections of Hückel and Iczkowski but, in contrast to the other authors, they suggest a fundamental contradiction between the concept of electronegativity and quantum mechanics and therefore they reject the concept itself. They called for the application in chemistry of the rigorous methods of quantum mechanics. However, the trouble is

that such methods do not exist at the present time and it is not clear whether the many-electron problem can be solved rigorously, in principle, in a general form. For this reason, no one, including Spiridonov and Tatevskii, uses rigorous quantum-mechanical methods in their practical work. In reply to the criticism of these workers[156,157], a detailed analysis of their comments was made and it was shown on concrete examples that their wish for more rigorous solutions is at the present time unrealistic. The views of Spiridonov and Tatevskii are indirectly disproved by the use and development of the method of electronegativity by outstanding specialists in the field of quantum chemistry such as Pauling, Mulliken, Hinze and Jaffe, and finally Coulson[158].

Considering the criticism of the concept of electronegativity as a whole, we arrive at the paradoxical conclusion that here everyone is right—both the adherents and the opponents of the concept. The question is evidently what are the limits of applicability of this method. The present author has already stated earlier and believes it superfluous to repeat that, with the aid of electronegativity, one can determine directly the sign and magnitude of the charge only for atoms in molecules and crystals. In all remaining cases it is necessary to determine whether or not the given property depends on the polarity of the chemical bond and only if the answer is in the affirmative can one proceed to consider the concrete application of electronegativity values in familiar or newly derived equations.

The greatest defect of the concept of electronegativity is that the simplicity of the mathematical formulation led to the disappearance of the potential barrier which must be overcome by the investigator in order to master a given field and therefore the concepts and values of electronegativity are sometimes employed by incompetent persons. Incorrect application of the method merely brings it into disrepute.

Returning to the problems of the chemical bond, one would wish to mention in conclusion, a general characteristic of the modern state of this field of science. As our knowledge about the electronic structure of matter deepens, the theory of the chemical bond simultaneously develops, many simple physical characteristics and concepts become complex, and acquire a characteristic "structure". This was the case earlier with the dipole moment. A similar change is now taking place in the "chemical shift". Simple facts such as the shortening of the bond or the increase of the dissociation energy are in fact the result of at least two simultaneous trends, changes in the polarity and hybridisation of bonds, and this is why it is impossible to derive from such values unambiguous information about the nature of the chemical bond.

Precisely for this reason our concepts such as atomic radii, refractions, and electronegativities become complex and require that account be taken of the specific features of the environment of the given element. This is quite reasonable and one may hope that, as science progresses, the theoretical armoury of structural chemistry based on the principle of additivity will constitute an organic component of a more general and rigorous theory.

Methods of Preparation and Chemical Properties of Aliphatic Halogeno-nitro-compounds

G.A.Shvekhgeimer, V.A.Smirnyagin, R.A.Sadykov, and S.S.Novikov

The review deals with the literature on the nitrohalogenation of unsaturated compounds by addition to the latter of nitryl and nitrosyl halides and by the reaction of the unsaturated compounds with mixtures of nitrogen tetroxide and halogens. The condensation of nitro-alkanes with halogeno-carbonyl compounds, the nitration of halogeno-derivatives of aliphatic hydrocarbons, and the halogenation of nitro-compounds have also been described. Work on the reaction of polyhalogeno-alkanes with metal nitrites and the replacement of a carboxy-group by a halogen and a nitro-group have been reviewed. Dehydrohalogenation, dehalogenation, and also reactions involving the substitution of the halogen atoms have been examined in the analysis of the chemical properties of halogenonitro-compounds. The review also deals with work on the reactions of halogenonitro-compounds with participation of the nitro-group. A brief report is given on the applications of halogenonitro-compounds.

IV. Applications of halogenonitro-compounds 360

I. INTRODUCTION

Among aliphatic nitro-compounds considerable interest attaches to halogenonitro-compounds in which there are two or three reaction centres: the halogen atom, the nitro-group, and, for substances with a primary or a secondary nitro-group, two or one "mobile" hydrogen atom. The presence of several reaction centres permits a wide range of reactions with these compounds.

Despite their undoubted interest, the chemistry of halogenonitro-compounds has not been reviewed so far. The present review presents a compilation of data on the syn

thesis and chemical properties of halogenonitro-compounds excluding α-halogenonitro-compounds. The latter, containing a halogen and a nitro-group at the same carbon atom, constitute a fairly large group of substances, which differs sharply in methods of preparation and properties from halogenonitro-compounds in which the halogen and the nitro-group are attached to different carbon atoms[1].

II. METHODS OF PREPARATION OF HALOGENONITRO-COMPOUNDS

1. NITROHALOGENATION OF UNSATURATED COMPOUND

a. Addition of Nitryl Halides to Unsaturated Compounds

Nitrohalogenation with nitryl chloride and fluoride only has been described[2-15] and the possibility of the addition of nitryl fluoride has been demonstrated in only one study[16]:

$$CF_3-\underset{\displaystyle R}{\underset{|}{C}}=CF-OR' + FNO_2 \rightarrow \begin{matrix} CF_3 \\ \diagdown \\ R \end{matrix}\!\!>\!C(NO_2)-CF_2-OR' ,$$

where R = F or CF_3 and R′ = alkyl.

Many investigators are inclined to believe that nitryl chloride adds to unsaturated compounds by a free-radical mechanism, although it is also capable of heterolytic dissociation[3,12,14]:

$$NO_2^+ + Cl^- \rightleftarrows NO_2Cl \rightleftarrows NO_2^{\cdot} + Cl^{\cdot}$$
$$\downarrow\uparrow$$
$$NO_2^- + Cl^+ .$$

However, in weakly polar media nitryl chloride largely dissociates with formation of free radicals[12]. This can account for the finding that, in the chloronitro-compounds formed, the nitro-group is attached to the terminal carbon atom of the double bond regardless of the electronic properties of the substituents:

$$R-CH=CH_2 \xrightarrow{NO_2^{\cdot}} R-\dot{C}H-CH_2-CH_2NO_2$$
$$R-\dot{C}H-CH_2NO_2 \xrightarrow{NO_2Cl} R-CHCl-CH_2NO_2 + NO_2^{\cdot} ,$$

where R = alkyl, CH_3OCO, CN, COOH, $C\begin{matrix} O \\ \diagdown\!\!\diagup \\ Cl \end{matrix}$, or a halogen.

The primary attack by the chlorine atom leads to the formation of dichlorides. There exist contradictory data on the reaction of styrene with nitryl chloride[2,3]. Steinkopf and Kühnel[2] isolated 2-chloro-1-nitro-1-phenylethane as the reaction product, but later Goddard[3] repeated the reaction and obtained 1,2-dichlorophenylethane and β-nitrostyrene, the formation of which takes place, in his view, according to the mechanism

$$C_6H_5-CH=CH_2 \xrightarrow{NO_2Cl} [C_6H_5-CHCl-CH_2NO_2] \xrightarrow{-HCl} C_6H_5-CH=CHNO_2 .$$

The isolation in a number of cases of 2-chloro-nitrites and pseudonitrosites[5,9] is evidence that either nitryl chloride reacts partially by a heterolytic mechanism or the $NO_2^{\cdot}$ radical attacks the carbon atom with formation of the

$$-\underset{|}{\overset{|}{C}}-ONO \text{ bond.}$$

The addition of nitryl chloride to acetylenic hydrocarbons can serve as a convenient method for the synthesis of unsaturated halogenonitro-compounds[11,14,15]:

$$RC\equiv CR' + NO_2Cl \rightarrow RCCl=CNO_2R' ,$$

where R = C_2H_5, C_4H_9, C_6H_5, or Cl and R′ = C_2H_5, C_4H_9, C_6H_5, Cl, or H.

In addition to α-chloro-β-nitrostyrene, Freeman and Emmons[14] isolated $\alpha\alpha$-dichloroacetophenone from the products of the reaction of phenylacetylene and nitryl chloride and proposed a probable mechanism for its formation:

$$C_6H_5-C\equiv CH \xrightarrow{NO_2} C_6H_5-\dot{C}=CHNO_2 \xrightarrow{NO_2Cl} C_6H_5CCl=CHNO_2$$
$$C_6H_5-C\equiv CH \xrightarrow{NO_2Cl} C_6H_5-\dot{C}=CHCl \xrightarrow{NO_2^{\cdot}} C_6H_5-\underset{|}{\overset{ONO}{C}}=CHCl \xrightarrow{NO_2Cl}$$
$$\rightarrow \left[C_6H_5-\underset{|}{\overset{ONO}{\dot{C}}}-CHCl_2\right] \rightarrow C_6H_5-\overset{O}{\overset{\|}{C}}-CHCl_2 .$$

The reaction of nitryl chloride with diene hydrocarbons has been little investigated[4,17]. When nitryl chloride was allowed to react with divinyl, isoprene, piperylene, and chloroprene, the products of the 1,4-addition of NO_2Cl and the products of their isomerisation with migration of the double bond towards the nitro-group were obtained together with dichlorides.

b. Reaction of Nitrosyl Halides with Unsaturated Compounds

Nitrosyl chloride adds to ethylenic hydrocarbons in accordance with the Markovnikov rule[18-37]. The primary product of the addition reaction, an unstable monomeric nitrosochloro-derivative, can react further in three principal ways[29]: (1) it can condense to a relatively stable dimer; (2) it can be oxidised to chloronitro-compounds; (3) it can isomerise to the oxime of a chloro-aldehyde (or ketone):

$$\left[\begin{matrix} C-CH \\ Cl\ NO \end{matrix}\right]_2 \rightleftarrows \begin{matrix} C-CH \\ Cl\ NO \end{matrix} \rightarrow \begin{matrix} C-CH \\ Cl\ NO_2 \end{matrix}$$
$$\downarrow$$
$$\left[Cl-\underset{|}{\overset{|}{C}}-CH-N=\underset{\downarrow}{\overset{\downarrow}{N}}-CH-\underset{|}{\overset{|}{C}}-Cl\right] \qquad \begin{matrix} C-C=NOH \\ Cl \end{matrix} .$$
$$O\ O$$

The mode of reaction depends on the structure of the initial hydrocarbon and its chloronitroso-derivative. The second and third processes, oxidation and isomerisation, depend on the first—the capacity of the monomeric chloronitro-compounds to be converted into the dimer and on the stability of the dimeric form.

The presence of electron-acceptor atoms and groups at the carbon atom adjacent to the nitroso-group reduces the electron density of the –N=N– bond and favours the dissociation of the dimer into monomeric molecules, and, conversely, electron-donor substituents increase the stability of the dimer.

As a rule the reaction mixture contains products formed by all three reactions. However, depending on the structure of the initial olefin, one or other product predominates. The nature of the product depends on the relative rate of addition of nitrosyl chloride (NOCl) to the olefin and the oxidation of the product to a chloronitro-compound and a dichloro-derivative. If the oxidation is faster than the addition, the main reaction product is the chloronitro-compound. Thus, symmetrical and asymmetric alkylethylenes, and particularly polyalkylethylenes, yield mainly crystalline dimeric chloronitroso-derivatives and only small amounts of chloronitro-compounds. Trimethylethylene, isobutene[38,39], 2,2,3-trimethylbut-3-ene[29], 1-methylcyclohexene, 1-ethylcyclohexene, but-2-ene[30], pent-2-enyl-2-methylbut-1-ene, 2-(*p*-tolyl)propene[29], and

tetramethylethylene[40] react in this way. The chloronitro- and dichloro-compounds are the main products of the reaction of nitrosyl chloride with monosubstituted alkylethylenes—isopropylethylene[21], pent-1-ene, hex-1-ene, hept-1-ene, and 2,2-dimethylbut-3-ene[29]. If in an asymmetrically disubstituted ethylene one of the substituents has electron-acceptor properties, the chloro-derivative and the dichloro-compound predominate in the reaction products. This has been demonstrated for α-methylstyrene[41].

The addition of nitrosyl chloride takes place in accordance with the polarisation of the double bond. Allyl chloride, vinyl chloride, trichloroethylene[19], 2-chloropropene[33], methyl methacrylate, 3,3,3-trichloromethylpropene, 2-nitropropene[34], and methyl acrylate[35] react in this way.

The conversion of chloronitroso-compounds into chloronitro-compounds probably takes place via a stage involving the formation of diazo-nitrates, for example[29]:

$$CH_3{-}CX{=}CH_2 \xrightarrow{NOCl} CH_3CX(NO){-}CH_2Cl \xrightarrow{2NOCl} CH_3{-}CX(N_2ONO_2){-}CH_2Cl + 2Cl;$$

$$CH_3{-}CX(N_2ONO_2){-}CH_2Cl \xrightarrow{NOCl} CH_3{-}CXCl{-}CH_2Cl + N_2 + 2NO_2;$$

$$CH_3{-}CX{=}CH_2 + NO_2^{\cdot} \rightarrow CH_3{-}\dot{C}X{-}CH_2NO_2 \xrightarrow{NOCl(Cl)} CH_3{-}CXCl{-}CH_2NO_2;$$

where X = Cl, $COOCH_3$, NO_2, or CCl_3.

When 2,2-dimethylpent-3-ene reacts with nitrosyl chloride, a mixture of chloronitro-products is formed[31]:

$$CH_3{-}\underset{\displaystyle CH_3}{\overset{\displaystyle CH_3}{\underset{|}{\overset{|}{C}}}}{-}CH{=}CH{-}CH_3 + NOCl \rightarrow \begin{cases} (CH_3)_3C{-}CHNO_2{-}CHCl{-}CH_3 \\ (CH_3)_3C{-}CHCl{-}CHNO_2{-}CH_3 \end{cases}.$$

Nitrosyl chloride reacts with tetrafluoroethylene, chlorotrifluoroethylene, and the asymmetric dichlorodifluoroethylene with formation of nitro-compounds when the mixture is passed through a heated glass tube[25]:

	Yield
$CF_2{=}CF_2 \xrightarrow[NOCl]{50^\circ} CF_2ClCF_2NO_2$,	63%
$CF_2{=}CFCl \xrightarrow[NOCl]{100^\circ} CF_2ClCFClNO_2$,	67%
$CF_2{=}CCl_2 \xrightarrow[NOCl]{100^\circ} CF_2ClCCl_2NO_2$.	57%

The same products are formed when the reaction is carried out in a sealed tube[18,23] or in an autoclave at room temperature[26].

When nitrosyl chloride, tetrafluoroethylene, and chlorotrifluoroethylene were passed through a tube over ferric chloride at 45°C, nitroso-compounds, dichloro-compounds, chloronitro-compounds, and dinitro-compounds were isolated[37]. Similar results were obtained when nitric oxide (NO) was used instead of nitrosyl chloride[32,42]. Probably in this case the first reaction stage is the formation of nitrosyl chloride from nitric oxide and ferric chloride.

The addition of nitrosyl bromide and fluoride to unsaturated compounds has been investigated to a lesser extent. Only one reaction of nitrosyl bromide is known[24-26]:

$$CF_2{=}CF_2 + NOBr \rightarrow CF_2NO_2CF_2Br.$$

Tetra- and tri-fluoroethylene, and vinylidene fluoride readily react with nitrosyl fluoride, but nitro-compounds were not found among the products. Perfluoropropene reacts with nitrosyl fluoride only at 150°C. In the presence of calcium sulphate as the catalyst the yield of nitroalkanes is slight and without catalyst radical nitration products are formed exclusively[43].

Degradation products were obtained from perfluorobut-2-ene and nitrosyl fluoride at 200°C: $CF_3CF_2NO_2$, CF_3NO_2, etc.[44]

Depending on the molar ratio of the reactants, diene hydrocarbons combine with one or two molecules of nitrosyl chloride[22]. Thus diallyl reacts with nitrosyl chloride to form 5-chloro-6-nitrohexene, 2,5-dichloro-1,6-dinitrohexane, and also 5,6-dichlorohex-1-ene and 1,2,5,6-tetrachlorohexane, i.e. the double bonds react completely independently of one another and the addition of nitrosyl chloride takes place as with monosubstituted olefins. Butadiene behaves similarly:

$$CH_2{=}CH{-}CH{=}CH_2 \rightarrow \begin{cases} \xrightarrow{+NOCl} CH_2{=}CH{-}CHCl{-}CH_2NO_2 \\ \xrightarrow{+2\,NOCl} CH_2NO_2{-}CHCl{-}CHCl{-}CH_2NO_2 \end{cases}.$$

Nitrochlorination of acetylene derivatives with nitrosyl chloride permits the synthesis of a wide variety of 1,2-chloronitro-alkenes in a single stage:

$$RC{\equiv}CR' \xrightarrow{NOCl} \underset{\displaystyle Cl\ \ NO}{RC{=}CR'} \xrightarrow{O} \underset{\displaystyle R\ \ R'}{ClC{=}CNO_2}.$$

Perrot and Berger[27] obtained α-chloro-β-nitrostyrene and its derivatives from phenylacetylene and nitrosyl chloride:

$$RC_6H_4C{\equiv}CH + NOCl \rightarrow RC_6H_4C(Cl){=}CHNO_2,$$

where R = H, p-CH_3, o- and p-Cl, or m-NO_2 and p-NO_2.

c. Nitrohalogenation of Saturated Compounds by Nitrogen Tetroxide–Halogen Mixtures

The structure of the products of the nitrohalogenation of olefins by N_2O_4–X_2 (X = Cl, Br, or I) in many ways depends on the reaction conditions, the structure of the initial olefin, and the nature of the halogen[45-52]. When the reaction is carried out in the vapour phase, free-radical processes predominate[47,53], since under these conditions N_2O_4 and X_2 dissociate into radicals: $N_2O_4 \rightleftharpoons 2NO_2^{\cdot}$, $X_2 \rightleftharpoons X^{\cdot} + X^{\cdot}$. The radical initiating the reaction can be either $NO_2^{\cdot}$ or $X^{\cdot}$ (the capacity for this decreases in the series Cl → Br → I). In the chloronitration of propene and butene at 260–275°C, the products are 1-chloro-2-nitro-alkanes[52] (the chlorine atom is more reactive):

$$R{-}CH{=}CH_2 + Cl^{\cdot} \rightarrow R\dot{C}HCH_2Cl,$$

$$R{-}\dot{C}HCH_2Cl + NO_2^{\cdot} \rightarrow RCHNO_2CH_2Cl,$$

$$R{-}\dot{C}HCH_2Cl + Cl_2 \rightarrow RCHClCH_2Cl + Cl^{\cdot}.$$

Vinyl chloride and bromide react with N_2O_4–Cl_2 and N_2O_4–Br_2 mixtures in different ways when the reaction temperature is raised from 250° to 325°C:[47]

$$CH_2{=}CHR + NO_2^{\cdot} \xrightarrow{255^\circ} CH_2NO_2\dot{C}HR$$

$$CH_2NO_2\dot{C}HR + X_2 \rightarrow CH_2NO_2CHRX$$

$$CH_2{=}CHR + X^{\cdot} \xrightarrow{325^\circ} CH_2X{-}\dot{C}HR$$

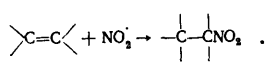
$$CH_2X{-}\dot{C}HR + NO_2^{\cdot} \rightarrow CH_2X{-}CHRNO_2$$

where R = Cl, Br. The different reactions can be accounted for by a change in the reactivity of the $NO_2^{\cdot}$ and $X^{\cdot}$ radicals with increasing temperature.

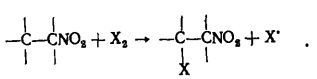
Sometimes a change in the relative proportions of the reactants (the olefin and the N_2O_4–X_2 mixture) leads to a change in the mode of addition[48]:

$$CH_2{=}CHCl \xrightarrow{N_2O_4+Br_2} \begin{cases} \rightarrow CH_2BrCHClNO_2 \\ \rightarrow CHClBrCH_2NO_2 \end{cases}.$$

Liquid-phase nitrohalogenation of unsaturated compounds takes place as a rule by a radical mechanism[45-50]. The reaction is then initiated by the $NO_2^{\cdot}$ radical:



The nitroalkyl radical formed is "captured" by the halogen:



For example,

$$CH_3{-}CH{=}CH_2 + N_2O_4 + I_2 \rightarrow CH_3{-}CHI{-}CH_2NO_2 ,$$
$$CH_3COO{-}CH{=}CH_2 + N_2O_4 + I_2 \rightarrow CH_3COOCHI{-}CH_2NO_2 ,$$
$$C_6H_5{-}CH{=}CH_2 + N_2O_4 + I_2 \rightarrow C_6H_5{-}CHI{-}CH_2NO_2 .$$

The free-radical mechanism explains particularly satisfactorily the reactions of fluoro-olefins with a mixture of N_2O_4 and I_2:[48,49]

$$N_2O_4 \rightarrow 2NO_2^{\cdot} ,$$
$$CF_2{=}CHX + NO_2^{\cdot} \rightarrow NO_2CHX\dot{C}F_2 + O_2NCF_2\dot{C}HX$$
$$\downarrow I_2 \qquad\qquad \downarrow I_2$$
$$O_2NCHXCF_2I + I^{\cdot} \quad O_2NCF_2CHXI + I^{\cdot} ,$$
$$CHX{=}CF_2 + ONO^{\cdot} \rightarrow CHX{-}CF_2ONO \xrightarrow{I_2} ICHX{-}CF_2ONO \rightarrow ICHX{-}COOH ,$$

where X = H, F, or perfluoroalkyl.

Bachman and Logan[51] carried out the reaction of ethylene, propene, and butenes with N_2O_4–I_2 and N_2O_4–Br_2 mixtures in the presence of an excess of nitrogen tetroxide and and isolated halogeno-nitrates, the formation of which they believe to be due to an ionic mechanism:

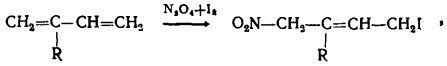
$$R{-}CH{=}CH_2 + Br_2 \rightarrow R{-}\overset{+}{C}H{-}CH_2Br + Br^- ,$$
$$R{-}\overset{+}{C}H{-}CH_2Br + N_2O_4 \rightarrow R{-}CHONO_2CH_2Br + NO^+ .$$

Stevens and Emmons[45] explain this finding by the presence of a large excess of nitrogen tetroxide in the reaction.

Diene hydrocarbons react with the N_2O_4–I_2 mixture by a 1,4-addition mechanism[46]:

$$CH_2{=}CH{-}CH{=}CH_2 \rightarrow CH_2NO_2{-}CH{=}CH{-}CH_2I .$$

With substituted butadienes, the attack by NO_2 radicals is directed preferentially to carbon atoms most highly enriched in electrons:



where R = CH_3 or Cl.

2. CONDENSATION OF NITROALKANES WITH HALOGENO-CARBONYL COMPOUNDS

The condensation of nitro-alkanes with halogeno-carbonyl compounds has been investigated relatively little[54-73]. It was first studied by Henry[54], who allowed chloral hydrate to react with nitromethane in the presence of potassium carbonate[54]:

$$CCl_3CH(OH)_2 + CH_3NO_2 \rightarrow Cl_3CCH(OH)CH_2NO_2 .$$

Later it was repeated[55,57,63,67,73] and extended to chloral homologues (butylchloral and bromal[63]) and other nitro-alkanes (nitroethane, phenylnitromethane[56], and 1-nitro-propane[55]).

The condensation of chloral hydrate with nitromethane takes place with an almost quantitative yield but the reaction is somewhat less complete with other nitro-alkanes. When the reaction was carried out in the vapour phase, contrary results were obtained—a better yield with nitro-butane[58].

The condensation of mono- and dichloroacetaldehyde and bromoacetaldehyde takes place with greater difficulty[59-62]. Fluoro-substituted aldehydes also enter into the condensation reaction with nitro-alkanes in the presence of alkaline catalysts[59-66,68,69]:

$$RCF_2CH(OH)_2 + R'CH_2NO_2 \rightarrow RCF_2CH(OH)CH(NO_2)R' ,$$

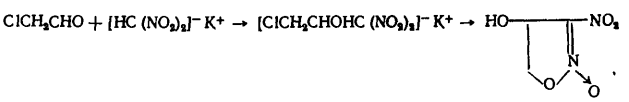
where R = F or C_2F_5 and R′ = H, CH_3, or C_2H_5.

Of the halogeno-substituted ketones, only 1,1,1-trifluoroacetone[68], 1,1,1-trifluorobutan-2-one[66], and perfluoroacetone[70] have been investigated in the condensation with nitro-alkanes:

$$CF_3COR + CH_3NO_2 \rightarrow CF_3CR(OH)CH_2NO_2$$

where R = CH_3, C_2H_5, or CF_3.

When the potassium salt of dinitromethane is condensed with chloroacetaldehyde hydrate, the product of the spontaneous cyclisation, 4-hydroxy-3-nitroisoxazoline *N*-oxide, was obtained instead of the expected potassium salt of γ-chloro-β-hydroxydinitropropane:[72]



3. NITRATION OF HALOGENO-DERIVATIVES OF ALIPHATIC HYDROCARBONS

a. Nitration with Nitrogen Oxides

When nitric oxide acts on chlorotrifluoroethylene and hexafluoropropane, nitro-derivatives are obtained in small amounts[42]:

$O_2NCF_2CFClNO$, $O_2NCF_2CFCl_2$, $O_2NCF_2CFClNO_2$, $CF_3CF(NO){-}CF_2NO_2$ и $CF_3CF(NO_2)CF_2NO_2$.

The addition of nitrogen dioxide to halogeno-olefins takes place by a free-radical mechanism with formation of dinitro-derivatives of halogeno-alkanes. This has been shown by numerous studies on the addition of nitrogen tetroxide to tribromoethylene[64], tetrachloro- and tetrabromoethylenes[65], tetrafluoroethylene[64,66-70], chlorotrifluoroethylene[24,66,71], and hexafluoropropene[69]. Together with halogenonitro-alkanes, the formation of halogenonitronitrites has been observed; on subsequent hydrolysis, the latter yield halogeno-substituted nitro-alcohols[74-87], nitrocarboxylic acids[78-80], or nitro-ketones[81].

In some cases the nitro-alcohol is formed preferentially[82-84]:

$$CH_2Cl{-}CH{=}CH_2 + N_2O_4 \rightarrow CH_2Cl{-}CH(OH){-}CH_2NO_2 ,$$
$$CH_2{=}\underset{\displaystyle CH_2Cl}{\underset{|}{C}}{-}CH_3 + N_2O_4 \rightarrow O_2NCH_2\underset{\displaystyle CH_2Cl}{\underset{|}{C}}(CH_3)OH$$

By allowing the complex $BF_3.N_2O_4$ to react with vinyl chloride at 0°C in chloroform, Bachman and Vogt[85] obtained 2,2-dichloronitroethane:

$$CH_2{=}CHCl + BF_3{\cdot}N_2O_4 \rightarrow Cl_2CHCH_2NO_2 .$$

They explained the formation of this product by the oxidative degradation of part of the vinyl chloride.

The nitration of perfluorobutadiene with N_2O_4 yields 1,4-dinitroperfluorobut-2-ene and 1-nitroperfluorobut-2-enyl nitrite[86]:

$$CF_2=CF-CF=CF_2 \longrightarrow O_2N-CF_2-CF=CF-CF_2-NO_2 \quad O_2N-CF_2-CF=CF-CF_2-ONO$$

On hydrolysis the nitrite is converted into γ-nitroperfluorobutyric acid and on treatment with alcohols or on ammonolysis it yields the esters of this acid or the amide.

Under the action of nitrogen oxides, halogenoacetylenes are converted into halogenonitro- and halogenodinitroethylenes[87-89]:

$$IC\equiv CI + N_2O_4 \rightarrow IC(NO_2)=C(NO_2)I,$$
$$IC\equiv CI + N_2O_3 \rightarrow I_2C=C(I)NO_2,$$
$$ClC\equiv CCl + N_2O_4 \xrightarrow{(C_2H_5)_2O} ClCH=C(Cl)NO_2.$$

Products of the substitution of halogen and hydrogen atoms were obtained in the nitration with N_2O_4 of 2,3-dibromopropene[90] and dichloroethylene[91] respectively:

$$CH_2=C(Br)-CH_2Br \rightarrow CH_2=C(Br)-CH_2NO_2$$
$$(CHCl)_2 \rightarrow NO_2CCl=CHCl.$$

b. Nitration of Halogeno-Alkenes and Halogeno-Alkanes with Nitric and Other Acids

The nitration of halogeno-alkenes with nitric acid or its mixtures with other acids takes place by an ionic mechanism and leads to the formation of products resulting both from the addition of the NO_2 group and the substitution of hydrogen or halogen atoms. In the latter case halogenonitro-alkenes are formed. The nitration process is complicated by side reactions involving oxidation. When a mixture of concentrated nitric and sulphuric acids reacts with tetrachloroethylene, tetrachloro-1,2-dinitroethane is formed[92]:

$$Cl_2C=CCl_2 + HNO_3 \xrightarrow[H_2SO_4]{} O_2NCCl_2CCl_2NO_2.$$

By nitrating 1,1,5-trichloropent-1-ene or 1,1-dichloropent-1-ene with nitric acid, Zakharkin[10] obtained both mono- and di-nitro-derivatives:

$$Cl_2C=CHCH_2CH_2CH_2Cl + HNO_3 \rightarrow Cl_2CCH(NO_2)CH_2CH_2CH_2Cl + Cl_2C(NO_2)CH(NO_2)CH_2CH_2CH_2Cl,$$
$$Cl_2C=CHC_3H_7 + HNO_3 \rightarrow Cl_2CCH(NO_2)C_3H_7 + Cl_2C(NO_2)CH(NO_2)C_3H_7$$

He believes that the formation of 1,1,1-trichloro-2-nitroalkanes can be explained by the reaction of hydrochloric acid (formed in the oxidation of the $Cl_2C=CH$ group) with nitric acid ($HNO_3 + HCl \rightarrow NOCl + Cl_2 + H_2O$)—the addition of nitrosyl chloride and the oxidation of the resulting products; the formation of nitryl chloride by the reaction of hydrochloric and nitric acids and its subsequent addition to the double bond cannot be excluded.

On being refluxed with an excess of nitric acid, dichloroethylene is converted into trichloronitroethylene in a good yield[93]. Under the action of fuming nitric acid or its mixtures with sulphuric acid, tetraiodoethylene yields 1,2,2-tri-iodonitroethylene[87].

Kooijman and Overhoff[94] nitrated chloro-olefins with nitric acid in such a way that the double bond in the initial olefins was not affected:

$$CH_2=C(CH_3)CH_2Cl + HNO_3 \rightarrow O_2NCH=C(CH_3)CH_2Cl.$$

A method of nitration of olefins with a mixture of sodium nitrite and dilute sulphuric acid has been patented[95,96]:

$$CH_2=C(CRR^1X)-CHR^2R^3 + NaNO_2 \xrightarrow{H_2SO_4} CH_2=C(CRR^1X)-CR^2R^3NO_2,$$

where R, R^1, R^2, and R^3 = H or alkyl and X = halogen.

The reaction of 2,3-dibromopropene with nitric acid in dichloroethane at 40–50°C yields a mixture of these products[97]:

$$BrCH_2C(Br)=CH_2 + HNO_3 \rightarrow (NO_2)_2CCH_2Br + (NO_2)_2CHCH_2Br + BrCH_2-C(NO_2)(Br)-COOH.$$

Martynov and coworkers[98-102] obtained the products of the oxidation of halogeno-olefins with the nitrating mixture. They isolated halogenonitro-acids and their chlorides.

Nitrofluorination of olefins and their halogeno-derivatives with a mixture of nitric acid and anhydrous hydrogen fluoride can serve as one of the methods of preparation of fluoronitro-alkanes:

$$HF + HNO_3 \rightleftarrows O_2N^+ + 2F^- + H_3O^+$$
$$>C=C< + O_2N^+ \rightarrow \left[>C(NO_2)-\overset{+}{C}<\right] F^- \rightarrow >C(NO_2)-C(F)<.$$

This reaction was achieved for the first time with tetrafluoroethylene[103]:

$$CF_2=CF_2 + HNO_3 + HF \rightarrow CF_3CF_2NO_2.$$

The study of the nitrofluorination of asymmetric halogeno-olefins showed that the mode of addition is determined by the polarity of the double bond[103-106]:

$$CHCl=CH_2 \xrightarrow{HF+HNO_3} CHFCl-CH_2NO_2,$$
$$CF_2=CFCF_3 \xrightarrow{HNO_3+HF} (CF_3)_2CFNO_2,$$
$$CH_2=CHCOOCH_3 \xrightarrow{HF+HNO_3} CH_2F-CH(NO_2)COOCH_3 + CH_2OH-CHNO_2-COOCH_3.$$

The nitration of saturated hydrocarbons and their derivatives was first investigated by Konovalov. By heating a mixture of dilute nitric acid with 1-chloro-2-methylpropane or 1-chloro-3-methylbutane in sealed tubes, he obtained the corresponding mononitro-derivatives, the nitro-group substituting the hydrogen at the tertiary carbon atom[107,108]:

$$(CH_3)_2CH(CH_2)_nCl + HNO_3 \rightarrow (CH_3)_2C(NO_2)(CH_2)_nCl,$$

where n = 1, 2.

Shechter and Conrad[109] achieved the vapour-phase nitration of 1,1,1-trifluoropropane at 437–462°C in the presence of oxygen and isolated 3,3,3-trifluoro-1-nitropropane. When the reaction was carried out at 395°C, a mixture of 3,3,3-trifluoro-1-nitropropane and 2,2,2-trifluoronitroethane was isolated in proportions of 3 : 2.[110]

Chloronitro-alkanes have been obtained by the action of a mixture of sulphuric acid and ammonium nitrate on the corresponding chloro-alkanes[111]:

$$RCH(Cl)CH_3 \xrightarrow[H_2SO_4]{NH_4NO_3} RCH(Cl)CH_2NO_2,$$

where R = CH_3 or C_2H_5.

4. HALOGENATION OF NITRO-COMPOUNDS

a. Halogenation of Nitro-Olefins

Unsaturated nitro-compounds (in solution) combine with chlorine or bromine at the double bonds in the cold or on heating, with formation of dihalogeno-derivatives[112-117]. The reaction involves a heterolytic mechanism:

$$RCH{=}C(NO_2)R' + X_2 \rightarrow RCH(X)C(X)(NO_2)R' .$$

When two electronegative substituents are present at the double bond, more severe conditions are required for the addition of the halogen. Thus chlorine adds to vicinal dinitro-olefins after the olefin has remained in contact for a long time with liquid chlorine in sunlight[115].

The double bond conjugated with the nitro-group in 1-nitrobutadiene[114] is deactivated and, when bromine reacts with 1-nitrobutadiene between −10° and 18°C, only one molecule of bromine adds to the olefin with formation of the dibromo-derivative in 99% yield:

$$NO_2CH{=}CH{-}CH{=}CH_2 + Br_2 \rightarrow NO_2CH{=}CHCHBrCH_2Br .$$

Since the nitro-group is a powerful electron acceptor, the electrophilic addition of bromine to β-nitrostyrene is difficult and therefore for this reaction to take place, the reaction mixture must be heated in chloroform[116].

b. Halogenation of Nitro-Alkanes

Riley and McBee[118,119] showed that the chlorination of nitro-alkanes in the absence of bases leads to the formation of β-chloronitro-alkanes. Bromination in the absence of base yields the same products as in the presence of bases, i.e. α-bromonitro-compounds are produced. The authors believe that substances such as phosphorus pentoxide favour the formation of the β-isomer by displacing the equilibrium of the reaction

$$RCH_2NO_2 \rightleftarrows RCH{=}N\begin{matrix}O\\ \diagup\\ \diagdown\\ OH\end{matrix} .$$

Riley and McBee explained the difference in the behaviour of chlorine and bromine by the fact that chlorine reacts very fast and the concentration of the nitronic acid is negligible, while bromination takes place slowly, and the conversion of the nitro-alkane into the aci-form takes place much more rapidly and therefore there is sufficient time for the aci-form to react with bromine with formation of α-bromonitro-alkane.

Sayles and Degering[120] described the chlorination of nitrobutane on irradiation with ultraviolet light in the presence of phosphorus pentoxide, the sole product according to their data being 4-chloro-1-nitrobutane:

$$CH_3CH_2CH_2CH_2NO_2 + Cl_2 \xrightarrow{P_2O_5} ClCH_2CH_2CH_2CH_2NO_2 .$$

However, in the chlorination of nitrobutane under analogous conditions Erm[121] obtained in addition 3-chloro-1-nitrobutane. He believes that the mode of reaction depends mainly on the intensity of the ultraviolet irradiation.

5. SUBSTITUTION OF A HALOGEN FOR THE HYDROXYL IN NITRO-ALCOHOLS

As in simple aliphatic alcohols, the hydroxy-group of nitro-alcohols can be replaced by a halogen when the latter reacts with the halides of phosphorus and sulphur acids[122-148]. This reaction is used to demonstrate the presence of the hydroxy-group in nitro-alcohols and for the preparation of halogenonitro-alkyls with a definite structure.

The substitution of the hydroxy-group of nitro-alcohols by a chlorine atom was first achieved by Henry[54,122-125], who treated the nitro-alcohols with phosphorus pentachloride:

$$RCH(NO_2)CH_2OH + PCl_5 \xrightarrow{K_2CO_3} RCH(NO_2)CH_2Cl ,$$

where R = H or CH_3, and

$$RCH(OH)CH_2NO_2 + PCl_5 \xrightarrow{K_2CO_3} RCHClCH_2NO_2 ,$$

where R = CH_3 or CCl_3. Other β-chloronitro-alkanes were prepared similarly[126-130].

The substitution of the hydroxy-groups in nitro-diols by halogens under the action of phosphorus pentachloride takes place with much greater difficulty[131,137], while with trihydric alcohols a mixture of chloro-derivatives of various degrees of substitution and of phosphoric acid esters of the nitro-alcohols is produced[133]. Kleinfeller[133] synthesised tri(bromomethyl)nitromethane by the bromination of nitroisobutylglycerol with elemental bromine in the presence of red phosphorus[133]. The nature of the side products formed in this process was similar to that in the chlorination reaction.

A more convenient method for the substitution of the hydroxy-group by a chlorine atom consists in the treatment of nitro-alcohols with thionyl chloride in the presence of pyridine. The following chloronitro-compounds have been obtained by this procedure: $ClCH_2CH_2NO_2$, $O_2NCH_2CHClCH_3$, $C_2H_5CH(NO_2)CH_2Cl$;[132] $CH_3C(Cl)(NO_2)CH_2Cl$, $O_2N(C_2H_5)C(CH_2Cl)_2$;[138] $O_2NC(CH_2Cl)_3$;[139] $CH_3C(NO_2)_2CH_2Cl$, $ClCH_2C(NO_2)_2CH_2Cl$;[148] $CH_2NO_2CHClCH_3$;[146] $(O_2N)_3CCH_2Cl$.[147]

In the study of the reaction of thionyl chloride with nitrodiols in the presence of pyridine, Novikov and coworkers[140] concluded that the chlorinating agent is a complex of thionyl chloride with pyridine, formed relatively slowly. Therefore, on rapid addition of $SOCl_2$ to the mixture of the diol and pyridine, there is not sufficient time for the formation of the complex and the reaction can lead to the formation of cyclic sulphites[133].

Halogenonitro-alkanes can be prepared from the acetals of nitro-alcohols by treating the latter with phosphorus pentachloride[141]:

$$RR^1C(NO_2)CHR^2OCHOR^3 \xrightarrow{PCl_5} RR^1C(NO_2)CH(R^2)Cl ,$$
$$\quad\quad\quad

6. DOUBLE DECOMPOSITION OF POLYHALOGENO-ALKENES WITH METAL NITRITES

Henry[54,149] achieved the synthesis of 2-chloronitroethane and 3-chloro-1-nitropropane by the reaction of silver nitrite with the corresponding $\alpha\omega$-chloroiodo-alkanes:

$$Cl(CH_2)_nI + AgNO_2 \rightarrow Cl(CH_2)_nNO_2,$$

where $n = 2$ or 3. A number of $\alpha\omega$-fluoronitro-alkanes have been synthesised by the reaction of the corresponding $\alpha\omega$-bromofluoro- or $\alpha\omega$-fluoroiodo-alkanes with silver nitrite[150]:

$$F(CH_2)_nX + AgNO_2 \rightarrow F(CH_2)_nNO_2,$$

where X = Br or I and $n = 3$, 4, 5, or 6.

Halogenonitro-alkanes can be obtained also from di-halogeno-derivatives in which both halogen atoms are identical. Thus Work carried out the reaction of silver nitrite with 1,5-dibromopentane[151] and 1,5-dibromo-3-propylpentane[152] at room temperature and obtained the corresponding $\alpha\omega$-bromonitro-alkanes:

$$RCH(CH_2CH_2Br)_2 + AgNO_2 \rightarrow NO_2CH_2CH_2CH(R)CH_2CH_2Br,$$

where R = H or C_3H_7. 2-Bromo-3-nitropropene was obtained similarly from 2,3-dibromopropene[90].

Freidlina et al.[153] obtained 1,1-dichloro-3-nitropropene from 1,1,3-trichloropropene and silver nitrite using the different reactivities of the chlorine atoms:

$$ClCH_2CH{=}CCl_2 + AgNO_2 \rightarrow NO_2CH_2CH{=}CCl_2.$$

A method for the preparation of halogeno nitro-compounds by the reaction of polyhalogeno-compounds with alkali or alkaline earth metal nitrites in aqueous ethanol was patented in 1944:[154]

$$ClCH_2CH_2Cl + MNO_2 \rightarrow O_2NCH_2CH_2Cl$$

$$ClCH_2{-}\underset{OH}{CH}{-}CH_2Cl + MNO_2 \rightarrow O_2NCH_2\underset{OH}{CH}{-}CH_2Cl.$$

7. REPLACEMENT OF A CARBOXY-GROUP BY A HALOGEN ATOM OR A NITRO-GROUP

Silver salts of *gem*-dinitro-carboxylic acids are converted into bromonitro-alkanes under the action of elemental bromine[155-157]. 4-bromo-2,2-dinitrobutane and 1,5-dibromo-3,3-dinitropentane have been obtained in this way:

$$CH_3\overset{NO_2}{\overset{|}{C}}(NO_2)-CH_2CH_2-COOAg \xrightarrow[CCl_4]{Br_2} CH_3-\overset{NO_2}{\overset{|}{C}}(NO_2)-CH_2CH_2Br,$$

$$AgOOCCH_2CH_2\overset{NO_2}{\overset{|}{C}}(NO_2)-CH_2CH_2COOAg \xrightarrow[CCl_4]{Br_2} BrCH_2CH_2\overset{NO_2}{\overset{|}{C}}(NO_2)-CH_2CH_2Br.$$

Scribner[158] showed that perfluoro-carboxylic acids are converted into nitroperfluoro-alkanes under the action of nitrogen dioxide:

$$C_7F_{15}COOH \xrightarrow{NO_2} C_6F_{13}NO_2 + C_7F_{15}NO_2.$$

8. SYNTHESIS OF γ-BROMODINITRO-COMPOUNDS

Novikov et al.[159] developed a new method for the synthesis of γ-bromodinitro-compounds, which consists in the reaction of the mercury-derivatives of nitro-alkanes with bromine:

$$(NO_2)_2CHCH_2CH_2HgCl + Br_2 \xrightarrow[\text{peroxide}]{\text{benzoyl}} (NO_2)_2CHCH_2CH_2Br + HgBrCl,$$

1-Bromo-3,3-dinitropropane, 1-bromo-2-methyl-3,3-dinitropropane, 1-bromo-3,3-dinitro-2-phenylpropane, 2-bromo-1-dinitromethylcyclopentane, and 2-bromo-1-dinitromethylcyclohexane have been obtained. The reaction involves a radical mechanism.

9. OTHER METHODS

When a stream of gaseous hydrogen chloride is passed through a mixture of β-nitro-alcohol and paraformaldehyde in concentrated hydrochloric acid, chloromethyl ethers of the β-nitro-alcohols are produced[160,161]:

$$R-\overset{R'}{\overset{|}{C}}(NO_2)-CH_2OH + (CH_2O)_x + HCl \rightarrow R-\overset{R'}{\overset{|}{C}}(NO_2)-CH_2OCH_2Cl,$$

where R = H or CH_3 and R' = CH_3 or C_2H_5. In the presence of sodium methoxide nitromethane adds to esters of $\alpha\beta$-unsaturated fluoro-substituted acids with formation of fluoronitro-compounds containing other functional groups[65]:

$$RCH{=}CHCOOC_2H_5 + CH_3NO_2 \xrightarrow{CH_3ONa} RCH(CH_2NO_2)CH_2COOC_2H_5,$$

where R = CF_3 or C_3F_7. Bromonitropentanone has been obtained by the addition of bromonitroform to methyl vinyl ketone[162].

Boyd and Hansen[163] obtained 1-iodo-2-methyl-2-nitropropane by refluxing 2-methyl-2-nitropropyl esters of arenesulphonic acids with sodium iodide in acetone:

$$RSO_3CH_2\overset{(CH_3)_2}{\overset{|}{C}}(NO_2) + NaI \rightarrow (CH_3)_2\overset{CH_2I}{\overset{|}{C}}(NO_2).$$

Under the action of nitrogen tetroxide in ether, the oxime of chloroacetone is converted into 1-chloro-2-nitro-2-nitrosopropane, which is oxidised by chromic acid to the *gem*-dinitro-compound[164]:

$$ClCH_2\underset{NOH}{\overset{\|}{C}}-CH_3 \xrightarrow{N_2O_4} ClCH_2-\overset{NO}{\overset{|}{\underset{NO_2}{\overset{|}{C}}}}-CH_3 \xrightarrow{[O]} ClCH_2-\overset{NO_2}{\overset{|}{\underset{NO_2}{\overset{|}{C}}}}-CH_3.$$

Nitrosoperhalogeno-alkanes, obtained by the irradiation of a mixture of nitric oxide and a monoiodoperhalogeno-alkane with ultraviolet light, are converted into halogeno-nitro-compounds on oxidation with Cr_2O_3, PbO_2, or Mn_2O_7:[165]

$$RCF_2I + NO \rightarrow RCF_2NO \xrightarrow{O} RCF_2NO_2,$$

where R = Cl, CF_3, or C_2F_5.

Knunyants and coworkers[166] obtained esters of α-nitro-perfluoropropionic acid by the action of nitrogen tetroxide on esters of α-nitrosoperfluoropropionic acid:

$$CF_3\underset{NO}{\overset{|}{C}}F-COOR + N_2O_4 \rightarrow CF_3\underset{NO_2}{\overset{|}{C}}F-COOR + N_2O_3.$$

Nitro-alcohols react with trichloroacetonitrile in the presence of hydrogen chloride or bromide with formation of the hydrohalides of the corresponding trichloronitroalkyl-acetimidates. On decomposition, the latter yield halogeno-nitro-alkanes[167]:

$$CCl_3C{\equiv}N + HOCH_2CH_2NO_2 \rightarrow CCl_3\underset{NH\cdot HX}{\overset{\|}{C}}-OCH_2CH_2NO_2 \rightarrow CCl_3CONH_2 + XCH_2CH_2NO_2$$

By this method 1-chloro-2-nitroethane and 1-bromo-2-nitroethane have been obtained from nitroethanol and 1-chloro- and 1-bromo-2-nitropropane from 2-nitropropanol.

III. CHEMICAL PROPERTIES OF HALOGENONITRO-COMPOUNDS

1. REACTIONS WITH PARTICIPATION OF THE HALOGEN ATOM

a. Dehydrohalogenation

The dehydrohalogenation of halogenonitro-compounds to form nitro-olefins can be achieved either by pyrolysis or by treatment with basic reagents. Gold[168,169] pyrolysed β-chloronitro-compounds in the gas phase; it is best to carry out the process in the presence of catalysts [for example, $CaCl_2$, $CaCO_3$, $Ca_3(PO_4)_2$, $CaSO_4$, $Al(SO_4)_3$][168-170], which partially reduces the reaction temperature and increases the yields of nitro-olefins:

$$RCHCH_2NO_2 \rightarrow RCH{=}CHNO_2 \ .$$
$$\quad\ Cl$$

Spontaneous thermal dehydrohalogenation takes place when the products of the addition of nitryl chloride to styrene[3] or acrylic acid[12] are heated:

$$C_6H_5CH(Cl)CH_2NO_2 \rightarrow C_6H_5CH{=}CHNO_2 \ ,$$
$$NO_2CH_2CH(Cl)COOH \rightarrow NO_2CH{=}CHCOOH \ .$$

A convenient method for the dehydrohalogenation of β-halogenonitro-compounds consists in the treatment of the latter with basic reagents: alkalis[45,171], alkali metal acetates[8,12,45,172-175], and organic bases[10,12,45,176]. The dehydrohalogenation takes place more readily when the halogen (chlorine) atom is attached to a primary carbon atom, as, for example, in chloronitroethane. The dehydrohalogenation of 2-chloro-1-nitrobutane is slower. That of 2-chloro-3-methyl-1-nitrobutane is even more difficult[8]. Perekalin and Lerner[177] obtained 1,4-dinitrobutadiene by the dehydrochlorination of the corresponding dichloro-derivative with lead acetate:

$$O_2NCH_2CH(Cl)CH(Cl)CH_2NO_2 \rightarrow NO_2CH{=}CHCH{=}CHNO_2 \ .$$

2-Nitrobuta-1,3-diene has been obtained from 1-chloro-2-nitro-3-butanol and 1,3-dichloro-2-nitrobutane by the treatment of the mixture with potassium hydroxide[132].

Nitro-alkadienes are readily formed on dehydroiodination of the products of the addition of N_2O_4 and I_2 to diene hydrocarbons in the presence of a solution of lead acetate in glacial acetic acid[178]:

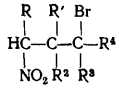
$$RCHI{-}CR'{=}CH{-}CH_2NO_2 \rightarrow R{-}CH{=}CR'{-}CH{=}CHNO_2 \ .$$

In the dehydrohalogenation of compounds in which the halogen and the nitro-group are further away than in β-halogenonitro-compounds, it is necessary to use strong bases, for example, sodium alkoxides[155]:

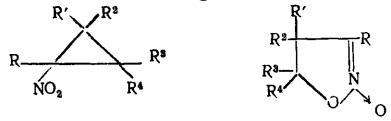
$$CH_3\underset{NO_2}{\overset{NO_2}{C}}CH_2CH_2Br \xrightarrow{NaOCH_3} CH_3\overset{NO_2}{C}{=}CH_2 \ .$$

On elimination of hydrogen halides from γ-halogenonitro-alkanes, nitrocyclopropanes have been obtained[179-185].

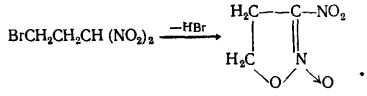
Koler and later Smith[179,180,184] showed that γ-bromo-nitro-compounds of the type



where R = $R^{1,2,3}$ = H, alkyl, or aryl and $R^4 = \diagdown C{=}O$ or -COAr, eliminate hydrogen bromide in an alkaline medium and form either the corresponding nitrocyclopropane derivatives or the isomeric isoxazoline *N*-oxides, depending on the structure of the starting material:



Intramolecular *O*-alkylation, which leads to the formation of 3-nitroisoxazoline-*N*-oxides under the action of alkaline reagents, is characteristic of γ-bromodinitro-compounds containing terminal *gem*-dinitro-groups[186]:



3-Nitro-2-isoxazoline has been obtained by treating 1-halogeno-3-nitropropanes with alkali metal nitrites[187]. Recently Bay[182,183] patented the synthesis of nitrocyclopropane by the dehydrohalogenation of 1-halogeno-3-nitropropanes under the action of sodamide in liquid ammonia or alkali metal carbonates and bicarbonates.

b. Reactions Involving the Substitution of the Halogen Atom

β-Halogenonitro-compounds readily react with aniline and its derivatives[3,7,8,53,188] forming *N*-nitroalkylanilines:

$$R{-}CHCl{-}CH_2NO_2 + C_6H_5NH_2 \rightarrow C_6H_5NH{-}CH\!\!\begin{array}{l}\diagup CH_2NO_2\\ \diagdown R\end{array} + HCl \ .$$

In the case of dichloronitropropane both halogen atoms are substituted[8]:

$$CH_2Cl{-}CHCl{-}CH_2NO_2 + 2NH_2C_6H_5 \rightarrow C_6H_5NHCH_2{-}\underset{NHC_6H_5}{\underset{|}{CH}}{-}CH_2NO_2 \ .$$

When 2,3,3,3-tetrachloro-1-nitropropane reacts with ammonia, *p*-toluidine, and phenylhydrazine, the products are the corresponding 2-amino-derivatives[189]. The study of the hydrolysis of β-halogenonitroalkanes with aqueous solutions of alcohol and dioxan showed that the reaction takes place by an S_N2 nucleophilic mechanism[8,134,190-193] with formation of nitro-alcohols:

$$\begin{array}{l}R\\ R'\end{array}\!\!\diagup CCl{-}CH_2NO_2 + H_2O \longrightarrow \begin{array}{l}R\\ R'\end{array}\!\!\diagup C{-}CH_2NO_2 + HCl \ ,$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \diagdown OH$$

where R = H, C_2H_5, or iso-C_3H_7 and R′ = H or CH_3. The rate of hydrolysis depends on the nature of the carbon atoms to which the halogen is attached, decreasing on going from a primary to a tertiary carbon atom, as clearly illustrated by the following data[8]:

	Hydrolysis rate constant	
	in 75% ethanol	in 75% dioxan
$ClCH_2CH_2NO_2$	7.15×10^{-5}	5.27×10^{-5}
$H_3C{>}CH{-}CHClCH_2NO_2$ (H_3C)	2.27×10^{-5}	1.30×10^{-5}
$CH_3CH_2{>}CCl{-}CH_2NO_2$ (H_3C)	0.25×10^{-5}	0.21×10^{-5}

The halogen atom in the γ-position relative to the nitro-group is less mobile. Thus, whereas both chlorine atoms of 2,2-dichloro-1-nitroethane are readily substituted during hydrolysis, in 2,3-dichloro-1-nitropropane only the chlorine atom in the β-position is hydrolysed[8]:

$$O_2NCH_2{-}CHCl_2 \xrightarrow{2H_2O} O_2NCH_2CH(OH)_2 \xrightarrow{-H_2O} O_2NCH_2CHO,$$

$$O_2NCH_2{-}CHCl{-}CH_2Cl \xrightarrow{H_2O} O_2NCH_2\underset{\displaystyle OH}{\underset{|}{C}}H{-}CH_2Cl.$$

When acetate salts react with halogenonitro-alkanes, it is possible to obtain the acetates derived from the corresponding nitro-alcohols[8,156,194]:

$$\rangle CCl{-}CH_2NO_2 \xrightarrow[CH_3COOH]{CH_3COOK} \rangle \underset{\displaystyle OCOCH_3}{\underset{|}{C}}{-}CH_2NO_2,$$

$$BrCH_2CH_2{-}\underset{\displaystyle NO_2}{\underset{|}{C}}{-}CH_2CH_2Br \xrightarrow[CH_3COOH]{CH_3COOAg} CH_3COOCH_2CH_2\underset{\displaystyle NO_2}{\underset{|}{C}}{-}CH_2CH_2OCOCH_3.$$

The reaction of β-chloronitro-compounds with mecarptans and their derivatives in the presence of sodium leads to the formation of sulphides[129,130]:

$$CH_3CHClCH_2NO_2 + HSCH_2CH(OC_2H_5)_2 \xrightarrow{Na} O_2NCH_2CH(CH_3)SCH_2CH(OC_2H_5)_2.$$

c. Dehalogenation

The dehalogenation of halogenonitro-alkanes has been little investigated. Only two reactions have been described in the literature: on heating above 120°C, 1,2-dibromo-1,2,2-trichloronitroethane decomposes with elimination of bromine[85]; on being refluxed with potassium cyanide, 1,2-dibromo-2-phenylnitroethane is converted into β-nitro-styrene[195]:

$$C_6H_5CHBr{-}CHBrNO_2 \rightarrow C_6H_5CH{=}CHNO_2.$$

2. REACTIONS WITH PARTICIPATION OF THE NITRO-GROUP

1. Reduction

Various methods may be used to convert halogenonitro-compounds into the corresponding aminohalogeno-derivatives. Konovalov[107] identified the nitro-derivatives which he obtained by reduction to the amines with zinc and hydrochloric acids. The reduction with iron and hydrochloric acid is also successful[139]:

$$NO_2C(CH_2Cl)_3 + Fe + HCl \rightarrow H_2NC(CH_2Cl)_3.$$

Another reagent used to convert halogenonitro-compounds into halogeno-amines is aluminium amalgam[133,188]. A number of investigators obtained aminohalogeno-compounds from the corresponding nitro-derivatives by reducing the latter with stannous chloride and hydrochloric acid[6,10,133,139,196].

Certain halogenonitro-compounds have been converted into halogeno-amines by catalytic hydrogenation over Raney nickel[8,55,65,67,197,198]. Hydroxylamines are then formed together with the amines. It has been mentioned that certain fluoronitro-compounds can be converted into amino-compounds with the aid of lithium aluminium hydride without affecting the C–F bond[57]. The electrolytic reduction of chloronitro-compounds to chloroalkylamines in aqueous alcohol in the presence of sulphuric acid has been reported[8].

When 6-chloro-5-nitrodec-5-ene is hydrogenated over PtO_2 in acetic acid in the presence of sodium acetate, simultaneous conversion of the nitro-group into NHOH and the replacement of the chlorine atom by hydrogen takes place[15]. Bromine atoms are replaced by hydrogen together with the reduction of the nitro-group in the hydrogenation of 1,2-dibromo-1-nitro-2-phenylethane over a palladium catalyst[148]:

$$C_6H_5CHBrCH(Br)NO_2 \xrightarrow{H_2} C_6H_5CH_2CH_2NH_2.$$

For the reduction of halogenonitro-compounds, see also the review of Novikov et al.[199]

b. The Effect of Mineral Acids

Under the action of mineral acids, halogenonitro-alkanes are converted into the corresponding halogeno-derivatives of carboxylic acids[19-22,105,200]. This reaction is so characteristic of fluoronitro-alkanes that it may serve as a convenient method for the synthesis of fluoro-carboxylic acids[200]:

$$-\underset{\displaystyle F}{\underset{|}{C}}{-}CH_2NO_2 \xrightarrow{H_2SO_4} -\underset{\displaystyle F}{\underset{|}{C}}{-}COOH.$$

When β-halogenonitro-alkanes are treated with aliphatic alcohols in the presence of strong acids (hydrochloric, sulphuric, and phosphoric), esters are produced[201]:

$$(CH_3)_2CClCH_2NO_2 + CH_3OH \xrightarrow{H_2SO_4} (CH_3)_2CClCOOCH_3.$$

When salts of the aci-forms of halogenonitro-alkanes are allowed to react with acids, halogeno-aldehydes are produced[109,121]:

$$NaOON{=}CHCH_2CH_2CHCl \xrightarrow[-15°]{H_2SO_4} CHClCH_2CH_2CHO.$$

3. OTHER REACTIONS

a. Reactions Involving a Mobile Hydrogen Atom

Reactions associated with the mobility of hydrogen atoms in the α-position relative to the nitro-group are characteristic of halogenonitro-alkanes as well as unsubstituted nitro-alkanes. Thus in the study of the condensation of trifluoro- and tetrafluoro-nitroethane with formaldehyde in the presence of alkalis, Knunyants et al.[198] obtained a good yield of fluoronitro-alcohols:

$$CF_3{-}CH_2NO_2 + 2CH_2O \xrightarrow{NaOH} CF_3{-}\underset{\displaystyle CH_2OH}{\underset{|}{\overset{\displaystyle CH_2OH}{\overset{|}{C}}}}{-}NO_2.$$

Chloronitro-alkanes enter into a similar condensation with formaldehyde in the presence of potassium carbonate[200]:

$$Cl_3CCHR'CH(NO_2)R + CH_2O \xrightarrow{K_2CO_3} Cl_3CCHR'\underset{\displaystyle CH_2OH}{\underset{|}{\overset{\displaystyle R}{\overset{|}{C}}}}NO_2,$$

where R = H or CH_3 and R′ = OCH_3, OC_2H_5, C_2H_5, or C_4H_9. When the reaction is carried out in an alcoholic medium, the corresponding ethers are formed in both cases.

The "mobile" hydrogen atom is readily substituted by halogens[77]:

$$CF_3CHCH_2NO_2 \xrightarrow{Br_2} \underset{OH}{CF_3CH}-\underset{OH\ \ Br}{CHNO_2}.$$

When aryldiazonium salts react with acetates derived from halogenonitro-alcohols, diazotisation takes place[202]:

$$RCCl_2CH(OCOCH_3)CH_2NO_2 \xrightarrow{ArN_2^+} RCCl_2CH(OCOCH_3)C(NO_2)=NNHAr,$$

where R = Cl or CH_3CHCl.

b. Reactions with Formation of New C–C Bonds

Sayles and Degering[120] carried out the condensation of 4-chloro-1-nitrobutane with ethyl acetoacetate in the presence of sodium:

$$O_2N(CH_2)_4Cl + CH_3COCH_2COOC_2H_5 \xrightarrow{Na} O_2N(CH_2)_4CH(COCH_3)COOC_2H_5.$$

2-Chloro-1-nitropropane reacts with benzene in the presence of aluminium chloride[203]:

$$CH_3CHClCH_2NO_2 + C_6H_6 \xrightarrow{AlCl_3} C_6H_5-CH\begin{matrix}CH_3\\CH_2NO_2\end{matrix}.$$

IV. APPLICATIONS OF HALOGENONITRO-COMPOUNDS

Compounds which contain both halogen atoms and nitro-groups are of definite interest because of their high physiological activity[200]. There have been a number of studies where it was shown that chloronitro-compounds can be used as insecticides[18,204-206], fungicides[57,71], bactericides[58,71,207], miticides[194], and herbicides[71].

When products of the addition of alcohols to β-(trichloromethyl)nitroethylene are reduced, amines are formed, some of which can be used as antispasmodic agents[196].

2-Chloro-1-nitro-olefins have been patented as fumigants, selective extracting agents, cellulose solvents, and varnish components[94,135].

Krug and Elmer[207] took out a patent for the application of the compounds $Cl_3CCH(R)C(R^1)(R^2)NO_2$ (where R = H or acyl containing 2–3 carbon atoms and R^1 and R^2 = H, CH_3, or C_2H_5) as additives (in amounts of 0.05–15%) to greases for gas-turbine engines. The same compounds are used for the dilution and dispersion of oils[208]. The application of bromonitro-alkanes and bromonitro-alkenes as additives to motor fuel has been mentioned[209].

Halogenonitro-alkanes are used as solvents[24] and additives to resin adhesives[111].

The application of 3,3,3-trichloro-1-nitropropane as a solvent for the copolymers of acrylonitrile with vinyl acetate and vinylpyridine in the dyeing of the polymeric products by organic dyes has been described[197].

The chloro-derivatives of 2,2-dinitropropanol and 2,2-dinitropropanediol have been proposed as plasticisers, solvents, and explosive components[148].

The Chemistry of Acyl and Sulphonyl Isocyanates, Isothiocyanates, and Isoselenocyanates

M.O.Lozinskii and P.S.Pel'kis

The review presents the latest advances in the chemistry of acyl and sulphonyl isocyanates, isothiocyanates, and isoselenocyanates. All the methods for the preparation of these compounds are examined and treated systematically. Their reactions and their physical properties are described and the problems of their structure and isomerisation are discussed. In conclusion the available literature data on the practical importance and applications of acyl and sulphonyl isocyanates, isothiocyanates, and isoselenocyanates are presented.

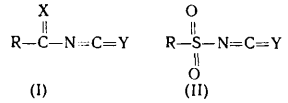
I. INTRODUCTION

Organic isothiocyanates and isocyanates, first obtained towards the end of the last century, are assuming increasing importance at the present time. The enormous interest in this class of compounds is due to the fact that, by virtue of their reactivity, they have become important starting materials and intermediates for the synthesis of a wide variety of organic compounds, many of which have found practical applications. Organic isocyanates are essential for the synthesis of polymeric materials, synthetic fibres, medicinal preparations, insecticides, herbicides, fungicides, nematocides, photographic materials, and many other products.

In 1964 an International Symposium was held in Czechoslovakia on the chemistry of isocyanates [1]. Novel synthetic methods have been described in papers published recently[2-5] and new synthetic and practical applications have been found for organic isocyanates, isothiocyanates, and thiocyanates[6-7]. Reviews of the chemistry of isocyanates have been published[8-10].

The data on acyl isocyanates, isothiocyanates, and isoselenocyanates are scattered in many sources and information about them has not been compiled. The present review is an attempt to fill this gap. It deals with new data on the structure, methods of preparation, properties, and practical applications of acyl isocyanates, isothiocyanates, and isoselenocyanates, thioacyl isocyanates, sulphonyl isocyanates, and sulphonyl isothiocyanates with the general formulae (I) and (II):



(I) (II)

where X and Y can have the following significance: X = Y = O, X = Y = S, X = Y = Se, X = O and Y = S or Se, and X = S and Y = O or Se; R may be a halogen, alkyl, aryl, or an alkoxy- aryloxy-, or dialkylamino-group, etc.

The chemical properties of sulphonyl isocyanates [(II), Y = O] have been examined in Ulrich's review[10]. We shall deal only with those data on this class of compounds which were not included in Ulrich's review, but which are nevertheless of considerable interest.

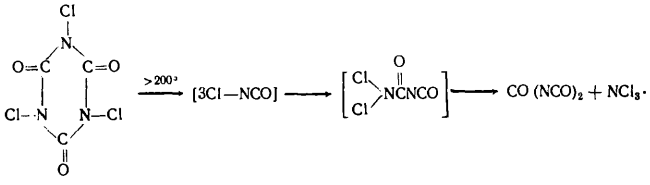
Of the two types of acyl isocyanates and isothiocyanates examined here, the first has been known for a long time, but recently there has been an increase of interest in these compounds. The chemistry of thioacyl isocyanates of the type R–C(=S)–N=C=O began to be studied in the last 4–5 years, while thioacyl isothiocyanates R–C(=S)–N=C=S and thioacyl isoseleno-

while thioacyl isothiocyanates R–C(=S)–N=C=S and thioacyl isoselenocyanates R–C(=S)–N=C=Se are still unknown. Acyl isoselenocyanates of the type R–C(=O)–N=C=Se have not been obtained in a pure form. Their existence has been demonstrated by conversion into selenourea derivatives. The first representatives of sulphonyl isothiocyanates $R-SO_2N=C=S$ have been obtained recently.

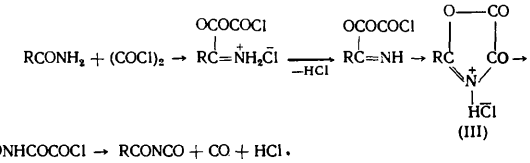
The review deals with papers published up to 1st June, 1967.

II. METHODS OF PREPARATION OF ACYL ISOCYANATES, ISTHIOCYANATES, AND ISOSELENOCYANATES

I. Carbonyl isocyanates. The simplest compound of this series, carbonyl diisocyanate O=C=N–C(=O)–N=C=O, was first obtained in 1966 by the thermal decomposition of trichloroisocyanuric acid at atmospheric pressure[11]. The reaction takes place via the intermediate formation of chloroisocyanate and *N*-dichloro-*N*-carbonylurea[12]:

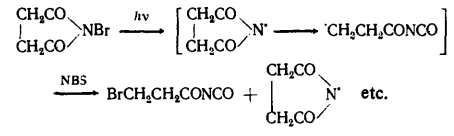


The corresponding chlorocarbonyl isothiocyanate ClCONCS and carbonyl di-isothiocyanate $CO(NCS)_2$ have not so far been obtained in a pure form. Their existence has been confirmed indirectly by the reactions of thiophosgene with lead thiocyanate, with subsequent conversion into thiourea derivatives[13,14]. The simplest acyl isocyanates have been obtained from the chlorides and salts of cyanic acid[15-24]. In recent years more convenient methods have been developed for the synthesis of acyl isocyanates. Recently a new and novel method has been proposed[25] for the synthesis of acyl isocyanates from unsubstituted amides and oxalyl chloride in dichloroethane with prolonged refluxing:



A ccording to the mechanism suggested for this reaction, *O*-acylation takes place in the first stage and is followed by intramolecular cyclisation with elimination of hydrogen chloride and the formation oxazolidin-4, 5-dione derivatives (III). On prolonged boiling, the latter are converted into acyl isocyanates with elimination of carbon monoxide and hydrogen chloride. In these reactions aromatic amides give yields of carbonyl isocyanates of 56–96%. Aliphatic amides react with somewhat greater difficulty, the yields of carbonyl isocyanates being 31–67%. The reaction of the amide of cyclopropanecarboxylic acid with oxalyl chloride takes place with opening of the cyclopropane ring and the formation of γ-chlorobutyryl isocyanate $ClCH_2CH_2CH_2CONCO$.[26] The possibility of preparing acyl isocyanates from acid amides and phosgene is mentioned in the patent of Waltmann and Wolf[27].

A method of preparation of acyl isocyanates by the rearrangement of cyclic *N*-bromo-imides was proposed by Johnson[28] and Martin[29]. Under the action of a catalyst (benzoyl peroxide, illumination) and in the presence of allyl halides, *N*-bromosuccinimide (NBS) forms the succinimide radical, which isomerises to the radical $^{\bullet}CH_2CH_2CONCO$, the latter being converted into β-bromopropionyl isocyanate under the action of NBS:



It has been shown[30] that this reaction does not take place with *N*-chloro- and *N*-iodo-succinimides but takes place smoothly in the case of *N*-bromoperfluoroglutarimine in the reaction with fully fluorinated olefins in the presence of benzoyl peroxide[31].

Acyl isocyanates are formed in high yields (greater than 90%) in the reaction of acid chlorides with isocyanic acid in the presence of tertiary amines (B)[32]:

$$RCOCl + HNCO + B \rightarrow RCONCO + BH^+Cl^- .$$

A wide variety of acyl isocyanates derived from carboxylic acids and mono- and di-isocyanates of silicon $[R_nSi(NCO)_{4-n}]$ and phosphorus $[R_nP(NCO)_{3-n}]$ derivatives have been obtained by this method.

Azidoformyl isocyanate has been obtained by the slow decomposition of oxalyl diazine[33]:

$$(N_3CO)_2 \xrightarrow[-N_2]{} N_3CONCO .$$

The formation of arylaminoformyl isocyanate has been observed in the decomposition of the azides of aryloxamic acids in the presence of aromatic amines[34].

2. Carbonyl isothiocyanate. The first representative of acyl isothiocyanates was synthesised from acid chlorides and thiocyanate salts as early as the 1880's. In most cases the reaction was carried out in inert solvents[35,47]. Later acetonitrile and acetone began to be used[36-44]. So far this is the only method for the preparation of acyl isothiocyanates.

By the reaction of the chlorides of arylazochloroacetic acids with sodium thiocyanate, the corresponding isothiocyanates of arylazochloroacetic acids were synthesised in high yields[42]:

$$ArNHN=C(Cl)COCl + NaSCN \rightarrow ArNHNC(Cl)CONCS .$$

The carbonyl isothiocyanates of the furan[39,43,44], pyridine[45], and pyrazolone[14] series have been synthesised by the reaction of acyl chlorides with thiocyanate salts. Carbonyl isothiocyanates have been obtained by the reaction of acylamino-carboxylic acids with the diphenyl ester of isothiocyanatophosphoric acid in the presence of triethylamine in acetonitrile[46]. This reaction is of exceptionally great importance in the synthesis of peptides. The formation of ethoxycarbonyl isothiocyanate was observed on heating *NN*- diethoxycarbonylthiourea up to the melting point.

Carbamoyl isothiocyanate can be obtained by the reaction of thiocyanic and isocyanic acids at a low temperature[48,49].

3. Thiocarbonyl isocyanates. These compounds have been investigated only in recent years [50-53]. So far however they have not been isolated in a pure form because of their exceptional reactivity. Their formation and existence in solutions have been demonstrated experimentally. Thiocarbonyl isocyanates are obtained by the thermal degradation of thiazolidin-4, 5-dione, which can in turn be synthesised by the reaction of thioamides with oxalyl chloride [54].

4. Carbonyl isoselenocyanates. These compounds were synthesised for the first time in 1937 by the reaction of acid chlorides with potassium selenocyanate in acetone solution [55,56]:

$$RCOCl + KSeCN \rightarrow RCONCSe + KCl.$$

However, they have not been isolated in pure form. Their existence has been demonstrated by conversion into the corresponding carbonylselenoureas. When an attempt was made to prepare the isoselenocyanates of arylazochloroacetic acid, the corresponding selenocyanates were isolated [42].

5. Sulphonyl isocyanates. Recently Smith and coworkers [57] put forward a method for the preparation of organic disulphonyl isocyanates by direct combination of phosgene with disulphonamides in nitrobenzene at 170–180°C. The yields are 54–67%:

$$R(SO_2NH_2)_2 \xrightarrow[170-180^\circ]{COCl_2} R(SO_2NCO)_2,$$

where R= $-(CH_2)_4-$, $-(CH_2)_6-$, or 1,5-naphthyl.

Ulrich and coworkers [58] synthesised a number of arylsulphonyl isocyanates in high yields by the reaction of arylsulphonamides with an excess of phosgene in the presence of butyl isocyanate as the catalyst. Treatment of *p*-aminobenzenesulphonamide with phosgene in nitrobenzene leads to various products, depending in the reaction temperature: *p*-(chloroformamide) benzenesulphonamide formed at 0°C is converted into *p*-isocyanatobenzenesulphonamide at 90°C and into *p*-isocyanatobenzenesulphonyl isocyanate at 150°C [57]. Benzenesulphonamide reacts with phosgene in 1, 2, 4-trichlorobenzene solution in an atmosphere of nitrogen to form benzenesulphonyl isocyanate [59]. When benzenesulphonamide was allowed to react with a four-fold excess of axalyl chloride in dichlorobenzene solution, benzenesulphonyl isocyanate was obtained in 81% yield [60].

Recently a method has been proposed for the preparation of sulphonyl isocyanates from 1-arylsulphonyl-3-alkylureas and alkylenedi(arylsulphonyl)ureas and phosgene at 120–180°C in non-polar solvents [58]:

$$RC_6H_4SO_2NHCONHAlk \xrightarrow[-HCl]{COCl_2} \underset{90\%}{RC_6H_4SO_2NCO} + AlkNCO.$$

Not long ago a method was described [61] for the preparation of sulphuryl di-isocyanate and chlorosulphuryl cyanate by the reaction of cyanogen chloride with sulphur trioxide at 200–250°C in the presence of iron, cobalt, nickel, chromium, molybdenum, copper, and aluminium salts:

$$ClCN + SO_3 \xrightarrow{200-250^\circ} ClSO_2NCO + SO_2(NCO)_2.$$

Chlorosulphonyl isocyanate can be completely converted by pyrolysis into sulphuryl di-isocyanate. The method proposed is dinstinguished by its simplicity, high yields of the final products, and the possibility of achieving a continuous synthesis.

6. Sulphonyl isothiocyanates. When dipotassium salts of sulphonyliminodithiocarbonic acids [62-66] were allowed to react with phosgene in benzene, carbon tetrachloride, or methylene chloride at a low temperature, sulphonyl isothiocyanates were obtained in yields up to 88% [65,66]:

$$RSO_2NC(SK)_2 + COCl_2 \rightarrow RSO_2NCS + COS + 2KCl,$$

where R=alkyl or aryl.

Phosgene can be replaced by the chloroformic ester, phosphorus pentachloride, thionyl chloride, and sulphuryl chloride [62-64]. On standing, sulphonyl isothiocyanates dimerise spontaneously.

Ulrich [67,68] proposed a method for the synthesis of sulphonyl isothiocyanates by the reaction of sulphonylthioureas and phosgene:

$$RSO_2NHCNHR + COCl_2 \rightarrow RSO_2NCS + RNCO.$$
$$\quad\quad\quad

asymmetric stretching vibrations of sulphonyl isocyanates differ little from those in the spectra of alkyl and aryl isocyanates.

Nevertheless we believe that in acyl isothiocyanates ($R-\overset{\overset{O}{\|}}{C}-N=C=S$ and $RSO_2N=C=S$) there is slight interaction (or inductive effect) between $R-C=O$, $-SO_2-$, and $-N=C=S$ groups. It is expressed in an increase of the proportion of the mesomeric dipolar structure $R-C(\bar{O})=\overset{+}{N}=C=S$, in an increase of the double-bond character of the bond involving the nitrogen atom, and in a slight displacement of the stretching-vibration bands of the N=C=S and C=O groups towards longer wave lengths. Thus, whereas the stretching vibration frequency $\nu_{(as)}$ for CH_3NCS is 2110 cm^{-1} it is 1980–1950 cm^{-1} for CH_3CONCS, 2095 cm^{-1} for C_6H_5NCS, 1970–1930 cm^{-1} for C_6H_5CONCS, and 1905 cm^{-1} for $C_6H_5SO_2NCS$. [10,73,76-76]

IV. THE STRUCTURE AND ISOMERISATION OF ACYL ISOCYANATES, ISOTHIOCYANATES, AND ISOSELENOCYANATES

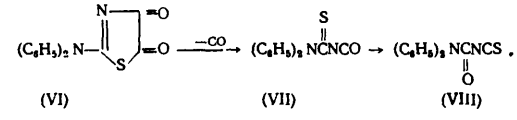
It is known that, in the synthesis of acyl isocyanates, isothiocyanates, and isoselenocyanates by the double decomposition reaction of acid halides with isocyanate, selenocyanate, and isothiocyanate salts, there is a possibility of the formation of compounds (IV) and (V):

$$\underset{}{AcHal} + MXCN \rightarrow \underset{(IV)}{AcNCX} + \underset{(V)}{AcXCN},$$

where M=K, Pb, Na, or NH_4 and X=O, S, or Se. The reasons for the preferential formation of compounds (IV) or (V) have not been adequately elucidated so far [79,80]. Some authors state that compounds (IV) form preferentially during the double decomposition process [81,82] while others isolated compounds (V) [83].

We believe that the preferential formation of acyl isothiocyanates relative to acyl thiocyanates is associated with the fact that, as a result of the mesomerism $^-S-C^-\equiv N \rightleftharpoons S=C=N^-$, it is easier for thiocyanate ions, on energy grounds, to form compounds (IV) rather than compounds (V) (according to Pauling [84], the energy of formation of the C–N bond is 67.7 kcal $mole^{-1}$, that of the C–S bond is 62 kcal $mole^{-1}$, the electronegativity of nitrogen is –3, and that of sulphur –2.5). Furthermore, there are literature data showing that the fraction of acyl thiocyanate which does form isomerises to acyl isothiocyanate under the action of thiocyanate salts [78].

The isomerisation of thioacyl isocyanate to acyl isothiocyanate was first observed for diphenylaminothiocarbonyl isocyanate obtained by the thermal decomposition of 2-diphenylaminothiazolidin-4,5-dione [51]:



(VI) (VII) (VIII)

Infrared absorption spectroscopic data showed that, in the decomposition of product (VI), there appears in the infrared spectrum an absorption band with $\nu_{(as)}$ (NCO)= 2230 cm^{-1}, which is characteristic of structure (VII). On further heating, the 2230 cm^{-1} band vanishes and is replaced by an absorption frequency at 1970 cm^{-1}, characteristic of the NCS group [compound (VIII)]. The mechanism of the conversion of compound (VII) into compound (VIII) proposed by the authors, including the formation of intermediates, was confirmed for other examples by chemical reactions involving tracer atoms. [53,85]

V. CHEMICAL REACTIONS OF ACYL ISOCYANATES, ISOTHIOCYANATES AND ISOSELENOCYANATES

Acyl isocyanates, isothiocyanates, and isoselenocyanates enter into the majority of chemical reactions characteristic of alkyl and aryl isocyanates, isothiocyanates, and isoselenocyanates. However, there are also differences, which are described below.

1. Reaction with Water and Alkalis

Carbonyl isocyanates react with water to form acid amides, carbon dioxide, and dicarbonyl ureas [18]. Carbonyl isothiocyanates are hydrolysed by water, also with formation of acid amides and carbon sulphide oxide [13]. They react more vigorously with alkalis, giving almost quantitative yields of acid amides. The hydrolysis of acyl isothiocyanates was investigated in detail by Elmore and Ogle [40,86]. The hydrolysis of sulphonyl isocyanates was studied recently by Smith [57]. By comparing the ease of hydrolysis of aliphatic and aromatic acyl isothiocyanates, Elmore and Ogle [87] established that phosphonyl isothiocyanates occupy an intermediate position between aliphatic and aromatic acyl isothiocyanates:

$$AlkCONCS > (RO)_2PONCS > ArCONCS.$$

2. Reactions with Aromatic and Aliphatic Alcohols and Mercaptans

Acyl isocyanates, isothiocyanates, and isoselenocyanates react with alcohols and mercaptans to form the corresponding urethanes, thiourethanes, and dithiourethanes. This reaction has been frequently studied with carbonyl isocyanates [26,88-92], carbonyl isothiocyanates [36,40,93,94], and sulphonyl isocyanates [59,95,96]. The preparation of urethanes by the reaction of carbonyl isocyanates with alcohols, glycols, and phenols constitutes a qualitative test for alcohols and phenols [88,89]. According to kinetic data, the formation of urethanes is a monomolecular reaction [93]. It takes place readily both at primary and sterically hindered alcohols and phenols [88,89,95]. The reaction of sulphonyl isocyanates with alcohols (2-methyl-2-propanol, 3-ethyl-3-pentanol) in toluene solutions takes place instantaneously even at 0°C.

3. Reactions with Ammonia, Amines, Aminonitriles, Amides, Substituted Hydrazines, Hydrazides, and Oximes

The reaction of acyl isocyanates, isothiocyanates, and isoselenocyanates with ammonia and amines has been thoroughly investigated and takes place smoothly both in polar solvents and in solvents of low polarity on heating [37,39-45,97-100]. The reactions of amines and diamines with carbonyl isocyanates [101-105], carbonyl isothiocyanates [86,97-100,106-117], thiocarbonyl isocyanates [52], carbonyl selenocyanates [55,118], and sulphonyl isocyanates [119-124] have been described.

Aliphatic and aromatic amines react with acyl isocyanates almost quantitatively. Aromatic polynitroamines do not enter into the condensation reaction [106].

Thiobenzoyl isocyanate does not react with ammonia and methylamine hydrochloride[52]. Amino-acids[40,86], carboxylic acid amino-esters[114], and heterocyclic bases[111,112] react similarly to aromatic amines. The acylureas and acyl thioureas obtained from them are widely used for the synthesis of heterocyclic compounds[111-114].

The mechanism of the reaction of acyl isocyanates and acyl isothiocyanates with amines was studied using as an example the reaction of sulphonyl isocyanates with primary and secondary amines in the presence of tertiary amines[119]. It has been shown that the mechanism proposed by Baker and Gaunt[125], according to which the reaction takes place via an intermediate donor–acceptor complex of the isocyanate with the tertiary amine, is entirely suitable for this process:

$$RSO_2NCO + R_3N \longrightarrow \left[RSO_2N=C-O^- \;\; \underset{NR_3^+}{} \right] \xrightarrow{R''NH_2} RSO_2NHCONHR''.$$

α-Aminonitriles and their substituted derivatives react with acyl isocyanates and acyl isothiocyan tes similarly to amines. The reaction usually leads to the formation of thioureas, thiazole, and mercaptoimidazole[126]. Aminoacetamide enters into similar reactions but less vigorously[127]. (Ethoxycarbonyl) carbonyl isothiocyanate reacts with α-amino-nitriles similarly to benzoyl isothiocyanate, with formation of thiazole and imidazole derivatives[128].

Tri(dimethylamino)phosphine reacts with benzoyl isothiocyanate to form the corresponding thiourea[129]. Similarly, dimethylsulphoxylidene reacts with acyl isocyanates and isothiocyanates to give dimethylsulphoxylideneureas and dimethylsulphoxylidenethioureas[130].

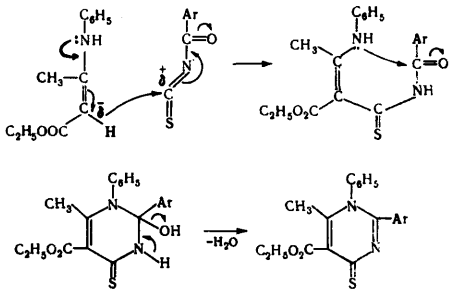
The reaction of acyl isocyanates with ureas and substituted thioureas in ether or benzene leads to the formation of biurets and thiobiurets RCONHCONHCNHR (where X= O or S) in high yields[16]. These compounds exhibit powerful physiological activity. Acyl isocyanates, isothiocyanates, and isoselenocyanates react with substituted hydrazines to form the corresponding 4-acyl-1-substituted semicarbazides and thiosemicarbazides[37,131-133] and selenosemicarbazides[134]. With thiocarbonyl isocyanate, substituted hydrazines form triazolone derivatives[52].

Unsubstituted hydrazine reacts with acyl isocyanates and isothiocyanates to form symmetrically substituted hydrazines[131] and sometimes, depending on the conditions, triazole derivatives[131]. The reaction of acyl isothiocyanates with acid hydrazides is similar to the reaction with substituted hydrazines; it has been investigated in detail using as an example the hydrazide of isonicotinic acid in alcohol, dioxan, and acetonitrile solutions. The resulting 1-isonicotinoyl-4-acylthiosemicarbazides exhibit high bacteriostatic activity[37,132,135].

The reaction of acetaldehyde-ammonia with carbonyl isothiocyanates was studied by Elmore and Ogle[136], who established that the product is 1,1-di[alkoxycarbonyl (thioureido)] ethane. The interaction of acyl isocyanates and isothiocyanates with oximes was investigated by Gheorghiu and coworkers[137,138]. However, the reaction mechanism was not elucidated. It has been shown that the reaction is exceptionally complicated, involving the formation of numerous products. Thus benzamide, benzonitrile, benzoylurea, benzoylcyanamide, carbon oxide sulphide, sulphur and other products have been isolated in the reaction of benzoyl isothiocyanate with aldoximes and ketoximes.

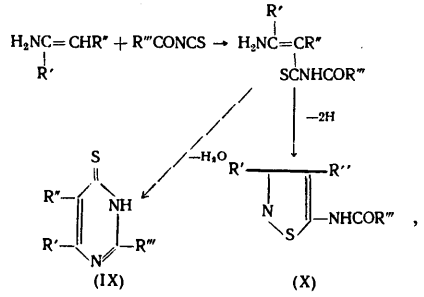
4. Reactions with Compound Containing an Active Hydrogen Atom

Acyl isocyanates and isothiocyanates react comparatively readily with organic compounds containing activated hydrogen atoms. An example is the reaction of acyl isothiocyanates with an $\alpha\beta$-unsaturated amino-ester, for example the β-anilinocrotonic ester[139]. It has been established that the primary product of this reaction is β-anilino-α-benzoyl thiocarbonyl crotonate[140]. However, when the latter is heated in ether or tetrahydrofuran, derivatives of 4-thiopyrimidine are obtained in yields up to 70%:



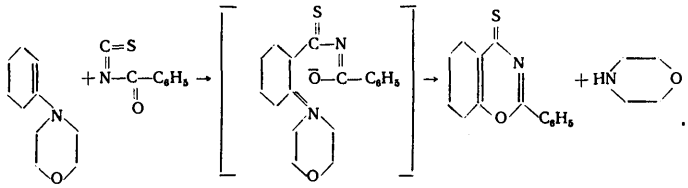
The reaction is general and can be applied both to $\alpha\beta$-unsaturated amino-esters and to various acyl isocyanates and isothiocyanates. The yield of the final product depends significantly on the nature of the substituent in the aromatic ring: electron acceptors increase and electron donors decrease the yield and favour the formation of side products.

In the reaction of carbonyl isocyanates with aliphatic amines, amino-esters, and diamines with the amino-group at the double bond, there is a possibility of the formation of pyrimidine (IX) and isothiazole (X) derivatives[141-144]:



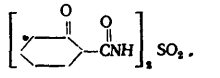
where R′ = NH_2, OC_2H_5.

Benzoyl isothiocyanate readily reacts with 1-morpholinylcyclohexene in chloroform to form 2-aryl-5,6,7,8-tetrahydro-1,3-benzoxazine-4-thione[145]:

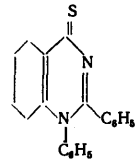


Similarly in the reaction with 1-morpholinylcyclohexene, sulphuryl di-isocyanate leads to the formation of the adduct

NN-di(2-morpholinyl-3,4,5,6-tetrahydrobenzoyl)sulphonamide, which is converted into *NN'*-di(2-oxohexahydrobenzoyl)sulphonamide on hydrolysis with 70% sulphuric acid[146]:

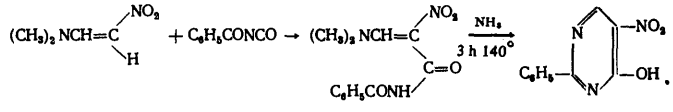


In a similar reaction with benzoyl isothiocyanate in ether 1-phenylaminocyclohexene gives 1,2-diphenyl-5,6,7,8-tetrahydroquinazolone-4-thione[140,147]:

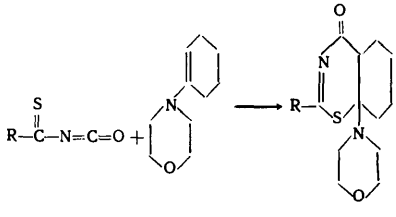


The above reactions involving the addition of acyl isocyanates and isothiocyanates to the β-carbon atom of primary and secondary enamines make possible the preparation by a new synthetic procedure of pyrimidine and quinazoline derivatives[147,148].

Acyl isocyanates readily add also to 1-dimethylamino--2-nitroethylene in benzene at 20°C with formation of *N*-benzoyl-β-dimethylamino-α-nitroacrylamide[149]. When the latter reacts with ammonia initially at 0°C and then at 140°C, it is converted over a period of 3 h into 4-hydroxy--5-nitro-2-phenylpyrimidine, which is otherwise difficult to obtain:



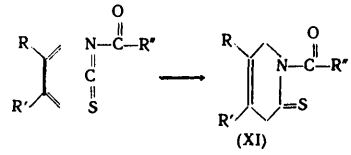
Thioacyl isocyanates react more vigorously with compounds containing active hydrogen atoms[151]. Thus, in the reaction of thioacyl isocyanates with 1-morpholinylcyclohexene in ether at 0°C and with 2,3-dihydropyran, the addition takes place in accordance with the 1,4-cycloaddition principle, with formation of 2-aryl-4a,5,6,7,8,8a-hexahydro-8a-morpholino-4*H*-1-benzothiazin-4-one,



and 2-aryl-8-oxa-1-thia-3-azabicyclo[4,4,0]dec-2-en-4-one.

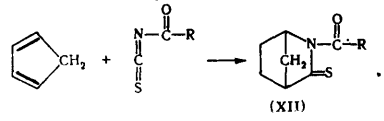
5. Acyl Isocyanates and Isothiocyanates in Diene Synthesis Reactions

The participation of acyl isocyanates and isothiocyanates in diene synthesis reactions has been investigated very little. The work of Arbuzov and Zobova deals with this question[150,151]. Using acetyl and benzoyl isocyanates and isothiocyanates as an example[150], they studied their interaction with a number of dienes: divinyl, isoprene, 2,3--dimethylbuta-1,3-diene, and cyclopentadiene. The reaction probably involves 1,4-addition with formation of 4(5)-substituted *N*-acyl-1,2,3,6-tetrahydro-2--thionopyridines (XI) in a yield of 40–45% in the presence of divinyl, isoprene, and 2,3-dimethylbuta-1,3-diene:



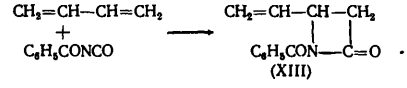
(XI)

and *N*-acyl-3-thiono-2-azabicyclo[2,2,1]hept-5-ene (XII) in a yield of about 50% in the presence of cyclopentadiene:



(XII)

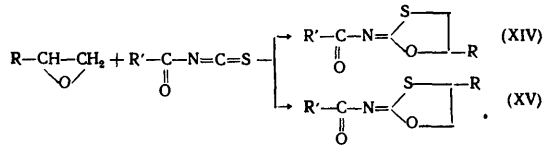
Benzoyl isocyanate reacts with 1,3-dienes to form 1,2--addition products[151] (XIII) in yields of 30–40%:



(XIII)

6. Reactions with Epoxides

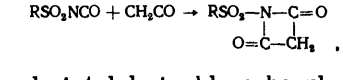
In contrast to other isothiocyanates[152,153], acyl isothiocyanates react with the double bond of the thiono-group C=S of the isothiocyanate[154,155] to form two five-substituted derivatives of 1,3-oxathiolane-(XIV)or(XV):



However, in the case of 2,3-epoxy-1-phenoxypropane the reaction with acyl isothiocyanate takes place with formation of compound (XIV) only, as demonstrated rigorously by synthesis. The formation of compound (XIV) can be explained by the fact that in most addition reactions the epoxy-ring is opened on the side of the unsubstituted carbon atom because of the steric hindrance due to substituents.

7. Reactions with Ketens

The reactions of acyl isocyanates and isothiocyanates with ketens have been almost not investigated. It has been established recently that keten reacts very readily with sulphonyl isothiocyanate to form the corresponding *N*-sulphonylazetidinediones[156]:



where R = phenyl, *p*-tolyl, *p*-chlorophenyl, *p*-fluorophenyl, etc, and if the products are unstable, polymers derived from the latter, of the type $[-COCH_2CONSO_2R]_n$, are formed. Usually the reaction takes place in ether or methylene chloride at a temperature between - 30° and - 10°C. Sulphonyl isocyanates also react readily with vinyl ethers, keten acetals[157], and olefins of the type, $[RCH{=}CR']_2S$ at 20–170°C.[158] Both di-isocyanate groups of di-isocyanates react with keten to form bis-*N*-sulphonylazetidines[156].

8. Reactions of Acyl Isocyanates with Orthocarbonic Esters

Recently Biener [159] described an interesting reaction of sulphonyl isocyanates with orthocarbonic esters. This reaction makes it possible to obtain yields up to 90% esters of *N*-sulphonyl-*N*-alkylcarbonic acids which cannot be obtained otherwise:

$$R''SO_2NCO + R'(COR)_3 \rightarrow R''SO_2N(R)CO_2R + R'COOR.$$

Usually the reaction takes place at a low temperature in methylene chloride or chloroform and virtually reaches completion in 1–2 h. In reactions with sulphonyl di-isocyanates, either one or two isocyanate groups may be involved, with formation of various products.

9. Acyl Isocyanates in the Grignard Reaction

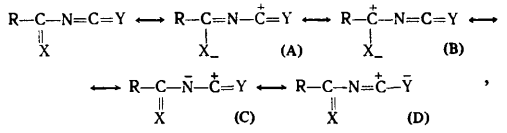
The Grignard reaction was studied in detail by McFarland between benzene- and *p*-toluene-sulphonyl isocyanates and alkyl- and aryl-magnesium bromides (or iodides) in ether at a low temperature. *N*-Sulphonamides are obtained in yields up to 88% when isocyanate or isothiocyanate is added to the Grignard reagent:

$$RSO_2NCO + R'MgX \xrightarrow[H^+,\ H_2O]{\text{ether}} RSO_2NHCOR'.$$

When the Grignard is added to the isocyanate or isothiocyanate, the reaction is accompanied by side processes and the yields of *N*-sulphonamides fall by a factor of 4–5. When the reaction is carried out with an excess of the Grignard reagent and the mixture is refluxed, the yield of the final product is appreciably reduced [160].

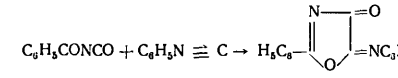
10. Acyl Isocyanates and Isothiocyanates in Reactions with Compounds Containing the C=N Bond

a. Reactions with isonitriles. The reactions of acyl isocyanates and isothiocyanates and thioacyl isocyanates with isonitriles and carbodi-imides can be regarded as dipolar 1,4-addition and dipolar 1,2-interaction [51,161]. In various reactions acyl isocyanates and isothiocyanates can be represented by dipolar structures:



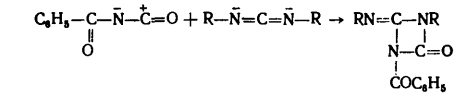
where Y, X=O, S, Se.

Benzoyl isocyanate reacts with phenylisonitrile in benzene with formation of 5-phenylimino-oxazolin-4-one in 96% yield:

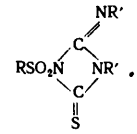


When isonitriles react with acyl isocyanates in the presence of carboxylic acids, intramolecularly acylated mixed amides of the type RNHCOCON(COR')COR", which are otherwise difficult to obtain, are formed in yields up to 90%. [162] Thiobenzoyl isocyanate and benzylmercapto-thiobenzoyl isocyanate react with the isonitrile in methylcyclohexane or toluene more vigorously, forming respectively 2-phenyl- and 2-benzylmercapto-5-phenylimino thiazolidin-4-one in 70–85% yield [51,53,161]. Di-isonitriles react with acyl isocyanates and isothiocyanates similarly, with formation of di-imino-thiazolin-4-ones [161,163].

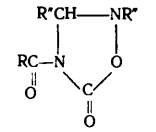
b. Reactions with carbodi-imides. It is known that compounds with cumulated double bonds (for example carbonylsulphonyl isocyanates and isothiocyanates) readily enter into dipolar 1,2-cycloaddition reactions. Thus benzoyl isocyanate reacts with carbodi-imide in a 1:1 benzene–ether mixture with formation of 4-imino--1,3-diazetidin-2-one in a yield up to 70% [53,161,164]:



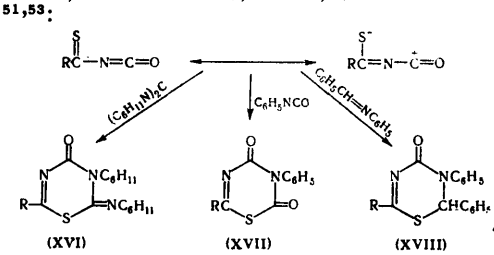
Under similar conditions [68,165] sulphonyl isothiocyanates give rise to quantitative yields of 2-imino-1,3-diazetidin-4--thione:



Another example of dipolar 1,2-addition may be the reaction of acyl isocyanates with *N*-ethylbenzaldoxime in a 1:1 benzene–ether solution, which leads to the formation of 1,2,4-oxadiazolidin-5-one in a yield up to 90% [161]:

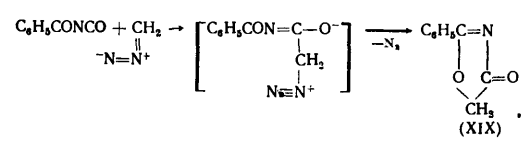


In view of the very pronounced nucleophilic properties of the sulphur atom in thioacyl isocyanates compared with the oxygen atom of acyl isocyanates, the former are more reactive. In addition reactions they probably have the dipolar structure (A) and this accounts for their interaction with carbodi-imides, isocyanates, and benzylideneamine by a 1,4-cycloaddition mechanism with formation of the corresponding substituted six-membered heterocyclic compounds—2-imino-1,3,5-thiadiazin-4-one (XVI), 1,3,5--thiadiazin-2, 4-dione (XVII), and 1,3,5-thiadiazin-4-one (XVIII) [51,53]:



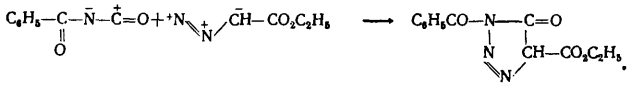
11. Reactions of Acyl Isocyanates and Isothiocyanates with Diazo-alkanes

The reactions of acyl isocyanates and isothiocyanates with diazo-alkanes began to be studied recently. It has been shown that benzoyl isocyanate reacts with diazomethane to form 2-phenyl-oxazol-4-one in yields up to 70% [166]. The mechanism of this reaction may be regarded as addition of diazomethane to the polarised carbonyl bond of the isocyanate in the first stage with subsequent elimination of nitrogen and formation of 2-phenyloxazol-4-one (XIX):

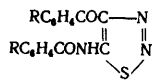


The structure of the latter has been demonstrated by hydrolysis and the formation of the amide of benzoylglycolic acid.

Benzoyl isocyanate reacts readily with ethyl diazoacetate, with formation of the ethyl ester of 1-benzoyl--1,2,3-triazol-5-one-4-carboxylic acid [167,168]:



Acyl isothiocyanates react with diazomethane, ethyldiazoacetate, diazoacetamide, ω-diazoacetophenone etc. [168-172] with formation of 1,2,3-thiadiazole derivatives. Substituted ω-diazoacetophenone derivatives react with benzoyl isothiocyanate to form 5-acetamide-4-benzoyl--1,2,3-thiadiazole:



Usually these reactions take place at 100°C and are virtually complete in 30–120 min [172]. The nature of the substituent in the diazoacetophenone molecule has a significant influence on the rate of the addition reaction. With electron-acceptor substituents, the reaction takes place very slowly or not at all, while electron-donor substituents accelerate the process [170].

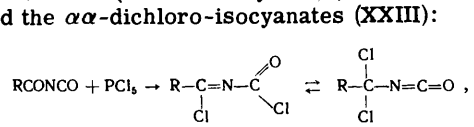
12. Reaction of Acyl Isocyanates and Isothiocyanates with Chlorine

The chlorination of benzoyl isothiocyanates was first studied by Johnson and coworkers [173,174]. The chlorination of acyl isothiocyanates $CH_3(CH_2)_n$-CONCS (where n=2,6,10, 12, or 14) in the presence of titanium tetrachloride in carbon tetrachloride has been described in a patent [175]. The chlorination of acyl isothiocyanates has been described in detail in the papers of Derkach and coworkers [176,177], who established that the chlorination products are the sulphenyl chloride derivatives of the chlorides of N-acyliminocarbonic acids (XX) and the dichlorides of N-acyliminocarbonic acids (XXI):

The dichlorides (XXI) are valuable starting materials for the synthesis of new heterocyclic compounds [178].

13. Acyl Isocyanates and Acyl Isothiocyanates in Reactions with Phosphorus Pentachloride

The reaction of acyl isocyanates with phosphorus pentachloride was studied only by Neidlein and coworkers [178-182]. On prolonged heating in chlorobenzene of benzoyl isocyanate and phosphorus pentachloride in proportions of 1 : 1, the chloride of α-phenyl-α-chloroalkylidene carbamic acid forms. Aliphatic acyl isocyanates react with phosphorus pentachloride to form an equilibrium mixture of the chlorides of N-(α-chloroalkylidene)carbamic acids (XXII) and the αα-dichloro-isocyanates (XXIII):



where R = $ClCH_2$, Cl_2CH, Cl_3C, etc. The mode of reaction was confirmed by infrared spectroscopy [181].

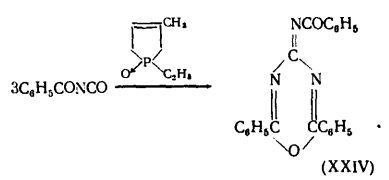
14. Acyl Isocyanates and Acyl Isothiocyanates in Alkoxycarbonylation Reactions

Acyl isothiocyanates readily enter into the alkoxycarbonylation of acylation reaction with phenoxides and phenyl sulphides. The presence in the phenoxide molecule of electronegative substituents facilitates the reaction [183]:

where Y = O or S and R′ = C_2H_5O, C_4H_9O, CH_3, C_6H_5, or C_2H_5S. It has been established that the acylating activity of acyl thiocyanates and isothiocyanates decreases in the series RCOSCN > RCONCS > ROCOSCN > ROCONCS > > RSCONCS. This reaction has found practical application in the synthesis of *OS*-di(alkoxycarbonyl)thiamine [78].

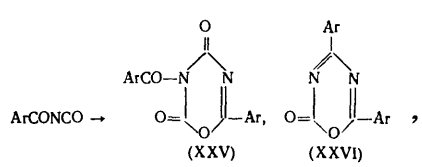
15. Dimerisation, Trimerisation, and Polymerisation of Acyl Isocyanates and Isothiocyanates

The first unsuccessful attempt to study the polymerisation of acyl isocyanates was undertaken in 1960. [184] The trimerisation of benzyol isocyanate under the action of a phospholene oxide in dry xylene with refluxing was studied by McGrew et al. [185]. On the basis of infrared absorption spectra and thermal and hydrolytic degradation of the reaction products, the authors attributed the structure of 4-benzoylimino-2,6-diphenyl-1,3,5-oxadiazine (XXIV) to the trimerisation product and proposed a mechanism for its formation:

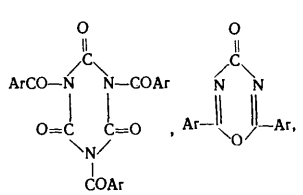


(XXIV)

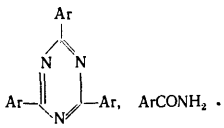
Japanese chemists [186,187] studied in detail the di- and tri-merisation of aroyl isocyanates in ether and cyclohexene in the presence of triethylamine, pyridine 1-oxide, and pyridinium salts as catalysts. They showed that the reaction is very complex. Depending on the conditions, the catalyst and the substituent in the aroyl isocyanate molecule, the products may be 5-aroyl-2-aryl-1,3,5--oxadiazin-4,6-dione (XXV), 2,4-diaryl-1,3,5-oxadiazin--6-one (XXVI), triaroyl isocyanurate (XXVII), 2,6-diaryl--1,3,5-oxadiazin-4-one (XXVIII), and also triaryl-s--triazine (XXIX) and aromatic acid amides (XXX):



(XXV) (XXVI)

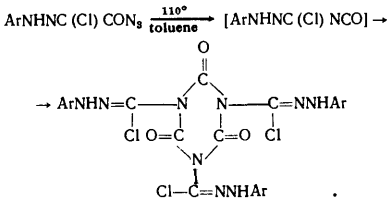


(XXVII) (XXVIII)



(XXIX) (XXX)

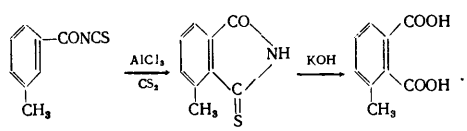
The present authors isolated the trimerisation products of arylazochloroacetyl isocyanates in an attempt to prepare the isocyanates of the arylhydrazones of chloroformaldehyde from arylazochloroacetyl azides [188,189]:



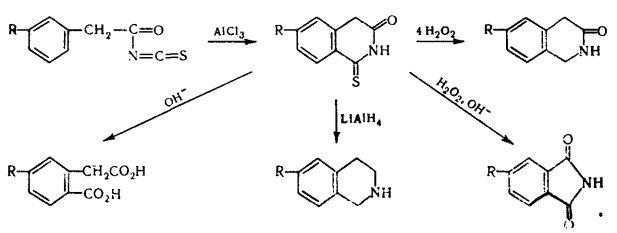
The isothiocyanates of iminocarboxylic acids readily dimerise in the light into quinazoline and *s*-triazine derivatives [190-192].

16. Acyl Isocyanates and Isothiocyanates in Intermolecular and Intramolecular Cyclisation Reactions

The intra- and inter-molecular cyclisation of acyl isothiocyanate was first studied in detail by Smith and Kan [193,194] and a novel method for the preparation of phenyl-substituted dicarboxylic acids was proposed on its basis:



It is noteworthy that the reaction does not take place with *p*-toluoyl, benzoyl, 3-methoxybenzoyl, 3,5-dimethoxybenzoyl, 3,4,5-trimethoxybenzoyl, and α-naphthoyl isothiocyanates. The cyclisation takes place smoothly when methyl groups are present in the *meta*-position with respect to the carbonyl isothiocyanate group (3-methyl, 3,5-dimethyl). Furthermore, it requires the presence of two free *ortho*-positions. When *m*-toluoyl isothiocyanate is used, the cyclisation takes place with formation of 2-methylphthalic acid only. The use of phenylacetyl isothiocyanate and its derivatives in a similar intramolecular cyclisation reaction opens up extensive possibilities for the synthesis of homophthalic acids and a number of heterocyclic compounds, in particular 1,2,3,4-tetrahydroisoquinoline and phthalimide:



In contrast to *m*-toluoyl isothiocyanate, *m*-tolylacetyl isothiocyanate cyclises exclusively in the para-position with respect to the methyl group with formation of 5-methyl-2a-thiohomophthalimide or 6-methyl-1-thio-1,2,3,4-tetrahydro-*2H*,*4H*-isoquinoline-1,3-dione†, 4-methylphthalimide and 4-methylhomophthalic acid being obtained from the latter.

3-Thienoyl isothiocyanate, βγ-saturated aliphatic carbonyl isothiocyanates and cyclohexen-1-ylacetyl isothiocyanate also undergo intermolecular cyclisation [193,194] Despite certain limitations, this reaction is of fundamental importance. It makes it possible to obtain a number of heterocyclic compounds, and from the latter substituted *ortho*-dicarboxylic acids, which are difficult to obtain.

17. Other Reactions of Acyl Isocyanates and Isothiocyanates

In 1966 Neidlein [195] described the reaction of carbonyl and sulphonyl isocyanates with hydrazoic acid under pressure in benzene solution, with cooling, leading to the formation of the azides of *N*-carbonyl- and *N*-sulphonyl-carbamic acids (XXXI) respectively:

$$AcNCO + HN_3 \rightarrow \underset{(XXXI)}{AcNHCON_3},$$

where Ac = RCO or p-$CH_3C_6H_4SO_2$.

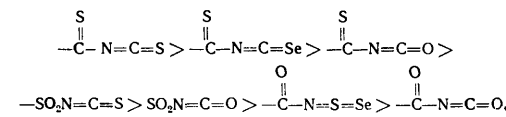
Carbonyl isothiocyanates react relatively smoothly also with dialkylsulphoxides to form *N*-acylsulphilimines [180]:

$$RCONCO + (R')_2SO \rightarrow RCONS(R')_2 + CO_2.$$

In a similar reaction sulphonyl di-isocyanates react with two moles of dimethylsulphoxide to form *NN*-sulphonylbis-(*SS*-dimethylsulphilimine) $(CH_3)_2S{=}N{-}SO_2{-}N{=}S(CH_3)_2$ in 54% yield. Chlorosulphonyl isocyanate gives rise to a 75% yield of *N*-chlorosulphonyl-*SS*-dimethylsulphilimine [196]:

$$ClSO_2NCO + (CH_3)_2SO \rightarrow (CH_3)_2S{=}NSO_2Cl \xrightarrow[HCl]{H_2O} (CH_3)_2S{=}N{-}SO_3OH.$$

In our examination of the chemical properties of acyl isocyanates and isothiocyanates, we frequently mentioned the unequal activities of the latter in various chemical reactions. The data reviewed here make it possible to arrange thio(seleno)acyl and acyl iso(thio, seleno)cyanates in the following series of decreasing activity in various chemical reactions:



VI. APPLICATIONS OF ACYL ISOCYANATES, ISOTHIOCYANATES, AND ISOSELENOCYANATES

Above it was shown that acyl isocyanates, isothiocyanates, and isoselenocyanates are very reactive organic compounds. They enter into a wide variety of chemical reactions, yielding organic products which are valuable for syntheses and for practical applications: urethanes, thiourethanes, urea, thiourea, selenourea, semicarbazides, thiosemicarbazides, and selenosemicarbazides. Various

† 
(Ed. of Translation).

derivatives of heterocyclic compounds have been prepared from them: pyrimidine [101,103,114,117,139,140,143,144,148,149,297], thiazole [111,112,126-128], imidazole [46,116,184], triazole [52,131,166], triazine [52,114,185,188,189], isothiazole [143,144], benzoxazine [145], quinazoline [148], oxathiolane [154], oxazoline [161,163], thiazoline [53,161,163], thiazine [53], thiadiazine [51,53], thiadiazole [170-172], oxadiazine [185-187], isoquinoline [194], and others.

Acyl isocyanates and isothiocyanates have found wide application for the identification of alcohols [88] and amines [98,106] and also for the determination of the structure of nucleic acids and peptides [46,101,103,198]. They are used as copolymers [23,38,199]. Valuable rubbers and fire-resistant polyurethane foam plastics have been obtained on their basis [102].

Acyl isocyanates and isothiocyanates and derivatives based on them exhibit a wide spectrum of biological and chemotherapeutic activity. Compounds with pesticide activity have been found among them [200]. A number of the substances synthesised have been tested as antidiabetic agents [122,124] and depressants of the central nervous system [201].

Many organic substances synthesised using acyl isocyanates and isothiocyanates exhibit considerable antitubercular [202], hypoglycemic [121], anaesthetic [203], anticonvulsant [202,204], and hypnotic [16] activity.

After this review had been submitted for publication, the following papers appeared.

1. On the methods of synthesis of acyl isocyanates [205-210,250-253], acyl isothiocyanates [211,212,251,254], thioacyl isocyanates [85,213,248], sulphinyl isocyanates [214], sulphonyl isocyanates [215-217,255-257], and sulphonyl isothiocyanates [218,220].

2. On chemical reactions with alcohols [221,258-260], mercaptans [222], amines [223-230,261-267], amides [231], hydrazines [232,233,268,269], aziridines [234], compounds containing an active hydrogen atom [235-239,270,271], dienes [240,272-274], Grignard reagents [241], azomethines [242,243,275], chlorine [244,245], nitrosonium salts [246], phosphorus pentasulphide [247], hydrazoic acid [248,276], heterocyclic compounds [248,249], hydroperoxides [277], carboxylic acids [278], and sulphonic acids [279].

New Data on Biradicals

I.D.Morozova and M.E.Dyatkina

Data on biradicals, including both the results of studies by pre-1947 methods (static magnetic susceptibility, ortho–para conversion of hydrogen, etc.) and the results of studies on biradicals by electron spin resonance are reviewed. Biradicals of various types are discussed—biradicals in the singlet ground state which pass to a triplet state on excitation and biradicals in the triplet ground state which arise in consequence of the degeneracy of higher occupied levels, the presence of an insulating group between the monoradical components, atropisomerism, etc. A complete compilation is also given of all the data on biradicals with heteroatoms. The application of the electron spin resonance method to biradicals permitted an approach to the problems of the interaction of unpaired electrons in these systems. The theory of such interaction and the form of the spectra which should be obtained in its presence and absence are discussed. However, many studies on this interaction have proved erroneous because the data obtained did not refer to the substances to which the observed spectra were attributed but to the products of their further reactions—the formation of di- and poly-mers. These problems are not usually discussed in sufficient detail in physical papers on biradicals, while in the present review special attention has been given to them.

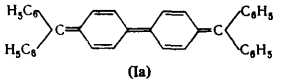
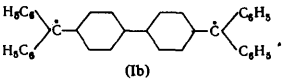
I. INTRODUCTION

Advances in the modern theory of organic compounds include significant progress in the solution of the problem of biradicals. These are compounds, the molecules of which have, in contrast to monoradicals, an even number of electrons (so structures can be written for them with all electrons paired), but which nevertheless exhibit the properties of radicals, in this case "double" radicals. This term includes substances of three different types. The first includes ordinary molecules with a singlet ground state which can exhibit the properties of radicals because of the possibility of transition to an excited triplet state, so that there is an appreciable concentration of molecules in the triplet state in equilibrium with those in the singlet ground state. Such an approach to biradicals of this type made it possible to resolve the old controversy about whether compounds such as Chichibabin's [frequently spelt Tschitschibabin's (Ed. of Translation)] hydrocarbon have a quinonoid or benzenoid structure:

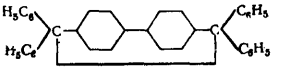


(Ia)

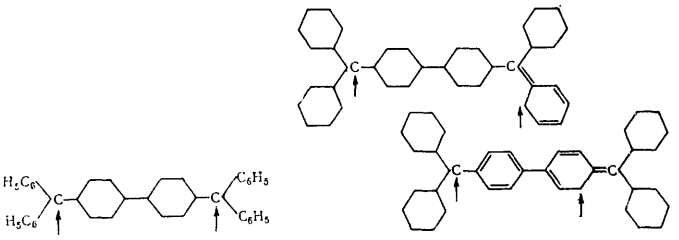


(Ib)

All the structures with the overall spin $S = 0$ (Ia) and others such as, for example,



have been represented in the singlet state, while the triplet state can be described as the superposition of the structures



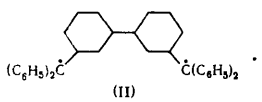
etc. For compounds of this class, the problem consists mainly in the detection of the triplet state and the explanation of the reasons for the relative ease of transition to the latter.

In any molecule with an even number of electrons a transition to the triplet state is possible in principle when the overall spin is equal to unity, i.e. there are two unpaired electrons. However, in the vast majority of organic compounds the excitation to the triplet state requires a very considerable energy and the equilibrium fraction of triplet molecules is low. The substances which exhibit the properties of biradicals are those in which the triplet state is separated from the singlet ground state by a relatively small energy difference. An attempt to account for such relations between the energies of substances of this type was made by Dyatkina and Syrkin [1] on the basis of calculations by the MOH method†. The authors postulated a correlation of the energy difference between the highest occupied and lowest free one-electron levels with the energy of excitation from the singlet to the triplet state. Strictly speaking these quantities cannot be regarded as identical. Calculations of the energy differences between the singlet and triplet states of the molecule as a whole require that the interelectronic repulsion be taken into account. Nevertheless the hypothesis of a parallel variation of the energies of the one-electron transition and the

† MOH—the molecular orbital method in Hückel's approximation.

energy of excitation to the triplet state agrees satisfactorily with the findings that the tendency towards the transition to the biradical state and the fraction of the biradical form in equilibrium clearly increase as the energy of the one-electron transition decreases.

The second type of biradicals constitute substances the molecules of which have a triplet ground state because of the degeneracy of the upper occupied levels, as should happen in cyclobutadiene and *meta*-quinonedimethane and substances such as the hydrocarbon of Schlenk and Brauns (II):



(II)

Cyclobutadiene and *meta*-quinonedimethane themselves have not been obtained. The hydrocarbon of Schlenk and Brauns and its analogues are probably dimers and the possible partial dissociation of such dimers at an elevated temperature does not present a special problem—it is fully included in the problem of the dissociation of dimers of monoradicals such as triphenylmethyl.

The third type of biradicals are molecules consisting of two parts each of which is an ordinary monoradical, but in which the overall molecule is constructed in such a way that the interaction between the unpaired electrons over a distance corresponding to a normal C–C π-bond is impossible because of the presence of an insulating group—for example, an oxygen atom, one or several $-CH_2$ groups, etc. This class includes substances which are formally derivatives of Chichibabin's hydrocarbon (I), but in which the two halves of the molecule are located in planes forming a considerable angle relative to one another due to the steric hindrance of the substituents, and this also prevents the interaction between the electrons of the two halves. With compounds of this type, the central problem is the question whether or not they consist of two completely independent halves, i.e. are in fact two radicals, or whether electron exchange takes place between the two components.

A review of information about biradicals which had accumulated towards the middle of the 1940's was published in 1947 by Dyatkina and Syrkin[2]. At that time the data on the biradical state were based mainly on measurements of static magnetic susceptibility. In some cases such data were confirmed by investigations of the ortho–para conversion of hydrogen.

However, the method of static magnetic susceptibility has considerable limitations. The magnetic susceptibility measured experimentally is the sum of two parts which have different signs: the diamagnetic and paramagnetic susceptibilities. In order to determine the paramagnetic susceptibility, it is necessary to subtract from the total susceptibility the diamagnetic component, which cannot be measured directly. Therefore the diamagnetic susceptibility is calculated from the increments corresponding to individual bonds or atoms. Such a procedure can involve considerable errors. When one deals with strongly paramagnetic substances, their paramagnetism obscures the diamagnetism to a large extent and experiment shows their behaviour to be paramagnetic. This is in fact the behaviour of organic substances when there is a large concentration of radical species, i.e. in the case of biradical molecules in the triplet state in which we are interested. The inaccuracy of the diamagnetic susceptibility may then lead to a small error in the numerical value of the paramagnetic susceptibility but does not prevent, in principle, the detection of radicals and biradicals. On the other hand, if the fraction of biradical species is small, the paramagnetic susceptibility corresponding to them may be extinguished due to the presence of a very large number of diamagnetic molecules. Then the substance behaves as a diamagnetic material, despite the presence of paramagnetic molecules. The fraction of such paramagnetic species, which are not taken into account, may reach 10%. This was in fact the reason for the prolonged controversy concerning the question of the presence of an appreciable fraction of biradical molecules in Chichibabin's hydrocarbon.

Furthermore, in the case of biradicals, apart from the equilibrium between the monomeric singlet and triplet molecules, there is a possibility of thermodynamic equilibrium between paramagnetic monomers on the one hand and diamagnetic dimers (or polymers) on the other. This is an additional complication, which makes it difficult to arrive at a conclusion concerning the concentration of biradicals on the basis of static magnetic susceptibility.

In biradicals there may be different degrees of interaction between the unpaired electrons—ranging from the case where the spins of the two electrons give a resultant spin equal to unity to those where the spins of both unpaired electrons are separated from one another and behave independently. These extreme cases correspond to different values of their magnetic susceptibility. (For $S = 1$, the magnetic moment $\mu = \sqrt{4S(S+1)}\mu_B = \sqrt{8}\mu_B$ and the magnetic susceptibility at 300°K is $N\mu^2/3kT = 3390 \times 10^{-6}$ e.s.u., while in the presence of two separated spins, each of the latter corresponds to a magnetic moment $\mu = \sqrt{3}\mu_B$ and the magnetic susceptibility is 1280×10^{-6} e.s.u., so that the overall susceptibility is 2560×10^{-6} e.s.u.). However, it is impossible to distinguish them on the basis of measurements of the static susceptibility, since systems in which all the molecules are in the biradical state are almost never investigated.

A new stage in the development of our knowledge about biradicals began when the method of electron spin resonance became available. Without changing significantly the basic postulates concerning biradicals, these investigations greatly extended the available information about this interesting class of substances. In the first place, the method makes it possible to establish the presence of biradicals in those cases where data on static magnetic susceptibility do not permit unambiguous conclusions. An even more significant factor is that, with the aid of this method, an approach is possible to the question of the interaction between the unpaired electrons in biradicals.

It is known from ESR theory that, when a conjugated organic system has only one unpaired electron, i.e. we are dealing with a monoradical, the spectrum of such a monoradical in solution can be described by a spin-Hamiltonian of the form

$$\hat{H} = g\beta \mathbf{H}_0 \mathbf{S} + \hat{A}\mathbf{S}\mathbf{I}, \qquad (1)$$

where the first term describes the interaction between the electron spin and the external magnetic field $\mathbf{H}_0$ and the second the hyperfine interaction of the electron spin with the magnetic moment of the nucleus (g is the factor and β a Bohr magneton). In this case the resonance condition can be written thus:

$$h\nu = g\beta H_0, \qquad (2)$$

which corresponds to the allowed transitions $\Delta m_S = +1$, where m_S is a projection of the electron spin. However, in a spin-Hamiltonian system consisting of two unpaired

electrons it is necessary to introduce an additional term describing the interaction between the electron spins:

$$JS_1S_2 ,$$

where J is an exchange integral of the type

$$J = \int \Phi_A(1)\Phi_B(2)\frac{e^2}{r_{12}}\Phi_A(2)\Phi_B(1)\,dv_1dv_2 , \qquad (3)$$

Φ_A the orbital of the unpaired electron in one half of the molecule and Φ_B the orbital in the second half, and r_{12} is the distance between the two electrons.

From the complete formulation of the spin-Hamiltonian in the form

$$\hat{H} = g\beta\mathbf{H}_0(\mathbf{S}_1 + \mathbf{S}_2) + A(\mathbf{S}_1\mathbf{I}_1 + \mathbf{S}_2\mathbf{I}_2) + J\mathbf{S}_1\mathbf{S}_2 \qquad (4)$$

it follows that the hyperfine structure in this case depends not only on the magnetic interaction between the electrons and nuclei but also on the extent of exchange J between the two electrons. If there is no interaction between the electron spins ($J = 0$), resonance will be observed under the same conditions as in a monoradical. If this interaction is sufficiently large and leads to an overall spin $S = 1$, then the transition $\Delta m_S = +2$ also becomes possible. The resonance condition can be written thus:

$$h\nu = 2g\beta H_0 , \qquad (5)$$

which in the presence of a field $0.5H_0$ corresponds to an ESR signal with a formal g-factor of 4.

The changes in the ESR spectra due to the presence of exchange can be best understood as follows. In the presence of exchange interactions between two electrons the energy levels can be described to a certain approximation by the magnetic quantum numbers M_1 and M_2 for the two nuclei, where M_1, $M_2 = -I, -I+1, \ldots, I-1, I$ are the projections of the spins of the nuclei on the z axis and m_1 and m_2 are the projections for the two electrons (m_1, $m_2 = -S, -S+1, \ldots, S$).

If it is assumed that each electron interacts only with its nucleus, the following expression is obtained for the energy:

$$E = g\beta H_0(m_1 + m_2) + A(m_1M_1 + m_2M_2) \qquad (6)$$

or

$$E = g\beta\left(H_0 + \frac{AM_1}{g\beta}\right)m_1 + g\beta\left(H_0 + \frac{AM_2}{g\beta}\right)m_2 . \qquad (7)$$

It is evident from the second equation that the hyperfine interaction for electron 1 is equivalent to a magnetic field $AM_1/g\beta$ set up by the nucleus with a spin I near this electron, while for electron 2 the field is $AM_2/g\beta$. Under the action of a high-frequency field ν applied at right angles to the direction of the permanent magnetic field H_0, resonance transition determined by the selection rules $\Delta m_1 = +1$, $\Delta m_2 = 0$, or $\Delta m_1 = 0$, $\Delta m_2 = 1$ will occur, i.e. the spin of each electron changes by unity. Since an electron transition does not involve changes in the orientation of the nuclear spin, the second selection rule can be written $\Delta M_1 = \Delta M_2 = 0$, i.e. the transitions will occur between states with the same projections of the nuclear spin. In Eqns. (2) and (7), it is possible to determine the resonance values of the magnetic field at which absorption takes place:

$$H_{1,2} = \frac{h\nu}{g\beta} \mp \frac{AM_1}{g\beta} . \qquad (8)-(9)$$

The difference between them is

$$\Delta H = \frac{2AM_1}{g\beta} . \qquad (10)$$

Such a system of equations can also be written for the second electron.

For two nuclei with the same spin values $I_1 = I_2 = I = 1/2$, we have $\Delta H = A/g\beta$, and the line splits into $(2I + 1)$ components, separated by a distance A.

When the exchange between the unpaired electrons is extensive, it can be assumed that the two electrons form a system described by the quantum numbers S and m, where $S = 0,1$ and $m = -S, \ldots, S-1, S$. As before, the nuclei are characterised by the magnetic numbers M_1 and M_2. Then the energy of the system can be expressed in the form[3]

$$E = g\beta H_0 m + \frac{A}{2}(M_1m + M_2m) + \frac{1}{2}J\left[S(S+1) - \frac{3}{2}\right] . \qquad (11)$$

If $g\beta H_0 \ll J$, $g\beta H_0 \gg A$, and $J \gg A$, then the levels of the triplet are of the form $\frac{1}{4}J$ and $\frac{1}{4}J \pm g\beta H_0 \pm \frac{1}{2}AM$, where $M = M_1 + M_2$. Taking into account the selection rules $\Delta m = +1$ and $\Delta M = 0$, we obtain an electron transition at $h\nu = g\beta H_0$ with $2M + 1$ hyperfine components. The distances between them are $A/2$ and not A as was the case for two independent electrons.

Apart from the $h\nu = g\beta H_0$ transition allowed by the selection rule $\Delta m = +1$, the interaction between the electrons also leads to partial absorption of the field energy on transitions between levels with spin projections $m_S = 1$ and $m_S = -1$ ($\Delta m = \pm 2$). It is evident from Eqn. (5) that this transition corresponds to a g-factor twice as large as for the free electron, i.e. here the g-factor should be approximately 4.

The derivation of expressions for the frequency of transitions and their probabilities in a general form on the basis of Eqn. (4) is a very complex problem, which has been solved only for certain special cases. Sakun et al.[4] describe the motion of unpaired electrons by an effective self-consistent potential, which for a biradical has the form of a well with two minima. Then calculation leads to an ESR spectrum consisting of three frequency groups:

$$\omega_{1,2} = A(M_1 + M_2) \pm 2\sqrt{J^2 + [(A/2)(M_1 - M_2)]^2} , \qquad (12)-(13)$$

$$\omega_3 = A(M_1 + M_2) . \qquad (14)$$

Taking into account the selection rules specified above, the intensities of the corresponding lines are

$$F_{\omega_{1,2}} = \frac{1}{1 + (J/A)^2\left(\frac{2}{M_1 - M_2}\right)^2} , \qquad (15)$$

$$F_{\omega_3} = \frac{2}{1 + (A/J)^2\left(\frac{M_1 - M_2}{2}\right)^2} . \qquad (16)$$

It follows from these formulae that, when $J = 0$, there are no ω_3 frequencies in the ESR spectrum, and there remain $(2I_{1,2} + 1)$ lines of equal intensity. In the case of rapid exchange ($J \gg A$) there are no lines corresponding to the frequencies ω_1 and ω_2 and there remain $4I + 1$ lines with the intensities $1:2:3:2I:2I+1\ldots 3:2:1$. In the intermediate cases there are only $(2I + 1)^2 + 2$ lines. Fig. 1 shows that, for two electrons located respectively at two nuclei with a spin $I = 1/2$, the number of lines ranges from 2 in the absence of exchange $[(2I + 1) = 2]$ to 3 $[(4I + 1) = 3]$ when the extent of exchange greatly exceeds the hyperfine interaction constant. With intermediate values of J, "satellite" lines, characteristic of biradicals, appear at the wings of the relevant absorption curve and between the principal lines.

Thus the value of the g-factor for those cases where there are $\Delta m = +2$ transitions, and also the number of hyperfine components and their intensities, which both

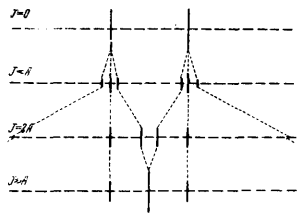


Figure 1. Theoretical spectrum for two electrons and two nuclei with a spin of 1/2.

depend on J, provide information about the degree of electron interaction in biradicals.

The aim of the present review is to examine the data on biradicals obtained with the aid of the ESR method. Furthermore, additional data on the chemical and physical properties of biradicals which have appeared in the literature since the 1947 review will be included. Molecules belonging to all three types of biradicals considered above will be discussed.

II. BIRADICALS WITH THE SINGLET GROUND STATE

When the ESR method appeared, the biradical nature of compounds could be established, among substances of this type, for which earlier results did not lead to unambiguous conclusions. This applies in the first place to the forerunner of such substances, namely Chichibabin's hydrocarbon, for which both the static susceptibility and the ortho–para conversion of hydrogen methods failed to solve the problem of whether the substance passes to a biradical state under normal conditions. In his measurements of the static magnetic susceptibility, Müller[5] observed diamagnetism and on this basis rejected the possibility of the presence of molecules in the triplet state. However, the work of Schwab and coworkers[6], who investigated the ortho–para conversion of hydrogen in the presence of Chichibabin's hydrocarbon, indicates the presence of a considerable fraction (up to 10%) of biradical molecules.

Even the first investigations of this compound by the ESR method, carried out by Hutchinson et al.[7], showed that 0.005 M liquid solution contains 4% of paramagnetic molecules and that this fraction can increase with temperature.

It should be noted that fully reproducible results are not always achieved in the synthesis of substances of the Chichibabin's hydrocarbon type. Some workers obtained very brightly coloured solutions and assumed that the reaction products are biradicals in the monomeric state. Others obtained colourless substances consisting in all probability of dimers or polymers. It was not until 1957 that Sloan and Vaughan[8] developed the most complete modern method for complex syntheses of biradicals[8]. They obtained a number of derivatives of Chichibabin's hydrocarbon showing as distinct a resonance paramagnetic absorption as in hydrocarbon (I)—the parent of this type of compounds (Table 1).

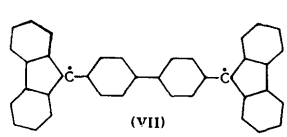
On the other hand Thiele's hydrocarbon(III) does not give rise to an ESR signal since the fraction of molecules in the triplet state is extremely low, but the tetra(biphenylyl) derivative (V) does exhibit resonance absorption. These data are in good agreement with the results of the calculations of the energies of the highest occupied and lowest free orbitals by the MOH method. In Thiele's hydrocarbon the energy of this transition (0.31β) is greater by a factor of 2 than in Chichibabin's hydrocarbon (0.15β). This explains why an appreciable fraction of biradical molecules is observed in the first compound, while in the second it is much smaller. The introduction into Thiele's hydrocarbon of biphenylyl groups [compound(IV)] instead of phenyl groups also reduces the energies of the highest occupied and lowest free orbitals (to 0.13β), which leads to a concentration of molecules in the triplet state susceptible to detection.

Table 1.

Compound	Presence of ESR signal	Colour of solution
 (III)	—	orange
 (I)	+	violet
 (IV)	+	brick red
 (V)	+	bright blue
 (VI)	+	dark purple

It is noteworthy that all these substances readily undergo changes in which the radical properties are probably lost. When air is admitted, only compound (III) and compound (IV) do not change colour, while compounds (I), (V), and (VI) are decolourised. This shows that conclusions concerning the biradical character of a substance can be arrived at only in those cases where special precautions have been taken to prevent dimerisation and polymerisation, oxidation, decomposition, etc.

A new compound of this class synthesised by Theilacker et al.[9] is 4,4'-bis(9-fluorenyl)biphenyl (VII):



(VII)

It proved to be a colourless sparingly soluble polymer. When a solution in α-methylnaphthane was heated from 80° to 165°C, its colour changed from brown to bright green. Depolymerisation with increase of temperature is accompanied by an appreciable increase in paramagnetism, possibly in consequence of dissociation into monomeric biradicals (Table 2).

The first investigations of biradicals, where only the presence or absence of paramagnetism in the given molecules was established, were followed by the study of the intramolecular interactions between the two unpaired electrons. For substances of the type of Chichibabin's hydrocarbon, which have a singlet ground state, this problem has no physical significance. In the triplet state of these molecules, as in the triplet states of any other normal molecules, there are no separate components where unpaired electrons could be localised. The problem of whether or not there is interaction between two halves,

Table 2.

Temperature, °C	$\chi_{exp}-\chi_{calc}$	biradical content, %

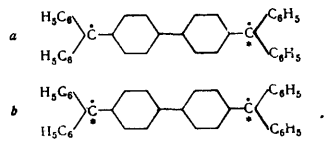
165	+153	9

constituting in fact a single conjugated system, arose only due to the traditional approach whereby the structure of the triplet form of Chichibabin's hydrocarbon was represented as consisting of two triphenylmethyl radicals joined by a C–C bond in the *para*-position. However, it is possible to demonstrate by this example the errors which can arise in studies of ESR spectra without due attention being given to a reliable identification of the compounds to which the spectra refer. We shall consider the relevant studies because they demonstrate the danger of theorising about unusual properties of molecules in those cases where there is no certainty that they are in fact the properties of the molecules under consideration and not of some others (for example conversion products), for which they are reasonable and by no means surprising.

In an early investigation[10] it was found that the g-factors of Chichibabin's hydrocarbon and its diphenyl and phenylnaphthyl derivatives [compounds (V) and (VI)] are 2.0025 ± 0.0004, although transitions corresponding to $\Delta m = +2$ might also have been expected. The spectra were poorly resolved so it was difficult to draw inferences concerning the number of hyperfine structure lines. Later Reitz and Weissman[11] investigated the electron spin resonance of Chichibabin's hydrocarbon where the carbon atoms marked with an asterisk were labelled with carbon-13, the atomic nucleus of which itself has a magnetic moment. One atom was labelled in case *a* and both atoms in case *b*:



For system *a* ($^{12}C-^{13}C$), where there is only slow exchange compared with the frequency of hyperfine interaction, i.e. $A \gg J$, a triplet spectrum should have been obtained with a central line originating from the part of the molecule where the nuclear spin is zero, i.e. from the $(C_6H_5)_3{}^{12}C$ group, and two outer lines with intensities smaller by a factor of 2, which are due to splitting by carbon-13 in the $(C_6H_5)_3{}^{13}C$ group (Fig. 2).

The spectrum of system *b* ($^{13}C-^{13}C$) should consist of two lines in the presence of slow exchange (each electron located at its nucleus and $A \gg J$) or three lines with intensities 1 : 2 : 1 in the presence of rapid exchange, when the spins migrate from one half of the molecule to the other (Fig. 1).

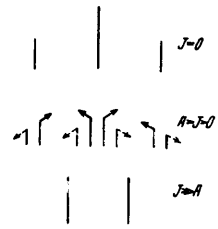


Figure 2. Theoretical spectrum of Chichibabin's hydrocarbon with a single ^{13}C tracer atom.

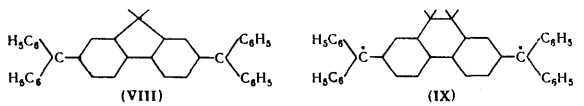
A surprising result of this investigation was the finding that the experimental data can be interpreted as demonstrating that the structure of the molecule of Chichibabin's hydrocarbon consists of two independent triphenylmethyl components with a frequency of exchange between the latter $< 7 \times 10^7$ s^{-1}, which was completely incomprehensible when the radical form of Chichibabin's hydrocarbon was treated as a triplet state of the molecule. However, instead of thoroughly testing the reliability of the experimental data and in the first place identifying the molecules which give rise to the spectra, a number of investigators undertook the development of a "theory" of these fantastic phenomena.

McConnell[12] estimated theoretically the frequency of hyperfine splitting on the basis of the singlet–triplet splitting Δ in the biradical, adopting for Δ the value found in the calculation by the simple MOH method, and obtained an exchange frequency of the order of 2.5×10^{13} s^{-1}. This discrepancy with the "experimental" value ($< 7 \times 10^7$ s^{-1}) led to the so called "biradical paradox", to the resolution of which a number of studies were devoted[12–14]. McConnell in fact started from the premise that Δ is determined only by the frequency of transmission of an electron from one half of the molecule to the other. Burshtein and Naberukhin[15] attempted to obtain a closer agreement between the theoretical estimate of the frequency of electron exchange and the "experimental" value by considering the mutual electrostatic repulsion of the electrons, i.e. by going over to the two-electron problem. When account is taken of the Coulombic interaction, singlet–triplet splitting is obtained corresponding to an exchange frequency of the order of 10^6 s^{-1}, i.e. a value close to or somewhat smaller than the frequency of hyperfine interaction. An impression was created that Chichibabin's hydrocarbon can indeed be regarded as consisting of two halves. However, the inconsistency of this conclusion with the general hypotheses concerning the origin of the biradical nature of substances of this type led to further studies in this field.

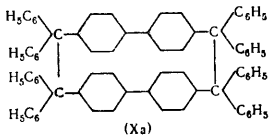
The latest results obtained by Waring and Sloan[16] provide a new interpretation of the observed independence of the unpaired electrons in Chichibabin's hydrocarbon: it is now attributed to a biradical dimer and not to the individual

monomeric molecule of the biradical. When, in experiments on Chichibabin's hydrocarbon and the biradicals (VIII) and (IX),



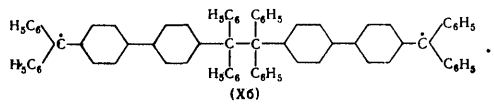
(VIII) (IX)

the specimen is cooled sufficiently rapidly, the intensity of the ESR spectrum observed at room temperature persists also at the low temperature. This can be regarded as proof that at sufficiently low temperatures the solution does not contain only monomeric biradicals but there is an equilibrium between paramagnetic and diamagnetic molecules. The most likely type of association is due to the formation of a weak C–C bond, as in hexaphenylethane. This may give rise to the formation of both diamagnetic cyclic dimers of the type



(Xa)

and linear dimers (or polymers) which retain a biradical character:



(Xб)

The linear dependence of the intensity of the ESR signal on concentration in the range between 5.04×10^{-3} and 7.7×10^{-5} M at room temperature (Fig. 3) shows that the associated paramagnetic and diamagnetic molecules have the same molecular weight.

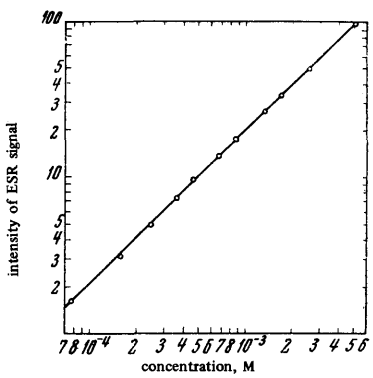


Figure 3. Variation of signal intensity with the concentration of Chichibabin's hydrocarbon in carbon disulphide.

The ESR spectrum of the biradical (VIII) at 25°C is shown in Fig. 4; the intensities of the lines in an individual section of the complete spectrum persist also on heating to 100°C, i.e. under these conditions there are no changes associated with the interaction between the electrons.

The presence of dimers or polymers of type (Xa) and (Xb) inevitably leads to observed independence of the unpaired electrons. These results provide a clear illustration of the danger of investigating exchange interactions on

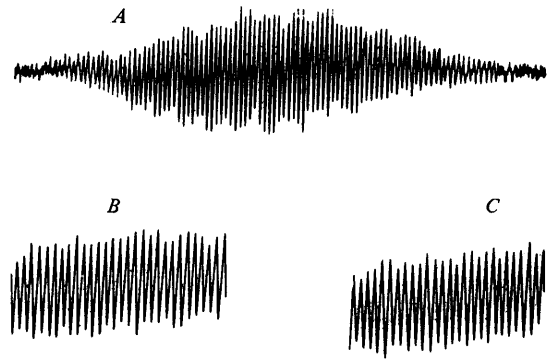

Figure 4. ESR spectrum of the biradical (VIII) in carbon disulphide: *A*) complete spectrum at 25°C; *B*) section of the spectrum at 25°C; *C*) section of the spectrum on heating to 100°C.

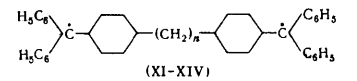
the basis of ESR spectra without a detailed identification of the molecules to which these spectra refer. Thus, the ESR data in no way contradicted the treatment of compounds of the type of Chichibabin's hydrocarbons as normal molecules with a low energy of excitation to the triplet state.

III. BIRADICALS WITH INSULATING GROUPS

Bridged biradicals [(IX)–(XII)], among which diphenylmethane and diphenylethane may be included, were obtained for the first time by Wittig and Leo[17,18].

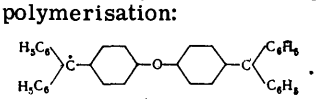


(XI-XIV)

(n = 1,2,3,4).

From the chemical point of view, they behave as free radicals; compound (XI) formed a bright red and compound (XII) a dark red solution exhibiting green dichroism in thin layers. However, in diphenylbutane derivatives (XIV) radical properties were completely absent according to the results of Wittig and Leo[18]. They attributed the weak colour, slow reaction with oxygen, and the constancy of the colour of this hydrocarbon to disproportionation. Nevertheless latest work[19] has shown that solutions of triarylmethyls frequently retain the initial colour although their paramagnetism falls to zero. All this weakens the arguments of Wittig and Leo.

Measurements of static magnetic susceptibility[20] led to the conclusion that hydrocarbon (XII) is diamagnetic; Müller failed to repeat the Wittig synthesis and his compound was completely colourless. Compound (XV), synthesised by Müller and Bunge[21], also proved to be diamagnetic (according to measurements of static magnetic susceptibility) and its diamagnetism was explained by dimerisation or polymerisation:



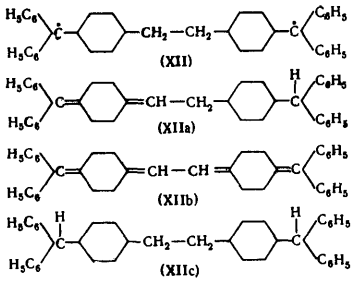
(XV)

The biradicals (XI)–(XV) have now been studied by the ESR method[10,11]. Table 3 shows that they exhibit intense paramagnetic absorption, but even in the absence of light and oxygen the paramagnetism vanishes after a time. This is evidently due to disproportionation. In his study of the

Table 3.

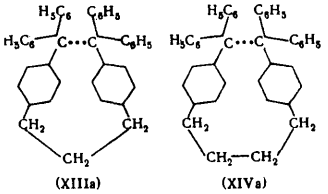
Compound	Initial colour	Presence of ESR signal	Colour of decomposed solution	Colour after access of air
(XI)	bright red	++	pale yellow	colourless
(XII)	wine red (green in thin layers)	++	pale blue	colourless
(XIII)	yellow	++	pale yellow	pale yellow
(XIV)	yellow	++	pale yellow	pale yellow
(XV)	yellow	++	pale yellow	pale yellow

biradical (XII), Müller obtained three decomposition products which he believed appeared as a result of subsequent inter- and intra-molecular disproportionation reactions.



It is interesting to note that, although compound (XIIb) is diamagnetic, it has a dark red colour and is sensitive to oxygen. Judging from Tables 1 and 3 compiled by Sloan and Vaughan[8], conversion into coloured diamagnetic compounds which retain their sensitivity to oxygen is a common property of biradicals.

Speaking of the disproportionation mechanism, it is difficult to explain why the colour of the decomposed solution of compound (XI) differs from that of the solution of compound (XII), if it is assumed that inter- and intramolecular disproportionation converts compound (XI) to the same product. Furthermore, it is not altogether clear why diphenylpropane and diphenylbutane differ so much from diphenylmethane and diphenylethane derivatives. Possibly the biradicals forms (XIII) and (XIV) are in equilibrium with monomeric diamagnetic compounds of the type (XIIIa) and (XIVa), since in compounds (XI) and (XII) intramolecular saturation of valence is impossible, because the bond between trivalent carbon atoms would have to extend over a very large distance. This difference in fact leads to different disproportionation mechanisms:



The central problem which arises in the examination of biradicals with insulating groups is the question whether the biradical in fact consists of two independent monomeric radicals or whether there is exchange interaction between the two halves, leading to a spin $S = 1$. The method of static magnetic susceptibility, which predicted a diamagnetic behaviour of the majority of these hydrocarbons, could not of course resolve this problem.

Analysis of the ESR spectra of bridged biradicals[10] (Fig. 5) favours the first hypothesis, namely that the two halves of the biradical are independent. The measured values of the g-factor proved to be similar to those of a free electron and the sharp resolution of the spectrum and the narrowness of the hyperfine components suggested the absence of appreciable dipole interaction between the unpaired electrons. The impairment of the resolution of the hyperfine structure on increasing the number of methylene groups favours the hypothesis that, with a longer molecular chain, anisotropic hyperfine interaction makes a contribution to line width. The line in the spectrum of compound (XV) again becomes sharp and the g-factor decreases somewhat (from 2.0025 to 2.0031), which is characteristic of free radicals with oxygen atoms[11,12] (Fig. 6).

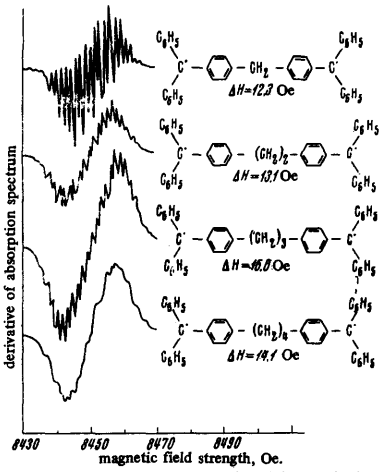


Figure 5. ESR spectra of biradicals with insulating groups.

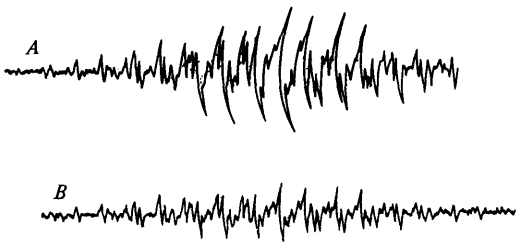

Figure 6. *A*) ESR spectrum of the biradical (XV) at 263°K; *B*) at 215°K.

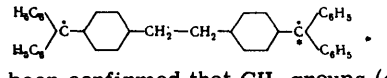
Analysis of the hyperfine structure in the spectra of biradicals (XII) and (XV) labelled with the carbon-13 isotope, similar to that discussed above, confirmed the independence of the spins of the unpaired electrons[11]. Thus at 297°K the spectrum of compound (XII), in which one of the atoms (marked with an asterisk) was labelled with carbon-13, contains a central line which originates from the part of the molecule in which the nuclear spin is zero. The two outer lines are due to splitting by carbon-13 in the group $(C_6H_5)_3{}^{13}C$. Such a triplet spectrum corresponds to the condition $J = 0$ (see Figs. 2 and 7):



Thus it has been confirmed that CH_2 groups (even one such group) clearly insulate two conjugated systems. It

has been suggested that conjugation via such groups is possible in the radical-anions (monoradicals) of diphenylmethane and dibenzyl[23,24]. However, this has been disproved by the work of Kazokova, Syrkin, and Shapiro, who

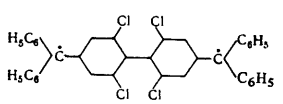
Figure 7. ESR spectrum of the biradical (XII) at 297°K (60% ^{13}C).

showed that the radical-anions are not in this case unchanged initial molecules to which an electron has been added, but undergo secondary reactions, which lead to a considerable rearrangement of the initial molecules[25-27].

IV. ATROPISOMERS

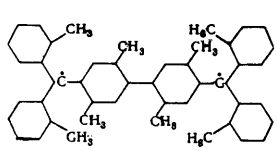
Numerous new data on static magnetic susceptibility were obtained in the 1950's for non-planar derivatives of diphenylquinonedimethane–atropisomers. The presence of bulky substituents in the *ortho*-position with respect to the central bond leads to the rotation of one part of the molecule relative to the other and both halves become just as independent as the bridged biradicals. Therefore, although formally these substances appear to be derivatives of compounds of type 1, in fact they belong to the third type.

The compound 2,6-2′,6′-tetrachloro-4,4′bis(diphenylmethyl)biphenyl (XVI), which in solution exhibits paramagnetism increasing with temperature and decreasing with concentration, was examined earlier by the method of static magnetic susceptibility[28]. Comparatively recently these data were confirmed by the study of the ortho–para conversion of hydrogen catalysed by compound (XVI).[29] It was found that this compound is a biradical to the extent of 100%:

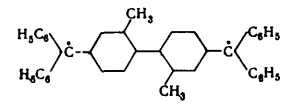


(XVI)

According to the results of Schwab and Baumel[30], compound (XVII) catalyses the ortho–para conversion of hydrogen with a conversion constant likewise corresponding to a 100% content of the biradical. Static magnetic measurements[9] fully confirm the data of Schwab and Baumel concerning the biradical nature of compound (XVII) (Table 4).



At one time Theilacker and Ozegowski[31] suggested that not four but two substituents are sufficient for the breakdown of coplanarity. They synthesised compound (XVIII), Theilacker's hydrocarbon, the solution of which is very sensitive to air and exhibits green-red dichroism. On this basis they suggested that the solution contained the biradical form (XVIII):



(XVIII)

It was not until much later that data on the percentage content of the biradical (XVIII) were obtained by measurements of the magnetic susceptibility of this hydrocarbon in α-methylnaphthalene[9] (Table 5).

Table 4. Magnetic susceptibility of 2,2′,5,5′-tetramethyl-4,4-bis(ditolylmethyl)biphenyl in α-methylnaphthalene (M) and benzene (B).

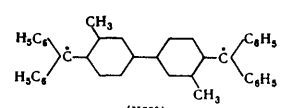
2.62	3	4	9	—	—

The substitution of methyl groups by fluorine atoms leads to a smaller percentage content of the biradical and therefore the equilibrium quinonedimethane ⇌ biradical is more strongly displaced to the left (Table 6).[9]

However, the steric effect is evidently not the only factor in such cases, since substance (XIX), with methyl groups in *meta*-positions with respect to the central bond, is also paramagnetic and actually more so than Theilacker's hydrocarbon[9,32] (see data in Table 7):



(XIX)

Apart from steric effects, the presence of substituents in the biphenyl system which reduce the energy of excitation to the triplet biradical state probably also plays a significant role in this case.

Table 7. 3,3′-Dimethyl-4,4′-bis(diphenylmethyl)biphenyl in α-methylnaphthalene.

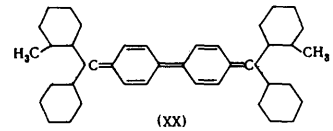
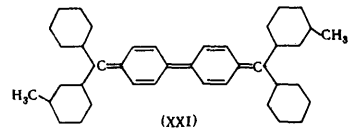
Compounds (XX) and (XXI) proved to be diamagnetic[32]:



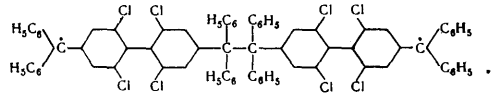
(XX)



(XXI)

It should be noted that data on the percentage content of the biradical forms in atropisomers listed in the tables were obtained on the assumption that both halves of the biradicals are completely independent ($\chi_p = 2560 \times 10^{-6}$ e.s.u.). However, in some cases the angles between the two halves of the biradical can assume intermediate values between 0° and 90°C, which should result in a weak π-bond. Therefore complete reliance cannot be placed on data obtained on the assumption that such a bond is altogether absent.

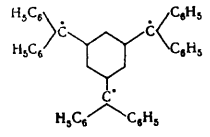
The extent of interaction between unpaired electrons might be inferred from ESR spectroscopic data, but unfortunately the only biradical [compound (XVI)] investigated by this method is appreciably associated in solution[16], forming open-chain biradical dimers (or polymers) of the type



Clearly such association prevents the correct interpretation of the ESR spectra.

V. POLYRADICALS

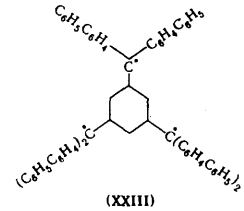
In 1965 there appeared a brief communication that German investigators[33] had succeeded in repeating Leo's attempt to obtain a hydrocarbon triradical of the type



(XXII)

However, the product did not have a definite melting point and, according to elemental analysis and molecular weight measurements, was a weakly associated polymer. On dissolution in benzene, an ESR spectrum with a resolved hyperfine structure appeared.

The replacement of phenyl groups by biphenylyl groups yields the triradical (XXIII)



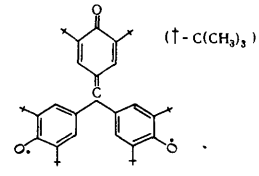
(XXIII)

which consists of red-violet crystals. It gives rise to an ESR signal but the hyperfine structure is not resolved in the spectra of either the solid radical or its solution in benzene. The solution also contains both monomeric and polymeric molecules.

VI. BIRADICALS WITH HETEROATOMS

Recently an intensive study of biradicals with heteroatoms by the ESR method was begun. With the exception of the previously known porphyrindine, most of the radicals constitute completely new classes of paramagnetic organic molecules. As with hydrocarbon biradicals, this method makes it possible to determine from the number of hyperfine components of the ESR spectrum and the g-factor the class of biradicals to which the given compound belongs, i.e. to elucidate whether it is simply a double monoradical or whether it is in the triplet state, like Chichibabin's hydrocarbon.

Jang and Castro[34] described the synthesis of a substance with the hypothetical structure (XXIV)



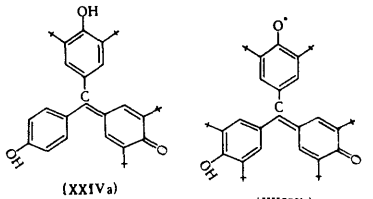
(XXIV)

Calculations were made on this molecule[35] by the MOH method on the assumption that the phenyl rings are displaced from a single plane and are rotated by 30°, as in triphenylmethyl. The calculation led to the conclusion that the last two electrons should occupy a degenerate nonbonding orbital when all the Coulombic integrals are equal, and a degenerate orbital with the energy 0.542β when the Coulombic integral for the oxygen atom is assumed to be $\alpha_O = \alpha_C + 1.5\beta$, so that in both cases there is a triplet ground state. The most significant results proved to be the theoretical prediction of a transition at very long wavelengths (20.000 Å) and its experimental observation in absorption spectra. This transition takes place from the bonding level with the energy 0.827β to the partially filled degenerate bonding levels (0.542β) where the unpaired electrons of the molecule are located.

Measurements of the static magnetic susceptibility gave 3.1×10^{-3} cm³ mole⁻¹ as the paramagnetic contribution. However, in the authors' view there is a possibility here of a large experimental error.

The ESR spectrum of Jang's biradical consists of seven overlapping lines (hyperfine constant $A_H = 0.86$ Oe), which indicates the interaction of the unpaired electrons with six equivalent protons[36]. Evidently the spin exchange is very rapid and each electron interacts with the six *meta*-protons

of the three aromatic rings. The addition to the biradical of the initial substance (XXIVa) in methyltetrahydrofuran leads to the formation of the monoradical (XXIVb):



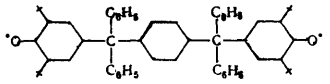
(XXIVa) (XXIVb)

Evidently a disproportionation reaction takes place:

XXIV + XXIVa ⇆ XXIVb.

On cooling a solution containing the biradical, the lines in the ESR spectrum broaden and at −50°C the spectrum consists of a single broad line. In the spectrum of the frozen solution (glass at −160°C) dipole splitting is observed, and the lines originating from the monoradical and the biradical become superimposed (large doublet splitting). The extent of this splitting depends on the dipole interaction between the unpaired electrons, which is inversely proportional to the cube of the distance between the magnetic dipoles. Thus the distance between the intense lines of the doublet enables (see Pake[37]) the distance between the two unpaired spins to be found, in this case 9 Å.

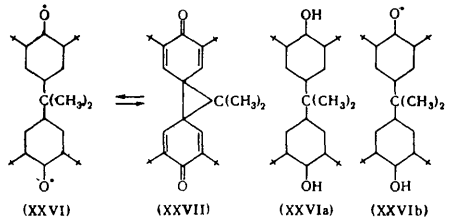
Another bisaroxyl biradical (XXV) was studied by Müller and coworkers[38]. Measurements of static magnetic susceptibility in benzene showed that the solution contained 88% of the biradical molecules. The ESR spectrum of this biradical consists of three lines, which can be attributed to two protons of the phenoxyl ring. Hence it follows that the unpaired electrons are localised only in the phenoxyl groups surrounding the molecule and do not interact with one another via the insulating $C(C_6H_5)_2$ groups, the biradical behaving simply as a double monoradical:



(XXV)

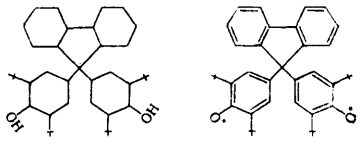
The attempt of Chandross and Kreilick[39] to detect by the ESR method the biradical (XXVI) obtained by the oxidation of compound (XXVIa) was unsuccessful, although the monoradical (XXVIb) gave rise to a distinct ESR spectrum consisting of a triplet (two equivalent *meta*-protons with a hyperfine structure constant of 1.67 Oe) split by the weaker interaction with the six equivalent protons of the isopropylidene group (hyperfine structure constant of 0.38 Oe).

The absence of an ESR signal due to the biradical (XXVI) can be attributed to the equilibrium between the biradical species and the diamagnetic spirodiene (XXVII):



(XXVI) (XXVII) (XXVIa) (XXVIb)

The replacement of the *gem*-dimethyl group in compound (XXVIa) by a 2,2-diphenylene group yields compound (XXVIIIa)[40]. The ESR spectrum obtaining during the oxidation of this substance was investigated. Initially three lines due to the monoradical appeared (hyperfine structure constant of 1.65 Oe). As the oxidation progressed, the intensity of the signal increased and then fell, but did not disappear altogether. At −180°C two groups of lines appeared in the spectrum, corresponding to the transition $|\Delta m| = 1$ with splittings of 126 and 30 Oe, and absorption corresponding to $|\Delta m| = 2$ occurred when the field strength was reduced to 50%. The larger splitting was attributed to the biradical (XXVIII) and the smaller to the dimer containing two molecules of compound (XXVIII), probably joined by a peroxide bond:

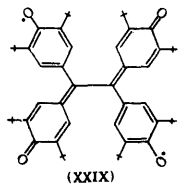


(XXVIIIa) (XXVIII)

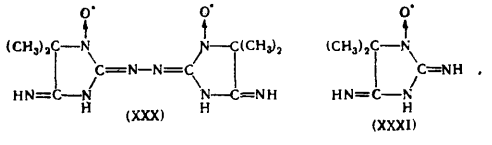
Although the formation of such a bond is fairly unusual in this case (due to the presence of bulky substituents in the phenyl ring), the concentration dependence of the extent of splitting in a zero field confirms the occurrence of dimerisation. On dissolution, the intensity of the smaller splitting decreases and vanishes much faster than that of the larger splitting, which persists for a fairly long time. The position of the lines indicates that the average distance between the unpaired electrons in compound (XXVIII) is 6 Å and in the dimer 9.8 Å.

Recently Chandross[41] obtained an interesting stable biradical (XXIX) which he called bisgalvinoxyl. It is a dark crystalline substance with a metallic lustre. In the solid state the biradical is very stable, but in inert solvents (10^{-3}–10^{-4} M) it is decolourised by air in several hours. The bisgalvinoxyl spectrum recorded in glasses at 77°K clearly shows that this substance is in the triplet state. In methyltetrahydrofuran a hyperfine line structure appears, transitions both from $|\Delta m| = 1$ and transitions at 1635 Oe, corresponding to $|\Delta m| = 2$, being observed. Using the model of 2 point dipoles, it can be shown that the splitting at $|\Delta m| = 1$ corresponds to an average interelectron distance of 6 Å.

In contrast to the biradicals (XXIV) and (XXIX), the ESR spectra of which indicate that these compounds have two unpaired electrons in different parts of the molecule interacting with one another, in the ESR spectrum of porphyrindine (XXX) there is no clear proof of the interaction between the two unpaired electrons[42].



(XXIX)



(XXX) (XXXI)

The spectrum of the dimethylsulphoxide solution of this substance consists of three groups of lines with a hyperfine structure constant of about 10 Oe. Each line is split further into four components with a hyperfine structure constant of the order of 3 Oe (Fig. 8). The main splitting is evidently due to the interaction of the unpaired electron with the nucleus of the nitrogen atom. In contrast to this,

the spectrum of compound (XXX) in ethanol at 300°K consists of only two lines, although porphyrexide (XXXI), which constitutes as it were one half of porphyrindine, gives rise under these conditions to an ESR spectrum consisting of three lines. Possibly in this case there are solvent and temperature effects on the exchange interaction.

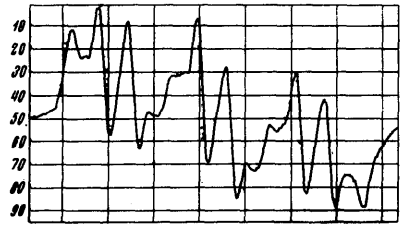


Figure 8. ESR spectrum of the biradical (XXX) in dimethylsulphoxide at 80°C.

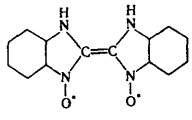
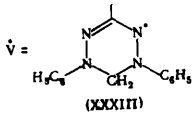
The decrease of the paramagnetism of porphyrindine on reducing the temperature previously, observed by the magnetic susceptibility method, is found to occur also for NO-indigo[43]:



(XXXII)

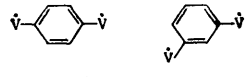
At room temperature the fraction of biradical molecules is high and the susceptibility of this compound is 10% higher than the value calculated for the double monoradical. However, at the temperature of liquid nitrogen it is diamagnetic. Evidently, in this case the diamagnetic form of NO-indigo, like the diamagnetism of porphyrindine at low temperatures, is associated with the displacement of the equilibrium between the diamagnetic and paramagnetic forms towards the former. The diamagnetic form may be either a polymer or, what is more likely, a diamagnetic monomer.

On the basis of the fragment



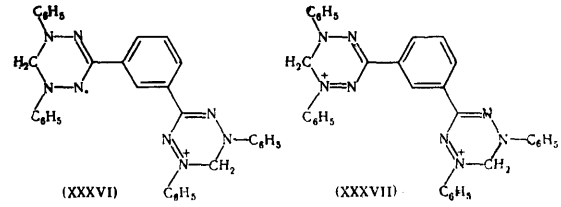
(XXXIII)

the green biradicals (XXXIV) and (XXXV) were obtained[44]:



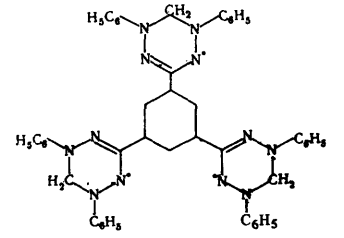
(XXXIV) (XXXV)

While the monomeric radical (XXXIII) gives rise to nine lines in the ESR spectrum, which can be accounted for by interaction with two nitrogen atoms, the spectra of biradicals (XXXIV) and (XXXV) contain a different number of lines, corresponding to exchange between two unpaired electrons. Reversible polarographic oxidation leads to the monocation (XXVI), violet in colour, the spectrum of which again shows the nine lines of the monoradical, and then the diamagnetic dication (XXXVII):



(XXXVI) (XXXVII)

The interesting triradical (XXXVIII) was also obtained on the basis of (XXXIII):[45]



The resultant magnetic spin moment of the molecule for three independent unpaired electrons is $\mu = \sqrt{9}\mu_B$. Table 8 shows that, in contrast to porphyrindine and NO-indigo, the paramagnetism of the triradical does not continue to decrease down to the temperature of liquid nitrogen. This suggests that the three electrons of the triradical are indeed independent. The hyperfine structure of the ESR spectrum of the triradical is unresolved.

Table 8.

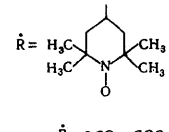
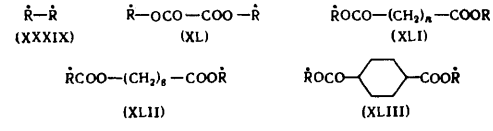
77	3.01

Because of the presence of an insulating grouping between the two halves of the molecules of the hydrocarbon biradicals examined above, there is no exchange between them, i.e. the σ-bond system of the bridge prevents interaction between the electrons. The insulating bridge in biradicals with heteroatoms plays the same role. However, it has been suggested that the exchange of unpaired electrons can occur also in the presence of insulating groupings, but by a different mechanism. Roxantsev, Buchachenko, and coworkers[46,49] and also Lemair and coworkers[50,51] obtained and investigated iminoxy-biradicals, which are exceptionally stable both in the solid state and in solutions. The iminoxy-biradicals contain the following residue with the unpaired electron:

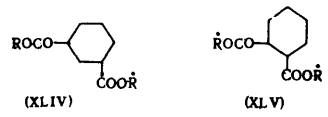


$n = 2, 4, 5$



(XXXIX) (XL) (XLI)

(XLII) (XLIII)



In the absence of exchange between the unpaired electrons in the two halves of the iminoxy-biradical, each electron interacts with the nucleus of the nitrogen atom of "its half" and the biradical behaves as a double monoradical. In this case the ESR spectrum consists of three lines with a hyperfine structure constant A. If there is strong exchange interaction between the two electrons, the spectrum consists of five lines with a hyperfine structure constant $A/2$ (see p. 378 and Fig. 9).

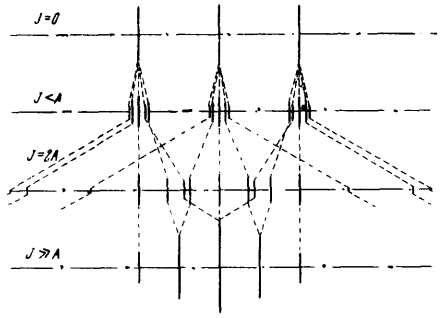


Figure 9. Theoretical spectrum as a function of the presence or absence of exchange interaction.

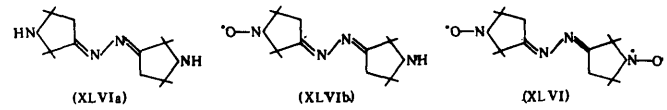
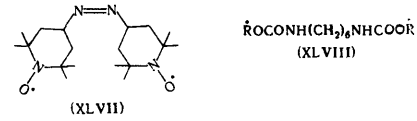
In contrast to the spectrum of the monoradical $\dot{R}$, the hyperfine structure of which consists of a triplet due to the ^{14}N nucleus (hyperfine structure constant $A_N = 15.6$ Oe) split by the β-protons ($A_H = 0.35$ Oe), in the spectra of the biradicals additional lines appear between the components of the triplet. Their number and intensity depend on the structure of the biradical. Thus the spectrum of the biradical (XXXIX), where the NO groups lie very close together, consists of five lines, which are regarded as due to the interaction of the two equivalent ^{14}N nuclei. In the spectrum of the biradical (XL), where there is an -OCO-OCO- group, additional lines do not appear and the spins behave independently. In the ESR spectrum of the biradicals (XLI) four additional lines appear, which Buchachenko et al. [48] believe to be due to the enhanced interaction between the unpaired electrons. The spectra of compounds (XLIII) and (XLIV) consist of triplets without additional lines, while in the spectrum of (XLV) there are again five lines, which are interpreted as indicating the occurrence of interaction between the two nitrogen atoms.

The monoradical (XLVIb) and the biradical (XLVI), which consists of large yellow crystals, were obtained by the oxidation of azine (XLVIa) [50]. The intensity of the ESR spectrum of the polycrystalline biradical is higher by a factor of 2.16 than the intensity of the polycrystalline monoradical containing the same number of molecules. In dimethylformamide the monoradical gives rise to the classical triplet with $A_N = 14.4$ Oe and $g = 2.0055$, while the biradical gives rise to a highly resolved triplet with $A_N = 7.2$ Oe. The authors explained these data by the occurrence of exchange interaction, the frequency of which is higher than that of the hyperfine interaction, i.e. $J \gg A$.



The width of the biradical line (2.4 Oe) does not differ much from the line width measured in the spectrum of the monoradical under the same conditions. (2.2 Oe). This means that the bond between the unpaired electrons is not strong enough to widen the ESR line due to dipole interaction.

The radical (XLVII) gives rise to a similar spectrum (Fig. 10a). [51] When the nitrogen atom in the iminoxy-groups is replaced by the ^{15}N isotope, three lines appear in the spectrum (Fig. 10b). This is accounted for by the interaction of the unpaired electron with the two nuclei of the ^{15}N atoms, which have a nuclear spin $I = \frac{1}{2}$ (case $J \gg A$, Fig. 1). The absence of splitting by the nitrogen atoms of the azine bridge shows that the electron exchange does not involve the system of σ-bonds. This is also indicated by the ESR spectrum of the biradical (XLVIII), in which there is no additional splitting by the ^{14}N nuclei of the heterochain bridge [48]:



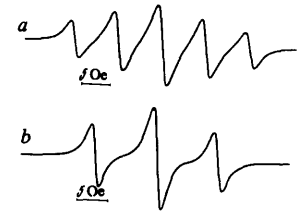


Figure 10. ESR spectra of the biradical (XLVII): *a*) unsubstituted biradical; *b*) biradical containing nitrogen-15.

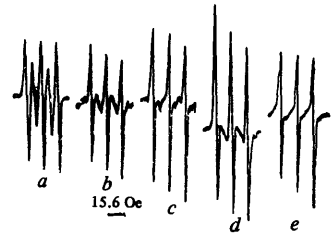

Figure 11. ESR spectra of the biradical (XLII) in different solvents: *a*) hexane; *b*) benzene; *c*) chloroform; *d*) carbon tetrachloride; *e*) acetic acid.

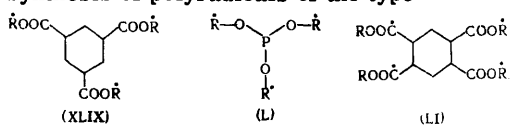
The ESR spectra of iminoxy-biradicals vary both with temperature and the nature of the solvent. Thus, when the temperature is raised, additional lines appear in the spectrum of compound (XL), the intensity of which increases with temperature. Fig. 11 presents the spectra of

the biradical (XLII)[47] in various solvents. Evidently here the shape of the spectrum is influenced not only by the viscosity of the solvent but also by the different solvation effects.

The synthesis of polyradicals of the type



(XLIX) (L) (LI)

on the basis of the monomeric biradical Ṙ has been described recently[52]. They have all been investigated by the ESR method.

It is interesting to note that the g-factors of iminoxy-biradicals are the same as those of the corresponding monoradicals and in none of the cases has it been possible to observe ESR signals with $g = 4$, which would correspond to $[\Delta m] = 2$ transitions.

Finally, the true mechanism of the exchange observed in the iminoxy-radicals has not yet been elucidated. Some workers[46-49] believe that the overlapping of the π-orbitals of the unpaired electrons and hence the exchange between the two halves of the biradical occur as a result of the bending of the molecules and the deformation of the chemical bonds and the angles between them, i.e. there is "conformational" exchange interaction when close mutual intramolecular approach of the paramagnetic fragments of the biradical takes place.

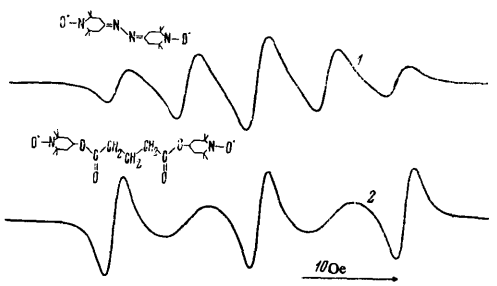


Figure 12. ESR spectra of the biradicals (XLVII) (curve *1*) and (LIII) (curve *2*).

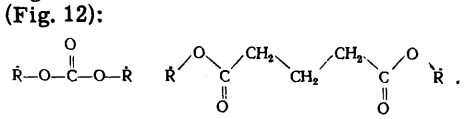
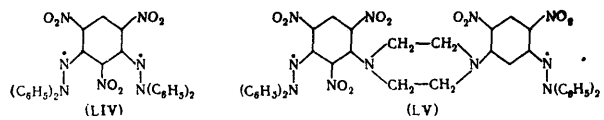
The influence of exchange interaction on line width has been investigated with the biradicals (LII) and (LIII) as examples[53] (Fig. 12):



(LII) (LIII)

When J varies in such a way that its average value $\overline{J}$ remains greater than A, the width of the central line and of the two outer lines remains constant, since their positions are independent of the changes in J. Other, intermediate lines become broader. This broadening is due to the modulation of the exchange integral J. When the exchange integral is expressed by formula (3), it is evident that its value depends on the extent of the overlapping $\Phi_A\Phi_B$ of the two wave functions $\Phi_A(1)$ and $\Phi_B(2)$, where $\Phi_A(1)$ is the orbital of the unpaired electron in one half of the molecule and $\Phi_B(2)$ is the orbital in the other half. When the extent of overlapping is low, the integral is large, and, correspondingly, a decrease in the extent of overlapping leads to a decrease of J. Since the biradical is not a rigid molecule, it can assume various configurations, each of which corresponds to a particular degree of overlapping $\Phi_A(1)\Phi_B(2)$ and different values of the integral J. This modulation of the integral J by intramolecular conformational changes does in fact constitute the relaxation mechanism which influences the biradical line width.

Biradicals of the hydrazine series (LIV) and (LV) have been synthesised recently and have been investigated by the ESR method[54,55]:



(LIV) (LV)

The theoretical spectrum of the biradical (LIV) is consistent with experiment (Fig. 13), provided that the unpaired electrons are localised in their halves and that each

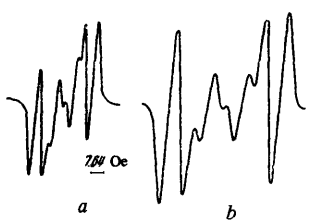


Figure 13. ESR spectra of the biradicals (LIVa) and (LIVb).

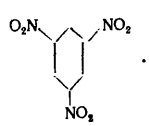
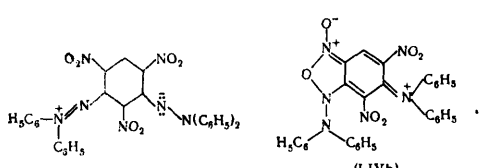
electron interacts only with the two non-equivalent nitrogen atoms and $A_{N_1}/A_{N_2} = 0.64$ and $A_{N_1} + A_{N_2} = 17.13$ Oe. This suggests that $J \ll A$ and there is thus no electron interaction via the bridge



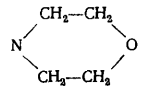
It is interesting to note that Heidberg and Weil[56] failed to observe the biradical form (LIV) in the oxidation of the bihydrazine monoradical and they attributed the singlet ground state of the resulting compound to the presence of ionic structures of the type



(LIVa) (LIVb)

The biradical (LV) gives rise to an ESR spectrum consisting of nine hyperfine structure components (Fig. 14). The theoretical spectrum containing nine components with intensity ratios 1 : 4 : 10 : 16 : 19 : 16 : 10 : 4 : 1 corresponds to four equivalent nitrogen atoms. Evidently each unpaired electron is not linked to its hydrazyl group and migrates from one half of the molecule to the other, i.e. in this case

$J \gg A$ and the electrons do interact with one another. Since in this case the interaction via the σ-bonds of the bridge



is excluded, it can be supposed that here the exchange mechanism is probably the same as in iminoxy-biradicals.

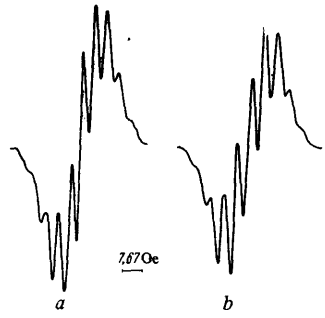


Figure 14. ESR spectra of the biradical (LV): *a*) experimental spectrum; *b*) theoretical spectrum.

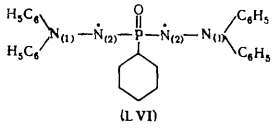
A variation of the intensity of the spectrum of the biradical (LV) with temperature in the range between +60°C and −50°C could not be observed. Further reduction of temperature leads to a broadening of the ESR lines and the disappearance of the hyperfine structure. The spectrum of the supercooled solution shows one ESR line with a width of about 20 Oe between the points of inflexion and a g-factor of 2.0035. Other lines, characteristic of $S = 1$ as well as $|\Delta m| = 2$ transitions, were not observed. This may be due either to the low intensity of the $|\Delta m| = 2$ transition, which is weaker by 3 powers of 10 than the $|\Delta m| = 1$ transition, or to the breakdown of the intramolecular exchange bond between the two halves of the molecule on going to the supercooled state. In this case the anisotropic hyperfine structure is not resolved because of the dipole-induced broadening.

A biradical based on a phenylphosphonic dihydrazide has also been obtained[55]:

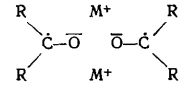


(LVI)

At the beginning of oxidation the ESR spectrum of the monoradical, consisting of seven hyperfine structure components, is observed. Comparison with the theoretical spectrum showed that the experimental spectrum results from the superposition of two quintets. The five lines in each quintet are due to the equally probable interactions of the unpaired electron with the two atoms of hydrazine. The isotropic hyperfine structure constant $A_N = 6$ Oe. The doublet with the constant $A_P = 10$ Oe must be assigned to the phosphorus nucleus. On further oxidation, the seven-component spectrum is converted into a quintet with the intensity ratios 1 : 2 : 3 : 2 : 1. The five lines of the hyperfine structure correspond to the delocalisation of each electron in its half of the molecule only, under conditions of interaction with the two nitrogen atoms of hydrazine. The form of the spectrum suggests that the nucleus of the phosphorus atom does not participate in splitting. There may be several reasons for the non-involvement of the phosphorus atom in hyperfine splitting and probably the main one is the breakdown of the p_π–d_π conjugation when the environment of the phosphorus changes on transition from the monoradical to the biradical. The constants A_{N_1} and A_{N_2} become larger by a factor of 1.5 than those of the monoradical, and the overall splitting $A_{N_1} + A_{N_2}$ increases from 12.2 to 17.6 Oe. An anisotropic hyperfine structure broadened by dipole interactions appears in the spectrum of the supercooled solution. No lines, additional to those with $g \simeq 2$, were observed.

VII. BIRADICALS OF METAL KETYLS

The study of the ESR spectra of the ketyls derived from hexamethyl- and pentamethyl-acetones showed that their hyperfine structure is due to splitting by protons in the ketone components, and furthermore that the unpaired electron is linked to the two equivalent nuclei of the alkali metal[59]. This finding can be accounted for on the basis of a dimeric structure of the ketyl molecule in which the two organic radicals are joined by two equivalent alkali metal ions:



The presence of dimers is also confirmed by optical spectra[57,59], which vary markedly with the concentration of the ketyls. Thus the spectrum of the fluorenonesodium ketyl in methyltetrahydrofuran at a high concentration shows a peak at 450 nm, while at lower concentrations this peak appears at 525 nm. Evidently there is a monomer–dimer equilibrium in the solution and since the spectra of the dimers and monomers are almost identical, it is evident that dimerisation does not involve any changes in the electronic structure. Thus the dimer molecules may be regarded as a kind of biradical system in which each electron spin belongs predominantly to one half of the dimer but is divided between the nuclei of the alkali metal. The ESR spectrum of solid ketyl solutions at 77°K shown in Fig. 15 is characteristic of triplet systems. The spectrum corresponding to the $|\Delta m| = 1$ transition results from the superposition of two spectra—a narrow central singlet and a broad doublet. With increase in the size of alkali metal ions, the doublet splitting increases from 118 Oe for the fluorenonelithium ketyl to 82 Oe for the fluorenonepotassium ketyl. The optical spectra at 77°K indicate the existence of both a monomeric and a dimeric form. The central singlet peak can be attributed to monomers (or dimers with a low degree of dipole interaction) and the doublet to dimers with a high degree of dipole interaction. Apart from the $|\Delta m| = 1$ transition, an absorption peak is observed when the field strength is reduced by one-half. This is due to the $|\Delta m| = 2$ transition (Fig. 15*f*). Its intensity is of the order of 10^{-3} of the intensity associated with the $|\Delta m| = 1$ transition.

The hyperfine structure of the spectra of liquid solutions of dimers with a high degree of dipole interaction is broadened by relaxation, while dimers with a low degree of dipole interaction give rise to a well resolved structure. Analysis of the Reitz–Weissman type of hyperfine splitting

in the spectra of ketyl dimers[11] shows that both the splitting by the ^{13}C nuclei and by protons in the ESR spectra of divalent- and trivalent-metal ketyls corresponds to the condition $A \gg J$. The rate of spin exchange between the two halves of the ion pair is thus much lower than the frequency of the hyperfine interaction and the spectrum of the dimer is similar to that of the monomer. The temperature variation of the absorption intensity is consistent with the low value of J.

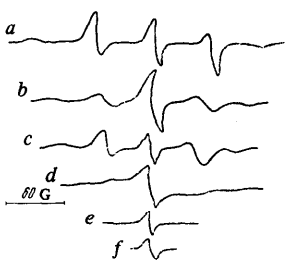


Figure 15. Spectra of paramagnetic ketyls in methyl tetrahydrofuran at 77°K; $|\Delta m| = 1$:

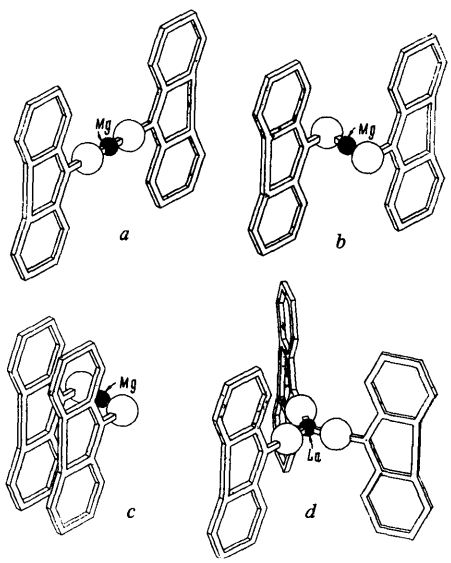

Figure 16. Possible structures of paramagnetic ketyls.

The possible structures of the dimeric ketyls can be inferred from the magnitude of the doublet splitting. Divalent-metal ketyls, apart from fluorenonebarium and fluorenonestrontium, give rise to spectra in which the half-width is about 10–15 Oe. Since divalent-metal ketyls do not dissociate, it can be assumed that the dipole interaction in them amounts to about 10 Oe. A possible structure of such a dimer is presented in Fig. 16*a*. The line half-width of 25 Oe observed in the spectra of trivalent-metal ketyls (Fig. 16*d*) indicates a high degree of dipole interaction. Structures of types *b* and *c* (Fig. 16) are possible in those cases where the line is broader and the dipole interaction more pronounced. In all probability there is an equilibrium between the dimeric forms and the most stable structure is determined by several factors: the structure of the initial ketone, the charge and the dimensions of the metal atom, and the nature of the solvent.

The data described above permit the following conclusions.

Electron spin resonance has proved most useful for the determination of the biradical nature of those compounds, the paramagnetism of which had not been demonstrated unambiguously by static magnetic susceptibility measurements and ortho–para conversion of hydrogen. For biradicals consisting of components separated by insulating groups, the ESR method permits certain inferences about their structure—the distribution of unpaired electrons. It follows from the hyperfine structure analysis of the spectra of biradicals of this type that each unpaired electron is localised in its own half and the biradical is a double monoradical.

However, there are as yet no convincing experimental data which would permit the analysis of the properties of systems of the type of Chichibabin's hydrocarbon in the triplet state (with "strong exchange interaction" between the two electrons). Possibly the absence of a hyperfine structure from the ESR spectra of certain biradicals of this type (and sometimes also the absence of an ESR signal at room temperature) is associated with the mechanism of the broadening, the main contribution to which comes from the spin–lattice relaxation. For this reason, the $|\Delta m| = 2$ transitions corresponding to the triplet state in these biradicals and also in the metal ketyl biradicals have been observed at very low temperatures only.

Atropisomers have not been investigated at all, although there is no doubt that the degree of coplanarity of the two halves of the biradical could be inferred from the hyperfine structure of the ESR spectra.

Further, more detailed study of the mechanism of the so called "conformational exchange" is essential.

Processes Occurring in Solids Under the Action of Powerful Shock Waves

A.N.Dremin and O.N.Breusov

The action of powerful shock waves on condensed materials can lead to a wide variety of physicochemical changes: polymorphic transformations, decomposition and synthetic processes, polymerisation of monomers, and defect-formation or conversely the formation of a more perfect structure. The study of these processes has shown that many of them take place exceptionally rapidly. The development of methods for the recovery of substances after the action of shock waves made it possible to employ high dynamic pressures for preparative purposes. Examination of the mechanism governing the compression of a substance by a shock wave shows that the transition from elastic monoaxial compression to bulk-phase compression may be identified with phase transformations as regards gas dynamics and thermodynamics and suggests that phase transitions in the shock wave cannot take place at pressures below the dynamic yield point of the substance. The presence of vigorous plastic flow in shock waves together with the operation of pressures reaching millions of atmospheres suggests that in many ways dynamic operations of this kind on various substances are comparable to methods combining high static pressures with shear stresses. Plastic flow in shock waves leads to the appearance of a characteristic mass-transfer mechanism which gives rise to diffusion processes during the very short period of shock-wave compression. Comparison of dynamic and static studies at high pressures reveals a very close correlation between them. However, a number of effects observed by shock-wave techniques are so far inconsistent with the phase diagrams of the corresponding substances.

I. INTRODUCTION

Numerous experimental data show that, under the action of shock waves due to the detonation of explosives and impact of bodies moving at a high velocity, various chemical and physicochemical transformations take place in condensed substances. In particular, certain substances subjected to the action of shock waves undergo polymorphic transformations. Attention was drawn to this for the first time by Bancroft et al.[1], who investigated the shock compressibility of iron and observed at 130 000 atm a break in the Hugoniot curve†, which they accounted for by polymorphic transformations occurring in iron under these conditions. Subsequently such breaks were observed also in the Hugoniot curves for a number of other substances, for example carbon[2], quartz[3,4], marble[5], potassium bromide and chloride[6-8], and other compounds[9]. Apart from polymorphic transformations, phenomena such as fusion[10,11] and plastic flow on transition from monoaxial elastic compression to bulk compression can also be reflected in breaks in the Hugoniot curves[3,4,12].

An important distinctive feature of these transformations in shock waves is their unusually high rate. Whereas the formation of new phases in static experiments requires times reckoned in seconds, minutes, and sometimes hours and even longer periods, in shock waves these processes are completed in fractions of a microsecond.

The observation of breaks in Hugoniot curves is only a part of the investigation of the transformations in substances under the action of shock waves. Successful studies of this kind permit the determination of the parameters of the shock-wave compression during which the transformation took place, which is itself of scientific interest. On the other hand, in order to determine what transformation is undergone by the substance and whether it is reversible or irreversible under the given conditions, it is desirable to recover the test specimen in the state which obtains at the instant when the shock wave ceases to operate. Such methods have been developed.

† The Russians refer to this as the shock compressibility curve or the adiabatic shock curve (Ed. of Translation).

2. RECOVERY OF SUBSTANCES SUBJECTED TO SHOCK-WAVE COMPRESSION

The first data derived from studies of substances recovered after shock-wave compression were published by Ryabinin[13] in 1956. Novosibirsk investigators[14] began their study by a similar method and later applied other procedures also[15]. Designs of cylindrical and flat iron and copper tubes, whereby substances can be recovered after being subjected to the action of detonation of charges consisting of the most powerful standard explosives, were developed in the laboratory of one of the authors[16,17]. The pressure which then arises in the tube depends not only on the power of the explosive charge used and the duration of its operation but also on the initial density and compressibility of the test substance. With dense comparatively compressible substances the pressures reached more than five million atmospheres and yet the test specimens were satisfactorily recovered. Readily compressible substances of low density are recovered with greater difficulty.

Similar studies are being carried out also outside the Soviet Union. For example the Japanese investigator Kimura[18] developed an unusual recovery method, while Israeli scientists[19] use a method similar to that of Ryabinin.

American investigators have also reported studies on the recovery of specimens (see, for example, Wackerle[3] and DeCarli and Jamieson[20]) but little information is available about the recovery methods which they used.

The study of specimens recovered after shock-wave compression confirmed that the breaks in the Hugoniot curves can indeed be caused by phase transformations. For example, the suggestion by Alder and Christian[2] that the break in the Hugoniot curve for graphite corresponds to the transformation of the latter into diamond was confirmed by DeCarli and Jamieson[20], who succeeded in obtaining diamond from graphite, containing regions of rhombohedral structure, after shock-wave compression at a pressure of up to 300 000 atm during 1 ms. The present authors also achieved partial conversion of ordinary graphite into diamond with a yield of 3%.

It has been shown[21] that there is also a break in the Hugoniot curve for hexagonal graphite-like boron nitride. Studies on the recovery of specimens confirmed that the break is due to the polymorphic transformation of boron nitride into a denser modification, namely the hexagonal wurtzite-like modification of borazon. Later it was shown that, together with the hexagonal wurtzite-like borazon, there forms also a certain amount of a cubic sphalerite-like modification of this ultrahard substance.

Batsanov and coworkers[22], who studied the shock-wave compression amorphous boron nitride synthesised in their laboratory, obtained a new form of this compound. Kennedy and Benedick[23] showed that wurtzite-like cadmium sulphide is converted in the shock wave into a modification with a structure of the sodium chloride type during a period not greater than 1 μs. Batsanov and Deribas[14] reported the transformation on shock-wave compression of the usual form of neodymium oxide into a new phase.

Deribas and coworkers[24] studied the effect of shock-wave compression on silica and obtained a number of interesting results. Wackerle[3] also recovered specimens of single-crystal silica subjected to shock-wave compression. Traces of coesite were detected by Deribas et al.[24] and by ourselves in silica subjected to shock-wave compression. Wackerle[3], Deribas et al.[24], and earlier DeCarli and Jamieson[25] showed that, when silica is compressed by sufficiently powerful shock waves, it is converted into a vitreous form although the maximum temperature of the specimens at the instant of shock was much less than the melting point of this compound. Albite underwent a similar transformation in the experiments of DeCarli and Jamieson[25]. Secrist and Mackenzie[26] attribute considerable importance to this method of preparation of substances in the vitreous state.

Shock-wave compression may lead not only to polymorphic transformations but also to chemical changes. For example, Kimura[18] showed that shock-wave compression of a mixture of iron and zinc oxides leads to the formation of ferrites. We achieved certain syntheses as a result of shock-wave compression. For example, a mixture of sodium and magnesium fluorides was almost completely converted into sodium fluoromagnate $NaMgF_3$, and a mixture of metallic indium and phosphorus gave rise to a satisfactory yield of indium phosphide. The shock-wave compression of a mixture of elemental boron and lithium nitride and also of boron oxide and ammonium chloride gave rise to the formation of small amounts of boron nitride, the reaction products containing its dense modifications—cubic and hexagonal borazon.

Ryabinin[13] noted significant defect formation in sodium chloride subjected to shock-wave compression, the decomposition of lead nitrate to the dioxide, the decomposition of magnesium carbonate to a mixture of magnesium oxide and carbon dioxide, and pyrolysis of hydrocarbons.

A large number of chemical reactions were observed by Batsanov and Deribas and coworkers. They noted the decomposition of a number of carbonates[27], sulphates, and nitrates[28]. By analysing their results, these investigators found that the changes occurring in the test substances subjected to shock-wave compression are associated in the first place with their thermodynamic stability. Under constant shock-wave compression conditions, the substances decompose if the heat of their formation is below a limiting value, the extent of decomposition being greater the lower is the heat of formation. If the heat of formation of the compound exceeds the limit, the effect is restricted to the formation of chemical or structural defects. In the most stable compounds, a more perfect structure of the crystal lattice is formed. The same investigators noted a number of interesting phenomena in the study of the effect of shock waves on potassium nitrate.

Our own data[16,29] confirmed the results of Batsanov et al.[28] Substances with high chemical and thermal stability, such as alkaline-earth fluorides, alumina, etc. acquire a more ideal crystal structure on shock-wave compression, approaching in their properties well-formed single crystals. However, since we used more powerful explosive charges, we observed the decomposition even of those substances which remained completely unchanged in the earlier experiments[13,27,28]. For example, copper sulphate was partially decomposed to cupric oxide and partially to metallic copper. Compounds such as PNO, Li_3N, $NiF_2 . 2H_2O$ etc. were found to decompose. Partial or complete decomposition of a number of metal oxides was observed (oxides of antimony, nickel, iron, titanium, molybdenum, tungsten, etc.), the free metal formed in the decomposition being sometimes observed in the form of large beads (1–3 mm) in the tubes used to recover the substance.

It has been established that porous substances can be significantly contaminated by the material of the tube wall, and therefore many chemical reactions may be due to the usual high-temperature interaction with the iron in the tube[16,30].

It is interesting that many dispersed substances (for example magnesium, nickel, and calcium fluorides) are converted into materials with much larger crystals after shock-wave compression[16]. Before shock-wave compression magnesium and nickel fluorides consisted of powders of very small particles, which gave rise to distinct powder diffraction patterns even without rotation of the specimens and proved to be optically isotropic on examination in a polarisation microscope. After shock-wave compression the particles of these substances became significantly larger, so that powder diffraction patterns recorded without rotation showed distinct reflections from individual crystals and the anisotropy characteristic of the substances became apparent in polarised light.

Many organic substances were found to polymerise under the action of shock waves[31]. Studies of the shock compressibility of monomeric and polymeric acrylamide showed that the polymerisation process takes place at an enormous rate when the density of the monomer reaches that of the polymer under shock conditions[32]. It was shown that the energy evolved in polymerisation intensifies the shock wave. (The dimerisation of cyclopentadiene under the influence of the detonation of tetryl was achieved by Vereshchagin and coworkers as early as 1945.[35]) Barkalov et al.[33] suggested the possibility of the shock polymerisation of infinitely large monomer blocks (polymerisation detonation).

3. ULTRAFAST PROCESSES IN SHOCK WAVES

The above findings show that, when various substances are acted upon by shock waves, the resulting processes do indeed take place at high rates. This applies also to non-diffusion reactions (certain polymorphic transformations) and reactions for which the occurrence of diffusional processes is inevitable (for example, syntheses and decompositions)‡.

At the present time there are no generally accepted hypotheses which would account for the unusually high rates of physicochemical reactions in shock waves. Probably this is caused in the first place by the lack of the necessary experimental data, for example, such as those on the dependence of the degree of conversion and the particle size of the new phase, on the parameters of shock-wave compression (pressure, temperature, time of operation of high pressure) and the initial state of the substance (in particular its degree of dispersion).

Roughly speaking all physicochemical changes occurring under the action of a shock wave (polymorphic transformations, conversion into the vitreous state, formation of a more perfect crystal lattice in relatively weak shock waves and defect formation in powerful shock waves, decompositions, syntheses, and polymerisation) can be divided into two classes. The first class includes those transformations which occur during the period of operation of the high pressure during shock-wave compression. Polymorphic transformations and polymerisation phenomena undoubtedly belong to this class. Indeed, as already stated above, shock-wave compression curves for substances undergoing polymorphic transformation or polymerising under the action of shock waves show breaks demonstrating that the corresponding phenomenon takes place directly in the shock-wave front. The first class also includes synthetic reactions with formation of phases which are thermodynamically stable only at a high pressure. For all other transformations, which belong to the second class, there is unfortunately no proof at present that they occur during the operation of the shock waves and not, say, during a much longer period under the action of high residual temperatures.

The effect of the high pressures generated in the shock wave cannot alone account for the enormous increase in the rate of processes. A series of investigations showed, in agreement with theory [36-40], that, on increasing the pressure, diffusional processes are not only not accelerated but in fact retarded as a rule. A wide variety of explanations have been put forward for this phenomenon. For example, Hilliard and Cahn [41] attribute the decrease of the rate of diffusion at high pressure merely to a decrease of the equilibrium concentrations of vacancies and not a decrease in their mobility. (So far there are no data about diffusion along grain boundaries.) In the same publication the authors write that at high pressures the rate of transformations should decrease mainly due to the decrease of atomic mobility. On the other hand, Pozin et al. [42] believe that the rate of "true" solid-phase reactions should increase on raising the pressure due to the increase of contact between the grains. Then, of course, it may again fall due to the decrease of the diffusion coefficient.

The ultrahigh rates of processes in shock waves have been attracting the attention of an increasing number of scientists, although ten years ago it was generally believed that during shock-wave compression of heterogeneous polycrystalline mixtures "such a wide variety of complex phenomena may be encountered that there are no means for a complete explanation" [43].

Attempts are now being made to investigate non-diffusional processes. Thus, after a long discussion, Anders and Lipschutz [44,45] concluded that diamonds in meteorites are formed by a direct solid-phase transformation under the action of the shock wave produced on impact of the meteorite against the earth. They believe that the usual mechanisms governing the appearance of a new phase (generation and growth of nuclei) cannot operate in shock waves because the process is extremely short-lived. Wentorf and Bovenkerk [46] share this view and note that the growth of nuclei from the melt also cannot play a significant role because the time is too short and the probability of any appreciable extent of diffusional processes during this period is low. Libby [47] likewise supports this view and suggests that polymorphic transformations in a shock wave take place directly over the entire bulk of the substance without the usual requirement of the growth of a new phase from the previously formed crystallisation centre. Another aspect of Libby's views is that the formation of new phases in a shock wave consists of two stages: the formation of "an activated complex" (the substance compressed to the metallic state is usually understood as the activated complex§) and the conversion of this complex, on expansion, into a new phase, which is thermodynamically stable at the temperatures and pressures corresponding to the loss of stability by the activated complex (i.e. the metallic state of substance). It is believed that shock-wave compression of two different modifications of the substance (for example, graphite and diamond) leads to the formation of identical activated complexes.

In an examination of decomposition of synthetic processes in shock waves one must inevitably invoke one or other diffusion mechanism, whereby one can explain how metal and oxygen atoms, for example, which are adjacent in the crystal lattice of the initial oxide, are sorted out after shock-wave compression and separated in space.

At the same time it appears unlikely that the usual diffusion mechanism, involving the motion of individual atoms or ions (or whole groups of atoms) among the surrounding neighbouring species, which are strongly compressed at the high pressures existing behind the shock-wave front, can lead to the formation, in a period of the order of 10^{-5}–10^{-7} s, of the particles of a new phase, which in practice reach dimensions of 0.1 mm and more. This is contradicted by abundant experimental data showing a decrease of the rate of diffusion with increasing pressure (see, for example, Refs. 36–40).

Probably the key to the solution of the problem of the unusually high rates of reactions of the first class should be sought in experiments on the effect of ultrahigh static pressures in combination with shear of the compressed

‡ In the light of the above findings the view expressed by Dachille and Roy [35] sounds a little odd: ".....it is clear that, in experiments with shock-wave pressures which act upon the specimen during periods of the order of a microsecond, it is difficult to achieve considerable chemical or structural changes in the specimen". In contrast, one may note that Kormer et al. [8] showed by direct experiments that in the compression of potassium chloride and bromide by a powerful shock waves phase transitions (fusion) take place over a period of 10^{-11} s.

§ In agreement with theory, numerous experiments show that sufficiently high pressures convert all substances into a metallic state (see, for example, Refs. 48–51).

specimen. Here the idea of the possibility of such an analogy for polymorphic transformations was put forward by Douglas et al.[52]

4. ULTRAHIGH PRESSURES AND SHEAR DEFORMATION

Many investigators have shown that at usual pressures shear deformation can have a significant effect on the rates of chemical and phase transformations in solids (see, for example, Refs. 53 and 54). Similar phenomena might have been expected also at ultrahigh pressures. However, it was found that under these conditions shear deformation not only accelerates the processes but also leads to a radical change in their character. For example, Bridgman[55-58] established that bismuth oxide Bi_2O_3 subjected to the simultaneous action of a pressure of the order of 25 000–50 000 atm and shear deformation breaks down into metallic bismuth and free oxygen. Under these conditions tin dioxide lost part of its oxygen and was converted into the monoxide, and metallic copper and elemental sulphur interacted with formation of copper monosulphide.

Vereshchagin and coworkers devoted much attention to this technique[59-66]. They showed that pressure combined with shear accelerates certain polymorphic transformations, lowers the temperature of some phase transitions, sometimes gives rise to phase transitions which are not observed in the absence of shear (for example, in metallic lithium), leads to the decomposition of a number of compounds (copper sulphide, lead oxide, molybdenum trioxide, and others), and permits a number of syntheses from the elements (iron, nickel, and cobalt sulphides and magnesium and zinc phosphides).

A general feature of these processes is that high pressures make their occurrence thermodynamically possible but their rates are fairly slow due to diffusion-dependent limitations. On the other hand, when a shear stress is applied to the test specimen during the operation of these pressures¶, the rates become much higher and frequently the process goes to completion during the period of the shear stress. For example, in a study of the effect of high pressures on potassium hexacyanoferrate(III), Larsen and Drickamer[67] showed that shear stresses accelerate the decomposition of this compound into potassium hexacyanoferrate(II), cyanogen, and free iron by a factor of 10^{14}. Enikolopov et al.[68] observed that at static pressures of tens of thousands of atmospheres many monomers virtually do not polymerise without the artificial creation of polymerisation centres. On the other hand, at the same pressures combined with shear polymerisation takes place at high rates without the introduction of any additional active centres.

Teller[69] believes that shear phenomena at high pressures can play a decisive role in chemical processes, in particular in the conversion of an exothermic reaction into an explosive process. However, he reduces the entire role of shear deformation to the accumulation of energy in the substance, which in turn helps overcome the activation barrier between the initial and final states. Leiserowitz et al.[19] draw a complete analogy between experiments on shock-wave compression and experiments on the effect of pressure combined with shear without taking into account the specific features of the effect of the shock-wave front.

¶ It is useful to note here that the plasticity of most substances increases with pressure[53,54].

5. THE MECHANISM OF SHOCK-WAVE COMPRESSION

Let us consider the mechanism of the compression of a substance by a shock wave. When the substance does not undergo any transformations on shock-wave compression, the shock-wave compression curve does not show any unusual features. The width of the shock-wave front (the region between the initial and final states of the substance subjected to shock-wave compression) is then very small: of the order of the free path in gases[70] and probably of the order of the interatomic distances in solids. On the other hand, if the substance does undergo a transformation on shock-wave compression, experiments show that the shock compressibility curve shows a break in one or other direction depending on the nature of the transformation, when the intensity of the shock wave is just below the intensity corresponding to the transformation. As predicted by Zel'dovich[71] and subsequently frequently confirmed experimentally, the shock-wave front then becomes diffuse and broadens, since the transformation requires a finite time.

If the transformation under shock-wave conditions takes place with increase in volume, the shock compressibility curve becomes steeper. The pressure profile in the stationary shock-wave front in such a substance is of the form shown in Fig. 1*b*. In principle, waves with such a profile are capable of steady-state propagation without the supply of energy from outside. A convincing example of the existence of such waves is the detonation waves in explosives.

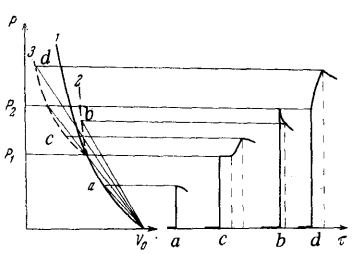

Figure 1. Hugoniot curves for various substances and the corresponding shock-wave profiles:
1) without transformations; *2*) transformation with increase in volume; *3*) transformation with decrease in volume;
a) pressure profile in the shock wave in the absence of transformations; *b*) transformation with increase in volume; *c*) transformation with decrease in volume; *d*) transformation with decrease in volume at sufficiently high pressures.

A break in the direction of smaller volumes has been observed for the polymorphic transformations investigated hitherto. Then, as shown by experiment, the shock wave loses stability over certain range of pressures. Initially a shock wave with an amplitude corresponding to the pressure of the onset of the phase transformation is propagated through the substance and then a slower second wave, in which the transformation itself occurs. The width of the front of the second wave corresponds to the duration of the transformation (Fig. 1*c*). At a pressure higher than P_2 (Fig. 1*d*) a single shock wave with the pressure profile shown in Fig. 1 is propagated in the substance undergoing polymorphic transformation; the width of the shock-wave front corresponds to the duration of the transformation.

Thus the complex form of the shock compressibility curve and the increase in the width of the shock-wave front constitute a direct demonstration of the occurrence of the transformation in the wave front, i.e. during a period less than 10^{-6} s.

Probably the unusually high rates of transformations with which we deal in these cases are due to the specific features of the compression of the substance by the shock wave. Shock-wave compression is a non-isentropic process. On the other hand, the flow before and beyond the shock-wave front in the rarefaction wave (in the system of coordinates associated with the front) is an isentropic process. Consequently the increase of entropy occurs in the front itself over a region corresponding to its actual width[70]. Physically the growth of entropy implies a transition from ordered translational motion of atoms or molecules of the substance in front of the wave into random motion in the front itself. This takes place in consequence of the non-head-on collisions between the moving atoms and the atoms already present in the front (in the system of coordinates associated with the shock-wave front). Thus in the shock-wave front there is always a sharp deviation from translational motion, i.e. components of atomic motion along the wave front appear.

From the macroscopic point of view, the shock wave effects monoaxial compression of the substance. When solids are compressed by shock waves with amplitudes less than the dynamic yield point, transverse displacements due to non-head-on collisions of atoms should also arise in the wave front. However, the energy of such displacements is less than the bonding energy in the crystal lattice. Therefore ultimately the atom remains at its original site but in an excited state. In this case compression leads to a change only in the interatomic distances along the wave, but the distances along the wave front remain the same. Such deformation of the crystal lattice is thermodynamically unfavourable, since a potential energy of displacement appears in addition to the potential energy of compression, so that the total potential energy is not a minimum[71].

Minimum potential energy is attained on compression from all sides when the crystal lattice undergoes a symmetrical deformation. Symmetrical compression of the crystal lattice by the shock wave occurs at compression pressures in excess of the dynamic yield point. Then tangential stresses in the solid exceed the critical value and the material begins to flow. In an examination of the process at an atomic level this implies that in a non-head-on collision the displacement of atoms along the shock-wave front becomes so great that the atoms acquire a certain freedom and no longer return to the previous site but remain in the coordination environment corresponding to the thermodynamic conditions (P, T) created on compression. If according to the phase diagram the substance should not undergo polymorphic transformations on shock-wave compression above the dynamic yield point, the state of the substance behind the shock-wave front corresponds to the initial crystal lattice but with lower parameters due to compression from all sides. On the other hand, if a new lattice is thermodynamically more favourable under the given conditions, a polymorphic transformation takes place.

Since a displacement of atoms from the equilibrium position, due to the passage of the shock wave, takes place in the matrix of the initial crystal lattice, it is possible that Libby's hypothesis[47], that the state of a substance subjected to shock-wave compression does not depend on the choice of the initial modification, is not always valid. This can be demonstrated by the fact that the Hugoniot curves for pyrolytic graphite and graphite containing domains of a rhombohedral structure are different. In the first case a transition to the diamond structure is not observed[72].

Two conclusions follow from the above discussion. Firstly the transition from elastic monoaxial compression to bulk-phase plastic compression is equivalent, as regards thermodynamics and gas dynamics, to a polymorphic transformation. Secondly the phenomenon of polymorphism under the action of a shock wave cannot occur at pressures below the dynamic yield point of the initial substance.

A change in volume along the shock compressibility curve during a polymorphic transformation is evidence that the transformation takes place to a very marked extent. In principle, one cannot exclude in this case the possibility that the rearrangement of the initial crystal lattice directly in the shock-wave front leads to the formation of large single crystals of a new phase, which then break down in the expansion wave after the removal of the pressure. However, it is probably more likely, and this follows from the considerations adduced above, that a large number of very small nuclei of a new phase, randomly distributed in relation to one another, are formed in the shock-wave front. Indeed it is difficult to suppose that the chaotic conditions arising in the shock-wave front simultaneously over the entire surface of the latter lead to a rigorously ordered arrangement of atoms corresponding to the crystal lattice of the new phase, i.e. it is essentially difficult to postulate an epitaxial growth of the crystals of the new phase in the shock-wave front. However, it is then necessary to explain how the substance consisting throughout of nuclei is converted into relatively large crystalline formations observed in the recovery tubes. Certain considerations concerning this problem will be put forward below in an examination of the possible mechanism of chemical reactions in a shock wave.

6. INCREASE IN THE PARTICLE SIZE OF NEW PHASES IN SHOCK WAVES

In crystalline lattices the position of atoms and the interatomic distances are determined by the equilibrium between forces of attraction and repulsion. The depth of the potential well in which each atom is located characterises the strength of the chemical bond. With increase of pressure, the atoms of the crystal lattice approach one another, the role of repulsion forces becomes more important, and the strength of chemical bonds falls. According to Kapustinskii[48], "the universal metallic state of matter", characterised by a complete disappearance of chemical differences between atoms and hence by the disappearance of all chemical bonds, arises when a substance is subjected to a sufficiently high pressure (about 10^8 atm).

In shock-wave compression we usually deal with much lower pressures (10^5–10^6 atm) and therefore there can be only a weakening of chemical bonds. The situation is of course complicated by the fact that the temperature of certain substances subjected to shock-wave compression can reach tens of thousands of degrees when the intensity of shock waves is high. It is reasonable to suppose that the weakening of the strength of chemical bonds will be different in different cases. Let us consider a compound AB which decomposes on increase of pressure. One can imagine a case such that, under normal conditions (P_0, T_0), A–B bonds are energetically more favourable ($2E_{A-B}$ is greater than $E_{A-A} + E_{B-B}$), while at sufficiently high P and T the bonds A–A and B–B become energetically more favourable, i.e. at P_0 and T_0 the phase AB is stable, while

at P and T the stable phases are A and B. In this case, after attainment of the pressure P and the temperature T, the thermodynamic conditions for the stability of the AB phase break down and decomposition of the compound becomes possible.

Examples of such reactions, found in the study of the effects of high static pressures on various substances, have been described in the literature. For example, according to Popova et al.[73], cuprous oxide disproportionates into metallic copper and cupric oxide at a pressure of 180 000 atm and 2000°C. According to Hoffman[74], Pb_2O decomposes at 2000 atm with liberation of metallic lead, while PbO_2 decomposes at 12 000 atm into lead oxide (PbO) and oxygen. Arkharov and Bulychev[75] have stated that an increase of pressure favours the decomposition of the $Fe_{1-x}O$ phase into iron and Fe_3O_4 with a simultaneous decrease of the number of defects in the initial phase. DeVries[76] showed that at 25 000 atm and 1500°C Al_2SiO_5 decomposes into corundum and a silicate melt. On the other hand, it has been stated[35] that Coesu succeeded in obtaining at a pressure of 40 000 atm a substance with the composition $Al_2O_3 \cdot 3SiO_2$, which cannot be synthesised at the normal pressure. All these processes take place relatively slowly. Thus high pressures and temperatures in the shock wave create a thermodynamic background which determines the *possibility* or *impossibility* of the occurrence of both polymorphic transformations and chemical reactions.

The momentum imparted to atoms by the shock wave is insufficient for virtually instantaneous interpenetration of the reacting species of the initial reaction mixture. It is sufficient to recall that α-particles moving at velocities higher by 3–4 powers of 10 than the velocity of matter in shock waves are stopped by layers a few tens of atoms thick. It would appear that even less comprehensible is the occurrence of decomposition processes in which separation of different types of atom from one another and not mixing at a molecular level is required, or the occurrence of synthetic processes where both requirements must be met. However, we believe that the occurrence of plastic flow makes it possible to overcome this difficulty. Here we have in mind the occurrence of extensive plastic flow of the substance in the recovery tubes. This is indicated by the significant residual deformation of the tubes themselves.

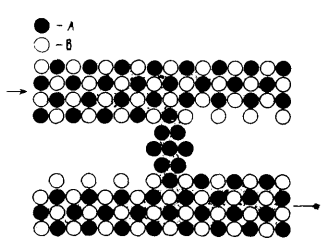

Figure 2. Scheme describing the decomposition of a compound AB during plastic flow in the rarefaction wave.

Fig. 2 presents a highly qualitative scheme representing chemical processes in the presence of plastic flow. When two layers of the substance are displaced relative to one another, the nuclei of phase A, located between them, can be regarded as a kind of roller about which oscillations are executed. With some approximation, phase A under these conditions can be regarded as a solid and phase AB as a liquid, since the strength of A–A bonds under these conditions is greater than that of A–B bonds. When the two layers of phase AB are displaced relative to one another, they transport past the nucleus, in its immediate vicinity, a multiplicity of atoms of both kinds. Since the time required for the rearrangement of electron shells (10^{-13}–10^{-14} s) is much shorter than the time required for contact between atoms (it is easy to calculate that for a plastic displacement over a distance of the order of 1 mm†, dimensions of a single atom of 2 Å, and duration if shock-wave compression of 10^{-5} s, the time required for contact between two atoms is 2×10^{-12} s) it follows that all the atoms A passing in the immediate vicinity of the nucleus have sufficient time to combine with the latter and this in fact may be the mechanism of the growth of the nuclei of the new phase. Of course, the same mechanism can operate also in the growth of phase B.

Thus, in contrast to the usual diffusional growth of crystallisation centres, in which each atom must find its way to the new phase, pushing apart its neighbours by virtue of the energy of thermal motion, in the growth of new-phase nuclei behind the shock-wave front the entire mass of the initial phase is transported by the plastic flow in the vicinity of the crystallisation centres and the required atoms combine selectively with the particles of the new phase undergoing continuous growth during this process.

An attempt may be made to estimate the dimensions of the new-phase particles, which can form by the mechanism proposed. For simplicity, it will be assumed that (a) the new phase forms in the plastic flow of an ideal crystal lattice of the initial phase, (b) the initial "nucleus" is a single atom X, (c) only atoms from a monatomic layer of the initial phase passing during the plastic flow above (below) the crystallisation centre can add to the latter, and (d) different crystallisation centres do not stick together.

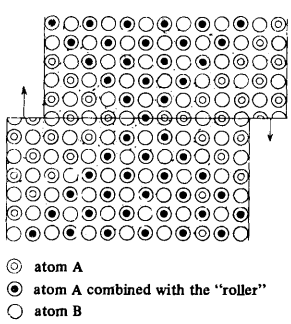

Figure 3. Representation of the phase AB in plan form along the slip plane during plastic flow; the atoms A which add to the initial atomic nucleus during plastic flow in the shock wave are indicated.

Fig. 3 shows in plan form the phase AB along the slip plane in plastic flow. The A atoms indicated add to the initial atomic nucleus when the AB phase moves in the vicinity of the roller being produced. The calculation of the number of atoms which can be combined into a new phase is simple. When two layers are displaced relative to one another over a distance H, the structure of each

† In practice up to 3–5 cm.[16]

layer is as shown in Fig. 3, and the distance A–B is L, then N, the number of atoms captured by the roller during the displacement of the layers, is defined by the expression,

$$N = 1 + 2\left[2 + 3 + \ldots + \left(\frac{H}{2L} - 1\right) + \frac{H}{2L}\right] = 1 + \frac{H}{2L}\left(\frac{H}{2L} + 1\right) \simeq \frac{H^2}{4L^2}.$$

For example, for $H = 1$ mm and $L = 1$ Å, we have

$$N = \frac{1}{(2 \times 10^{-7})^2} = 2.5 \times 10^{13} \text{ atoms.}$$

When the particles of the new phase are assumed to be cubic, their dimensions are $\sqrt[3]{2.5 \times 10^{13}} = 2.92 \times 10^4$ atoms $\simeq$ $2.92 \times 10^4 \times 1 \times 10^{-7} \simeq 0.003$ mm.

The same mechanism of the growth of new-phase particles can also operate in polymorphic transformations in the shock wave. In this case the relative motion and rotation of the nuclei insures their adhesion in a definite regular crystallographic arrangement. The return to the initial state on removal of pressure in those cases where polymorphism does not obtain is ensured by the usual processes, which also occur on removal of pressure in static experiments.

It is readily seen that in shock-wave compression of finely crystalline substances the random states of the single-phase particles in contact are identical and the particles are combined into a single mass during the plastic flow of which there is a possibility of the growth of larger particles. This can account for the increase in size and the improvement of the structure of a number of substances after shock-wave compression. Probably the maximum size of crystalline particles in the recovered specimen is restricted by the dynamic strength of the substance and the pressure gradient in the rarefaction wave. An approximate estimate of this size for real dimensions of explosive charges shows that it can reach several millimeters. However, it should be noted that plastic flow which, on the one hand, favours the growth of very small crystalline phase nuclei, can, on the other hand, break down fairly large particles.

The following considerations can be put forward concerning the polymerisation phenomenon in shock waves. Calculation of the temperature of acrylamide immediately behind the shock-wave front shows that, over the entire pressure range, between 20 000 and 80 000 atm, it is less than the melting point of the compound. This means that the polymerisation takes place in the solid phase. It may be suggested that the rearrangement of the crystal lattice, which leads to a decrease of the number of defects, plays an important role also in polymerisation process. At the very beginning of the crystal lattice rearrangement zone, active centres initiating polymerisation may arise. The polymerisation itself probably takes place during the formation of the new crystal lattice. The unusually high, explosive rates of polymerisation are probably due to the favourable relative orientation of the molecules in the monomer crystal[77], particularly when it is remembered that the monomer is compressed to the density of the polymer. The "roller" mechanism of the growth of polymer chains is of course also possible.

7. COMPARISON OF DYNAMIC AND STATIC STUDIES

The most interesting aspect of the investigation of the action of shock waves on matter is comparison of static and dynamic studies. However, methodologically it is a fairly difficult task. The point is that in static studies the aim is as a rule to investigate the P–T diagrams, while in dynamic studies data on P–V diagrams are most readily obtained. Experimental determination of temperatures in shock waves has been achieved for an extremely limited range of compounds[6]. In other cases one is restricted to calculated data and furthermore only the Hugoniot curves without breaks or, more precisely, only those sections of Hugoniot curves which correspond to pressures below the first break, are susceptible to exact calculations. At the present time such calculations have been made mainly for metals[3].

Another methodological difficulty encountered in the comparison of static and dynamic data consists in the fact that in most cases static experiments are performed at pressures up to 100 000 atm, while published dynamic data usually refer to pressures starting with 50–100 000 atm. A decrease of the initial density (increase of porosity) of the test specimen increases the temperature in the shock wave, which permits the use of dynamic methods in the region of the P–T diagram above the Hugoniot curve. The same result can be obtained when preheated monolithic specimens are investigated. The region of the P–T diagram below the Hugoniot curve of the monolithic specimen can be penetrated to some extent by carrying out preliminary cooling of the specimen or be applying special methods of shock-wave compression in which the final pressure in the specimen is attained in stages. This lowers the temperature developed in the specimen at the same final pressure. However, the region of the P–T diagram immediately adjacent to the pressure coordinate is in principle inaccessible to dynamic investigations.

At the present time comparable experimental data derived from dynamic and static studies are available for only a small range of substances. These are mainly metals. For example, it is possible to compare the P–T diagrams for iron[78] with data obtained in dynamic studies[79,80].

McQueen and Marsh[79] present data for the Hugoniot curve of the iron calculated from the results of an investigation of the shock compressibility of iron. The point of intersection of the P–T Hugoniot curve with the curve for the α-Fe $\rightleftharpoons$ ϵ-Fe phase equilibrium agrees fairly well, as regards pressure, with the beginning of the break in the shock compressibility curve (131 000 atm). Jonson et al.[80] studied the temperature variation of the phase-transition pressure in iron by subjecting to the action of shock waves specimens which had been first heated or cooled. It was assumed that in the shock-wave compression the temperature virtually did not change and the transition pressure was estimated from the depth of the iron layer in which irreversible phase transitions were observed and from the rate of decay of the waves in iron, which the author determined. Despite these assumptions and other simplifications made in the interpretation of the results, the data obtained agree entirely with the phase diagram for iron. It is surprising that, at the time of the publication of their paper, Jonson et al. were apparently unaware of the existence of the ϵ-modification of iron. The existence of this modification, which is stable at high pressures, was confirmed by Jamieson and Lowson[81] one month later in static experiments, but this result might have been suggested also by the work of Balchan and Drickamer[82].

It is also interesting to compare the data from static and dynamic studies on germanium. Two breaks were found in the Hugoniot curve for this element[83], corresponding to the onset of plastic flow (44 000 ± 4000 atm) and the phase transformation (114 000–122 000 atm at 160°C). The values obtained for the phase transition in germanium by the dynamic method differ to a smaller extent from the results

of static studies carried out by various investigators than they differ from one another [78,84].

Static [78,85] and dynamic [12] data for silicon are similar to those for germanium. The Hugoniot curve for this element also shows two breaks, the first corresponding, as in germanium, to the onset of plastic flow and the second to a polymorphic transformation.

Fig. 4 presents the phase diagram for metallic bismuth [86,87], the points corresponding to the breaks in the Hugoniot curve for bismuth specimens subjected to preliminary heating or cooling being indicated [88]. The breaks in the Hugoniot curve for bismuth evidently correspond to the bismuth I–bismuth III transition. The region of stability of the bismuth II phase, located between them, is so narrow that it is not reflected in the dynamic curve. The fact that the point x is in the region of stability of the liquid phase appears so far incomprehensible. On the whole, the agreement between dynamic and static experiments on bismuth may be regarded as satisfactory.

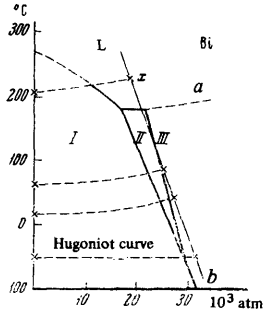

Figure 4. Phase diagram for metallic bismuth and data obtained in dynamic experiments; *a*) Refs.86 and 87; *b*) Ref.88.

However, the agreement between static and dynamic studies is not always as good as this. For example the Hugoniot curve for graphite, treated, following Alder and Christian [2], as corresponding to the transformation of graphite into diamond, occurs at a pressure of the order of 200 000 atm and a temperature of about 300°C, while the P–T diagram for carbon [78] (Fig. 5) does not show any phase equilibrium lines in this region. If it is assumed that the agreement between static and dynamic studies must be always satisfactory, then the transition may be attributed only to metastable fusion of graphite. However, so far there are no data confirming such a view.

A similar situation is observed also in the analogue of crystalline carbon–boron nitride. According to Bundy [89], the dense modifications of boron nitride (borazon) become stable at comparatively low pressures (not greater than 40 000 atm). However, our data on the shock compressibility of the graphite-like boron nitride [21] show that under dynamic conditions the phase transition begins at only about 130 000 atm, although the temperature does not then exceed 200–300°C. On the other hand, according to the indirect data obtained by Bundy [89], unstable fusion occurs at very much higher pressures. However, it should be noted that, when boron nitride specimens subjected to shock-wave compression are preserved, the formation of the hexagonal wurtzite-like variety of borazon is observed and not the cubic sphalerite-like modification. The region of stability of the former modification in the phase diagram for boron nitride and the corresponding phase-equilibrium lines have not been elucidated hitherto. One cannot exclude the possibility that the break in the Hugoniot curve is associated with the phase-equilibrium line of precisely this modification.

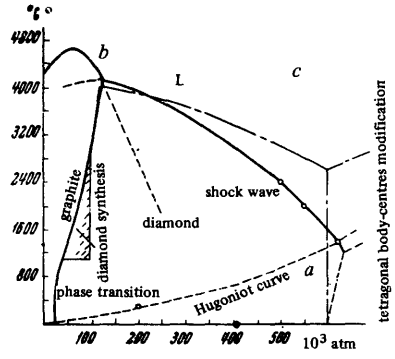

Figure 5. Phase diagram for carbon and data obtained in dynamic experiments: *a*) Ref.2; *b*) Ref.78.
* Tentative interpretation (Ed. of Translation).

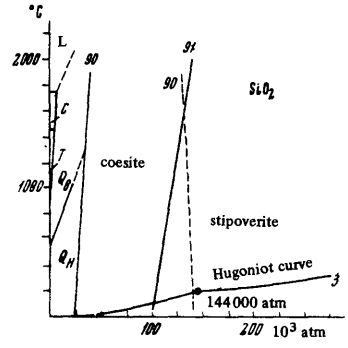

Figure 6. Phase diagram for silica and data obtained in dynamic experiments [3,90,91] (the numerals against the curves denote literature references).

The question of whether or not dynamic and static studies on crystalline quartz are comparable has not been inadequately elucidated. On the one hand, it follows from the work of Wackerle [3] that the latter observed a phase transition at 144 000 atm under dynamic conditions. The temperature (about 200°C) and pressure of this transition lie satisfactorily on the coesite–stishovite phase-equilibrium curve determined in Boyd's experiments [90], but differ markedly from the static experiment of Stishov [91] (Fig. 6). At the same time the point of intersection of Wackerle's Hugoniot curve [3] with the coesite–stishovite phase-equilibrium line obtained by Stishov [91] corresponds satisfactorily to the first break in the compressibility curve for vitreous silica obtained in Wackerle's dynamic experiments. On the other hand, Adadurov et al. [4], who used the method of dynamic volume compression ("method of mixtures") [92], showed that the phase transformation under these experimental conditions begins only at 200 000 atm,

but no phase-equilibrium lines are found in this region of the phase diagram for silica.

Although the possibility of achieving both chemical and phase transformations is determined by the thermodynamic background, it is probable that significant deviations from results expected on thermodynamic grounds may also occur due to the peculiarities of shock-wave compression. Here we have in view both the enormous rates of application of the load (small width of the shock-wave front) and the high rates of removal of the load (the duration of application of high pressures to the substance).

As already stated, plastic flow in shock-waves accelerates various transformations but does not make them infinitely fast. Under favourable conditions the transformation can occur immediately beyond the intersection of the Hugoniot curve and the corresponding phase-equilibrium line on the P–T diagram. However, it should be noted that the transformation induced by the shock wave can begin also at much higher pressures than the pressure corresponding to the above point of intersection. This can be due to at least two factors. On the one hand, the dynamic yield point can exceed the pressure indicated by the phase diagram, and, until this yield point is passed, the compression remains monoaxial and the mobility of atoms is insufficient for a change in their coordination environment during short periods. Possibly the characteristic features of the shock-wave compression of crystalline quartz and the absence of breaks in the compressibility curves in the region of the quartz–coesite equilibrium are due precisely to the exceptionally high yield point of both crystalline and vitreous quartz (the dynamic yield point of crystalline quartz is 35 000–60 000 atm along the x axis, 65 000–80 000 atm along the z axis, and 98 000 atm for fused quartz [3]). On the other hand, one cannot exclude cases where, despite a vigorous plastic flow, the duration of the transformation is nevertheless fairly high and there is not sufficient time for the process to occur in the shock wave. Here there may be two cases. If the relaxation time falls with increasing pressure, then at a sufficiently high shock pressure there may come a moment when there is sufficient time for the transformation to occur in the shock wave and we obtain results differing significantly from static experiments, i.e. higher pressures. The characteristic features of the shock-wave compression of graphite and boron nitride can be fully accounted for by the effect of this factor. On the other hand if the relaxation time increases with impact pressure, then the transformation cannot be achieved at all.

Polycrystalline or powdered materials rather than single crystals are most frequently investigated by dynamic methods, particularly in experiments with recovery of the specimen. In such cases it should be borne in mind that pressures significantly exceeding the average pressure which obtains in the specimen after all the pores have been closed up inevitably arise in microregions. This local excess pressure may give rise to local thermodynamic conditions suitable for the transformations, although the average pressure in the specimen is still much lower than would be required in accordance with the phase diagram.

The irreversibility of the processes occurring in the shock wave is determined not only by the phase diagram but also by kinetic factors, in the first place the characteristic features of the removal of shock-wave load. The removal of load during the passage of the rarefaction wave occurs much more slowly than the generation of high pressures and temperatures in the application of the shock-wave load to the substance and there is then no random mobility of the atoms. However, the time of removal of pressure is still smaller by a factor of many powers of ten than can be achieved in static experiments. Since the removal of load is adiabatic, just as rapid a fall of temperature is observed simultaneously. As a result, it is possible to quench the high-pressure phases, provided of course that they are capable of metastable existence at the residual temperatures which obtain after the passage of the shock wave. If the residual temperatures are fairly high, the phases formed at high pressures (metastable under normal conditions) may be annealed. Thus, despite the fact that Hugoniot curves indicate virtually complete conversion of graphite into diamond on shock-wave compression, the temperatures in the recovered specimens are so high that the diamond formed is almost completely reconverted into graphite. On the other hand, we have already mentioned that in many cases there is so far no direct evidence of the occurrence of processes in the shock wave itself during the application of high pressures. One cannot exclude the possibility that many processes occur exclusively due to the residual temperatures. A good example of this may be the present authors' investigation of the behaviour of antimony oxides, which decompose until the liberation of metallic antimony when the specimens are kept in iron tubes but remain virtually unchanged when copper tubes are used. In the first case the appearance of metallic antimony is entirely due to the interaction of the oxides with the material of the tube walls.

---o0o---

Shock-wave compression of condensed systems makes it possible to achieve a number of chemical and phase transformations in unusually short times. The pressures set up by shock waves are at present unattainable in static apparatus. Furthermore, shock waves can also affect the substances to which they are applied as a result of very high temperatures (up to tens of thousands of degrees in the shock wave and up to several thousand degrees after the passage of the expansion waves).

The possibility of applying such high pressures and temperatures to matter arose in chemical investigations only in recent years. As in any new field of study, so far the number of problems and puzzling phenomena is much greater than the available answers. Only the first steps have been taken to bring into closer correspondence and make more consistent the dynamic and static experiments and to elucidate the mechanism of the processes occurring in the shock wave.

However, it is quite clear that the elucidation of the laws governing the reactions in shock waves would not only provide experimenters with the means of obtaining thermodynamic parameters in those regions of temperature and pressure which will remain unattainable by other methods in the forseeable future, or a method whereby it will be possible to influence radically the kinetics of many processes, but also it will provide the means for a significant modification of the properties of many substances and their preparation in new, previously unknown forms. Further development of experimental methods for the recovery of substances on removal of the high pressures associated with shock-wave compression and the theoretical study of this aspect of the problem will play a special role in this.

Until recently the sole aim of deformation was destruction. The development of studies on the effect of shock waves on matter will make it possible to consider the application in synthetic chemistry of the energy of powerful explosions, including nuclear explosions.

Application of Electrical Spin Resonance in Chemical Kinetics

Ya.S.Lebedev

The application of electron spin resonance (ESR) in the study of the kinetics of chemical reactions involving free radicals and paramagnetic ions is a very promising and rapidly developing field of study. In the first part of the review certain theoretical aspects and latest advances in studies on the kinetics of chemical reactions by the ESR method are discussed. Particular attention has been given to methods of analysis of the ESR spectra of free radicals, to methods for the calculation of concentrations, and also to a new method for the determination of local concentrations of paramagnetic centres from the dipole-dipole contribution to ESR line width.
In the second part of the review examples of the application of electron spin resonance in chemical kinetics are examined, and studies on radical reactions and the cage effect in solid matrices, and also measurements of steady-state concentrations of active radicals directly in the course of chemical reactions are discussed in detail.

I. INTRODUCTION

This review was written on the suggestion of the late V. V. Voevodskii, one of the first scientists to understand the exceptionally great promise of the application of electron spin resonance in chemical studies. Thanks to him, Soviet science now occupies a leading place in the field of chemical ESR spectroscopy.

The application of radiospectroscopic methods, nuclear magnetic resonance (NMR), and electron spin resonance (ESR) led to significant advances in studies on the fundamental problems of theoretical and applied chemistry. Radiofrequency techniques enable often hitherto unobtainable information about the structure of matter and the dynamics of the processes occurring in it to be obtained. In particular, electron spin resonance

permits the observation of signals (arising as a result of the absorption of energy on transitions between Zeeman sublevels) from unpaired electrons; the actual carriers of such electrons may be a wide variety of paramagnetic centres (PC)—atoms, molecular fragments (free radicals), molecular ions, individual paramagnetic ions, solid-state defects, molecules in the triplet state, etc. On the other hand, real chemical processes usually take place via a series of fundamental intermediate stages, with participation of chemically active valence-unsaturated species—radicals, ions, etc. Thus the ESR method is, as it were, specially suitable for the study of the mechanism of chemical reactions, because such study in fact consists in the identification and quantitative investigation of the sum total of intermediate processes.

One of the valuable features of the ESR method is the fundamental ease of the quantitative measurement of the effect: in the absence of saturation, the total intensity of the absorption lines is proportional to the number of absorbing species, the spectroscopic absorption coefficients being the same for the majority of paramagnetic centres. Furthermore, the ESR method is sensitive only to paramagnetic centres, regardless of the remaining species in the system, which leads to high sensitivity of the method, permitting the detection of paramagnetic centres at concentrations of 10^{-10}–10^{-11} M. However, the value of the ESR method does not lie solely in the quantitative detection of signals from paramagnetic centres. The interaction of an unpaired electron with paramagnetic nuclei and neighbouring electrons and the dependence of these interactions on the geometry of the species and internal motions are all reflected in the ESR spectrum in the form of a hyperfine structure (HFS), fine structure, line broadening due to relaxation, displacement of the positions of the lines, etc. The physical principles of electron spin resonance and nuclear magnetic resonance are now widely known and it is therefore unnecessary to dwell on these problems. The above features of the ESR spectrum permit an approach to the determination of the true structures of complex paramagnetic centres, the details of their geometry, the distribution of unpaired electron density among various functional groups, and can even provide information about the interaction of the paramagnetic centres with the surrounding medium and the internal motions in the medium.

Nowadays several dozen papers on the study of chemical problems by the ESR method are published every month. The ESR method is used in a wide variety of chemical fields—organic chemistry, electrochemistry, radiation chemistry, polymer chemistry, quantum chemistry, chemical kinetics, and catalysis. It would clearly be unreasonable to attempt to describe all the aspects of the chemical applications of electron spin resonance. However there is one problem which combines all the studies in this field—the problem of the extraction of "chemical" information from ESR spectra. With the existing experimental techniques, it is relatively easy to detect the ESR spectra of a wide variety of chemical systems, but it is much more difficult to interpret correctly these spectra and to obtain from them the chemical information concealed in the various features of the hyperfine structure and the line form of the signal. Certain fundamental problems of the analysis of ESR spectra from the standpoint of obtaining "chemical" information will therefore be discussed in the first part of the review.

In the second part the use of electron spin resonance to study the kinetics and mechanism of chemical reactions will be mainly examined. The use of electron spin resonance in the investigation of the kinetics and mechanism of reactions is one of the most important and most interesting aspects of the application of this method.

Chemical applications of electron spin resonance outside the scope of this theme can be roughly characterised as structural–chemical studies. A much larger number of reviews and monographs have been devoted in recent years to these investigations than to studies on the kinetics and mechanism of reactions.

II. ANALYSIS OF ESR SPECTRA

In chemistry, the analysis of ESR spectra should usually provide an answer to the following questions[1]: (1) what paramagnetic centres are formed under particular conditions; (2) what is the concentration of these centres and how does it vary under different conditions; (3) what is the distribution of spin density of the unpaired electron in the active centre; (4) in what way does the unpaired electron interact with the surrounding medium, etc.

In order to calculate the concentration of paramagnetic centres, it is necessary to calculate the area under the absorption curve and to compare it with the area under the signal from a standard (with a known number of paramagnetic centres). Such standard signals may be provided by stable radicals (diphenylpicrylhydrazyl, diphenylnitric oxide, etc.) and ions [manganese(II) compounds, $CuCl_2.2H_2O$ crystals, etc.] Here the most difficult problem is the calculation of the area and, in some cases, the evaluation of the absorption coefficient.

To obtain an answer to the remaining questions, it is in general necessary to perform an analysis in two consecutive stages—formal mathematical and then quantum-chemical analysis of the spectrum. In the first stage one must establish from the experimental spectrum, which may consist of a large number of weakly resolved lines, which interaction determines the formal spectrum, i.e. one must usually establish with which nuclei the unpaired electron reacts, what are the interaction constants, line widths, etc.

In the second stage, using quantum-chemical relations, it is possible to establish the structure of the radical, the distribution of spin density, and the nature of the motion of certain functional groups. There is an extensive literature on this question, including reviews and textbooks, and therefore it will be considered only briefly. The problems of the formal mathematical analysis of the spectra will be discussed in greater detail. Although the creation of effective methods for the mathematical analysis of complex ESR spectra is absolutely essential for the successful application of this method, detailed studies of the problems of formal mathematical analysis developed only very recently.

1. Determination of Average Absolute Concentrations

In principle this is a simple problem. The integral intensity of the ESR signal is proportional to the number of paramagnetic centres, consequently in the simplest case, when there is a standard with a known number of unpaired electrons N_{st}, we have

$$N_{sp} = N_{st}\frac{S_{sp}}{S_{st}},$$

where S_{sp} and S_{st} are the areas under the ESR absorption curves for the specimen and the standard respectively. Since the signal is usually recorded in a differential form,

the calculation requires graphical integration. One can use the relation

$$S = \int_{-\infty}^{\infty} I(x)\,dx = \Big|_{-\infty}^{\infty} xI(x) - \int_{-\infty}^{\infty} xI'(x)\,dx\,. \qquad (1)$$

Since the first term on the right-hand side of Eqn. (1) is zero both for the Lorentzian and Gaussian line forms, Eqn. (1) permits the replacement of double integration by a single determination of the first moment of the spectral line.

The last operation was further facilitated[2] by the introduction of nomograms consisting of a family of hyperbolae $xI' = C_i$. After the superposition of the nomograms on the spectrum, the integration reduces to adding together the values of C_i corresponding to the experimental curve (see Fig. 1). The accuracy of such treatment is 20–30%,

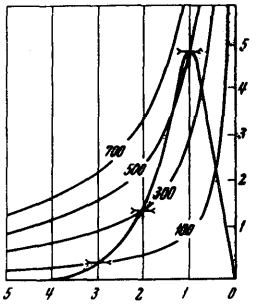

Figure 1. Diagram illustrating the use of a nomogram for the calculation of the first moment of the ESR line[2]; $S = 2(100 + 300 + 500) = 1800$ arbitrary units.

as in graphical integration. It is then found[3] that the integration step Δx should not be made too small, a sufficient condition is $\Delta x < \frac{1}{2}\Delta H_u$. The blurring of the hyperfine structure due to modulation is not reflected in the value of S. Furthermore, S does not depend in principle on the starting point of the calculation (but the accuracy is greater if the starting point of the calculation coincides with the true centre of the spectrum). However, the greatest error can be introduced by the superposition of a "parasitic" line due to the drift of the zero or due to the presence of a paramagnetic background. To take this superposition into account it is necessary to recover the background line, to determine the first moment for the latter, and to subtract the result from $M_{1\,\mathrm{exp}}$. If it is assumed that the zero shift is linear, then it is easy to show that

$$M_{1\,\mathrm{drift}} = 2\int_0^{\infty} \frac{\Delta I_0'}{2\Delta H_0}\,HdH = \frac{1}{3}\Delta I_0'(\Delta H_0)^2$$

and

$$S = M_{1\,\mathrm{exp}} - \frac{1}{3}(\Delta H_0)^2\,\Delta I_0'\,,$$

where ΔH_0 is the distance from the zero line to the last point of the integration and $\Delta I_0'$ is the total zero shift (see Fig. 2). In some cases one can determine the area more simply from the formula

$$S = \alpha\varkappa\Delta H_{\frac{1}{2}}^2 I_m'$$

where $\alpha = \Sigma A_i/A_m$ (A_i are the intensities of the hyperfine structure components) and the line form coefficient is

$$\varkappa = \begin{cases} \pi/\sqrt{3} & \text{for Lorentz line form} \\ \frac{1}{4}\sqrt{\frac{\pi e}{2}} & \text{for the Gaussian line form.} \end{cases}$$

Since the form and width of an individual line are not usually evident, the empirical coefficient is preferred:

$$\varkappa_{\mathrm{eff}} = S/I_m'\,. \qquad (2)$$

When a large series of measurements is made, one can determine κ_{eff} at only a few reference points and at the remaining points the area S can be measured on the basis of I_m' and the value of κ_{eff} interpolated for the given point (see Fig. 3).

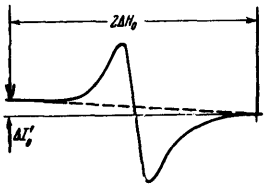

Figure 2. Diagram illustrating how the shift of the zero line is taken into account in the calculation of the first moment.

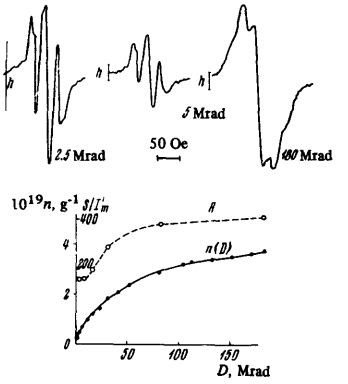

Figure 3. An example of the construction of the kinetic curve on the basis of ESR data (kinetics of the accumulation of free radicals in the low-temperature β-radiolysis of glycine); A—calibration curve for the determination of the ESR line form coefficient.

Additional difficulties arise when the standard and the specimen differ in the effective spin S, temperature, g-factor, etc. The spin and temperature can be easily taken into account, since

$$S \sim N\,\frac{S(S+1)}{T}\,.$$

When there is a considerable difference between the g-factors, it is necessary to take into account the difference between the probabilities of the transition.

We shall now discuss two examples, which are important in practice, of the calculation of the absolute concentrations of paramagnetic centres for which the absorption

coefficients differ significantly from the coefficients for the free spins. The existing theoretical formulae for signals from triplet molecules with $g = 4(\Delta M_S = 2)$ are complex and inaccurate. Alfimov et al.[4] proposed a novel method for the determination of the number of triplet centres based on recording by the ESR method the time of the increase and fall of the intensity of the signals from the triplets. On the basis of the simplest kinetic mechanism,

$$M_0 \xrightarrow{\beta j} M_\tau ,$$
$$M_\tau \xrightarrow{1/\tau} M_0 ,$$

the curve for the accumulation of triplets under the action of a beam of electrons with an intensity j is given by

$$N_\tau = N_0 \frac{\beta j}{\beta j + 1/\tau} \{1 - \exp[-(\beta j + 1/\tau) t]\} \qquad (3)$$

and, after the beam is switched off, the steady-state concentration becomes

$$(N_\tau)_{cr} = \frac{\beta j N_0}{\beta j + 1/\tau} .$$

From Eqn. (3), the time constant for the accumulation of triplets is

$$\tau_a = \frac{1}{\beta j + 1/\tau} .$$

On eliminating βj from the last two equations, we obtain

$$(N_\tau)_{st} = N_0 \left(1 - \frac{\tau_a}{\tau}\right) .$$

Finally specific difficulties arise in the identification and determination of the concentrations of free atoms (except H atoms) and radicals in the gas phase. Here, in contrast to a condensed phase, the orbital motion of the electrons may not be frozen and therefore the g-factors and spectroscopic absorption coefficients are significantly smaller and larger than for the condensed phase and vary from species to species. Furthermore, the spectra of di- and poly-atomic radicals show a rotational structure which leads to a very complex system of ESR lines, spreading over a range of several kilo-oersteds; however, as a rule it is possible to record only part of these lines. In this connection, the determination of the absolute concentrations of species in the gas phase requires special calculations every time. The first such calculation, the aim of which was to calibrate O against O_2, was performed by Krongebb and Strenberg[5]. Later calibration calculations for OH against NO and for halogen atoms against O_2 were performed independently by Nalbandyan et al.[6] and by Westenberg[7]. In such calculations account is taken of the fact that the absorption in OH, NO, etc. is due to electric dipole transitions. The resonator is usually completely filled with the gas, so that the paramagnetic OH species come within the region of the antinode of the electric field and the NO used as standard permits automatic allowance for the effect of the configuration of the fields. However, if the measurements are made at high temperatures, considerable temperature differences always appear in the resonator, and nitric oxide cannot be used, since its signal depends markedly on temperature. In these cases Nalbandyan and coworkers[6] use molecular oxygen as an intermediate standard.

2. Measurement of Local Concentrations of Paramagnetic Centres

The methods for the determination of the number of paramagnetic centres by the ESR method have already been examined. On dividing this number by the volume of the specimen, we can always determine the average concentration of paramagnetic centres in the specimen. However, this quantity can be usefully employed in physicochemical calculations only when it is certain that the distribution of paramagnetic centres throughout the volume is uniform (equally probable). If we are dealing with a gas or liquid phase, such a problem does not arise—here the distribution of all the active centres is homogeneous. However, in a solid phase and in heterogeneous svstems it is easv to imagine a non-uniform distribution of paramagnetic centres —such non-uniformities can arise from radiation tracks on irradiation, phase separation on freezing, active sites on the surface, etc. Here the study of the intensity of the signal is of no avail and it is necessary to seek other ways of estimating the true density of paramagnetic centres. In principle, one can use the fact that, at the concentrations usually recorded by the ESR method, the average distance between paramagnetic centres is such that their dipole–dipole interaction should influence the form of the spectrum (0.1–1 Oe). According to fairly simple calculations[8,9], there is a relation between the dipole–dipole contribution to line width between the points of maximum slope and the concentration of paramagnetic centres (for $n < 1\%$, which is always the case in chemical studies):

$$\Delta H_i(\text{Oe}) = Bn \ (\text{cm}^{-3}), \qquad (4)$$

where

$$B = \begin{cases} 5.4 \times 10^{-20} \text{ Oe cm}^3 \text{ (random distribution, Lorentz line form)} \\ 4.9 \times 10^{-20} \text{ Oe cm}^3 \text{ (uniform distribution, Gaussian line form).} \end{cases}$$

If this interaction determines the apparent line width, the problem may be regarded as solved. Wyard[9] observed directly in irradiated frozen solutions of hydrogen peroxide the variation of line width with concentration (i.e. the area of the signal). According to his estimate[9], $B = 7.5 \times 10^{-20}$ Oe cm^{-3}. In this case the ESR signal consists of a single line. For complex ESR spectra the detection of line broadening appeared at first to be a hopeless task, but thorough analysis of the accumulation curve recorded up to large doses enabled the present author together with Mikhailov[10] to detect the broadening of the hyperfine structure components at average concentrations of the order of 10^{19} cm^{-3} (Fig. 4). The quantity $\sqrt{\kappa_{\text{eff}}}$, where the line form coefficient κ_{eff} was determined from Eqn. (2), served as a measure of the width ΔH_i of an individual component. For complex spectra, this method proved to be more sensitive than the direct measurement of line width or the calculation of the second moment. The undefined multiplier in the formula $\Delta H_i = \beta\sqrt{\kappa}$ was determined for the most highly resolved signal with the aid of the "Atlas of ESR Spectra". Fig. 4 shows that ΔH_i increases linearly with the average concentration n (this can be regarded as proof of the dominant contribution of spin–spin interaction to ΔH_i), and n_{loc} exceeds n significantly but increases together with the latter. Thus here the hyperfine structure components are homogeneous. In the most complex case of non-homogeneous lines, consisting of a large number of unresolved spin packets, ΔH_i in Eqn. (4) must be replaced by the width of the spin packet ΔH_S. The relaxation characteristics of the ESR signal obtained by the spin-echo or successive saturation methods have begun to be used recently for the determination of ΔH_S.

The application of the spin-echo method (based on Hann's principle[11,12]) in the study of free radicals in solid matrices was first described by Raitsimiring et al.[13] Despite certain theoretical difficulties in the interpretation of the experimental data, this method is extremely promising.

In particular, it is also evident from the results of Raitsimiring et al.[13] that the local radical concentration measured from ΔH_S increases in parallel with the average concentration, remaining higher than the latter in a number of cases.

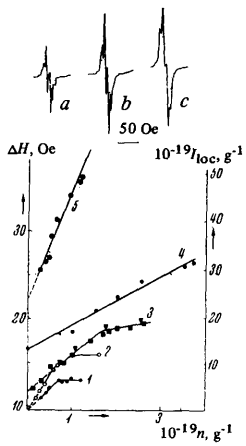

Figure 4. Variation of the width of the hyperfine structure components of the ESR spectra of irradiated substances with the average concentration (i.e. radiation dose):
1) cytidine; *2*) guanosine; *3*) thymine; *4*) glycine; *5*) DNA.

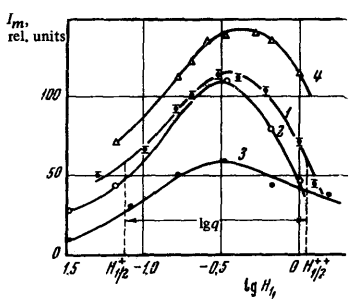

Figure 5. Example of the analysis of microwave saturation curves; variation of the intensity of the ESR signal in irradiated substances with the power of microwave detector[14] (77°K):
1) α-alanine; *2*) guanine hydrochloride; *3*) phenol; *4*) glycine.

The present author initiated a simpler (but less sensitive) method for estimating ΔH_S from the width of microwave saturation curve[14] based on the theory of inhomogeneous saturation of Portis[15] and Castner[16]. Some of the results[14] are presented in Fig. 5. At saturation the homogeneous line broadens because its centre is saturated to a greater extent than the edges, so that, when the power applied is high, the intensity of the signal falls to zero. If the effective width of an inhomogeneous line $\Delta H^* \gg \Delta H_S$, an increase of ΔH_S will not affect ΔH^* and the intensity of the signal will cease to depend on the amplitude of the microwave field H_1, i.e. the width lg$q$ of the $I'_m - \lg H_1$ saturation curve becomes infinite. Theoretical calculation of saturation curves for various $\Delta H^*/\Delta H_S$ makes it possible to plot a calibration curve: $\Delta H^*/\Delta H_S = f(q)$. Such a calculation has been performed by Castner[15] and then used for estimating ΔH_S.[17,18] However, Castner's calculation[15] was made for an ESR spectrometer without magnetic modulation and this was not stated. Zhidkov et al.[14] carried out the calculation for the usual experimental conditions (modulation of the magnetic field with an amplitude $\Delta H_S \leq \Delta H_M < \Delta H^*$; in view of the slow-pass conditions obtaining the modulation frequency $\nu_M \ll 1/T_1$; in the experiments[14] $\nu_M = 333$Hz). Then for $q < 50$ the calibration relation is described by an almost linear function

$$\frac{\Delta H^*}{\Delta H_S} \simeq 0.72\,q - 6.15\,,$$

In the experiments, apart from the cases where $n_{loc} \gg n$, the equality $n_{loc} \simeq n_{av}$ was obtained for certain specimens, which may be regarded as confirmation of the validity of the calculation. In the general case the theoretical interpretation of continuous saturation curves is also quite difficult, since the calculations were made on the assumption of non-interacting spin packets (i.e. the absence of spectral diffusion) and without taking into account the contribution of exchange interaction. (It has now been shown that at concentrations less than 10^{20} cm^{-3} the exchange contribution to line width may be disregarded).

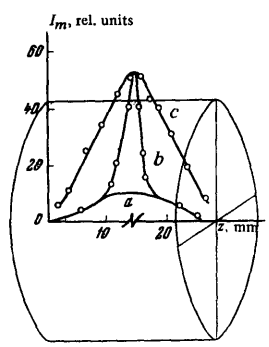

Figure 6. Distribution of sensitivity in an ESR resonator:
a) in the normal case; *b*) in a resonator with a spiral nozzle;
c) in a resonator with mobile packing[19].

In connection with the measurement of the concentrations, it is interesting to consider briefly also the following problem. The microwave resonator usually consists of a "transducer" with a linear dimension of about 30 mm (X-range) or 8 mm (K-range) and therefore if the measurements are on an extended volume (paramagnetic centres in a jet, in a gas mixture, etc.), we can determine only the concentration averaged over the resonator. We believe that an interesting possibility for the determination of local concentrations at a "point" with dimension smaller by a factor of 10 than that of the resonator arises from the effect, observed by the present author together with Taranukha, involving the localisation of the microwave power by a spiral section[19]. It was found that, when one or two turns of a conducting spiral are placed along the antinode of the lines of force H_1, then it is possible to obtain at the location of the spiral a δ-flash of microwave power, so that the instrument begins to "see" virtually only whatever is located in the zone of its spiral (see Fig. 6). Measurements on model objects confirmed this possibility, but a very unfavourable feature of this system is the necessity for a spiral of very small diameter (1–2 mm for a 3 cm resonator).

3. Formal Mathematical Analysis of ESR Spectra

The ESR spectrum is a system of lines, the derivation of chemical information from which constitutes a special task. For chemically active species (free radicals) the complexity of the spectrum is usually due to the hyperfine structure (i.e. the interaction of the unpaired electron with the nearest paramagnetic nuclei) and also the anisotropy of the hyperfine structure and the positions (g-factor) of the lines. Two stages are required for the identification of the paramagnetic centres: (1) one must establish with which nuclei (and with what constants) the unpaired electron interacts; (2) on the basis of the findings in the first stage, one must establish, using the methods of quantum chemistry, the chemical structure of the paramagnetic centre and, as far as possible, its geometrical structure and the distribution of the spin density of the unpaired electron.

We shall consider initially a spectrum consisting of well—resolved lines (i.e. line width $\Delta H_i < a_{\min}$). This spectrum must correspond to a system of levels (under the conditions of a strong field):

$$\Delta E = g\beta H + \sum_k a_k I_{z_k} \ ,$$

where a_k are hyperfine structure constants and I_{zk} the projections of the nuclear spins.

As a result of the interaction of the unpaired electron with the kth nucleus, $2I_k + 1$ lines are produced, and if there are N nuclei, the number of lines is $\prod_{k=1}^{N} (2I_k + 1)$. These lines are distributed in such a way that the distances from the extreme line to the others are a_1, a_2, a_3, ...; $a_1 + a_2$, $a_2 + a_3$ ...; $a_1 + a_2 + a_3$, ... etc. (see Fig. 7).

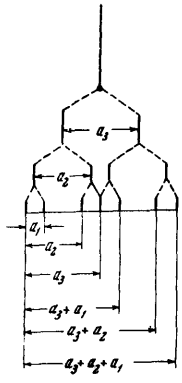

Figure 7. Diagram illustrating the formation of the hyperfine structure (splitting by three protons with $a_1 : a_2 : a_3 = 1 : 3 : 4$).

Therefore it is readily seen that the hyperfine structure of the ESR spectrum can be represented by the polynomial

$$\prod_{k=1}^{k_m} (1 + z^{\alpha_k})^{S_k} \quad \text{for } I = 1/2$$

$$\prod_{l=1}^{l_m} (1 + z^{\alpha_l} + z^{2\alpha_l})^{S_l} \quad \text{for } I = 1 \text{ etc.}$$

where α_k represents the different splittings measured in relative units ($\alpha_k = a_k/a_{\min}$) and S_k the number of nuclei for which $a = a_k$, i.e. the multiplicity of the degeneracy. After carrying out the multiplication, we obtain a polynomial $\Sigma A_m z^m$, in which the coefficients A_m correspond to the relative line intensities (the multiplicity of the degeneracy) and the exponents to their distances from the first left-hand line in units of $a_{\min}$. In particular, for n equivalent protons the characteristic polynomial is $(1 + z)^n$, which corresponds to $n + 1$ lines with a binomial distribution of intensities. Such formalised representation of the hyperfine structure makes it possible to formulate the problem of the analysis of the spectrum. The polynomial $\Sigma A_m z^m$ is known from experiments. The problem is how to recover from it the initial product. We shall examine, for simplicity, only nuclei with $I = 1/2$. The total number of lines is 2^N, where N is the number of nuclei, and therefore

$$N = \log_2 \frac{\Sigma A_i}{A_0} \ .$$

It is then clear from the structure of the characteristic polynomial that $A_1/A_0 = S_1$, the number of nuclei with minimum splitting. Finally the ratio of the total splitting in the spectrum to the smallest is

$$\frac{a^*}{a_{\min}} = \sum_{k=1}^{k_m} \alpha_k S_k \ .$$

In spectra corresponding to not more than two groups of non-equivalent nuclei, the number of these relations is sufficient for the determination of all the α_k and S_k. In the general case Dobryakov[20] obtained recurrent relations, from which all the α_k and S_k can be found from specified A_m. Thus the problem can be regarded as solved in principle (for $I = 1/2$), but since A_1 and a_1 (the intensity of the weakest component and the minimum splitting) enter into all the formulae, the above analysis is applicable only to relatively rarely encountered ideal "line" spectra.

Real spectra, particularly those of condensed phases, usually have line widths comparable to (or greater than) the minimum splitting. The method of trial and error has been used for a long time to analyse such spectra—a spectrum with a given structure is constructed taking into account the finite width and form (Lorentzian or Gaussian) of the individual line and the resulting curve is compared with experiment; when there is agreement, the theoretical spectrum yields a set of α_k and S_k values. Such construction is laborious and, in order to facilitate it, an atlas of theoretically calculated ESR spectra[21], containing a large set of spectra with various A_i and different resolutions ($\Delta H_i/a_{\min}$), was produced in 1962 at the Institute of Chemical Physics of the USSR Academy of Sciences. Experiments showed that the atlas causes the investigator to adopt fairly specific habitual procedures to interpret poorly resolved signals, but of course the atlas could embrace only a small part of line combinations encountered experimentally. At the present time there are specialised computers which can be used also for the synthesis of theoretical spectra. Finally the attempts to find the parameters of the theoretical spectrum by adjusting them on an electronic computer to fit the experimental spectra may be regarded as an improved version of the method of trial and error[22,23]. However, all this applies only to symmetrical multicomponent spectra, the description of which requires, apart from a set of S_k and α_k, the specification of only two parameters—$a_{\min}$ and ΔH_i. The line form due to the axial anisotropy of the g-factor is also described by only two parameters (Δg and H_i), and several studies have been devoted to the analysis of such lines[24-28].

In more complex cases where 3–4 or more parameters must be specified in order to describe the theoretical spectrum, the line form can be calculated only for definite sets of parameters specified *a priori*. Lefebvre and Maruani published recently a very complete programme for the computer calculation of spectra taking into account the splitting and the triaxial anisotropy of the g-factor and the hyperfine interaction[29]. The method of moments is also used for the analysis of poorly resolved ESR spectra[30]. However, the present author believes that the most logical formulation of the problem is analogous to that used by Dobryakov[20] for the analysis of line spectra. An attempt must be made to construct functional transformations, whereby the initial "physical" parameters of the spectrum can be found from its finite line form. It will be shown below on the simplest example that this can be done at least for spectra with a symmetrical hyperfine structure.

Let us examine the construction of the transformation, the reverse of the synthesis of the spectrum with a hyperfine structure, using a doublet as an example

$$F(x) = f(x+b) + f(x-b) \qquad (5)$$

where $b = \frac{1}{2}a_{\mathrm{H}}$. It is evident that

$$F(x+2b) = f(x+3b) + f(x+b)$$
$$F(x+4b) = f(x+5b) + f(x+3b),$$

where the left-hand side contains known functions. If we form an infinite series with alternating signs from $F(x+2kb)$, then all the terms on the right-hand side vanish except $f(x+b)$:

$$f(x+b) = \sum_{k=0}^{\infty} (-1)^k F(x+2kb). \qquad (6)$$

Thus, from the form of the envelope (apparent) of the lines, we can in principle find the form of the individual line (when b is known). The significance of transformation (6) can be readily elucidated from Fig. 8, which shows that, for sufficiently large k, the terms have virtually no effect on the pattern near $x = 0$. If b is unknown (and this is usually the case in the problem of spectral analysis), the following procedure can be used.

1. The right-hand side of Eqn. (6) is regarded as a function of x and b and preliminary differentiation of Eqn. (5) is carried out:

$$\Phi(x, y) = \sum_{k=0}^{\infty} (-1)^k F'(x+2ky).$$

Here y is a variable distance between the centres of the spectra and the terms of the summation have alternating signs. If $y = b$, then $\Phi(x, y) = f'(x+b)$. However, when $x = -b$, we have $\Phi(-b, b) = f'(0) = 0$ and therefore the function $\Phi(-y, y)$ has a remarkable property, namely it becomes zero when $y = b$. Hence it is possible to find b and then $f(x)$, i.e. to analyse the spectrum. This method of analysis was published by Newton et al.[31] The same method in principle was developed independently by Dobryakov and the present author[32], but in our version the analysis is carried out as follows.

2. It is clear from the scheme in Fig. 8*a* that, when the summation (5) is extended to $-\infty$, then along any section $0 \ldots y_0$ the modulus of the area under $\Phi(x, y_0)$ will become zero when $y = b$. Therefore we introduce the function

$$\psi_l(y) = \int_0^{ly} \left| \sum_{k=-\infty}^{\infty} (-1)^k F(x+2ky) \right| dx,$$

where l is an integral number which can be assumed to be 1 or 2 and the summation with respect to k can be carried out virtually from $-n$ to n, where $n \gg l$. This function becomes zero abruptly when $y = b$. Indeed, more rigorous treatment and model calculations showed[32] that, even for more complex cases, $\psi_l(y)$ is of the form shown in Fig. 8*b*, where a_N is the splitting of the nitrogen type, present in the spectrum of diphenylpicrylhydrazyl. Characteristic functions of a similar type can be constructed also for other values of I.

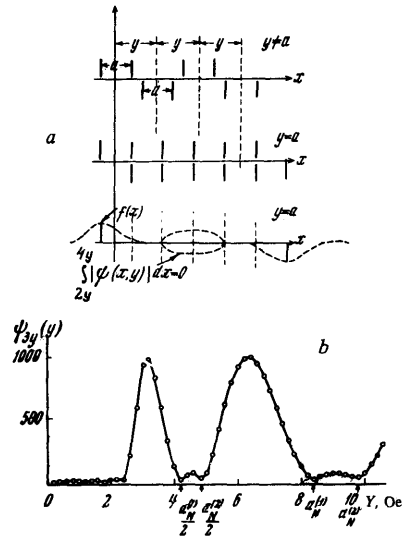

Figure 8. *a*) Diagram illustrating the analysis of a spectrum with a symmetrical hyperfine structure by the construction of the reverse transformation; *b*) analysis of the experimental spectrum of diphenylpicrylhydrazyl in dilute solution.

The method of Fourier transformations also opens up interesting possibilities for the analysis of ESR spectra[20,32]. Here the roots of the Fourier integral of the experimental function of line form are used to calculate the hyperfine structure constants.

The recently published "electronic" method for the sharpening of spectra by graphical differentiation or special magnetic modulation[33,34] and also of course the method of double electron–nuclear resonance[35] gives rise to specific possibilities in the analysis of poorly resolved spectra. However, all these procedures involve an appreciable loss of sensitivity in the recording of the signal.

In the identification of spectra the problem of how many different types of paramagnetic centres are responsible for the spectrum often arises. Generally, if the system of lines can be subdivided into a number of subsystems, each of which is consistent with the laws governing the formation of the hyperfine structure, then these systems can be logically attributed to different paramagnetic centres. However, for poorly resolved signals, it is difficult to arrive at any definite findings by this procedure. The method of microwave line saturation is more promising here (although it by no means always works). For example, when the system contains alkyl and peroxy-radicals, the signal from the first can be "suppressed" by high microwave power[36]. In general, for a quantitative separation of a two-component signal, it is sufficient to obtain two linear

sections on the saturation curve, since the slopes of these lines are proportional to $n_1 + n_2$ and n_2 respectively. Finally the change in line form on saturation may be regarded as qualitative evidence of the presence of more than a single signal. The point is that at saturation the form of the lines due to paramagnetic centres should either remain unchanged (inhomogeneous lines) or it should broaden symmetrically (narrow, almost homogeneous lines with $\Delta H_1 > \Delta H$). When it is certain that there is no impurity causing dispersion, asymmetric deformation of the spectrum is evidence of the superposition of two or several signals with different T_1 and T_2 and different g-factors[37]. †

4. Quantum-chemical Analysis of ESR Spectra

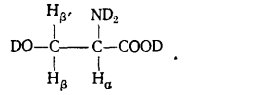
After formal mathematical analysis of the spectrum, we know in the general case all the constants of the magnetic interaction leading to the splitting or broadening of the ESR lines. Further analysis is based on the relations between the structure (electronic or geometrical) of the paramagnetic centres and the magnetic interaction obtained from the theory of ESR spectra. This theory has been described in detail in a number of monographs and reviews[1,38-43].

Only the following remarks need be made in addition to the data presented in the literature[1,38-43].

1. Refined effects involving changes in line form are increasingly used at the present time, after the publication of the elegant theoretical studies of Freed and Fraenkel[44], for the determination of the details of the electronic structure of radicals in liquid solutions[45].

2. When the g-factors are measured to within the 4th or 5th decimal place, they too can provide information about the chemical nature and the electronic structure of radicals. For example, Thomas[46] showed that peroxy-, hydroxy-, and alkyl radicals can be distinguished on the basis of the g-factors. Recently it has also been shown that the g-factor depends on temperature and the nature of the substituents in the radical[37,47].

We shall consider as a concluding example the "complete" analysis of the signal arising on γ-irradiation of α-substituted serine:



The spectrum, presented in Section III (Subsection 3) of this review, consists of 7 lines with the experimental intensities 12 : 16 : 21 : 31 : 25 : 18 : 20. The distances between the lines are approximately the same and equal to 13 Oe. The sum of the coefficients is

$$\frac{\Sigma A_m}{A_0} = \frac{143}{16} = 9 (= 3^2 \text{ or } 2^3),$$

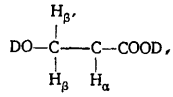
Since two nitrogen atoms cannot be present, it will be assumed that the hyperfine structure is due to three protons. Further,

$$\frac{A_2}{A_1} = \frac{18+16}{20+12} \simeq 1, \text{ i.e. } S_1 = 1; \; S_2 + S_3 = 2,$$

and therefore $S_1 = S_2 = S_3 = 1$. This means that the total splitting is

$$6 : 13 = 1 : 13 + (\alpha_2 + \alpha_3) \cdot 13 \text{ (oersteds)},$$

i.e. $\alpha_2 + \alpha_3 = 5$, so that $\alpha_2 \neq \alpha_3$. Hence $\alpha_2 = 2$ and $\alpha_3 = 3$. We conclude that the hyperfine structure is due to 3 non-equivalent protons with splittings of about 13.26 and 39 Oe. Such a situation can occur only in the radical



The splitting by the α-proton is evidently due to dipole–dipole nuclear spin interaction. For the β-splitting, we have $a_\beta \simeq 45 \rho_C^\pi \cos^2 \varphi$, and $\varphi_1 - \varphi_2 = <\text{HCH}$. With a favourable orientation, one of the β-splittings can reach 40 Oe, while the other should be small. Therefore it can be suggested that $a_\beta = 39$, $a_{\beta'} = 13$, and $a_\alpha = 26$ Oe. These figures are of course correct to within the line width and therefore the multiplicity of the splittings is only apparent. Next, with the aid of the Atlas[21], it is possible to obtain improved values of the constants: 40, 14, and 23 Oe respectively.

III. STUDY OF THE KINETICS AND MECHANISM OF CHEMICAL REACTIONS BY THE ESR METHOD

1. Gas-phase Reactions

The mechanism of gas-phase chemical reactions has been more thoroughly investigated than the mechanism of reactions in condensed phases. However, as regards the application of radiospectroscopic, methods the situation is reversed. This is probably because stable paramagnetic species do not exist in the gas phase (apart from the paramagnetic molecules of the type of O_2 and NO, which are not of particular chemical interest) and it is difficult to obtain high concentrations of active atoms and radicals. The ESR spectra recorded for H, O, S, K, Na, etc. atoms obtained in high-frequency discharges or by thermal dissociation are not themselves of significant interest to chemistry. A considerable advance took place after Voevodskii and coworkers[48] demonstrated the possibility of recording the ESR spectra of H atoms directly in the zone of a rarefied hydrogen flame in oxygen. According to Semenov and Hinshelwood's theory of branched-chain processes, the reaction $2H_2 + O_2 \rightarrow 2H_2O$ proceeds at low pressures via the active centres H, O, and OH, which should give rise to an ESR signal. By drawing the flames from the combustion zone into the resonator, Voevodskii and coworkers[48] succeeded in recording considerable (up to 10^{15} cm^{-3}) concentrations of H atoms. Later these investigations were continued vigorously at the Institute of Chemical Kinetics and Geology [? tentative interpretation of abbreviation (Ed. of Translation)] of the Siberian Division of the USSR Academy of Sciences and at the Institute of Chemical Physics of the USSR Academy of Sciences, where V. N. Kondrat'ev and A. B. Nalbandyan and coworkers succeeded in recording, using a special cell, the signals from O and OH in the $H_2 + O_2$ flame and then also the signals from the active centres in a number of branched-chain combustion reactions: H, O, and OH in the $CO + O_2$ flame with small amounts of added H_2; O and SO in the $S + O_2$ flame and O in the $CS_2 + O_2$ flame; H, O, OH, and SO in the $H_2S + O_2$ flame[49,50]. The ESR spectra of H, O, and OH generated in the combustion of hydrogen in oxygen, obtained by Nalbandyan and coworkers[49], are presented as an example in Fig. 9*a*. Using the calibration method discussed earlier (with O_2 and NO), the absolute concentrations

† A more complete discussion of the methods of analysis of ESR spectra of free radicals is given by Dobryakov and Lebedev[32].

of the active centres in experiments with different jet velocities (i.e. different reaction times) were calculated from these spectra (Fig. 9*b*). The same Figure also presents the variation of the concentrations of H, O, and OH with reaction time calculated on a computer from the known kinetic constants; comparison of the experimental and theoretical curves constitutes very convincing confirmation of the existing theories concerning the mechanism of the process. By changing the initial values of the constants k_i in the calculations, it is possible to achieve complete agreement with experiment and thereby improve (or redetermine) the fundamental kinetic constants.

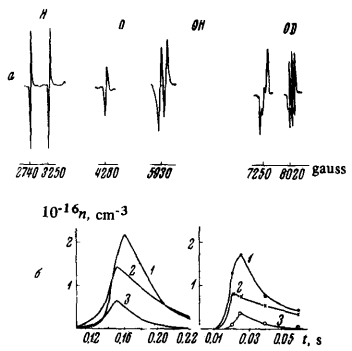


Figure 9. An example of the study of the mechanism of a gas-phase reaction—combustion of hydrogen in oxygen[49]: *a*) ESR spectra of active H, O, and OH centres; *b*) kinetic curves representing the variation of the concentration of the active centres with reaction time (comparison of the calculation with experiment); *1*) [O]; *2*) [H]; *3*) 10[OH].

However, the scope of the ESR method is not restricted to the confirmation and improvement of existing hypotheses. At the Institute of Chemical Physics of the USSR Academy of Sciences the ESR method has been used to justify certain new hypotheses of Semenov and Shilov concerning the role of chemical activation in branched-chain reactions[51]. Such a reaction should be a source of atomic concentrations (I and F) in excess of their equilibrium values. Indeed, by carrying out the reaction in the resonator, Shilov and coworkers[52] observed the spectra of atomic iodine (18 lines in the range between 3000 and 6300 Oe). The F and Cl signals were detected in the reaction between F_2 and C_2Cl_4 and the spectrum of atomic bromine was observed in the reaction between F_2 and CH_3Br.

No less interesting is the possibility of using ESR for the quantitative study of the fundamental stages of gas-phase reactions. Voevodskii and Panfilov[53] studied the reactions of atomic hydrogen with various hydrocarbons, by adding the latter to the $H_2 + O_2$ reaction zone and following the decrease of the intensity of the H signal as a function of the amount of additive and the extent of its combustion. This showed that, with rarefied flames, one hydrocarbon molecule can give rise to a chain of reactions involving the destruction of H atoms (from 2–3 for ethane to 75 for benzene). Nalbandyan and coworkers[54] established by the ESR method the pathway of the reaction between atomic oxygen and methanol:

$$O + CH_3OH \rightarrow \dot{O}H + \dot{C}H_2OH \quad \text{or} \quad \dot{O}H + \dot{C}H_3O \ .$$

For this purpose, they introduced CH_3OD or CD_3OH to $CO + O_2$ flames and determined the ratio [OD]/[OH] from the ESR signals. It was found that oxygen attacked mainly the methyl group.

Cold flames are not necessarily the only source of active species for the investigation of fundamental reactions. For example, Westenberg and coworkers in the USA made a quantitative study by the ESR method of the reaction of hydroxyl with OH, H_2, and CO, in which the very rapid reaction $H + NO_2 \rightarrow OH + NO$ served as a source of OH, and hydrogen was generated in the discharge[55]. In this investigation the rate constants for the reactions $OH + OH \rightarrow$, $OH + H_2 \rightarrow$, and $OH + CO \rightarrow$ at room temperature were determined with high accuracy and for the last two reactions the activation energies were also estimated (5.2 and 0.6 kcal mole^{-1}).

The active species produced in gas-phase reactions can be frozen out on cooled surfaces in order to accumulate them in high concentrations and to investigate in detail their ESR spectra. For example, by withdrawing atomic hydrogen from the discharge, it is possible to obtain phenyl radicals by the reaction[56]

$$H^{\cdot} + C_6H_6 \rightarrow H_2 + C_6H_5^{\cdot} \ .$$

The value of such preparations of radicals lies in the fact that their chemical structure is known *a priori* and the ESR spectra obtained can be used to identify the signals in other systems. A series of such radicals (propyl, butyl, heptyl, allyl, phenyl, and others) were obtained by Bennett and Thomas[57], with the aid of a technique involving a rotating cryostat and sodium beams, by the reaction

$$Na + RHal \rightarrow NaHal + R^{\cdot} \ .$$

The design of the experimental apparatus[57] is such that, by condensation of a third beam (in addition to RHal and Na), it is possible to study further reactions of the R$^{\cdot}$ radicals, for example:

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot} \ ,$$
$$R^{\cdot} + C_2H_4 \rightarrow RCH_2CH_2^{\cdot} \ .$$

It was then found that oxygen reacts even at 77°K, while ethylene must be heated to 90–500°K. Bennett and Thomas[57] believe that, when account is taken of the gradual cooling of ethylene, it is possible to calculate the true rate constant for the reaction from the degree of conversion of R$^{\cdot}$ into $RCH_2CH_2^{\cdot}$ using an electronic computer. For example, they obtained in this way $E = 0.15$ kcal mole^{-1} for the reaction between C_6H_5 and C_2H_4. However, the accuracy of the determination of the constants by comparing the results of very cumbersome calculations with experiment is doubtful. Panfilov[58] applied the method involving the freezing out of the products from rarefied flames near the reaction zone in order to accumulate large amounts of free radicals. The sensitivity with respect to hydrogen atoms then increases at least by a factor of 50.

2. Liquid-phase Reactions

The paramagnetic centres (free radicals and radical-ions) in liquid and solid phases can have a wide variety of lifetimes, and henceforth we shall find it convenient to distinguish arbitrarily kinetically active and stable radicals. The application of electron spin resonance in chemistry began of course with the study of stable radicals and radical-ions. From stable radicals, interesting data were obtained on the electronic and geometrical structure, delocalisation of the unpaired electron, and internal motions

in molecules—data, which, as already stated, will not be discussed in great detail in the present review. From the standpoint of the kinetics and mechanism of chemical reactions, stable radicals as a rule do not behave as intermediate centres which can propagate real chemical reactions, but they can serve as models for the investigation of the most important problems of kinetics and reactivity. One of the first studies on the application of electron spin resonance in chemistry was the investigation of the rate of dissociation of hexaphenylethane into stable triphenylmethyl radicals, whereby it was possible to determine the heat of this reaction[59]. The capacity of stable radicals to recombine with active radicals makes it possible to follow the latter on the basis of the intensity of the ESR signal due to the stable radical. Diphenylpicrylhydrazyl is used particularly frequently as such a label. Buchachenko and others[39] investigated the kinetics of several hydrogen transfer reactions, such as the reaction between tri-t-butylphenoxyl and phenol, and determined the rate constant for the reactions and their dependence on the physical properties of the medium and the nature of the reacting molecules; these studies revealed a marked influence of hydrogen bonds on the rate constants. The effect of π-complex formation on the reaction rate has also been observed for aromatic radicals such as diphenylnitric oxide.

As far as the present author is aware, the first ESR study of "live" chemically active radicals directly in the course of the reaction was carried out by Shlyapintokh and Tsepalov with the present author's participation, using as an example the liquid-phase chain oxidation of hydrocarbons[60]. The "classical" mechanism of such a process is as follows:

$$\text{decomposition of initiator} \xrightarrow{W_i} 2\,R_i^{\cdot} \rightarrow 2R^{\cdot},$$

$$\left.\begin{array}{l} \rightarrow R^{\cdot} + O_2 \rightarrow RO_2^{\cdot} \\ RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot} \end{array}\right| ,$$

$$RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_3} \text{destruction}.$$

As long as the reaction proceeds, a steady-state concentration of RO_2 (the $R^{\cdot}$ radicals are more active and their number is much less) should be maintained:

$$[RO_2^{\cdot}]_{st.} = \sqrt{\frac{W_i}{2k_3}}.$$

The rate of oxidation is then

$$W = k_2[RH][RO_2^{\cdot}] = \frac{k_2}{\sqrt{2k_3}}\sqrt{W_i}\,[RH].$$

Since W and W_i are known, the combined rate constants $k_2/\sqrt{2k_3}$ have been determined for a long time for many reactions. The ESR method permitted the measurement of the steady-state concentration $[RO_2^{\cdot}]$, which led to the determination of both rate constants for the process.

The ESR signal due to $RO_2^{\cdot}$ peroxy-radicals, which consists of a singlet with a displaced g-factor $g = 2.015$, was first recorded in the oxidation of cumene. The reaction at 60–100°C was performed directly in the resonator, where a special device ensured a continuous supply of an excess of oxygen (otherwise the relation specified above would be invalid). Fig. 10 presents the results of the measurement of $[RO_2^{\cdot}]_{st}$ and their comparison with the available data for cumene, obtained by the method of discontinuous illumination. Good agreement between the results showed that ESR can be used to determine the rate constants k_2 and k_3 also as an independent method; the rate constants for the oxidation of diphenylmethane, diphenylethane, etc. were obtained in this way. Somewhat later the signal due to $RO_2^{\cdot}$ in the oxidation of cumene was investigated independently in a jet by Thomas[61], who showed that the radicals may be stabilised by the formation of a complex with pyridine.

Nowadays the study of active radicals in the liquid phase (with purely chemical initiation) is almost always carried out in flow systems. Such systems are now widely known and their design has been frequently described. The flow rates are usually 10–100 cm sec^{-1} and the idle time (from the instant of the mixing of the reactants to the instant when the resonator is reached) amounts to hundredths of a second. The advantage of flow systems is that it is possible to maintain a high reaction rate over a long period (i.e. a high rate of initiation of active centres) without having to worry about the consumption of the reactants: while under static conditions the time constant for the recording of a signal should be much less than the lifetime of a radical or the time required for the consumption of the reactants, in a jet apparatus the time required for the mixture to flow out is the only limiting factor. It can be shown that under optimum conditions the gain in sensitivity is approximately $\sqrt{V_0 V_c}$, where V_0 is the volume of liquid which has passed through the resonator during the time when the signal was recorded and V_c the effective volume of the capillary in the resonator. Depending on the experiment, this gain does in fact reach 10–20.

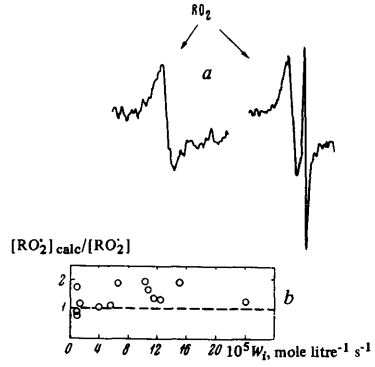

Figure 10. An example of the investigation of a liquid-phase reaction—chain oxidation of cumene[59]:
a) ESR spectra of cumenylperoxy-radicals; *b*) comparison of the calculated and experimental steady-state concentrations of radicals for different rates of initiation.

It has been shown in recent years that, it is possible with flow systems to obtain sufficient concentrations of active radicals at room temperature for recording ESR signals and for the investigation of the reactions of these radicals. In one of the first studies (using a jet) Dixon and Norman[62] obtained OH radicals by a reaction similar to Fenton's reaction:

$$Ti^{3+} + H_2O_2 \rightarrow Ti^{4+} + OH^{\cdot} + OH^{-}.$$

By adding various alcohols to the system, it is possible to observe the transformation of the $OH^{\cdot}$ spectrum into the signal of the alcohol radical, which is evidence of a reaction of the type

$$O\dot{H} + CH_3OH \rightarrow H_2O + \dot{C}H_2OH,$$

Analysis of the secondary ESR spectra established that in saturated alcohols a hydrogen atom is always split off from an α-carbon atom, while in unsaturated compounds the incorporation of OH at the double-bond was observed.

Similar flow ESR studies on radicals obtained by a one-electron transfer reaction are now being carried out on a wide scale. These are described in greater detail in the review by Waters[63]. They are undertaken mainly in order to elucidate the structure of the radicals formed and hence the mode of the fundamental reactions, but evidently the technique also permits quantitative kinetic studies.

For example, Blyumenfel'd and coworkers[64] studied the kinetics of the reactions of OH^- ions (in a flow system) with tetracyanoethylene, p-benzoquinone, and o-naphthoquinone, which lead to the formation of the corresponding radical-ions. The activation energies were determined and the effect of ionic strength and the addition of oxygen, hydrogen peroxide, and certain anions was investigated. It was shown that the effect of hydrogen peroxide depends on the pH of the medium, since molecular and ionic (HO_2^-) forms of hydrogen peroxide exist at different pH.

Another possibility of the kinetic and structural study of active radicals in the liquid phase was demonstrated by Fessenden and Schuler[65] in the USA, who directly recorded the spectra of C_2H_5 radicals (concentration about 4×10^{13} cm^{-3}, dose rate 10^8 mrad h^{-1}) with specially adapted apparatus in the radiolysis of liquid ethane. So far they have investigated the ESR spectra of a number of active radicals ranging from CH_3, C_2H_5, and FO_2 to 2,2-diethyl-1-methylbutyl. It has been shown that in all cases the destruction of radicals is probably determined by their diffusion, since a change in the viscosity of the solution (by the addition of glycerol) alters significantly the steady-state concentration of the radicals.

The possibilities for the investigation of short-lived species have also been greatly extended by a method involving the accumulation of the useful signal[66]. The principle of this method consists in synchronised n-fold recording of the signal with subsequent summation, as a result of which the sensitivity increases by a factor $\sqrt{n}$. The accumulation method in effect permits longer recording times without risk of a drift in the zero line, etc.; as far as one can judge from published data, this results in a sensitivity gain by a factor of 10. In the study of short-lived species, this method can be very effective only in combination with a flow system whereby long recording times can be achieved. On the other hand, the accumulator can be synchronised with a source of active species, as was done by Piette[67] (USA). Simultaneously with the flash of the photo-source or a specified time afterwards the instrument was switched on and the signal was recorded (at one point): at each point corresponding to specified time intervals from the start of the flash, the signal was recorded 25 times. This yielded a kinetic curve for the destruction of the cumenyloxy-radical (obtained by the photolysis of cumenyl hydroperoxide) at room temperature, where the reaction time constant amounts to about 0.03–0.05 s. Piette[67] hoped to obtain in this way the rate constant for the removal of hydrogen from solvent molecules, but the identity of the constants in cumene, ethylbenzene, and toluene shows that even at 20°C the reaction rates are limited by diffusion. The method described would probably permit the investigation of rapid reactions in any phase ("active" radicals are investigated as "stable" radicals), but it should be noted that we are unaware of any other publications on this question after Piette's communication in 1963, apart from the data presented in Soutif's review[40] on the study of rapid ($\tau = 0.01$ s) oxidation–reduction reactions of enzymes with the aid of a low-inertia jet system produced by the Varian Company. The method is admittedly fairly complex experimentally and it is not always possible (only for $\tau > 0.1$ s) to record the entire ESR spectrum, so that correct kinetic data can be obtained only when the line form coefficient does not change.

The kinetics of rapid processes have been investigated not only on the basis of the intensity of the ESR signals, but also on the basis of changes in line form. If as a result of a fast exchange reaction there is a transition of the unpaired electron from one molecule to another, and the transition frequency ν is greater than the line width (in terms of frequency units), a broadening of the lines in the spectrum is observed and then (when $\nu > \gamma a$) also blurring of the hyperfine structure. This phenomenon was used as early as 1954 by Weissman[68] to study the electron exchange between paramagnetic molecules. However, the reaction rate must not be less than 10^7–10^8 s^{-1}. [The author probably means that the bimolecular rate constants lie in the range 10^7–10^9 l mole^{-1} s^{-1} (Ed. of Translation)]

The rates of electron exchange in paramagnetic complexes can be studied similarly. Exchange of this type in aqueous solutions of copper(II) complexes of ethylenediamine, ammonia, etc. has been studied in detail by Voevodskii and Zamaraev[61]. The observed effect is the broadening of all the components of the quadruplet signal of Cu^{2+} ions with decrease of the concentration of copper $(Cu)_0$ and then

$$\Delta H_i = \Delta H_i^{\circ} + \frac{k_1}{[Cu]_0} .$$

It has been shown[69] that in the region of line narrowing due to exchange the principal contribution to the variable component of line width ΔH_i^* comes from the isotropic hyperfine interaction, and

$$\gamma \Delta H_i^{\bullet} = \frac{5}{4} \frac{a_{Cu}^2}{\omega_l} .$$

Thus $\omega_i = k_i[Cu]_0$ and the exchange rate constant can be determined at room temperature:

$$k_i \simeq 10^9 \text{ litre mole}^{-1} \text{ s}^{-1}.$$

Finally, the broadening of the ESR line may also be used to investigate a rapid kinetic process such as collisions in a liquid[39]. At high concentrations of stable radicals line broadening δH_l is observed, associated with exchange relaxation during collisions, as suggested by Buchachenko. If p is the probability of such relaxation on collision, then the exchange frequency is

$$\nu_i = \gamma \delta H_i = p k_2 \frac{Z n_r}{n_s} ,$$

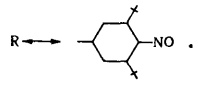
where k_2 is the number of collisions per unit time, n_r and n_s are the concentrations of the dissolved radicals and solvent molecules, and Z is the coordination number of the cage.

Assuming that $p \simeq 1$ and measuring the broadening δH_i at various n_r, it is thus possible to determine k_2 and, by making measurements at various temperatures, also the activation energy for the collisions. For 2,4,6-tri-t-butylphenoxyl in benzene and ethylbenzene, we have

$$k_2 = 3.5 \times 10^{-10} \exp\left(\frac{-2200}{RT}\right) \text{ cm}^3 \text{ s}^{-1}.$$

Recently Buchachenko and coworkers initiated on the investigation of collisions between the ends of the same molecules by studying line form changes in the ESR spectra

of biradicals and polyradicals[70]. They managed[70] to investigate the ESR spectra of nitrogen oxide radicals of the form R'–R, $ROOC(CH_2)_4COOR$, and others, where



It was found that the hyperfine structure corresponds to splitting by all the nitrogen atoms. Since in this case there is no possibility of electron delocalisation, it was suggested that electron exchange takes place as a result of the collisions between the paramagnetic ends of the molecule on the "claw" principle. In fact the frequency of the "averaging out" of the hyperfine structure proved to depend on the temperature and the structure of the central bridge. On the basis of a model involving special modulation of isotropic hyperfine interaction, developed by Freed and Fraenkel[44], it is possible to calculate further the frequency of the exchange interaction by the formula

$$\Delta H_i(\pm 1) - \Delta H_i(\pm 2) = \frac{1}{8}\gamma a_N^2/\nu_i ,$$

where $\Delta H_i(\pm 1)$ is the line width for the components with $\Delta m_N = \pm 1$ and ± 2 and a_N is the constant for the hyperfine splitting by nitrogen. It has been found that, for biradicals with pronounced exchange, ν_i is in the range 10^7–10^8 s^{-1}, with $\nu_i^0 \simeq 10^8$–10^9 s^{-1} and $E_i \simeq 1$–3.5 kcal mole^{-1}.

Thus application of electron spin resonance in the study of reactions in gas and liquid phases has been developing in the following ways.

1. The study of the mechanism of complex reaction by analysing (on the basis of the ESR spectra) the structure of the radicals formed in the process.
2. The determination of the rate constants for various radical reactions from the changes in the intensity of the ESR signals. Here the ESR method is used as a very sensitive and selective analytical procedure.
3. The determination of the mechanism and kinetic constants of fundamental reactions from the steady-state concentrations of the paramagnetic centres generated by the chemical reaction or external radiation (for a known rate of initiation).
4. Quantitative study of fast chemical and physicochemical processes (exchange reactions, collisions) on the basis of the changes in the width and form of ESR lines as a result of the paramagnetic relaxation induced by these processes.

3. Reactions in Solids

The study of chemical processes in the solid phase by the ESR method must be considered in greater detail, since in this field electron spin resonance is at present the most universal method for the investigation of fundamental reactions. The application of the ESR method led to the discovery of a very interesting field of radical chemistry, previously experimentally inaccessible, the study of radical reactions initiated by light, hard radiation, and chemical reactions in solids.

Examination of the specific questions associated with the application of electron spin resonance in photochemistry and radiation chemistry (the so called high-energy chemistry) is outside the scope of the present review. Here only the most interesting advances in this field will be briefly described (see Voevodskii's review[71]). By the stabilisation of radicals at low temperatures, the primary radicals formed on irradiation proved to be so stable that their chemical structure can be determined by the ESR method and sometimes it is possible to obtain information about their geometrical structure and orientation in the matrix. The study of the chemical nature of radiation damage at the instant when only a fraction of 10^{-8}–10^{-10} of all the molecules have been damaged leads of course to a completely new approach to the elucidation of the mechanism of this effect. ism of this effect.

A significant advance in these investigations was made in the Soviet Union in 1958–1960 when the formation of radicals during irradiation by ultraviolet light and fast electrons was investigated. Subsequent studies permitted a clear separation of the primary and secondary processes much more reliably than before, the determination of the radiation yields of chemical damage (i.e. the number of bond dissociations per 100 eV of energy absorbed), and the finding that the dominant chemical step in the radiolysis of hydrocarbons is the dissociation of C–H bonds. The same measurements led to unambiguous demonstration of energy migration preceding the primary dissociation and the formulation of the general hypothesis concerning the dependence of the radiation stability of hydrocarbons on structure (see, for example, Refs. 72 and 73). The structure of the ESR spectra showed that the breakdown of chemical compounds takes place with formation of the same radicals almost independently of the type of influence on the system —ranging from ionising irradiation and photo-irradiation to high-frequency discharge[74] and mechanical degradation[75]. It has also been shown that these influences can themselves initiate further reactions of the radicals produced[76–78].

In the field of purely photochemical investigations, the determination of the mechanism of a number of sensitised photochemical reactions[79], the observation and study of signals from triplet molecular states[80], and the study of two-quantum reactions[81] may be mentioned as interesting advances achieved with the aid of electron spin resonance. However, the application of electron spin resonance in the investigation of "stabilised" radicals is by no means confined to primary reaction steps. By studying the change in the ESR spectrum on heating the specimen, under the influence of various additives, and on repeated irradiation of the system with light of different wavelengths, etc., it is possible to obtain exceptionally interesting (both for radiation chemistry and for chemical kinetics in general) data on the mode and rates of the fundamental reactions in the solid phase, approximately in terms of the scheme formulated above for liquid-phase reactions. One of the most effective examples of reaction mechanism elucidation is the unambiguous demonstration of the existence of the so-called "adhesion" radical formed by a reaction of the type $H^{\cdot} + C_6H_6 \rightarrow C_6H_7^{\cdot}$.

The ESR spectrum of C_6H_7 radicals should of course differ sharply in its hyperfine structure (three lines with $a \simeq 46$ Oe × a quartet with $a \simeq 10$ Oe) from the spectrum obtained in the usual reaction of phenyl radicals C_6H_5 (four lines with $a = 18$ Oe × three lines each with $a = 8$ Oe).

C_6H_7 radicals were identified in solid benzene in 1961 (almost simultaneously) by Buben and coworkers[82], Fischer[83], and somewhat later by two groups of investigators in the USA[84,85]. Then it was shown, by direct experiments on the interaction between atomic hydrogen and benzene in the gas phase and the same reaction in the solid phase in a specially prepared solid matrix containing, at the beginning of the experiment, H atoms stabilised at 77 °K and molecules of aromatic compounds, that atomic hydrogen does indeed adhere to aromatic molecules. Analysis of the hyperfine structure of the ESR spectra of the radicals formed in the interaction of hydrogen atoms with various phenols actually permitted the determination of the site of adhesion of the H atom in each individual case[86].

One of the first quantitative studies on the kinetics of radical reactions was undertaken by Voevodskii et al.[85], who determined the rate constants for the reactions $R^{\cdot} + O_2 \rightarrow RO_2^{\cdot}$, $RO_2^{\cdot} \rightarrow R^{\cdot} + O_2$, etc. involving fluoroalkyl radicals in irradiated polytetrafluoroethylene and also measured the diffusion coefficients of O_2, H_2, and NO in Teflon and the radical recombination rate constants. Measurements were made at the same time of the heat of the reversible oxygen elimination reaction: $\Delta H_{R-O_2} = -6$ kcal mole^{-1}. Quite recently Janzen et al.[88] reported the measurement of the heats of the reaction of triphenylmethyl radicals with oxygen $\Delta H_{R-O_2} = -9$ kcal mole^{-1}. The radicals were obtained by γ-irradiation of triphenylacetic acid.

In principle, when the above methods are used for the measurement of concentration, the determination of kinetic curves (the time variation of the intensity of the signal) and their treatment by the usual methods of formal kinetics do not present special difficulties; for a unimolecular reaction, $\ln([R^{\cdot}]/[R^{\cdot}]_0) = -k_1 t$, for a bimolecular reaction, $1/[R] - 1/[R]_0 = k_2 t$, etc. However, further interpretation of these data does present a fundamental difficulty. The point is that when we measure by the ESR method say, the rate of disappearance of $R^{\cdot}$ radicals by the reaction $R^{\cdot} + R^{\cdot} \rightarrow M$ in a condensed phase, then the measured rate constant is not in general a fundamental constant. If we denote by k_m an average frequency of migration of the radical from one cage to another (diffusion coefficient $D = \frac{1}{6}\lambda^2 k_m$), then the number of collisions of radicals in a single cage with a volume V^* is $k_m V^*$. However, in the simplest case the probability of reaction is then $k_i/(k_i + k_m)$, where k_i is the rate constant for the intrinsic chemical reaction $|R^{\cdot} \ldots R^{\cdot}| \rightarrow M$ in the cage. Thus one measures the effective constant

$$k_2 = \frac{k_i k_m V^*}{k_i + k_m} . \qquad (4)$$

Consequently, for fast reaction where $k_i \gg k_m$, one measures essentially the rate constants for diffusion, $k_m V^* \sim D\lambda$, and only for slow reactions, where $k_i \ll k_m$, is it possible to measure the rate of the reaction itself. These considerations must be taken into account when electron spin resonance is used to study kinetic processes in solid and liquid phases. For reactions of stabilised radicals with mobile molecules, usually $k_m \gg k_i$, but when only stabilised radicals participate in the reaction, measurements are as a rule made on "diffusion" kinetics[89,90]. The cage effect can be taken into account similarly also in unimolecular decomposition reactions in the condensed phase; if k_i is the true rate constant for decomposition and k_t the rate constant for the reverse reaction in the cage, then the probability of emergence from the cage is $f = k_m/(k_m + k_t)$, and the measured rate constant for decomposition is

$$k_1 = \frac{k_i k_m}{k_m + k_t} = f k_i . \qquad (5)$$

With these simple hypotheses at our disposal, we shall examine in greater detail several examples of the application of electron spin resonance in the study of fundamental reactions in the solid phase.

a. Recombination Kinetics and Spatial Distribution of Paramagnetic Centres in the Solid Phase

When specimens containing free radicals accumulated in them at a low temperature (usually 77°K) are heated, the concentration of the radicals begins to decrease at certain temperatures and the kinetics of the recombination reaction can be studied from the decrease of the intensity of the ESR signal. It follows from the above considerations that it is then possible to measure the constants k_m, i.e. to obtain information about the mobility of free radicals.

Thus Buben and coworkers[91] measured the rate of recombination of radicals in irradiated cyclohexane near the gas-crystalline transition temperature state; the reaction kinetics were described by a second-order equation:

$$-\frac{dn}{dt} = k_2 n^2 \qquad (6)$$

and the measured radical mobility constant k_m agreed satisfactorily with the self-diffusion coefficients already available from NMR data. Similar measurements were made for a number of more complex organic substances and polymers at temperatures close to the melting point or a phase-transition temperature[87,89,92]; these measurements led to the hypothesis that in most cases the mobility of active centres is not determined by the diffusion of the molecules in the usual sense but by the transfer of the active centre by reactions of the type

$$R^{\cdot} + RH \rightarrow RH + R^{\cdot},$$
$$M^{-} + M \rightarrow M + M^{-} \quad \text{etc.}$$

However, in a very large number of cases the destruction of paramagnetic centres does not obey simple relations of the type of Eqn. (5). Two types of deviation are observed.

1. After heating at high initial radical concentrations, there is initially a sharp fall of the intensity of the ESR spectrum by a certain amount and then "steady-state" destruction begins described by Eqn. (6).[93]

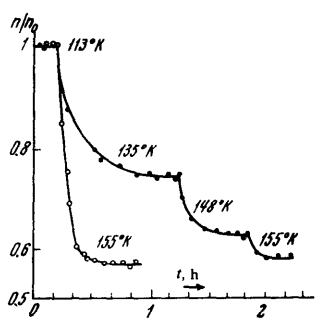


Figure 11. Stepwise kinetics of the recombination of free radicals in β-irradiated phenol[94].

2. The destruction of radicals at temperatures far removed from the melting point or a second-order phase transition is in most cases "stepwise", i.e. at each temperature a definite concentration of paramagnetic centres remains[94]. The experimental curves illustrating these phenomena are presented in Figs. 11 and 12. The behaviour of the destruction curves over a wide range of initial concentrations n_0 is independent of the latter, i.e. the curves can be made to coincide after replotting in terms of the coordinates n/n_0 and t. Nevertheless, the rate of normal recombination [Eqn. (6)] should depend significantly on n_0.

Both these kinetic phenomena can be explained if it is assumed that the paramagnetic centres are not distributed uniformly throughout the solid substance but in groups or

pairs[93,94]. Consequently the concentration of paramagnetic centres determined from the ESR signals does not reflect their true density in the specimen. Thus, we return to the problem formulated in Section II (Subsection 2)—the problem of the measurement of local concentrations of paramagnetic species. Attempts at such estimates were made on the basis of the measurement of the dipole–dipole contribution to the ESR line width either directly[10] or by the method of successive saturation[14,17,18] and the electron spin-echo method[13]. In general, these measurements confirmed (so far semiquantitatively) the conclusion concerning the possibility of non-uniform distribution of radicals in irradiated solids. Similar non-uniform distribution of paramagnetic centres has been detected in frozen solutions of stable radicals (diphenylpicrylhydrazyl[95]) and in a non-radical system[96] (frozen solutions of the ions Mn^{2+} and Gd^{2+}), where the non-uniformity is due to segregation. The study of this effect is also very important chemically.

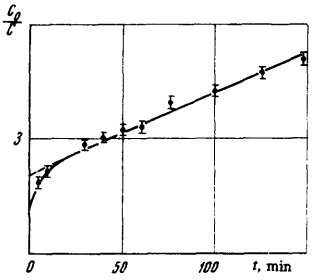

Figure 12. Kinetics of the recombination of free radicals in γ-irradiated polyethylene (according to the data of A.Arvia et al., see Lebedev[93]) [This is probably a reference to A.J.Arvia, F.Cracco, and M.Dole, J.Chem.Phys., 37, 2449)1962) (Ed. of Translation).]

At the present time new data have been obtained by the ESR method, concerning the non-uniform distribution of "heavy" radiation defects and also of dissolved paramagnetic centres in crystallising systems.

b. H–D Exchange Reactions of Free Radicals in Irradiated Amino-Acid Single Crystals.

Isotope exchange is one of the direct methods for the investigation of mechanism and reactivity and therefore the present author attaches great interest to the data published recently concerning the solid-phase H–D exchange in free radicals stabilised in irradiated single crystals of amino-acids—alanine[97], aspartic acid[98], and (indirect data) glycine[99]. The authors of these investigations made no attempt to explain in detail the chemical mechanism of the reactions, but it was shown that the ESR method reveals the successive substitution of H atoms in the aliphatic chain in partially deuteriated (at the sites containing mobile protons) amino-acids, and a detailed investigation of the kinetics of the changes in the ESR spectra made gave the kinetic constant for the reactions of aspartic acid. Together with Almanov, the present author made a similar study[100] of possible H–D exchange in the previously uninvestigated single crystals of DL-serine (monoclinic system, symmetry class C_{2h}, monoclinic angle 106°) grown from a solution in 90% D_2O:

$$DO{-}CH_2{-}CH(ND_3^+){-}CO_2^-.$$

After irradiation at room temperature from a cobalt-60 γ-source with a dose of about 20 mrad, the ESR spectrum was as in Fig. 13*a*, which corresponds (see Section II, Subsection 4) to radicals of the type

$$DO{-}CH_2{-}\dot{C}H{-}COOD.$$

In the orientation corresponding to $H_0 \parallel b$, $\Delta H_\alpha = 23$ Oe, $\Delta H_\beta = 40$ Oe, and $\Delta H_{\beta'} = 14$ Oe. On further heating of the single crystal to 50–100°C, the ESR spectra changed significantly, as shown in Fig. 13*c*, the total concentration of radicals not decreasing by more than 20%. Analysis of the structure of the ESR spectra presented in Fig. 13 indicates the occurrence of the following consecutive reactions:

$$-CH_2{-}CH_2 \xrightarrow{(1)} CHD{-}CH{-} \xrightarrow{(2)} -CDH{-}CD{-} \xrightarrow{(3)} -CD_2{-}CD-.$$

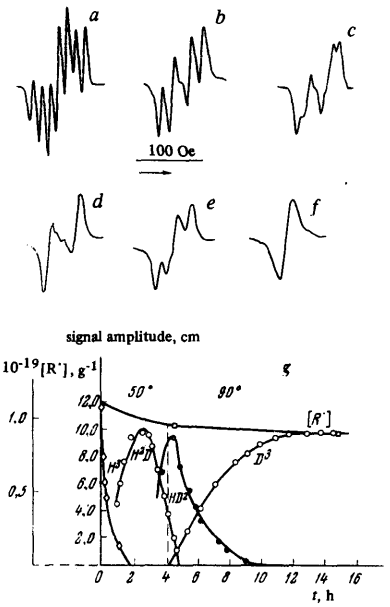

Figure 13. An example of the investigation of H–D exchange in the solid phase—exchange undergone by free radicals in γ-irradiated DL-serine[98]:
a) ESR spectrum obtained after γ-irradiation of a deuteriated single crystal at room temperature; *b*)–*f*) changes in the spectrum as a result of successive heat treatment for 2 h at 50°C (*b*), 4 h at 50°C (*c*), 2 h at 90°C (*d*), 4 h at 90°C (*e*), and 10 h at 90°C (*f*); *g*) kinetics of the change in the overall concentration of R· and the concentration of radicals corresponding to different degrees of substitution of α- and β-protons by deuterium.

Fig. 13*g* shows the kinetic curves determined from the intensities of the corresponding components of the hyperfine structure, which also indicate the occurrence of the irreversible consecutive reactions $H^3 \rightarrow H^2D \rightarrow HD^2 \rightarrow D^3$. The variation of the reaction rate with temperature corresponds to $E_1 \simeq 25$ kcal mole^{-1} and $k_1^0 \simeq 5 \times 10^{13}$ s^{-1} for reactions (2) and (3); according to previous data, E does not differ appreciably from E_1, but k^0 is significantly smaller than k_1^0. The findings described here are thus

almost completely consistent with the results obtained earlier for alanine and aspartic acid[97,98].

On the basis of the available data[97-100], the following interesting features of H–D exchange reactions in the solid phase may be noted.

1. The reaction involves free radicals only.
2. The reaction is stereospecific, i.e. the protons located in different positions relative to the free valence are substituted in a definite sequence. Of the two β-protons, the one whose hyperfine splitting constant is smaller is substituted first.
3. In irradiated methylsuccinic acid the reaction virtually does not take place, although the radical formed is quite similar (H^3).
4. The reactions are irreversible up to the complete substitution of all the hydrogen atoms in the radical.

The last finding immediately excludes the hypothesis that the exchange takes place within the limits of a single molecule or crystal unit cell: since $\Delta G \simeq 0$, equilibrium should then be established between the deuteriated and the initial radicals. It must be postulated that the exchange reaction is of second order and the concentration of H donors is much higher than the concentration of radicals, i.e. there is a possibility of the transfer of deuterium and hydrogen atoms over long distances, a possibility which has been frequently postulated to account for the kinetics of radical reactions in solids[74,90]. The present author believes that in the present concrete case the transfer of deuterium atoms can be achieved via molecules of D_2O of crystallisation, which are known[101] to be entrained in crystalline amino-acids in an amount approximately equal to the number of molecules of the acid and which probably acquire diffusional mobility at 50–100°C. Then the exchange mechanism can be represented thus:

$$-CH_2-\dot{C}H- + D_2O \rightarrow -CH_2-\underset{\displaystyle D}{\overset{\displaystyle O}{\overset{/\quad\backslash}{C}}}-CH- \rightarrow -\dot{C}H-CHD + HDO,$$

$$-\dot{C}H-CHD- + D_2O \rightarrow -CHD-\dot{C}D- + HDO,$$

$$-CHD-\dot{C}D- + D_2O \rightarrow -CD_2-\dot{C}D- + HDO.$$

The suggested reaction mechanism explains in broad outline the experimental findings 1–4, but is of course only a preliminary hypothesis. In principle, the role of D_2O can be fulfilled by D_2 or ND_3 (however, $[D_2]$, and $[ND_3] \simeq [R^\cdot]$, while $[D_2O] \gg [R^\cdot]$). On the other hand, the general conclusion concerning the possibility of a solid-phase bimolecular exchange reaction in which the rate-limiting stage is the transfer of hydrogen seems to be adequately justified. Further study of the kinetics of such reactions can provide valuable information about fundamental processes in the solid phase.

c. Kinetics of the Polymerisation of the Oligomers of Acrylate Esters

The description of the application of electron spin resonance in the study of polymerisation reactions might have constituted a large section of the present review‡. One may refer to studies on growing-chain radicals[102,103], the cross-linking of polymers under the action of radiation[104], etc. However, here this problem is examined only as part of the general problem of solid-phase reactions, using a single concrete example.

‡ See, for example, the review of Buchachenko et al. on electron spin resonance in polymers[114].

Korolev et al.[105] made a series of studies by the ESR method on the initiation of polymerisation and polymerisation kinetics at advanced stages. They investigated the ESR signals from radicals entrained in the course of thermo- or photo-initiation of the three-dimensional polymerisation of acrylate ester oligomers—such as butylene glycol dimethylacrylate and others. They used phenyl peroxide, azobisisobutyronitrile, etc. as initiators. The typical radical accumulation curve in thermally initiated polymerisation has a maximum, according to Smirnov et al.[105] The decrease of the intensity of the ESR signal after prolonged periods is evidently associated with the disappearance of the initiator. In accordance with Eqn. (5) derived above, the rate of decomposition is

$$W_i = fk_i[I]_0 e^{-k_i t},$$

where f is the efficiency of the initiation and $[I] = [I]_0 e^{-k_i t}$ is the initiator concentration. The equation describing the accumulation of radicals is

$$\frac{d[R^\cdot]}{dt} = W_i - k_2[R^\cdot]^2,$$

whence

$$[R^\cdot] = \sqrt{\frac{W_i}{k_2}}\tanh\sqrt{W_i k_2}t),$$

at small values of t, i.e. at the beginning of the curve we have

$$[R^\cdot] \simeq W_i t = fk_i[I_0].$$

For large values of t, one may assume that $\tanh(\sqrt{W_i k_2}t \simeq 1$: then $\ln[R^\cdot] = \text{const.} - \frac{1}{2}k_i t$.

Hence it is clear that one can estimate from the experimental curve a quantity which is very important chemically —the initiation efficiency. Admittedly, it is assumed that the radicals which did not emerge from the cage give rise to the same initiator I molecule. The photo-initiation kinetics can be investigated similarly. In particular, Smirnov et al.[105] concluded that polymerisation in the systems investigated is initiated by a radical-acceptor mechanism of the type

$$R_i^\cdot + \underset{|}{\overset{|}{CH_2}} \rightarrow R_iH + \underset{|}{\overset{|}{\dot{C}H}}.$$

This conclusion is confirmed by the ESR spectra of radicals (doublet with a splitting of 22.5 Oe) recorded at −10°C. On raising the temperature to 80°C, it is converted into a signal of the growing-chain radical, which is subsequently in fact entrained in the polymer.

d. Detection of Radical Pairs and the Study of the Cage Effect

The characteristics of chemical reactions in condensed phases can be associated to a large extent with the Franck–Rabinowitch cage effect, which so far has been inferred solely from kinetic data, since there exists no direct method for the detection of species in the "cage". Nevertheless, in principle the ESR method makes it possible to distinguish the free radicals in the "cage" from isolated radicals, since the mutual approach of paramagnetic centres to a distance up to 5–10 Å should entail the appearance in the ESR spectrum of dipole–dipole and exchange interaction of electron spins. Recently data have been published on ESR spectra of radical pairs stable at the temperature of the measurement for large concentrations of radicals entrained in single crystals[106,107] and glasses[108].

The radical pairs formed in the cage during a real chemical process cannot of course be stable, but, if their steady-state concentration is not too low, it is evident from what has been said above that in principle they might be detected by the ESR method. Recently the present author succeeded in showing[109] that "active" radical pairs can indeed be detected directly during the low-temperature photochemical decomposition of azobisisobutyronitrile (AIBN) and in measuring the probability of the emergence of the radicals from the "cage" by the ESR method. AIBN is known to decompose readily into two radicals with evolution of a nitrogen molecule; by virtue of the high rate of initiation of the pairs and the relatively large distance between the radicals in the cage, relatively high concentrations of pairs can be obtained in this case. Earlier the present author observed together with Shuvalov and Zhuravleva[110] that, apart from the ESR spectrum due to the radicals $(CH_3)_2C(CN)$, which consists of a septet (a_H = 21 Oe) of triplets (a_N = 7 Oe) (see the analysis of this spectrum in Fig. 14), a signal unusual for this system, namely a doublet with a splitting of about 160 Oe and an additional hyperfine structure, appears in the first minutes of the photolysis of AIBN. Next the author postulated that this signal is due to radicals which failed to emerge from the cage, and carried out spectroscopic and kinetic studies which confirmed this hypothesis.

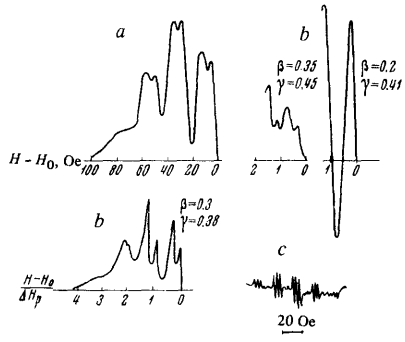

Figure 14. Analysis of the ESR spectrum of the cyanoisopropyl radical based on the comparison with calculated line form: *a*) ESR spectrum of the radicals produced in the photolysis of azobisisobutyronitrile; *b*) calculated spectra corresponding to different ratios $\beta = \Delta H_n/a_N$ and $\gamma = a_N/a_H$; *c*) spectrum obtained in the thermal decomposition of azobisisobutyronitrile in the liquid phase[110].

AIBN specimens obtained in the form of a crystalline powder were photolysed with light from a DRSh lamp in the resonator of an EPR-2 spectrometer of the Institute of Chemical Physics at 77°K; to prevent heating by the light, the tube with the specimen was filled with liquid nitrogen. When the light was switched on (effective spectrum with $\lambda < 330$ nm), the signal I shown in Fig. 15*a* appeared—a doublet with a splitting of 160 Oe and an additional hyperfine structure consisting of 11 lines with intensity ratios of approximately 1 : 5 : 20 : 45 : 75 : 90 : 75... In the course of further photolysis this spectrum is accompanied by the appearance of another (Fig. 15*b*), which is stable at 77°K, while the doublet signal disappears 30 s after the light is switched off (Fig. 15*c*). When the experiments were performed with isolated crystals, there appeared in spectrum I yet another similar system of lines II, the doublet splitting in which changed from 0 to 300 Oe on rotating the crystal. Spectra I and II can be attributed to the radical pair (R'...R'), since here one should in fact observe spin-spin splitting, changing on rotation of the single crystal from $D_\perp = D_0$ to $D_\parallel = -2D_0$ according to the law $D = D_0(1-3\cos^2\theta)$. The orientation-independent signal in the single crystal can be due to an admixture of an amorphous phase or other causes, which are not discussed here, since we did not have at our disposal "true" single crystals with indexed crystallographic axes. Therefore the principal conclusions were based on the study of the signals I in polyoriented specimens.

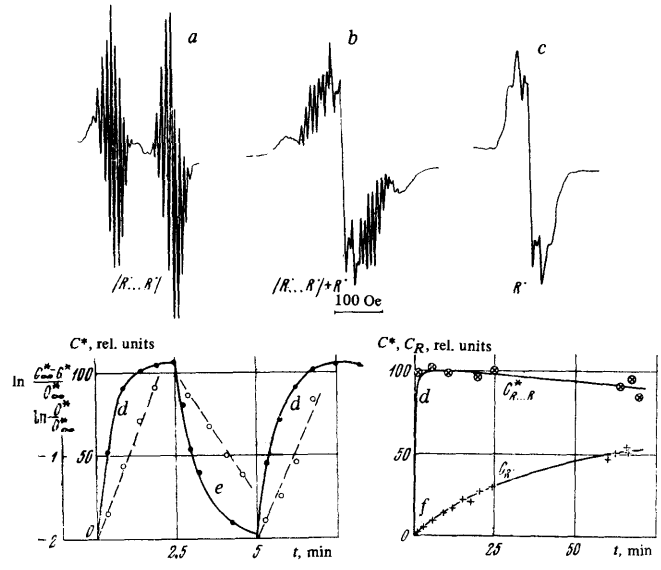

Figure 15. ESR spectra (*a*, *b*) and the kinetics of the formation (*d*) and destruction (*e*) of radical pairs and radicals [*c*) spectrum; *f*0 accumulation kinetics] in the photolytic breakdown of azobisisobutyronitrile[109].

At first sight the possibility of the observation of a strongly anisotropic signal in polycrystalline specimens appear strange. However, the point is that in the case of axial splitting anisotropy, which obtains here, the probability of perpendicular orientations is greatly enhanced and the spectrum shows almost only the lines corresponding to this orientation. Fig. 16*b* shows a calculated ESR spectrum made up of "asymmetric" lines (without taking into account the additional hyperfine structure)[25]. This spectrum agrees satisfactorily with the experimentally observed spectrum of AIBN powder when the latter is recorded over a wide range of scan of the magnetic field and the hyperfine structure is artificially "blurred" (Fig. 16*a*). Analysis of the experimental spectra showed that the splitting of 160 Oe observed in experiments with AIBN powder corresponds to $D_\perp$, which in turn corresponds to dipole–dipole interaction between electron spins over a distance of 5.6 Å, approximately the same as the distance between the radicals in the initial molecule. Finally, the additional hyperfine structure can be due to splitting by the 12 protons present in the pair (only 11 lines are shown, since the two

extreme components have an intensity lower by a factor of 10; the calculated intensity ratios of the observed 11 components, 12 : 66 : 220 : 495 : 792 : 924 : 792:..., are in agreement with experiment). It is interesting that the splitting by the protons is smaller by a factor of 2 than in isolated radicals and that all the protons are equivalent, in agreement with the theoretical postulate of Kurita and Kashiwagi[107], according to which the structure of the spectrum of the radical pair is described by the relation (taking into account the fact that $a_N \ll a_H$):

$$H = \frac{h\nu}{g\beta} \pm \frac{D}{2} - \frac{1}{2}\sum a_H m_H .$$

In contrast to the work of Kurita and Kashiwagi[107], who investigated stable radical pairs in dimethylglyoxime, the present author failed to observe signals corresponding to $\Delta M_S = 2$, which is probably due to an insufficient concentration of the pairs and the fact that the intensity of the signal with $\Delta M_S = 2$ is smaller approximately by three powers of 10 than the intensity of the main spectrum.

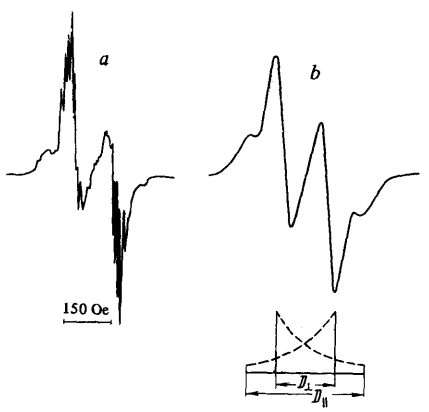

Figure 16. Experimental and calculated (without hyperfine structure) line form of the ESR signal due to polyoriented radical pairs.

It is also interesting to note that in their experiments on the low-temperature photolysis of AIBN, Ayscough et al.[111] obtained an ESR spectrum which they interpreted as a quintet with a splitting of 60–70 Oe and attributed to the radical R–N=N·. The present author regards this interpretation as insufficiently unambiguous, since the spectrum recorded with the signal only slightly greater than the noise can constitute the sum of the spectra of the "pair" |R·...R·| and isolated cyanoisopropyl radicals (see Fig. 15*c*).

Fig. 15 presents the result of an investigation of the kinetics of the accumulation and destruction of "pairs" and also the accumulation of radicals; these results are consistent with the above hypotheses. The transformed curves in Fig. 16*e*–16*f* show that the accumulation of "pairs" on illumination and their disappearance in the dark are consistent with destruction by a first-order reaction with approximately the same rate constant $k_1 = 0.03 \pm 0.01$ s^{-1}. On the basis of the usual kinetic mechanism of "cage" decomposition [Eqn. (5)], it is not difficult to show that the ratio of the initial yields of individuals radicals and radical pairs is equal to the probability of the emergence of the radicals from the cage. Nor can one exclude the possibility that the photochemical decomposition of AIBN takes place by the mechanism

$$M \rightsquigarrow |R\cdot\cdots R\cdot|^* \rightarrow R\cdot + R\cdot$$
"hot" pair
$$\downarrow$$
$$M' \leftarrow |R\cdot\cdots R\cdot|$$
thermolysed pair

which differs somewhat from the "classical" mechanism, but such a change in mechanism does not affect the determination of f. From the data in Figs. 15*d*–15*f*, one can estimate that $f = (1\text{–}3) \times 10^{-2}$, which is in satisfactory agreement with the value of f obtained by Smirnov et al.[105] for the decomposition of AIBN in polymeric matrices (admittedly for very much higher temperatures).

The following equation has been obtained for the rate constant for the destruction of cyanoisopropyl radicals in the AIBN cage in the temperature range 63–77°K:[112]

$$k \simeq 10^8 \exp(-3500/RT)\ (s^{-1}).$$

Thus with AIBN as an example, it proved possible to investigate directly the cage effect by the ESR method§. The possibility of direct determination of the probability of emergence from the cage and the constants for the decomposition and entrainment of radical pairs can prove extremely useful for the elucidation of the detailed mechanism of the cage effect. To an equal extent, it is interesting to investigate the structure of the spectra of radical pairs, the electronic structure of which has much in common with the electronic structures of both molecules in the triplet state and activated complexes in recombination–dissociation reactions.

---o0o---

The scope of the application of electron spin resonance in the study of the kinetics and mechanism of chemical processes has been examined. A fairly wide range of problems has been covered, but certain specific questions, such as the study of catalysis and reactions on the surface, electrochemical reactions, biological processes, etc. have not been touched upon at all. It should be understood that the separation of problems associated with the study of the kinetics and mechanism of reactions from structural and chemical investigations is purely arbitrary. Frequently such investigations are carried out simultaneously. In particular, one of the most interesting problems of chemical physics involves the comparison of data on the structure and kinetics (reactivity) of free radicals. Electron spin resonance is a very suitable method for this purpose, because for example, it makes it possible to measure the spin density of the unpaired electron ρ_S at different centres (the spin density is in some measure usually related to electron density) and to determine simultaneously the rate constants for the reactions of the atoms split off. In principle, one may hope to observe a correlation between these two quantities, which would permit the prediction of chemical activity on the basis of hyperfine structure data. However, sufficient quantitative data are not as yet available for a test of such a correlation. Thus in the studies on H–D exchange[97–100] described towards the end of Section III the hyperfine structure constants and H–D exchange rate constants for all the protons (α, β, and β') of the aliphatic chain were determined for three substances. However, the difference in the rates is due to the differences

§ At the present time radical pairs have been investigated also in the decomposition of tetraphenylhydrazine and certain organic peroxides[115].

between the pre-exponential factors and is probably associated with geometrical factors. The activation energies E (the correlation of which with ρ_S appears most likely) are indistinguishable because of the considerable error in the determination. Admittedly, more promising results have also been published recently. For example, Solodovnikov et al.[113] investigated by the ESR method the distribution of spin density in 4-aryl-2,6-di-t-butylphenoxy-radicals simultaneously with the investigation of the reactivity of these radicals in reactions with peroxides and oxygen. The measured activation energies range from 9.9 to 11.9 kcal mole^{-1}, the accuracy being 0.2 kcal mole^{-1}. Carbon-13 has been used to measure the spin density at a reaction centre—the tertiary carbon atom of the C_6H_5–C_6H_5 bond. A fairly clear correlation between ρ_S and E was obtained in this investigation.

Even the artificially restricted range of problems which could be discussed here appears to show quite convincingly that the ESR method has already found wide application in chemical studies but that its possibilities are by no means completely discovered. Further development of the application of electron spin resonance in chemistry will probably involve both thorough and comprehensive use of the information contained in the ESR spectra and a rational combination of the ESR method and other physical and chemical techniques.

Oxidation of Sterically Hindered Phenols

L.M.Strigun, L.S.Vartanyan, and N.M.Emanuel'

The homolytic oxidation of sterically hindered phenols has been reviewed. The possible criteria of the reactivity of phenolic compounds, the properties of phenoxy-radicals–the primary products of oxidation by bound oxygen in non-polar media, and the kinetics of the reactions of phenoxy-radicals in the presence and absence of oxidants, have been discussed. Particular attention has been devoted to the oxidation of sterically hindered phenols in polar media by molecular oxygen, which exhibits a number of characteristic features. The bibliography comprises 84 references.

V.	Oxidation of sterically hindered phenols by molecular oxygen in polar media	430

I. INTRODUCTION

In recent years there has been an exceptionally vigorous development of the chemistry of sterically hindered phenols. To a high degree, this is due to practical requirements, the phenols being used to suppress undesirable free-radical (chain) processes. Various sterically hindered phenols are widely employed as effective antioxidants for the stabilisation of polymers, for the inhibition of the oxidation processes of fats used as food, etc.[1,2]

Considerable interest attaches to the chemistry of phenols from the standpoint of their role in biochemical processes[3]. In this connection the study of the mechanism of the oxidation processes of sterically hindered phenols assumes special importance. The present review deals with the homolytic oxidation of sterically hindered phenols. Reactions of type (1) and (2) take place under the influence of homolytic oxidants:

$$R_2R'H_2C_6O{-}H \rightarrow R_2R'H_2C_6O\cdot + \cdot H\ , \qquad (1)$$

$$(R_2R'H_2C_6O{:})^- \rightarrow R_2R'H_2C_6O\cdot + e\ . \qquad (2)$$

Processes of the first type include reactions of phenols with peroxy-radicals[4,5], diphenylpicrylhydrazyl (DPPH)[6,8], and tri-t-butylphenoxy-radicals[9,10]. One-electron processes of type (2) take place under the action of oxidants such as potassium hexacyanoferrate(VI)[11-14], potassium permanganate[15], cerium sulphate[16], and molecular oxygen in alkaline media[16,17]. The products of reactions (1) and (2) are phenoxy-radicals. Most of the work on the oxidation of sterically hindered phenols has been devoted to the identification of the phenoxy-radicals, the study of their properties, the reactions with oxidants, and the identification of the final oxidation products. On the other hand, the studies on the kinetic features of the behaviour of phenoxy-radicals are relatively few. In the examination of the available data on the oxidation of sterically hindered phenols particular attention will be given to the kinetics and mechanism of oxidation.

II. CRITERIA OF THE REACTIVITY OF PHENOLIC COMPOUNDS

The ease of the homolytic dissociation of the O–H bond in phenol is due to the dissociation energy of this bond. Accurate values of bond dissociation energies have been

determined mainly for simple organic molecules[18]. Accurate bond energies have been obtained only quite recently for several sterically hindered phenols[19]. To a first approximation, the dissociation energy of the PhO–H bond ($D_{O...H}$) may be regarded as the energy of the highest occupied molecular orbital (E_{HOMO}).[20-22] Consequently the change in the overall π-electron density at the oxygen atom (q_0) on going from one phenol to another, differing in the substituents, determines the differences in the dissociation energies of the O–H bonds in these phenols[23] and hence also the different capacities of the phenols to undergo oxidation. The effect of substituents is shown to the greatest extent when the substituent and the OH group are in the same conjugation system, i.e. are located in the *ortho*- or *para*-positions relative to one another[24,25]. The influence of the substituent in the *meta*-position is due solely to the inductive effect, since the conjugation effect of the *meta*-substituent is zero. Since the inductive effect decreases rapidly with distance[26], in the studies of the relative reactivities of sterically hindered phenols appreciable differences in reactivity may be expected in phenols having different substituents in the *para*-position.

Electron-donor substituents in the *para*-position increase the overall π-electron density at the oxygen atom[22], while electron-acceptor substituents decrease it. To characterise the capacity of the phenol for participation in a reaction involving the dissociation of the O–H bond, q_0 and E_{HOMO} will be used as the parameters of reactivity. Quantum-mechanical study of the activity of phenolic compounds as inhibitors of oxidation processes established a satisfactory correlation between the inhibiting activity of phenolic compounds and q_0 and E_{HOMO}.

Earlier it was established empirically that the activities of phenols as oxidation inhibitors are proportional to their redox potentials (v_0).[26,27] For certain stable phenol–phenoxy-radical systems, v_0 may be determined directly[27,29]; however, most of such systems are unstable under the conditions necessary for the determination of the potential. Fieser[30] proposed a method for the determination of v_0 of unstable redox systems, which consists in the determination of the potential of a stable redox system in the presence of the unstable system. In such cases one measures the minimum potential at which the rate of electron transfer from the phenol to the reference oxidant reaches a minimum value. This potential is called the "critical potential" v_c. For monohydric phenols, $v_c = v_0 - 0.136$ V, i.e. the critical potentials of the systems indeed characterise their redox potentials.

Calculations show the presence of a linear relation between the experimental criterion v_c of the capacity of phenols to be oxidised and the calculated reactivity parameter q_0 [20] and E_{HOMO}.[21] Hush[20] showed that $v_c = 3.0\,(q_0 - 1) - 0.55$ V. The highest occupied molecular orbital of the phenoxide ion is a non-bonding molecular orbital (NBMO), whose energy can be calculated from the formula

$$E_{HOMO} = \alpha + (c_{nx})^2 k_x \beta\,, \qquad (3)$$

where α and β are the coulombic integrals of the carbon atom and the resonance integral of the C=C double bond respectively, c_{nx} is the coefficient of the NBMO of the oxygen atom, and k_x the coulombic parameter of the oxygen atom. Fueno et al.[21] calculated $(c_{nx})^2$ for 200 phenols by the NBMO method. Comparison of the known values of v_c with $(c_{nx})^2$ revealed a linear relation between the two quantities (Fig. 1), which can be described by the equation:

$$v_c = 2.807\,(c_{nx})^2 - 0.459\,. \qquad (4)$$

Since β is negative and k_x is positive, it is evident from a comparison of Eqns. (3) and (4) that the NBMO becomes more stable when $(c_{nx})^2$ increases and the less stable is the NBMO the greater is the ease of oxidation of the phenol. Thus the capacity of the phenol to be oxidised can be estimated from the value of $(c_{nx})^2$, which is linearly related to v_c. Using this relation, the authors calculated v_c for about 180 phenols. In addition it has been shown that for phenols $D_{O...H} = v_c + 57$ kcal mole^{-1}, which made it possible to estimate the dissociation energies of O–H bonds for certain phenols[20].

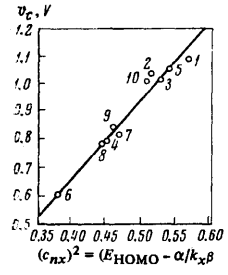

Figure 1. Variation of critical redox potentials of phenolic compounds with the energy of the highest occupied molecular orbital:

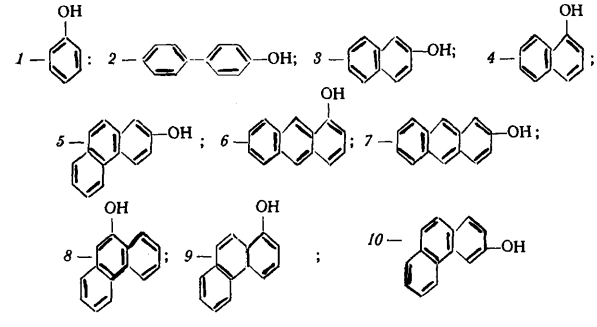
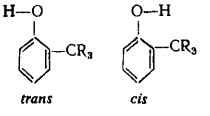


Another physicochemical quantity in which the dissociation energies of the bonds ruptured and formed in molecules of reactants and final products play a major role is the activation energy E_A. However, there is no exact correlation between E_A and bond dissociation energies, particularly in solutions, since effects associated with the electrostatic interaction between ions or dipoles and effects due to changes in solvation during the reaction are important for reactions in solution[31]. For this reason, the activation energies E_A cannot be used to estimate the relative reactivities. The determination of E_A is important for the study of the process mechanism (for example, in the determination of the rate-limiting stage or the changes in the mode of a complex process).

One of the important physicochemical characteristics of phenols dependent on the total π-electron density at the oxygen atom is the characteristic vibration frequency of the free hydroxyl ν_{OH}, which may be regarded as a measure of the polarity of the O–H bond[32]. The total π-electron density which has been increased, for example, by the introduction of electron-donor substituents in the *para*-position reduces the electronegativity of the oxygen atom and renders the coulombic integral of the σ-orbitals of oxygen more positive. This change in the coulombic integral then induces a change in the σ-electron structure of the phenol, particularly in the O–H bond[22], reducing the polarity of the latter[33]. Electron-acceptor substituents increase the

polarity of the O–H bond. The vibration frequency ν_{OH} increases with increasing bond polarity. However, experiments have shown[5,34,35] that the frequencies for phenols containing tertiary alkyl groups in the *ortho*-position are too high to be accounted for solely by their electron-donor properties. Thus, for *ortho*-substituted phenols, the average ν_{OH} is 3610 ± 2 cm^{-1}, for *ortho*-disubstituted phenols which do not contain two tertiary alkyl groups it is 3620 ± 2 cm^{-1}, and for phenols which do contain two such groups it is 3642 ± cm^{-1}.[35] Such powerful influence of tertiary alkyl groups in the *ortho*-position on ν_{OH} is due to two effects of these groups on the polarity of the O–H bond: in the first place the electron-donor effect and in the second the steric interaction of the tertiary alkyl groups with the hydroxyl, the O–H bond being coplanar with the benzene ring or nearly so[34,35]. Ingold's study of the infrared spectra of *o*-alkyl, *o*-t-alkyl-, and *o*-di-t-alkyl-phenols[34,35] showed that also other *o*-alkyl groups interact sterically with the hydroxyl, but this is restricted to the case where the OH group is oriented in the direction of the *ortho*-substituent.

According to Ingold[35,36], *o*-t-alkyl and *o*-alkyl-phenols exist in the form of two isomers corresponding to the *cis*- and *trans*-orientation of the hydroxyl relative to the *ortho*-substituent. Two bands have been observed in the infrared spectra of *o*-t-alkylphenols: the more intense band at the lower frequency corresponds to the *trans*-isomer and the less intense band at the higher frequency to the *cis*-isomer. These isomers have different properties. Thus, when the polarity of the solvent is varied, the *trans*-isomer behaves like phenol (with increasing polarity of the medium, ν_{OH} decreases appreciably), while the behaviour of the *cis*-isomer is similar to that of the corresponding 2,6-di-t-alkylphenol, which exhibits steric hindrance of the effect of the solvent[36,37].



Analysis of the half-width $\Delta\nu_{1/2}$ of the *o*-alkylphenol infrared band shows that the latter consists of two unresolved components. The fraction of the *cis*-isomer is determined by the bulk of the substituent in the *ortho*-position and also by the substituents in positions 5 and 6. In the *cis*-isomer there is steric repulsion between the phenolic hydrogen and the *ortho*-alkyl substituent, leading to an increase of frequency; in 2,6-di-t-alkylphenols there is a possibility of the interaction of the hydroxyl with the second t-alkyl group, reflected in the attraction of the unshared electron pairs of oxygen, which leads to a displacement of the absorption band towards longer wavelengths. These problems have been discussed in detail in Ingold's papers[35,36].

Attempts to use ν_{OH} as a criterion of reactivity were made in studies of the inhibiting activity of phenolic compounds. This criterion is based on the fact that the greater is the polarity of the O–H bond the greater is the displacement of the O–H band in the spectrum towards lower frequencies and the greater is the energy necessary for its homolytic dissociation and conversely. On this basis, it was to be expected that the inhibiting activity of a particular phenol can be assessed from the position of the free hydroxyl vibration band. Indeed comparison of the antioxidant activities and O–H bond polarities showed that the activity of monosubstituted phenol with different substituents in the *para*-position, expressed in terms of the ratio k_7/k_2 of the rate constants for the reactions

$$RO_2^{\cdot} + RH \xrightarrow{k_2} RO_2H + R^{\cdot},$$

$$RO_2^{\cdot} + C_6H_5OH \xrightarrow{k_7} RO_2H + C_6H_5O^{\cdot},$$

increases with ν_{OH}.[2] A rigorous linear relation between k_7/k_2 and ν_{OH} has been established[5] for phenols with substituents in the *ortho*-position, i.e. there is a proportional change in k_7/k_2 as ν_{OH} varies. However, for di- and trisubstituted phenols sterically hindered to different extents, there is a different relation. The efficiency of the inhibiting effect of phenols decreases with increasing ν_{OH} (Fig. 2). However, for phenols sterically hindered to the same extent there is again a possibility of a linear relation between k_7/k_2 and ν_{OH}.[5,38] Thus the use of ν_{OH} to estimate the relative reactivities is possible only within a series of phenols having similar steric structures. This is consistent with the results of the comparison of the inhibiting activities of phenols with the energies of the highest occupied molecular orbital[5]: the correlation curves for two groups of phenols (*o*-t-alkyl phenols and phenols without t-alkyl groups in the *ortho*-position) have different slopes.

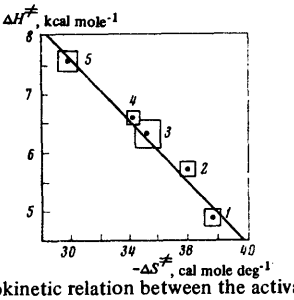


Figure 2. The isokinetic relation between the activation parameters: *1*) cyclohexane; *2*) benzene; *3*) chlorobenzene; *4*) anisole; *5*) benzonitrile.

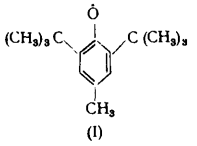
Table 1. Reactions of 2,6-di-t-butyl-4-R-phenols with peroxy-radicals.

R	k_7, litre $mole^{-1}$ s^{-1} (styrylperoxy-radical) (Ref.39)	k_7/k_2 (tetralkyl-peroxy-radical) (Ref.5)	ν_{OH}, cm^{-1} (Ref.5)	ν_{OH}, cm^{-1} (Ref.38)	σ (Ref.24)
H	$2.35 \cdot 10^3$	967	3640	3648	0
CH_3	$7.95 \cdot 10^3$	1990	3643	3651	—0.17
t-C_4H_9	$7.3 \cdot 10^3$	1430	3642	3650	—0.20
OCH_3	$31.2 \cdot 10^3$		3652	3652	—0.27

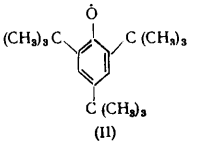
However, within a series of phenols with the same steric hindrance, the changes in frequency are small. Thus, for a series of *para*-substituted phenols, the difference in frequency between the extreme members, with *p*-NO_2 (σ = +0.78) and *p*-OH (σ = −0.46) groups, amounts to 23 cm^{-1}, the resolution being 2–3 cm^{-1}.[5] The introduction of an alkyl substituent in the *para*-position of 2,6-di-t-butylphenol increases the inhibiting activity by a factor of more than two, while the change in frequency amounts to 2–3 cm^{-1} (Table 1). All this restricts the use of ν_{OH} as a reactivity index.

III. PROPERTIES OF PHENOXY-RADICALS—PRIMARY PHENOL OXIDATION PRODUCTS

Phenoxy-radicals are fairly stable. Their lifetimes depend on the structure of the radical, the polarity of the medium, and the presence of an oxidant in the system. In polar media the lifetimes of sterically hindered phenoxy-radicals are measured in fractions of a second[39], and therefore the ESR spectra of radicals generated in the oxidation of phenols in polar media, obtained by the usual steady-state technique, refer to secondary radicals[18,40,41]. On the other hand, in non-polar solvents the lifetimes of primary phenoxy-radicals are measured in minutes and even hours[42]. In the presence of an oxidant the primary phenoxy-radicals are converted into more stable secondary radicals[43]. If, for example, after the preparation of the radical (PbO_2 oxidant in an organic solvent) the excess PbO_2 is separated and the solvent is distilled off, the radical remains stable for several months[43]. The stability of sterically hindered phenols is determined by the steric hindrance and delocalisation of the unpaired electron over the benzene ring. The delocalisation of the unpaired electron is reflected in the infrared spectra of phenols. The 2.7 μm band associated with the O–H bond vibrations vanishes from the infrared spectra and a double bond, with frequencies similar to those of the vibrations of the C=O double bond conjugated with a C=C double bond appears in the region 6.0–6.4 μm.[44,45]. The delocalisation of the unpaired electron is confirmed by the analysis of the ESR spectra of phenoxy-radicals. The ESR spectrum of the free electron should have $g = 2.0013$ and comprise a single resonance line. The ESR spectra of phenoxy-radicals have a hyperfine structure (HFS), reflecting the distribution of the unpaired electron over the π-electron system of the phenoxy-radical. For example, the spectrum of 2,6-di-t-butyl-4-methylphenoxy-radical (I) consists of four triplets with the intensity ratios 1 : 3 : 1, the intensity ratios within each triplet being 1 : 2 : 1; the spectrum of 2,4,6-tri-t-butyl-phenoxy-radical (II) consists of a triplet with the intensity ratios 1 : 2 : 1.[42,44]



(I)



(II)

The appearance of four lines in the spectrum of compound (I) is due to the interaction of the unpaired electron with the three equivalent protons of the CH_3 group and the splitting of each line into three components by the interaction with the two equivalent protons in the *meta*-positions of the ring. The degree of interaction of the unpaired electron with β-protons is low, since the effect associated with the hyperconjugation overlapping of the orbitals falls sharply with distance and therefore usually the spectrum of compound (II) consists of a triplet due to the interaction with the metastable protons of the ring. The degree of interaction of the unpaired electron with the ring is characterised by the hyperfine splitting constant a_H, which can be calculated from the ESR spectrum. The observed splitting is proportional to the spin density ρ^π at the corresponding carbon atom. According to Mc Connel's equation, $a_H = Q\rho_C^\pi$. Assuming that Q_{CH}^H and $Q_{CCH_3}^H$ are 23.7 and 27.2 Oe respectively, Stone and Waters[39] calculated from the ESR spectra of phenoxy-radicals the distribution of electron density in the ring.

The data of Table 2 are in good agreement with the absolute values of ρ for the unsubstituted phenoxy-radical, quoted by Buchachenko[44]: $\rho_o = 0.29$, $\rho_m = 0.08$, $\rho_p = 0.45$. The spin densities calculated for theoretical models of these radicals differ significantly from those quoted above. The simplest model[46] represents the radical as a benzyl cation in which only five electrons are associated with the ring, the splitting constants a_{H_o} and a_{H_m} being then identical. A more complex model[47] yields $\rho_o = 0.32$, $\rho_m = 0.21$, and $\rho_p = 0.28$ for phenoxy-radicals. Taking into account the dipolar character of the C–O bond, the following distribution of spin density has been obtained for tri-t-butylphenoxy-radicals by semiempirical calculations[48]:

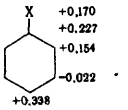


Table 2. Spin density of phenoxy-radicals[39].

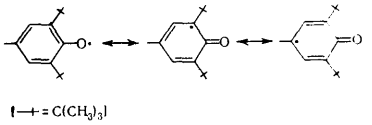
Radical from	ρ_o	ρ_m	ρ_p	$\rho_p+2(\rho_o+\rho_m)$
Phenol	0.28	−0.075	0.42	0.83
p-Cresol	0.25	−0.06	0.44	0.82
2,6-Dimethylphenol	0.24	−0.07	0.40	0.74
2,4,6,-trimethylphenol	0.22	−0.06	0.44	0.76

The negative spin density in the *meta*-position implies that the direction of the spin of the unpaired electron at the *meta*-carbon atom is opposed to the direction of the spin of the radical as a whole[48,49]. Possibly the density at the C_1 atom is also negative; it has been suggested[48] that it is similar to the density at C_3 and C_5.

Despite such differences in experimental data, one can say that the major part of the unpaired electron is associated with carbon atoms C_2 and C_6, 20–25% being associated with the oxygen atom and C_1.[6,39,44,50].

Thus ESR spectroscopy of phenoxy-radicals demonstrates the existence of several reaction centres, which can be represented by three mesomeric structures in equilibrium[13]:



(5)

The reactivity of the reaction centres is determined by the electron density at the corresponding carbon or oxygen atom. This permits the prediction of the possible mode of oxidation reactions of phenols and of the nature and relative amounts of the products.

The introduction of substituents into the phenyl ring causes a redistribution of the electron density, which is reflected in a change of the splitting constants. Alkyl substituents reduce the splitting constants for the *ortho*- and *para*-positions, and alkoxy-substituents reduce the splitting constants for the *ortho*-position to a much greater extent than do alkyl substituents and also to a much greater extent than the constants for splitting by the *meta*-protons of the ring[39]. Probably a considerable proportion of the unpaired electron of such radicals is associated with two oxygen atoms. Table 3 presents the splitting constants for sterically hindered phenoxy-radicals[44]. The constant for splitting by *meta*-protons depends little on the alkyl substituent in the *para*-position, while the constant for splitting by the α-protons of the *para*-substituent has been

found to vary markedly with its structure. The replacement of methyl by t-butyl leads to a decrease of the constant by a factor of more than two[44]. For *para*- and *ortho*-alkyl-substituted unhindered phenoxy-radicals, the constant for splitting by α-protons decreases in the sequence $CH_3 > C_2H_5 > n\text{-}C_3H_7 \simeq C_6H_5CH_2 > iso\text{-}C_3H_7 > s\text{-}C_4H_9$.[37] A relation of this kind cannot be explained solely by a change in spin density ρ^{π}; it is probably also related to changes in the constants $Q^{H}_{C\text{-}Alk}$. The value of $Q_{C\text{-}H}$ for α-CH groups depends on the orientation of the C–H bond in relation to the electronic symmetry axis and hence also on the average conformations of CH_2R or CHR_2 in relation to the benzene ring[39,44]: the α-CH groups coplanar with the CH groups of the ring make a bigger contribution than the CH-groups oriented at a large angle with respect to the ring.

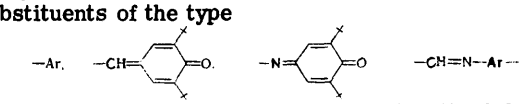
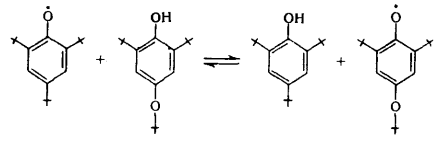
Buchachenko[44] made a thorough examination of the effect of the *para*-substituent on the splitting constants of sterically hindered phenoxy-radicals. The influence of the substituent can be explained by two factors: inductive and resonance effects. The inductive effect leads to a redistribution of the charges, which can lead to a change in spin density. The resonance effect implies the incorporation of the π-orbitals of the substituents in the general molecular orbital, resulting in a change of Q. At the same time there is a possibility of a redistribution of electron density. One can only put forward certain hypotheses concerning the effect of these factors on the splitting constants (see Table 15 in Buchachenko's book[44]). In a few cases one can speak of one or other effect predominating. Thus the increase in the stability of sterically hindered phenoxy-radicals on introduction into the *para*-position of substituents of the type



must be attributed to an increase in the length of the resonance conjugation chain, which favours greater delocalisation of the unpaired electron[43].

IV. FUNDAMENTAL REACTIONS OF PHENOXY-RADICALS: RECOMBINATION, ISOMERISATION, DISPROPORTIONATION, AND REACTION WITH OXYGEN

As already stated there are three reaction centres in phenoxy-radicals: the *ortho*- and *para*-carbon atoms and the oxygen atom. Only the *para*-carbon atom participates in the recombination reaction of sterically hindered phenoxy-radicals: the oxygen and *ortho*-carbon centres are blocked by bulky t-butyl groups. The capacity of 4-alkyl-2,6-di-t-butyl phenoxy-radicals for recombination is restricted by the bulk of the *para*-substituent: for example 2,4,6-tri-t-butylphenoxy- and 2,6-di-t-butyl-4-triphenylmethylphenoxy-radicals do not yield recombination products[44]. 4-Alkoxy-2,6-di-t-butylphenoxy-radicals exhibit higher stability in solution compared with alkyl derivatives. Direct comparison of the stabilities of 4-alkyl- and 4-alkoxy-2,6-di-t-butylphenoxy-radicals was achieved in experiments designed to investigate the equilibrium between phenoxy-radicals[9]. It was shown that the addition of a small amount of 4-butoxy-2,6-di-t-butyl phenol to a blue solution of 2,4,6-tri-t-butylphenoxy-radicals instantly results in the appearance of the red colour of 4-butoxy-2,6-di-t-butylphenoxy-radicals: on addition of a sufficient amount of 2,4,6-tri-t-butylphenol, the blue colour can be restored.



(6)

Spectrophotometric study of equilibrium (6) made it possible to estimate the equilibrium constant. The equilibrium constant for 4-butoxy-2,6-di-t-butylphenol at 25°C is 51.7 ± 4.1 and $\Delta H = -3.4 \pm 0.17$ kcal mole^{-1} and for 2,6-di-t-butyl-4-methoxyphenol $K = 210$ and $\Delta H = -5$ kcal mole^{-1}. Such a difference in the constant on going from 4-butoxy- to 4-methoxy-phenol can be accounted for by the fact that, on replacement of the methoxy-group by the butoxy-group, there is an increase in the polarity of the OH bond and therefore methoxyphenol is oxidised more rapidly. The constant for an equilibrium of this kind can be used in principle as a quantitative criterion of the capacity for oxidation but this is hindered by serious technical difficulties[9].

The recombination of 4-alkyl derivatives of phenoxy-radicals was investigated in detail by Land and Porter[51]. In the analysis of the electronic spectra of the photolysis product of phenols a characteristic group of bands (two or three) was observed in the region of 4000 Å; at longer wavelengths weak absorption was found. In their experiments involving the observation of the change in absorption at 4000 Å, Land and Porter investigated the kinetics of the decomposition of phenoxy-radicals. The results obtained are presented in Table 4.

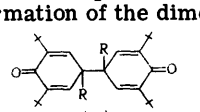
The decomposition of all the phenoxy-radicals investigated is a second-order reaction. The fact that the rate

constant is smaller by a power of ten than the calculated rate constant for a process the rate of which is controlled by diffusion suggests that the authors in fact observed dimerisation. 2,6-Di-t-butyl-4-methoxy- and 2,6-di-t-butyl-4-ethyl-phenoxy-radicals showed an interesting feature. These radicals initially disappear according to a second-order reaction and then, when the concentration of the radicals is still fairly high, the reaction deviates from the second order. Probably two processes are superimposed—rapid dimerisation [reaction (7)] and slow isomerisation.

Table 4. Rate constants for the initial decomposition of phenoxy-radicals by a second-order reaction at 20° ± 3°C. [51]

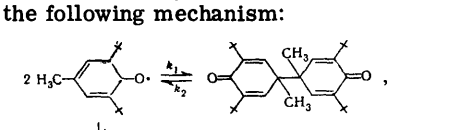
Radical	Solvent	k/ε, cm s^{-1}	k_1, litre $mole^{-1}$ s^{-1}; ε = 1800 max	$k_{calc} = \frac{8RT}{3000\eta}$, litre $mole^{-1}$ s^{-1}	K
	H_2O	$3\cdot10^5$	$5.4\cdot10^8$	$6.4\cdot10^8$	—
	CCl_4	$8.2\cdot10^4$	$1.5\cdot10^8$	$6.7\cdot10^8$	$7\cdot10^{-7}$
	CCl_4	$7.4\cdot10^3$	$1.3\cdot10^7$	$6.7\cdot10^8$	$1\cdot10^{-6}$
	liquid paraffin	$1.1\cdot10^4$	$2.0\cdot10^7$	$4.6\cdot10^7$	—

Neglecting the isomerisation process along the section of the curve which follows the second-order equation, one can determine the dimerisation constant k_1 and the equilibrium constant K, and the dimer dissociation constant k_2 (the final concentration of radicals was determined from the intensity of absorption and the initial concentration by extrapolation of the second-order curve to zero time). Comparison of the constants k_1 for methyl and ethylderivatives confirms the formation of the dimer (III):

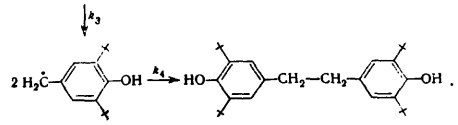


(III)

since on formation of a dimer with a different structure the *para*-substituent would have no steric effect. The slow isomerisation of the phenoxy-radical to a benzyl radical, with a rate constant k_3, is terminated by subsequent rapid dimerisation. Thus the process as a whole can be represented by the following mechanism:



(7)



(8)

Much work has been done on the isomerisation of phenoxy-radicals to benzyl radicals. The appearance of the intermediate benzyl radical makes it possible to explain the formation of 3,5,3′,5′-tetra-t-butylstilbene-4,4′-quinone (IV) in the oxidation of 2,5-di-t-butyl-4-methylphenol (V) with benzoyl peroxide[52]. The predominance (75% yield) of the stilbenequinone (IV) in the oxidation products (V) is observed also when other oxidants are employed[53,54]. Cook et al.[55] explained the formation of the benzyl radical as a result of the rearrangement of the primary phenoxy-radical and proposed the following oxidation mechanism:

$$\text{phenol} \rightarrow \text{phenoxy-radical} \xrightarrow[\text{(rearrangement)}]{} \text{benzyl radical} \xrightarrow[\text{(dimerisation)}]{} \text{final products.} \quad (9)$$

This mechanism can now be regarded as proved. The application of the ESR method in the study of the oxidation showed that the primary radical produced in the oxidation of compound (V) is 2,6-di-t-butyl-4-methylphenoxyl (I).[56] The study of the kinetics of the oxidation of sterically hindered phenols by the ESR method[57] revealed that the kinetic curve for the disappearance of radicals derived from 2,6-di-t-butyl-4-methyl- and 2,6-di-t-butyl-4-ethyl-phenols distinctly follows a first-order process, which suggests that the rate-limiting stage in the oxidation of these phenols is intramolecular rearrangement of the phenoxy-radical to a benzyl radical. Table 5 shows that in a polar solvent the isomerisation rate constant is markedly reduced. This may be due to the solvation of the phenoxy-radical. It has been noted[58,59] that solvation leads to the delocalisation of the unpaired electron over the solvent shell.

Table 5. Kinetic data on the oxidation of sterically hindered phenols in various media[57].

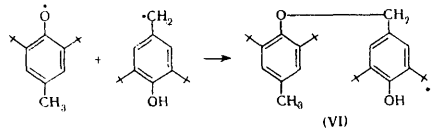
Phenol	Solvent	k, s^{-1}; t = 25°C	E, kcal $mole^{-1}$	k_0, s^{-1}
2,6-Di-t-butyl-4-methylphenol	benzene	$1.33\cdot10^{-2}$	11.4	$3.1\cdot10^8$
	methylcyclohexane	$1.23\cdot10^{-2}$		
		$0.35\cdot10^{-2}$		
2,6-Di-t-butyl-4-ethylphenol	benzene	$0.75\cdot10^{-2}$		

The low value of k_0 can be explained by the fact that in the intramolecular rearrangement the bulky substituent prevents the formation of a π-complex between the migrating group and the ring. However, the temperature range in which the reaction was studied has not been indicated[57].

According to the data of Brodskii and coworkers[60], the disappearance of 2,6-di-t-butyl-4-ethylphenoxy-radicals is a first-order reaction only close to room temperature. On increase of temperature, the first order is gradually replaced by the second. At room temperature the rearrangement of the phenoxy-radical to a benzyl radical in fact determines the nature of the process. The occurrence of the intramolecular rearrangement has been demonstrated directly by the oxidation with PbO_2 of 2,6-di-t-butyl-4-methylphenol deuteriated at the hydroxy-group, in solution not containing mobile protons[61]. The oxidation leads to a product the infrared spectrum of which contains a band with ν_{OH} = 3647 cm^{-1}, while ν_{OD} for the initial phenol is 2692 cm^{-1}.[62] On the other hand, the oxidation of 2,6-di-t-butyl-4-methylphenol deuteriated in the CH_3 group results in the appearance of a 2692 cm^{-1} band in the infrared spectrum of the product. The replacement of OD by OH and conversely is possible only when the

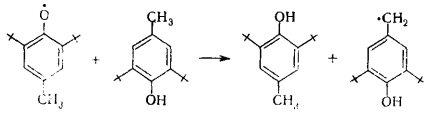
phenoxy-radical rearranges to a benzyl radical. On increase of temperature, the disproportionation reaction begins to make a significant contribution.

On the basis of the above mechanism, it would appear that the product of the cross recombination of the phenoxy- and benzyl radicals should be expected in the reaction products:



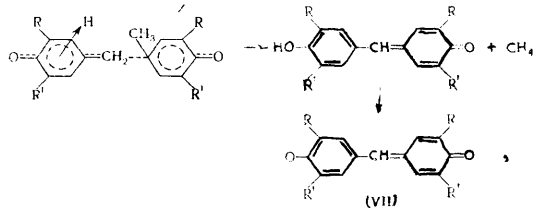
(VI) (10)

However, compound(VI) was not detected. Bennett[57] explained the absence of the product of cross recombination of the phenoxy- and benzyl radicals by the low rate of interaction of phenoxy-radicals with other free radicals[63]. One can add to this that the reaction at the oxygen atom is in general not characteristic of sterically hindered phenoxy-radicals, with the exception of the proton transfer reaction (the reaction with hydrocarbons[64,65], with another molecule of the same compound[66], and with oximes and hydroperoxides[67]). In the reaction between the phenoxyl and another radical the addition takes place as a rule in the *ortho*- or *para*-position. The benzyl radical may be regarded as a variety of alkyl radicals which are known to add to phenoxy-radicals (in the inhibition of the polymerisation of styrene for example) in accordance with the general rule, the addition to the oxygen atom with formation of an ether occurring only partially[44,45]. Apparently the absence of the cross recombination product cannot be regarded as a criterion in the assessment of the oxidation mechanism, as was suggested earlier[40]. The formation of the benzyl radical by reaction (11) is also unlikely[40]:

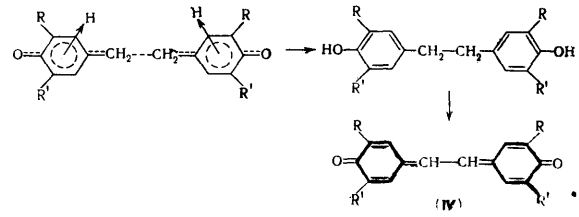


(11)

since the reaction of 2,4,6-tri-t-butylphenoxy-radicals with toluene, which has a similar mechanism, takes place at a low rate, the activation energy for such a reaction amounting to 23 kcal mole^{-1} and $k_0 = 9.7 \times 10^{-13}$ cm^3 s^{-1}.[65] In this case the independence of the rate constant of the initial phenol concentration may be regarded as direct proof. However, in the literature there are only Bennett's data[57], which show that the initial concentration varied within a 5% range. The range of variation of concentration is in this case too narrow to conclude that the rate constant for the disappearance of 2,6-di-t-butyl-4-methylphenoxy-radicals is independent of the concentration of phenol. Becconsall et al.[40] put forward the following mechanism to account for the appearance of compound (VII) among the reaction products:

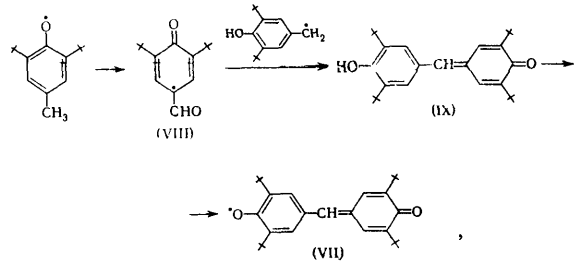


(VII) (12)



(IV)

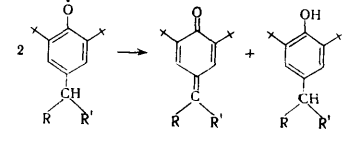
This mechanism does indeed account for the formation of compound (VII), which was detected by Coppinger[68], but it is difficult to accept it since it contradicts the first-order of the radical disappearance reaction, which has been firmly established[57,59]. It can be supposed that the formation of radicals (VII) is preceded by the oxidation of the phenoxy-radical, for example with formation of compound (VIII). The subsequent removal of the *para*-substituent as a result of the interaction of compound (VIII) with the benzyl radical,



(VIII) (IX) (VII) (13)

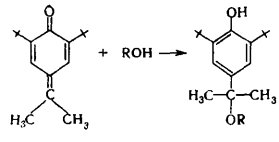
leads to the phenol (IX), whose further oxidation results in the formation of the radical (VII).

A characteristic reaction in the absence of oxygen of sterically hindered phenoxy-radicals with a *para*-substituent containing a tertiary α-hydrogen atom is disproportionation with formation of the corresponding quinone methide and the initial phenol[45,69]:



(14)

A detailed study has been made of the properties of 2,6-di-t-butyl-4-isopropylidene-2,5-cyclohexadien-1-one the reduction of which with lithium aluminium hydride results in the regeneration of the initial phenol and its reduction with zinc in acetic acid leads to the dimeric product 1,2-bis-(3,5-di-t-butyl-4-hydroxyphenyl)-1,1′,2,2′-tetramethylethane. In the presence of an alcohol the acid-catalysed reaction (15) takes place:

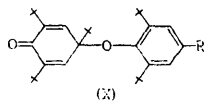


(15)

The phenols formed give rise to radicals, the stability of which is similar to that of the 2,4,6-tri-t-butylphenoxy-radical.

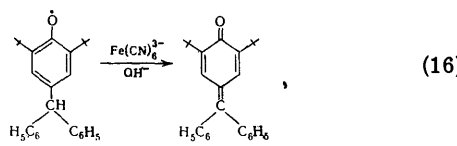
The disproportionation reaction of 2,4,6-tri-t-butylphenoxy-radicals exhibits certain characteristic features[70]. The products of this reaction are 2,4,6-tri-t-butylphenol and at least two dimeric products. Elemental analysis

and the ultraviolet and infrared spectra of one of these dimers suggest the structure (X):

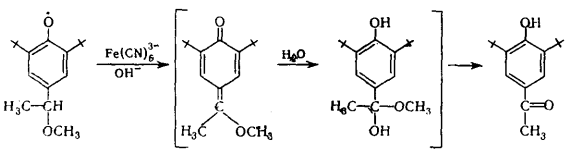


(X)

The behaviour of phenoxy-radicals containing $(C_6H_5)_2CH$ or $CH(CH_3)OCH_3$ groups in the *para*-position is interesting; the oxidation of the initial phenols is accompanied by disproportionation or, in the presence of an excess of alkaline hexacyanoferrate(III), by decomposition according to reactions (16) and (17) respectively:



(16)



(17)

The kinetics of the disproportionation reaction were investigated for a series of sterically hindered phenoxy-radicals differing in the *para*-substituent [71]. The disappearance of the radicals was followed from the decrease of the optical density at 630 nm (phenoxy-radicals absorb in the visible region). Analysis of the kinetic curve shows that the reaction is of second order with respect to the radicals. Comparative studies of a number of phenoxy-radicals demonstrated that the rate of disproportionation decreases for the following series of substituents: $CH_3 > C_2H_5 >$ iso-C_3H_7 > cyclohexyl > s-C_4H_9 (this might have been expected bearing in mind the increasing bulk of the substituent in this series). The activation energy for the reaction increases in the sequence iso-C_3H_7 < s-C_4H_9 < cyclohexyl. The activation parameters were calculated from the results (Table 6).

Table 6 shows that the disproportionation rate constant for the 2,6-di-t-butyl-4-isopropylphenoxy-radical changes little on going from one solvent to another. However, this is not due to the absence of interaction with the solvent

Table 6. Rate constants and activation parameters for the disproportionation reaction [71].

Radical	Solvent	k, litre mole^{-1} s^{-1}; 25°C	E, kcal mole^{-1}	$\Delta H^{\neq}$, kcal mole^{-1} 25°C	$\Delta S^{\neq}$, kcal mole^{-1} deg^{-1}

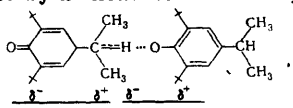
but to the presence of a compensation effect with an isokinetic temperature of −9°C, as shown by the linear relation between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for various solvents (Fig. 2). The authors explain this effect by the different degrees of solvation of the reaction and transition states; the latter can be represented by a "head-to-tail" complex:



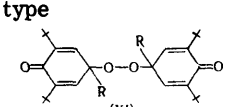
The formation of the transition state is accompanied by desolvation. Close to the isokinetic temperature, a linear relation between the rate constant (and hence also the free energy of activation) and the dielectric constant of the solvent cannot be observed. At temperatures differing significantly from the isokinetic temperature, the difference in the dipole neutralisation energy in the "head-to-tail" orientation in two media with different dielectric constants D_1 and D_2 is defined by the formula

$$\Delta E = \frac{28.9\mu_A \mu_B \Delta D}{D_1 D_2 r^2},$$

where μ_A and μ_B are the dipole moments of the two dipoles and r is the difference between them. Near the isokinetic temperature a not entirely rigorous (large scatter) linear relation between $\Delta H^{\neq}$ and $(D-1)/D$ is observed in this case, in agreement with the results of Leffler and Alder [72]. Thus the results indicate the possibility of a polar factor in radical reactions.

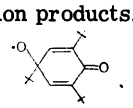
As already stated for 2,6-di-t-butyl-4-methylphenol, in the presence of an oxidant the spectrum of the primary radical varies in time. Table 7 presents the parameters of the spectra of primary and secondary phenoxy-radicals obtained in the oxidation of a number of phenols with PbO_2 in cyclohexane in the absence of oxygen [42]. The primary radical derived from compounds having an α-methylene group is replaced by a more stable secondary radical, which is formed from the primary radical as a result of the oxidation of the *para*-substituent. The spectrum of such a secondary radical consists of a triplet with a_H = 1.2 Oe, which suggests that the splitting is due to the equivalent *meta*-protons.

The presence of oxygen leads as a rule to the formation of peroxides of the type



(XI)

where R = alkyl, alkoxy-group, C_6H_5, C_6H_5CO, etc. [40,44,45,73] The study of the properties of quinolide peroxides showed that the peroxide derived from the 2,4,6-tri-t-butylphenoxy-radical decomposes, at 100–120°C for example, with formation of unstable radicals [40,44], the spectra of which consist of a triplet with a_H = 1.2 Oe. It is believed that the breakdown of the peroxide takes place at the O–O bond with formation of a radical with structure (XII); 2,6-di-t-butylbenzoquinone and isobutene have been detected in the decomposition products.



(XII)

A comparative study of the reaction of phenoxy-radicals with oxygen has been made for a series of radicals obtained by the oxidation of the corresponding phenols with alkaline potassium hexacyanoferrate(III). [70] The reaction rate was estimated from the disappearance of the colour of the radical. It was shown that the rate of disappearance of the

Table 7. ESR spectra of phenols undergoing oxidation[42] (oxidant—PbO_2 in cyclohexane).

Phenol	Description of spectrum	Time of observation	Splitting constants, Oe					Radical

	(b) triplet		—	—	—	1.25	—		(a) triplet of triplets	immediately	—	—	11.6	1.8	—		(b) triplet		—	—	—	1.2	—		(a) triplet of quintets	immediately	—	—	10.4	1.9	1.9		(b) triplet		—	—	—	1.2	—		(a) triplet	immediately	—	—	—	1.3	—		(a) triplet	immediately	—	—	—	1.8	—	

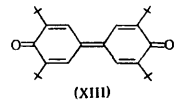
colour decreases in the following series of *para*-substituents: $t\text{-}C_4H_9 > C_6H_5 > (C_6H_5)_3C > C_6H_5CO > CN$. On going from C_6H_5 to CN, the rate decreases by a factor of ten, while on going from C_6H_5 to $t\text{-}C_4H_9$ it increases by a factor of ten. Such reduction of sensitivity with respect to oxygen can be due to enhanced resonance stabilisation or partial lowering of electron density at the *p*-carbon atom. Analysis of the oxidation products revealed an appreciable yield of biscyclohexadienone peroxides when the groups C_6H_5 and C_6H_5CO are located in the *para*-position. The oxidation of 2,6-di-t-butyl-4-nitrophenol and 3,5-di-t-butyl-4-hydroxybenzoic acid leads to the formation of the dimeric product (XIII), which is characteristic of the oxidation of 2,6-di-t-butylphenol[17].

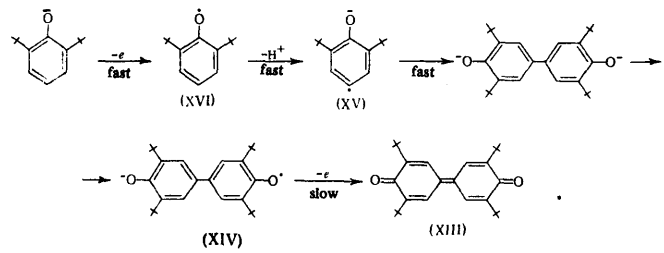


(XIII)

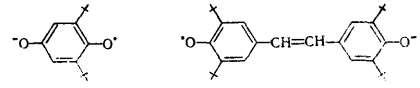
V. OXIDATION OF STERICALLY HINDERED PHENOLS BY MOLECULAR OXYGEN IN POLAR MEDIA

So far we have discussed the reactions of phenoxy-radicals obtained by the homolytic oxidation of phenols in the absence of oxygen. The oxidation of phenols with molecular oxygen in an alkaline medium shows certain characteristics features. In the first place the study of the oxidation by the ESR method revealed the presence of radicals of the semiquinone type and in the second place the kinetic oxygen absorption curve is of an autocatalytic type. Finally, analysis of the molecular oxidation products showed the presence of hydroperoxides and their decomposition products (quinols).

We shall consider the ESR study of the oxidation of the simplest representative of sterically hindered phenols—2,6-di-t-butylphenol[17]. Its oxidation product in an alkaline medium is dibenzoquinone (XIII). If alcoholic potassium hydroxide is added to a tube containing an alcoholic solution of phenol saturated with air and the tube is closed to prevent further diffusion of oxygen and placed in the resonator of a radiospectrometer, the ESR spectrum of this system shows in the first minutes a broad singlet with increasing intensity, which is subsequently split into a quintet with intensity ratios of 1 : 4 : 6 : 4 : 1 and a splitting constant of 0.6 Oe; the 5-line spectrum then disappears and a triplet remains with intensity ratios of 1 : 2 : 1 and a_H = 1.5 Oe. The triplet spectrum persists for several hours. The broad singlet line is probably due to the 2,6-di-t-butylphenoxy-radical (a 6-line spectrum with intensity ratios of 1 : 1 : 2 : 2 : 1 : 1 is expected) and almost simultaneously a radical forms which gives rise to a quintet. The quintet spectrum can be attributed to the radical-ion (XIV), since an identical spectrum arises in the reduction of dibenzoquinone (XIII). The triplet spectrum can be attributed to 2,6-di-t-butyl-4-benzosemiquinone. A radical of this kind can form from the intermediate hydroperoxide. The triplet splitting may be due also to the radicals (XV), which form from the phenoxy-radicals when the number of protons available is insufficient. The existence of the (XVI)–(XV) stage can be postulated also on the basis of the fact that in the oxidation of phenol with neutral potassium permanganate in acetone there appears initially a broad singlet line, which then splits into a quintet. Analysis of the spectrum suggests the following mechanism for the oxidation:

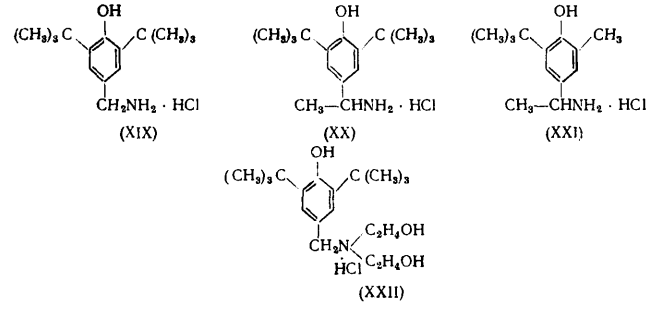


In the oxidation of 2,6-di-t-butyl-4-methylphenol (ionol) with air in alkaline acetone a radical forms whose ESR spectrum consists of eight lines[18]. In the presence of a deficiency of oxygen the 8-line spectrum disappears and is replaced by a triplet with a splitting of 1.3 Oe and intensity ratios of 1 : 2 : 1. This spectrum may be due either to the radical (XVII) or to the radical (XVIII)[40]. A triplet of this kind was observed after three days in the oxidation of ionol in alkaline methanol; the initial spectrum consists of fifteen lines and appears to result from the superposition of the spectra of several radicals[40]. The present authors'[41] study of the oxidation of four 4-aminoalkyl-2,6-di-t-butylphenols (XIX)–(XXII) in alkaline aqueous alcoholic (1 : 1) solution saturated with oxygen showed that, for all four phenols, which differ in the *para*-substituent, the reaction mixture has a yellow-green colour and even in the first minute gives rise to an ESR signal in the form of a triplet with a splitting of 1.4 Oe and intensity ratios of 1 : 2 : 1.[42] The structure of this spectrum persists for tens of minutes at 45–67 °C. The kinetic curve of the radical with a triplet ESR spectrum passes through a maximum, the descending branch representing the disappearance of the radicals. Most of the curve can be formally described by the equation for first-order kinetics.



(XVII), a_H = 1.5 Oe (XVIII), a_H = 1.6 Oe

The radicals generated in the oxidation of phenols (XIX), (XX), (XXI), and (XXII) disappear with the same activation energy (23 kcal mole^{-1}).



(XIX) (XX) (XXI)

(XXII)

All these findings confirm that we are dealing with the same radical in all four cases and that this radical is not a primary phenoxyl. The spectra of primary phenoxy-radicals derived from these phenols should show significant differences. Thus the primary phenoxy-radical from 4-aminomethyl-2,6-di-t-butylphenol (XIX) obtained in the oxidation of this phenol with PbO_2 in benzene has an ESR spectrum in the form of a triplet of quintets with a splitting of 10.4 Oe in the triplet and 1.9 Oe in the quintet[43], while

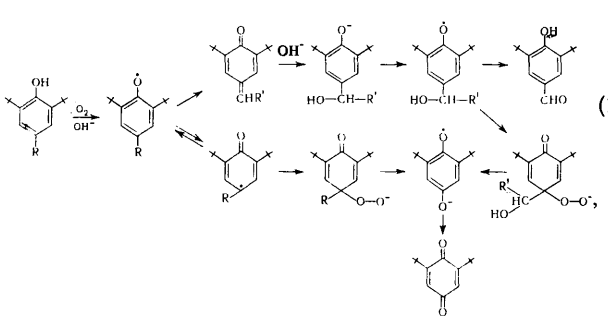
the spectrum of the phenoxy-radical from 4-aminoethyl-2,6-di-t-butylphenol (XX) should consist of a doublet of quintets with a splitting of about 8.5 Oe in the doublet and 1.8–1.9 Oe in the quintet.

The spectrum obtained by the authors can be attributed to 2,6-di-t-butyl-1,4-benzosemiquinone (XVII). The absence of splitting by *ortho*-substituents under these conditions leads to identical spectra of the semiquinone radical-ions derived from 4-aminoethyl-6-t-butyl-2-methylphenol (XXI) and phenols containing two t-C_4H_9 groups in the *ortho*-positions.

The radical detected by Adams et al.[17] and Becconsall et al.[40] in the oxidation of ionol in a polar medium, which has a triplet spectrum with a splitting 0.1 Oe, is also 2,6-di-t-butyl-1,4-benzosemiquinone (XVII). We have shown[74] that the formation of 2,6-di-t-butyl-1,4-benzosemiquinone is characteristic of the oxidation with molecular oxygen in alkaline aqueous alcoholic solution of 2,6-di-t-butylphenols containing electron-donor substituents in the *para*-position. The oxidation of alkylphenols with oxygen in alkaline aqueous alcoholic solution probably begins with the stage involving the formation of the corresponding phenoxy-radicals, which are extremely unstable under the experimental conditions and can either disproportionate to the corresponding methylenequinones or interact with oxygen to form 2,6-di-t-butyl-1,4-benzosemiquinone, which leads as a rule to the removal of the *para*-substituent regardless of the structure of the initial 4-substituted 2,6-di-t-butylphenol.

In our experiments on the oxidation of certain 4-substituted phenols, quinone methides stable in an alkaline aqueous alcoholic solution were also isolated. Such methides are 2,6-di-t-butyl-4-*NN*-dimethylaminomethylenecyclohexa-2,5-dien-1-one and 2,6-di-t-butyl-4-methoxymethylenecyclohexa-2,5-dien-1-one, which are converted under the action of acid into 3,5-di-t-butyl-4-hydroxybenzaldehyde (XXIII). This benzaldehyde was also detected in the oxidation products of 2,6-di-t-butyl-4-(β-hydroxyethyl)aminophenol (XXII) on addition of concentrated hydrochloric acid to the reaction mixture. The formation of quinone methides in the reaction is confirmed also by the ultraviolet spectra of the reaction mixture. The absorption by the reaction mixture obtained from 2,6-di-t-butyl-4-dimethylaminomethylphenol in the region of 340 nm is due to aminomethylenequinone[75]; 2,6-di-t-butyl-4-methoxymethylenecyclohexa-2,5-dien-1-one gives rise to an absorption band with a maximum at 325 nm.

2,6-Di-t-butyl-1,4-benzosemiquinone (XXII) is formed from an intermediate hydroperoxide with a *para*-quinolide structure. On the basis of the results of Strigun et al.[41,74] and other literature data, the oxidation with molecular oxygen in polar media of alkylphenols with electron-donor substituents in the *para*-position can be represented by the following mechanism:

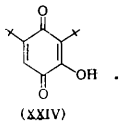


(18)

where R = CH_3, C_2H_5, $CH(CH_3)_2$, CH_2OCH_3, $CH_2OC_2H_5$, CH_2NH_2, $CH_2N(CH_3)_2$, $CH_3-CH(CH_2)$, or $CH_2N(CH_2CH_2OH)_2$.

The relative amounts of reaction products depend on reaction conditions. 3,5-t-Butyl-4-hydroxybenzaldehyde formed during the reaction is not oxidised by oxygen under the experimental conditions and does not interact with any of the other reaction products and therefore the mode of the disproportionation reaction of the phenoxy-radical can be assessed from the amount of the hydroxy-aldehyde. When the concentration of oxygen in the system is sufficiently high, the phenoxy-radicals are rapidly converted into semiquinone radical-ions. As a result, the oxidation process is determined by the characteristics of the oxidation of the semiquinone. According to the above mechanism, semiquinone radicals disappear in the disproportionation reaction, which leads to the formation of quinone in the system. At advanced stages of the reaction the quinone accumulated in the system is reduced. The formation of semiquinone by the reduction of the quinone in the alkaline medium[76,77] is superimposed on the disproportionation process, as a result of which the kinetic curve describing the disappearance of the radicals is of a complex form and cannot be fully described by simple equations.

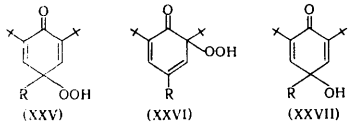
The hydroxy-quinone with the structure (XXIV) has been detected in the oxidation products of the phenol (XXII)[74], its structure having been demonstrated by infrared, ESR, and NMR spectra. It has been shown that this hydroxy-quinone is formed on direct interaction between 2,6-di-t-butyl-1,4-benzoquinone and alkali. All these findings indicate that, at advanced stages of the reaction, the system containing a phenol undergoing oxidation obeys the general laws governing the reduction of quinones[74,76,77].



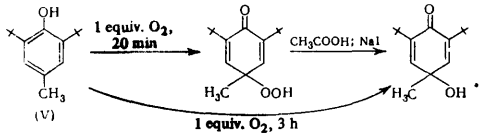
(XXIV)

Hydroperoxides with structures (XXV) and (XXVI) are characteristic products of the oxidation with molecular oxygen of sterically hindered phenols[78–80]. In an alkaline solution they isomerise and decompose into the quinols (XXVII) or the initial phenol.

The absorption of one equivalent of oxygen by a solution of ionol (V) in alkaline ethanol leads to the formation of the hydroperoxide (XXV) with a yield of 86%.[78] Slow absorption (restricted access of the gas) of the same amount of oxygen results in the formation of the corresponding quinol[19]:



(19)



The oxidation of 2,4,6-tri-t-butylphenol under similar conditions yields the *o*-hydroperoxide as the main product together with a small amount of *p*-hydroperoxide. The properties of these hydroperoxides are interesting[79]. The reduction of *p*-hydroperoxides with hydrogen iodide leads to the corresponding quinols. When the *p*-hydroperoxide (XXV, R = C_4H_9) is heated for 2 h at 40°C and pH 14 in

alcohol in the presence of oxygen, the isomeric *o*-hydroperoxide (XXVI, R = C_4H_9) and the corresponding quinol (XXVII, R = C_4H_9) are formed. Under the same conditions the *o*-isomer gives rise to the *p*-hydroperoxide and the corresponding quinol but the relative amounts of the two products are different (Table 8).

Table 8. Isomerisation of hydroperoxides (XXV) and (XXVI) (R = t-C_4H_9.[75]

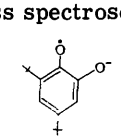
Hydroperoxide	% formed on heating		isomer / quinol
	of isomer	of quinol	
p-Hydroperoxide	19.5	30.5	0.64
o-Hydroperoxide	21	29	0.72

Table 8 shows that the isomerisation is accompanied by the decomposition of the hydroperoxide. It has been shown that when the *p*-hydroperoxide (XXV, R = CH_3) is heated under the above conditions for 4 h, it is decomposed to the extent of 80%, the main product being the quinol (XXVII, R = CH_3); heating in nitrogen leads to the decomposition of the peroxide to the extent of 90%, the reaction products—quinol (XXVII) and ionol—being formed in proportions of 2 : 3. On decomposition in a stream of nitrogen, the yield of the phenol and oxygen can reach 70%. The study of this reaction in 50% aqueous t-butyl alcohol[80], with potassium cyanide added to bind heavy metal ions which catalyse the decomposition of the peroxide, showed that the decomposition is a first-order reaction and depends on the pH of the medium. This suggested that the reaction proceeds as follows:

$$ROO^- \rightarrow R^- + O_2 \,. \qquad (20)$$

The *p*-hydroperoxide (XXV, R = C_4H_9) undergoes a similar reaction, but the yield in this case is lower.

The ESR study[78] of the decomposition of the *p*-hydroperoxide (XXV, R = CH_3) in an alkaline medium showed that after heating for 4 h in the system gives rise to the characteristic spectrum of the catechol semiquinone (XXVIII); the presence of isobutene was demonstrated by gas–liquid chromatography and mass spectroscopy.



(XXVIII)

When equimolar amounts of solutions of the *p*-hydroperoxide (XXV, R = CH_3) and ionol or of cumenyl hydroperoxide and the quinol (XXVII, R = CH_3) are mixed, this type of spectrum appears instantly. The characteristics of the spectra of these semiquinones are presented in Table 9.

Gersmann and Bickel[80,81] suggested that the *o*-quinone or *o*-semiquinone radical-ions formed in the decomposition of *o*-hydroperoxides can catalyse the oxidation of phenols. The data of Conradi and McLaren[82] demonstrate that the *o*-quinone is definitely formed in the oxidation of phenols. Gersmann and Bickel made a detailed study of the kinetics of the oxidation of sterically hindered phenols in polar media[80,81]. The kinetic oxygen absorption curve is of an autocatalytic type. The authors explained the autocatalysis of the oxidation of sterically hindered phenols by the catalytic effect of the *o*-hydroperoxide (Fig. 3); *p*-hydroperoxides do not exhibit a catalytic effect. The catalytic effect of the *o*-hydroperoxide is in all probability associated with its decomposition accompanied by the formation of the active catalyst: *o*-quinone or a radical. The attempts to show that the auto-oxidation of sterically hindered phenols in polar media with molecular oxygen is a radical chain process proved unsuccessful: the addition of hydrogen donors (9,10-dihydroanthracene) and initiators ($\alpha\alpha$-azobisisobutyronitrile) did not show a definite effect on the rate of oxidation; the addition of free-radical reaction inhibitors (quinones and aromatic polynitro-compounds) accelerates the oxidation. This favourable catalytic effect will be discussed in detail below.

Table 9. Properties of the ESR spectra of *o*-semiquinones observed in the oxidation of 2,6-di-t-butyl-4-R-phenols.

R	Intensity ratio	Splitting constants	
		a_1	a_2
CH_3	1:1:3:3:3:3:1:1	5.2	2.5
Benzyl	1:1:2:2:1:1	4.1	2.5
iso-C_3H_7	1:2:1	2.4	2.4
t-C_4H_9	1:1		2.5

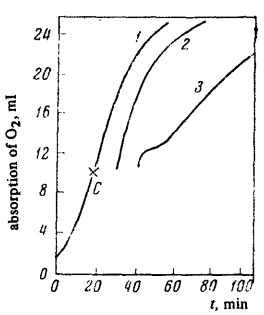


Figure 3. Auto-oxidation of 2,4,6-tri-t-butylphenol: *1*) phenol alone, initial concentration 4 x 10^{-2} M; *2*) phenol mixed with the *o*-hydroperoxide in proportions corresponding to the content of both components in the reaction mixture at point *C*; *3*) phenol alone, initial concentration equal to the concentration of the phenol in the reaction mixture at point *C*.

Comparative study of the auto-oxidation of sterically hindered phenols in various solvents showed that oxidation in the 1 : 1 mixture of t-butyl alcohol and 1,2-dimethoxyethane containing potassium butoxide is much faster than in 90% ethanol; the kinetic [oxygen] absorption curve does not show an induction period in this case, but the yield of hydroperoxide in ethanol is higher. The reaction remains of first order with respect to the phenoxide ion up to 80% conversion; at the same concentration of alkali the reaction is of first order with respect to oxygen pressure. Table 10 presents data on the oxidation of ionol.

The much higher rate of oxidation in the presence of potassium t-butoxide in the t-butyl alcohol–1,2-dimethoxyethane mixture is due to the fact that in this solution the phenol is evidently completely ionised while in 90% ethanol

at pH 13 ionol is dissociated only to the extent of 20%. Furthermore, the difference in solvation may play a significant role. The formation of hydrogen bonds is in this case difficult due to steric hindrance. The importance of the size of solvent molecules can be seen from the low rate of oxidation in 100% methanol containing potassium methoxide.

Table 10. Auto-oxidation of ionol (0.5 - 1.0 mole/30 ml).[81]

№	Molarity of base	Solvent*	p_{O_2}, mmHg	t, °C	k, min^{-1}
1	0.10	A	76	25	0.92
2	0.10	A	76	0	0.12
3	0.25	A	76	0	0.12
4	0.25	A	53	0	0.075
5	0.25	A	34	0	0.052
6	0.10	A	76	0	0.644
7	0.10	A	76	0	0.253
8	0.10	90% C_2H_5OH	76	0	0.0024
9	0.10	100% CH_3OH	76	0	0.0005

* A represents a 1 : 1 mixture of t-butyl alcohol and 1,2-dimethoxyethane; in experiment No. 6 20 mg of 2,6-di-t-butylbenzoquinone and in experiments Nos. 7 and 8 20 mg of *m*-dinitrobenzene were added.

As stated above, 2,6-di-t-butylbenzoquinone, duroquinone, and *m*-dinitrobenzene proved to be effective catalysts of the oxidation of sterically hindered phenols (Table 11). The study of the kinetics of the catalysis by quinones and polynitrobenzenes showed differences which the authors attributed to differences in the mechanism of the catalysis. Thus the oxidation catalysed by *m*-dinitrobenzene depends on the concentration of the catalyst, is of first order with respect to the phenol (as shown by the analysis of the kinetic oxygen absorption curves) and is independent of oxygen pressure in the range between 0.5 and 1 atm which Gersmann and Bickel believe[81] to indicate the usual catalytic mechanism involving the formation of a catalyst–substrate complex.

Table 11. Activation energy for the catalysed oxidation of 2,6-di-t-butyl-4-methylphenol in 90% ethanol.[80]

Catalyst	E, cal mole^{-1}
2,6-Di-t-butylbenzoquinone	12000
m-Dinitrobenzene (20 ml/mole)	8900
m-Dinitrobenzene (50 ml/mole)	9400
No catalyst	20000

In the catalysis by quinones the rate of reaction is independent of quinone concentration in the range of the latter investigated and is proportional to oxygen pressure. In the catalytic oxidation of polyphenols such a phenomenon is called saturation of quinone catalysis[83,84]. The independence of the catalytic effect of the concentration of the quinone is due to the formation of a complex[80] between the phenol and the quinone, the interaction with another quinone molecule becoming unlikely.

However, with duroquinone, the catalytic effect does vary with catalyst concentration somewhat. It has been shown[80] that *m*-dinitrobenzene and quinones catalyse the decomposition of *p*-hydroperoxides. Since the decomposition is accompanied by isomerisation, then, on the basis of the data presented, one can probably postulate that the catalytic effect of both nitrobenzenes and quinones is not direct. It is due to the catalytic effect of these compounds on the decomposition of the hydroperoxide.

Since the catalytic effect of *m*-dinitrobenzene on the decomposition of *p*-hydroperoxides is weaker than the effect due to 2,6-di-t-butylbenzoquinone, in the oxidation of phenol higher concentrations of *m*-dinitrobenzene than of the quinone are required for catalysis. It may be supposed that further increase in the amount of catalyst would result in the independence of the reaction rate constant of the concentration of *m*-dinitrobenzene. The possible saturation of the catalytic effect of *m*-dinitrobenzene in the oxidation of trialkylphenols is indicated by the comparison of the activation energies for processes catalysed by different amounts of *m*-dinitrobenzene (Table 11). Table 11 shows that, on going from 20 to 50 ml of *m*-dinitrobenzene per mole, the activation energy is virtually constant, but the rate constant increases almost by a factor of two.

In our experiments the addition of benzoquinone at the beginning of the oxidation with molecular oxygen of 4-aminoalkyl-2,6-di-t-butylphenols in a 1 : 1 alkaline aqueous alcoholic medium leads to an increase of the induction period on the kinetic curve for the consumption of the phenol. The addition of 2,6-di-t-butyl-1,4-benzoquinone at the beginning of the oxidation of 4-aminoethyl-2,6-di-t-butylphenol (XX) does not affect the induction period, but after the induction period the rate of consumption of the phenol (XX) is much lower in experiments with the addition of this quinone than without it. Probably the observed effect is associated with the reduction of the phenoxy-radicals under the influence of the benzoquinone to the initial phenol, while in the presence of 2,6-di-t-butyl-1,4-benzoquinone the phenoxy-radicals are not reduced. The effect of 2,6-di-t-butyl-1,4-benzoquinone begins when a sufficient amount of hydroperoxides accumulates in the system, their decomposition to the initial phenol and the quinone being catalysed by 2,6-di-t-butyl-1,4-benzoquinone. As a result, the *o*-quinone does not accumulate in the system in amounts necessary for an autocatalytic process.

Stable Phenoxy-radicals

V.D.Pokhodenko, V.A.Khizhnyi, and V.A.Bidzilya

The present review is devoted to an examination and analysis of published data on reactions leading to the formation of phenoxy-radicals, and the structures and properties of these radicals.
In the description of the methods of preparing phenoxy-radicals, we examine the interaction of sterically hindered phenols with organic peroxides and inorganic oxidising agents, the mechanism of the thermal decomposition of cyclohexadienones, the autoxidation of sterically hindered phenols, and also the action of γ-radiation and ultraviolet radiation on phenols.
In the section devoted to the properties of phenoxy-radicals, we discuss the influence of steric hindrance of the reactive centre, and also the degree of delocalisation of the unpaired electron, on the stability of the phenoxy-radicals.
The available published data on the chemical transformations of substituted phenoxy-radicals are reviewed. Their recombination, disproportionation, isomerisation, and reaction with oxygen and halogens are examined. The influence of the steric and polar properties of substituents on the kinetics and mechanism of the transfer of hydrogen from organic compounds to stable phenoxy-radicals is analysed. The bibliography contains 180 references.

I. INTRODUCTION

Sterically hindered phenols are now widely used as inhibitors of the thermal-oxidative degradation of polymeric materials, and the oxidation of motor fuels, oils, and edible fats[1-3]. Moreover, as shown by Emanuel' and coworkers[4-6], sterically hindered phenols can be used as physiologically active substances in various areas of biological studies.

The protective action of inhibitors of the phenol type is associated with the removal, from the substrate being oxidised, of the $RO_2^{\cdot}$ and $R^{\cdot}$ radicals responsible for the chain reaction: $RO_2^{\cdot} + PhOH \rightarrow ROOH + PhO^{\cdot}$. As a result of this reaction, the active $RO_2^{\cdot}$ or $R^{\cdot}$ radicals are replaced by the $PhO^{\cdot}$ radicals, which have a low activity and are incapable of maintaining the autoxidation chain reaction.

The retarding action of the inhibitor added to the substance being oxidised depends on[1,3]: (1) the activity of the $PhO^{\cdot}$ radical (the lower the activity of the $PhO^{\cdot}$ radical, the stronger the retarding effect), and (2) the rates of the reactions of the radicals $RO_2^{\cdot}$ and $R^{\cdot}$ with the inhibitor.

The development of a modern theory of the action of inhibitors, which might make it possible to control the selection and application of these inhibitors, is closely related to the development of the chemistry of free radicals and the establishment of the regular features of the dependence of their formation and behaviour on structure. In recent years, significant results have been obtained in this field, but these have not been reviewed to a sufficient extent in the chemical literature.

The present review examines reactions leading to the formation of stable phenoxy-radicals from sterically hindered phenols, and also the structure and behaviour of these radicals.

I. REACTIONS LEADING TO THE FORMATION OF PHENOXY-RADICALS

The chief method for the preparation of phenoxy-radicals is by the interaction of phenols with various organic and inorganic oxidising agents, leading to the removal of a hydrogen atom from the hydroxyl group. Phenoxy-radicals can also be obtained by the action of γ-radiation and ultraviolet radiation on phenols, and also as a result of homolytic bond rupture in various organic molecules. In the present chapter we shall examine reactions leading to the formation of stable phenoxy-radicals from sterically hindered phenols, that is, phenols containing various bulky substituents in the *ortho*-position relative to the hydroxyl group.

1. Reaction of Sterically Hindered Phenols with Peroxo-compounds

The thermal decomposition of organic peroxides in inert solvents is a spontaneous unimolecular reaction which takes place with the formation of free radicals[7,8]:

$$ROOR \rightarrow RO^{\cdot} + RO^{\cdot}$$

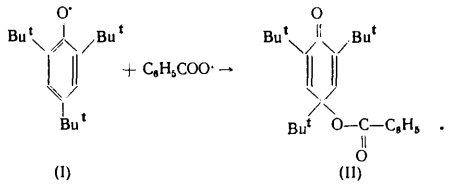
The $RO^{\cdot}$ radicals formed in this reaction can attack phenol molecules, giving the corresponding phenoxy-radicals:

$$PhOH + RO^{\cdot} \rightarrow PhO^{\cdot} + ROH .$$

Phenols react in analogous fashion with the free radicals formed by the decomposition of hydroperoxides, catalysed by cobalt naphthenate[9,10].

The reaction of 2,4,6-tri-t-butylphenol with benzoyl peroxide produces in the solution the blue colour characteristic

of the 2,4,6-tri-t-butylphenoxy-radical (I)[11]. Spectrophotometric study of this process[12] showed that the reaction obeys a second-order kinetic equation and includes as an intermediate stage the formation of the corresponding phenoxy-radical, which subsequently disappears, apparently according to the reaction:



(I) (II)

The direct detection of phenoxy-radicals in the reaction of sterically hindered phenols with peroxo-compounds is now possible using electron paramagnetic resonance (EPR). It was found that the reaction of 2,6-di-t-butyl-4-methylphenol[13,14], 2,6-di-(1,1-dimethylpropyl)-4-methylphenol, 2,6-di-(1,1-dimethylhexyl)-4-methylphenol[13], and 2,4,6-tri-t-butylphenol[14] with benzoyl peroxide, *p*-t-butylcumenyl hydroperoxide, or cyclohexyl peroxocarbonate, leads to the production of EPR spectra which show good agreement with the structures of the corresponding phenoxy-radicals. An interesting feature is that in the work cited no change in the structure of the EPR spectra was observed during the reaction. This indicates that the radicals formed by the decomposition of the peroxides react rapidly with the phenoxy-radicals, and this prevents their further transformation. The nature of the alkyl substituents in the *ortho*- and *para*-positions relative to the phenoxy hydroxyl group influences not only the structure of the final products of the reaction of the phenols with the peroxides, but also its velocity. The study of the dependence of the rate of the reaction of peroxo-radicals with phenols on the structure of the substituents in the phenol molecule is of considerable practical as well as purely theoretical interest, since the retarding action of inhibitors is to a large extent determined by the rate of the reaction of the peroxo-radicals with the inhibitor molecules (the efficiency of the inhibitor); when various inhibitors are introduced into a reaction in equal concentrations, the most effective inhibitor is that which reacts most rapidly.

Ingold[15], in a study of the oxidation of mineral oil in the presence of a number of 2,6-di-t-butyl-4-substituted phenols, found that electron-donating substituents in the *para*-position of the phenol, if their volume is small, increase the relative activity of the inhibitor. A linear relationship is observed between $\lg(k/k_0)$ (where k and k_0 are the rate constants of the inhibitor being studied and a standard inhibitor for the given reaction) and the Hammett constants σ of the substituents. A similar good correlation between the inhibiting activity of 2,6-di-t-butyl-4-alkylphenols and the Hammett constants σ was observed for the oxidation of methyl oleate[16]. With bulky substituents in the *para*-position, the relative inhibiting activities show a good correlation with the Taft constants of the substituents[15], which make allowance for steric factors. Study of the reaction of t-butoxy-radicals with 2,6-di-t-butyl-4-methylphenol† and 2,6-di-t-butylphenol, both deuteriated in the OH group, and also the reaction of styrylperoxo-radicals with 4-alkylphenols, revealed kinetic isotopic effects ($k_H/k_D = 6.14$[17] and $k_H/k_D = 10.5$[18] respectively), indicating that the stage limiting the rate of the process is the transfer of hydrogen from the phenol molecules to the attacking radical. To investigate the influence of substituents on the ease of formation of the polar transition state in the reaction of styrylperoxo-radicals with *meta*-, *para*-,[18] and *ortho*-substituted phenols[19], and also in the reaction of the t-butoxy-radical with 2,4,6-trialkylphenols[20], a correlation was established between the logarithms of the rate constants and the Brown constants σ^+ for electrophilic substituents. A linear relationship was observed with values of the constants for the reaction ρ equal to 1.30 for 2,6-dimethylphenol and 1.11 for 2,6-di-t-butylphenol. The small value of ρ for these phenols indicates only slight separation of the charges in the transition state of this reaction.

Like the RO· and ROO· radicals, hydroxyl radicals react with phenols with the formation of peroxo-compounds of the type PhO–OPh and PhO–OH.[21,22] The system $H_2O_2 + FeSO_4$ (Fenton's reagent) is usually employed as source of ·OH radicals. The formation of phenoxy-radicals in the reaction of 2,6-di-t-butyl-4-methylphenol with hydroxyl radicals was observed by Ershov and Zlobina[23] using the EPR method. The source of hydroxyl radicals used in this instance was peroxonitrous acid, which undergoes homolytic splitting in solution with the formation of ·OH and $\cdot ONO \rightleftharpoons \cdot NO_2$ radicals[24,25]. Analogous results were obtained by Ershov and coworkers[26] using alkyl nitrites as oxidising agents; these compounds readily undergo homolytic splitting with the formation of RO· and NO· radicals. The decomposition of alkyl nitrites in the presence of alkylphenols leads to the production of the corresponding phenoxy-radicals, detected both from the appearance of the characteristic colour and from the EPR spectra.

2. Reaction of Sterically Hindered Phenols with Inorganic Oxidising Agents

The reactions of sterically hindered phenols with peroxo-compounds, described above, generally produce, in addition to the primary phenoxy-radical, various products of the addition of the peroxide residue to this radical. In order to study the stability and behaviour of phenoxy-radicals it is necessary to carry out the oxidation of the phenols in such a way that the substrate containing the PhO· radicals does not contain other active radicals capable of recombining with the PhO· radicals. These requirements are satisfied by such oxidising agents as lead dioxide[12,14,27-33,35-37], silver oxide, potassium hexacyanoferrate(III)[38-42], and cerium(IV) sulphate[43,44]. The oxidation of phenols by these oxidising agents can be represented in general form as follows:

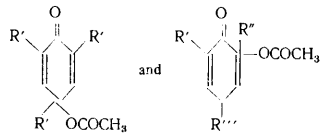
$$PhOH + M^{n+} \rightarrow PhO^{\cdot} + M^{(n-1)+} + H^+.$$

Using these oxidising agents, it has been established that the phenoxy radicals formed by the oxidation of phenols have different stabilities, and this determines their ability to undergo further transformations. Thus the oxidation of 2,4,6-tri-t-butylphenol[28,45-48] and various other phenols leads to the formation of phenoxy-radicals which are able to "live" in the absence of oxygen for a very prolonged period. On the other hand, the oxidation of 2,6-di-t-butyl-4-methylphenol produces a less stable phenoxy-radical, transformation of which gives various final products. Phenols which do not contain bulky substituents in the *ortho*-position are oxidised with the formation of even less stable radicals, whose lifetimes decrease to hundredths of a second. In order to study these radicals by the EPR method, it is necessary to establish a steady-state concentration of the radicals sufficient for their detection. Parti-

† In the Russian text here and subsequently this compound is incorrectly referred to as Ionol [which is 2-(3-hydroxybutenyl)-1,3,3-trimethylcyclohexene]. This has been corrected in the translation (Ed. of Translation).

cularly fruitful results have been obtained using a flow system in which the solutions of the phenol and the oxidising agent are mixed directly in the resonator of the EPR spectrometer. Stone and Waters[43,44] used this method to study the EPR spectra and structure of the radicals formed in the oxidation of a number of unhindered or weakly hindered phenols. In some instances, when the oxidation of the phenols takes place too rapidly, a milder oxidising agent—mercuric oxide HgO—is used[37]. The formation of phenoxy-radicals in the oxidation of 2,6-di-t-butyl-4-methylphenol by HgO is observed only when the solution is heated to 60°C,[50] whereas oxidation by means of PbO_2 or $K_3Fe(CN)_6$ leads to the immediate production of phenoxy-radicals even at room temperature[50-53].

The oxidation of phenols by lead tetra-acetate [$Pb(CH_3COO)_4$] and acetyl peroxide leads to the formation of the corresponding *p*- and *o*-quinol acetates[54-58]:



where R′ = CH_3, R″ = CH_3 or H, and R‴ = CH_3.

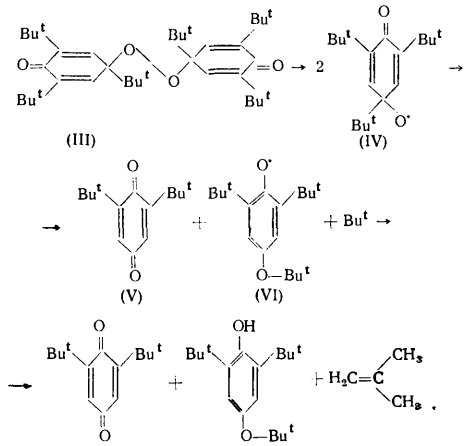
The radical mechanism of the reaction of phenols with $Pb(CH_3COO)_4$ was proved by Emanuel' and coworkers[59] by the production, in the EPR spectra, of signals due to primary phenoxy radicals from 2,4,6-tri-t-butylphenol, 2,6-di-t-butylphenol, and 2,6-di-t-butyl-4-ethylphenol. These workers also noted the formation of radicals from unhindered phenols such as *p*-cresol, *p*-ethylphenol, and phenol, confirming that this reaction also takes place by a radical mechanism with unhindered phenols. The formation of radicals from unhindered phenols in this instance is rather surprising, since when other oxidising agents were used, these radicals could not be recorded, because of their extremely low stability. It may be suggested that the short-lived radicals produced in the oxidation of phenols by lead tetra-acetate may form a complex with the oxidising agent or with its decomposition products, leading to their stabilisation.

The oxidation of sterically hindered phenols by salts of carboxylic acids, for example $Cu(OCOR)_2$, probably also takes place by a radical mechanism, since the chief reaction products, as in the reactions of such one-electron oxidising agents as PbO_2 and $K_3Fe(CN)_6$, are dimers, which are paired in the *ortho*- and *para*-positions, depending on the structure of the original phenol[60].

Phenoxy-radicals were observed directly by the EPR method by Razuvaev and coworkers[61,62] in a study of the oxidation of phenols in the presence of a complex Cu^{2+} + amine catalyst.

3. Decomposition of Cyclohexadienones

As already noted, the homolytic mechanism of the decomposition of organic peroxides of the type ROOR is now generally accepted[36]. The production of radicals in their decomposition has been confirmed by various methods, in particular from the initiation of autoxidation and polymerisation in the presence of the decomposing peroxide, from the decrease in the rate of decomposition of the peroxide in the presence of inhibitors of free-radical reactions, etc. Until recently, however, it was not possible to observe free radicals directly in the thermal decomposition of organic peroxides, since these radicals are insufficiently stable for detection by the EPR method. Brodskii and Pokhodenko[63] tried to prove the homolytic mechanism of the decomposition of peroxides using the EPR method. They started from the assumption that if the RO residues in the molecule of the peroxide ROOR were stable phenoxy-radicals, the decomposition by a homolytic mechanism would give radicals sufficiently stable to be recorded by the EPR method. For this purpose, bis-(1,3,5-tri-t-butyl-4-oxocyclohexa-2,5-dienyl) peroxide (III) was synthesised[27,28,46,64]. It was previously found[28,65] that the products of the decomposition of this peroxide are 2,6-di-t-butyl-4-t-butoxyphenol, 2,6-di-t-butylbenzoquinone, and 2-methylpropene. To explain the formation of these products, Muller[65] suggested that the decomposition of the peroxide takes place by an ionic mechanism with transfer of the t-butyl residue from the carbon atom to the oxygen atom. When this peroxide was heated to 200°C, however, an intense EPR signal was observed[63], consisting of three components 1 : 2 : 1 with a splitting between them equal to 1.3 Oe. The infrared spectra of the decomposition products of the peroxide[63], unlike the spectrum of the original peroxide, showed a band at 3650 cm^{-1}, corresponding to the OH group of sterically hindered phenols. On this basis, the following mechanism was proposed for the decomposition of the peroxide (III); this mechanism explains the production of the final products:

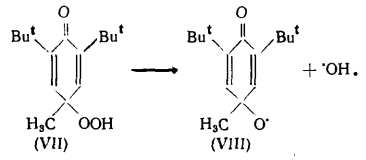


The observed EPR spectrum of the decomposition products of the peroxide is due to the phenoxy-radical (VI), in which the unpaired electron interacts with two equivalent *m*-hydrogen atoms. The constant for the splitting between the components of this signal has a value which is close to that previously obtained[53] for this radical, formed by the oxidation of the corresponding phenol. The suggestion[66,67] that the triplet EPR signal observed in the decomposition of the peroxide is due to the radical (IV), in which the presence of the oxygen atom in the *para*-position leads to a decrease in the splitting constant, which is usually equal to 1.7 Oe for the 2,4,6-tri-t-butylphenoxy-radical, to 1.3 Oe, appears erroneous if allowance is made for the low probability of the observation of this radical in the EPR spectra, resulting from its low stability, which is due to the impossibility of delocalisation of the unpaired electron in the benzene ring and the absence of bulky groups screening the reactive centre.

The radical mechanism for the decomposition of the peroxide (III) was later proved by the EPR method by carrying out the reaction in xylene solution at 80°C.[68]

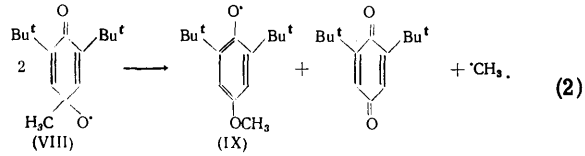
The thermal decomposition of 2,6-di-t-butyl-4-hydroperoxy-4-methylcyclohexa-2,5-dienone (VII) is also accompanied by the formation of phenoxy-radicals[69]. On the

basis of generally accepted ideas, this process should be represented as follows:



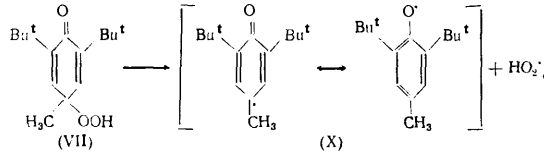
(VII) (VIII) (I)

Subsequent disproportionation of the radicals (VIII) should produce the phenoxy-radical (IX), as described above:



(VIII) (IX) (2)

The EPR signal observed in this work (1 : 3 : 3 : 1 quadruplet, 1 : 2 : 1 triplet, a_1 = 11 Oe, and a_2 = 1.7 Oe), however, cannot be attributed either to radical (VIII) or to radical (IX), formed according to schemes (1) and (2). The parameters of this spectrum (the number of lines, the ratio of the intensities, and the splitting constants) correspond completely to the 2,6-di-t-butyl-4-methylphenoxy-radical (X)[51,52,66]. On this basis it was suggested[69] that the first stage in the decomposition of the hydroperoxide is the removal of the hydroperoxo-radical with the formation of a phenoxy-radical:



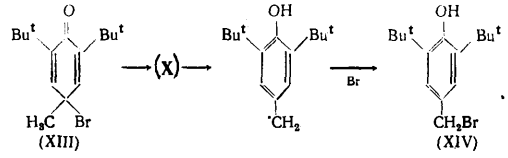
(VII) (X)

This unusual course of the thermal decomposition of organic peroxo-compounds without rupture of O–O bonds was also observed by the action of heat on 2,6-di-t-butyl-4-t-butylperoxy-4-methylcyclohexa-2,5-dienone (XI), leading to the formation of 2,6-di-t-butyl-4-methylphenoxy-radicals[70], and on bis-(3,5-di-t-butyl-4-oxo-1-phenyl-cyclohexa-2,5-dienyl) peroxide (XII), accompanied by the formation of 2,6-di-t-butyl-4-phenylphenoxy-radicals[71].

The radicals formed by the thermal decomposition of organic peroxides are effective initiators of polymerisation processes[7,8]. The thermal decomposition of the peroxide (III)[50], which, as indicated above, takes place with rupture of the O–O peroxide bond, gives radicals which initiate the polymerisation of methyl methacrylate. On the other hand, the decomposition of the hydroperoxide (VII) in the presence of methyl methacrylate and vinyl acetate does not lead to polymerisation of the latter[69], in agreement with the earlier observation[71] that the polymerisation of acrylonitrile is not initiated by the decomposition products of the peroxide (XII), whose decomposition also takes place without rupture of the peroxide bond.

It can be seen from the foregoing that the peroxo-compounds formed from sterically hindered phenols may decompose in two ways when heated: with splitting of the peroxide bond [peroxide (III)] or with splitting of the C–O bond of the C–O–O–R group [peroxides (VII), (XI), and (XII)]. In this instance, when splitting takes place at the O–O bond, active radicals of type (IV), which initiate the polymerisation of monomers, are produced. On the other hand, the phenoxy and peroxo-radicals produced in the decomposition of peroxides with rupture of the C–O bond of the C–O–O–R group do not initiate the polymerisation of monomers, because of their comparatively high stability.

One example of the decomposition of cyclohexadienone structures with the formation of phenoxy-radicals is the quinonone-benzyl rearrangement of 2,6-di-t-butyl(-4-methylphenol quinobromide (XIII)[72], which reacts when heated to give the corresponding hydroxybenzyl bromide (XIV). The available published data could be used to ascribe to this process either an ionic mechanism[73] or a radical mechanism[74]. According to recent results[72], thermal treatment of (XIII) in the resonator of an EPR spectrometer leads to the production of an EPR signal corresponding to the 2,6-di-t-butyl-4-methylphenoxy-radical (X)[51,52]. On this basis, the following reaction scheme was suggested[72]:



(XIII) (XIV)

The phenoxy-radical (X) is also formed when (XIII) is treated with benzoyl peroxide, metallic mercury, or ultraviolet light. The formation of the corresponding phenoxy-radical has also been recorded by similar treatment of the quino-bromide of 2,4,6-tri-t-butylphenol[72].

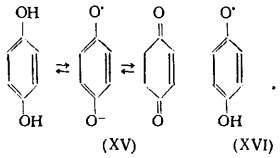
4. The Autoxidation of Sterically Hindered Phenols

The autoxidation of organic compounds is accompanied by the formation of free radicals[1,3] which in a number of instances are recorded by the EPR method[66].

In the oxidation of sterically hindered phenols, the formation, as final products, of compounds of the type PhO–OH and PhO–OPh[75–80], analogous to the products of the radical reaction of sterically hindered phenols with organic peroxides (see part 1 of this section), has been observed. The radical mechanism of the autoxidation of phenols was recently confirmed experimentally by the EPR method.

Adams and coworkers[81] observed the production of eight lines (1 : 1 : 3 : 3 : 3 : 3 : 1 : 1) in the EPR spectrum during the autoxidation of 2,6-di-t-butyl-4-methylphenol in alkaline medium. No explanation was put forward in the work cited for this structure of the EPR spectrum. Autoxidation was later studied in more detail[82] for the example of a number of 2,6-di-t-butyl-4-R-phenols. It was shown that the reaction leads to the formation of radical-ions of the semiquinone of the substituted pyrocatechol, recorded by the EPR method.

The autoxidation of *p*-hydroxyphenols (hydroquinones) is also accompanied by the formation of semiquinone radical-ions; this was proved as early as the nineteen-thirties by Michaelis and coworkers[83,84]:



(XV) (XVI)

The radical-ion formed in this reaction is stabilised by resonance, so that it can be observed by the EPR method. The EPR spectrum of (XV)[85,86], consisting of a quintuplet 1 : 4 : 6 : 4 : 1 (a = 2.37 Oe), is in agreement with the equivalence of all four protons of the benzene ring.

The semiquinone radical-ion has proved to be a convenient object for the study of the influence of substituents on the distribution of spin density in the ring[87], for the investigation of the inductive effect of substituents[88,89], and for the experimental verification of the theory of hyperconjugation[90].

Unlike (XV), the undissociated semiquinone (XVI) has a low stability and it has not been detected by the direct method.

Recently, Pokhodenko and Khiznhyi[91] detected uncharged semiquinone radicals in neutral medium (benzene) by the EPR method during the oxidation of hydroquinones containing bulky alkyl substituents in the *ortho*-positions. Thus in the oxidation of a solution of 2,6-di-t-butylhydroquinone in benzene with PbO_2, a triplet signal (1 : 2 : 1) is produced with splitting constant 1.75 Oe, corresponding to the uncharged semiquinone radical. The autoxidation of this compound in alkaline medium also gives a triplet signal, but with a reduced hyperfine splitting constant (1.2 Oe), assigned to the semiquinone radical-ion. The stabilities of the uncharged and charged semiquinone radicals differ considerably from one another: removal of the oxidising agent (PbO_2) in the first instance leads to the immediate disappearance of the EPR signal, whereas thorough evacuation of the oxidising agent (oxygen) in the second instance does not lead to rapid disappearance of the EPR signal.

5. Action of γ-Radiation and Ultraviolet Radiation on Phenols

It can be seen from the foregoing that most reactions leading to the formation of phenoxy-radicals are associated with the removal of hydrogen from the hydroxyl group of the phenol under the influence of oxidising agents. In recent years it has been shown that the rupture of the O–H bond in phenols with the formation of radicals may be brought about under the influence of ionising radiation. Thus the action of X-rays or ultraviolet light on 2,4,6-tri-t-butylphenol in the solid state or in benzene solution leads to the formation of a stable radical, whose EPR spectrum consists of a single line with a breadth of 3 Oe[92]. The irradiation of 2,4,6-tri-isopropylthiophenol leads to the formation of the corresponding disulphide[92], but the EPR spectrum could not be recorded, apparently due to the low stability of the radical produced. The detection of unstable radicals on irradiation is facilitated by the use of low temperatures. Thus the EPR spectra of radicals obtained by the photolysis of a number of thiophenols at 77°K [93] or by the γ-irradiation of solid bis-phenol[94] have been studied. The EPR method has been used to detect the formation of primary phenoxy-radicals when ultraviolet radiation is used for the initiation of the decomposition of t-butyl peroxide in the presence of a number of phenols at temperatures reaching −30°C.[95]

III. THE PROPERTIES OF PHENOXY-RADICALS

1. Properties of Sterically Hindered Phenols

Sterically hindered phenols, whose oxidation produces phenoxy-radicals, exhibit a number of specific properties. The presence of screening alkyl substituents in the *ortho*-positions relative to the hydroxyl group of the phenol leads to the loss of such typical properties of phenols as solubility in water and alkalis, the ability to give colour reactions with $FeCl_3$, and the ability to react with metallic Na, RMgBr, or diazomethane[96,97].

Bulky *ortho*-substituents hinder the reaction of the hydrogen of the O–H group with other molecules, and this influences reaction rates and the ability to form a hydrogen bond. The retarding action of bulky substituents on the rate of the reaction of phenols with peroxides was noted earlier. Thus in a study of the reaction of $RO_2^{\cdot}$ radicals with 2,6-dialkyl-4-methylphenols it was found that the rate of the process decreases with increase in the volume of the substituents in positions 2 and 6, in the following order: 2,6-dimethyl > 2,6-di-isopropyl > 2-t-pentyl > 2-t-octyl > > 2,6-di-t-butyl > 2,6-di-t-pentyl > 2,6-di-t-octyl > > 2-t-butyl-6-t-octyl[19,20]. An analogous influence of substituents was also noted in studies of the rates of the oxidation of phenols by lead tetra-acetate[55] and the acetylation[98] and alkylation of alkyl halides[99].

Steric hindering of the hydroxyl group of the phenol leads to a sharp decrease in its acidity, as with carboxylic acids[100–102]. Large groups hinder the solvation of the anion formed as a result of the dissociation, and hence decrease its stability. Moreover, it is possible that alkyl substituents in the phenol molecule, as in hindered acetic acids, decrease the effective dielectric constant around the OH group, increasing the electrostatic energy of the anion and hence decreasing the dissociation constant[100,101].

It is natural to assume that the steric hindering of the hydroxyl group is also responsible for the decrease in the electrical conductivity of solutions of substituted phenols. The ratio of the conductivities of the *p*-alkylphenol and its *o*-isomer in solution is equal to 14 for the cresols, 336 for the isopropylphenols, and 136 for the t-butylphenols[103].

As already noted, the hindering of the hydroxyl group by bulky substituents in the *ortho*-positions prevents the formation of associates of the substituted phenols with other molecules. A large number of studies have shown that unlike unsubstituted phenol[104–106], sterically hindered phenols show no tendency to form intermolecular hydrogen bonds[107–110]. For 2,6-di-t-butyl-4-methylphenol, the appearance in the infrared spectra of weak bands corresponding to hydrogen bonds is observed only in strongly basic solvents[111]. Groups which are less bulky than t-butyl have a smaller influence on hydrogen bond formation[109,112,113].

The study of phenol solutions by nuclear magnetic resonance (NMR) also confirms that steric factors have a decisive influence on the possibility of hydrogen bond formation[114–117]; a good correlation is observed between the magnitude of the chemical shift resulting from hydrogen bonding[117] and the displacement of the frequencies in the infrared spectra[107].

The frequencies of the stretching vibrations of the hydroxyl group in phenol are altered by the introduction of alkyl substituents in the *ortho*-positions, and the increase in frequency for 2,6-di-t-alkylphenols relative to unsubstituted phenol ($\Delta\nu = 34$ cm^{-1})[118–120] is too large to be attributed entirely to the inductive influence of the alkyl substituents.

At first sight, this increase in the frequency of the stretching vibrations of the hydroxyl group can be attributed to the breakdown of the coplanarity of the OH group and the ring, since this would lead to a decrease in conjugation and an increase in frequency. Proof of this influence of substituents on the coplanarity of individual groups of molecules has been published[121–124]. Study of the frequencies of the stretching vibrations of the OH group in 4-substituted

and 2,6-dialkyl-4-substituted phenols shows, however, that the frequencies and intensities of the bands show a good correlation with the Hammett constants σ of the substituents[108,118-120]. The slope of the straight lines is the same in both instances[118] and is equal to 13.7 cm^{-1}. On this basis it was concluded that the OH group in 2,6-dialkylphenols, as in phenols which have no substituents in the *ortho*-positions, is coplanar with the ring. Ingold[120] attributed the observed increase in frequency to the interaction of the electron clouds of the hydroxyl and *ortho*-alkyl groups. A similar explanation was used to interpret the results of a study of the chemical shifts of the NMR signal from the OH group of a number of mono- and di-ortho-substituted phenols, which showed that the screening of the hydroxyl proton increases with increase in the volume of the *ortho*-substituent[125]. Comparison of the values of ν and τ shows a correlation between these quantities, apparently indicating that the same factors are responsible for the change in these quantities. Although these results confirm the coplanarity of the OH group and the ring, the accuracy of the experiments does not exclude the possibility that there is slight rotation. The energy of conjugation of this group with the ring changes as $\cos^2\theta$ (where θ is the angle of rotation)[121,126], that is, even a fairly marked rotation of the bond under the influence of bulky substituents does not eliminate the conjugation completely. Thus for small values of θ this difference in the infrared spectra may not be detected.

The facts examined in this section indicate the highly specific nature of sterically hindered phenols, resulting from the presence of bulky alkyl substituents in the *ortho*-positions relative to the hydroxyl groups. The steric screening is also responsible for a number of the unusual properties of the radicals formed by the removal of hydrogen from the hydroxyl group of these phenols, particularly their high stability.

2. Stability of Phenoxy-radicals

The factors leading to the stabilisation of radicals have been examined in most detail for the example of the triphenylmethyl radicals formed by the dissociation of hexaphenylethane[7,127-129]:

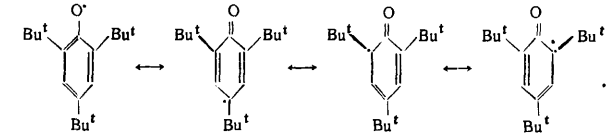
$$(C_6H_5)_3C{-}C(C_6H_5)_3 \rightleftarrows 2(C_6H_5)_3C^{\cdot}.$$

The chief factors determining the stability of free radicals are: (1) the extent of the steric hindrance of the atom formally carrying the unpaired electron; and (2) the extent of the delocalisation of the unpaired electron.

The introduction of phenyl groups into the *para*-positions of the benzene rings of the triphenylmethyl radical leads to an increase in the stability of the radical[130,131], due to the additional possibilities for delocalisation of the unpaired electron[132]. An analogous influence is observed when the phenyl rings are replaced by naphthyl rings. On the other hand, substituents in the *ortho*-positions of the phenyl rings lead to greater stabilisation of the radical than the same substituents in the *para*-position[133,134]. In the opinion of Razuvaev and coworkers[135], the stability of the radical may be due to intramolecular and intermolecular stabilisation. Study of the kinetics of the disappearance of substituted naphthoxy-radicals has shown the importance of both steric and energetic factors. Increase in the stability of radicals also takes place as a result of the formation of complexes with electron-donating solvents. The possibility of interaction between free radicals and the medium was also proved[137] by the EPR method for the example of nitrogen oxide radicals, which form a hydrogen bond with the participation of the unpaired electron with polar solvents.

Let us now consider the factors leading to the stabilisation of phenoxy-radicals.

The infrared spectra and EPR spectra‡ have shown that sterically hindered phenoxy-radicals are characterised by delocalisation of the unpaired electron[138]:



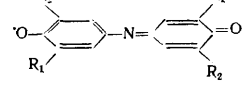
The infrared spectra of phenoxy-radicals shows a doublet band in the range 1600–1660 cm^{-1}. The presence of this band, which is characteristic of the C–O bond in 2,5-cyclodienones and substituted diphenoquinones[80,142-146], indicates that there is a marked contribution from the quinonoid structure in the overall state of the radical. This delocalisation of the unpaired electron leads to an increase in the stability of the phenoxy-radical.

When the t-butyl group in the *para*-position of the radical is replaced by a methoxy- or t-butoxy-group, the stability of the radical remains unchanged. This is apparently due to the participation of the ether oxygen in the overall conjugation, and this stabilises the radical to a sufficient extent, although the ether group in the *para*-position occupies less space than the t-butyl group[138].

The most important factor responsible for the stabilisation of phenoxy-radicals, however, is the steric hindering of the phenoxy-oxygen by bulky alkyl substituents. Thus the 2,4,6-tri-t-butylphenoxy-radical in the absence of oxygen may exist for as long a period as desired, whereas the 2,4,6-trimethylphenoxy-radical has a low stability and undergoes various changes. As already noted, the replacement of a t-butyl group in the *para*-position by the t-butoxy-group does not alter the stability of the radical. On the other hand, the replacement of an *ortho*-t-butyl group by an *ortho*-t-butoxy-group leads to a sharp decrease in stability. The gain in conjugation energy obtained due to the ether oxygen is insufficient to stabilise the sterically less hindered radical.

In recent years a number of attempts have been made to study the stability of phenoxy-radicals quantitatively. Thus Cook and coworkers[33] studied the disappearance of 2,6-di-t-butyl-4-isopropylphenoxy-, 2,6-di-t-butyl-4-cyclohexylphenoxy-, and 4-s-butyl-2,6-di-t-butylphenoxy-radicals from the change in the optical density of their solutions at 630 nm. The kinetic results obtained show that the rate of disappearance of these radicals decreases in the following order of substituents in the 4-position of the phenol: isopropyl > cyclohexyl > s-butyl. The rates of disappearance of the 2,6-di-t-butyl-4-methylphenoxy- and 2,6-di-t-butyl-4-ethylphenoxy-radicals was found to be so great that it could not be measured by the spectrophotometric method.

Extensive possibilities for the study of the stability of free radicals are provided by the EPR method. By using this method, it has been possible to determine the influence of the degree of steric hindrance of the phenoxy-oxygen of a number of indophenoxy-radicals on their stability[147]:



$R_1 = R_2 = t\text{-}C_4H_9$, (XVII)
$R_1 = R_2 = t\text{-}C_5H_{11}$, (XVIII)
$R_1 = R_2 = \text{cyclo-}C_6H_{11}$, (XIX)
$R_1 = R_2 = \text{iso-}C_3H_7$, (XX)
$R_1 = t\text{-}C_4H_9$; $R_2 = CH_3$. (XXI)

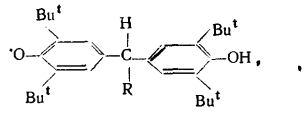
‡ The EPR spectra of a large number of phenoxy-radicals have now been studied[52,53,66,181].

It was shown that the radicals (XVII) and (XVIII), which do not contain α-hydrogen atoms in the *ortho*-substituents, have an extremely high stability; their concentrations in benzene or xylene solutions do not change to a significant extent as far as 70°C. On the other hand, the radicals (XIX), (XX), and (XXI), which contain α-hydrogen atoms in the *ortho*-substituents, have a much lower stability.

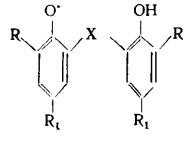
Comparison of the rate constants for the disappearance of the three indophenoxy-radicals (XIX), (XX), and (XXI) showed that their stability depends to a marked extent on the structure of the *ortho*-substituents. The ratio of the rate constants for the disappearance of the radicals studied is approximately

$$K_{XIX} : K_{XX} : K_{XXI} = 1 : 2 : 50.$$

The sharp increase in the rate of disappearance on going from the radicals (XIX) and (XX) to the radical (XXI) is due to the increase, by four orders of magnitude, in the value of the pre-exponential term, indicating that the *ortho*-substituents have a much smaller hindering effect on the reactive centre in radical (XXI) than in the radicals (XIX) and (XX). It is of interest to compare the stability of the radicals formed by the oxidation of *p*- and *o*-bis-phenols[148]. In the study of the oxidation of *p*-bis-phenols by the EPR method:



where R = H or C_6H_5, it was found that the phenoxy-radicals formed in the reaction have a high stability (for the radical with R = C_6H_5, $\tau_{1/2}^{40^\circ}$ = 1050 s). This is due to the extremely low value of the pre-exponential term ($K_0 = 3.2 \times 10^3\ s^{-1}$, $\Delta S^{\neq} = 60$ e.u.), and this in turn is due to the marked restrictions in the elementary stage of the disappearance of the phenoxy-radical. On the other hand, the phenoxy-radicals formed in the oxidation of *o*-bis-phenols have such a low stability that the authors cited[148] could not determine it quantitatively by the EPR method



X = CH_2, CH-C_6H_5, -S-;
R = t-C_4H_9, $C(CH_3)_2C_6H_5$;
R_1 = CH_3, C_2H_5, t-C_4H_9.

The reason for such a sharp decrease in stability on going from the *p*- to the *o*-bis-phenoxy-radicals is apparently the marked decrease in the steric hindering of the phenoxy oxygen by the ortho-substituents. In the *p*-bis-phenoxy-radicals studied, the oxygen is surrounded by bulky *o*-t-butyl groups, whereas in the *o*-bis-phenoxy-radicals one of the *ortho*-positions relative to oxygen is occupied by $-CH_2-$ or $-CH-C_6H_5$-groups or sulphur atoms, which have a smaller hindering effect than the *o*-t-butyl groups. Decrease in the degree of hindrance of the phenoxy-oxygen by *ortho*-substituents, as shown above for substituted indophenoxy-radicals, leads to a sharp decrease in the stability of the resulting radical.

The stability of phenoxy-radicals is also influenced to a significant extent by the degree of branching of the carbon atom of the alkyl substituent in the *para*-position.

Comparison of the rate constants of the disappearance and the transformation half-periods for 2,6-di-t-butyl-4-R-phenoxy-radicals (R = CH_3, C_2H_5,[149] or t-C_3H_7 [33]) indicates that their stability increases in the order of *para*-substituents: $CH_3 < C_2H_5 <$ iso-$C_3H_7 <$ t-C_4H_9.

An interesting feature is that the stability of the radicals formed by the oxidation of 2,6-di-t-butyl-4-alkylphenols is much less than that of the *p*-bis-phenoxy-radicals, due to the additional possibilities for delocalisation of the unpaired electron in the second instance. The 2,4,6-tri-t-butyl-phenoxy-radical, which does not contain α-hydrogen atoms in the *para*-substituent, is exceptionally stable and may exist for a prolonged period in the absence of oxygen.

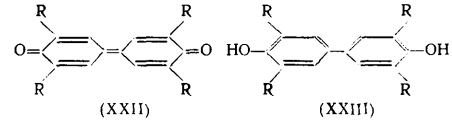
The examples considered in this section show that, as with the triphenylmethyl radicals, the chief factors responsible for the stability of phenoxy-radicals are the delocalisation of the unpaired electron and the extensive steric hindrance of the atom carrying a large proportion of the charge of the unpaired electron. These two effects explain the characteristic behaviour of phenoxy-radicals in chemical reactions. Let us consider some of these reactions.

3. Reactions of Phenoxy-radicals

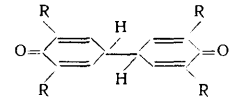
a. Recombination. As already noted, the phenoxy-radicals formed by the oxidation of 2,4,6-trialkylphenols which do not contain labile α-hydrogen atoms in their substituents are generally stable and do not undergo significant changes in the absence of oxygen. The recombination of these radicals is prevented by bulky substituents in the *ortho*- and *para*-positions. On the other hand, 2,6-di-t-alkylphenoxy-radicals with substituents in the *para*-position capable of conjugation with the unpaired electron exist in equilibrium with their dimers[53,150]. This dimer exists, for example, for the 2,6-di-t-butyl-4-cyanophenoxy-radical, whose unpaired electron is capable of conjugation with the substituent and can be found on the nitrogen atom.

The existence of a dimer has also been demonstrated[151] for the 2,4,6-triphenylphenoxy-radical, but its structure has not been determined[136,152].

The oxidation of 2,6-dialkylphenols containing a hydrogen atom in the *para*-position is accompanied by the formation of phenoxy-radicals and produces dimeric final products. Thus in the oxidation of 2,6-dimethylphenol or 6-t-butyl-2-methoxyphenol by lead dioxide[64], potassium hexacyanoferrate(III) in an alkaline medium[141,153,154,156], organic peroxides[21,22,79,157], and oxygen[62], the chief products of the reaction are the diphenoquinone (XXII) and its dihydroxy-derivative (XXIII), whose structures were confirmed from the infrared and ultraviolet spectra:



(XXII) (XXIII)



(XXIV)

The intermediate product (XXIV) is comparatively stable only in non-polar solvents and undergoes rapid isomerisation to the corresponding dihydro-derivative in polar media[64,141].

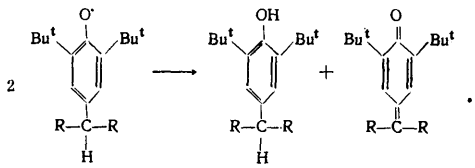
Analogous dimeric products are also formed in the oxidation of 2,6-di-t-butyl-4-chloro(bromo)phenols[36].

Study of the oxidation of phenols in which one or both *ortho*-positions were unsubstituted[21,22,60,62,71,154-156] showed that dimers joined in the *ortho*-positions are formed. These reactions involving the recombination of phenoxy-radicals show the importance of the influence of steric factors on the direction of the process. In all instances,

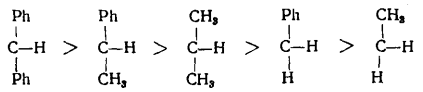
recombination takes place at the least screened position of the radical, carrying the unpaired electron.

b. Disproportionation of phenoxy-radicals. The introduction of secondary alkyl substituents into the *para*-position of 2,6-di-t-butylphenols leads to a decrease in the stability of the corresponding radicals relative to radicals whose *para*-position is occupied by tertiary alkyl substituents.

In a study of the disappearance of the blue 2,6-di-t-butyl-4-isopropylphenoxy- and 4-s-butyl-2,6-di-t-butylphenoxy-radicals, it was found that they are converted not into dimeric products but into the corresponding yellow quinone methides. Spectrophotometric study of the kinetics of this reaction showed that the rate of disappearance is described by an equation of second order with respect to the radical. On this basis, the following reaction scheme was proposed:



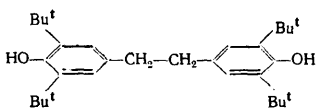
The formation of quinone methides and the original phenols was also observed in a study of the disappearance of a number of other phenoxy-radicals[158,159]. Study of the rate of disappearance of phenoxy-radicals by disproportionation has made it possible to estimate qualitatively the influence of a substituent in the *para*-position on the stability of the radicals[158,159]. It was found that the stabilities of the phenoxy-radicals decrease in the following order of substituents:



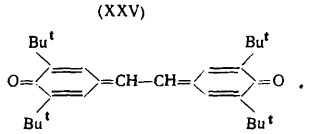
Examination of this series of substituents confirms the stabilising influence of the phenyl group on the radical.

c. Isomerisation of phenoxy-radicals. When the number of α-hydrogen atoms in the *para*-substituent of a 2,6-di-t-butylphenol is increased, the products of the oxidation of these phenols differ from those obtained from *p*-s-alkylphenols.

Thus the chief products of the oxidation of 2,6-di-t-butyl-4-methylphenol are 4,4′-ethylenebis-(2,6-di-t-butylphenol) (XXV) and 4,4′-ethanediylidenebis-(2,6-di-t-butylcyclohexa-2,5-dien-1-one) (XXVI):



(XXV)

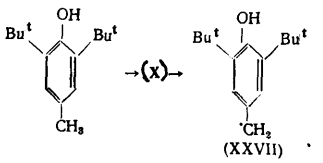


(XXVI)

The formation of these products led a number of authors[27,79,80] to suggest that the primary act in the oxidation of 2,6-di-t-butyl-4-methylphenol involves the removal of a hydrogen atom of the methyl group with the formation of the hydroxybenzyl radical (XXVII), whose dimerisation produces (XXV). Subsequent oxidation of (XXV) gives the final stilbenequinone (XXVI).

On the other hand, the formation of cyclohexadienone structures in the oxidation of 2,6-di-t-butyl-4-methylphenol by organic peroxides suggests the existence of phenoxy-radicals, whose presence in 2,6-di-t-butyl-methylphenol undergoing oxidation was later established reliably by spectroscopic methods, including the EPR method[51-52,141]. The formation of phenoxy-radicals as primary products of the oxidation of 2,6-di-t-butyl-4-methylphenol made it difficult to explain the production of the dimers (XXV) and (XXVI), since direct conversion into these compounds from the phenoxy-radical is impossible.

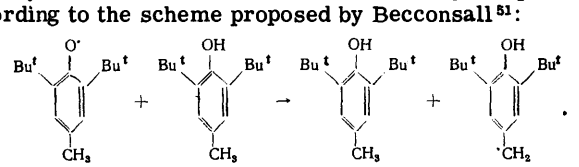
To resolve these contradictions, Cook[29] suggested that the initially formed phenoxy-radical (X) subsequently undergoes isomerisation to form the hydroxybenzyl radical, according to the scheme:



(XXVII)

The radical (XXVII) then undergoes dimerisation to 4,4′-dihydroxybibenzyl and is oxidised to the stilbenequinone.

Experimental confirmation of the isomerisation of the phenoxy-radical into the hydroxybenzyl radical was obtained by Brodskii and Pokhodenko[49,160,161], who studied the oxidation of 2,6-di-t-butyl-4-methylphenol containing deuterium in the methyl group. It was found that the oxidation of 2,6-di-t-butyl-4-methylphen[^{2}H]ol gives a dimeric product whose infrared spectrum, instead of the 2690 cm^{-1} band due to the stretching vibrations of the OD group, contains a band at 3650 cm^{-1} due to the OH group. This result shows that the primary act in the oxidation of 2,6-di-t-butyl-4-methylphenol involves the removal of hydrogen from the hydroxyl group, since the primary removal of hydrogen from the methyl group would have produced a dimer containing the OD group of the original phenol. An analogous result was obtained[161] in the oxidation of 2,6-di-t-butyl-4-perdeuteriomethylphenol. The infrared spectrum of the dimeric product was found to contain the band due to the stretching vibrations of the OD group, instead of the 3650 cm^{-1} band present in the original 2,6-di-t-butyl-4-perdeuteriomethylphenol. The results obtained in the works cited indicate isomerisation of the initially formed phenoxy-radical to produce the hydroxybenzyl radical, with transfer of hydrogen from the methyl group to the oxygen. These results also make it possible to reject the possibility of formation of benzyl radicals by the reaction of phenoxy-radicals with molecules of the original phenol according to the scheme proposed by Becconsall[51]:



The reaction of organic peroxides with trialkylphenols containing a methyl group in the *para*-position is interesting. The reaction of 2,4,6-trimethylphenol (XXVIII) and 2-t-butyl-4,6-dimethylphenol (XXIX) with peroxo-compounds gives the corresponding stilbenequinones as the final product[9]. On the other hand, the reaction of 2,6-di-t-butyl-4-methylphenol with peroxides gives cyclodienone structures of type (II)[10].

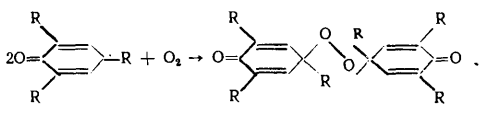
The only reaction of 2,6-di-t-butyl-4-methylphenol in which the formation of stilbenequinone is observed is that with triphenylmethyl hydroperoxide. This difference in the

behaviour of these phenols[9,10] can be explained as follows. The phenoxy-radical formed as a result of the primary attack of the peroxide residue on the phenol containing a methyl group in the *para*-position may react in two ways: in the first place, it may undergo isomerisation to an unstable hydroxybenzyl radical, whose dimerisation with subsequent oxidation of the dimeric products gives finally the stilbenequinone, or, in the second place, it may react with a new peroxide residue to give a cyclodienone derivative.

From the fact that the reaction of the phenols (XXVIII) and (XXIX) with peroxides gives stilbenequinones, it may be assumed that in this instance isomerisation takes place much more rapidly and more readily than their reaction with the peroxide residues. The phenoxy-radical formed in the oxidation of 2,6-di-t-butyl-4-methylphenol is much more stable than the phenoxy-radical formed in the oxidation of the phenols (XXVIII) and (XXIX), since both of its *ortho*-positions are occupied by bulky t-butyl groups. As a result, the rate of its isomerisation is decreased to such an extent that the main process leading to the disappearance of the radical is its reaction with the peroxide residues with the formation of cyclohexadienone structures of type (II). In the reaction with triphenylmethyl hydroperoxide, however, the rate of the reaction between the phenoxy-radical from the 2,4-di-t-butyl-4-methylphenol and the peroxide residue is decreased as a result of the marked steric hindrance of the reactive centre of the peroxide residue by the phenyl groups, and this prevents the reaction. The rate of this reaction is less than the rate of isomerisation of the phenoxy-radical to form the hydroxybenzyl radical, so that stilbenequinone is formed as the final reaction product.

The reaction of 2,6-di-t-butyl-4-methylphenol with alkyl nitrites, which readily decompose in solution to RO· and NO· radicals, leads to the corresponding quinonitrole (XXX) and hydroxybenzaldehyde (XXXI)[26]. To explain the formation of these products, a reaction mechanism which in our opinion is quite correct, was proposed[26]. The radical (X) formed as a result of the attack on the phenol molecule by the RO· radical either reacts with NO· with the subsequent formation of the quinonitrole or undergoes isomerisation to the hydroxybenzyl radical and then recombines with NO· to form the oxime of the corresponding hydroxybenzaldehyde; the oxime is readily converted into the aldehyde under the influence of the alkyl nitrite.

d. Reaction with oxygen. On contact with atmospheric oxygen, the usual bright blue or red colours of trialkylphenoxy-radicals gradually change to yellow, due to the formation of the bis-(1,3,5-trialkylcyclohexa-2,5-dienone) peroxides (XXXII)[27,28,30,46,64,65]. The formation of these peroxides is also observed in the oxidation of the phenols by PbO_2 or $K_3Fe(CN)_6$ in the presence of atmospheric oxygen:

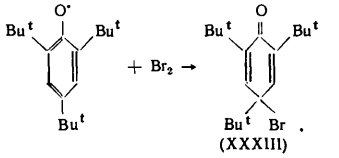


Proof of this structure for the peroxo-compounds is provided by the fact that the infrared spectra contain a doublet at 6.0 μm and 6.2 μm, corresponding to the quinonoid structure, and do not contain the band due to the hydroxyl group of the original phenols.

When the products of the reaction of phenoxy-radicals with oxygen are treated with hydriodic acid or sodium iodide in acetic acid, free iodine is liberated, indicating that they contain the peroxo-group O–O [50].

The ease of formation of bis-peroxides from phenoxy-radicals depends on the type of substituent in the *para*-position of the radical. Thus the rate of the reaction of 2,6-di-t-butylphenoxy-radicals with oxygen decreases with change in the substituents in the following order[36]: C_6H_5 > > $(C_6H_5)_3C$ > C_6H_5CO > C–N. A decrease in the rate of the reaction of phenoxy-radicals with oxygen is also observed when the t-butyl group in the *para*-position of the radical is replaced by methylphenyl or naphthyl groups, due to the additional stabilisation of the radical resulting from delocalisation of the unpaired electron[36,163]. An interesting feature is that the rate of the reaction with oxygen for the radical in which the *para*-position is occupied by the *p*-methylphenyl group is only half the rate of the reaction of the radical containing the *o*-methylphenyl group in the *para*-position[163]. This increase in reaction rate is apparently due to the decrease in the stability of the radical containing the *p*-methylphenyl group as a result of its displacement from the coplanar state, leading to the loss of conjugation energy.

e. Reaction with halogens. The addition of bromine solution to a solution of the 2,4,6-tri-t-butylphenoxy-radical in the absence of atmospheric oxygen produces a yellow crystalline precipitate[28], whose infrared spectrum[46] does not contain the band due to the hydroxyl group, but contains a double band at 6.0 μm and 6.2 μm, corresponding to the quinonoid structure (XXXIII):



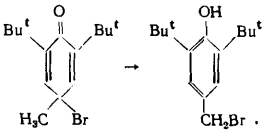
(XXXIII)

Compound (XXXIII) is also formed by the reaction of the phenol itself with bromine[164]. Study of the bromination of a number of phenols showed that in all instances the products are *p*-quinonoid structures, even when attack at the *ortho*-position is less hindered than attack at the *para*-position. This phenomenon is explained by the fact that electrophilic substitution in the phenol series takes place with a much smaller activation energy in the *para*-position than in the *ortho*-position[164].

All the quinobromides isolated have an absorption maximum in the range 248–251 nm, confirming the formation of the *p*-quinonoid structure (*o*-quinonoid structures have an absorption maximum in the range 320–360 nm [164]).

The stability of the quinobromides depends to a marked extent on the size of the substituents. Thus mesitol quinobromide exists for only 8 min at 20°C, whereas 2,6-di-t-butyl-4-methylphenol quinobromide exists for several days[162].

The instability of quinobromides with a methyl group in the *para*-position is due primarily to their spontaneous rearrangement with transfer of the bromine from the benzene ring to the methyl group



At elevated temperatures in the solid state and in non-polar solvents, this rearrangement takes place by a radical mechanism[72].

The reaction of phenoxy-radicals with (dichloroiodo)-benzene or with free chlorine gives quinochlorides similar

to the quinobromides described above. These compounds are unstable, and when heated they liberate chlorine and the original phenoxy-radicals.

f. Dehydrogenation of phenoxy-radicals. An extremely characteristic reaction of phenoxy-radicals, as of other free radicals, is the removal of hydrogen from organic compounds; the hydrogen becomes attached to the oxygen atom of the phenoxy-radical, and the radical formed from the molecule donating the hydrogen often recombines with the original phenoxy-radical with the formation of a quinol ether [165,166]. An example is the reaction of phenoxy-radicals with aromatic aldehydes [12] and with oximes of various structures [167].

The reaction of phenoxy-radicals with hydroperoxides leads to decomposition of the latter with the formation of stable products, and this is of considerable importance for processes of inhibited oxidation. The hydroperoxides in this instance cannot initiate new oxidation chains. Study of the kinetics of the disappearance of the 2,6-di-t-butyl-4-(3′,5′-di-t-butyl-4-hydroxydicyclohexa-2′,5′-dienylidenemethyl)phenoxy-radical in the presence of propene hydroperoxide [168] showed that the reaction is of first order with respect to each component. A bimolecular reaction mechanism with first-order kinetics with respect to each component was also found [169] in a study of the reaction of the 2,4,6-tri-t-butylphenoxy-radical with t-butyl hydroperoxide. The 2,4,6-tri-t-butylphenoxy-radical also removes a hydrogen atom from diethyl phosphite molecules. On the basis of kinetic data it was shown [170] that the reaction with diethyl phosphite involves the removal of hydrogen from the P–H bond of the monomeric form of the phosphite.

Stable phenoxyl radicals readily dehydrogenate phenols. An example is provided by the reaction of the 2,4,6-tri-t-butylphenoxy-radical (ArO·) with 4-t-butylphenol (PhOH) [171]. The observed ratio of the reacting components (2 moles ArO· per mole of PhOH) corresponds to the following reaction scheme:

$$\underset{\text{stable}}{ArO^{\cdot}} + PhOH \rightleftarrows ArOH + \underset{\text{unstable}}{PhO^{\cdot}}$$

$$ArO^{\cdot} + PhO^{\cdot} \underset{\text{slow}}{\overset{\text{rapid}}{\rightleftharpoons}} ArOOPh$$

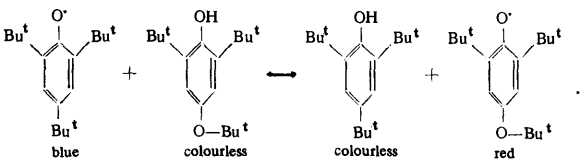
$$2ArO^{\cdot} + PhOH \rightarrow ArOH + ArOOPh$$

The formation of the quinol ether was also observed [172] in the reaction of the 2,6-di-t-butyl-4-phenylphenoxy-radical with 2-naphthol.

All the quinol ethers obtained are unstable. When heated in organic solvents they undergo reversible dissociation to the original radicals. The rate of dissociation is greater, the more marked the screening of the hydroxyl group of the phenol. Thus the quinol ether formed by diphenylnitroxide and the 2,4,6-tri-t-butylphenoxy-radical, formed by removal of a hydrogen atom at 20°C by the 2,4,6-tri-t-butylphenoxy-radical, undergoes reversible dissociation to the extent of 1%. [66]

The reaction of stable phenoxy-radicals with sterically hindered phenols in which the *para*-position is free or contains halogens, produces other reaction products [173]. For example, the reaction between the 2,4,6-tri-t-butylphenoxy-radical and 2,6-di-t-butylphenol leads to condensation of the benzene rings of the latter with subsequent dehydrogenation of the dimeric products and the formation of the corresponding diphenoquinone. The reaction of 2,6-di-t-butyl-4-methylphenol with stable radicals is analogous [143].

The reaction of stable phenoxy-radicals with phenols which also give stable radicals on dehydrogenation is an equilibrium reaction of the type:



The equilibrium constant for this reaction at 25°C is 51.7 ± 4.1, [35] that is, for the same initial concentrations of the components, the equilibrium is displaced towards the formation of the more stable alkoxyphenoxy-radical.

The same equilibrium reaction with the 2,4,6-tri-t-butylphenoxy-radical is undergone by 2,6-di-t-butyl-4-methoxyphenol [174] and 2,4,6-triphenylphenol [151].

Kreilick and Weismann [175] used the NMR method to determine the rate constant for the reaction of the 2,4,6-tri-t-butylphenoxy-radical with a molecule of the corresponding phenol, from the broadening of the signal due to the protons of the hydroxyl group. The rate constant found in this way at 30°C in CCl_4 was 300 litre mole^{-1} s^{-1}, and the value found for the activation energy was 1.0 ± 0.5 kcal mole^{-1}.

On the basis of a study of a large number of dehydrogenations, Muller and coworkers [176] suggested that the first stage in the dehydrogenation of organic compounds by phenoxy-radicals is the formation of an ion pair (A), stabilised with the formation of a new radical (B), which subsequently undergoes further transformation:

$$ArO^{\cdot} + HXR \rightleftarrows \underset{(A)}{[Ar\bar{O}\cdots H\cdots \overset{+}{X}R]} \rightleftarrows \underset{(B)}{ArOH} + RX^{\cdot}.$$

The dehydrogenation of various organic compounds by stable radicals provides a convenient method for studying the reactivity of these compounds. Kinetic studies of dehydrogenation by stable radicals make it possible to estimate the part played by energetic and steric factors in kinetics and to reach conclusions regarding the reaction mechanism. Here, promising possibilities are provided by the EPR method.

Buchachenko and coworkers [177] have used this method to study the reactivity of C–H bonds in various hydrocarbons with respect to the 2,4,6-tri-t-butylphenoxy-radical. It was found that in the hydrocarbon series n-decane–trimethylheptane and toluene–ethylbenzene–cumene, it is possible to follow the influence of methyl groups on the reactivity of the C–H bond being attacked, and in the series toluene–diphenylmethane it is possible to follow the influence of phenyl groups. The data obtained indicate that the reaction of the 2,4,6-tri-t-butylphenoxy-radical with hydrocarbons is characterised by relatively high activation energies, due to the endothermic nature of the removal of hydrogen, and that the activation energy decreases regularly with decrease in the strength of the C–H bond being attacked, from n-decane to diphenylmethane. Comparison of the activation energies in the toluene–diphenylmethane series shows that the introduction of phenyl groups has a much more marked influence on the kinetics of the process than the introduction of methyl groups. Examination of the values of the pre-exponential term (K_0) and entropy of activation ($\Delta S^{\neq}$) revealed the screening influence of the methyl and more particularly the phenyl groups, leading to a decrease in the probability of formation of the activated complex.

The 2,4,6-tri-t-butylphenoxy-radical has also been used to study the reactivity of the OH bonds in nitrophenols and the influence of solvents on this reaction[178].

The data obtained indicate that when nitro-groups are introduced into the phenol molecule, the activation energy for the removal of hydrogen from the hydroxyl group of the phenol is increased, but when several nitro-groups are introduced the effect is not additive. Measurement of the rate constants for the removal of hydrogen from *o*-nitrophenol in hexane, benzene, acetone, or methanol showed that the rate constant is independent of the nature of the medium. In the opinion of the authors cited[178], this indicates that the phenol taking part in the reaction is not solvated, apparently because of steric hindrance, in contrast to *m*-nitrophenol, which forms stable hydrogen bonds with the solvent.

As already noted, the thermal decomposition of the peroxide of the substituted cyclodienone (III) and ionol hydroperoxide (VII) is accompanied by the formation of phenoxy-radicals. It has been shown by the EPR method that these radicals are capable of removing hydrogen from the OH and NH groups of sterically hindered phenols.

The kinetics of the reaction of the stable tetra-t-butylindophenoxy-radical (XVII) with various aromatic amines and phenols were studied recently[179,180]. These compounds were chosen in order to study the influence of steric factors on the rate of hydrogen transfer, and also to study the influence of substituents and the applicability of the Hammett equation to radical reactions of this type.

Comparison of the activation energies, pre-exponential terms, and entropies of activation for the reaction of (XVII) with diphenylamine (DPA) and aniline shows that the replacement of one hydrogen atom in the NH_2 group of aniline by a phenyl group does not alter significantly the stability of the bond being attacked: the activation energy changes only slightly on going from aniline to DPA. The pre-exponential term, however, decreases by two orders of magnitude (the entropy of activation, which is a measure of the probability of formation of the active complex, decreases by 8 e.u.), indicating marked steric hindrance by the phenyl group. Thus the decrease in the rate constant for the reaction with DPA relative to the reaction with aniline is due to steric hindrance of the reactive centre of the DPA molecule by the two phenyl groups. A similar marked steric hindrance by the phenyl group was also observed[177] in a study of the removal of hydrogen from toluene and diphenylmethane by the 2,4,6-tri-t-butylphenoxy-radical.

The kinetics of the reaction of the radical (XVII) with aniline and its *para*-derivatives were studied[180] to investigate the influence of substituents on the reactivity of the NH bond in anilines. The values found for the rate constants for this reaction show that electron-donating substituents in the *para*-position of aniline increase the rate of removal of hydrogen, whereas electron-accepting substituents decrease the rate of hydrogen removal. The values of the logarithms of the reaction rate constants as functions of the corresponding values of the Hammett constants σ lie satisfactorily on a straight line, whose slope gives a value for ρ equal to 2.58. This high value of ρ indicates the importance of the polar influence of the substituents on the rate of removal of hydrogen from the NH bond of amines. A study of the rate of removal of hydrogen from DPA and aniline labelled with deuterium in the amino-group showed the existence of isotopic effects k_H/k_D, indicating that the stage determining the rate of the radical reaction of hydrogen removal is the rupture of the NH bond in the amine.

To investigate the influence of polar and steric factors on the reactivity of phenols, a study was made[179] of the reaction of the radical (XVII) with 2,6-di-t-butyl-4-R-phenols and phenols which did not contain alkyl substituents in the *ortho*-positions.

The reaction was carried out at phenol concentrations in the range 10^{-4}–10^{-3} M, in which displacement of the band due to the monomeric form of the OH group of the phenol in the infrared spectra is not observed. On this basis the results of the study were related to non-associated phenol molecules.

The data obtained show that on going from *ortho*-unsubstituted phenols to 2,6-di-t-butyl-4-R-phenols the pre-exponential term decreases by more than two orders of magnitude, corresponding to a decrease in the entropy of activation by 6 e.u. This indicates marked screening of the O–H group of the phenols by the two ortho-t-butyl groups. Despite this, the rate of transfer of hydrogen to the radical (XVII) from the 2,6-di-t-butyl-4-R-phenols is much greater than that from *ortho*-unsubstituted phenols. Comparison shows that the activation energy for the reaction of the radical (XVII) with sterically hindered phenols is only one-third of that with *ortho*-unsubstituted phenols. Thus in the reaction of the radical (XVII) with sterically hindered phenols there is a strong compensation effect, so that in spite of the marked screening action of the two *ortho*-t-butyl groups on the OH bond of the sterically hindered phenols, these groups at the same time alter the properties of the OH bond being attacked to such an extent that the transition state of the reaction is realised with a smaller expenditure of energy for 2,6-di-t-butyl-4-R-phenols than for *ortho*-unsubstituted phenols. For this reason the reactivity of sterically hindered phenols in the transfer of hydrogen to a stable radical is greater than that for *ortho*-unsubstituted phenols.

The rate of transfer of hydrogen to the radical (XVII) decreases in the order 2,6-di-t-butylphenol–2,6-di-t-butyl-4-methylphenol–2,6-di-t-butyl-4-ethylphenol, and the electron-donating properties of the substituents in the *para*-position increase in the same order.

Comparison of the rate constants for the reactions of the radical (XVII) with diphenylamine and phenols shows that the rate of the reaction with diphenylamine is less than that with phenols by a factor of 100–1000. This is due to the marked hindrance of the reactive centre in DPA and its derivatives, resulting in lower values of the pre-exponential term, compared with phenols. Similar low values of the pre-exponential terms were previously observed in the reaction of DPPH with a number of amines[66].

Practical requirements in the development of new and effective phenolic inhibitors of radical reactions should be turning the attention of research workers primarily to the study of the influence of the steric and polar properties of substituents on the stability and reactivity of the radicals formed in the oxidation of sterically hindered phenols, since detailed information in this field will open up new perspectives in the scientific selection of substances capable of retarding undesirable changes in organic compounds chiefly polymers, during their exploitation.

Retention of Configuration in Reactions with Opening of an Epoxide Ring

A. A. Akhrem, A. M. Moiseenkov, and V. N. Dobrynin

Information on the opening of an epoxide ring with retention of the initial configuration under conditions of catalytic hydrogenation and under the action of various nucleophilic reagents is examined. It is noted that when an electron-donating *p*- or π-grouping is present in the α position to the epoxide ring the retention of the initial configuration is more probable than its inversion. Bibliography of 182 references.

I. INTRODUCTION

A large number of reactions of epoxides with various reagents has now been studied. The great mass of results that had accumulated were summarised in several exhaustive reviews[1-6], and the most recent of these also dealt with the stereochemical aspect of the transformations. In 1951 Fürst and Plattner[7] formulated the "rule for the biaxial opening of the expoxide ring", which three years later Cookson[8,9] and Angyal[10] extended its applicability from the position of conformational analysis to cyclic systems. According to these ideas, the opening of the oxide should be accompanied by inversion of the configuration of one of the carbon centres of the three-membered ring. However, at approximately the same time publications appeared showing that in several instances opening of the epoxide ring takes place with retention of the original configuration. An analysis of the constantly increasing number of experimental results shows that the so-called "sterically anomalous (*cis*-)opening of an epoxide ring" is observed among various representatives of the class of oxide compounds when various reagents act on them. The present review considers those instances which have not yet been summarised in the literature and covers information published up to July 1966.

II. SOME GENERAL FEATURES OF THE CHEMISTRY OF EPOXIDES

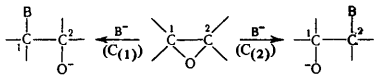
In the reviews mentioned above the correctness of the following general features of the chemistry of epoxides has been demonstrated convincingly.

1. The epoxide group often reacts in two ways, interacting with both electrophilic and nucleophilic agents under definite conditions. However, information on reaction with the latter predominates in the literature. The changes in the presence of electrophilic and radical reagents, and also on irradiation, lead mainly to the formation of products of various rearrangements of the oxide ring.

2. Breaking of the C–O bond of the epoxide takes place under the influence of various agents. Breaking of the C–C bond of the oxide ring is improbable and is observed only in the presence of strongly electronegative substituents, as occurs, for example, for oxides of cyclic trienes[11] and pentaenes[12], tetracyanoethylene oxide[13], etc.

3. The mechanism of the opening of the epoxide under the action of a nucleophilic reagent depends on the electronic and steric properties of the two reagents and on the reaction conditions. The results of the opening of the oxide are usually explained by schemes of the unimolecular and bimolecular substitution type. The direction of

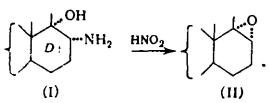
the opening of unsymmetrically substituted epoxides depends on the above factors and in general the formation of two structural isomers is possible:



The ratio of the latter cannot be predicted, although in some particular instances useful empirical relations exist.

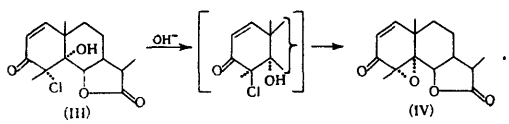
4. The stereochemistry of the opening of epoxy-compounds is determined by the steric rules for the occurrence of S_N1 and S_N2 processes. The stereochemical requirements for an S_N2 mechanism arise in the formation of a *trans*-coplanar transition state as a result of axial attack by the nucleophilic reagent on one of the carbon atoms of the epoxide with subsequent inversion of the configuration of the centre being attacked. In the cleavage of the epoxide ring by an S_N1 type mechanism as a result of the interaction with the nucleophilic reagent formation of products with both retention and inversion of the initial configuration can be expected.

5. A necessary condition for the closing of an epoxide ring is the coplanar antiparallel location of the attacking and leaving substituents. However, some departures from the classical scheme of closing of an epoxide ring are known. Thus Shoppee and coworkers[14] found that on treating the D-homopregnane amino-alcohol (I) with nitrous acid the α-oxide (II) is obtained in good yield. The explanation for this type of closing of the oxide ring is that the OH group of the *cis*-*e*, *a*-amino-alcohol (I) is in a position convenient for the formation of a pyramidal transition state, and consequently the removal of the diazonium group proceeds as a result of a synchronous process of the pinacoline type without formation of an intermediate carbonium ion.



(I) (II)

Moreover, it is known that in the diazotisation of *threo*-1,2-diphenyl-2-aminoethanol the oxide of *trans*-stilbene is produced in low yield[15]. The retention of the initial configuration is also observed in the treatment of the *cis*-chlorohydrin (III) with alkali[16]. However, here it is suggested that the ketol (III) is first isomerised by a retro-aldolisation type of mechanism into an intermediate *trans*-chlorohydrin, which is then converted into the keto-oxide (IV):



(III) (IV)

A similar process evidently takes place in the series of diastereoisomeric esters of α-chloro-β-hydroxy-β-trifluoromethylpropionic acid, which give only one epoxypropionate on treatment with sodium hydride[17].

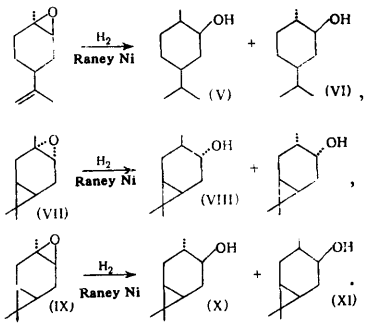
III. STEREOCHEMISTRY OF EPOXIDE RING OPENING PROCEEDING WITH RETENTION OF THE CONFIGURATION

It must be noted that the presence in the literature of isolated information on the "sterically anomalous" opening of an oxide ring, and also the absence, with a few exceptions, of systematic investigations in this field still do not allow a satisfactory classification to be given for all instances of this interesting phenomenon. Nevertheless we can provisionally distinguish two large groups of epoxy-compounds in which this phenomenon is observed.

A. Epoxy-Compounds in which the Effect of Conjugation is Absent

The *cis*-opening of the oxide ring in this group of compounds is encountered extremely rarely and is characteristic for the conformationally rigid secondary-tertiary and ditertiary cyclic epoxy-compounds. It is therefore quite probable that in all the examples considered below the steric factor plays a paramount part.

1. Reductive *cis*-opening of an oxide ring. Examples are known when the catalytic hydrogenation of cyclic epoxides leads to cleavage products with retention of the configuration of the initial oxides. Evidently such conversions were first observed by Brunel[18,19] and Kötz and Hoffman[20] in studying the hydrogenation of methylcyclohexene oxides in the presence of nickel and platinum catalysts. According to their results, for example, 1-methylcyclohexene oxide gives *trans*-2-methylcyclohexanol. This result signifies that the entry of hydrogen and the breaking of the C–O bond probably occur at the same side of the cyclohexane molecule, which also ensures the *cis*-opening of the oxide ring. On the basis of an analysis of the complex mixture of products obtained in the hydrogenation of 1,2-, 2,3-, and 3,4-epoxymethanes in the presence of palladium hydroxide, Pigulevskii and Kozhin[21] assumed the similar possibility of the retention of the configuration of the original oxide as did Kergomard and Geneix[22,23], who studied the catalytic hydrogenation of tetrahydromyrcene oxide, pinene oxide, carbomenthene oxide, and limonene oxide. It was recently shown that the products of the hydrogenation of the sterically homogeneous *trans*-*p*-menthadiene oxide contain not only neoisocarbomenthol (V) but also carbomenthol (VI),[24,25] which arises as a result of the *cis*-opening of the epoxide ring.

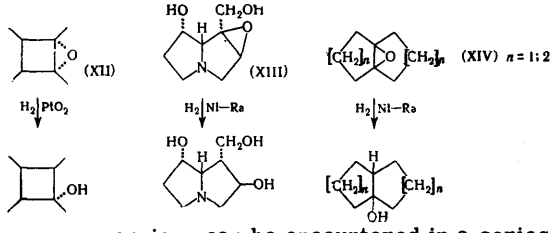


(V) (VI) (VII) (VIII) (IX) (X) (XI)

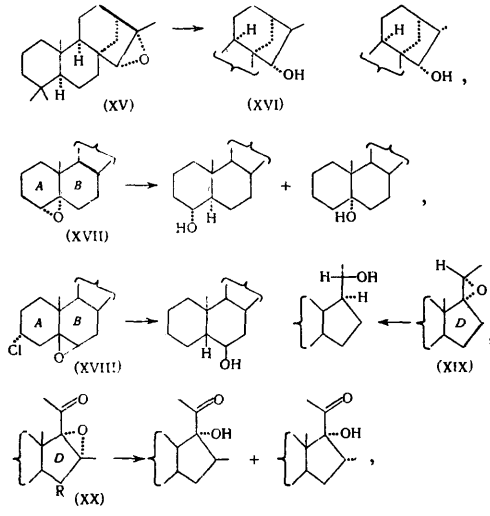
Similar results are obtained in investigating the hydrogenation of isomeric carene oxides (VII) and (IX) over Raney nickel catalyst under pressure[26]. Here with the oxide (VII) there is 82% *cis*-opening of the epoxide ring—formation of product (VIII)—and with oxide (IX) the products of the *cis*- and *trans*-opening, (X) and (XI), are formed in approximately equal amounts.

Retention of the initial configuration is observed in the catalytic hydrogenation of epoxytetramethylcyclobutane

(XII)[27] and of the oxides of the bicyclic alkenes (XIII)[28] and (XIV)[29].

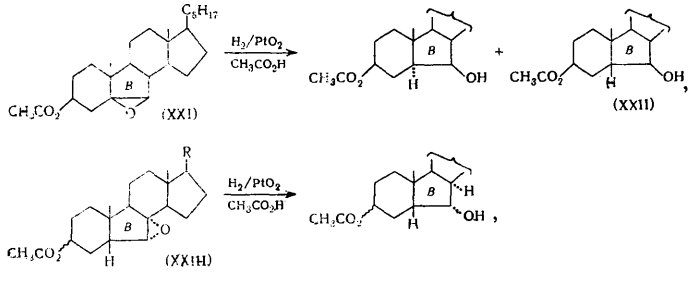


Analogous conversions can be encountered in a series of polycyclic epoxy-compounds. Thus isophyllocladene oxide (XV) in the presence of Adams catalyst gives a mixture of epimeric alcohols with a preponderance of the product of *cis*-cleavage (XVI)[30]. Under the same conditions 4α,5α-epoxycholestane (XVII) is converted into a mixture of approximately equal amounts of the 4α- and 5α-alcohols[31], whereas only the 6β-alcohol is obtained from 3α-chloro-5β,6β-epoxycholestane (XVIII)[32]. Furthermore, exclusively *cis*-opening is observed[33,34] in the catalytic hydrogenation of pregnane 17α,20α-oxides (XIX) over Raney nickel. As regards the ditertiary pregnane keto-acids (XX) in the presence of a palladium catalyst they undergo either partial or complete *cis*-opening, depending on the hydrogenation condition[35,36]:



where R = H or Br.

Recently, Šorm and coworkers[37,38] described the opening of oxides of the B-norcholestane and B-norandrostane series. Here the 5β,6β-oxide (XXI) gave a mixture of alcohols with a considerable preponderance of product (XXII), which exhibits the configuration of the original epoxide. With the 6α,8α-oxide (XXIII) the opening proceeds exclusively with retention of the original configuration

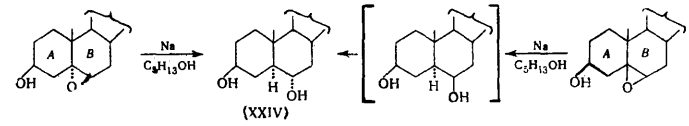


where R = C_8H_{17}, O_2CCH_3.

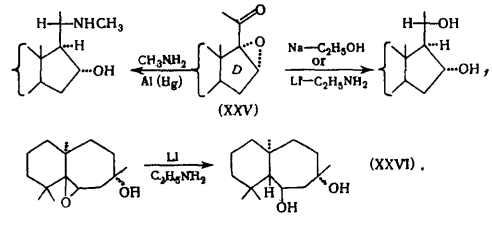
To explain the conversions mentioned it is necessary to assume that the generally accepted ideas about the mechanism of catalytic hydrogenation of steroidal alkenes[39] are also applicable to steroidal epoxides.

It is extremely probable that here also the reaction proceeds by *cis*-addition of a molecule of H_2, adsorbed on the surface of the catalyst, to the sterically most accessible C–O bond of the oxide ring.

cis-Opening is much more rarely encountered for other methods of reducing the oxides. Thus, Urushibara and Chuman[40] observed the reduction of 5α,6α-oxides of cholesterol by sodium in pentyl alcohol to give the 3β,6α-glycol (XXIV):



They obtained the same product in identical conditions from cholesterol 5β,6β-oxide. However, it appeared that initially there is *trans*-opening of the cholesterol β-oxide to the intermediate 3β,6β-glycol, which subsequently isomerises to the more stable 6α-epimer under the conditions of the redox reaction. It is also known that the reductive amination of the steroidal 20-keto-16α,17α-oxides (XXV) is accompanied by their *cis*-opening[41]. The same result is observed in the reduction of oxides (XXV) by sodium in alcohol[42] or by lithium in ethylamine[43]. With the aid of the last reagent Widdrol β-oxide† was converted into the glycol (XXVI) in ~ 40% yield[44].

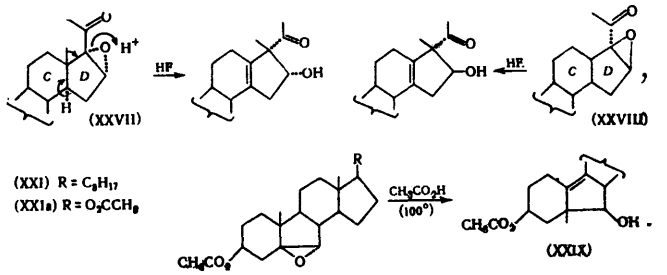


2. Oxides in Wagner–Meerwein type rearrangements. The reaction of cyclic secondary-tertiary and ditertiary oxides with acids, just like the epoxidation of the corresponding alkenes, often leads to the formation of products of various rearrangements[3,6]. It is usual to explain these conversions by the concept of the carbonium-ion intermediate, the manner of the "neutralisation" of which determines the structure of the final products. Sometimes these can be products of a Wagner–Meerwein type rearrangement. It is well known that the latter includes the simultaneous formation of an electron-deficient centre and an antiparallel *cis*-1,2-displacement of the migrating substituent (usually methyl), that for an epoxide will signify its *trans*-opening. Such a situation is preferable, since this process does not result in the formation of a discrete carbonium ion. However, it is possible for there to be a non-simultaneous process including the anticipatory stage of the formation of a stable carbonium ion at the site of the rupture of the C–O bond of the oxide ring[45,46]. The latter implies that with the mutual *cis*-arrangement of the epoxide and migrating groups the configuration of the two carbon centres of the original oxide will be retained. Both these types of mechanism

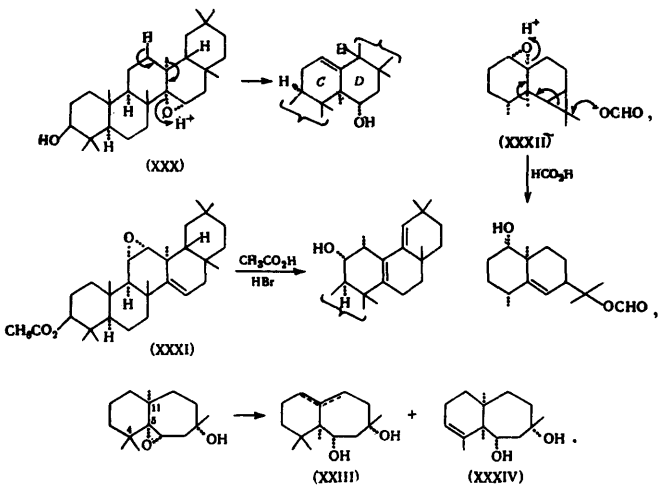
† The symbols α and β in the present review signify, as in steroids, the configuration of the three-membered oxide ring.

are observed experimentally, as is illustrated by the conversion of isomeric keto-oxides of the pregnane series (XXVII) and (XXVIII)[47,48].

On the other hand, on heating the 5β,6β-oxides (XXI) and (XXIa) in acetic acid *cis*-opening takes place exclusively[37], and the formation of 19,B-bis-nor-products (XXIX) does not have an analogy in the normal steroidal series which contains a six-membered ring B.



The literatures also describes the "anomalous" opening of terpene epoxides in the presence of acids, as is shown by the examples of taraxerine oxides (XXX)[49] and (XXXI)[50] and calarene oxide (XXXII)[51]:

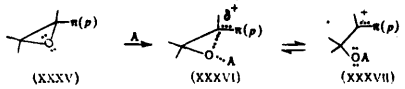


An interesting example is Widdrol α-oxide itself, which on boiling in water gives a mixture of homoallyl alcohols (XXIII) and (XXXIV)[44]. It is suggested that the configuration at $C_{(5)}$ is retained as a result of the formation of an hydrated carbonium-ion intermediate which is subsequently stabilised by a displacement of the methyl group at $C_{(4)}$ or $C_{(11)}$.

B. Epoxy-Compounds in which the Effect of Conjugation Appears

To this group belong the compounds in which the oxide ring is adjacent to an unsaturated bond or to an atom with an unshared *p*-pair of electrons. Like conjugated cyclopropanes and aziridines, the epoxy-compound (XXXV) displays the conjugation, as is shown by the ultraviolet spectra of monoepoxides of conjugated dienes[52], aryl oxides[53] and keto-oxides[54]. However, it must be stated that the investigation of infrared spectra of acyclic keto-oxides[55] and epoxypropionates[56] did not disclose any appreciable conjugation between the oxide ring and the C=O group, although this effect probably occurs to an insignificant extent in several cyclic keto-oxides[57].

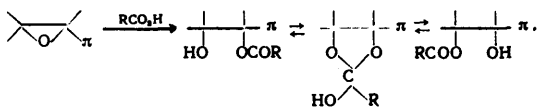
The greatest number of examples of *cis*-opening have been described for epoxides of the type of (XXXV). In all these examples, except for the reaction of indene oxide[58] and phenylcyclohexene oxide[59] with dilute alkali and also the reduction of certain oxides by alkali metal complex hydrides[60-62] or by lithium in ethylamine[63] the reaction takes place under conditions of electrophilic catalysts. According to generally accepted ideas, under such conditions partial or complete rupture of the C–O bond of the epoxide is possible with formation of cationic intermediate transition states (XXXVI) and (XXXVII):



where $\pi(p)$ is aryl or ester; and A is a Lewis acid.

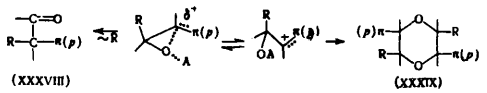
Here it is considered that the existence of this type of transition state is the main reason determining the "sterically anomalous" opening of the oxide ring (XXXV). A similar approach to the solution of the problem under discussion is justified by the following observations.

1. The primary change leading to products of the *cis*-opening of the oxide ring takes place at the carbon atom connected to the electron-donating substituent. This is not always evident for the reactions of oxides with carboxylic acids owing to the frequently observed secondary process of the migration of the acyl residue and the possible formation of a mixture of monoesters[59,64-71]:



To show the direction of attack of the nucleophilic reagent it is convenient to use an acid the acyl residue of which exhibits reduced tendency to migration, for example, mesitylenecarboxylic acid[65,66]. The determination of the direction of acid hydrolysis of the epoxy-compounds (XXXV) is more complex. Definite results in this instance can be obtained with the aid of optically active substances, as was done for styrene oxide[65] and phenylpropene oxide[72].

2. The opening is often accompanied by the formation of carbonyl products (XXXVIII), which arise as a result of the rearrangement of the epoxide under the action of electrophilic catalysts[3,6]. Sometimes such a direction for the reaction predominates, this being especially characteristic for oxides of type (XXXV). Under certain conditions stabilisation of the new electron-deficient centre can be brought about by dimerisation (XXXIX), as for example, with 3-methoxydihydronaphthalene oxide[73,74]:



where R = H, alkyl, aryl, acyl.

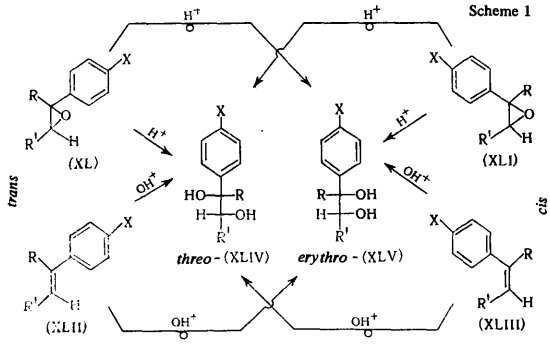
3. Kinetic investigations show that the opening of the oxide (XXXV) can be described by either S_N2 or S_N1 mechanisms with each of these taking part in different proportions in any particular instance[3,6]. In this connection the production of a mixture of products with inversion and retention of the configuration of the reaction centre can be expected. The *cis*-opening of the oxides (XXXV) is usually connected with the possibility of unimolecular substitution, although this viewpoint has been criticised[2,3].

1. *cis*-Opening of Aryloxides. The account of the information on the *cis*-opening of one of the most widely studied groups of epoxides of type (XXXV)—the aryl-

oxides—must begin with consideration of some of the conversions of styrene oxide, although in view of the primary–secondary nature of the latter the stereochemistry of these changes cannot be discussed conclusively. For example, it is found that the attack of carboxylic acids[64,65,67] and hydrogen halides[67,75-78] is directed preferentially at the benzyl carbon atom and the products of the reaction of optically active styrene oxide with weak acids (benzoic and mesitylenecarboxylic) are racemates. On treatment with trichloroacetic (in benzene), acetic, and dilute sulphuric acids, and also with phenylmercaptoborane[79] (in tetrahydrofuran) inversion is observed, equal respectively to 37, 62, 66, and 85%. On this basis it was suggested[65,67,79] that opening of styrene oxide, which is catalysable by weak acid, proceeds preferentially by an S_N1 mechanism with formation of a rather stable intermediate benzyl carbonium ion.

With the appearance in the molecules of styrene oxides a second asymmetric centre it seems possible to consider definitely the stereochemistry of the opening of the epoxide ring as a process depending on the steric and electronic factors of the substituents, the nature of the attacking agent, etc. In the general form, such opening is represented in scheme I by hydrolysis of the isomeric oxides (XL) and (XLI), and also by the equivalent epoxidation of alkenes (XLII) and (XLIII) by some certain per-acids. In this the "sterically anomalous" process in a series of *trans*‡-compounds (XL) and (XLII) should lead to *threo*-glycols (XLIV), but in the *cis*§-systems (XLI) and (XLII), to the *erythro*-glycols (XLV). Böeseken and coworkers[80,81] evidently were the first to observe such changes; they isolated a mixture of monoacetates of racemic and meso hydrobenzoins in the epoxidation of stilbenes (XLII, XLIII; R = X = H; R′ = C_6H_5). Analogous results on the opening of aryl oxides and the epoxidation of the corresponding alkenes obtained by other authors are summarised in Table 1.

Scheme 1



The data in this table show that in a comparatively non-polar medium the predominating direction of the opening of the *trans*-oxides (XL) by acids is, like the addition of the elements of per-acids to *trans*-alkenes (XLII), "sterically anomalous". In the *cis*-series (XLI, XLIII) these reactions are characterised by a lower degree of stereospecificity, and moreover the yield of final products is somewhat less. In almost every instance carbonyl compounds are observed as side-products, their formation depending to a considerable extent on the pH of the medium. For example, the amount of 4-methoxybenzyl phenyl ketone is increased threefold when the reaction of *trans*-4-methoxystilbene with $C_6H_5CO_3H$ takes place in benzene saturated with water (Table 1, Nos. 21 and 22). When a non-polar solvent is used the pH of the medium has little effect on the yield of products with retained configuration (Table 1, Nos. 9–16) but considerably affects the rate of the process. Thus for the opening of *trans*-stilbene oxide chloroacetic acid (p*K* 2.81) requires the reaction mixture to be boiled for several hours, whereas with trichloroacetic acid (p*K* 0.1) the reaction is completed in the cold in a few minutes (in benzene)[86,87]. Probably the increased reaction rate in the presence of a strong acid can also explain the formation of trichloroacetates of hydrobenzoins (instead of benzoates) in the epoxidation of stilbenes by an equimolecular mixture of perbenzoic and trichloroacetic acids (Table 1, Nos. 17, 18, 33).

The data in Table 1 show that *cis*-opening of the oxide ring of the systems being considered is evidently not characteristic in a strongly polar medium. For example, acid hydrolysis and acetolysis of isomeric oxides of methylstyrene (XL, XLI; R = X = H, R′ = CH_3), or the epoxidation of the corresponding alkenes (XLII, XLIII) with performic acid leads predominantly to products with inverted configuration (Table 1, Nos. 1–8). Similarly, the acid hydrolysis of *trans*-anisyltolylethylene (XL; R = H, X = OCH_3, R′ = *p*-$CH_3C_6H_4$) gives a mixture of diastereoisomeric glycols (Table 1, No. 26), whereas treatment with benzoic acid in chloroform (rather low polarity) results in full retention of the configuration (Table 1, Nos. 25).

Instances of the stereospecific opening of aryl oxides irrespective of the polarity of the medium have been described. Thus, it is known that acid hydrolysis of the secondary-tertiary *trans*-α-methylstilbene oxide (XL; R = CH_3, X = H, R′ = C_6H_5) gives *threo*-α-methylhydrobenzoin[90-92]. Complete retention of the initial configuration i observed in the opening of the same oxide under milder con ditions, and also in the epoxidation of the corresponding *trans*-alkene (XLII; R = CH_3, X = H, R′ = C_6H_5) (Table 1, Nos. 29–33).

The effect, mentioned above, of the polarity of the solvent on the nature of the opening of the epoxide ring is illustrated by the celebrated examples of the reaction of hydrogen halides with aryl keto-oxides, β-phenylepoxypropionates, and stilbene oxides. Thus, Jorlander[93] found that, depending on the solvent used (alcohol or acetic acid), 1-anisyl-2,3-epoxy-3-phenylpropan-1-ol forms various chlorohydrins with hydrogen chloride. Later it was shown by other examples that such compounds are not structural isomers. Moreover it was found that in every instance the halogen atom is attached in the β position to the C=O group and that frequently such addition proceeds with retention of the configuration of the original oxide (Table 2).

As Table 2 shows, when hydrogen halides react with disecondary carbonyl-containing phenyl oxides (XLVI) and (XLVII) in non-polar solvents there is a stereospecific *cis*-opening of the epoxide ring, whereas in polar media there is complete inversion of the configuration (Table 2, Nos. 1, 2, 12, 13). With the secondary-tertiary dypnone oxide and *cis*-bromodiphenacyl oxide, irrespective of the polarity of the solvent there is a "sterically anomalous" reaction (Table 2, Nos. 6, 7, 10, and 11). In this respect these epoxides behave completely analogously to the *trans*-α-methylstilbene oxide (XL; R = CH_3, X = H, R′ = C_6H_5) mentioned above.

The stereospecific *cis*-opening of the oxides (XLVI and XLVII) proceeds in the presence of Lewis acids (Table 2, Nos. 3–5, 8, and 9). When using boron trifluoride–diethyl

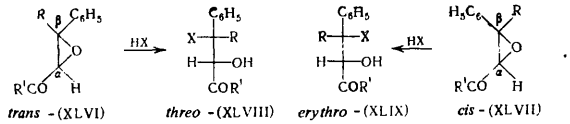
ether, House[97] noted the formation of carbonyl side-products, the quantity of which increases rapidly with increase in the concentration of the complex:



trans -(XLVI) *threo* -(XLVIII) *erythro* -(XLIX) *cis* -(XLVII)

Somewhat unexpectedly there is complete inversion of the configuration in the reaction of a *cis*-epoxypropionamide (XLVII; R = H, R′ = NEt_2) with HCl, both in benzene and in methanol (Table 2, Nos. 14 and 15). Here the *erythro*-isomer (XLIX) is formed. The strict stereospecificity of this reaction is evidently due to the thermodynamic stability of the corresponding transition state, and will be discussed in detail below.

Thermodynamic control probably plays a decisive part in the conversions of some other epoxypropionates. Thus it is well known that acid hydrolysis of *trans*-β-phenylepoxypropionic acid (XLVI; R = H, R′ = OH) proceeds with retention of the configuration and gives *threo*-diol (XLVIII; R = H, R′ = X = OH)[103]. House and Blaker[56] assume the possibility of side reactions for epoxy-β-methyl-β-phenylpropionates (XLVI, XLVII; R = CH_3, R′ = OC_2H_5). However, the available published information on this subject does not permit any general conclusions to be drawn.

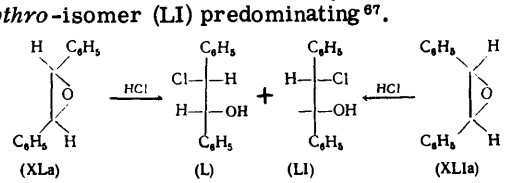
* Acetate of the bromohydrin.

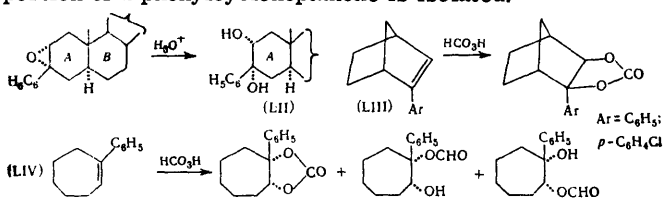
Extremely interesting results were obtained by Berti and coworkers[67] who reexamined previous studies[104-106] of the addition of HCl to isomeric oxides of stilbene (XLa, XLIa). In investigating the effect of solvents of various polarities on the stereochemistry of the reactions, they succeeded in showing (Table 2, Nos. 16–23) that in a comparatively non-polar medium the *trans*-isomer (XLa) undergoes *cis*-opening exclusively, as took place when the same oxide was treated with chloroacetic acids (Table 1, Nos. 9–13). With increase in the polarity of the solvent there is an increase in the yield of the product of the *trans*-opening of the oxide (XLa) and, for example, in the medium of moist ether a mixture of the chlorohydrins is formed with the *erythro*-isomer (LI) predominating[67].



(XLa) (L) (LI) (XLIa)

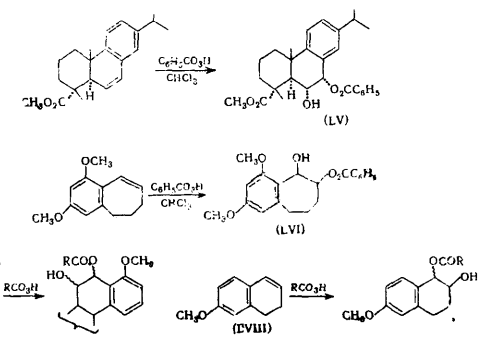
Unlike the *trans*-oxide, the *cis*-isomer (XLIa) in all the solvents used gave mainly the product of *trans*-opening (L) together with small amounts of the diastereoisomer (LI) and carbonyl compounds. These results differe from those in which there is exclusively *cis*-opening of oxide (XLIa) under the action of chloroacetic acids (Table 1, Nos. 14–16), which could be due to the nature of the carboxylate and halide nucleophilic ions, which participate in the realisation of the corresponding transition states[67].

The epoxides of aryl cyclenes stand somewhat apart from the aryl oxides considered above. There is extremely little information on their *cis*-opening, just as for the *cis*-addition of the elements of per-acids to the corresponding alkenes. It is known, for example, that acid hydrolysis of 2α,3α-epoxy-3β-phenylchloestane gives only the 2α,3α-glycol (LII)[107]. A similar result is obtained in the epoxidation with performic acid of the arylnorbornenes (LIII)[108,109] and phenylcycloheptene (LIV).[110] In the latter instances, in addition to the orthocarbonate and a mixture of monoformates (the secondary formate arises as a result of the migration of the formyl group) a considerable proportion of a phenylcycloheptanone is isolated.



Only keto-products are formed in the epoxidation of Δ⁶-dehydroabietane by perbenzoic acid[111]. For the same reason the yield of the *cis*-benzoate (LV) from methyl Δ⁶-dehydroabietate is only 43%.[111]

On the basis of the spectroscopic results and analogies in the literature, the sole product of the epoxidation of dimethoxybenzocycloheptadiene was ascribed the structure of the *cis*-monobenzoate (LVI).[112] More frequently, however, examples are encountered when arylcyclenes and their oxides give mixtures of substances which are epimeric at a benzyl centre. Thus, the addition of the elements of per-acids to the steroidal fragment (LVII), used by Johnson and coworkers[113,114] in the synthesis of aldosterone proceeds non-selectively and gives a mixture of monoesters of isomeric diols. A similar picture is observed in the epoxidation of methoxydihydronaphthalene (LVIII)[73,74] and in the conversions of the oxides and alkenes (LIX)–(LXII) shown in Table 3.



The data given in Table 3, while not so complete as for the acyclic aryl oxides considered above, nevertheless permits the conclusion that the opening, which is catalysed by acids, of the phenylcyclohexene oxide (LIX) and indene oxide (LXI) in polar media takes place with considerable inversion of the initial configuration. This conclusion is confirmed by the results on the opening of oxide (LIX) by an aqueous solution of sodium nitrite in acetic acid[126] and also by the preliminary results of Berti and coworkers[127] in respect of the influence of polar and ionising strength of the medium on the direction of the opening of phenylcyclohexene oxides. In investigating, in particular, the

Table 3. Cleavage of cyclic aryl oxides and epoxidation of arylcyclenes.

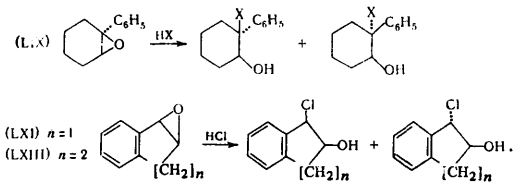
[a] Secondary trichloroacetate. [b] 2-Formate.

acid hydrolysis in various media, including such strongly ionising solvents as dimethyl sulphoxide (DMSO) and hexamethylphosphoric triamide (HMTA), Italian investigators[127] found that the percentage retention of the configuration of these oxides falls rapidly in the following sequence of solvents: $C_6H_6 > HCO_2H > H_2O >$ dioxan + $H_2O >$ DMSO + $H_2O >$ HMTA + H_2O.

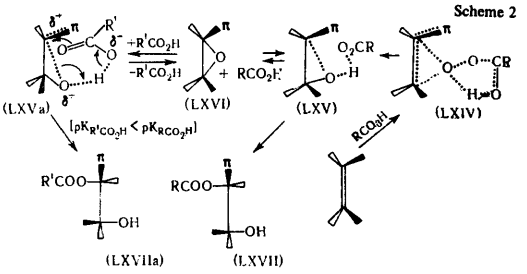
The meagre available information suggests that the above regularity is also observed in the opening of aryl oxides by hydrogen halides[128-130]. Thus, in the treatment of the oxide (LIX) with hydrogen chloride or bromide in the relatively non-polar chloroform, only the product of *cis*-opening is produced, whereas in alcoholic medium a mixture of halogenohydrins epimeric at a benzyl centre is formed[128]. A mixture of *cis*- and *trans*-isomers is also produced in the reaction of hydrogen chloride with indene oxide (LXI) and dihydronaphthalene oxide (LXIII) in dioxan[129]:



The above influence of the polarity of the medium on the direction and stereochemistry of the opening of cyclic aryl oxides should probably appear in the epoxidation of arylcyclenes. The published information confirms this suggestion. In fact, in a comparatively non-polar medium the process proceeds with a high degree of selectivity, giving products of the *cis*-addition of the elements of the per-acids at a double bond (Table 3, Nos. 5–7, 13). Here it must be noted that both in the epoxidation of phenylcyclohexene by performic acid and in the opening of epoxide (LIX) with formic and trichloroacetic acids (Table 3, Nos. 3 and 4) an increase in the yield of the *trans*-compounds on reducing the reaction temperature is observed[59]. As for the influence of conformational factors on the direction and stereochemistry of the opening of cyclic arylepoxides, except for a preliminary report[127] on the opening of the conformationally fixed phenylcyclohexene oxides, there is hardly any published information on this subject at present.

2. Mechanism of the *cis*-opening of aryl oxides. An examination of the material shows that analogous final results are obtained irrespective of whether one is dealing with the addition of per-acids to aromatic alkenes or with the opening of the corresponding oxides under conditions of electrophilic catalysis. In the general form this can be expressed by Scheme 2.

Scheme 2



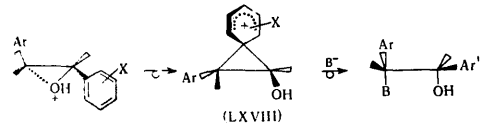
It is well known that the epoxidation of alkenes is an irreversible process, which is evidently not subject to the action of acid catalysis[6,89,131,132] and probably proceeds through the formation of a spiran[133] transition state (LXIV). The geometry of the latter is evidently not symmetrical[134,135] and reflects both the state of the electron density of the double bond being attacked (determined, in turn, by the nature of the substituent) and also by the nature of the attacking electrophilic reagent. Such a view of the nature of the transition state (LXIV) is purely speculative but it finds indirect confirmation in the kinetic results for the oxidation of a series of alkenes by per-acids. For example, whereas, according to Lynch and Pausacker[132] and Campbell and coworkers[89], if the rate of oxidation of *trans*-stilbene (XLII; R = X = H; R' = C_6H_5) by perbenzoic acid (benzene, 25°C) is taken as unity, then the ratios of the oxidation rates of the corresponding 4-Cl-, 4-CH_3O-, and 4-CH_3O-4'CH_3O-substituted compounds under the same conditions is approximately 0.6 : 5 : 20. Similar results were obtained by Ogata and Tabushi[134,135] in the epoxidation of certain α-methylstilbenes. It also follows from the kinetic results that the irreversible decomposition of the transition state (LXIV) should lead to the formation of the protonated oxide (LXV). The latter, in its turn, is in equilibrium with a carboxylic acid produced from the per-acid and with the epoxide (LXVI), which is the final product of the reaction on using per-acids of the monoperphthalic type. The existence of such an equilibrium was convincingly demonstrated by experiments on the oxidation of *trans*-4-methoxystilbene with perbenzoic acid containing labelled benzoic acid[89]. It appeared from this that the formation of the final benzoate is equally probable from both the labelled $C_6H_5CO_2H$ initially present in the substrate and the $C_6H_5CO_2H$ produced from the perbenzoic acid. The oxidation of stilbene by perbenzoic acid in the presence of trichloroacetic acid, as a result of which trichloroacetates (but not benzoates) of hydrobenzoins (Table 1, Nos. 17, 18, 33) are obtained also shows the probability of the existence of an intermediate oxide (LXVI) in view of the impossibility of the exchange reaction[89,136]:

$$RCO_3H + R'CO_2H \rightleftarrows RCO_2H + R'CO_3H.$$

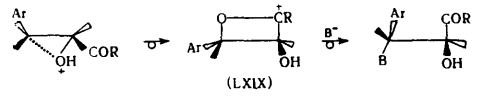
Furthermore, experiments with mixtures of acids clearly demonstrate the well known fact that the opening of an epoxide ring is catalysed by acid; therefore in the presence of two acids of unequal strength the conversion of the oxide (LXVI) into the final products (LXVII, LXVIIa) proceeds more rapidly with the stronger acid.

Consequently, both the addition of the elements of the per-acid to an aromatic alkene, and the acid-catalysable opening of the corresponding oxide proceeds through an intermediate protonated epoxide (LXV, LXVa), the conversion of which is a kinetically controllable stage of both processes[89,132]. Thanks to the appearance of a dynamic effect of conjugation, the protonated oxide, which, like transition state (LXIV), probably cannot be symmetric, is characterised by the presence of a broken C–O bond and consequently a rather stable carbonium ion in the vicinity of the electron-donating substituent[65,128,134,135].

To explain the formation of products of the *cis*-opening of aryl oxides several schemes have been proposed. According to one of these, a double inversion with participation of the "phenonium" ion (LXVIII),[88] or of a four-membered oxide ring (LXIX),[98] is assumed to be possible in systems of the stilbene oxide or dypnone oxide type:

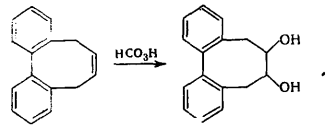


(LXVIII)



(LXIX)

These schemes have been criticised repeatedly[87,92,110], although decisive arguments against them have not been forthcoming. However, such hypotheses can explain only a few particular examples and in several other instances the formation of a "phenonium" ion is improbable (for example, phenylpropene, indene, etc.). Furthermore, it must be noted that the formation of a four-membered transition state, in particular (LXIX), is energetically unfavourable[137]. Nevertheless, the recently described *cis*-addition of the elements of performic acid to dibenzocyclooctatriene (LXX)[138] can be regarded as the result of the stabilisation of the corresponding transition state by a mechanism of the "phenonium" ion type:

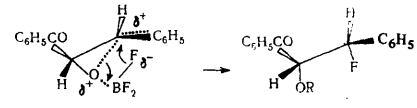


(LXX)

In fact, both reaction centres of the original alkene are homobenzylic and for such systems a transition state of type (XXXVI) cannot be represented.

According to the scheme which seems most probable at present, the *cis*-opening of the oxide ring is described by a "push-pull" process taking place in the "solvent cage".[92] Here the state of the mutual orientation of the C–O bond of the epoxide and the molecule of proton-donating nucleophilic reagent is considered. The molecules of the epoxy-compound and of the proton donor, being included in the "solvent cage", interact with one another in the way typical of hydrogen bond formation[3,6,98]. The "pulling" force here is the progressing protonation of the oxidic oxygen atom. As a result of this protonation there is a removal of the stress in the three-membered ring and the formation of a stabilised carbonium ion, together constituting the driving force of formation of a transition state of type (LXV). Because the elements of the "ion pair"[92,98] are favourably arranged in this way at the side of the nucleophilic reagent, a minimal "push" is required for converting the transition state (LXV) into the final product (LXVII) with the configuration of the initial oxide (LXVI). Here the role of the steric factors, which hinder the approach of the nucleophilic reagent, are probably insignificant.

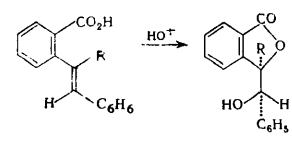
The "phenonium" ion and "ion pair" schemes have been widespread in the literature and there has recently been a worthy attempt to combine them[67]. However, the scheme involving the "ion pair" is preferred more often as it allows a large number of experimental facts to be explained. For example, by starting from these hypotheses the *cis*-opening of epoxides under the action of a Lewis acid can be described by a scheme which House[139] proposed when he obtained the *cis*-fluorohydrin on treating *trans*-benzalacetophenone oxide with boron trifluoride–diethyl ether:



where R = BF_2 or H.

An analogous succession of changes occurs apparently in the reaction of stilbene oxides with phenylmercaptoborane[79] and hexadeuteriodiborane[140].

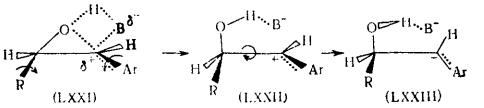
The idea of the orientated complex of the epoxide and the proton-donating nucleophilic reagent allow the influence of the solvent on the occurrence of the "sterically anomalous" opening of the oxide ring to be explained. In fact it is easy to suggest that the formation of this complex, considering the nature of the forces acting, which was discussed above, will be more probable in a non-polar (non-ionising) solvent. On the other hand, in an ionising solvent its destruction will be more probable. Therefore a greater percentage of configuration retention is to be expected in non-polar systems, which agrees with the results shown in Tables 1–3. Furthermore, in a polar (non-ionising) solvent the degree of dissociation of the acidic nucleophilic reagents considered in the tables is increased. This indicates that there is a simultaneous increase in both the number of protonated (and more solvated) epoxide molecules of the (XXXVI; A = H^+) type and the concentration of strongly nucleophilic ions RCO_2^- and X^-. Hence conditions are created for the attack of the oxide ring from any side and the probability of an energetically favourable bimolecular *trans*-opening increases. An analogous situation is observed when a nucleophilic reagent is fixed by the structure of the molecule itself so that attack with formation of inverted products is always possible, as occurs in the opening of the isomeric 2-stilbazole oxides[141] and the epoxidation of stilbene-2-carboxylic acids[142–144]. In these instances, irrespective of the polarity of the medium, *trans*-opening of the epoxide ring is observed exclusively, for example:



where R = H, CH_3.

This scheme explains the reduced stereospecificity observable during the opening of the *cis*-aryl epoxides (Tables

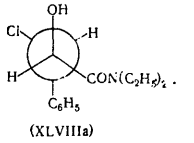
1 and 2), in which the "*cis*-effect"[145] of neighbouring bulky groups appears. This effect should facilitate the conversion of the transition state (LXXI) of the *cis*-aryl oxide into its extreme state (LXXII) with sp^2-hybridised benzyl carbon atom. For the same reason rotation of the plane of this centre around the C–C bond by 90° is possible before attack by the nucleophilic ion B^- takes place.



(LXXI) (LXXII) (LXXIII)

As a result of the isomerisation[67] of cisoid cation (LXXII) into the stable transoid one through intermediate state (LXXIII), a product should arise with inverted configuration of the initial oxide and such an explanation of its formation seems better founded than direct *trans*-addition of the nucleophilic reagent. The probability of the isomerisation should increase on using a polar solvent, just as it should on increasing the steric capacity of the neighbouring substituents (increase in the "*cis*-effect"). Tables 1 and 2 confirm this assumption. We can take as an example the epoxidation of the 4-methoxystilbenes by perbenzoic acid: from the *trans*-isomer only the *threo*-monobenzoate is obtained, whereas the *cis*-isomer gives a mixture of diastereoisomers (Table 1, Nos. 21–24). Analogous results are obtained in the opening of the stilbene oxide by hydrogen chloride (Table 2, Nos. 16–23). The observed preferential formation of reaction products with retention of the configuration of the *cis*-isomer does not agree with the behaviour of the same oxide in relation to chloroacetic acids, where there is *cis*-opening (Table 1, Nos. 14–16). Berti and coworkers[67] explain this difference by the reduced nucleophilic nature of the chloride ion in comparison with carboxylate ions, which attack the cisoid intermediate state of type (LXXII) before its isomerisation takes place. The results of Tung and Speziale on the opening of the *cis*-epoxypropionamide by hydrogen chloride (Table 2, Nos. 14 and 15) can be explained similarly,

Probably the already rather weak protonation of the oxide ring for the interaction between the two hindered bulky groups in the transition state (LXXI; R = $CONEt_2$, Ar = C_6H_5, B = Cl) led to the energetically more favourable state of type (LXXIII), the subsequent neutralisation of which gives the *threo*-chlorohydrin (XLVIIIa):

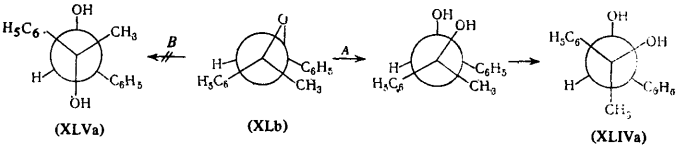


(XLVIIIa)

There is also the noteworthy fact that in the treatment of the *threo*-chlorohydrin (XLVIIIa) with sodium methoxide in addition to the expected *cis*-epoxypropionamide (XLVII; R = H, R′ = NEt_2) the *trans*-isomer (XLVI; R = H, R′ = NEt_2) is obtained, in the ratio 3 : 2. On the other hand, the *erythro*-chlorohydrin (XLIX; R = H, R′ = NEt_2, X = Cl) under these conditions is converted quantitatively into the *trans*-epoxypropionamide[102].

So far we have discussed examples which illustrate the dependence of the *cis*-opening of the oxide ring on the polarity of the solvent, on the nucleophilic nature of the reagent, and also on the steric factors which influence the formation of the transition state, leading to this type of result. It was noted above, however, that the secondary-tertiary α-methylstilbene oxide undergoes *cis*-opening irrespective of the polarity of the solvent (Table 1, Nos. 29–31). An analysis of the results in Table 2 allows a similar steric selectivity to be found for secondary-tertiary bromodiphenacyls and dypnone oxides.

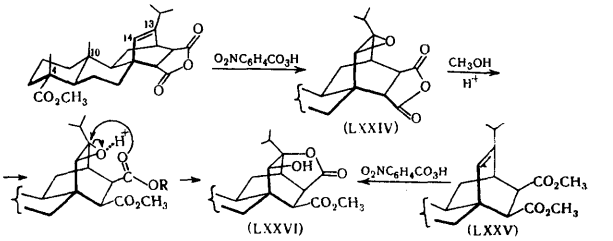
Purely qualitative consideration of the acid hydrolysis of *trans*-α-methylstilbene oxide (XLb) which takes place with breaking of the tertiary C–O bond[66] suggests with a high degree of probability that here also the predominating influence is the steric factor, which determines the formation of the energetically most favourable transition state. In fact, path *B*, as a result of which the *erythro*-diol (XLVa) should be formed, corresponding to the *trans*-opening of the initial oxide, requires the surmounting of a considerable energetic barrier in the transition state, due to the interaction of hindered methyl and phenyl groups.



(XLVa) (XLb) (XLIVa)

On the other hand, for the realisation of the transition state from which the experimentally observable *threo*-diol (XLIVa), with the configuration of the initial oxide, is obtained, the surmounting of a minimal energetic barrier is necessary (path *A*). It is easy to see that analogous considerations can lead to identical conclusions for the secondary-tertiary dypnone oxide and halogenodiphenacyl oxides. Unfortunately, a more rigorous discussion of these energetic factors is impossible owing to lack of quantitative data.

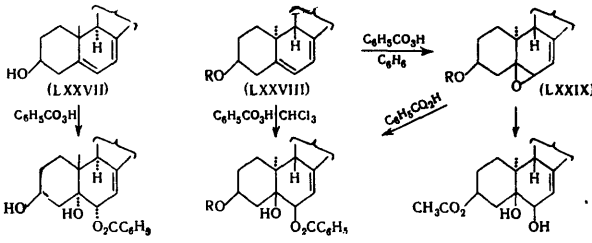
The influence of the steric factor on the direction of the acid-catalysed opening of an epoxide ring can be illustrated by the methanolysis of oxide (LXXIV) obtained from the adduct of methyl laevopimarate with maleic anhydride, and also the epoxidation of the unsaturated diester (LXXV)[146]. The *cis*-hydroxylactone (LXXVI) which is liberated in both instances with a yield of ~ 45% is evidently formed by intramolecular attack on the protonated epoxide by the solvated carboxyl group. Intermolecular attack of the nucleophilic reagent, leading to products of *trans*-opening, is probably hindered by screening of the $C_{(13)}$–$C_{(14)}$ bond by the axial methyl groups at $C_{(4)}$ and $C_{(10)}$. The examples examined show the possibility in principle in some instances of the *cis*-opening of epoxide in systems which differ from oxides of the (XXXV) type.



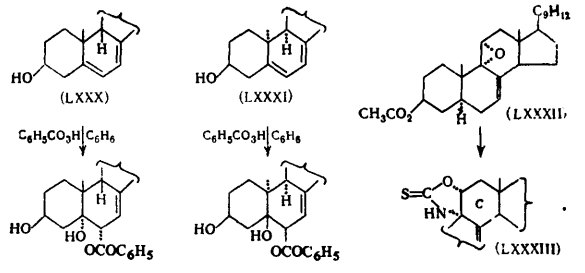
(LXXIV) (LXXVI) (LXXV)

3. *cis*-Opening of mono-oxides of conjugated dienes and of oxides of enol-esters. The *cis*-opening of monoxides of conjugated dienes was observed mainly in the steroid series. In every instance in discussing the reaction mechanism the stable allyl carbonium ion is considered, nucleophilic attack of which should be effected from the sterically least hindered region of the steroidal molecule. In fact, on treating ergosterol (LXXVII) with perbenzoic acid only the 5α,6α-glycol benzoate is formed[147]. On the other hand the conversion of

lumisterol (LXXVIII), which exhibits "unfavourable" combination of rings A, B, and C, leads exclusively to the 5β,6β-diol monobenzoate[148-150]:



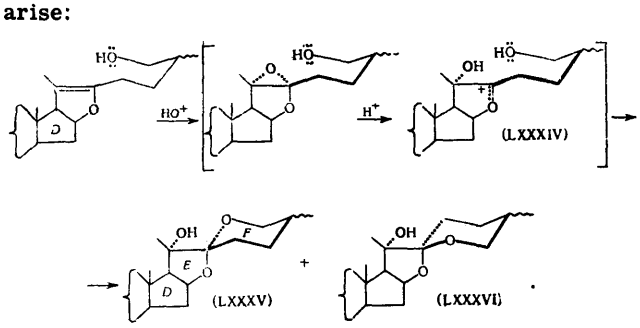
The opening by benzoic acid and water[148-150] of lumisterol β-oxide (LXXIX) obtained by oxidation of the diene (LXXVIII) in benzene[149,150] proceeds in an analogous manner. The epoxidation of 9β-ergosterol (LXXX) and of 9α-lumisterol (LXXXI) by perbenzoic acid in benzene is also accompanied by the formation of considerable quantities of the products of the *cis*-opening of the corresponding unstable allyl epoxides. The authors[151] think that the latter are intermediates in both reactions:



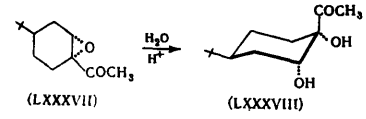
Mention must also be made of the result obtained by Ueda and Mosettig[152], who observed the *cis*-opening of ergostadiene 9α,11α-oxide (LXXXII) into the thio-oxazolidone (LXXXIII) in the presence of hydrogen thiocyanate.

Apart from what has been considered above there is hardly any published information on the "sterically anomalous" opening of other monoxides of conjugated dienes. Reference can only be made to results on the epoxidation of cyclopentadiene by peracetic[153] and performic[154] acids and the hydrolysis of the corresponding monoepoxides[155]. In every instance a complex mixture of products is obtained, among which *cis*-cyclopentene-1,2-diol is observed.

In the steroidal series several instances have been described of the stabilisation of the carbonium ion produced during epoxidation by the unshared pair of *p*-electrons of a neighbouring oxygen atom. Thus, in the treatment of pseudosapogenions with per-acids the kinetically controllable rear attack of the OH group of the side-chain of the stabilised carbonium ion (LXXXIV) can lead to the formation of products of *cis*-opening (LXXXV) of the intermediate oxide[156,157]. In the presence of destabilising thermodynamic factors[157] *trans*-opening products (LXXXVI) also arise:

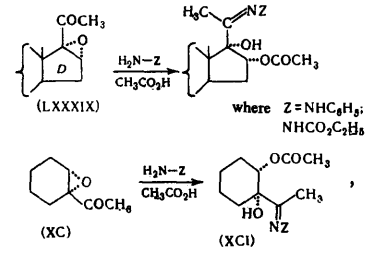


4. *cis*-Opening of oxides of conjugated ketones. Information has recently been published on the *cis*-opening of αβ-epoxyketones of the cyclohexane and steroid series under conditions of acid catalysis. The main distinguishing characteristic of these conversions is evidently the fact that in every instance, as will be shown below, the C–O bond in the α position to the keto-group of the initial epoxide is broken. This signifies the appearance in the corresponding transition state of a deficiency in the electron density adjacent to the carbonyl function. By virtue of the electron-withdrawing nature of the latter such a state should exhibit high energy[158,159]; however, there is the possibility of its being reduced, owing to enolisation of the C=O group[160]. Here the transition state will be represented by the special case of the states of type (XXXVI) considered above, and probably in acid hydrolysis of the keto-oxide (LXXXVII) it is partly realised with formation of the *cis*-diol (LXXXVIII)[161].



This example is still the only one in the keto-oxide series, analysis of the conversions of which is often hindered by the possible formation of secondary products as a result of enolisation, retroaldolisation, epimerisation, etc. taking place. All the remaining known instances of *cis*-opening relate to the reactions of keto-oxides in the presence of reagents at the carbonyl group.

Such a reaction was first described in the patent literature[162] as a method for obtaining substituted 16α,17α-glycols from pregnane 20-keto-16α,17α-epoxides (LXXXIX) in the presence of phenylhydrazine. The latter was soon replaced by ethoxycarbonylhydrazine (ECH)[163]. Subsequently it was shown by the example of acetylcyclohexene oxide (XC) that products with retained configuration (XCI) are also formed in the presence of semicarbazide, 2,4-dinitrophenylhydrazine, and hydroxylamine[164]

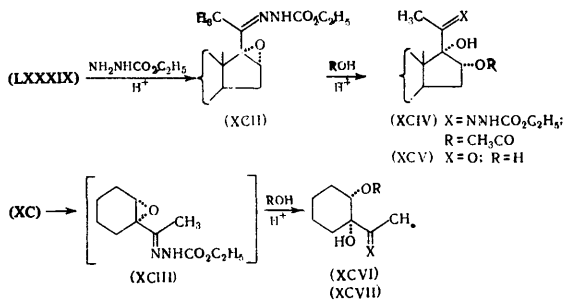


where Z = $NHCO_2C_2H_5$, $NHCONH_2$, $NHC_6H_3(NO_2)_2$, or OH.

As a result of a thorough study of the reactions of steroidal keto-oxides (LXXXIX) with ECH it was found that the opening of the epoxide ring precedes the formation of the corresponding carbonyl derivatives (XCII)[69,165,166], and in some instances the process almost stops at this stage[167,168]. An analogous sequence of changes is also observed in the cyclohexane series, although for the keto-oxide (XC) the intermediate ethoxycarbonylhydrazone (XCIII) could not be isolated[164].

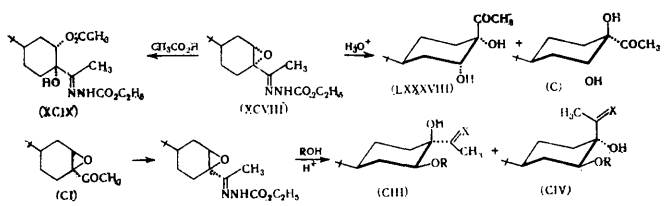
A detailed analysis of the way in which these reactions proceeded showed that the stages of "sterically anomalous" hydrolysis of the hydrazone-oxides (XCII) and (XCIII) and the removal of the hydrazone grouping from compounds of

the type (XCIV) and (XCVI) can coincide, which was verified in practice.



Hence the keto-oxides (LXXXIX) and (XC) could be converted, formally in one stage, into the corresponding *cis*-keto-glycols (XCV) and (XCVII)[169,170] and a synthesis of the latter in the steroidal series by this path is probably the simplest and most reliable[171].

Interesting results were obtained in investigating similar changes of the conformationally fixed stereoisomeric keto-oxides (LXXXVII) and (CI)[172,173]. In the presence of ECH they are also converted into ethoxycarbonylhydrazones (XCVIII) and (CII), the acetolysis of the α-isomer being strictly stereo-directed, leading exclusively to the secondary acetate (XCIX):



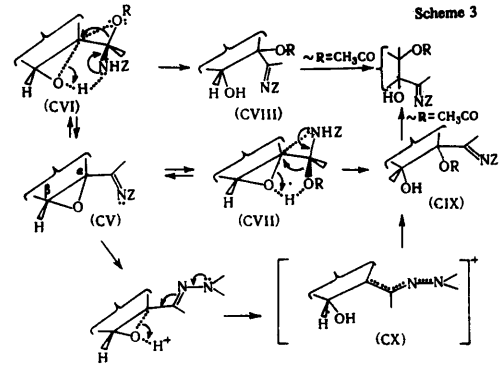
where X = O, $NNHCO_2C_2H_5$; R = H, CH_3CO.

The acid hydrolysis of the α-hydrazono-oxide (XCVIII) proceeds less selectively and gives a mixture of keto-glycols (LXXXVIII) and (C) in the ratio ~ 3 : 2. In acetolysis and hydrolysis of the β-isomer (CII) such selectivity in the opening of the oxide ring is not observed. However, in these instances in the mixture of products (CIII) and (CIV), the *trans*-diequatorial isomer (CIV) predominates. This emphasises the fact that as a result of the acetolysis of the ethoxycarbonylhydrazones of the oxides secondary acetates are isolated in all the examples examined.

The acid hydrolysis of the ditertiary oxide of 1-acetyl-2-methylcyclohex-1-ene in the presence of ECH gives a mixture of diastereoisomeric keto-glycols[168]. In this respect the results obtained are analogous to those given above for the conversion of keto-oxides (LXXXVII) and (CI) under the same conditions. However, with the conformationally labile ditertiary keto-epoxide an analysis of the results is hindered by the observed isomerisation of the product of the *cis*-opening of the oxide into the *trans*-glycol[168].

The available results, in particular those on the opening of the keto-oxides (XCVIII) and (CII) allow us to speak about the structural directionality of the conversions. Namely, in every instance the introduction of a molecule of water or acetic acid takes place at the carbon centre of the epoxide adjacent to the hydrazone group. The formation of secondary acetates of keto-diols is the consequence of the instability of the initially formed tertiary esters, which then undergo intramolecular reesterification[70,71]. These results show the presence of an electron-deficient α carbon atom of the hydrazono-oxide in its opening. The possibility of attack at this centre by molecules of nucleophilic reagents is shown in Scheme 3.

Scheme 3



According to Scheme 3, under the reaction conditions the carbonyl derivative (CV) is in equilibrium with the isomeric carbinolamines (CVI) and (CVII). As a result of the intramolecular attack of the residue OR situated in the immediate vicinity of the reaction centre keto-glycols and their derivatives (CVIII) and (CIX) are formed. Here it is considered[69,166] that the stabilisation of the electron-deficient α carbon centre in the transition states (CVI) and (CVII) is effected by the unshared p-pair of electrons of the oxygen and nitrogen atoms respectively. On the whole this scheme is similar to the "ion pair" scheme considered above.

However, it was shown that the keto-oxides (LXXXVII), (XC), and (CI) do not undergo opening on replacing the reagents for the carbonyl group by primary amines of various basicities[172-174]. This fact suggests the participation in the redistribution of the electron density of the second nitrogen atom of the hydrazine derivatives, or of the oxygen atom of the hydroxylamine derivatives. The protonation of the oxygen atom of the epoxide leads to the formation of transition state (CX) which is characterised by the presence of a positive charge on the α carbon atom, stabilised by $p\pi$-conjugation. Furthermore, it cannot be ruled out that stabilisation is effected by the unshared p-pair of electrons of the imine nitrogen atom of the hydrazonium group. The subsequent attack of this centre by the nucleophilic reagent can lead to products with either retention or inversion of the configuration of the original keto-oxide.

It should be noted that the schemes discussed allow these transformations to be considered as formally similar in mechanism to the reduction of a keto-oxide in the presence of chromium(II) salts[175,176], by the method of Huang-Minlon[177], by the method of Wharton and Bohlen[178], and also to conversions of α-substituted ketones in the presence of hydrazine derivatives[179-182]. At present it is quite difficult to choose between the schemes for the conversion of the carbonyl derivatives of cyclic $\alpha\beta$-epoxy-ketones that we have considered. In these systems, just as in a series of aryl oxides, the decisive role is evidently played by the nucleophilic nature of the reagent, the polarity of the medium, and also the steric and conformational factors.

---oOo---

The material considered on the "sterically anomalous" opening of an epoxide ring allows the conclusion that reactions leading to the formation of products with retention of the configuration of the initial oxide include the act of

interaction of the nucleophilic reagent with the deficit in electron density arising on one of the carbon centres of the epoxide ring in the transition state. The solvated carbonium ion intermediate is usually stabilised by π- or p-electrons adjacent to the epoxide ring grouping. The formation of products with retention of the configuration of the original epoxy-compound depends on the direction of nucleophilic attack, which is determined by the steric effects of the addition of the nucleophilic reagent to the carbon atom carrying a stabilised positive charge. In this discussion the term "sterically anomalous" opening of the oxide ring acquires formal significance.

Polymerisation of Lactones

Yu.N.Sazanov

This is a review of investigations on the polymerisation of lactones. The author briefly touches on the history of the subject, the advantage of the synthesis of polyesters by the method of polymerisation over polycondensation, and the essential nomenclature of lactones. The polymerisation of β-, γ-, and δ-lactones, both unsubstituted and with various substituents, in the presence of anionic and cationic catalysts, and also under the action of ionising radiation, is considered in detail. Conditions and possible schemes of mechanism for the polymerisation of these lactones, and also the effect of substituents on the course of the process, are given. Examples of the copolymerisation of this class of compounds with either vinyl or cyclic monomers are considered separately. The available published data on the physicochemical properties of polyesters synthesised from lactones and their applications as fibre- or film-forming polymers is presented. Bibliography of 80 references.

CONTENTS

I. Introduction 463
II. Polymerisation of β-lactones 463
III. Polymerisation of γ- and δ-lactones 466
IV. Copolymerisation of lactones 467

I. INTRODUCTION

The first communications on the polymerisation of lactones date from 1903, when Fichter and Beisswenger[1] and later Hollo[2] obtained from liquid monomeric δ-valerolactone a waxy crystalline mass, m.p. 47–48°C. Carothers and coworkers[3] showed that a mixture of oligomers with $M = 3000–4000$ is formed.

Great attention is now being paid to the polymerisation of oxygen-containing cyclic esters, especially lactones. The formation of polyesters in this manner has considerable advantages over polycondensation. Firstly, the process can be carried out under milder conditions, at negative or near-room temperatures; secondly, the need for removing side-products disappears, which is not true for polycondensation. These advantages enable polyesters of high molecular weight which exhibit a series of valuable physicochemical properties and are suitable for the preparation of high-quality fibres and films to be obtained.

Lactones are polymerised in the presence of acid and basic catalysts, complex catalysts, and under the action of ionising radiations. They are not polymerised by a radical mechanism.

There is some confusion in the literature concerning the terminology of lactones. Usually the name of a lactone is derived from the name of the acid on the basis of which it is constructed, but some authors name the lactone by starting from the total number of carbon atoms entering into the lactone, and others, from the number of carbon atoms forming the lactone ring. We think that the second principle of classification is the more rigorous and subsequently will adhere to the following nomenclature: four-membered lactone, β-propiolactone; five-membered γ-butyrolactone; six-membered, δ-valerolactone; seven-membered, ε-caprolactone. The positions of the substituents at carbon atoms of the lactone ring will be shown by starting the numbering from the carbonyl-carbon.

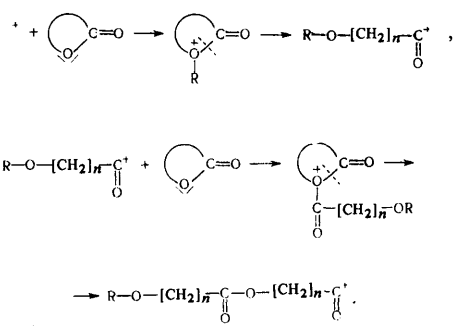
II. POLYMERISATION OF β-LACTONES

1. Unsubstituted β-Lactones

One of the most studied representatives of the class of lactones is β-propiolactone:

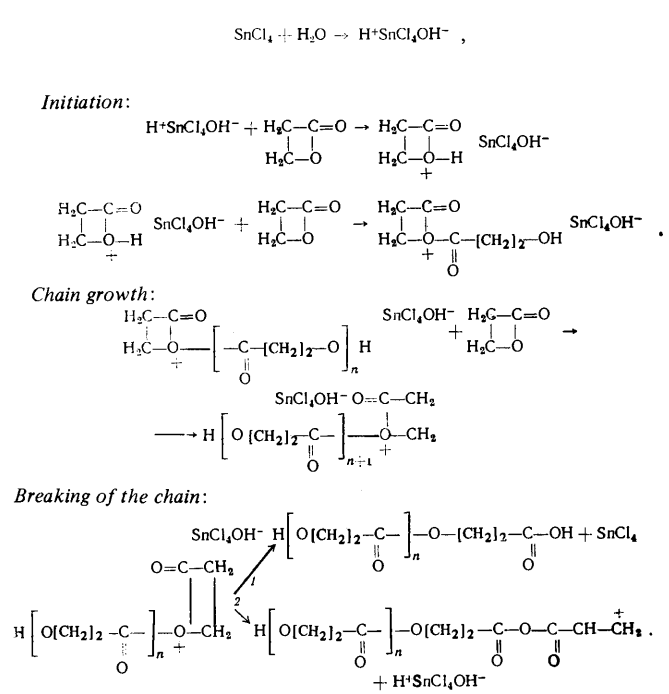
The reactions of β-propiolactone with various organic and inorganic compounds were investigated in detail by Gresham and coworkers[4–15].

Cationic polarisation. In 1948 Gresham and coworkers[6] first described the formation of a polymer with $M = 800–1000$ in the reaction of β-propiolactone with conc. H_2SO_4 or $FeCl_3$. In 1962, Cherdron and coworkers[17] investigated the polymerisation of β-propiolactone in the presence of $AlCl_3$ and acetyl perchlorate. The initial β-propiolactone was distilled in thoroughly dried apparatus under a vacuum in the presence of 2% tolylene di-isocyanate. The purity of the product was checked by gas chromatography and from the stability of the monomer on storage (at a temperature $\gtrsim$ 60°C). The polymerisation was carried out at 20°C without solvent under an atmosphere of nitrogen in the presence of the above catalysts, in 1×10^{-3} M concentration. The polymers obtained had a polyester structure with $M \simeq 100\,000$. The following mechanism was proposed for the cationic polymerisation of lactones:



Yamashita and coworkers[18] carried out the polymerisation of β-propiolactone in the presence of conc. H_2SO_4 and also Lewis acids ($FeCl_3$, $SnCl_4$, $AlCl_3$, $ZnCl_2$, and BF_3. ether) at 0° and 20°C for a long time (24 h to 5 months). Low-molecular weight polymers were obtained ($\eta_{sp}/c = 0.05$) with m.p. 76–80°C. Polymers are not formed in the presence of $ZnCl_2$ and $HgCl_2$. On the basis of the infrared

spectra and the terminal groups of the polymers the following mechanism of polymerisation in the presence of the $SnCl_4$–H_2O system was proposed:



The first mechanism of chain rupture mainly prevails, but at elevated temperatures the second reaction is also possible. In another study [19] Yamashita states that the principal reason for the breaking of the chain is the presence in the reaction system of negligible amounts of water. Recently, patents [20,21] and a paper [22] have appeared dealing with the polymerisation of β-propiolactone in the presence of Ti, Zr, and V phosphates. The polymers obtained had $[\eta]$ from 1 to 5.

Anionic Polymerisation. There have been more studies of the anionic polymerisation of β-propiolactone than of its cationic polymerisation. This is due to the principal possibility of carrying out the process in the presence of a series of catalytic systems without breaking of the chain and this in turn leads to the preparation of polymers with a higher molecular weight.

Gresham and coworkers [16] were the first to find that a low-molecular-weight product is formed by the action of NaOH on β-propiolactone, In continuing the work on the polymerisation of cyclic esters, Furukawa and coworkers [23,24] tested a series of organometallic compounds as catalysts for the polymerisation of β-propiolactone. These compounds are used both in the pure state and with cocatalysts. Low-molecular-weight polymers with $[\eta] < 0.2$ were synthesised.

Unlike the Japanese investigators, Cherdron and coworkers [25] found that thoroughly purified β-propiolactone in the presence of anionic catalysts gives high-molecular-weight polymers even at room temperature. Under the action of sodionaphthalene in dioxan solution at 100°C a polymer with $[\eta] \simeq 3$ is formed, but on polymerisation in the presence of aluminium alkyls products with M = 70 000–100 000 are obtained without cocatalysts. Use of water as cocatalyst leads to a considerable increase in the molecular weight of the polyester in accordance with the ratio of aluminium alkyl (or halogenoalkylaluminium) to water.

In their discussion of the mechanism of the anionic polymerisation the authors consider that, just as in the cationic process, the opening of the lactone ring takes place at the acyl bond, at which a negative charge passes from the initiator to the oxygen atom of the ring, which then reacts with a new molecule of the monomer.

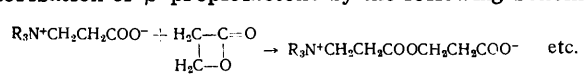
Japanese investigators [18,19,22,26–28] tested a large number of inorganic and organic compounds of basic nature as catalysts for the polymerisation of β-propiolactone (Table 1). Of the compounds examined, the most effective catalysts are betaine, pyridine, and pyridine derivatives. Kagiya and coworkers [27,29] studied the polymerisation of β-propiolactone in the presence of pyridine and tried to relate the process determining the rate of reaction, the molecular weights, and the yield of polymers to the concentrations of the monomer and catalyst, the temperature, and the polymerisation time. The variation of the rate of the process with the ratio of monomer to catalyst is expressed by a curve with a maximum. On carrying out the reaction in a solvent, the activity of the catalyst increases with the dielectric strength of the medium and the monomer concentration. The scheme of the process is analogous to that of anionic polymerisation proposed earlier [25], with the addition of possible variants in the chain breaking and transfer.

Table 1. Polymerisation of β-propiolactone in the presence of various anionic catalysts.

Catalyst, class of compound, and example	Conditions of reaction			Yield, %	η	Reference
	Temp., °C	Time, h	concn. of catalyst, mole per mole monomer			
Metal hydroxides (calcium, potassium, barium)	0—80	1—360	10^{-2}	70—90	0.1—0.5	22,26,28
Salts (potassium, sodium, or rubidium carbonates, etc.)	30	72—600	0.5—$2\cdot10^{-2}$	20—70	0.4	22,26,28
Alkoxides (sodium ethoxide, magnesium isopropoxide)	15	1000	0.3—$3\cdot10^{-3}$	50—70	0.4—0.6	19
Organic bases (triethylamine, betaine, pyridine, alkaloids)	0—25	200—800	$4\cdot10^{-3}$	70—90	0.5—1	19,22,27

In 1963 Etienne and Soulas [30] reported that in the presence of betaine β-propiolactone forms polymers of high molecular weight. It was noted earlier [31–33] that betaine or betaine-like complexes are formed by the action of tertiary amines on β-propiolactone:

which under appropriate conditions then leads to the polymerisation of β-propiolactone by the following scheme:



The authors of this scheme consider that the best catalyst of this type is the compound obtained in the reaction of a lactone and a tertiary amine; however, ordinary betaine (the internal salt of hydroxycarboxymethyltrimethylammonium or glycine trimethylbetaine) and glycine benzyldimethylbetaine are only slightly inferior. In the presence of these catalysts at a concentration of 0.1 mole % for 8–10 h at 15–20°C polymers of β-propiolactone with $[\eta] = 1.5$ were obtained. There is also a series of patents on the

polymerisation of β-propiolactone under the influence of organic compounds of the metals of Periodic Groups I and III,[34,35] alkalis on cotton wool[36] or wool[37], salts of Group I metals, and weak inorganic acids[38].

Polymerisation under the action of ionising radiations. Okamura and coworkers investigated the polymerisation of β-propiolactone under the action of γ-rays in the solid state[39-41] and in solution[42] at −78° and −196°C. Large and small crystals of β-propiolactone were irradiated (power of dose 10^3–10^6 roentgen h^{-1}). The products of highest molecular weight are formed from coarse crystals, hence the growth of the polymeric chain proceeds in a direction perpendicular to the long axis of the crystal monomer, and hence with increase in the size of the crystal the molecular weight of the polymer rises. At −78°C a crystalline polymer is formed even on irradiating fine crystals, but at −196°C an amorphous polymer is obtained. On the basis of X-ray investigations[39] and electron microscopy[40] it is suggested that the act of initiation takes place at the junctions of crystals and especially at places of crystal lattice defects. The yield of poly-β-propiolactam does not exceed 15–20%, $[\eta] = 0.15$–0.2, m.p. 110–120°C. In these studies the effect of post-polymerisation after cessation of the irradiation of the specimen is noted. The yield and viscosity of the polymer rise with increase in the dose power[43]. An anionic mechanism is proposed for the polymerisation of β-propiolactone under the action of γ-rays.

Apart from γ-irradiation, visible light in the presence of uranyl nitrate as an activator of the reaction[44], ultraviolet radiation[45], and beams of electrons with dose power 1.6×10^{-4}–20 Mrad min^{-1} [46] are also used for the initiation of the polymerisation of β-propiolactone, but only in the last instance could a polymer with $[\eta] = 1.4$–2.56 be isolated, though in very low yield. In the other instances low-molecular weight products were obtained in low yield.

Structure and properties of poly-β-propiolactone. Elemental analysis of the synthesised polymers and of the products of their acid and alkaline hydrolysis[18,26], chemical analysis of the terminal groups[17,18,25,47], infrared spectra[18,22,26,27,47,48] and the results of differential thermal analysis[22] show that the poly-β-propiolactone has the structure of a complex polyester, however, in connection with the absence of a common opinion about the site of the opening of the lactone ring during polymerisation there is still no definite conclusion concerning the regularity of the alternation of the links in the chain of the macromolecule. It is found, however, that the structure of the polyester obtained from the lactone differs from that of the polyester obtained in the polycondensation of diols and dicarboxylic acids[25].

In studying the infrared spectra of polymer films two types of structure were observed, the formation of which depends on the polymerisation conditions, particularly the nature of the catalyst[28]. However, the polymers of different structure did not exhibit differences in chemical properties and there were no differences in the infrared spectra of solutions of these polymers. The possibility of polymorphism of these polymers was suggested[47]. The existence of different crystal structures of poly-β-propiolactone was confirmed by Furukawa's investigations and also by Kagiya and coworkers[22]. Crystalline poly-β-propiolactone was obtained, which contained α and β forms with crystallisation temperatures of 65° and 20°C respectively and differed in X-ray diagrams and infrared spectra. It was found that the α form, with a repeat unit of 7.02 Å, has a 2_1 helical structure, whereas the β form, with repeat unit 4.28, has a planar zig-zag structure. The β form can be converted into the α by slow heating of a film of the polymer to 65°C. The β form is formed when the film is obtained from chloroform solution by slow evaporation; after rapid evaporation the α form predominates.

Similar investigations were made by Gianalvise[49], who determined, from the X-ray patterns of powders and fibres of poly-β-propiolactone, the repeat unit (6.02 Å) and also the unit-cell parameters and proposed the most probable helical structure of the macromolecule and its packing.

Poly-β-propiolactone is a mainly crystalline product with decomposition temperature 80–122°C and density from 1.2 to 1.4 (depending on the molecular weight). It is soluble in several organic solvents. According to the differential thermal analysis[22], the decomposition temperature of the polymer lies within the limits 230–250°C, but these values can be raised by increase in the molecular weight of the polymer. Owing to its low softening temperature poly-β-propiolactone is used as a modifier in natural fibres[36,37] or is mixed with other polymers which are more stable on heating.

2. Alkyl-Substituted β-Lactones

A patent[50] which appeared in 1960, and an article by the same authors[51] in 1962, described the production of polymers of a series of substituted β-propiolactones in the presence of triethylamine or triethylenediamine in bulk and in solution at 80–100°C. Some of the polymers obtained have high melting points (Table 2), and the lactones with a more symmetrical structure gave polymers with a higher molecular weight and which were more crystalline.

Table 2. Melting points of polymers of alkyl-substituted β-propiolactones.

Most of the polymers synthesised are soluble in chlorine-containing solvents and form flexible transparent films which have a higher hydrolytic stability, and are more resistant to the action of HBr, dilute alkalis, and hydrazine solution than the polyesters obtained by polycondensation.

The polymerisation of $\alpha\alpha\beta$-trisubstituted lactones in the presence of betaine [30] is analogous to the polymerisation of the unsubstituted lactone [30], and the presence of alkyl substituents in the α position facilitates attack of the carbonyl carbon of the ring at the COO^- side of the anion and accelerates the polymerisation.

Yamashita and coworkers [18,26] carried out the polymerisation of α-methyl-, β-methyl, $\beta\beta$-dimethyl-, and β-isopropyl-β-propiolactones in the presence of anionic and cationic catalysts. All the polymers synthesised had low molecular weights ($[\eta] = 0.03-0.1$). The following series of activities of the β-propiolactones was compiled on the basis of the size of the molecular weight and the polymerisation times. In polymerisation in the presence of acid catalysts: $\beta\beta$-dimethyl > unsubstituted > α-methyl $\geq$ $\geq$ β-methyl > β-isopropyl; for basic catalysts: unsubstituted > α-methyl $\geq$ β-methyl > β-isopropyl > > $\beta\beta$-dimethyl. The polymerisation of $\alpha\alpha$-dimethyl-β-propiolactone [19] and $\beta\beta$-dimethyl-β-propiolactone [52] was investigated in greater detail. In the polymerisation of the former in the presence of CH_3CO_2K or KOH at 50°C high-molecular weight ($[\eta] = 1.7-2.6$) polymers, m.p. 230–240°C, were obtained in ~ 100% yield. The polymers are soluble in phenol, cresol, and trichloroacetic acid at elevated temperature. It was found that increasing the polymerisation time and also the $[M]/[C]$ ratio facilitates an increase in the degree of polymerisation. It was suggested that under these conditions "living polymers" are formed. In the polymerisation of $\alpha\alpha$-dimethyl-β-propiolactone in the presence of acid catalysts at 100°C only low-molecular-weight products are obtained. For the polymerisation of $\beta\beta$-dimethyl-β-propiolactone in the presence of $SbCl_5$, $SnCl_4$, and $ZnCl_2$ at 0°C polymers with $[\eta] = 0.08-0.12$ are formed after several days in yields of ~ 30%. When $Al(C_2H_5)_3$ or $Al(C_2H_5)_3-H_2O$ are used as catalysts under the same conditions polymers with a higher molecular weight ($[\eta] = 0.2-0.37$) are formed; however, in comparison with unsubstituted β-propiolactone and $\alpha\alpha$-dimethyl-β-propiolactone the activity of the β-substituted lactone during polymerisation is less. The reduction of activity is explained [52] firstly by the instability of the monomer itself at elevated temperature ($\beta\beta$-dimethyl-β-propiolactone readily decomposes into isobutene and CO_2), and secondly by the presence of a chain-transfer reaction, especially in the presence of cationic catalysts.

Interesting work on the determination of the activity of α-substituted β-propiolactones during polymerisation in the presence of basic catalysts, particularly pyridine, was begun by a group of Japanese investigators [53], who calculated, on the basis of the C–C "skeleton method" the delocalisation energy of the electrons in the lactone ring and also the frontal distribution of electron density as a function of the nature of the substituents at the carbon atoms of the lactone ring. Starting from the calculated values of the coulombic and resonance integrals, schemes of the frontal distribution of electron densities were drawn up for four types of α-substituted β-propiolactones and the following series of their polymerisation rates in decreasing order (substituents shown) given: $\alpha\alpha$-bis(chloromethyl) > α-chloromethyl-α-ethyl > α-chloromethyl-α-methyl > unsubstituted > $\alpha\alpha$-dimethyl.

3. Halogeno-substituted β-Lactones

Only a few papers have been published on the polymerisation of halogeno-substituted β-propiolactones and these deal only with the polymerisation conditions and certain properties of the polymers obtained. Thus in the polymerisation of $\alpha\alpha$-bischloromethyl-β-propiolactone [54] in the presence of powdered KOH for 6 h at 40–50°C a polymer with decomposition temperature ~ 300°C is obtained, from which fibres can be spun which exhibit a capability for cold drawing. On heating this monomer at 100–120°C for 5 h a polymer was obtained [55] with m.p. ~ 300°C, insoluble in most organic solvents and thermally stable at 230–250°C. A polymer of $\alpha\alpha$-bischloromethyl-β-propiolactone was obtained in the presence of KOH, triethylamine, and pyridine at 50°C. [56] Under these conditions $\beta\beta$-bischloromethyl-β-propiolactone was polymerised only in the presence of acid catalysts ($AlCl_3$, $SnCl_4$, BF_3.ether) and the above basic catalysts were ineffective [56]. The melting point of the polymer of $\beta\beta$-bischloromethyl-β-propiolactone is 150–160°C. Apart from the chloromethyl derivatives of β-propiolactone mention has been made of the production of polymers from $\alpha\alpha$-bisbromomethyl-, $\alpha\alpha$-bisfluoromethyl-, and α-bromomethyl-α-ethyl-β-propiolactones in the presence of triethylamine or triethylenediamine [51].

III. POLYMERISATION OF γ- AND δ-LACTONES

Nothing has been published on the production of homopolymers from γ-lactones, and only two papers have been published about the copolymerisation of γ-butyrolactone, which will be discussed below.

Six-membered or δ-valerolactones easily form polymers in the presence of ionic catalysts, sometimes even more easily [17,25] than β-lactones and polymers were first synthesised from lactones on the basis of δ-valerolactone [1,2]. Carothers and coworkers [3] obtained poly-δ-valerolactone with $M = \sim 4000$ by heating the monomer at 150°C in the presence of K_2CO_3 for 5 h. The polymers were waxy products with m.p. 53–55°C. Cherdron and coworkers [17,25] not only studied the polymerisation of β-propiolactone but also investigated the polymerisation of δ-valerolactone and ϵ-caprolactone. They proposed a mechanism of cationic and anionic polymerisation of these lactones analogous to the mechanism of cationic and anionic polymerisation of β-propiolactone with breaking of the acyl bond of the ring, in which the anionic mechanism differed from that proposed earlier by Stannett and Szwarc [57]. On the basis of a comparison of polymerisation rates and molecular weights of the polymers the following series of activities was found for the three lactones: ϵ-caprolactone > δ-valerolactone $\geq$ $\geq$ β-propiolactone, and from ϵ-caprolactone and δ-valerolactones polymers with $M \simeq 100\,000$ were obtained.

Satome and Hadira [58] effected the polymerisation of δ-valerolactone in the presence of ethyleneglycol and ethanolamine for 10 h at 100–180°C. Since the molecular weight of the polymers obtained did not exceed 2000 and the melting point was < 50°C, the course of the process was followed by the change in the refractive index n_D^{50} of the reaction mixture. The molecular weight of the polymer formed increased linearly with the ratio $[M]/[C]$; water in the system at a concentration < 0.01% had no significant effect on the rate of the process but catalytic additions of H_2SO_4, $AlCl_3$, or Na accelerated the reaction, their activity falling in the sequence H_2SO_4 > $AlCl_3$ > Na. The activation energy of the process was 6.4 kcal $mole^{-1}$. The suggested mechanism of initiation and growth of the polymeric chain is analogous to that proposed earlier [17]. On esterification of the synthesised polymer at the terminal OH groups a polyester thermostable at 200°C (it did not lose weight on heating at 200°C for 6 h) was obtained.

Several patents dealing with the polymerisation of ϵ-caprolactones in the presence of chelates of the Group IV metals of the Periodic System and of acylates of fatty acids[59]; a series of alkoxides of Sn, Pb, and Mn[60]; mineral acids and Lewis acids[61]; alcohols, amines, and amino-alcohols[62]; alkoxides of Na, K, Li; $LiAlH_4$; $NaBH_4$;[63] organometallic compounds of Periodic Group I, II, and III;[64,65] borates and oxides of Zn and Pb; and organotitanium compounds[66] have been published. The molecular weights of polymers described in the patents listed varied in a wide range from 900 to 250 000. These polymers are recommended to be used for obtaining fillers, coatings, lacquers, films, and fibres, and mixed with other polymers[67,68], for the preparation of various plastics.

IV. COPOLYMERISATION OF LACTONES

With the aim of increasing the thermal stability and of simultaneously retaining the valuable properties of lactone polymers, studies were undertaken on the copolymerisation of a series of lactones with vinyl or other cyclic monomers. The greatest number of papers deals with the copolymerisation of β-propiolactone and the second component most frequently used is a cyclic ether. The copolymerisation of β-propiolactone with 3,3-bischloromethyloxacyclobutane (BCCB)[69-67] in the presence of BF_3.ether and of the $Al(C_2H_5)_3-H_2O$ system at $-50°$ and 0°C has been described. On the basis of the elemental analysis and infrared spectra it has been found that both components react and form a copolymer, which consists of chloroform-soluble and chloroform-insoluble fractions, with m.p. ~ 125° and ~ 160°C respectively. BCCB is a more active monomer both in cationic and in anionic copolymerisation. Alkaline hydrolysis shows the block structure of this copolymer. Furukawa and coworkers[72] carried out the copolymerisation of β-propiolactone with tetrahydrofuran, epichlorohydrin, and ethylene oxide in the presence of the same catalysts at 0°C. Tetrahydrofuran and especially epichlorohydrin form with β-propiolactone in the presence of $Al(C_2H_5)_3-H_2O$ almost alternating copolymers. In using BF_3.ether copolymers are obtained only with tetrahydrofuran ($r_1 = 2.9$, $r_2 = 0.4$). Propylene oxide does not undergo copolymerisation with β-propiolactone.

An interesting attempt to obtain a copolymer of β-propiolactone with γ-butyrolactone was made by Furukawa and coworkers[73], who carried out the copolymerisation of these monomers in the presence of $Al(C_2H_5)_3-H_2O$, $Zn(C_2H_5)_2-H_2O$, $Al(iso\text{-}C_3H_7O)_3$, KOH, and K_2CO_3 at 0° and 25°C in the bulk and in solution (toluene, methylene chloride). The copolymer of β-propiolactone with γ-butyrolactone is formed only in the presence of the catalytic system $Al(C_2H_5)_3-H_2O$. From the constant activity of the monomers ($r_1 = 18 \pm 2$, $r_2 = 0.36 \pm 0.1$) it was concluded that γ-butyrolactone enters into the composition of the copolymer to an insignificant amount in the form of blocks with not more than two or three units of γ-butyrolactone.

The possibility of the copolymerisation of β-propiolactone with vinyl compounds was also studied. In the reaction[74] of acrylonitrile with β-propiolactone in the presence of such organometallic compounds as $SrZn(C_2H_5)_4$, $Al(C_2H_5)_3$, sodium naphthenate, and systems of C_4H_9Li with $Al(C_2H_5)_3$, $B(C_4H_9)_3$, $Cd(C_2H_5)_2$ at room temperature a mixture of chloroform-soluble and chloroform-insoluble products was formed. The soluble fraction consisted of a homopolymer of β-propiolactone and the insoluble contained a homopolymer of acrylonitrile and its copolymer with β-propiolactone. However, the yield of copolymer was insignificant and the rate of reaction low.

The grafting of β-propiolactone to the copolymer of acrylonitrile and diketen has been described[75]. The addition of β-propiolactone here proceeded owing to the opening of the diketen ring in the copolymer, that is, the diketen served as a transition link between the vinyl and the cyclic compound, uniting two types of polymerisation. Therefore a direct relation was observed between the diketen concentration in the copolymer of it with acrylonitrile and the quantity of graft β-propiolactone.

In the radical copolymerisation[76] of styrene with β-propiolactone in the ratio 85 : 15 a block copolymer with terminal OH and COOH groups is formed correspondingly. Block copolymers of styrene and β-propiolactone are also obtained in cationic copolymerisation ($SnCl_4$, 0°C, in toluene)[77].

In an attempt to obtain copolymers of β-propiolactone with propylene sulphide in the presence of $(C_2H_5)_3N$ and also with the *N*-carboxy-anhydride of DL-valine in the presence of pyridine it was found that in the first instance copolymerisation does not take place and in the second a compolymer with $M \simeq 1200$ is formed, with the copolymerisation constant showing low activity of the β-propiolactone[78].

The copolymerisation of β-propiolactone, γ-butyrolactone, and ϵ-caprolactone with ethyleneimine has been investigated[79]. The copolymerisation was carried out in the presence of $SnCl_4$, BF_3.ether, $(C_2H_5)_3N$, NaCN, and $HgCl_2$, in various solvents with dielectric constants from 2.38 to 37.6 at temperatures of $-35-0$°C, 35–100°C, and 100°C, for the β-, γ-, and ϵ-lactones respectively. Low-molecular-weight products were obtained. The yield of copolymers increases with increase in the dielectric constant of the solvent. On the basis of a comparison of the infrared spectra of the products synthesised and of model compounds containing the elementary unit of the polymer, five different structures were proposed according to the site of the opening of the lactone ring. Two structures are formed owing to the breaking of the Alk-O bond in the β-propiolactone in solvents with a high dielectric constant. In a medium with a low dielectric constant ring opening takes place at the acyl bond in all the lactones listed, independently of the medium.

Yamashita and coworkers described the copolymerisation of $\beta\beta$-dimethyl-β-propiolactone with 3,3-bischloromethyloxacyclobutane[52] and with styrene[77]. In addition, they investigated the copolymerisation of 3,3-bischloromethyloxacyclobutane with unsubstituted β-propiolactone, α-methyl-, β-methyl-, $\alpha\alpha$-dimethyl-, $\beta\beta$-dimethyl-, and β-isopropyl-β-propiolactone, which was carried out in the presence of BF_3.ether at 0°C. The greatest activity in cationic copolymerisation is exhibited by $\beta\beta$-dimethyl-β-propiolactone. It is thought that the mechanism of the ring opening of this monomer differs from the others because the two methyl groups at the β-carbon atom, owing to a redistribution of the electron density of the ring, facilitate breaking of the Alk–O bond with the formation of a tertiary carbonium ion. In the remaining investigations of lactones under the selected conditions ring opening takes place at the acyl–O bond. The following series of activities of these lactones in cationic copolymerisation with 3,3-bischloromethyloxacyclobutane was obtained: $\beta\beta$-dimethyl- $\gg$ $\gg$ β-methyl > unsubstituted $\geqslant$ α-methyl > $\alpha\alpha$-dimethyl. The activity of lactones in copolymerisation increases with increase in the number of alkyl substituents at the β-carbon atom, owing to an increase in the nucleophilic nature of the ester oxygen of the lactone ring. However, this value in β-lactones is low in comparison with simple cyclic esters, which is particularly clear on comparing the values

of the copolymerisation constants. Thus for the most active ββ-dimethyl-β-propiolactone $r = 1.42 \pm 0.1$ but for 3,3-bischloromethyloxacyclobutane $r = 7.24 \pm 0.32$. The reason for the comparatively low activity of β-lactones is thought to be the low nucleophilic nature of the ester oxygen owing to the drawing off of the electrons by the adjacent carbonyl group. A general tendency was noted for a decrease in the activity of β-lactones on the introduction of alkyl substituents in the α-position in anionic polymerisation and an increase in activity on the introduction of alkyl substituents in the β-position in cationic polymerisation, which is correspondingly reflected in the properties of the polymers.

Higher lactones, for example, γ-butyrolactone and ε-caprolactone give copolymers with ethyleneimine[79], as mentioned above, and also with 3,3-bischloromethyloxacyclobutane and β-propiolactone[80]. In the last instance the copolymerisation was carried out in the presence of BF_3.ether at room temperature or at 0°C. These lactones form copolymers with 3,3-bischloromethyloxacyclobutane, the activity in the copolymerisation of the lactones being in the following order: ε-caprolactone > γ-butyrolactone > > β-propiolactone. On the basis of the copolymerisation constants it was found that the activity of ε-caprolactone is higher than that of 3,3-bischloromethyloxacyclobutane but that of γ-butyrolactone is somewhat less. In the copolymerisation of β-propiolactone products of comparatively low molecular weight ($[\eta] = 0.06-0.25$) are obtained.

On the basis of the studies reviewed it can be concluded that lactones are of interest both for studying polymerisation processes connected with ring-opening and as prospective raw materials for obtaining polyesters which exhibit several valuable properties.

Gas Hydrates

S.Sh.Byk and V.I.Fomina

This review states contemporary views about gas hydrates, and also about non-stoichiometric clathrates with the general formula $M.nH_2O$. The known types of the hydrates and their crystal structure are described. The thermodynamics of hydrate formation is considered. Methods of determining the composition of the hydrates are described. Factual information concerning the hydrates of individual gases and organic liquids and mixed hydrates (binary and multicomponent) is given. The problem of the stabilisation of hydrates by an auxiliary gas is considered. Information is given about the density of hydrate crystals and the physical kinetics of the hydrate formation. Equations are given which are obtained by the methods of statistical mechanics and are based on the use of Lennard-Jones and Kihara potentials, and allow the main thermodynamic properties of the hydrates to be calculated. The problems of the industrial utilisation of the hydrates are examined (desalination of sea water, separation of liquid and gaseous mixtures, etc.). The theoretical principles of the inhibition of hydrate formation processes are stated. Bibliography of 180 references.

I. INTRODUCTION

Gas hydrates are solid crystalline substances with the appearance of snow or loose ice and the general formula $M.nH_2O$, where M is the hydrate-forming molecule. There is considerable theoretical interest in the investigation of gas hydrates, as they allow general laws to be formulated which describe the unique physical properties of an extensive group of clathrate compounds† in which the crystal

† Contemporary views about gas hydrates as non-stoichiometric clathrates are presented in Chapter II of this review.

lattice is constructed from water molecules but nevertheless differs appreciably from the lattice of ordinary ice (stability at temperatures > 0°C, presence of cavities of strictly determined diameter, etc.).

Practical interest in gas hydrates is connected with the following features. A series of processes which are carried out in the oil, gas, and petrochemical industries is accompanied by the formation of hydrocarbon hydrates which clog pipelines and equipment. To prevent hydrate formation it is necessary to know the conditions of formation of the hydrates for various compositions of the gas phase, temperatures, pressures, and other parameters, which determine this process. Three prospective directions for the industrial use of gas hydrates must also be noted: (1) the desalination of sea water (semi-industrial plants are already known to be in operation); (2) the separation of binary and multicomponent gas and liquid mixtures; (3) the storage of gases.

Davy[1] first obtained a gas hydrate of chlorine in 1811 on cooling a saturated aqueous solution of chlorine at 9°C. In the first half of the XIXth century hydrates of Br_2, SO_2, and H_2S were obtained in this way.

Thanks to the work of Cailletet, Vroblevskii, Villard, de Forcrand, and other investigators[1] in the 1850s to 1890s, the hydrates formed by CO_2, CS_2, C_2H_2, PH_3, AsH_3, CH_4, C_2H_6, C_2H_4, C_3H_8, N_2O, Ar, Kr, and Xe became known.

A large group of so-called "double hydrates"‡ was then studied, formed by H_2S or H_2Se with hydrocarbons and their halogen derivatives (predominantly of the aliphatic series): CH_3Cl, C_2H_5Br, C_2H_5I, etc. and also hydrates formed by the mixtures: $CO_2 + PH_3$, $CS_2 + PH_3$, $C_2H_2 + CCl_4$, and hydrates obtained from halogen-substituted aliphatic hydrocarbons and such compounds as C_2H_4, CO_2, SO_2, and others.

In the first third of the XXth century the investigation of gas hydrates was mainly connected with the defining of the conditions for the formation of previously known hydrates and of obtaining some new hydrates (CF_4, CHF_3, SO_2Cl_2, I_2, etc.)[1-3]. There was an appreciable increase in interest in studying gas hydrates after the publication of Hammerschmidt's first work[4], who showed in a study of the hydrates of individual C_1–C_4 aliphatic hydrocarbons, that the serious difficulties arising in the transport of natural gas were connected with the formation in the pipelines of the so-called "mixed hydrates". During these years there appeared a great number of papers devoted to defining the equilibrium conditions for the formation of hydrates by individual hydrocarbons, their mixtures, the composition of the hydrates, and methods of preventing hydrate formation. All these problems have been covered completely enough in Frost and Deaton's monograph[5]. As a result of the fundamental investigations made by Stackelberg[6-18], Claussen[19,20], and also Pauling and Marsch[21], in the 1950s the structure of the hydrate crystals was determined, the ideas about "mixed hydrates" were significantly extended, the stabilising influence of foreign gases was studied, and the thermodynamics of hydrate formation and other problems were considered.

At the end of the 1950s and start of the sixties theoretical studies devoted to the statistical mechanics of gas hydrates appeared[22-29]. Between 1960 and 1966 the existence of hydrates of oxygen and nitrogen at high pressures was shown experimentally[30,31] and the theoretical investigations were pursued further[32-37].

‡ As will be shown below, "double hydrates" are particular examples of "mixed hydrates".

II. CONTEMPORARY VIEWS ABOUT GAS HYDRATES

Current literature[38] devoted to the structure of gas hydrates recognises the viewpoint first expressed by Nikitin[39-43]. According to this viewpoint, gas hydrates (formed by individual gases or their mixtures) are non-stoichiometric inclusion compounds, "gas clathrates"[28,44,45], in which the "included" molecules of gas are held by van der Waals forces in a metastable crystal lattice, the "host", which is constructed from water molecules.

The investigations of Claussen[19,20], Pauling and Marsch[21], Stackelberg and Müller[8,9], and Mandelcorn[46] have shown conclusively that gas hydrates crystallise in one of two cubic structures, (I) or (II), the interaction between the water molecules from which the lattice is constructed being effected by means of hydrogen bonds.

The hydrates of structure (I) are described by space group $Oh^3 = Pm3n$ and are characterised by the crystal lattice parameter 12 Å. The unit cell is constructed from 46 water molecules and in it there are eight cavities available for gas molecules, including 2 "small" cavities and six "large". The "small" cavities of structure (I) are regular pentagonal dodecahedra with mean free diameter ~ 5.1 Å; each of the six "large" cavities is tetrahedral with a mean free diameter of ~ 5.8 Å, formed by two opposing hexagons and 12 pentagons situated between them.

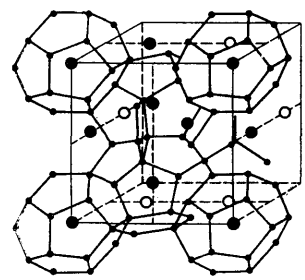

Figure 1. Crystal lattice of a gas hydrate of structure (I).

The hydrates of structure (II) are described by space group $Oh^7 = Fd3n$ with crystal lattice parameter 17.4 Å. The unit cell is constructed from 136 water molecules, contains 24 cavities, including 16 "small" and 8 "large". The "small" cavities, as for structure (I), are pentagonal dodecahedra, but somewhat deformed, as a result of which the mean free diameter is ~ 5 Å. The "large" cavities of structure (II) are hexadecahedra, each of which is constructed from four hexagons and 12 pentagons. The mean free diameter of this cavity is ~ 6.7 Å.

When the effective diameter of the hydrate-forming molecule ($d_{eff}^{M_1}$) < 5.1 Å, then a hydrate of structure (I) is formed in the presence of water; in principle, all the eight cavities can be filled (hydrates of Ar, CH_4, H_2S, etc.) and consequently the ideal formula of this hydrate will be $8M_1.46H_2O$ or $M_1.5.75H_2O$, where M_1 can be a molecule of Ar, CH_4, H_2S, etc. When 5.8 Å > $d_{eff}^{M_2}$ > 5.1 Å, then the hydrate-forming molecules can fill only the six large cavities: in this instance the ideal formula of the hydrate will be $6M_2.46H_2O$ or $M_2.7\frac{2}{3}H_2O$ ($M_2 = C_2H_6$, Cl_2, SO_2, etc.). When two types of molecule are present simultaneously in the gas mixture (a mixture of $M_1 + M_2$) a so-called "mixed hydrate" with the ideal formula $2M_1.6M_2.46H_2O$ is formed, which can

be considered as a solid solution[28,40-42] with a composition which changes during fusion of the hydrate. An example of a "mixed hydrate" of structure (I) is $2H_2S.6C_2H_6.46H_2O$.

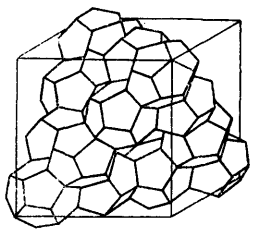

Figure 2. Crystal lattice of a gas hydrate of structure (II).

Analogous considerations apply for a hydrate of structure (II). When 5 Å $< d_{\text{eff}}^{M_3} <$ 6.7 Å (C_3H_8, iso-C_4H_{10}, $CHCl_3$, etc.), then the ideal formula of the hydrate will be $8M_3.136H_2O$ or $M_3.17H_2O$. For the mixture $M_3 + M_4$ (under the conditions: $d_{\text{eff}}^{M_4} < 5$ Å), the "mixed hydrate" which is formed is characterised by the ideal formula $16M_4.8M_3.136H_2O$ or $2M_4.M_3.17H_2O$; for example, $2H_2S.C_3H_8.17H_2O$ or $2CH_4.C_3H_8.17H_2O$.

Figs. 1 and 2 show schematically hydrates of structures (I) and (II).

III. CONDITIONS FOR THE FORMATION OF HYDRATES

A clear presentation of the conditions of formation of hydrates according to the equation $M + nH_2O \rightleftharpoons M.nH_2O$ can be obtained by considering the diagram of heterogeneous equilibrium in P–t coordinates proposed by Roozeboom[47] and given in one of Stackelberg's papers[10]. On this diagram (Fig. 3): (a) curve *I* characterises the saturation vapour pressure of the hydrate-forming substance P_M which in its turn is saturated with water vapour; (b) curve *II*, the vapour pressure of the hydrate-forming substance M over the hydrate in the presence of liquid water; (c) curve *II′* is the vapour pressure of M over the hydrate in the presence of ice; (d) curve *III* is the variation of the melting point of the hydrate with the pressure; (e) curve *IV* is the depression of the freezing point of water during the dissolution of M in it under pressure.

As Fig. 3 shows, the region of existence of hydrates is situated to the left of curves *II* and *III*. The intersection of these curves gives the so-called "critical point for the decomposition of the hydrate" P_c, which is simultaneously the upper quadruple point of the system; at this point hydrate + M_{gas} + M_{liq} + water coexist. It should be noted that point P_c is absent from the hydrates formed by such gases as Ar, CH_4, C_2H_4, Kr, Xe, N_2, and O_2, since owing to the low values of the critical temperature, curve *I* for these gases falls below curve *II* up to the intersection point. The intersection of curves *II′* and *II* gives the so-called "lower quadruple point" at which hydrate + ice + water + M_{gas} coexist. When the pressure in the system is below P_c, then on heating the hydrate decomposes into water and gas (on crossing curve *II*).

When the pressure in the system exceeds P_c, then on raising the temperature (passage through curve *III*) the hydrate decomposes into two liquid phases, H_2O and M_{liquid}.

Curve *III* itself characterises the P–t_f dependence for condensed systems. For the hydrates this curve is almost vertical. The slope of the curve to left or right ($dt/dp < 0$ or $dt/dp > 0$) will depend on how much the volume of the solid hydrate is greater or less than that of the liquid phase which is formed in the fusion of the hydrate§. From the equation given above for the formation of a hydrate comes the idea of dissociation pressure (P_{diss}). Evidently each hydrate is characterised at a given temperature by a definite value of P_{diss}. In principle

$$P_{diss} = P'_M + P'_{H_2O},$$

where P'_M is the vapour pressure of the hydrate-forming substance M over the hydrate and P'_{H_2O} the vapour pressure of the water above the crystal lattice of the same hydrate, constructed from H_2O molecules. In practice, $P_{diss} \simeq P'_M$ (since $P'_M \gg P'_{H_2O}$).

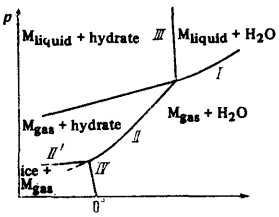

Figure 3. P–t phase diagram.

From what has been said above, at constant temperature there are two boundary conditions[48], which determine the possibility of existence of a hydrate: (1) $P'_M < P_M$, and (2) $P'_{H_2O} < P_{H_2O}$, that is, the equilibrium pressure of the vapour of M above the solid hydrate (P'_M) should be less than the pressure P_M in the system, and simultaneously the equilibrium pressure of water vapour above the hydrate crystal (P'_{H_2O}) should be less than the partial pressure of water vapour (P_{H_2O}) in the same system. Investigations made by many authors have shown[4,5] that this second condition is observed in practice only for the presence of drops of liquid water in the system (that is, at 100% humidity at the given temperature).

The relation between the equilibrium pressure of the hydrate-forming substance over the hydrate (in the literature it is usually denoted simply by the symbol P) and the temperature is described by the well-known equation[49-51]:

$$\lg P = A - B/T,$$

where T is in °K. Tamman and Kriege[52] showed that for most gas hydrates the connection between the equilibrium pressure and temperature can be represented by an equation of the type:

$$t = a(\lg P + B).$$

Diagrams[53] constructed on a semilogarithmic scale for methane, ethane, propane, and isobutane well reflect the linear character of the relation between $\lg P$ and t and allow the equilibrium conditions for hydrate formation for each of these hydrocarbons to be found readily by interpolation.

§ For hydrates of structure (I) $dt/dp > 0$; for structure (II) $dt/dp < 0$.[10]

IV. METHODS OF PREPARATION AND OF DETERMINING THE COMPOSITION OF HYDRATES

Experimental methods for the preparation of hydrates are considered in the papers of Frost and Deaton[51], Hammerschmidt[4], and the reviews of Czaplinski[2,3]. Hydrates can be formed both in a closed system (most convenient for laboratory investigations) and in a flow system (gas pipes, petrochemical industrial plant).

The formation of hydrates can in principle be compared with crystallisation from a supersaturated solution or the freezing of a supercooled melt[2]. Therefore the general rules formulated by Eucken[54] for crystallisation can be transferred to the process of hydrate formation. This process is greatly facilitated[4] by increasing the rate of gas flow, saturation with water vapour, pressure pulsations, the introduction of small crystals of the hydrate or other nuclei for the crystallisation (for example, crystallites of AgI[55]).

From the very definition of gas hydrates as non-stoichiometric clathrates it follows that in the formula $M.nH_2O$ the value of n is variable¶, depending on the degree of filling of the cavities†. The minimal value of n is reached when all the cavities of the clathrate crystal are filled with molecules of the hydrate-forming substance.

In this sense it is possible to speak about the "ideal" formula of the hydrate. For hydrates of structure (I) the ideal formula $8M.46H_2O$ or $M.5.75H_2O$ (when only the six large cavities are filled, $6M.46H_2O$ or $M.7\frac{2}{3}H_2O$). For the hydrates of structure (II) the eight large cavities ($d_{eff} < 6.7$ Å) are usually filled and the ideal formula of such a hydrate is $8M.136H_2O$ or $M.17H_2O$.

1. DIRECT EXPERIMENTAL DETERMINATION OF COMPOSITION

The direct determination of the composition of a hydrate is carried out as follows[2,51]: a definite quantity of liquid water and of compressed gas is put in a thick-walled glass tube at ~ 0°C and, with periodic shaking, the system is kept for several days. After complete bonding of the water in the hydrate the tube is cooled below the temperature at which $P_{diss} = 1$ atm, and the excess of gas, bonded with the water, is removed. Then the hydrate is decomposed by heating and the volume of gas liberated is measured, after which the composition of the hydrate is calculated from the ratio between the initial amount of water and the volume of gas liberated.

It should be noted that for any one hydrate many authors have obtained quite different results[51,55]. The explanation is firstly that the conditions of carrying out the experiment are not comparable and secondly the serious experimental difficulties that arise in carrying out the method. Of the many studies devoted to the direct experimental determination of the composition of hydrates, the most precise are those of Marshall and coworkers[57] and Ceccoti[55]. The former determined the composition of methane hydrate in the pressure range 150–680 atm, and in the calculations they took account of the compressibility of methane and its solubility in water. The same authors observed an interesting fact: the occlusion of water by the hydrate lattice which is formed prevents the interaction between gas and water proceeding to completion.

Ceccoti studied the formation of hydrates by propane directly in the gas phase in the presence of microcrystallites of AgI, which, as he showed, serve as effective catalysts for hydrate formation. In this instance the result of the experiment was not distorted by the occlusion of the liquid phase (aqueous or hydrocarbon) of the crystal lattice of the hydrate. At a temperature somewhat above the lower quadruple point the propane hydrate was found to have the composition $C_3H_8 . 19.7H_2O$ (which corresponds to 86% filling of the large cavities). Ceccoti first suggested that propane hydrate, by analogy with bromine hydrate[58], has a tetragonal structure. A method first proposed by Bigorné[59] belongs among the direct experimental methods of determining the composition of hydrates. He found that when the hydrate is formed from an aqueous solution of a salt (for example, $NiSO_4$), which does not itself react with a hydrate-forming substance (ClO_2), then after the formation of the hydrate the quantity of "free" water in the system decreases, since part of it is converted into the hydrate lattice, but the concentration of the salt in the solution rises correspondingly. Knowing the decrease in the hydrate-forming substance in the system, it is easy to calculate the composition of the hydrate. The precision work of Khayano and Takasi[60] was based on the principle stated above; they determined the composition of isobutane hydrate ($M.17.1H_2O$) with the aid of a series of NaCl solutions of different concentration.

2. SEMIEMPIRICAL METHOD OF CALCULATING THE COMPOSITION OF HYDRATES

This method, first proposed by de Forcrand[61] and perfecte by Scheffer and Meyer[62], allows the value of n at the lower quadruple point to be determined, that is, the point of intersection of the two curves "ice–hydrate–gas" and "water–hydrate–gas". As stated above, each of these curves is described by an equation of the type $\lg P = A - B/T$, in which the constants A and B are found by experiment. The number of water molecules connected with one molecule of the hydrate-forming substance is calculated by the simple formula:

$$n = \frac{\Delta H_1 - \Delta H_2}{Q},$$

where ΔH_1 and ΔH_2 are the molar heats of formation of the hydrate from liquid water and from ice, and Q is the molar heat of fusion of ice (at 0°C, $Q = 1430$ cal mole^{-1}). The values of ΔH_1 and ΔH_2 for the specific hydrate were calculated in the usual way, by combining the equation given above with the Clausing–Clapeyron equation:

$$T\frac{\Delta P}{\Delta T} = \frac{\Delta H}{\Delta V}.$$

In this way the compositions of the hydrates of methane, ethane, propane, and natural gas were determined for the lower quadruple point[49–51].

In the same way van Cleef and Diepen[31] calculated the composition of the hydrates of oxygen and nitrogen which they obtained for the first time at high pressures. The calculations were sufficiently rigorous: the density of the hydrated crystals, the solubility of the gas in water, and its coefficient of compressibility were calculated. For nitrogen hydrate at the lower quadruple point ($t = -1.3$ °C, $P = 141.5$ atm) the composition $N_2(6.01 \pm 0.23)H_2O$ was

¶ According to van der Waals (grandson) and Platteeuw[28,55], with rise in temperature along curves *II* and *III* on the *P–t* diagram the degree of filling of the cavities of the hydrate lattice increases, that is, the value of n decreases.

† When a hydrate is formed directly from an aqueous solution, for example, ethylene oxide hydrate[56].

found and for oxygen hydrate ($t = -1.0°C$, $P = 104.2$ atm), the value $n = 6.06 \pm 0.21$.

It is interesting to note that even at $P > 100$ atm not all the cavities of the hydrate lattice are completely filled.

Among the indirect methods of determining n must be included the method proposed by Miller and Strong[48].

On applying the law of mass action to the formation of propane hydrate

$$C_3H_8 + nH_2O \rightleftarrows C_3H_8 \cdot nH_2O\,(\text{hydr.})$$

in terms of activities

$$[a_{C_3H_8}][a_{H_2O}]^n = K[a_{C_3H_8} \cdot n_{H_2O}]$$

and then converting to fugacities the authors obtained the expression:

$$f_2(a)^n = f_1(a_1)^n = K,$$

where f_2 is the fugacity of propane in equilibrium with the hydrate and pure liquid water, f_1 the fugacity of propane in equilibrium with the hydrate in aqueous solution, a the activity of pure liquid water ($a = 1$), and a_1 the activity of water in the solution. From the equation given above,

$$n = \frac{\lg (f_2/f_1)}{\lg (a_1/a)} = \frac{\lg f_1 - \lg f_2}{-\lg a_1}.$$

By using aqueous 2 M solutions of methanol, ethanol, acetone, and KOH for hydrate formation, Strong and Miller obtained at 1.9°C for all four solutions the value $n \simeq 6$. It should be noted that this result does not agree with the values of n for propane hydrate found by other investigators[51] ($n = 17.95$).

V. THERMODYNAMICS OF HYDRATE FORMATION

Problems connected with the calculation of the energy of formation of hydrates, the entropy and enthalpy of this process, and the work of expansion of the crystal lattice of the hydrate were considered in detail by Stackelberg[13]. On the basis of the general premises that simple gas hydrates are formed from molecules of water and the hydrate-forming substance with the aid of van der Waals forces and that in energetic respects the crystal lattice of the gas hydrate differs very little from the lattice of ordinary ice[12]. Stackelberg suggested that the entropy of the reaction:

$$M_{gas} + nH_2O_{solid} = M.nH_2O_{hydr.}$$

equals the entropy of freezing of 1 mole of gas (ΔS):

$$\Delta S = \Delta S_1 + \Delta S_2.$$

In this instance ΔS_1 (the entropy of condensation of 1 mole of gas) according to Trouton's rule is 21 cal deg^{-1} and ΔS_2 (entropy of freezing of 1 mole of liquefied gas) was 1 cal deg^{-1}, and consequently $\Delta S = -22$ cal deg^{-1}. By analogy with physical adsorption, according to Eucken[54] the energy of formation of the hydrate is

$$W_{ads} = W_{hydr} \simeq -\sqrt{21 T_b} \times 8000,$$

where T_b is the boiling point of the hydrate-forming substance at atmospheric pressure in °K, 8000 cal mole^{-1} is the heat of vaporisation of water not entering into the pseudocrystalline group; hence $W_{hydr} \simeq -400\sqrt{T_b}$.

The change in free energy (ΔG) in hydrate formation is here described by the equation (for 273°K):

$$\Delta G = W_{hydr} - T\Delta S = -400\sqrt{T_b} + 6000. \quad (1)$$

At the same time

$$\Delta G = RT \ln P_{diss}, \quad (2)$$

where P_{diss} is the dissociation pressure of the hydrate in atmospheres.

On combining Eqns. (1) and (2) it is easy to obtain the relation

$$\lg P_{diss.} = 4.8 - 0.32\sqrt{T_b}. \quad (3)$$

Eqn. (3), which connects P_{diss} with the boiling point of the hydrate-forming substance, is true only at 0°C.

For $t > 0°C$ ($M_{gas} + nH_2O_{liquid} \rightarrow M.nH_2O_{hydr}$), Stackelberg obtained the general equation:

$$4.57 \lg P_{diss.} = -400\sqrt{T_b} - n1437 + 22T + 1437T/273. \quad (4)$$

With the aid of Eqn. (3) he calculated P_{diss} at 0°C for hydrates which had been studied well and obtained values which were compared with experimental data (Table 1).

Table 1.

M	B.p., T_b, °K	P_{diss}, atm	
		expt	calc.
CH_4	112.0	26	26
C_2H_4	171.0	5.5	4.2
C_2H_6	180.0	5.2	3.2
C_2H_2	189.0	5.7	2.5
C_3H_8	228.0	1.0 (1.7)	0.9

As noted above, one of the main conditions for the existence of a hydrate is the relation[48]: $P'_M = P_{diss} < P_M$, where P_M is the saturated vapour pressure of the hydrate-forming substance.

By using the combined Clausing–Clapeyron and Trouton equation $\lg P_M = 4.60 - 0.0169\, t_b$ and Eqn. (3) the boundary condition for the formation of the hydrate can be obtained ($P_M = P_{diss}$): $t_b = 60°C$. Hence gases and volatile organic liquids with $t_b > 60°C$ cannot form hydrates. The extensive experimental results agree with this statement (an exception is chloroform, for which $t_b = 61°C$).

ENTHALPY OF FORMATION OF HYDRATES

Stackelberg showed[7,13] that for the process $M_{gas} + nH_2O_{liquid} \rightleftharpoons M.nH_2O_{hydr}$ the enthalpy calculated on the basis of calorimetric and tensimetric measurements for $n \simeq 6$, varies within limits from −14 to −17 kcal mole^{-1}; at $n \simeq 9$, from −19 to −20 kcal mole^{-1} and at $n \simeq 17$, from −29 to −32 kcal mole^{-1}. For the process $M_{solid} + nH_2O_{solid} \rightleftharpoons M.nH_2O_{hydr}$ both the enthalpy (±2 kcal mole^{-1}) and entropy (±5 cal deg^{-1}) are almost equal to zero. Simultaneously with this Stackelberg found that for the formation of "double hydrates":

$$M_{gas} + 2H_2S_{gas} + 17H_2O_{liquid} \rightleftarrows M \cdot 2H_2S \cdot 17H_2O_{hydr},$$

the enthalpy and entropy are rather significant ($\Delta H =$ 70 kcal mole^{-1} and $\Delta S = -200 - 250$ cal deg^{-1}).

The work of expansion of the crystal lattice of the hydrate on increasing the diameter of the molecule introduced into its internal cavities was calculated by Stackelberg and Jahns[14].

As a result of careful X-ray diffraction measurements of the crystal lattice parameters of the hydrates of structures (I) and (II) they found that the parameters a increase with the diameter of the molecule of the hydrate-forming substance. Thus a change in d_{eff} from 5.2 to 5.7 Å increases the lattice parameter of structure (I) by 1%. The same effect is observed in structure (II) for "double hydrates", where the increase in a becomes noticeable at $d_{eff} > 6.3$ Å. Evidently the value of the work of expansion of the crystal lattice of the hydrate produced by large molecules allows the stability of the hydrate to be evaluated.

Starting from the general definition, the work of expansion is $-W_{exp} = \int_{v_0}^{v} p\,dv$, where p is the dissociation pressure of the hydrate, and introducing the value of the coefficient of compressibility of the hydrate, which characterises the force opposing the expansion of the lattice,

$$\chi = -\frac{1}{v_0}\cdot\frac{dv}{dp},$$

the authors[14] obtained the following expression for the work of expansion:

$$-W_{exp.} = \frac{[9Na_0^4(\Delta a)^2]}{8\cdot 2\cdot\chi\cdot a_0^3\cdot 41} = \frac{8{,}3\cdot 10^{21}\cdot a_0^3}{\chi}\left(\frac{\Delta a}{a_0}\right)^2 \text{ cal}, \quad (5)$$

where a_0 is the parameter of the normal lattice (before expansion), $a = a_0 + \Delta a$ is the parameter of the expanded lattice.

On converting to numerical values: $\chi = 4\times 10^{-5}$, $a_0 = 12\times 10^{-8}$ cm, structure (I), and $a_0 = 17.3\times 10^{-8}$ cm, structure (II), the final form can be obtained.

$$-W_{I} = 36\left(100\frac{\Delta a}{a_0}\right)^2 \text{ cal, structure (I)} \quad (6)$$

$$-W_{II} = 107\left(100\frac{\Delta a}{a_0}\right)^2 \text{ cal, structure (II).} \quad (7)$$

The work performed in the expansion of the crystal lattice increases the chemical potential of the molecule of the complex-forming substance by $\Delta\mu$:

$$-W_{exp} = \Delta\mu = RT\ln(P/P_0). \quad (8)$$

From this equation, on increasing the chemical potential, P_{diss} for the hydrate increases and consequently the "upper quadruple point" of the hydrate is shifted to lower temperatures. This depression of the critical temperature for the decomposition of the hydrate (ΔT_C) is described by the equation:

$$\Delta T = (-W_{exp}\cdot T)/(\lambda_{hydr} - \lambda_M) = -W_{exp}\cdot T/\lambda \quad (9)$$

where λ_{hydr} is the heat of the reaction $M.nH_2O \rightarrow M_{gas} + nH_2O_{liquid}$; λ_M the heat of vaporisation of the hydrate-forming substance, and λ the heat of the reaction $M.nH_2O \rightarrow M_{liquid} + nH_2O$.

For structure (I) (at $n \simeq 6$), $\lambda_I \simeq 10\,000$ cal, λ_{II} (at $n \simeq 17$) = 25 000 cal, and consequently after substituting in Eqn. (9) the corresponding values of W^{I}_{exp} and W^{II}_{exp} the approximate formula

$$\Delta T = 1.1\left(100\frac{\Delta a}{a_0}\right)^2 \quad (10)$$

can be obtained; it is true for structures (I) and (II).

From Eqn. (10) it follows that an increase of 3% in the lattice dimensions depresses the temperature of the upper quadruple point by 10 deg. This conclusion agrees with the experimental results[14].

VI. STABILISATION OF HYDRATES WITH THE AID OF AN "AUXILIARY GAS"

The stabilising action on hydrate formation of a so-called "auxiliary gas", that is, a gas the molecules of which are not held in the internal cavities of the hydrate crystal, was first observed by Villard in 1897.[63] In studying the hydrate of N_2O, Villard found that in pure compressed N_2O at 14°C the decomposition pressure of the hydrate formed is 250 atm.

When the experiment is carried out at the same temperature but in the presence of air the decomposition pressure of the hydrate is reduced to 100 atm. In 1923 Villard[1] observed a still more interesting effect: iodine, which itself is incapable of hydrate formation (b.p. 183°C), forms in the presence of oxygen or nitrogen (which form hydrates only at very high pressures[31]) a brick-red, crystalline hydrate, stable at 3°C (P_{N_2} = 200 atm) and even at 8°C (P_{O_2} = 330 atm). Further investigations of the "stabilisation effect" carried out by Stackelberg and Meinhold[11] allowed a general experimental rule to be established: certain gases (N_2, O_2, CO_2, etc.) which fill only an insignificant part of the cavities of the hydrate lattice appreciably raise the critical temperature for the decomposition of a hydrate by their presence (usually at $P > 1$ atm). The degree of elevation of the decomposition temperature of the hydrate depends on the nature of the gas. Thus in studying the influence of CO_2 and N_2 on the decomposition temperature of hydrates (CCl_4, $CHCl_3$, CH_2Cl_2)‡ Stackelberg and Meinhold established that the effect which could be produced by the presence of CO_2 is twice as much as that obtainable in the presence of N_2 (~ 10 deg and 5 deg). It is also interesting to note that the stabilising influence of n-butane§, which was recently unambiguously shown not to form hydrates itself[60], but nevertheless on being present as one of the components of a gaseous mixture considerably alters the value of the equilibrium pressure over the "mixed hydrate". Extensive investigations of the stabilising action of "auxiliary gases" were made by Barrer and Ružicka[64]. In studying the hydrates of chloroform the authors established that such gases as H_2, Ne, N_2, Ar, O_2, CH_4, Kr, Xe, C_2H_4, C_2H_6, and CO_2 not only appreciably change the equilibrium conditions of hydrate formation but also partially fill the small cavities of structure (II), that is, here it is possible to speak not about an individual hydrate of chloroform but about its "mixed hydrates".

VII. HYDRATES OF INDIVIDUAL GASES AND VOLATILE ORGANIC LIQUIDS

Schroeder's monograph[1] contains the most complete information about the hydrates of the individual gases and the volatile organic liquids relating to the experimental results published up to 1923. Frost and Deaton's monograph[5] contains data embracing the period up to 1945 and relating mainly to hydrates of hydrocarbon gases. The studies made in the last two decades are surveyed in the review part of Stackelberg's papers[10,11], the fundamental handbook edited by Katz[65], and also in a series of articles published between 1960 and 1966.

‡ Carbon tetrachloride forms hydrates only in the presence of a stabilising gas.

§ In this connection indications of the possibility of the formation of hydrates of n-butane[3,53] must be considered extremely doubtful.

Methane

Villard first obtained a hydrate of methane[66] at $t > 0°C$ and $P > 1$ atm; the maximal temperature at which he succeeded in obtaining the hydrate was 21.5°C. Methane hydrate was then investigated by Deaton and Frost[67] and Roberts[68] who studied the $P-t$ dependence for temperatures from 0.5° to 12.8°C. The part of the $P-t$ diagram in the region of existence of ice (from −10° to −5°C) was also investigated[68]. The construction of apparatus needed for working at high pressures allowed Kobayashi and Katz[69,70] to obtain the $P-t$ dependence at pressures from 333 atm (22.5°C) to 762 (28.8°C).

Campbell and McLeod[71] studied methane hydrate in the same pressure interval and obtained results agreeing with those of Kobayashi and Katz. In 1964, Marshall and coworkers published a study[72] in which with the aid of a specially constructed chamber, using an original method of "pressure jump" they studied hydrates of CH_4 in the pressure range from 157 atm (17°C) to 3915 atm (47°C). Table 2 gives their equilibrium $P-t$ data.

Table 2.

28.4	645.3	46.44	3627.1
		46.88	3915.4

In their monograph[28] van der Waals and Platteeuw give the following physicochemical characteristics for the hydrate of CH_4, structure (I): $P_{diss} = 26$ atm at 0°C; the heat of formation from water and the gas is 14.5 kcal mole^{-1} at 0°C; the decomposition temperature at $P = 1$ atm is $t = -29.0°C$.

Ethane

The hydrate of C_2H_6 was first obtained by Villard[73]. Deaton and Frost[74] obtained the $P-t$ dependence for ethane hydrate at pressures of 5.4–54 atm and temperatures 0–14.4°C. Roberts[68] studied ethane hydrate at pressures up to 64 atm (this also embraces the region of existence of the liquid hydrocarbon phase). Deaton and Frost[51] obtained equilibrium $P-t$ data in the region of negative temperatures; they investigated temperatures from −9.6° to −1.1°C and pressures from 3.09 to 4.51 atm. Their results are presented in Table 3.

On the basis of the equilibrium data given above and obtained earlier[74,75] for $t > 0°C$ and pressures up to $P =$ 68 atm, Deaton and Frost calculated the heats of decomposition of ethane hydrate at $t > 0°C$ (17 796 cal mole^{-1}) and $t < 0°C$ (6069 cal mole^{-1}) and used Forcrand's method to determine the composition of the hydrate at the lower quadruple point: $C_2H_6 \cdot 8.25H_2O$. The most recent results on the equilibrium $P-t$ data are given in Reamer and coworkers' work, carried out at a high experimental level. These results, which agree well with those obtained by other authors, are given in Table 4.

The following constants for ethane hydrate, structure (I), are given by van der Waals and Platteeuw[28]: $P_{diss} = 5.2$ atm at 0°C; maximal temperature of existence of the hydrate 14.5°C; heat of hydrate formation at 0°C, $\Delta H = 16.3$ kcal mole^{-1}.

* Values of P_{equil} too low.

Stackelberg gave[10] $\Delta H = 15.0$ kcal mole^{-1}, decomposition temperature of hydrate $t = 15.8°C$ at $P = 1$ atm.

Ethylene

Ethylene hydrate was first obtained by Villard[66], who determined P_{diss} for the hydrate at 0° and 17°C (5.5 atm and 44.8 atm). More extensive investigations in this field were made by Deaton and Frost[67], Kobayashi and Katz[69], and by Diepen and Scheffer[77], who investigated ethylene hydrate at pressures up to 50.5 atm. Reamer and coworkers[76] made a careful determination of the equilibrium $P-t$ values; their results are given in Table 5.

Snell and coworkers[78] studied the conditions of formation of ethylene hydrate and of the hydrate of a $CH_4 + C_2H_4$ mixture at pressures up to 612 atm. Fig. 4 shows the $P-t$ dependence they obtained.

Stackelberg[10] gives the following values of the constants for ethylene hydrate, structure (I); $P_{diss} = 5.5$ atm at 0°C (5.44 according to Diepen), $\Delta H = 15.2$ kcal mole^{-1}; decomposition temperature −13.4°C at $P = 1$ atm; composition found by Claussen[20] by an X-ray diffraction method $C_2H_4 \cdot 7.4H_2O$.

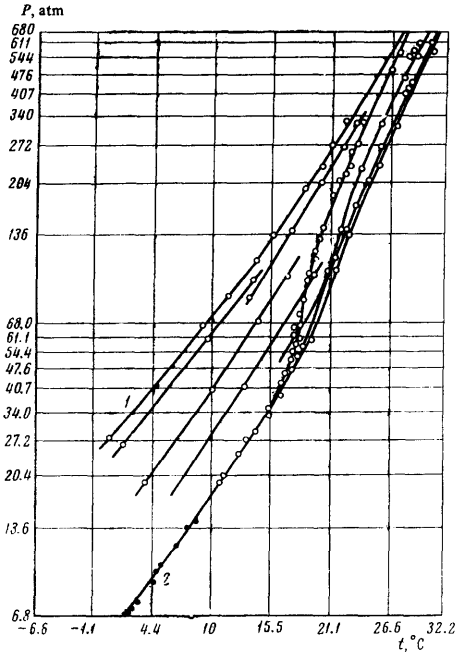

Figure 4. Conditions of formation of the mixed hydrate of CH_4 (*1*) and C_2H_4 (*2*).

Acetylene

Acetylene hydrate was first obtained from the compressed gas in 1877 by Cailletet[1]. Villard[73] measured the pressure of C_2H_2 vapour over its hydrate at 0°C (P = 5.5 atm) and 17°C (P = 44.8 atm). In a summary table Stackelberg[10] gives: (a) decomposition temperature of hydrate 15.4°C at P = 1 atm; (b) temperature of upper quadruple point, 16°C; (c) heat of formation of hydrate 15 000 cal mole^{-1}.

Propane

Propane hydrate was first obtained by Villard[73]. Deaton and Frost determined the equilibrium P–t values for this hydrate[74,75] (Table 6). On the basis of the P–t values given above the heats of formation of propane hydrate at $t > 0$°C and $t < 0$°C and its composition at the lower quadruple point ($C_3H_8 \cdot 17.95H_2O$) were calculated[79].

The conditions of formation of propane hydrate at high pressures (in the region of existence of the liquid hydrocarbon phase) were also studied by Wilcox and coworkers[79], Reamer and coworkers[76] (at temperatures from 1.1° to 5.7°C and pressures from 2.4 to 20 atm), and Teodorovich[80].

The following values of the constants for propane hydrate structure (II), are given by van der Waals and Platteeuw[28]: P_{diss} = 1.74 atm at 0°C (Stackelberg[10] gave P_{diss} = 1 atm), maximal temperature of existence of hydrate t = 5.69°C, heat of formation 32 000 cal mole^{-1} at 0°C, crystal lattice constant 17.4 Å.

Propene

The first information about propene hydrate is contained in a paper by Reamer and coworkers[76]. They succeeded in obtaining P–t values for the pressure range 5–20 atm and temperatures from 0.5° to 1.7°C (the pressure interval also embraces the region of existence of the liquid hydrocarbon phase). A precision investigation of propene hydrate, during which even the pressure of water vapour in the system was calculated, was made by Clarke and coworkers[81]. Table 7 gives their equilibrium results. They obtained the following expression for the volatility (f) of propene over its hydrate:

$$\lg f = 24.8309 \pm 0.0001 - (6610 \pm 20)\ 1/T$$

and calculated the heat of decomposition of the hydrate at t = 0°C (ΔH = 30230 ± 90 cal mole^{-1}). P–t values in the range of negative temperatures (from −3.7° to −14.7°C) were found by Byk and coworkers[82], who obtained an equation for the above temperature range, $\lg f = 4.4853 - 1072/T$ and calculated the heat of decomposition of the hydrate for $t < 0$°C (ΔH = 4920 cal mole^{-1}).

According to Clarke and coworkers[81] the temperature of the lower quadruple point of propene hydrate is −0.134°C, that of the upper is 0.958°C, and the composition of the hydrate is $C_3H_8 \cdot 17H_2O$.

Isobutane

Deaton and Frost obtained the first reliable experimental equilibrium P–t data for isobutane hydrate[83]. Kayano and Utida[60] made a careful investigation of isobutane hydrate, including the determination of its composition (iso-$C_4H_{10} \cdot 17H_2O$ and quadruple points (0°C and 847 mmHg for the lower point; 1.8°C and 1268 mmHg for the upper); they obtained the following equations:

$$\lg P_{mm} = 29.33 - 7210/T \ (\text{at } t > 0°),$$
$$\lg P_{mm} = 9.106 - 1688/T \ (\text{at } t < 0°).$$

Their calculated heats of decomposition of the hydrate are respectively ΔH = 32 960 cal mole^{-1} (t > °C) and ΔH = 7716 cal mole^{-1} (t < 0°C).

Hydrogen Sulphide

Hydrogen sulphide hydrate was first obtained in 1840 by Beller[1]. Systematic investigations of this hydrate were carried out by de Forcrand and Villard[84], who measured P_{diss} of the hydrate at 0.5°C (1.1 atm) and 28.5°C (16 atm). Sheffer[85] determined the quadruple points of the hydrate (−0.389°C and 0.917 atm for the lower point; 29.6°C and 22 atm for the upper), and Kolvezce and Scheffer[86] its composition: $H_2S.6H_2O$.

Careful measurements of the equilibrium P–t values (the water–hydrate–H_2S_{gas} system in the region close to the freezing point of water) were made by Wright and Maas[87].

The most extensive investigation of the H_2S–H_2O system (in the region of existence of the hydrates) was made by Selleck and coworkers[88], who obtained equilibrium P–t values for the temperature range from −0.389° to 29.45°C and pressures from 0.917 to 22.10 atm. These results are given in Table 8.

Table 8.

* Quadruple point.

For the system hydrate + H_2O_{liquid} + H_2S_{gas} these same authors obtained the equation:

$$\lg P_{atm} = 15.11835 - \frac{6867.98}{T}.$$

Sulphur Dioxide

Sulphur dioxide hydrate, with m.p. 4–5°C was obtained in 1829.[1] Having obtained a hydrate from liquid SO_2, Villard[73] proposed the formula $SO_2.6H_2O$. Roozeboom[47] determined, in a sealed glass ampoule, the critical decomposition temperature of SO_2 hydrate (12.1°C) and the decomposition temperature at P_{SO_2} = 1 atm (7.1°C).

Tamman and Kriege[52] proposed for sulphur dioxide hydrate the equations $t = 16.75\,(\lg P + 0.4179)$ at $t > -2.6$°C, and $t = 41.60\,(\lg P + 0.4904)$ at $t < -2.6$°C, where t is the temperature of hydrate formation, and P the dissociation pressure, atm. The same authors found that $t = -2.6$°C is the eutectic point, at which the hydrate has the composition $SO_2.6H_2O$. Stackelberg[10] gives the following values for the constants of sulphur dioxide hydrate, structure (I): P_{diss} = 0.39 atm at 0°C; heat of hydrate formation from gaseous SO_2 and H_2O = 16.6 kcal mole^{-1}, crystal lattice constant 11.94 Å.

Carbon Dioxide

Carbon dioxide hydrate was obtained in 1882 by Wroblewsky[89] at ~ 0°C and a CO_2 pressure of ~ 30 atm. Villard[76] proposed the formula $CO_2.6H_2O$ for the hydrate Tamman and Kriege[52] measured P_{diss} of the hydrate in the temperature range from −20° to −43°C (106.4 mmHg and 9.2 mmHg) and obtained the equation $t = 22.0\,(\lg P - 1.0904)$, where t is in °C and P in cmHg.

Wiebe[90], having studied the CO_2 + H_2O system at pressures up to 700 atm, obtained for carbon dioxide hydrate the formula $CO_2.7H_2O$. Deaton and Frost[74] obtained equilibrium P–t data for a wide temperature range (including $t > 0$°C).

Table 9.

t_{equil}, °C	P_{equil}, atm
4.6	20.1
6.0	25.5
7.7	31.8
9.2	36.4
9.2	42.4

Unruch and Katz[91] studied the conditions of hydrate formation in the CO_2 + H_2O system up to the upper quadruple point (9.8°C, 42.4 atm). Their results are given in Table 9.

Dinitrogen Oxide (N_2O)

Villard obtained dinitrogen oxide hydrate in 1888.[79] He measured P_{diss} of this hydrate at −9.1°C (P_{diss} = 3.6 atm) and 10.7°C (P_{diss} = 34.7 atm), and also proposed for it the formula $N_2O.6H_2O$. Tamman and Kriege[52] obtained for dinitrogen oxide hydrate the equation:

$$t = 1.9\,(\lg P - 0.9795),$$

where t is in °C, and P_{diss} in atm.

Stackelberg[10] gives the following constants for dinitrogen oxide hydrate, structure (I): P_{diss} = 10 atm at 0°C, decomposition temperature −19.3°C at P_{N_2O} = 1 atm. The critical decomposition temperature is 12.0°C, the heat of formation of the hydrate (from water and gas) 14.7 kcal mole^{-1}. The crystal lattice constant is 12.03 Å.

Hydrogen Selenide (H_2Se)

Hydrogen selenide hydrate was obtained by de Forcrand in 1902.[1] Experimental P–t values have not been published. Stackelberg[10] gives the following constants for this hydrate: P_{diss} = 0.45 atm at 0°C, decomposition temperature of the hydrate 8.0°C at P = 1 atm; t_c = 30°C; lattice parameter 12.06 Å.

Sulphur Hexafluoride (SF_6)

Sulphur hexafluoride hydrate was studied by Sortland and Robinson[36]. The authors obtained $P-t$ data for the temperature range from −9 to 15° they calculated the composition of the hydrate at the lower (~ 0°C) quadruple point: $SF_6.17.02H_2O$, determined the upper quadruple point (14.0°C, 19.9 atm), and also calculated the heat of formation of the hydrate at $t < 0$°C (5140 cal mole^{-1}) and at $t > 0$°C (29570 cal mole^{-1}).

PH_3, AsH_3, and SbH_3

1. Phosphine hydrate was obtained by Skinner[1] by condensing phosphine vapour in the presence of water. The same author measured P_{diss} at 1°C (P = 2 atm) and 25.0°C (P = 16 atm).

According to Stackelberg[10] P_{diss} = 1.6 atm at 0°C, decomposition temperature of the hydrate = −6.4°C at P_{PH_3} = 1 atm, critical decomposition temperature = 28.0°C.

2. According to Schroeder[1] arsine hydrate has the composition $AsH_3 . 6.14H_2O$ and is characterised by the following values: t = 0°C at P = 613 mmHg; t = 1.6°C at P = 760 mmHg; t = 21°C at P = 8.85 atm.

According to Stackelberg[10], the constants of arsine hydrate are: decomposition temperature = −1.8°C at P = 1 atm. Critical decomposition temperature 28.3°C.

3. For stibine hydrate, Schroeder[1] gives the value P_{diss} = 760 mmHg at t = 10.9°C.

Chlorine

Chlorine hydrate, as already stated above[1], was obtained in 1810 by Davy. The decomposition temperature of this hydrate (determined in a sealed glass ampoule) is 28.7°C, according to Schroeder[92].

van der Waals and Platteeuw[28] give data for chlorine hydrate: P_{diss} = 252 mmHg at 0°C; heat of formation 16.0 kcal mole^{-1}; crystal lattice parameter 12.03 Å. Tamman and Kriege[52] proposed for this hydrate the formula $Cl_2.8H_2O$ and for $t < 0$°C (the ice–hydrate–vapour system) obtained the equation $t = 49.0\ (\lg P + 0.4757)$, where t is in °C and P in mmHg. Careful X-ray diffraction investigation of chlorine hydrate was made by Pauling and Marsh[21,93], and also Allen[94]. The latter found that at the lower quadruple point the Cl_2 molecule (for the formation of a hydrate from liquid chlorine) occupies only 16% of the small cavities of the crystal lattice, the parameter of which is 11.82 Å. The composition of this hydrate is $Cl_2 . 7.27 + 0.17H_2O$. Investigations, made by Glew and Rath[56], showed that when the hydrate is in equilibrium with gaseous chlorine, then 81% of the small cavities of structure (I) are occupied and the hydrate has the composition $Cl_2 . 6.04 \pm 0.13H_2O$.

Bromine (Br_2)

As already mentioned above, bromine hydrate was first obtained by Levig[1]. Roozeboom[47] determined the critical decomposition temperature of the hydrate (in a sealed ampoule), ~ 6.2°C, and proposed for the hydrate the formula $Br_2.10H_2O$. Tamman and Kriege[52] obtained for Br_2. $.10H_2O$ the formula $t = 43.0\ (\lg P + 0.2465)$ ($t < 0$°C), where t is in °C and P in mmHg. Mulders[28] determined P_{diss} = 43.90 mmHg at 0°C, maximal temperature of existence of the hydrate 5.81°C, heat of hydrate formation 20.83 cal mole^{-1} at 0°C and he proposed the composition $Br_2 . 8.47H_2O$ for the lower quadruple point. From Stackelberg's review[10], bromine hydrate is characterised by structure (I) with lattice parameter 12.0 Å. In addition Jeffrey and McMullan[58] proposed in 1963 that bromine hydrate crystals are tetragonal.

Iodine (I_2)

Iodine hydrate can be obtained, as was shown experimentally in 1923 by Villard[1], only in the presence of "stabilising" gases (N_2, O_2, CO_2). The highest positive temperature (8.0°C) at which the crystalline iodine hydrate is still stable could be attained in the presence of oxygen under a pressure of 300 atm.

Inert gases (Ar, Kr, Xe)

Villard obtained hydrates of Ar, Kr, and Xe in 1896[95] and then de Forcrand[96] in 1925. Nikitin[43] in 1956 also mentioned the ability of radon (Rn) to form a hydrate.

Waller[97] carried out an X-ray diffraction investigation of the hydrates of Ar, Kr, and Xe and found that all three hydrates have structure (I), with ideal formula $M . 5.75H_2O$.

Godhot[98] obtained hydrates of Kr and Xe with heavy water, $Kr.6D_2O$ and $Xe.6D_2O$.

Argon. According to Diepen, cited by van der Waals and Platteeuw[28], P_{diss} = 95.5 atm at 0°C (according to Stackelberg[10] P_{diss} = 105 atm, and the decomposition temperature of the hydrate is −42.8°C at P = 1 atm). Tamman and Kriege[52] obtained an equation for argon hydrate ($Ar.5–6H_2O$): $t = 19.6(\lg P - 2)$, where t is in °C and P in atm. The equilibrium $P-t$ values were obtained by Marshall and coworkers[72] for the wide temperature range 1.65° to 31.0°C and pressures from 105 to 3780 atm (Table 10).

Table 10.

t_{equil}, °C	P_{equil}, atm	t_{equil}, °C	P_{equil}, atm
1.16	105.0	25.6	1807.4
3.7	130.2	26.7	2040.6
2.9	121.2	26.8	2049.8

11.8	316.5	28.9	2662.2
11.1	314.8	29.7	3031.4
15.3	494.0	30.4	3336.7
17.8	659.9	31.0	3717.2
19.3	807.5	31.1	3777.4
23.5	1400.1	30.9	3729.1

Krypton. According to de Forcrand[96], P_{diss} = 14.5 atm at 0°C and at t = 12.5°C P_{diss} = 47.5 atm. Tamman and Kriege[52] obtained for krypton hydrate the equation: $t = 21.2\ (\lg P - 1.1698)$ where t is in °C and P in atm. Stackelberg[10] gives the following values of the constants for ($Kr.5–6H_2O$): decomposition temperature −27.8°C at P = 1 atm, heat of hydrate formation 13.9 kcal mole^{-1}.

Xenon. According to Waller's results[97] xenon hydrate is the most stable in the series Ar < Kr < Xe. de Forcrand[96] measured its P_{diss} at the temperatures 1.4°C (P = 1.45 atm) and 23.5°C (P = 17 atm). For Xe($n \simeq 6H_2O$) Stackelberg[10] gives the following values of the constants: P_{diss} 1.5 atm at 0°C (van der Waals and Platteeuw[28] give P_{diss} = 1.15 atm). The decomposition temperature of the hydrate is −3.4°C at P = 1 atm. The heat of hydrate formation is 16.7 kcal mole^{-1}; the crystal lattice parameter is 11.97 Å.

Nitrogen

As already stated above, nitrogen hydrate was first obtained by van Cleef and Diepen[30] in a specially constructed apparatus which allows hydrates to be studied at very high pressures, ~ 1000 atm. On the basis of the experimental P–t data they found for the temperature range from 0° to 18°C, they obtained the equation given below for the hydrate–water–gas system and calculated the heat of formation of the hydrate:

$$\lg P_{atm} = 14.1293 \pm 0.0006 - \frac{3257 \pm 23}{T};$$

$$\Delta H_1 = 12380 \pm 310 \text{ cal mole}^{-1}.$$

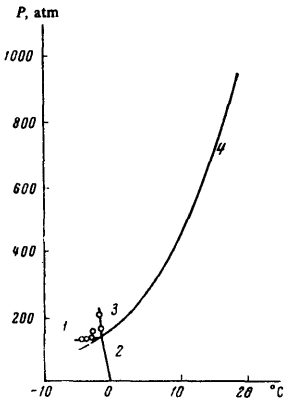

Figure 5. Conditions of hydrate formation by nitrogen: *1*) hydrate–ice–gas; *2*) ice–water–gas; *3*) hydrate–ice–water; *4*) hydrate–water–gas.

Subsequently the same authors[31] determined the equilibrium P–t values at t < 0°C for the temperature range −1.17° to −4.45°C and obtained the equation $\lg P_{atm}$ = 5.5598 ± 0.0002 − (927 ± 17)/T, calculated the heat of hydrate formation ΔH_2 = 3810 ± 110 cal mole^{-1} and also determined the lower quadruple point of the hydrate in the ice–hydrate–gas system, t = −1.3°C, P = 141.5 atm. Fig. 5 shows a correlation of the P–t results of van Cleef and Diepen for N_2.6.01 ± 0.23H_2O¶.

Nitrogen hydrates were also studied by Marshall and coworkers[57] over a wide range of temperatures and pressures. Table 11 shows their experimental P–t values.

¶ Composition of the hydrate calculated by the same authors.

Oxygen

Oxygen hydrates were first obtained by van Cleef and Diepen[31] and published P–t equilibrium data for oxygen hydrate over a wide range of temperatures from −1.8° to +18.0°C and pressures from 100 to 938 atm. The same authors proposed the equations:

$$\lg P_{atm} = 14.3082 \pm 0.0005 - \frac{3340 \pm 21}{T}$$

(for the hydrate–water–gas system), and

$$\lg P_{atm} = 5.1168 + 0.0006 - \frac{838 \pm 38}{T}$$

(for the hydrate–ice–gas system), and calculated the heats of formation of the hydrate (O_2 . 6.06 ± 0.21H_2O): ΔH_1 = 11 840 ± 260 cal mole^{-1} and ΔH_2 = 3190 ± 160 cal mole^{-1} corresponding to the parts of the P–t curves above and

below the quadruple point ($t = -1.0°C$, $P = 109.2$ atm). The experimental results of van Cleef and Diepen are given in Table 12 and Fig. 6.

HYDRATES OF VOLATILE ORGANIC LIQUIDS

The review part of Stackelberg's paper[10] and the monograph of van der Waals and Platteeuw[28] give the characteristics of a series of hydrates formed by volatile organic liquids. All these results are given in Table 13, which also contains information about certain hydrates taken from later original papers.

There are also reports[1] of the existence of hydrates of such compounds as CF_4, CHF_3, $C_2H_2F_2$, and C_2F_4. Ethylene oxide (C_2H_4O) hydrate was investigated by Glew and Rath[56] and also by Jeffrey and McMullan[58]; Glew and Rath found that the hydrate of C_2H_4O belongs to structure (I). Depending on the C_2H_4O concentration in the aqueous solution, which is found in equilibrium with the hydrate, there is a different degree of filling the cavities of the hydrate lattice. At the temperature of congruent fusion of the hydrate (11.1°C) the filling is 100% of all six of the large cavities of the crystal and 34% of the small cavities. This corresponds to the composition $C_2H_4O \cdot 6.89 \pm 0.06H_2O$.

Glew[99] studied the hydrate of bromochlorodifluoromethane ($CBrClF_2$) and found that this hydrate belongs to structure (II). Tetrahydrofuran hydrate $[CH_2]_4O.17H_2O$, was obtained by Stackelberg[18], who found its melting point to be 5.1°C.

Pinder's investigation of this hydrate[100] showed that the melting point of $[CH_2]_4O.17H_2O$ depends on the THF concentration in the equilibrium solution.

Ponyet and Mealier[101] obtained the hydrate of propylamine and Jordan and Mac[102] studied the structure of diethylamine hydrate.

McMullan and coworkers[103] investigated the hydrate of t-butylamine.

VIII. MIXED HYDRATES

As already stated above, when the hydrate-forming substance is not an individual gas, but a mixture of gases or volatile organic liquids, then the hydrate which is formed is a solution, the composition of which varies during its fusion. Such a hydrate is usually called "mixed".

The simplest examples of a "mixed hydrate" are the so-called "double hydrates" formed by a mixture of two types of molecule: $M_1 + M_2$ or $M_3 + M_4$†.

1. DOUBLE HYDRATES, FORMED BY H_2S AND H_2Se

de Forcrand[1] first observed the ability of hydrogen sulphide to form "double hydrates" when mixed with other gases. Somewhat later[1], double hydrates of hydrogen selenide were obtained. de Forcrand established the experimental fact that H_2S forms hydrates with halogen derivatives of aliphatic hydrocarbons. These hydrates are readily obtained on passing moist H_2S through the corresponding liquid at $t \simeq 0°C$.

Below, in Table 14, are listed the organic compounds which, according to de Forcrand, readily form double hydrates

Table 14.

1. CH_3Cl	8. $C(NO_2)Cl_3$	15. C_2H_5I	22. C_3H_5Br
2. CH_2Cl_2	9. C_2H_5Cl	16. C_3H_3I	23. iso-C_4H_9Cl
3. $CHCl_3$	10. $C_2H_4Cl_2$	17. C_3HCl_3	24. iso-C_4H_9Br
4. CCl_4	11. $C_2H_3Cl_3$	18. C_3H_7Cl	
5. CH_3Br	12. $C_2H_2Cl_2$	19. C_3H_7Br	
6. CH_2Br_2	13. C_2H_5Br	20. iso-C_3H_7Br	
	14. $C_2H_4Br_2$	21. C_3H_5Cl	

de Forcrand studied the $H_2S + CHCl_3$ system most carefully, having shown that the hydrates formed by this system belong to structure (II).

Lui[1] studied a group of double hydrates formed by H_2Se and halogen derivatives of hydrocarbons and found that hydrates of the type $M.2H_2Se.17H_2O$ are formed from the following compounds: CCl_4, $CHCl_3$, CH_3Br, CH_3I, C_2H_5Cl, C_2H_5Br, C_2H_5I, $C_2H_2Cl_2$, iso-C_3H_7Br, iso-C_4H_9Cl. As already stated, CCl_4 itself does not form hydrates.

At the end of the 1890s it was shown[1] that acetylene forms double hydrates with CCl_4, $CHCl_3$, $C_2H_4Cl_2$, CH_3I, $CHBr_3$, C_2H_5Br, CH_2Cl_2, and CH_2I_2.

Halogen substituted hydrocarbons also give double hydrates with C_2H_4, CO_2, and SO_2. Hydrates of such mixtures as $PH_3 + CS_2$, $PH_3 + CO_2$, and $(C_2H_5)_2O + CO_2$ are known[1]. The mixed hydrate[105] $Cl_2.Br_2.7\frac{2}{3}H_2O$, decomposition temperature 14°C, is interesting.

The double hydrates formed by H_2S with the hydrocarbons CH_4 and C_3H_8 were studied comparatively recently (1940s to 1950s). The hydrate of the mixture $CH_3 + H_2S$ was obtained by Noaker and Katz[106] and simultaneously with their obtaining equilibrium P–t values (15–19°C, 47–60 atm), the authors determined the composition of the coexisting equilibrium phases for the hydrate $2H_2S.6CH_4.46H_2O$.

The results of a study of the hydrate $2H_2S.C_3H_8.17H_2O$, which was made by van der Waals and Platteeuw in 1959[29] are of independent interest for the following reason. Up to 1959 the literature devoted to "double hydrates" had been dominated by Stackelberg's viewpoint[12], according to which

† See Chapter I of the present review.

the "double hydrates" formed by hydrogen sulphide (or H_2Se) differ from other binary mixed hydrates by their being compounds of constant composition with a definite, stable dissociation pressure at a given temperature whereas all other double hydrates are characterised by variable composition and corresponding different values of P_{dis}. Van der Waals and Platteeuw showed that the hydrate $2H_2S.C_3H_8.17H_2O$ does not differ in principle from other binary hydrates in which H_2S or H_2Se is absent and is an ordinary non-stoichiometric binary clathrate.

3. DOUBLE HYDRATES FORMED BY HYDROCARBONS

Hydrates Formed by Mixtures of Alkanes

Campbell and McLeod studied[71] hydrate formation in the binary systems: (a) $CH_4 + C_2H_6$; (b) $CH_4 + C_3H_8$; (c) CH_4 + iso-C_4H_{10}, and Deaton and Frost[5] that in the system (d) $CH_4 + C_3H_8$ and (e) $CH_4 + C_2H_6$.

System (a) was investigated at temperatures from 11.6° to 31.0°C and pressures from 68 to 680 atm (at ethane concentrations from 5.4 to 19.1%).

				104	22.1

For system (b), containing 3.5 and 5.5% C_3H_8, the equilibrium P–t values were found in the temperature range 17.2–31.0°C and pressures from 68 to 680 atm.

System (c), containing 1.4 and 4.6% iso-C_4H_{10} was investigated at 15.5–32.2°C and pressures 68–680 atm. The same authors found that the equilibrium P–t values for the CH_4 + n-C_4H_{10} system (with 0.5, 2.0, and 5.3% n-C_4H_{10}) agree, within the limits of error of the experiment with the P–t values of pure CH_4.

Experimental P–t data for mixtures (d) and (e) are given in Deaton and Frost's monograph[5]. They studied the $CH_4 + C_3H_8$ system at temperatures from 0° to + 6°C and pressures from 1 to 50 atm and the $CH_4 + C_2H_6$ system at temperatures from 2° to 10°C and pressures from 2 to 60 atm.

The experimental P–t data of McLeod and Campbell for mixtures (a) (gases Nos. 2 and 3), (b) (gas No. 5), and (c) (gases Nos. 8 and 9) are given in Table 15.

Carson and Katz[107] obtained equilibrium P–t data for the four-phase, three-component system $CH_4 + C_3H_{8\,liquid} + C_3H_{8\,gas} + H_2O_{liquid}$ in the temperature range 12.3–22.5°C and pressures from 12 to 71.5 atm. Their results are given in Table 16.

Hydrates Formed by Alkane–Alkene Mixtures

Hydrate formation in the binary systems (a) $CH_4 + C_2H_4$, (b) $CH_4 + C_3H_6$, and (c) $C_3H_6 + C_3H_8$ were studied by Snell and coworkers[78] (a), Otto and Robinson[108] (b), and also Reamer and coworkers[76], Teodorovich[80], and Byk and coworkers[82] (c).

For system (a) with from 1.9 to 92.4% C_2H_4 equilibrium P–t data were obtained in the temperature range from 1.1° to 21.0°C and pressures up to 600 atm. Some P–t values were also obtained[82] for the ternary system with CH_4 32.6, C_2H_4 60.6, C_3H_6 6.8% (Fig. 7).

System (b) with from 0.5 to 23.0% C_3H_6, was studied at pressures up to 130 atm in the temperature range from 0° to 21.1°C (Fig. 8).

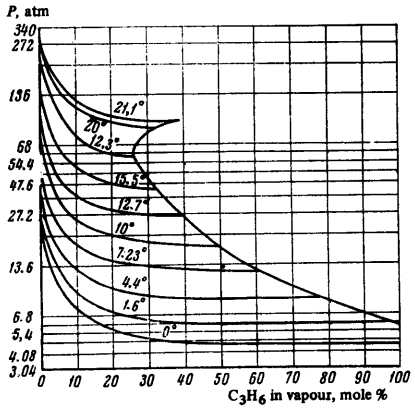

Figure 8. Effect of composition on the conditions of formation of a mixed hydrate containing CH_4 and C_3H_6.

The conditions of hydrate formation in system (c) were studied[76] for two propane–propene mixtures of different composition ($C = 0.3148$ and $C = 0.5246$, where

$$C = \frac{X_{C_3H_6}}{X_{C_3H_6} + X_{C_3H_8}},$$

at pressures from 2.9 to 26 atm (including the range of existence of a liquid hydrocarbon phase) and temperatures from 0.55° to 3.8°C (Table 17). Teodorovich[80] concluded, on the basis of the P–t values they obtained, that propene does not enter into the composition of the hydrate (contrary to the results of other authors). Byk and coworkers[82] obtained equilibrium P–t data for two gaseous mixtures which are characterised by the ratio $X_{C_3H_6}/X_{C_3H_8} = 2.87$ and 0.67. The experimental results relating to this system are given in Table 18.

Double Hydrates Formed by Methane with Carbon Dioxide, Nitrogen, and Argon

Unruch and Katz[91] studied the conditions of hydrate formation in the $CH_4 + CO_2$ system. They obtained P–t equilibrium data for pressures from 27 to 68 atm and temperatures from 1.1° to 11.0°C.

The $CH_4 + N_2$ system was studied by Ichaveri and Robinson[109], who experimentally determined P–t values for mixtures with various N_2 concentrations from 18 to 90% at temperatures from 0° to 22°C and pressures up to 350 atm.

Table 18.

		3.4	4.25
		4.2	5.18
		4.3	5.21
		4.35	5.24

Equilibrium P–t values for the systems: (1) $CH_4 + Ar$ and (2) $Ar + N_2$ were obtained experimentally by Saito and Kobayashi[34] in a specially constructed apparatus by the "pressure jump" method. System (1) was investigated at temperatures from 2.7° to 25.7°C and pressures from 56 to 1120 atm; system (2) at temperatures from 2.2° to 17°C and pressures from 142 to 605 atm.

Mixed Hydrates Formed by Inert Gases

Hydrates formed by molecules of inert gas (Ar, Kr, Xe) with molecules of organic liquids (acetone, methylene, dichloride, chloroform, carbon tetrachloride) were first obtained by Waller[97]. With ideal filling of all the cavities of structure (II) these hydrates can be characterised by the general formula $A.2B.17H_2O$, where A is the organic component and B the inert gas.

Table 19.

Gas	Temperature, °C, at which P_{diss} of the mixed hydrate equals 1 atm			
	organic liquid			
	acetone	methylene dichloride	chloroform	carbon tetrachloride
Ar	−8.0	−7.0	− 4.8	− 1.6
Kr	−5.0	+6.2	+ 9.0	+11.3
Xe	+3.0	+8.6	+10.9	+13.7

As was shown by Waller, argon forms hydrates of the above type at pressures of 200–400 atm, krypton at $P \simeq$ 30 atm, and xenon at $P \simeq 1$ atm. Table 19 shows the relative stability of the $A.2B.17H_2O$ hydrates.

From Table 19, xenon gives the most stable hydrates with organic solvents. These hydrates could be obtained by simply bubbling the moist gas through the organic liquid at $P = 1$ atm and $t \sim 0$°C. Waller also states that O_2 forms mixed hydrates with acetone and N_2 with acetone and carbon tetrachloride.

Mixed Hydrates Formed by Organic Liquids

Binary hydrates A.B.17H_2O, where A and B are organic liquids (for example, A = C_2H_5Cl, B = CH_3CHCl_2, or A = C_2H_5Cl, B = $CHCl_3$ were studied by Stackelberg and Meinhold[11].

A large group of mixed (binary) hydrates formed by chloroform (or methyl iodide) with such gases as H_2, Ne, N_2, Ar, O_2, CH_4, Kr, Xe, C_2H_4, C_2H_6, and CO_2 was studied by Barrer and Ružicka[64] and is of considerable interest. Barrer and Ružicka showed that even such gases as hydrogen and neon, which themselves are incapable of hydrate formation, are retained by the small cavities of structure (II) in quantities appreciably greater (34 times for H_2 and 220 times for Ne) than in the ordinary physical dissolution of H_2 and Ne in liquid water at 0°C.

Hydrates of Multicomponent Gas Mixtures

Natural Gas

The first systematic study of the conditions of formation of hydrates was made by Hammerschmidt[4], who showed that the so-called "freezing" of gas pipes, in which natural gas is present at high ($P \gg 1$ atm) pressures and temperature $\simeq$ 0°C, is connected with the formation of solid crystalline hydrate "plugs". The natural gas investigated by Hammerschmidt had the composition (vol.%): CH_4 82.5, C_2H_6 5.99, C_3H_8 3.26, n-C_4H_{10} 0.49, iso-C_4H_{10} 0.30, CO_2 0.20, C_5 0.07, N_2 (residue) 7.19.

On the basis of their treatment of the experimental P–t values they obtained the relation: $y = 8.9(x)^{0.285}$, where y is in °F and x in lbf dm^{-2}.

In the same work, as stated above, the general premises of the hydrate formation process (thermodynamic, hydrodynamic, etc.) were examined. After the appearance of Hammerschmidt's work, which in application to natural gas can be considered classical, a large number of papers were published by foreign and Russian investigators devoted to various aspects of hydrate formation in natural gas. Carson and Katz[73] [? wrong ref. (Ed. of Translation)] studied the relation between the conditions of formation of hydrates of natural gas and its density (actual composition). They showed that an increase in the concentration of the C_2 and C_3 hydrocarbons in the natural gas appreciably raises (at constant pressure) the temperature of hydrate formation or lowers the pressure of hydrate formation (at t = const). The same problem was dealt with in a paper by Katz[110] who had studied various specimens of natural gas, the density of which varied between broad limits (from 0.55 to 1.0). Fig. 9 shows the influence of the density of natural gas on the equilibrium P–t values.

The presence in the natural gas of the impurities N_2, CO_2, and H_2S appreciably raises the temperature of hydrate formation (Fig. 10 shows the effect of N_2).

The presence of H_2S is especially effective on the equilibrium P–t values, as was shown by Molinero[111].

Campbell and McLeod[71] studied the conditions of formation of hydrates of natural gas at high pressures (up to 700 atm). Among the Russian investigations devoted to the hydrates of natural gas, the series of papers by Trebin and Makogon stand in the forefront[112–117].

Of this series of papers the investigation dealing with the problem of the formation and decomposition of hydrates of natural gas at negative temperatures[115] is of considerable interest. Trebin and Makogon showed that at the time of decomposition of the hydrate at $t < 0$°C (by reducing the pressure) there is a rearrangement of the crystal lattice of the hydrate into the ice lattice according to the scheme: hydrate → water → ice.

On passage of the hydrate from the region of positive into that of negative temperatures, the rearrangement of the hydrate lattice does not take place. In the above papers detailed consideration is given to the methods of calculation and application of appropriate nomograms which allow the conditions and place of formation of hydrates in pipelines to be determined.

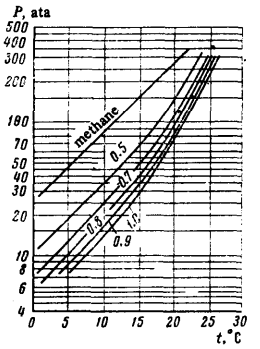

Figure 9. Conditions of hydrate formation for natural gases of various densities relative to air.

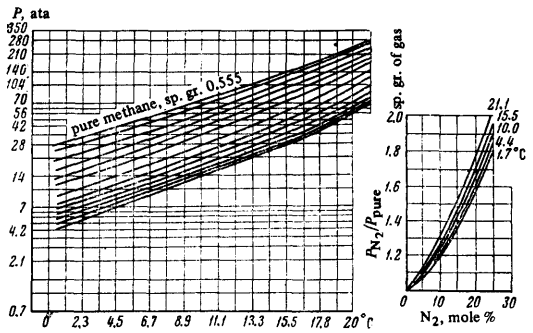

Figure 10. Conditions of hydrate formation in the presence of nitrogen in natural gas. Density of gas (from top to bottom): *1*) pure methane 0.555; *2*) 0.56; *3*) 0.57; *4*) 0.58; *5*) 0.59; *6*) 0.60; *7*) 0.62; *8*) 0.64; *9*) 0.66; *10*) 0.68; *11*) 0.70; *12*) 0.80; *13*) 0.90.

The influence of stabilising gases was considered simultaneously[115].

Ponomarev's studies[118,119] examined the problem of the formation of hydrates of natural gas of different composition, and also commercial gases containing a relatively large proportion of propane. For natural gas, Ponomarev obtained numerical values of the constants K and B in equations of the type $t = K \lg P - B$ where t and P are respectively the temperature and pressure of hydrate formation.

Khoroshilov[120–122] gives methods of calculating the equilibrium parameters of hydrate formation for natural gas.

Liquefied Hydrocarbon Gases

Hydrate formation in mixtures of liquid hydrocarbon gases (C_3H_8 + n-C_4H_{10}) has been considered by Musaev[123-125].

The same author investigated the hydrate formed by the liquid products of the thermal treatment of petroleum, having the following fractional composition (wt.%) C_2 4.3, C_3 16.9, iso-C_4 8.2, n-C_4 18, iso-C_5 18.4, n-C_5 17.0, C_6 17.3. Musaev's conclusions concerning the influence of n-C_4H_{10} on hydrate formation in C_3H_8 + n-C_4H_{10} mixture and also the influence of the rate of cooling on the temperature of formation of the hydrate of liquid propane are interesting. According to Musaev, n-C_4H_{10} does not participate in the hydrate formation.

Hydrocarbon Mixtures Formed in the Pyrolysis of Petroleum Products

The conditions of formation of hydrates of pyrogas were studied by Byk[126]. The material selected for investigation was an industrial gas from the pyrolysis of benzines of the following composition (vol.%): H_2 14.8, CH_4 45.1, C_2H_4 21.9, C_2H_6 10.0, C_3H_6 5.3, C_3H_8 0.9, ΣC_4, C_5 5.0. For two pressure ranges (20–35 and 35–50 atm) empirical equations connecting the temperature of hydrate formation (°C) and the corresponding equilibrium pressure (atm) were obtained: (1) $t = 0.27P + 2.4$, and (2) $t = 0.105 P + 8.5$.

IX. CALCULATION OF THE CONDITIONS OF HYDRATE FORMATION AND OF THE COMPOSITIONS OF THE SOLID (HYDRATE) AND GAS PHASES

As already stated above, mixed hydrates formed by binary and multicomponent mixtures are now considered to be solid solutions, the composition of which varies during the decomposition of the hydrate. On the basis of the analogy between the solid and liquid solutions (from the standpoint of the gas or vapour phase found in equilibrium with them) Wilcox and coworkers[79] proposed a method of calculating the conditions for the formation of hydrates from gas mixtures. The method is based on the use of numerical values of the "equilibrium constant" $K_{v/s} = y_i/x_i$ where y_i is the mole fraction of component i in the gas (vapour) phase, and x_i the mole fraction of the same component in the solid hydrate phase. The value of $K_{v/s}$, just as for liquid solutions, depends on the temperature, pressure, and composition of the mixture. The conditions of formation of a mixed hydrate from an i-component gas mixture is determined by the equality:

$$\sum_{i=1}^{i=n} \frac{y_i}{K_{v/s}} = \sum_{i=1}^{i=n} x_i = 1.$$

Hence when the nature of the dependence $K = f(t, P)$ is known for all the components of a gas mixture (the authors considered natural gas), then by carrying out the simplest linear interpolation the temperature at which the condition $\sum_{i=1}^{i=n} x_i = 1$ is observed for a given pressure can be determined (or, on the other hand, for a specified temperature the corresponding equilibrium pressure can be calculated).

This method was developed further in a series of later papers by Carson and Katz[107,127,128], who constructed $K_{v/s} = f(P)$ and $K_{v/s} = f(t)$ diagrams for the individual components of natural gas: methane, ethane, propane, and isobutane. In constructing such diagrams naturally it is necessary to locate experimental data on the compositions of coexisting solid (hydrate) and gas phases.

These results were taken from Hammerschmidt's work[4] (gas phase: natural gas at a pressure of 41 atm, Table 20) and from the publications of Deaton and Frost[83], who studied the compositions of the coexisting phases in the systems: (1) $CH_4 + C_2H_6$, (2) $CH_4 + C_3H_8$, and (3) CH_4 + iso-C_4H_{10}. For natural gas containing hydrogen sulphide and carbon dioxide as impurities in order to carry out calculations by the method of Wilcox and coworkers it is necessary to allow for the values of $K_{v/s}$ for H_2S and CO_2.

Table 20.

Component	Composition of gas phase, vol. %	Composition of hydrate, vol. %
CH_4	82.5	56.95
C_2H_6	5.99	5.66
C_3H_8	3.26	24.97
iso-C_4H_{10}	0.30	4.69
n-C_4H_{10}	0.49	0.83
C_5H_{12}	0.07	0.00
CO_2	0.20	0.44
N_2	7.19	0.46

The nature of the dependence $K_{v/s} = f(P, t)$ for these two gases was investigated by Noaker and Katz[106] (H_2S + CH_4 system) and by Unruch and Katz[91] (CO_2 + CH_4 system). A handbook[65] edited by Katz gives $K = f(P, t)$ diagrams for CH_4, C_2H_6, C_3H_8, iso-C_4H_{10}, CO_2, and H_2S.

It should be noted that on all these diagrams the maximal pressure is ~ 280 atm. Consequently the conditions of hydrate formation for mixtures of the natural gas type can be calculated by the method of Wilcox and coworkers only at $P_{dis} \leq 280$ atm.

In this connection the work of McLeod and Campbell[71] is interesting; they proposed a method for calculating the temperature of hydrate formation of natural gas in the pressure range 400–680 atm.

The authors, using a modernised form of the Clausius–Clapeyron equation $d \ln P/dT = m$, obtained in the general form the equation $C = mT^2$, where $C = \Delta H/zR$.

Having found that in C_1–C_4 alkane mixtures (not containing n-C_4H_{10}) in the pressure range 400–680 atm, m = const = 0.066, McLeod and Campbell obtained the formula $C = 0.066T^2$, in which the temperature is expressed in degrees Rankine.

To calculate the hydrate formation temperature the value of C for the specified pressure must be found by using the additivity rule ($\sum_{i=1}^{i=n} C_i = C$). Naturally, in making such calculations it is necessary to know the value of C for each hydrocarbon at various pressures. These values were obtained by McLeod and Campbell experimentally for methane ethane, propane, and isobutane and given in the form of Tables[7].

It should be noted that the number of papers in which the information given about the composition of the coexisting solid (hydrate) and gas phases was found directly by experiment is comparatively small.

Apart from those mentioned above, they include:

1. An investigation by Otto and Robinson[108], who determined the compositions of the equilibrium phases in the

$CH_4 + C_3H_8$ system in the temperature range from 0°to21°C and pressures from 7 to 204 atm.

2. An investigation of the compositions of the coexisting phases in the system $CH_4 + C_2H_4$ made at temperatures from 0° to 29°C and pressures from 6.8 to 612 atm by Snell and coworkers[78].

3. Equilibrium compositions in the $C_3H_8 + C_3H_8$ system‡, determined at 0.3°C by Fomina and Byk[129] and presented as a P–X diagram in Fig. 11.

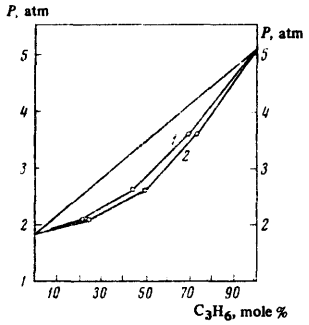

Figure 11. P–X isothermal equilibrium diagram for the C_3H_6–C_3H_8–H_2O system.
1) Hydrate; *2*) gas.

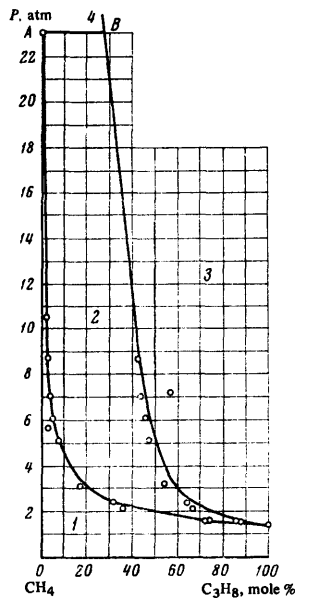

Figure 12. P–X isothermal equilibrium diagram for the C_3H_8–CH_4–H_2O diagram.
1) Gas-ice; *2*) hydrate-gas-ice; *3*) hydrate-ice; *4*) hydrate$_I$–hydrate$_{II}$-ice.

‡ The first attempts to determine the compositons of the equilibrium phases in the $C_3H_6 + C_3H_8$ system was made by Reamer[76] but the relative volatilities (α) found were almost equal to 1.

4. The same authors[130] determined, at 0.65° and 1.2°C, the compositions of the coexisting phases in two systems containing 2-methylpropene:

(a) $C_3H_8 + i\text{-}C_4H_{10} + i\text{-}C_4H_8$;

(b) $C_3H_8 + i\text{-}C_4H_{10} + i\text{-}C_4H_8 + C_3H_6$.

During the investigations a mixed hydrate was obtained which contained up to 82.5 vol.% 2-methylpropene and by extrapolation for the temperature range 0.66–1.2°C the equation $\lg P = 27.9298 - 7629/T$ was found, where P is the dissociation pressure of the hypothetical hydrate of pure 2-methylpropene.

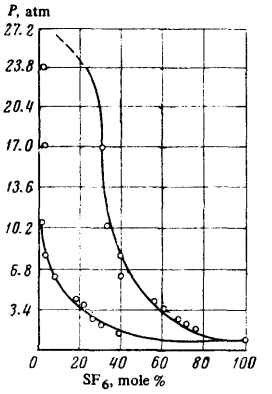

Figure 14. P–X isothermal equilibrium diagram for the CH_4–CF_6–H_2O system.
Continuous curves: experimental; points: calculated.

5. The isothermal "hydrate–gas phase" equilibrium ($t = -3$°C) in the $CH_4 + C_3H_8$ and $C_3H_8 + H_2S$ systems, including the determination was investigated by van der Waals and Platteeuw[28,29]; this involved the determination of the compositions of the coexisting phases. Figs. 12 and 13 give their P–X equilibrium diagrams they obtained. In the $C_3H_8 + H_2S$ system they observed an interesting phenomenon, analogous to anisotropy in liquid solutions: at $t = -3$°C and $P_{diss} = 0.48$ atm the compositions of the hydrate and gas phases agree (~ 75 mole % H_2S).

Hence the constancy of the value of P_{diss} for this hydrate observed by Stackelberg and Frühbuss[12] is connected with the existence of an azeotrope.

6. Ichaveri and Robinson[109] studied the compositions of the coexisting gas and hydrate phases in the $CH_4 + N_2$ system at −0.1° and 6.6°C.

In this system methane is the less volatile component ($K_{v/s} < 1$).

The compositions of the equilibrium gas and hydrate phases in the $CH_4 + SF_6$ system were studied at $t = -3$°C over the whole concentration range and pressures from 0.72 to 23.2 atm by Sortland and Robinson[36]. Fig. 14 shows their experimental results as a $P-X$ diagram.

X. USE OF THE PRINCIPLES OF STATISTICAL MECHANICS IN STUDYING GAS HYDRATES

The possibility of using the principles of statistical mechanics in studying solid non-stoichiometric clathrates, and consequently, hydrates, was shown in the studies[22-28] of Barrer, and of van der Waals (grandson) and Platteeuw. This subject is covered most fully in the monograph of the last two authors[28].

By applying the methods of statistical mechanics to a three-dimensional Langmuir model for the ideally localised adsorption of spherical molecules in the cavities of a clathrate (hydrate) lattice and by considering the hydrate phase as a solid solution obeying Raoult's law, van der Waals and Platteeuw obtained equations which allow several fundamental (principally thermodynamic) properties of gas hydrates to be calculated (dissociation pressure of the hydrates at various temperatures, their heats of formation, the compositions of the coexisting equilibrium phases, etc.). The main equations of van der Waals and Platteeuw are:

$$\text{(I)}\ \Delta\mu = kT\Sigma\nu_i \ln(1 + \Sigma C_{K_i} f_K),$$

$$\text{(II)}\ y_{K_i} = C_{K_i} f_K/(1 + \Sigma C_{K_i} f_K),$$

where $\Delta\mu = \mu^\beta - \mu^\alpha$ is the difference in chemical potentials of the empty crystal lattice of the hydrate (μ^β) and stable ice (μ^α), f_K is the fugacity of the adsorbed substance (K); v_i, the crystallographic constant of the cavities of the hydrate lattice with radius a_i, characterises the number of molecules of K per molecule of water. For structure (I), $\nu_1 = \frac{1}{23}$ and $\nu_2 = \frac{3}{23}$. For structure (II), $\nu_1 = \frac{2}{17}$ and $\nu_2 = \frac{1}{17}$. y_{Ki} is the probability of finding a molecule of gas K in a cavity of a hydrate lattice of type i, and C_{Ki} is the Langmuir constant for molecules of K in cavities i.

$$\text{(III)}\ C_{K_i} = \frac{4\pi}{kT}\int \exp[-\omega(r)/kT]\, r^2\, dr.$$

Here $\omega(r)$ is the spherical symmetrical potential of molecule K at distance r from its centre to the wall of the cavity. In the general form for a characteristic of the interaction between the cavity walls and the molecule K the authors employed the Lennard-Jones–Devonshire (12–6) potential:

$$\{\omega(r) = 4\varepsilon\{(\sigma/R)^{12} - (\sigma/R)^6\}.$$

On the basis of Eqns. (I), (II), and (III) given above, van der Waals and Platteeuw[28] calculated the dissociation pressure of a series of hydrates at 0°C (Table 21).

As Table 21 shows, good agreement between experimental and calculated values of P_{diss} is observed for hydrates of Kr and Xe (monatomic molecules) and to a lesser extent for almost spherical molecules (C_2H_4, C_2H_6).

The fundamental equations (I), (II), and (III) given above allow the composition of a solid hydrate phase in equilibrium with a gas phase to be calculated. Such calculations were made by van der Waals and Platteeuw[28,29] for the systems $CH_4 + C_3H_8 + H_2O$ and $C_3H_8 + H_2S + H_2O$ with the aid of the equations:

$$\text{(a)}\ y_{A_1} = C_{A_1} P_A/(1 + C_{A_1} P_A);\quad y_{A_2} = C_{A_2} P_A/(1 + C_{A_2} P_A),$$

$$\text{(b)}\ \nu_1 \ln(1 - y_{A_1}) + \nu_2 \ln(1 - y_{A_2}) = \frac{-\Delta\mu}{kT},$$

$$\text{(c)}\ Y_A = \nu_1 y_{A_1} + \nu_2 y_{A_2},$$

Table 21.

Hydrate-forming substance	P_{diss} at 0°C, atm	
	expt.	calc.
Ar	95.5*	95.5*
Kr	14.5	15.4
Xe	1.15	1.0
CH_4	26	19
CF_4	1	1.6
C_3H_8	5.2	1.1
C_2H_4	5.44	0.5

* The experimental value of P_{diss} for argon hydrate was used in the calculation. The constant thus found was used to calculate P_{diss} for the remaining hydrates.

where y_{A_1} is the fraction of small cavities of the hydrate lattice filled with molecules of A, y_{A_2} the fraction of large vacancies of the hydrate lattice filled with molecules of A, P_A the partial pressure of component A in the equilibrium gas phase, C_{A_1} the Langmuir constant of component A for when it fills the small vacancies, C_{A_2} that for when it fills the large vacancies, and Y_A the concentration of component A in the equilibrium hydrate.

As the authors showed, for a mixed hydrate of structure (I) $\Delta\mu = 0.167$ kcal mole^{-1} (Br_2 hydrate model). For a hydrate of structure (II), $\Delta\mu = 0.196$ kcal mole^{-1} SF_6 hydrate model). The results of the calculations for $t = -3$°C showed good agreement with experimental results, as is clear from the $P-X$ diagrams for the two systems (Figs. 12 and 13).

A theory of solid hydrate solutions using the principles of statistical mechanics has obtained its furthest development in the studies of Saito and coworkers[32,34], who somewhat modified the equations of van der Waals and Platteeuw[28] and proposed a method of calculating several properties of gas hydrates at temperatures above the lower quadruple point (in practice at $t > 0$°C). The objects of their investigations were the hydrates of methane, argon, and nitrogen, and also mixed hydrates in the $CH_4 + Ar + H_2O$ and $Ar + N_2 + H_2O$ systems. P_{diss} for the individual hydrates of CH_4, Ar, and N_2 were calculated as functions of temperature and pressure up to 3000 atm and agree well with the experimental results, the heats of formation of the hydrates, and also the number of water molecules (n).

In finding the nature of the $n = f(P)$ dependence, Saito and coworkers[32] showed that for the hydrates of Ar and N_2 complete filling of the small and large cavities of the hydrate lattice ($n = 5.75$) is attained only at very high equilibrium pressures, of the order of 3400 atm. For $CH_4 \cdot nH_2O$ complete filling is attained at $P = 1300$ atm. Their calculated values of the heats of formation of these (Ar, N_2, and CH_4) hydrates agreed well with the values obtained from $P-t$ results with the aid of the Clausius–Clapeyron equation. Saito and Kobayashi[34] calculated for $CH_4 + Ar$ and $Ar + N_2$ mixtures the conditions of hydrate formation over a wide range of temperature and pressures, which also

agreed well with those they obtained experimentally. The same authors calculated the composition of a mixed argon–methane hydrate which coexists in equilibrium with the gas phase at the temperatures 4.4°, 10.0°, 15.5°, and 21°C.

All the above-mentioned calculations of the properties of hydrates were based on the use of the Lennard-Jones–Devonshire potential, which is known not to take into consideration the form and size of the gas molecules. The first successful attempt to calculate P_{diss} of hydrates by use of the values of the Kihara potential, the value of which, in principle, depends on the form and size of the interacting molecules, was made by McLeod and McKoy and Sinanoglu[33]. The authors calculated P_{diss} for a series of hydrates by using the Lennard-Jones (28–7) potential, the Lennard-Jones (12–6) potential, and the Kihara potential. They showed that the least satisfactory agreement with the experimental results is given by using the Lennard-Jones (28–7) potential. As might be expected, the (12–6) potential gives satisfactory results for molecules of monatomic gases and CH_4 but is not very satisfactory for the molecules C_2H_6, CO_2, N_2, O_2, C_2H_4. Furthermore, the use of the Kihara potential allows sufficiently good agreement with experimental values of P_{diss} to be obtained for the above rod-shaped molecules. The Kihara potential found further use in Nagata and Kobayashi's work[35,37]. In the first of these papers, on the $CH_4 + N_2$ binary system, the hydrate formation pressure was calculated for a mixture with 55% CH_4 and also the compositions of the coexisting hydrate and gas phases in equilibrium at −0.1° and 6.6°C. Satisfactory agreement was shown with experimental P–X data published earlier[109]. In the second paper the authors calculated P_{diss} for the mixed hydrates formed in the $CH_4 + C_2H_6$ and $CH_4 + C_3H_8$ systems, using only the constants given in the literature which characterise the individual hydrates of CH_4, C_2H_6, and C_3H_8. Their results also agree well with the experimental data.

Use of statistical mechanical methods allowed Barrer and Stuart[23] and then Barrer and Ružicka[64], to make quantitative evaluations of the stabilising influence of an auxiliary gas on the hydrate formation temperature. Their approximate calculations for the mixed hydrate formed by chloroform and nitrogen showed that when the N_2 is in the small cavities of structure (II) and partly in the large cavities, then $\Delta\mu = \mu^{\beta} - \mu^{\alpha} = -115.2$ kcal mole^{-1}. In the absence of nitrogen the value is −112 kcal mole^{-1} and consequently the difference is 3.2 kcal mole^{-1} and is due to the effect of the rise in the $CHCl_3$ hydrate formation temperature in the presence of nitrogen.

XI. PHYSICAL KINETICS OF THE FORMATION OF HYDRATES

The problem of the dependence of the rate of formation of gas hydrates on various factors in one form or another is treated in many papers devoted to the determination of their formation conditions. They include the investigations of Hammerschmidt[4], Ceccoti[55], Tesner and co-workers[131], Musaev[125], etc. Indications of the promoting action of certain additions (which by themselves do not enter into the composition of the hydrate) are contained in the work of van der Waals and Platteeuw[28] and also van Cleef and Diepen[31]. We know of only five studies specially devoted to the physical kinetics of hydrate formation, and with the exception of one[132] which examined the kinetics of hydrate formation, they all deal solely with the hydrates of organic liquids, and the conclusions drawn in these papers cannot, according to the authors's own statements, be extended to purely gas hydrates. Pinder[100] studied the dependence of the rate of formation of tetrahydrofuran hydrate $[CH_2]_4O.17H_2O$ on the processes of mutual diffusion of the two complexes with a hydrogen bond which exist in the initial solution. Keneth and Pinder[133] investigated the rheological properties of the hydrate system of tetrahydrofuran + hydrogen sulphide. The hydrate they investigated exhibits high stability (at $P = 1$ atm, $THF.2H_2S.17H_2O$ is destroyed at $t > 21$°C). They also studied the viscosity of hydrate *slush* at a function of time, rate of growth of individual crystals, etc.

Saito and Sadanaga[134] studied the process of formation of the hydrate of dichloromonofluoromethane ($CHCl_2F.17H_2O$) and obtained a series of empirical equations connecting the rate of formation of crystalline hydrate nuclei with the degree of supercooling of the solution and the number of revolutions of the stirrer.

The most fundamental investigation on the physical kinetics of the hydrate formation process is, perhaps, the work by Barrer and Ružicka[135]. They measured the rate of formation of binary hydrates produced by chloriform or THF with Ar, Kr, Xe, and CH_4, at various temperatures (−78° and ~ 0°C).

Their method of investigation (measurements of the quantity of gas absorbed after definite intervals of time) allowed them to obtain at constant P, t a series of single-valued curves (almost straight lines) which characterise the rate of formation of the hydrates mentioned above. With the binary hydrate of THF + argon as example, these authors also examined in detail the factors which determine the growth of the crystallisation nuclei in the formation of the hydrate.

XII. DENSITY OF HYDRATE CRYSTALS

The density of the crystals of the hydrates was first measured by Stackelberg[7,11] for the following organic compounds (Table 22).

Table 22.

Hydrate	Density, g cm^{-3}
SO_2	1.23
$CHCl_3$	1.11
C_2H_5Cl	<1.0
$CCl_4 + H_2S$	1.272±0.01
$CHCl_3 + H_2S$	1.216±0.01
Cl_2*	1.29±0.1

* Calculated from the slope of the curve (dT/dP).

Precision measurements of the density of hydrate crystals were made by Saito and Sadanaga[136]. In a specially equipped room with a temperature of 0°C they used a float method to measure the density of hydrates of propane and also of several chlorofluoro-derivatives of methane (CHF_2Cl, $CHFCl_2$, CF_2Cl_2, and $CFCl_3$).

From propane hydrate, $d = 0.88$ g cm^{-3}; for the hydrates of the above chlorofluoromethanes, the density lay within the limits 1.04–1.24 g cm^{-3}.

Saito and Sadanaga also proposed formulae for calculating the density of hydrates of structures (I) and (II):

$$d_I = \frac{(46\,H_2O + 6\,M\cdot\alpha_1)\,1/N}{a^3}; \quad d_{II} = \frac{(136\,H_2O + M\cdot\alpha_2)\,1/N}{a^3}$$

where M is the molecular weight of the hydrate-forming substance, α_1 and α_2 are the degree of filling of the cavities in the crystal lattice of the hydrate ($1 \geqslant \alpha > 0$), N is Avogadro's number, and a the crystal lattice parameter of the hydrate, Å. They found good agreement between experimental and calculated values of the density of the hydrates mentioned.

Van Cleef and Diepen[31] give the values of the densities they found for the hydrates of oxygen ($d = 1.03 \pm 0.02$ g cm^{-3}) and nitrogen ($d = 1.02 \pm 0.02$ g cm^{-3}).

XIII. INDUSTRIAL USE OF GAS HYDRATES

1. DESALINATION OF SEA WATER

A process first proposed by Donath[137] for the desalination of sea water is based on the use of hydrocarbon hydrates (of ethane, propane, and isobutane), and also of hydrates formed by halogen derivatives of methane, mainly the Freons and certain other gases (Cl_2).

The paper by Kuoch and coworkers[138] gives the principles of the method in greatest detail, and also the technological scheme of the process, based on the formation and subsequent decomposition of propane hydrate.

According to the scheme given, the hydrate ($C_3H_8.17H_2O$) is made in a special reactor at 1.1°C and a pressure of 3.9 atm. In a second reactor, into which the hydrate mud is brought by means of a conveyor belt, the hydrate is decomposed at 7.2°C and 4.7 atm, with the liberation of pure distilled water (the salt dissolved in sea water is known not to permeate the hydrate lattice). In this way, 40% of the sea water put into the first reactor was desalinated.

The process for the desalination of sea water with the aid of hydrates is covered by a series of foreign patents[139,140] and also by papers of Caryofcky[141], Barduhn[142], and Medvedev[143].

2. USE OF HYDRATES FOR THE STORAGE OF GASES

The storage of natural gas as hydrates is considered in several patents and publications[48,49,144]. Mock[145] has proposed an interesting method for the storage of inert gases (Ar, Kr, Xe).

3. SEPARATION OF GASEOUS AND LIQUID MIXTURES WITH THE AID OF HYDRATES

The separation of these mixtures with the aid of hydrates has been considered in detail in a paper by Barrer and Ružicka[64] which gives the principles of the method and considers some specific separable gaseous and liquid mixtures ($O_2 + N_2$, Kr + Ar, Xe + Kr, $CH_3I + CHCl_3$, $C_6H_5CH_3 + CHCl_3$, $C_6H_6 + CHCl_3$, $CH_2Cl_2 + CHCl_3$). These problems are also covered in the patent literature. Thus, Crowther[146] proposed a method of separating the gaseous mixture $CH_4 + C_2H_6$. Glew's patent[147] deals with the separation by hydrate formation of the liquid hydrocarbon mixture $C_3H_6 + C_3H_8$. Kinney and Kahre[148] proposed a method of separating helium from natural gas. The patent proposes that in the last stage of the process an N_2 + He mixture is separated by adding propane, which forms a mixed hydrate with the nitrogen. Byk and Fomina's patent[149] covers the separation of the gaseous mixtures n-C_4H_{10} + iso-C_4H_{10}, and $C_3H_6 + C_3H_8$.

XIV. PREVENTION OF HYDRATE FORMATION

Methods for preventing hydrate formation derive directly from the equilibrium conditions for their existence given above (P_{gas}, P_{H_2O}, and t°C): (1) raising the temperature in the system where a hydrate has already formed or can be formed; (2) reducing the pressure of the hydrate-forming gas; (3) reducing the concentration of water in the gas by drying it or by using special inhibitors which lower the partial pressure of water vapour in the system.

Detailed consideration of all the methods for preventing hydrate formation has been given in the extensive Russian and foreign literature on the subject, dealing mainly with the problems of the drying of gases[150-155] and the use of various inhibitors[117,156-174].

Measures against hydrate formation are considered in the Russian monographs by Sarkis'yants and Makagon[175,176], and also in Frost and Deaton's monograph[5].

The theoretical principles of the inhibition of hydrate formation, which are of independent interest, and also the specific possibility of using individual inhibitors (methanol, ethanol, isopropyl alcohol, glycine solutions, propanol, aqueous solutions of $CaCl_2$, NaCl, LiCl, $AlCl_3$, NH_3, etc.) have been considered[177-180].

The most complete theory of the inhibiting action of a "third" component has been given by Pieroen[180], who by using the concepts of the chemical potentials of the components, participating in the hydrate formation, and of the "activities" of the aqueous solutions obtained the equation

$$\Delta T = -\frac{nRT_0^2}{\Delta H} X_{t.c.},$$

in which ΔH is the heat of formation of one mole of hydrate containing n moles water at T_0; $\Delta T = T_0 - T$; T_0 is the equilibrium temperature (°K) of formation of the hydrate in the absence of inhibitor; T that in the presence of the inhibitor; and $X_{t.c.}$ the mole fraction of the inhibiting third component in the water. For the natural gas–water system, the above equation acquires the form:

$$\Delta T = \frac{nRT_0^2}{\Delta H} \frac{18\omega}{(100-\omega)M} (1 - X_{t.c.}),$$

since $X_{t.c.} \ll 1$, then

$$\Delta T \sim \frac{nRT_0^2}{\Delta H} \frac{18\omega}{(100-\omega)M},$$

where w is the inhibitor concentration (wt.%) in the water, M the molecular weight of the inhibitor at $T = 280$°K, and $\Delta H \simeq -41$ kcal mole^{-1}, so that

$$\Delta T \sim 1240 \frac{\omega}{M(100-\omega)}.$$

Earlier[178], Hammerschmidt obtained an analogous formula with the numerical coefficient equal to 1297 for inhibiting aqueous solutions of electrolytes.

Synthesis of Technical Tanning Agents

Ya.P.Berkman

The review gives data mainly on Soviet investigations on the preparation and application of synthetic tanning agents, comprising auxiliary syntans and substitutes for vegetable tannins. A detailed account is given of the processes used in the synthesis of Soviet heavy-duty syntans and some information on the production of substitute syntans abroad. The bibliography contains 83 references.

I. INTRODUCTION

Since the earliest times tanning agents, found in the bark, wood, leaves, and roots of various plants, have been used for the production of leather. The structure of these substances, which are known generally as "tannins", was elucidated as a result of the large amount of work done during the second half of the nineteenth century and the beginning of the twentieth century. All natural tanning agents are derivatives of polyhydric phenols, and are divided into two groups: the chief structural unit of hydrolysable tannins is digallic acid, which forms esters with hexoses; non-hydrolysable tannins are based on catechol units linked together either directly or through carbon atoms [1].

At the same time as the investigation of the structure of vegetable tannins, and directly connected with it, work was also done on the synthesis of tanning agents with the above main structural units as starting materials. Such syntheses were undertaken by Schiff, Baeyer, Fischer, Melau, and others, who by various methods obtained condensation products of arenepolyols and hydroxybenzoic acids.

The work of Schiff is of especial interest for the history of synthetic tanning agents. Having obtained digallic acid from gallic acid by the action of phosphoryl chloride, he applied this method to pyrogalloisulphonic acid and hydroxybenzenesulphonic acid [2], and assigned to the products the formulae

$$C_6H_2(OH)_3—SO_2—O—C_6H_2(OH)_2—SO_3H,$$
$$C_6H_4(OH)—SO_2—O—C_6H_4—SO_3H.$$

While differing from digallic acid in composition, these compounds showed some analogy with it in molecular structure: they contained phenolic rings linked by ester groups (-CO.O- or $-SO_2.O-$) and one of the rings contained an acidic group (-COOH or $-SO_3H$). Both compounds possessed tanning properties, and underwent all the reactions characteristic of vegetable tannins.

Schiff also obtained a tanning agent [3], probably hydroxyphenylsulphonylbenzenesulphonic acid

by dehydrating hydroxybenzenesulphonic acid at a high temperature.

These compounds obtained by Schiff must be regarded as direct precursors of modern synthetic tanning agents.

The history of modern industrial synthetic tanning agents, usually termed syntans (synthetic tannins), began in 1911, when Stiasny made a patent application covering the production of tanning materials by the condensation of hydroxybenzenesulphonic acids with formaldehyde [4,5]. Synthetic tanning agents have come a long way. More than a thousand patents have been issued on processes for their production, while the total number of brands manufactured in various countries reaches two hundred.

Synthetic tanning agents can be divided into two main groups—"light" and "heavy"—from the point of view of leather technology. Those of the first group possess weak

forming and filling power. They do not confer the required commercial properties on leather, but their use together with vegetable extracts or mineral salts has a substantial effect on the tanning process and on the properties of the leather. In conformity with this they are usually termed auxiliary.

Synthetic tanning agents of the second group approach vegetable tannins in their tanning action, and several of them even surpass the latter. Therefore the "heavy" syntans can replace vegetable extracts either completely or to a considerable extent. Hence the name substitute syntans.

Only very few synthetic tanning agents are individual compounds. Most of them are polydisperse mixtures of oligomers. Their tanning ability depends both on the chemical type and on the physicochemical characteristics of the product (degree of polycondensation, degree of dispersion). The range of possible variation in physicochemical characteristics differs in different chemical types, so that the range of technical properties with respect to leather (tanning action) which is possible for them also differs. From sulphonic acids of aromatic hydrocarbons, for example, only auxiliary tanning agents can be obtained, whereas hydroxybenzenesulphonic acids enable syntans to be prepared with any properties–from light auxiliaries to complete substitutes.

II. AUXILIARY SYNTANS

The group of auxiliary synthetic tanning agents was the first to appear, remained the only group for twenty years, and until now has been the most widely used in foreign countries.

Brands belonging to this group are used for two main purposes: (1) they are combined with vegetable extracts to improve the dissolution of the latter, accelerate tanning, lighten the leather, and protect the tanning solutions from fermentation and putrefying processes, the partial replacement of vegetable tannings being of second importance; and (2) they are combined with a mineral tannage (mainly chrome) to thicken the leather, enhance the plasticity of the fare side, bleach the skin, and prepare it for dyeing and finishing operations.

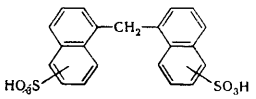
A. Auxiliary Syntans for Use with Vegetable Tanning Agents

This category was first realised in production as the synthetic tanning agent Neradol D, manufactured by the Badische Anilin- und Sodafabrik in conformity with Stiasny's patent. The idea underlying the process was that, in order to obtain an economically acceptable product, possessing the three main chemical and physicochemical characteristics of vegetable tannins–phenolic nature, a large molecule and solubility in water–the most accessible starting material was phenol and its homogues, the molecule was enlarged by condensation with formaldehyde, and solubility could be ensured by introducing a sulpho-group.

Neradol D was dihydroxydiphenylmethanedisulphonic acid. It precipitated gelatin from solution, and showed some resemblance to vegetable tannins in its qualitative reactions, but it differed sharply from them in its tanning power. It was not an analogue of vegetable tannins, but a representative of a new type of tanning material, giving a special kind of leather–light, smooth, and not compact–unsuitable for those purposes for which vegetable-tanned leather is used. Without being a complete substitute, Neradol D was, however, useful for combining with vegetable extracts: it lightened the leather, and prevented the formation of precipitates in the tanning solutions, which economised the consumption of tannins.

The industrial realisation of Stiasny's patent stimulated the development of analogous processes for obtaining tanning agents, and during the following years it was established that the presence of a hydroxy-group was not necessary for an aromatic sulphonic acid to exert a tanning action, this being possessed also by sulphonic acids of hydrocarbons and of certain heterocyclic compounds.

The first patent on syntans from hydrocarbons was issued[6] in 1916. The product was a mixture of naphthalene-1- and -2-sulphonic acids condensed with formaldehyde



and was named Neradol ND. The naphthalene syntan possessed poorer tanning power than the phenol syntan, but differed little from it in the effect achieved on being combined with vegetable extracts.

Neradol ND was succeeded by Ordoval, a product resulting from the sulphonation of mixtures of carbazole and anthracene, crude anthracene, or "anthracene residues".[7] This syntan, in contrast to the Neradols, possessed no brightening power, but in its tanning action even somewhat surpassed Neradol ND.

The absence of special advantages in the phenolic syntan and its relative dearness pushed it into the background.

The blockade of Germany during the First World War led to a shortage of tanning materials, and at first syntans were widely used to replace them. The large-scale application of syntans and the ignorance of their specific features and differences from natural tannins resulted in wholesale damage to leather, caused by the hydrolysis of collagen. The consequences of this were very unfavourable for syntans. By 1923 the manufacture of Neradols and Ordoval had fallen to a very low level. The use of artifical tanning materials as replacements for vegetable tannins almost ceased in the West for more than a decade[8].

During this period, in which interest in synthetic tanning agents dropped sharply in the West, the present Reviewer together with Kiprianov and Tolkachev began investigations in this field at the Ukrainian Institute of Applied Chemistry in Kharkov. At that time a large quantity of tanning extracts were imported into the USSR from abroad, and therefore even a partial replacement of vegetable by artificial tanning agents would have been of great economic value. In addition, the industrial manufacture then of new chemical products involved serious difficulties, and the contingency depended on the choice of raw material and the necessary equipment. The German commercial brands were soon identified and data were obtained which might serve as a control in our experiments[9].

Crude anthracene– a technical mixture of polycyclic aromatic hydrocarbons and heterocyclic compounds, which is precipitated from anthracene oil on cooling–was selected as the most accessible starting material. The composition of crude anthracene is variable: the solid part constitutes ~70%, and contains on the average 60% of phenanthrene, 20% of carbazole, and 15% of anthracene[10]. The first two components are of great value for the production of tanning materials. They are considerably more readily sulphonated, and give clearer solutions. Increasing the content of anthracene in the mixture makes it difficult to

obtain a product of satisfactory quality. Enriched anthracene must be regarded as, in general, unsuitable for the synthesis of tanning agents.

Crude anthracene was sulphonated with 150% of 92% sulphuric acid at 120°C for 5 h, with formation of a mixture of sulphonic acids of equivalent weight 210–220, which corresponds approximately to equal proportions of mono- and di-sulphonic acids. Sulphonation is accompanied by some resinification of the product with liberation of sulphur dioxide. The addition of a small amount of naphthalene helped to stabilise the solution [11]. Condensation of the sulphonated mass with formaldehyde, which is necessary with hydroxybenzene- and naphthalene-sulphonic acids, proved to be unnecessary, the sulphonic acids of tricyclic compounds exhibiting sufficient tanning action even without condensation. However, this process led to some improvement in the properties of the tanning agent, more rapid dyeing of the leather, and considerable lightening. The optimum effect was achieved with a small quantity of formaldehyde, 0.1–0.2 mole per mole of anthracene (compared with 0.5 mole of aldehyde per mole of phenol or naphthalene). In order to diminish the acidity the product was partly neutralised with sodium carbonate. In its final form it was a mixture of sulphonic acids, their sodium salts, and sodium sulphate.

The above process was put into practice at the Rubezhanskii Chemical Works with the production of two brands of tanning agents, AN (anthracene normal) and AK (anthracene condensed)†. They were widely used in the leather industry, especially the AN brand, which found application up to the end of the 1950s in the manufacture of sole leather.

In order to improve the colour of leather obtained by tanning with anthracene syntans, the sulphonated mass was oxidised with sodium hypochlorite, chlorine, and dichromate. Oxidation produced considerable clarification of the tanning solutions, but had little effect on the colour of the leather. However, provided that the sulphonated mass had first been condensed with formaldehyde, oxidation gave a very favourable effect [12]. Production of the tanning agent AKO (anthracene condensed, oxidised) involved the operations of sulphonation of crude anthracene, condensation with a small quantity of formaldehyde, neutralisation, crystallisation of sodium sulphate, making alkaline with caustic soda, oxidation with chlorine, and acidification with sulphuric acid. This tanning agent conferred a light, natural colour on the leather, but the complexity of the technique prevented its introduction into industry.

Oxidation with dichromate provided a considerably simpler method of obtaining the tanning agent. After condensation with formaldehyde the sulphonated mass was treated with a small quantity of water to lower the viscosity, and was three-quarters neutralised with sodium carbonate. The product was then oxidised with a concentrated solution of sodium dichromate, in amount such that all the remaining acid was neutralised by the bases formed on reduction of the dichromate [13]. The dry tanning agent comprised 30% of chromium sulphonate, 40% of sodium sulphonate, and 30% of sodium sulphate [14].

The tanning action of this syntan (Bestan AS) was considerably greater than that of the anthracene brands, since it was accomplished not only by the anion of the sulphonic acid but also by the chromic cation. The leather obtained was well formed and was stable to temperature. But the most valuable aspect was the safety in use of Bestan AS. In contrast to the anthracene brands, this tanning agent contained no free sulphonic acids. The acidity of its solutions was due solely to hydrolysis of the chromium salts. This kept the active acidity at a relatively low level, and conferred a buffer stability on the solutions, thereby preventing the possibility of hydrolysis of the collagen with weakening of the fibre [14].

Manufacture of Bestan was begun by the Rubezhanskii Chemical Works in 1930, and production soon reached several thousand tons per annum.

In 1934 the building was completed at Konstantinovka (Donets Region) of a factory for the manufacture of synthetic tanning agents. This works' range included five brands of syntans and an auxiliary type–Bestan AS, Bestan N (from naphthalene), the anthracenic AN and AK, and the naphthalenic NK–among which AK and Bestan AS were used for the accelerated tanning of Russia leather by a syntan–vegetable process, in which a considerable proportion of vegetable tannins had been replaced by synthetic tanning agents. The practical value of the brands AN and NK was determined mainly by their dispersing action on vegetable tannins. Their application to the manufacture of sole leather considerably improved the solubility of the vegetable extracts, stabilised the solutions [15], and accelerated the tanning process. Syntan NK has been widely used for this purpose up to the present time.

B. Auxiliary Syntans for Special Purposes

Other conditions for synthetic tanning agents arose in the West during the period following the First World War. As has already been stated, their use in Germany as substitutes for vegetable extracta almost completely ceased. However, specific features of these products maintained interest in their use for special purposes in the manufacture of both vegetable-tanned and chrome-tanned leather. As a consequence of this, new processes continued to be developed in the West for obtaining synthetic tanning agents. These processes were essentially variations on known methods. They can be divided into several groups: (*a*) the range of starting materials was expanded to naphthalene homologues, tetralin, benzylnaphthalene, naphthols, aromatic hydroxy-carboxylic acids, ethers of phenol with aliphatic alcohols, and esters thereof with aliphatic acids; (*b*) substituents–chloro-, nitro-, and amino-groups–were introduced into the aromatic rings; (*c*) various substances–acetaldehyde, paraldehyde, acetone, carbohydrates, sulphur, sulphur monochloride–were condensed with naphthalene- and hydroxybenzene-sulphonic acids; and (*d*) the sequence or the conditions of the operations–condensation under pressure, condensation at the instant of formation of the aldehyde (by passing acetylene into the sulphonated mass in the presence of a mercury salt), condensation of aromatic compounds by means of an aldo-group or an alcoholic group present in them, condensation before sulphonation, the introduction of substituents before or after sulphonation, the sulphonation of a compound containing an aldo-group or an alcoholic group and subsequent condensation with an unsulphonated compound–were varied.

These and similar modifications, described in European and American patents, are summarised in Bergmann and Grassmann's encyclopaedia of the leather industry [16]. It must be said that only a few of them were used industrially.

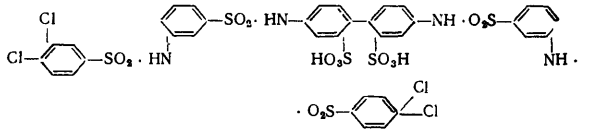
By contrast, in the manufacture of special-purpose auxiliary syntans based on hydroxybenzene- and naphthalene-sulphonic acids, various secondary procedures came into wide practical use, with the aim of improving the properties of the tanning agent, intensifying some particular

† The name "anthracene" is, of course, conventional indicating that the product has been obtained from crude anthracene.

feature in relation to a definite purpose, or increasing convenience in use. Among such procedures are removal of the inorganic portion, control of acidity, neutralisation with volatile bases (ashfree state), the addition of various salts (sodium chloride, sodium hydrogen sulphate, or potassium oxalato-aluminate, or -chromate, or -titanate) addition of organic acids (acetic, formic, oxalic, lactic), addition of preparations to prevent discoloration by iron ions (Trilon B)[17]. The differences between many brands of auxiliary syntans, even those manufactured at the present time, reduce to the use of particular supplementary procedures of the above type.

Special difficulties were presented by the synthesis of tanning agents which would make it possible to obtain a pure white leather fast to light, in particular a leather which would preserve its natural grain and colour (e.g. the leather of reptiles).

A great advance on these lines was represented by tanning agents proposed at the beginning of the 1930s, which contained several aromatic rings linked by sulphonamide groups[18]. It was found that the $-SO_2.NH-$ group, like a hydroxy-group in an aromatic ring, was a "tannophore", and a compound containing three or four such groups in the molecule possessed active tanning power. An industrial tanning agent of this type, manufactured in Germany by the firm IG. Farbenindustrie AG. under the brand name Tannigan LL, was identified and reproduced[19]. It was prepared from benzidine-2,2'-disulphonic acid by acylation with *m*-nitrobenzenesulphonyl chloride, followed by reduction of the nitro-group and further acylation with dichlorobenzenesulphonyl chloride, which yielded:



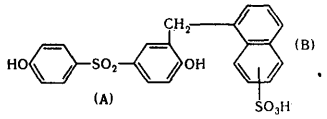
This syntan gave a white leather highly resistant to light, and also possessed considerably greater forming power than any other auxiliary tanning agent known at that time. It was also of theoretical interest, since it was the first individual, crystalline tanning agent. Brands of tanning agents of polysulphonamide type are still being manufactured in the Federal Republic of Germany.

Colourless syntans, stable to light and based on phenol, were also proposed, A peculiarity in their method of preparation was that the intercyclic methylene link formed by condensation with formaldehyde was replaced by other groups, such as $C(CH_3)_2$, $CH_2.NH.CO.NH.CH_2$, and SO_2. This resulted in a considerable diminution in the oxidisability of the condensation product compared with diphenylmethanediol, and on storage the leather preserved a light colour for a long time.

An isopropylidene link is formed by condensing the hydroxybenzenesulphonic acids with acetone[20], and a ureylenedimethylene link by simultaneous condensation with formaldehyde and urea[21] or by condensation with bishydroxymethylurea[22]. The use of urea to lighten leather was widely introduced into practice, and at the present time is often employed in the synthesis of tanning agents belonging to various chemical types.

Among the above variants, however, the use of aromatic hydroxy-compounds in which the rings were linked through a sulphonyl group acquired the greatest value, primarily bis-*p*-hydroxyphenol sulphone, which became one of the most important intermediates in the synthesis of tanning agents. Syntans based on bishydroxyphenyl sulphone are prepared in three ways–(*a*) sulphonation followed by condensation with an aldehyde[23], (*b*) simultaneous condensation with an aromatic sulphonic acid and formaldehyde[24], and (*c*) sulphomethylation and condensation with formaldehyde[25]–brands for white leather being produced mainly by the latter two methods.

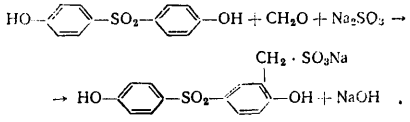
The purpose of simultaneous condensation of the sulphone with naphthalenesulphonic acid is to link the two molecules through a methylene group, with formation of a water-soluble product:



A and B condense in the various permutations so that the final product is a mixture of $A.CH_2.A$, $B.CH_2.B$, and $A.CH_2.B$, together with a certain amount of unchanged A and B. Reich[26], in an investigation of the analogous product of the simultaneous condensation of bis-*p*-hydroxyphenyl sulphone and 6-hydroxynaphthalene-2-sulphonic acid with formaldehyde, showed that only 50% of the sulphone gives a mixed condensation product, the remainder going into colloidal solution as a consequence of the protective action of the sulphonic acid.

Tanning agents of this type, obtained from pure starting materials (sulphone and naphthalene), yield a white leather having a plastic surface layer. The conditions for carrying out the synthesis were studied, and the dependence of the tanning action–the increase in the forming and filling power–on the relative proportions of sulphone and naphthalenesulphonic acid was established[27].

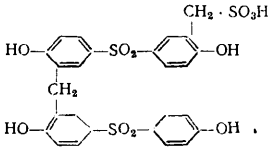
The method of sulphomethylating (or ω-sulphonating) a sulphone consists in the simultaneous condensation of the sulphone with formaldehyde and with sodium sulphite or a mixture of the sulphite and the hydrogen sulphite. This involves the introduction of a sulphomethyl group into the ring:



In the presence of excess of the aldehyde, ω-sulphonation is accompanied by condensation of the sulphone with the aldehyde[28].

As in the co-condensation of bishydroxyphenyl sulphones with naphthalenesulphonic acid and formaldehyde, sulphomethylation yields products which surpass the average of auxiliary syntans in their tanning action. The solubility of a product and its tanning action are greatly dependent on the relative proportions of sulphone, sulphite, and formaldehyde.

A detailed investigation of the condensation of bis-*p*-hydroxyphenyl sdulphone with formaldehyde[29] led to the isolation in crystalline form of an intermediate hydroxymethyl derivative, and it was shown that, with molar proportions of sulphone, sodium sulphite, and formaldehyde of 1.10 : 1.0 : 0.5, the chief product is a tetracyclic compound containing one sulphomethyl group[30]:



The advisability was also established[31] of conducting the process in two stages: (*a*) the sulphone was condensed with formaldehyde in the presence of small amounts of the sulphite as catalyst; and (*b*) sulphomethylation was effected with formaldehyde and the sulphite present in equimolecular quantities. This process was used for several [years?] to produce in an experimental plant Tanning Agent SB (Sulphone White), which was used by the works as a levelling agent in the dyeing of chrome leather in pale colours.

III. SYNTANS USED AS SUBSTITUTES FOR VEGETABLE TANNINS

A. Development of Methods for the Production of Substitute Syntans in the USSR

During the middle 1930s synthetic tanning agents of a novel type appeared in Germany under the name "Tannigans extra". Leather obtained by tanning with these syntans was closely similar to vegetable-tanned leather in physical properties and in yield by volume and weight. This permitted them to be used as complete substitutes for natural tanning materials.

The patent literature of those years revealed no fundamentally new methods for the synthesis of tanning agents, and the mode of production of Tannigans extra remained unknown, although papers in the periodical literature indicated that the new syntans were distinguished from the previous (auxiliary) syntans in starting materials, the functional groups responsible for their tanning action, and the active acidity of the solutions[32].

From this it must be supposed that the German Tannigans extra were weak acids: i.e. unlike the auxiliary syntans they could not be classed as aromatic sulphonic acids. This formed the starting point for the work of Konovalenko et al. on the preparation of a tanning agent free from sulpho-groups condensing resorcinol with acetaldehyde[33]. Their product, to which the name "Rezotan" was given, possessed good tanning power, but its industrial production was prevented by its high cost.

At the same time an investigation was being made at the Ukrainian Institute of Applied Chemistry into the possibility of obtaining substitute syntans of the sulphonic-acid type by varying the conditions under which the individual stages were conducted and varying the quantitative proportions of the reactants[34]. This work was based on an observation made in an attempt to increase the organic content in the anthracene brands by introducing a phenolic, Novolak resin into the sulphonated mass. It was supposed that excess of sulphuric acid present in the sulphonated mass, although at a low concentration, would be able to sulphonate a certain amount of the resin, with a consequent diminution in the organic content of the tanning agent, and an increase in the so called quality–the content of adsorbable material.

It was found that the resin was sulphonated to a very slight extent, but a homogeneous product, forming quite stable colloidal solutions, was obtained by stirring it with the sulphonated mass and heating[36]. By means of such dispersion it proved possible to bring into a soluble state up to 100% of resin based on the quantity of crude anthracene in the sulphonated mass. With increase in the quantity of resin the stability of the colloidal solution diminished: the quantity of resins which could be salted out by electrolytes increased. This was accompanied by increase in the volume yield and the tanning coefficient of the leather [(Table 1)]: i.e. its properties approached closer and closer to those of vegetable-tanned leather.

A similar result was obtained with naphthalenesulphonic acids condensed with formaldehyde. Thus recourse to other chemical types was not necessary in order to obtain heavy-duty synthetic tanning agents, possessing fundamentally new technical properties towards leather, for this could be accomplished within the limits of the same type of aromatic sulphonic acids as for the production of light duty, auxiliary syntans. It was achieved by increasing the organic loading on the sulpho-group by intermolecular bonding of a sulphonic acid with a phenolic resin of low degree of polymerisation.

Table 1.

Phenolic resin, % on crude anthracene	Vol. yield of leather, % on hide	Tanning coeff. of leather
0	165	20
30	222	25
50	251	31
100	292	55

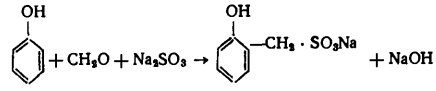
The dispersion of a phenolic resin in the sulphonic acids raised their tanning action to a higher level: i.e. it "improved" the tanning agent, as it were. Hence our brand letters–AO and NO–for the new anthracene and naphthalene tanning agents.

A very favourable result was obtained by dispersing a phenolic resin in ligninsulphonic acids (concentrates of waste sulphite liquors from the manufacture of cellulose)[34]. These liquors were suggested for use in leather production as early as the end of the nineteenth century, and were employed in industry, after preliminary purification, under the name of sulphite–cellulose extracts. However, their very feebly developed shaping power allowed them to be used only as an ancillary product, predominantly as a filler to increase the density of the leather and raise the yield by weight. Numerous attempts to improve the tanning power of sulphite–cellulose extracts produced only a very insignificant effect[37].

The dispersion of a phenolic resin in sulphite concentrates led, as with aromatic sulphonic acids, to a series of syntans the later members of which were not inferior to vegetable tannins in their tanning ability. These improved sulphite–cellulose extracts were denoted by the letters LF (lignin–phenolic).

The results of applying the same method to condensed hydroxybenzenesulphonic acids were very significant for subsequent work. Dispersion of a phenolic, Novolak resin in them yielded purely phenolic syntans, which exhibited a gradual change in tanning ability from the auxiliary type to well defined full substitutes[38]. This suggested the possibility of obtaining a similar series of phenolic syntans not by dispersing but by directly sulphonating the phenolic resin with a diminished quantity of sulphuric acid, so that only a proportion of the phenolic resins could undergo sulphonation, the proportion decreasing as the molar ratio of sulphuric acid to phenol was decreased. The part of the resin which had not been sulphonated would then be dispersed in the sulphonated product. This hypothesis was confirmed. Soluble products could be obtained even with a molar ratio of monohydrate to phenol in the resin of 0.15 : 1.00.[39] The corresponding series of tanning agents proved to have the widest range of variation in technical properties towards leather. The series was denoted by FT (phenolic heavy)[35].

Decreasing the ratio of sulphonating agent to the phenol, which was used to obtain the FT series of syntans, was applied also to another method of obtaining synthetic tanning agents–the condensation of phenols with formaldehyde and sodium sulphite, resulting in sulphomethylation of the phenol (termed also ω-sulphonation).



This process, known since the early years of the appearance of industrial syntans [40,41], acquired no practical value, since it yielded tanning agents of the same light type as did the condensation of hydroxybenzenesulphonic acids with formaldehyde. When the quantity of sulphite was diminished and that of the aldehyde increased, products were obtained which were typical heavy syntans, denoted by the letters FB (phenolic with a sulpho-group in the side-chain).

Thus by the prewar period synthetic methods had been developed which yielded a number of Soviet brands of synthetic tanning agents, making it possible, depending on the type of leather production, to replace vegetable extracts either completely or to a considerable extent [35]. Since 1938 these new brands have been manufactured in experimental production batches, and have been tested with positive results on various types of leather. The potentially most useful were the purely phenolic tanning agents of the FT series and ligninsulphonic concentrates improved with a phenolic resin (LF series). By combining them it was possible to obtain, without the use of vegetable extracts, both stiff and supple types of leather (sole leather and Russia leather) having normal physicomechanical properties.

B. Processes employed in the Synthesis of Soviet Heavy-duty Syntans

1. PREPARATION OF PHENOLIC RESIN

In Stiasny's original patent two methods were proposed for obtaining condensation products of hydroxybenzenesulphonic acids with formaldehyde, which differed in the sequence in which the operations of sulphonation and condensation were carried out. No distinction was made between them in the patent, and the first tanning agent, Neradol D, was obtained by sulphonating phenol and then condensing with formaldehyde. Subsequently Wolesensky [42] noted peculiarities in the products obtained by these methods, and pointed out that the second method (preliminary condensation of phenol with the aldehyde) yields a well filled leather, but involves difficulties in sulphonation and the possibility of "charring" of the resin.

A comparative study of the two alternatives has confirmed the difference in properties of the leather pointed out by Wolesensky, but no difficulty was found in the sulphonation. On the contrary, prelimary condensation had a decided advantage over subsequent condensation also in conducting the synthesis. With the stoichiometric proportion of sulphuric acid stable solubility for the resin was reached considerably more rapidly and at a less elevated temperature. With smaller amounts of acid a soluble condensation product could not be obtained at all from the sulphonated phenolic mass. In the synthesis of heavy-duty phenolic tanning agents, therefore, preliminary condensation of the phenol with aldehyde is of very great value.

The condensation of phenols with formaldehyde has been studied thoroughly, and its mechanism is known. The preparation of synthetic tanning agents requires a resin of Novolak type: i.e. condensation should be conducted in acid medium. A resin obtained by alkaline condensation leads to complications in subsequent sulphonation, owing to the presence of hydroxymethyl groups and the consequent tendency to thermosetting. In the presence of concentrated sulphuric acid and at high temperatures such a resin readily forms compounds which do not pass into a soluble state, diminish the yield of tannins, and lower the quality of the product.

The relative proportions of aldehyde and phenol effect the quantity of free phenol in the resin and the mean molecular weight of the oligomer. Subsequent sulphonation imposes no special restrictions on the degree of condensation. Up to 0.8 mole of aldehyde per mole of phenol, stable solubility of the product is reached even with small amounts of sulphuric acid. With regard to the relation between the extent of condensation and tanning ability, it was found that, contrary to expectation, no appreciable change in tanning properties was observed from the stoichiometric proportion and above. The optimum ratio can be regarded as 0.6 mole of aldehyde per mole of phenol. The condensation product is a mixture of molecules containing different numbers of rings linked through methylene groups. Analysis indicates that, with the above reactant ratio, the free phenol content is 15%, while the mean molecular weight of the polymer is about 500.

2. SULPHONATION OF PHENOLIC RESIN

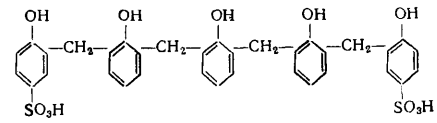
Sulphonation is the stage in the synthesis which determines the principal tanning parameters of the product. The same phenolic resin can yield tanning agents differing in forming and filling power from the lightest to complete substitutes, merely by variation in the proportion of acid to the resin. As this ratio is decreased, it becomes more difficult to obtain a product having stable solubility: it is necessary first to lower the moisture content of the resin, increase the acid concentration, raise the temperature, and prolong the process.

After separation from water the phenolic resin contains 15–20% of moisture. It is easily sulphonated by concentrated sulphuric acid in close to stoichiometric proportions (1.0 mole of monohydrate per mole of phenol), as is required in the preparation of light syntans. For heavy syntans the amount of acid should be halved, and here it is necessary to lower the moisture content in the resin to 3–4%. With further decrease in the proportion of acid, dissolution is achieved only by using oleum.

The results obtained on the relation between the tanning action of the product and the ratio of the reactants in sulphonation of the resin are given in Table 2.[35]

When small amounts of acid are used for sulphonation, a large proportion of it undergoes reaction. Thus with 0.5 mole of acid on the phenol, not more than 10% of the acid taken remains free in the sulphonated mass [43]. Calculation indicates that in this case the equivalent weight of the sulphonic acid is ~300.

With the molecular weight indicated above for a polymer of a normal phenolic resin ($M = 500$), the molecule of the tanning agent comprises on the average five phenolic rings associated with two or three sulpho-groups:



3. SECONDARY CONDENSATION

A feature of the entire series of tanning agents obtained by sulphonating a phenolic resin is their slow penetration into the leather in comparison with tanning agents obtained by the first alternative, i.e. products formed by the condensation of hydroxybenzenesulphonic acids. However, with the first few members of the series having a high proportion of sulphuric acid to resin this retardation is slight. As the quantity of acid decreases, the tendency of the tanning agent solutions to coagulate increases, and penetration into the leather becomes increasingly difficult, entailing very serious difficulties in practical application.

Table 2.

Molar ratio of acid (monohydrate) to phenol	Quality (ratio of adsorbable to dry substance)	Vol. yield of leather	Tanning coeff. of leather
0.9	49.5	220	34
0.5	65.9	301	56
0.4	79.0	322	60
0.3	84.6	378	87

This defect could be overcome by introducing an additional condensation of the sulphonated mass with small amounts of formaldehyde [44], which was carried out, after preliminary dilution of the sulphonated mass with water, at a low temperature (not above 50°C). Raising the temperature results in the appearance of insolubles, or even in complete insolubility of the product. A second condensation enhances the stability of the solutions, increases the content of tanning agents, considerably accelerates penetration into the leather, and improves its colour because dark, resinified particles are not now retained on the surface, but penetrate inside the leather. Thus a secondary condensation provides a very important method for all modifications of the given series of tanning agents, while for the heavier agents (in practice the most valuable) this can be regarded as essential.

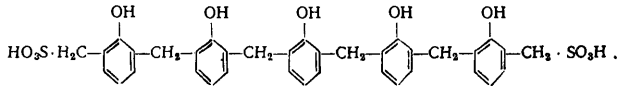
The course of the process depends to a considerable extent on the reaction of the medium. A decrease in acidity (partial or complete neutralisation of the sulphonated mass) lowers the reaction velocity, and condensation can be effected without complication at temperatures up to 75°C.[45] The quantity of aldehyde introduced in the second condensation has a fundamental effect on the properties of the tanning agent. It was established that, as the quantity of formaldehyde increased, the tanning properties passed through an optimum, after which they deteriorated considerably. With a normal resin (see above) this optimum occurs at a molar ratio of formaldehyde to phenol of ~0.1 : 1.0.

The presence of a maximum on the curve for the variation in the tanning properties of phenolic syntans as the quantity of formaldehyde is increased applies only to condensation after sulphonation. Such a maximum is not observed with preliminary condensation. Consequently this finding cannot be attributed to the increase in size of the molecule. It must probably be ascribed to the introduction of hydroxymethyl groups into the phenolic rings, which takes place under the mild conditions of the secondary condensation. In small quantities hydroxymethyl groups may have a favourable effect, by enhancing the hydrophilic character of the product and promoting the penetration of enlarged particles of the tanning agent into the fibrillar structure of the leather. However, the intensification of this property leads to a diminution in bonding and affects the occurrence of osmotic processes linked with the formation of the structure of leather.

4. SULPHOMETHYLATION OF PHENOL

With formaldehyde and sodium sulphite phenol undergoes two simultaneous reactions—the usual condensation with an aldehyde and sulphomethylation or introduction of a $CH_2.SO_3H$ group into the phenolic ring—the degree of condensation and the extent of sulphomethylation (mean equivalent weight of the sulphonic acid) depending on the proportions of the reactants and also on the process conditions. The best results with respect to product quality and reproducibility are obtained when the process is conducted in stages. The first stage—preliminary condensation of phenol with formaldehyde—is conducted under the same conditions—in acid medium with 0.5—0.6 mole of aldehyde based on the phenol—as for the sulphonic acid type of tanning agent. The second stage (sulphomethylation) requires, according to the equation for the reaction, equimolecular quantities of formaldehyde and sulphite; thus the proportion of sulphite based on the phenolic resin predetermines the proportion of formaldehyde. The sulphite : phenol ratio, however, can be varied within wide limits. Depending on this the tanning properties of this type of syntans also vary, just as those of the condensed hydroxybenzenesulphonic acids vary with the acid : phenol ratio adopted in sulphonating the resin.

By decreasing the proportion of sulphite to the initial phenol in the resin it is possible to obtain a series of tanning agents (FB) having enhanced tanning power like the FT series, obtained by sulphonating a phenolic resin. The molecule of the FB tanning agent from a normal resin with a molar ratio of sulphite to phenol of 0.5 : 1.0 contains on the average two sulphomethyl groups associated with five phenolic rings:



This product is a complete substitute syntan.

During sulphomethylation part of the aldehyde is consumed in further condensation with the phenolic resin, so that the sulphite does not enter completely into the condensation. With small amounts of sulphite this may result in inadequate solubility of the product, to prevent which it is advisable to increase the proportion of formaldehyde, i.e. to add rather more than an equimolecular quantity relative to the sulphite. Use of an increased proportion of aldehyde gives a soluble product even with 0.25 mole of sodium sulphite based on the initial phenol. As with an additional concentration after sulphonation of the resin, the variation in tanning properties with increasing amount of formaldehyde passes through an optimum here.

Compared with the analogous tanning agents of the FT series, the FB syntans, obtained by sulphomethylation of a phenolic resin, are distinguished by improved filling power and are less sensitive to changes in the active acidity of the solutions [35].

5. DISPERSION OF PHENOLIC RESIN IN SULPHONIC ACIDS

A phenolic resin is brought into colloidal solution by prolonged stirring with a solution of a sulphonic acid at

80–100°C. The process is favoured by high solute concentrations. Dilution considerably lengthens the process and diminishes the amount of resin which can be dispersed.

Before addition of the phenolic resin the sulphonic acids should be brought to their normal tanning power by condensation with aldehyde. Dispersion of the resin in uncondensed naphthalene- or hydroxybenzene-sulphonic acid gives a tanning agent of poor quality, which cannot be substantially improved by subsequent condensation of the dispersed product with formaldehyde.

Sulphonic acids exhibit active dispersing power only in the free state. Salts of sulphonic acids do not possess this ability, even in concentrated solutions, but sulphonic acids which have undergone normal improvement with a phenolic resin can, in the concentrated state or in solutions, be neutralised or subjected to other chemical treatments without breakdown of the colloidal system.

As has already been stated, the quantity of resin which can be introduced into the sulphonic acid depends on the solute concentration. Therefore the preliminary condensation of sulphonic acids with a considerable volume of formalin is an unfavourable factor in this respect. Modified processes in which preliminary condensation is not required, or is limited to a small quantity of aldehyde, permit greater improvement (e.g. the sulphonic acids from crude anthracene). The dispersing power depends also on the nature of the acid. In this respect sulphonic acids of tricyclic hydrocarbons are superior to those of bicyclic hydrocarbons. But ligninsulphonic acids (sulphite liquors) are especially active dispersing agents for phenolic resins: even in the neutralised state at a concentration not exceeding 50% they can bring up to 30% of the resin (based on the dry substance) into colloidal solution.

The tanning properties of the products obtained by dispersing a phenolic resin in any sulphonic acid are improved by further condensation with small amounts of formaldehyde.

6. ADJUSTMENT TO NORMAL ACIDITY

The final stage is adjustment of the acidity of the tanning agent to that required for practical application. Products of sulphonation of the resin or its dispersion in aromatic sulphonic acids require to be neutralised, which is accomplished with sodium carbonate or ammonia to a slightly acid reaction. Sulphomethylation produces a considerable quantity of alkali, and the product must be acidified with sulphuric acid. Dispersion of a phenolic resin in concentrates of sulphite liquors takes place in weakly acid medium, and these tanning agents do not require adjustment.

The shortage of phenol during the postwar period made it necessary to use more readily available starting materials—technical mixtures of phenols which could be extracted from tar waters formed in the thermal processing of bituminous shales and in the low-temperature carbonisation of coal. Work on these lines was conducted in the Central Scientific Research Institute for the Leather Industry by Konovalenko, Khadyk, Kuraitis, Golubeva, and Filippova.

By means of procedures developed previously (condensation with formaldehyde and subsequent sulphomethylation or dispersion in sulphonic acids) it proved possible to obtain from the extractable phenols a series of brands of substitute syntans, which found wide practical application under the designations No. 5, No. 12, SL, and SPS [46-48].

The most interesting of these tanning agents is SPS, obtained by the method proposed by Konovalenko [49]. The extractable shale phenols (mainly homologues of resorcinol) are condensed by this method with ligninsulphonic acids and formaldehyde, and the condensation product is dispersed in the spent liquor from the fermentation of sulphite-cellulose liquors to alcohol. From its tanning power SPS cannot be regarded as a full substitute, but it confers a light natural colour on leather and is readily compatible with other types of tanning agents.

Syntans obtained by the sulphomethylation of a polyphenolic resin possess substantial disadvantages—the dark colour and unpleasant odour which they confer on the leather, and also the inadequate standardisation of the product due to the variability in composition of the raw material—which suggests that such brands will not be kept in the range, and in the very near future will be replaced by syntans based on crystalline phenol. The production of brands from pure phenol by the methods described above has been growing rapidly during recent years. Among them are No. 2 [50] (an analogue of ST-50, differing from the latter in the use of ammonia for neutralisation), No. 3 (identical with LF), and FB-2 [51] (a modified form of FB, in which phenol has been replaced by the phenolic fraction of coal-tar).

C. Methods of Producing Substitute Syntans Abroad

At the end of the war information was published on German materials [52] and also literature surveys [17] on the production of German brands of synthetic tanning agents, so that it became possible to compare the development of ideas and practical methods for obtaining substitute syntans in the USSR and in Germany.

It turned out that the features which were mentioned in the pre-war foreign literature (see above) were secondary criteria. The German Tannigans extra did not belong to any new chemical types, but were the same sulphonic acids improved with phenols or their derivatives. Thus the general direction of German and Soviet work in producing substitute syntans was the same, but the initial attitudes and the methods by which improvement was accomplished were fundamentally different. The same task—to enlarge the particle size and increase the phenolic loading on the sulpho-group—was understood differently by the German chemists and by ourselves. Soviet investigators started from the observed possibility of dispersing the phenolic resin, and saw a solution to the problem in obtaining a coarse colloidal particle by intermolecular interaction between the phenolic oligomer and condensed sulphonic acids. German chemists thought it necessary to increase the size of the tanning agent molecule, i.e. to combine phenolic and sulphonic-acid components chemically by condensing them simultaneously with aldehydes ("mixed" condensation) [53].

In spite of the fundamental difference, these methods yield products which are analogous chemically and exhibit similar behaviour towards leather. As a consequence of this there is a considerable affinity between the German Tannigans extra and the same types of Soviet brands of heavy syntans.

It should be remarked that mixed condensation is a more complicated procedure than dispersion. It breaks down into several individual condensation of the initial compounds in various combinations, and results in the formation of a mixture of substances differing in chemical composition and structure, whereas with dispersion the final

result is determined unambiguously by the relative proportions of the components. In virtue of this, colloidal improvement creates more favourable conditions for studying theoretical aspects of the interrelation between the structure and the tanning properties of synthetic tanning agents. This may well be the reason why the researches aimed at producing the Soviet substitute syntans led to broader generalisations than did the foreign work. Among such generalisations are—(*a*) the absence of a direct connection between the chemical class of a tanning agent and its properties in relation to leather, (*b*) the concept of the chemical type of tanning agent as a kind of "homologous series" with a gradual change in tanning power, (*c*) the difference in the ratio between the parameters of forming and filling power for different chemical types ("homologous series" of tanning agents), and (*d*) the possibility of a rational specification of syntans from the point of view of leather technology, based on the ratio of the parameters representing forming and filling power[54].

Examination of prewar German methods for obtaining substitute syntans and their comparison with postwar methods described in foreign patents show that the principles laid down in this field in the 1930s have been fully maintained. A few new specialised brands of synthetic tanning agents have appeared since the war, but nothing fundamentally novel has been introduced into the methods of synthesising the substitutes. The present-day range of substitute syntans abroad comprises brands belonging to the same chemical types as were developed in Germany and in the USSR during the prewar period.

1. IMPROVED SULPHONIC ACIDS OF AROMATIC HYDROCARBONS

Tanning agents of this type are obtained by linking aromatic sulphonic acids with phenolic rings through a methylene group. This can be accomplished by the simultaneous condensation of sulphonic acids and phenols with formaldehyde, or by the condensation of sulphonic aicds with phenolic alcohols or resol resins[55]. Methods have been described also for linking through sulphur (condensation with sulphur monochloride) or through the sulphonyl group heating naphthalenesulphonic acids with hydroxybenzenesulphonic acids to a high temperature, when sulphonic acids of mixed hydroxyphenyl naphthyl sulphones are formed)[56]. Naphthalene- or benzylnaphthalene-sulphonic acid is used as the acid component, and ordinary phenol, tricresol, a polyhydric phenol, or bishydroxyphenyl sulphone as the phenolic component.

The simultaneous condensation of hydrocarbons with phenols is made difficult by the marked difference in their reactivity towards formaldehyde. As a consequence, the condensation products are very inhomogenous in composition, and contain a considerable quantity of insoluble compounds dispersed in the sulphonic acids.

Tanning agents of this type are not above the average in forming and filling power, and they cannot be regarded as complete substitutes. Rather they must be included in an intermediate group of syntans, destined for the manufacture of light types of leather or for combination with vegetable extracts in relatively small proportions.

The best product of this type is that resulting from the mixed condensation of naphthalenesulphonic acids with bishydroxyphenyl sulphone. With a high sulphone : naphthalene ratio it reaches the level of complete substitutes in its tanning action[27].

2. IMPROVED HYDROXYBENZENESULPHONIC ACIDS

This is the most widely represented type of tanning agents, and several methods have been proposed for obtaining them—mixed condensation of hydroxybenzenesulphonic acids with phenols and aldehyde, condensation of hydroxybenzenesulphonic acids with phenolic alcohols, etc.

Phenol, tricresol, the naphthols, mono-, and dihydroxybiphenyls, polyhydric phenols, and bishydroxyphenyl and bishydroxytolyl sulphones have been used as the initial compounds containing phenolic hydroxyls. Besides the usual mixing of the components, mixtures of them are sometimes obtained from the same starting material by an incomplete intermediate process. For example, a mixture of hydroxybenzenesulphonic acid and bishydroxyphenyl sulphone is obtained from phenol by heating it to a high temperature with a quantity of sulphuric acid insufficient for sulphonation[57]. The preliminary or mixed condensation of hydroxybenzenesulphonic acids with formaldehyde and phenols is often carried out with the addition of urea, which improves the colour of the leather[58].

The most valuable variant in practice is sulphonation of a Novolak phenolic resin until it is completely soluble, followed by condensation with formaldehyde[59]. The tanning agent "extra B" obtained in this way is very similar in tanning properties to our FT-50.[60]

Tanning agents of this type are characterised by a predominance of forming over filling ability. Their chief purpose, therefore, is the tanning of Russia leather, as well as of the less durable types of leather for the base of footwear and for technical uses.

3. PRODUCTS OF THE SULPHOMETHYLATION (ω-SULPHONATION) OF PHENOLS

Sulphomethylation is one of the processes generally used to obtain substitute syntans, and is employed in various ways. The starting materials used are phenol and its homologues, polyhydric phenols, dihydroxybiphenyl, bishydroxyphenyl sulphone, or products of their preliminary condensation with formaldehyde in acid or alkaline medium. In foreign practice, however, this process is probably used predominantly to obtain tanning agents of mixed types. By itself the ω-sulphonic-acid type is of secondary practical value. This can be explained by the lower solvent power of such sulphonic acids for vegetable extracts in comparison with the usual hydroxybenzenesulphonic acids.

Independent application is found mainly with products of the sulphomethylation of bishydroxyphenyl sulphones[61].

4. LIGNINSULPHONIC ACIDS IMPROVED WITH PHENOLS

A feature of substitute syntans obtained by improving ligninsulphonic acids is their good filling power and the enhanced durability conferred on the leather, which makes them especially valuable for the manufacture of sole leather. With respect to the place they occupy in the foreign range, tanning agents of this type are as important as improved hyroxybenzenesulphonic acids.

The starting material for their production consists of the waste lyes from the manufacture of sulphite cellulose or the spent liquor remaining after their fermentation into alcohol. These liquids are usually freed from calcium salts; sometimes they are subjected to other forms of preliminary treatment, e.g. heating with alkalis under pressure to diminish the quantity of combined sulphurous acid.

A general method of improvement is the mixed condensation of sulphite concentrates with phenols or their derivatives in acid or alkaline medium[62]. The chief brand of this type, which has remained in the German range for thirty years, is a product of condensation with bishydroxyphenyl sulphone ("extra A"), which is similar to our LF in tanning properties[60].

Various ways of using mixed condensation to improve ligninsulphonic acids are given in patents. Conducting the process in two stages is of practical value: (*a*) preliminary condensation of a phenol or a sulphone with formaldehyde is followed by mixed condensation of the product with the sulphite liquor; (*b*) mixed condensation of the liquor with a phenol or a sulphone yields a product which is separated from the solution, and dispersed in a fresh portion of liquor. Ligninsulphonic acids improved with phenols are easily salted-out from solution by electrolytes. This enables a tanning agent of this type to be obtained as a solid product having a high content of tanning agent[63].

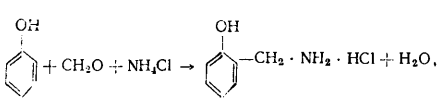
Together with tanning agents belonging to the individual chemical types described above, the foreign range contains a large number of brands of mixed types, i.e. obtained by combining two or more modes of improvement, or representing simply mixtures of ready made tanning agents of different types. For example, phenol (cresol) is condensed with a mixture of hydroxybenzene- and naphthalene-sulphonic acids[64]; phenol or bishydroxyphenol sulphone is condensed with a mixture of ligninsulphonic and aromatic sulphonic acids[65]; hydroxybenzene- or hydroxynaphthalene-sulphonic acids, after being condensed simultaneously with phenol and an aldehyde, are mixed with ligninsulphonic acids which have previously been improved by condensation with phenol and formaldehyde[66]; a product of the sulphomethylation of bishydroxyphenyl sulphone is subjected to mixed condensation with hydroxytoluenesulphonic acid, bishydroxyphenylpropane, and formaldehyde; etc.[67]

A noteworthy feature of the numerous variants of this kind encountered in patents of the war and postwar periods is that they reflect no tendency at all to further specialisation of the tanning agents in relation to leather technology, in particular any strengthening of the characteristics of substitute syntans. On the contrary, these modifications are directed to obtaining tanning agents of intermediate type as regards leather technology, in which the forming and filling ability is controlled at the level necessary for the solution of additional problems not directly connected with the replacement of vegetable extracts.

IV. NEW TYPES OF SYNTHETIC TANNING AGENTS

1. Amphoteric Tanning Agents

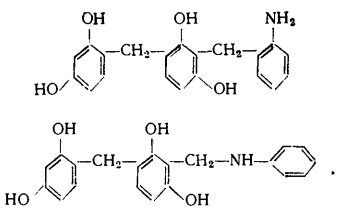
Up to the end of the 1940s all methods for obtaining synthetic tanning agents, whether operated industrially or only described in the literature, yielded products in which the tanning action was located in an anion. At the beginning of the past decade tanning agents of a new chemical type, have a tanning cation, appeared in the Federal Republic of Germany. Their mode of production, developed by Mauthe and Farber[68], consisted in the simultaneous condensation of an ammonium or an amine salt with a phenol and an aldehyde:



Compounds of this type dissolve readily in acid medium as substituted ammonium salts, and in alkaline medium as phenoxides. The tannophoric groups—phenolic hydroxyls—are located in the former case in the cation, and in the latter case in the anion. This gave rise to the name amphoteric synthetic tanning agents[69,70] which is really incorrect, since they exhibit tanning activity only in acid medium. In contrast to the usual synthetic tanning agents, the tanning power of amphoteric syntans (their combination with a protein) increases as the acidity diminishes. At the isoelectric point they are precipitated from solution. A characteristic property of the new tanning agents is the formation with anionic compounds—tanning agents, dyes, fat-liquoring sulphonated products—of insoluble salts: this property permits their use both as tanning agents and as fixing agents, anchoring the anionic products in the leather. This second use, which requires only a relatively small amount of the syntan, is of far greater practical interest than is the first. However, the simultaneous tanning action gives a substantial additional effect, which is a valuable distinguishing feature from other types of fixing agents.

The tanning action of amphoteric syntans depends on the nature of the initial compounds and on their relative proportions. In this respect these agents resemble anionic syntans. The tanning power of sulphonic acids improved with phenols increases with increase in the phenolic loading on the sulpho-group; in amphoteric tanning agents the phenolic loading on the amino-group has an analogous effect: as the amount of phenol combined with the amine increases, the tanning agent approaches closer and closer to the heavy type.

Products obtained by the Mannich reaction from phenols possess very weak tanning action, since they achieve stable solubility only at a high amine : phenol ratio. Products whose tanning action is comparable with that of substitutes can be obtained only by the simultaneous condensation of a polyhydric phenol with formaldehyde and an aromatic amine, e.g. by the condensation of resorcinol with formaldehyde and aniline with a molar amine : phenol ratio not exceeding 0.5 : 1.0. In this case the reaction can go in two ways, with formation of the compounds:



The condensation leads predominantly to a product of the type (I).

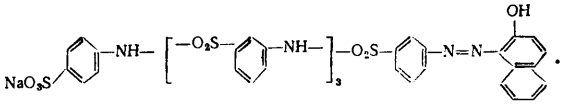
Methods were developed for obtaining amphoteric tanning agents based on technical mixtures of polyhydric phenols from tar water from the low-temperature carbonisation of coal. In the first modification the process is conducted in stages, the amine being introduced into the reaction in two portions with intermediate cooling[71]. This makes solubility easier to achieve, and enables mixtures of polyhydric and monohydric phenols to be used. In a second modification formaldehyde is replaced by bishydroxymethylurea[72], which lowers the heat of reaction and facilitates its occurrence.

When tried on an industrial scale the amphoteric tanning agent LAF, which we have obtained, exhibited a high tanning power.

2. Dyes with Tanning Ability

Acid and direct dyes exhibit some structural similarity to synthetic tanning agents. This explains their tanning ability, which is developed to different extents depending on the molecular weight and structural features[73]. In the usual dyeing of leather, in spite of the small consumption of dye, the tanning action of certain dyes has an appreciable effect on the physical properties of the surface layer. In comparison with syntans, of course, the tanning power of dyes is small, not surpassing the lower grades of the auxiliary type. However, it could be considerably strengthened by increasing the organic loading on the sulpho-group and introducing tannophoric groups into the molecule, provided that the chromophoric system is not disturbed.

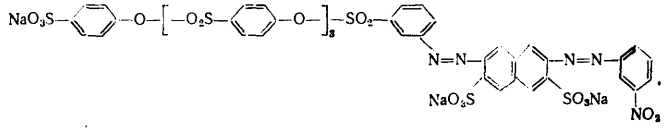
Dyes of this type were first prepared by Berkman and Gordinskii[74]. They were azo-dyes in which the diazo-component contained a polycyclic polysulphonamide chain as is usual for synthetic tanning agents of the polysulphonamide type[75,76]:



Further studies have been made of the synthesis and properties of polysulphonamide azo-dyes[77,78]. Analogous compounds were obtained containing sulphonamide groups in the coupling component, and symmetrical and unsymmetrical *cis*- and polyazo-dyes containing chromophores isolated by a polycyclic polysulphonamide chain.

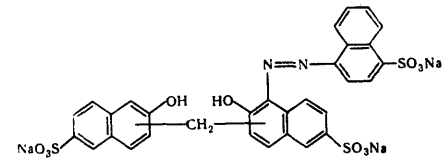
All these dyes exhibited high tanning power, evenness of coloration, and fastness to wet rubbing. The increase in levelling power is interesting, for this usually becomes worse with increase in size of the dye molecule. In the present case the colour is probably influenced favourably by the simultaneous differentiation of the fibre structure of the outer layer of the leather, which contributes to a uniform distribution of the dye.

Azo-dyes having similar properties are obtained[79] by introducing a polyaryloxysulphonyl chain or a mixed chain containing sulphonic ester and sulphonamide groups into the molecule[80,81]:



Polysulphonamide and poly(sulphonic ester) dyes are individual compounds, and can be obtained as crystals. By varying the length of the chain it is possible to obtain for each dye a series of compounds containing the same chromophoric system but differing in number of tannophoric groups and in molecular weight. This makes it possible to study certain aspects of the relation between the molecular structure and the physicochemical and dyeing properties of dyes[75,77,78,81].

Dyes which already contain tannophoric groups (phenolic hydroxyls), but exhibit only slight tanning activity, can be made active tanning agents by enlarging the molecule. This is accomplished by condensing the base or the coupling component with an aldehyde or a ketone, as in the analogous condensation of sulphonic acids in the preparation of synthetic tanning agents. Various dyes of this type, e.g.



have been prepared[82], and found to possess high forming and filling power.

An analogous method was suggested at the same time in the German Democratic Republic for the preparation of tanning agents possessing dyeing properties by coupling ordinary diazo-components with phenolic syntans of various types[83].

Dyes exhibiting tanning properties may be of considerable interest in the production of leather for shoe uppers and especially for special types of leather—fancy, garment, glove leathers.

---o0o---

The production of synthetic tanning agents is at the present time an established branch of fine organic synthesis with a wide range of products intended to replace vegetable tanning extracts and for several purposes of ancillary or special character. The development of this industry in individual countries is determined by the economic conditions, which differ fundamentally.

On the world market vegetable tanning materials, imported predominantly from former colonies or semi-colonial territores, are considerably cheaper than artificial tanning agents. In capitalist countries (especially England and the USA), therefore, the use of substitute syntans on a large scale is not yet justified. Practical interest attaches mainly to their application for special purposes.

The position in the USSR is completely different. Although we have fairly large potential resources of raw materials for the production of tanning extracts, the raw material itself is characterised by a low content of tannins, and is mostly situated in remote, relatively undeveloped regions. Its procurement and transport involve great organisational difficulties and great expense. In the USSR, therefore, vegetable tanning agents are almost twice as dear as the synthetic products. In this situation our most important task is to use syntans to replace vegetable extracts in as large a volume as possible. With an annual demand by the leather industry for ~ 150 000 tons of dry tanning extracts, this provides grounds for developing the manufacture of syntans to the level of a large-scale and economically very efficient branch of the chemical industry.

The possible applications of artificial tanning agents are not restricted to the leather industry. In their structure and physicochemical characteristics these substances are water-soluble polymers, and may find various uses as a special group of such substances. Recent developments in the synthesis of products which combine tanning action with other functions—fixing, dyeing, emulsifying—open up for synthetic tanning agents new prospects of theoretical and practical interest.

Organophosphorus Complexones

M.I.Kabachnik, T.Ya.Medved', N.M.Dyatlova, O.G.Arkhipova, and M.V.Rudomino

Organophosphorus complexones represent a new class of multidentate reagents. The paper gives a broad survey of methods for the preparation of aminoalkylphosphonic acids, which include the organophosphorus complexones, and their complexing and biological properties are described. The specific characteristics of these complexones are revealed with respect both to certain elements—beryllium, the rare-earth metals, heavy elements, etc.—and with respect to extending the pH range of complex formation. The mode of reaction of organophosphorus complexones is discussed. The bibliography contains two hundred references.

I. INTRODUCTION

An examination of research on complexones[1] leads to the conclusion that the most important tasks of coordination chemistry in general and the chemistry of complexones in particular are problems of the stability of chelates and the selectivity of chelation.

At one time the synthesis and application of derivatives of iminodiacetic, ethylenediaminetetra-acetic (EDTA), cyclohex-1,2-ylenediaminetetra-acetic (CHDATA), diethylenetriaminepenta-acetic (DETAPA), and certain other acids solved the problem of producing a universal complexone that was highly effective for most cations over a definite pH range. Their multidentate character and configurational mobility, enabling them to assume various conformations corresponding to the structural peculiarities of the cations, make these complexones highly effective for many cations. Thus great stability of the chelates was to a considerable extent achieved, but the problems of selectivity of chelation and also those of complex formation in strongly acid and strongly alkaline media still remained unsolved. The necessity thus arose of seeking new complexing reagents.

The production of highly specific reagents is difficult, since such substances should selectively chelate cations which are very closely similar to one another in physical and chemical properties, dimensions, spatial configuration, and tendency to complex formation.

Selective multidentate complexones can probably be prepared in several ways, e.g. by building up a multidentate reagent having maximum geometrical correspondence between the internal ligand profile and the cation, by introducing into the complexone molecule electron-donor atoms and groups which interact specifically with particular cations, or by building up a multidentate reagent able to satisfy the geometrical and donor–acceptor coordination requirements of the ions of one metal while, as completely as possible, not satisfying those of the ions of all other metals. To solve these problems, it is necessary to study the influence of the structural features and the nature of complexones on complex formation and on the selective character of their action. Although consideration of these questions is at present only qualitative, it is to be hoped that the accumulation of data in this field will reveal some quantitative relations.

The chemistry of organophosphorus complexones is one of the new lines of complexone research which will lead to a solution of the above problems. We include in this group those complexones in which carboxyls have been partly or completely replaced by organophosphorus acidic groupings. Whereas the complexing properties of many organophosphorus compounds, mainly extractants (phosphates, phosphonates, and phosphines and their oxides), have been widely investigated[2-8], very little work has yet been done on organophosphorus complexones. The present review systematises published information on their synthesis and properties.

Organophosphorus complexones possess several specific properties which distinguish them fundamentally from their carboxylic analogues and enable several aspects of the selectivity of chelation to be settled. The development of organophosphorus complexones became possible only after methods had been worked out for the synthesis of aminoalkylphosphonic acids, to which group these complexones belong.

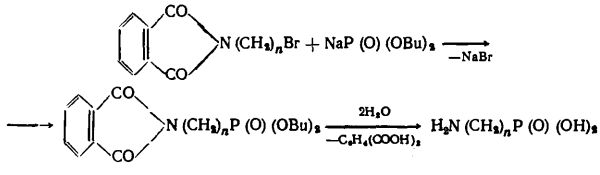
II. METHODS OF SYNTHESIS

The methods available for the preparation of aminoalkylphosphonic acids can be divided into three main groups.

1. Phosphorylation of Substituted Amines

This division comprises methods for the synthesis of aminoalkylphosphonic acids based on the introduction of a phosphonic grouping into an organic amine. The various modifications of these methods usually include either an Arbuzov rearrangement or a Michaelis–Becker reaction. The phosphorylating agents used include sodium dialkyl phosphites, trialkyl phosphites, alkylphosphonous esters, and phosphorus trichloride. In order to prevent side-reactions, the amino-group in the amines is usually blocked by easily removable protective groups.

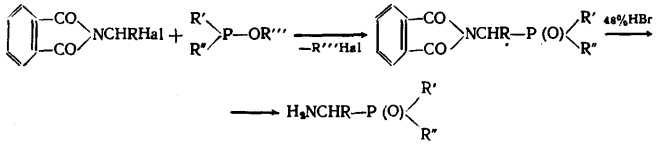
Rumpf and Chavane[9] obtained aminoalkylphosphonic acids by the action of sodium dibutyl phosphite on bromoalkylphthalimides followed by hydrolysis of the resulting phthalimidoalkylphosphonic esters:



where n = 1, 2, 4, 5, 10.

Kosolapoff[10] obtained 2-aminoethylphosphonic acid by the reaction between bromoethylphthalimide and triethyl phosphite.

This method has since been used[11] for the synthesis of α-amino-s-alkylphosphinic acids and α-aminoalkylphosphine oxides. Alkyl- and aryl-phosphonous and -phosphinous esters were subjected to Michaelis–Arbuzov condensation with N-bromomethyl- and N-1-chloroethyl-phthalimides:



where R = H, CH_3; R′ = CH_3, C_2H_5; R″ = C_6H_5, OAlk (OH after hydrolysis); and R‴ = Alk.

ω-Aminoalkylphosphonic esters are formed also by the reaction of bromoalkylamine hydrobromides with sodium dialkyl phosphites (in the proportions 1 : 2 to neutralise the hydrobromic acid liberated[12]):

$$H_2N(CH_2)_nBr\cdot HBr + 2NaP(O)(OR)_2 \rightarrow H_2N(CH_2)_nP(O)(OR)_2 + HP(O)(OR)_2 + NaBr.$$

Owing to the insolubility of hydrobromides in inert anhydrous solvents, however, the yields of the final products are low.

Phosphorus trichloride reacts with alkoxymethylamines to give derivatives of aminomethylphosphonic acid[13-15]†. Thus by adding hydroxymethylamides of aliphatic acids to excess of phosphorus trichloride, Engelmann and Pikl[17,18] obtained the corresponding substituted alkyl phosphorodichloridites $R.CO.NR'.CH_2.O.PCl_2$, which then isomerised into the substituted aminomethylphosphonic dichlorides. Hydrolysis of the latter readily yielded substituted aminomethylphosphonic acids $R'.NH.CH_2.PO(OH)_2$.

Taking the reaction of substituted alkoxymethylamines with phosphorus trichloride as example, Kreuzkamp and Genser showed[19] that this reaction takes place in two stages, with the formation of trialkyl phosphites and chloromethyldialkylamines as intermediate products:

$$PCl_3 + (C_2H_5)_2NCH_2OC_2H_5 \rightarrow (C_2H_5O)_3P + (C_2H_5)_2NCH_2Cl$$
$$(C_2H_5O)_3P + (C_2H_5)_2NH_2Cl \rightarrow (C_2H_5)_2NCH_2PO(OC_2H_5)_2 + C_2H_5Cl.$$

The facility of the first stage is, perhaps, due to the formation of a resonance-stabilised carbonium–immonium cation and an alkoxide anion:

$$R_2NCH_2OR' \rightarrow [R_2\ddot{N}-\overset{+}{C}H_2 \leftrightarrow R_2\overset{+}{N}=CH_2] + R'O^-.$$

In spite of the ease of the synthesis, however, this reaction has not become widely used, since its application is restricted to derivatives of aminomethylphosphonic acid.

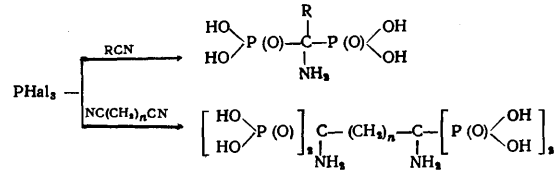
Ivanov and his coworkers have recently shown[20,21] that a similar mechanism is probably involved in the reactions of triethyl phosphite with alkoxymethylamines and with diethylaminoacetonitrile, which also yield diethylaminomethylphosphonic esters:

$$\left.\begin{matrix} R'_2NCH_2OR \\ R'_2NCH_2CN \end{matrix}\right| \xrightarrow[CH_3COOH\ or\ HCl]{(C_2H_5O)_3P} R'_2NCH_2P(O)(OC_2H_5)_2.$$

In contrast to this the reaction between triethyl phosphite and acetamidoacetyl chloride gives an ester of the corresponding amino-α-ketophosphonic acid[22]:

$$RCONHCH_2COCl + (C_2H_5O)_3P \rightarrow RCONHCH_2COP(O)(OC_2H_5)_2.$$

With nitriles and dinitriles phosphorus trihalides undergo a different type of reaction[23,24], yielding in the presence of organic (acetic) and inorganic (phosphorous) acids, on subsequent hydrolysis, the corresponding aminoalkylenepolyphosphonic acids:



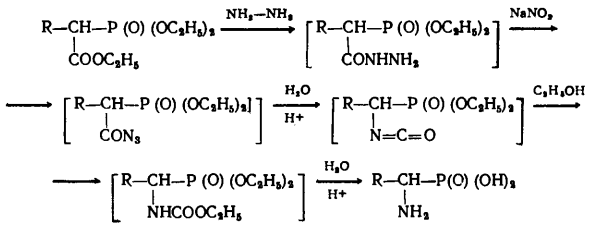
where R = Alk, Ar.

† With white phosphorus alkoxymethylamines give trisaminomethylphosphine oxide, accompanied by aminomethylphosphonic and bisaminomethylphosphinic acids as side-products[16].

2. Amination of Substituted Phosphonic Acids

In most cases classical methods of introducing an amino-group are used for the amination of substances containing a phosphonic group.

Thus by the reaction of α-ethoxycarbonylalkylphosphonic esters with hydrazine Chambers and Isbell[25] obtained the corresponding hydrazides, which after treatment with sodium nitrite and ethanol, followed by hydrolysis with concentrated hydrochloric acid, were converted into α-aminoalkylphosphonic acids in yields of 55–80%. Although the intermediate compounds in this synthesis were not isolated, there is no doubt that the process is a Curtius reaction:



where R = H, CH_3, $CH_2C_6H_5$.

Hydrazoic acid can also be used to convert carboxyalkylphosphonic into aminoalkylphosphonic acids[26]:

$$HOOC(CH_2)_nP(O)(OH)_2 + HN_3 \rightarrow H_2N(CH_2)_nP(O)(OH)_2 + N_2 + CO_2$$

as well as Hofmann decomposition of the amide[27]:

$$(C_2H_5O)_2P(O)(CH_2)_nCOOC_2H_5 \rightarrow (C_2H_5O)_2P(O)(CH_2)_nCONH_2 \xrightarrow{Br_2,KOH,H_2O}$$

$$\rightarrow (C_2H_5O)_2P(O)(CH_2)_nCH_2NH_2 \xrightarrow[H_2O]{H^+} (HO)_2P(O)(CH_2)_nCH_2NH_2,$$

Reaction of α-ketophosphonic acids with mono- and dinitrophenylhydrazines gives the corresponding phenylhydrazones, which can be converted by catalytic hydrogenation into the aminoalkylphosphonic esters[10,28]. Kosolapoff used this method to prepare α-aminobenzylphosphonic acid $C_6H_5.CH(NH_2).PO(OH)_2$.

The addition of amines at a double bond present in a phosphonic acid was described by Pudovik[29] as a case of phosphonoethylation. The reaction is usually conducted in the presence of an alkali metal or an alkali-metal alkoxide[30–33].

The above methods for obtaining aminoalkylphosphonic acids are employed comparatively rarely, since they involve the use of starting materials which are not readily available and are specific for each particular compound, and the more complicated polyaminepolyphosphonic acids cannot be obtained by these reactions. A method which eliminates to some extent these disadvantages is based on the replacement by an amino-group of the halogen in a halogenoalkylphosphonic acid.

Comparison of the kinetics of the replacement of halogen by an amino-group in methyl chloride[34] and in chloromethylphosphonic acid[35] led two of the present Reviewers to the conclusion that the phosphonic group in the latter compound has a deactivating effect on the chlorine atom. In fact, the conversion of iodo- or chloro-methylphosphonic acid into aminomethylphosphonic acid necessitates heating with concentrated ammonia in a sealed tube at 100–120°C,[36,37] and the reaction of 3-bromopropylphosphonic acid with concentrated ammonia to form 3-aminopropylphosphonic acid lasts for 2–3 weeks.[10]; the yields of amino-acids are low (around 20–25%). Still more severe conditions (150–160°C) are required to replace halogen by an amino-group in arylhalogenoalkylphosphinic acids[38].

Halogen present *ortho* to the phosphonic group in an aromatic ring is replaced by an amino-group on treatment with concentrated ammonia under the conditions of the Ullmann reaction, i.e. in the presence of freshly prepared copper(I) oxide[39,40].

Primary and secondary amines react more readily than does ammonia: in strongly alkaline aqueous solution the halogen in chloromethylphosphonic acid is replaced in yields of ~ 50% at only 90–100°C. In many cases, however, mixtures of amines phosphorylated to different extents are formed, and it is frequently difficult to separate them.

In 1949 Schwarzenbach et al. synthesised dihydroxyphosphinylmethyliminodiacetic acid $(HO)_2PO.CH_2.N(CH_2COOH)_2$ and its *N*-methylbetaine $^-OPO(OH).CH_2\overset{+}{N}(CH_3)(CH_2COOH)_2$ by condensing chloromethylphosphonic acid with iminodiacetic and *N*-methyliminodiacetic acids respectively[41].

This acid has been obtained also by condensing aminomethylphosphonic acid with chloroacetic acid[42]. An analogous reaction using chloroacetic acid has been described recently for the preparation of bisdihydroxyphosphinylmethylethylenediaminediacetic acid[43].

Bersworth, Westerback and Martell, and other workers have extended to polyamines the substitution of halogen in a halogenoalkylphosphonic acid by an amino-group. Reaction of the simplest polyamine, ethylenediamine, can in principle be represented by the scheme

$$H_2NCH_2CH_2NH_2 + (n+m)\,ClCH_2PO_3^{2-} + (n+m)\,OH^- \rightarrow$$

$$\rightarrow (^{2-}O_3PCH_2)_mNH_{2-m}CH_2CH_2NH_{2-n}(CH_2PO_3^{2-})_n + (n+m)\,Cl^- + (n+m)\,H_2O$$

where n and m have the values 0, 1, 2.

It has been mentioned above that this reaction is usually accomplished by heating an aqueous solution of a mixture of ethylenediamine and chloromethylphosphonic acid at 90–100°C for several days, the pH of the medium being kept within the range 10–11 by the continual addition of aqueous alkali or sodium carbonate[44–49]. Depending on the proportions of the reactants and the reaction conditions, the product may be predominantly mono-, di-, tri-, or tetra-phosphonic acid. The polyaminepolyphosphonic acids are isolated and purified via their lead salts or by means of ion-exchange resins. Most of the acids have been isolated and identified as their sodium or potassium salts[46–49]. However, it is probably not possible to obtain individual acids in the pure form.

The reaction of chloromethylphosphonic acid with ethylenediamine has been studied in greatest detail by Uhlig and Achilles[50], who have shown that copper(II) salts have a substantial catalytic effect on the reaction. In their presence the duration of the reaction is greatly shortened (from 90–100 to 2–8 h), and preferential formation of the triphosphonic acid can be achieved. These workers isolated and identified ethylenediamine-mono-, -bis-, -tris-, and -tetrakis-methylphosphonic acids.

Besides ethylenediamine, the method has been applied also to alkylenediamines containing 2–6 carbon atoms in the chain[44,47,48,50]; to *N*-alkylated and *NN'*-dialkyl(aralkyl)-ated alkylenepolyamines of the type $RNH.A.[NH.A]_n.NHR$, where R = H, C_2H_5, C_4H_9, $C_{18}H_{37}$, $CH_2C_6H_5$, A = CH_2CH_2, $CH_2CH_2CH_2$, $CH(CH_3).CH_2$, and n = 0–4 [45,51]; to alkylenediaminediacetic acids of the type $HOOC.CH_2.NH.[CH_2]_n.NH.CH_2.COOH$, where n = 2–6;[46] and to alicyclic diamines[49], aromatic amines[52], and mono-, bis-, and poly-hydroxyalkylamines[53–56].

Esters and amides of other chloroalkylphosphonic[57,58] and bischloromethylphosphinic[59] acids also exchange their chlorine for an amino-group.

It has been claimed in a patent[60] that the use of chloromethylphosphonous acid $ClCH_2P(OH)_2$ instead of chloro-

methylphosphonic acid yields alkylenediaminetetrakismethylphosphonous acids $[(HO)_2PCH_2]_2N[CH_2]_nN[CH_2P(OH)_2]_2$.

In most cases it is not possible from patent information to assess the purity of the products, but the wide possibilities of applying this method to the phosphorylation of various polyamines indicate that it is extremely promising.

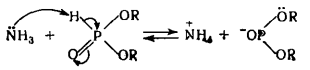
3. Condensation of Dialkyl Phosphites and their Analogues with Amines and Aldehydes or Ketones

In 1952 Kabachnik and Medved' [61,62] suggested a new method for synthesising α-aminoalkylphosphonic acids, which was based on the condensation of dialkyl phosphites with ammonia and a carbonyl compound. The resulting aminoalkylphosphonic esters were saponified to the free acids:

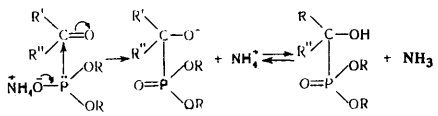
$$(RO)_2PHO + R'—CO—R'' + NH_3 \rightarrow (RO)_2P(O)—\underset{R'\ \ R''}{C}—NH_2 \xrightarrow[H_2O]{H^+} (HO)_2P(O)—\underset{R'\ \ R''}{C}—NH_2 .$$

A little later Fields reported [63] the preparation of esters of substituted α-aminoalkylphosphonic acids by the action of dialkyl phosphites on primary or secondary amines and aldehydes. He was unable to obtain the free acids by saponifying the esters. Although the mechanism of this reaction was not investigated, several suggestions have been made concerning its course.

According to Kabachnik and Medved' [64] the first stage in the reaction might be ionisation of the dialkyl phosphite under the influence of ammonia, with migration of the reactive centre and formation of a phosphite anion containing a tervalent phosphorus atom‡:



followed by addition of the phosphite anion to the carbonyl compound:



after which the hydroxy-group is replaced by amino:

To verify this hypothesis, diethyl α-hydroxybenzylphosphonate, obtained by the condensation of diethyl phosphite with benzaldehyde in the presence of a basic catalyst under the conditions of Abramov's reaction [65], was converted by heating with alcoholic ammonia into diethyl α-aminobenzylphosphonate [66].

Another possibility, suggested by Fields [63], consists in the formation of an aminomethanol derivative R_2NCH_2OH as intermediate. Hellmann and Opitz [67] also regard this reaction as a typical α-aminoalkylation.

The first interpretation of the reaction mechanism is supported by its analogy with several well know reactions. In the field of amino-carboxylic acids such a reaction is Rodionov's synthesis—the interaction of aldehydes with ammonia and malonic acid [68]

$$RCHO + NH_3 + CH_2(COOH)_2 \rightarrow RCH_2(NH_2)CH_2COOH + H_2O + CO_2 .$$

In many reactions dialkyl phosphites resemble malonic and acetoacetic esters [69]. Since, however, hydrogen attached to the phosphorus atom plays the part of the reactive methylenic hydrogen, α-amino-phosphonic acids are formed in the present case, in contrast to Rodionov's synthesis (where β-amino-carboxylic acids are formed).

Another closely analogous reaction is Zelinskii's—the formation of amino-nitriles by the action of ammonium cyanide on aldehydes [70]—where the nucleophilic cyano-group is added to the carbonyl group to form a hydroxy-nitrile, which is converted into an amino-nitrile by the action of ammonia§:

$$RCH{=}O + CN^- \rightarrow RCH\langle_{CN}^{O^-} \rightarrow RCH_2\langle_{CN}^{OH} \xrightarrow{NH_3} RCH\langle_{CN}^{\overset{+}{N}H_3} + OH^- \rightleftarrows RCH\langle_{CN}^{NH_2} + H_2O .$$

Ammonium hydrogen sulphite also adds to aldehydes with the formation of α-amino-sulphonic acids [72,73]:

$$NH_4HSO_3 + RCHO \rightarrow RCH\langle_{SO_3H}^{NH_2} .$$

Finally, these reactions resemble the Mannich reaction, the mechanism of which has been vigorously discussed during recent years [67,74,75]. Thus phosphine, organic phosphines, and organic diphosphines react with formaldehyde and amines or with hydroxymethyl derivatives of amines under the conditions of the Mannich reaction to give the corresponding polyaminomethyl-phosphines and -diphosphines [76-79].

A common property of dialkyl phosphites, malonic ester, hydrocyanic acid, and sulphurous acid is their ability to give two series of derivatives. From this it might be supposed that the formation of amino-derivatives of the type $R.CHX.NH_2$ by the action of carbonyl compounds and ammonia is characteristic of all compounds HX which are weak acids and capable of reacting in two ways.

The above reaction was subsequently extended by the same workers to dialkyl thiophosphites [80], diaryl phosphites [81], arylphosphonous esters [64], and diarylphosphine oxides [82], compounds capable of diad tautomerism. The respective products were α-aminoalkylphosphonothioic esters, α-aminoalkylphenylphosphinic esters, and α-aminoalkyldiarylphosphine oxides

$$(RO)_2P(S)—\underset{NH_2}{C}—R'R'' \quad ; \quad \underset{C_6H_5}{RO}\rangle P(O)—\underset{NH_2}{C}R'R'' \quad ; \quad Ar_2P(O)—\underset{NH_2}{C}R'R'' .$$

This method has been developed by Moedritzer and Irani [83], who use phosphorous acid as the phosphorus component. In syntheses with formaldehyde, ammonia, and various amines in strongly acid medium they obtained good yields of a series of α-aminoalkyl-phosphonic and -polyphosphonic acids:

$$R_{3-n}NH_n + n\,CH_2O + n\,HP(O)(OH)_2 \xrightarrow{[H^+]} R_{3-n}N[CH_2P(O)(OH)_2]_n + n\,H_2O .$$

Advantages of this reaction are the absence of a stage in which esters are saponified and the ease with which the products can be isolated.

Just like the phosphorus component, the amine and carbonyl components can also be varied. Hence the condensation of amines and carbonyl compounds with phosphorus compounds can be regarded as the most general method for the synthesis of α-aminoalkylphosphonic acids.

Formaldehyde has been used as the carbonyl component, usually as paraformaldehyde [31,84-86] or 40% aqueous formalin [87-93]. Use has been made also of aliphatic [62,66,95,96], alicyclic [62,95], aromatic [61,63], and heterocyclic [97] aldehydes and ketones. Aliphatic ketones react most readily;

‡ It is probable that complete transfer of the proton does not occur here, but a strong hydrogen bond is formed, which promotes transfer of the proton in the second stage.

§ It is known that hydroxy-nitriles can be converted into amino-nitriles by the action of ammonia [71].

alicyclic and alkyl aryl ketones react with greater difficulty. Purely aromatic ketones (e.g. benzophenone) and aliphatic aldehydes give only low yields of amino-phosphonic esters[95,96].

The range of application of amines—ammonia[61,62,64,66,76,95,97], primary and secondary aliphatic amines[31,63,85,93,94,98], nitrogen heterocycles[31,90], and mono- and bis-hydroxyalkylamines[88]—is also immense.

The interaction of dialkyl phosphites and carbonyl compounds with polyamines yields polyaminebisalkylphosphonic acids, which possess several interesting properties (see Section III). The reaction has been studied on alkylene-diamines[84,89,99,100] and -polyamines containing heteroatoms in a chain of methylene groups[100-102]:

$$2\,(RO)_2PHO + 2\,R'COR'' + H_2NCH_2[CH_2{-}A{-}CH_2]_nCH_2NH_2 \xrightarrow[-H_2O]{}$$
$$\rightarrow (RO)_2P(O)C(R'R'')NHCH_2[CH_2{-}A{-}CH_2]_nCH_2NHC(R'R'')P(O)(OR)_2 \xrightarrow[H_2O]{H^+}$$
$$\rightarrow (HO)_2P(O)C(R'R'')NHCH_2[CH_2{-}A{-}CH_2]_nCH_2NHC(R'R'')P(O)(OH)_2$$

where R = CH_3, C_2H_5, C_4H_9, $CH_2C_6H_5$; R′ and R″ = H, CH_3, C_2H_5, C_6H_5; n = 0, 1; and A = CH_2, O, S, NH.

The present Reviewers and their coworkers have shown that alkylenediaminebisalkylphosphonic esters can be obtained in yields of around 70–80%. The optimum reaction conditions are stoichiometric proportions of the reactants, simultaneous addition of phosphorus and carbonyl components to the polyamine (to avoid side-reactions), and a definite reaction temperature (60°C).[100,103] Hydrolysis of the esters with hydrochloric acid results in several cases in the formation of dihydrochlorides of the acids of general formula

$$[(HO)_2P(O)C(R'R'')NHCH_2CH_2{-}A{-}CH_2CH_2NHC(R'R'')P(O)(OH)_2].2HCl.$$

These are converted into the free acids by treatment with silver oxide or an organic α-oxide[100,101].

It is noteworthy that the condensation of dialkyl phosphites and carbonyl compounds with alkylenediamines yields only diphosphonic acids, in contrast to the reaction of chloromethylphosphonic acid with alkylenediamines (see subsection 2), where mixtures are always obtained of di-, tri-, and tetra-phosphonic acids, the separation of which involves great difficulties.

Apart from the fact that alkylenediaminebisalkylphosphonic acids have been especially interesting complexones of the aminoalkylphosphonic class, the presence of secondary amino-groups enables them to be used to obtain more complicated complexing agents of the phosphonic–carboxylic type. Thus by carboxymethylating ethylenediaminebismethylphosphonic acid we obtained bis-dihydroxylphosphinylmethylethylenediaminediacetic acid[84]:

$$(HO)_2PCH_2NHCH_2CH_2NHCH_2P(OH)_2 \xrightarrow[\text{then HCl}]{NaCN,\ CH_2O,\ NaOH}$$
$$\rightarrow (HO)_2P(O)CH_2\diagdown\!\diagup N(CH_2CH_2N\diagup\!\diagdown CH_2P(O)(OH)_2)\diagdown\!\diagup CH_2COOH \cdot HOOCCH_2$$

Carboxymethylation of diethylenetriamine-*NN*″-bisisopropylphosphonic acid yields *NN*″-bis-(1-dihydroxyphosphinyl-1-methylethyl)diethylenetriamine-*N*′-acetic acid[104]:

$$(HO)_2P(O)C(CH_3)_2NHCH_2CH_2NHCH_2CH_2NHC(CH_3)_2P(O)(OH)_2 \xrightarrow{ClCH_2COOH}$$
$$\rightarrow (HO)_2P(O)C(CH_3)_2NHCH_2CH_2N(CH_2COOH)CH_2CH_2NHC(CH_3)_2P(O)(OH)_2 .$$

A related method is based on the addition of dialkyl (or diaryl) phosphites to Schiff bases, the latter obtained from carbonyl compounds and amines:

$$R{-}CO{-}R' + H_2NR'' \xrightarrow[-H_2O]{} R'\diagdown\!\diagup C{=}NR'' \xrightarrow{(R'''O)_2PHO} (R'''O)_2P(O)C(RR'){-}NHR''.$$

This method permits prior removal of water in the condensation, facilitating in some cases the isolation of the aminoalkylphosphonic esters. This procedure, suggested by Pudovik[105-107], has been applied mainly to aromatic carbonyl compounds and amines, because of the ease with which the corresponding Schiff bases can be obtained[108-112]. Kennedy and Ficken[113] employed this method for synthesising α-aminoalkylphosphonate polymers of the two types

$$\vdots\ \vdots$$
$$(CH_2CHCH_2O)_2P(O)CH(CH_3)NHC_6H_5 \text{ and } (C_6H_5O)_2P(O)CH(CH_3)NHCH_2C_6H_4CHCH_2 .$$
$$\vdots\ \vdots$$

The hydrolysis of the aminoalkylphosphonic esters obtained in this way has not been described, and only when hypophosphorous acid was used were the free acids obtained[114,115]:

$$RN{=}CHAr + H{-}P(H)(=O){-}OH \rightarrow HO{-}P(H)(=O){-}CH(Ar)NHR.$$

The interaction of phosphorous and hypophosphorous esters with alkoxyalkylamines or substituted methylenediamines yields respectively substituted aminoalkylphosphonic[91] and bisaminoalkylphosphinic[116] esters:

$$HP(O)(OR)_2 \xrightarrow{H_2NCH_2X} (C_2H_5)_2NCH_2P(O)(OR)_2$$
$$H_2P(O)OR \xrightarrow{H_2NCH_2X} [(C_2H_5)_2NCH_2]_2P(O)OR$$

where X = $N(C_2H_5)_2$, OCH_3, OC_2H_5. In the case of the lower ($< C_6$) hypophosphorous esters, a mixture of esters of the above two types is usually obtained.

Evdakov and his coworkers have shown that α-aminoalkylphosphonic esters can be formed also by the interaction of dialkyl *NN*-dialkylphosphoramidites with aliphatic and aromatic aldehydes and alicyclic ketones[117,118]:

$$(RO)_2PN(C_2H_5)_2 + R'COR'' \rightarrow (RO)_2P(O)C(R'R'')N(C_2H_5)_2 .$$

A detailed study of this reaction has been made by Hudson et al.[119], who have extended it to arylamides of diphenylphosphinous acid:

$$R_2PNHPh + PhCHO \rightleftharpoons R_2P{-}\overset{+}{N}HPh\ (\text{O{-}CHPh}) \rightleftharpoons R_2\overset{+}{P}H{-}NPh\ (\text{O{-}CHPh})$$
$$R_2\overset{+}{P}H{-}NPh\ (\text{O{-}CHPh}) \rightarrow R_2PO{-}CH(Ph){-}NHPh$$
$$R_2PO{-}CH(Ph){-}NHPh \rightarrow R_2PO^- + Ph\overset{+}{N}H{=}CHPh$$
$$R_2PHO + PhCH{=}NPh \rightarrow R_2P(O)CH(Ph)NHPh \leftarrow R_2PO^- + Ph\overset{+}{N}H{=}CHPh$$

III. COMPLEXING PROPERTIES

The first paper on the complexing properties of aminoalkylphosphonic acids was published in 1949 by Schwarzenbach et al.[41]. Seven years later communications appeared by Martell and his coworkers[47,120] on the potentiometric titration of these acids with metals, followed somewhat later by our own papers[84,99]. However, this early work did not reveal those interesting properties of aminoalkylphosphonic and especially polyaminepolyphosphonic acids which placed them among the most interesting and important of complexones. The most detailed studies of the complexing properties of phosphorylated polyamines have been made during recent years in the laboratories of the present Reviewers in the Institute of Organoelementary Compounds of the USSR Academy of Sciences and the Institute of Chemical Reagents and High-purity Chemicals.

Structural examination of organophosphorus complexones shows that they possess potentialities for complex formation similar to those of their carboxylic prototypes. These substances have the donor functions of the amine nitrogen atoms and the oxygen atoms of the phosphonic group, a tendency to form chelate rings, and the ability to adopt various conformations according to the configurational requirements of metal ions.

Tables 1 and 2 give the stability constants of the complexes for all the phosphorylated polyamines which have been studied up to the present, and also for comparison the stability constants of complexes of certain amino-carboxylic complexones. These data show that amino-alkylphosphonic acids are highly efficient complexing agents, in several cases not inferior to carboxylic complexones. However, in spite of the above similar prerequisites for complex formation, aminoalkylphosphonic acids possess a number of special features.

The specific character of the behaviour of organophosphorus complexones is primarily due to their increased number of donor atoms. The peculiarities of the stereochemistry of the PO_3 group also play an important part. Organophosphorus complexones differ from their carboxylic analogues in exhibiting—(1) preferential complex formation with cations of small atomic radius (beryllium, germanium, iron) and also with cations of large radius, such as the rare-earth elements, (2) diminished complex formation with the alkaline-earth metals, (3) an unusual stability sequence with transition metals, (4) the ability to form stable complexes in the acid pH range, and (5) the ability to form homo- and hetero-dinuclear complexes.

Henceforward in the text we have adopted for convenience the abbreviations for the names of the complexones listed in Table 3.

Table 1. Logarithms of stability constants for complexes of alkaline-earth and transition metals (for abbreviations for complexones see Table 3).

1. Acid Dissociation

Among the aminoalkylphosphonic acids which have been investigated, two main groups of substances can be separated, which give metal complexes comparable in stability with—and in some cases even surpassing—the corresponding complexes of amino-carboxylic acids. These groups comprise (1) alkylenepolyaminebis(tris, tetrakis, and pentakis)-alkylphosphonic acids and (2) mixed alkylenepolyaminepoly-alkylphosphonic–polyacetic acids.

From a study of the titration of aminoalkylphosphonic acids with dilute acids and alkalis, Chavane[121] and Schwarzenbach[41] showed that these substances had a betaine structure. This has since been confirmed by

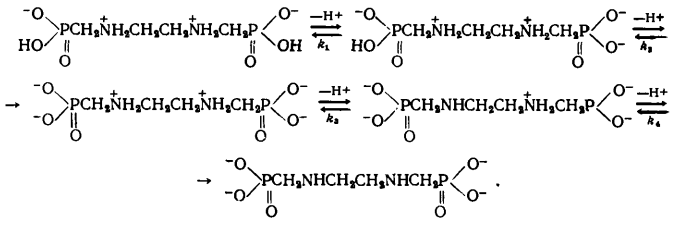
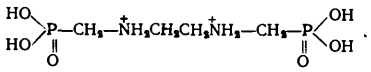
results for the infrared spectra[86] and by X-ray examination[122]. Recently Burpitt and Goodlett have shown[123] by means of nuclear magnetic resonance (n.m.r.) that several dimethyl esters of substituted α-aminoalkylphosphonic acids are also internal salts.

For the initial member in the first group of organophosphorus complexones—ethylenediaminebismethylphosphonic acid (EDBMP)[84,101]—the possible stages of dissociation can be represented, according to our results, by the equations



An analogous scheme of dissociation is probably applicable in the remaining cases. In strongly acid media the original betaine is able to take up two protons to form the doubly charged cation



Comparison of the dissociation constants of aminoalkylphosphonic acids of the first group (Table 4) and of analogous carboxylic acids reveals a difference in the properties of these substances. For example, aminoalkylphosphonic acids have values of the latter two dissociation constants,

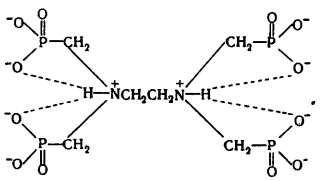
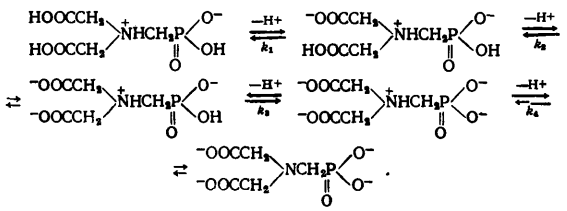
corresponding to elimination of the betaine protons, which are unusually large but differ relatively little from one another. This is observed especially clearly in the diphosphonic acids as the methylene chain linking the aminoalkylphosphonic groups becomes longer, when the difference in the latter two dissociation constants decreases to factors of $10^{1-0.5}$, which can be explained by the weakening of the inductive effect exerted by one $^+NH_2.C.PO_2^{2-}$ group on the other[101]. Introduction of a heteroatom—nitrogen, oxygen, or sulphur—into the methylene chain has no significant effect on the dissociation constants of the corresponding acids[100].

In the case of tri-, tetra-, and penta-phosphonic acids the decrease in repulsion between the two positively charged nitrogen atoms is probably due partly to the high charge on the anion and partly to electrostatic bonding (a weak hydrogen bond) of the betaine protons to the negatively charged oxygens of the phosphonic groups[48]:



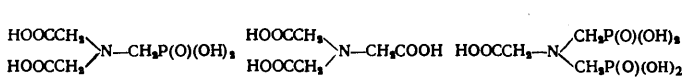
The dissociation constants of the mixed polyamine-polyphosphonic-polyacetic acids are given in Table 4. In view of the difference in basicity between carboxyl and phosphonic acid groups, it may be supposed that in this case the betaine structure is produced at the expense of the hydrogens of the latter groups. Further assignment of the individual dissociation constants of these acids to the successive elimination of carboxylic, the second phosphonic, and then the betaine protons enables the following dissociation scheme to be put forward[41,120,124,125]



2. Effect of Increase in Multidentate Character

It might have been expected that successive replacement of one, two, . . . , and finally all the carboxymethyl groups in polyamino-polycarboxylic acids by dihydroxyphosphinylalkyl groups would be accompanied by a corresponding regular change in the complexing properties of these substances. However, this is not observed.

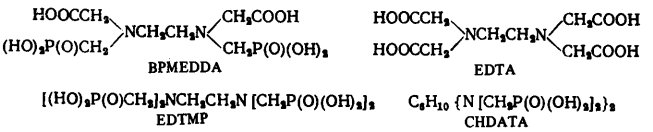
Whereas dihydroxyphosphinylmethylamine-*NN*-diacetic acid (PMADA) gives more stable complexes, both with alkaline-earth metals and with transition-metal ions, than does nitrilotriacetic acid (NTA)[41,120], bisdihydroxyphosphinylmethylaminoacetic acid (BPMAA) gives less stable complexes than does nitrilotriacetic acid throughout a comparable series of metals[48].



PMADA NTA BPMAA

Bisdihydroxyphosphinylmethylethylenediaminediacetic acid (BPMEDDA) forms with copper(II) and the rare-earth elements more stable complexes than does ethylenediaminetetra-acetic acid (EDTA)[124,125], while ethylenediaminetetrakismethylphosphonic acid (EDTMP)[48,126] and cyclohex-1,2-ylenediaminetetrakismethylphosphonic acid (CHDATMP)[49]¶ exhibit weaker complexing powers than do their carboxylic analogues—EDTA and CHDATA.

¶ The stability constants of the metal complexes of CHDATMP seem too low, since they have probably been calculated without regard to the hydrogen complexes [see subsection 3, below].

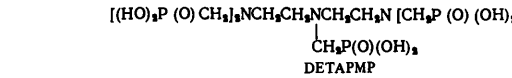


BPMEDDA EDTA

$[(HO)_2P(O)CH_2]_2NCH_2CH_2N[CH_2P(O)(OH)_2]_2$ $C_6H_{10}\{N[CH_2P(O)(OH)_2]_2\}_2$

EDTMP CHDATA

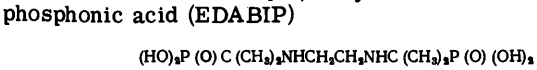
Moreover, the increase in the number of dihydroxyphosphinyl groups on passing from EDTMP to DETAPMP (diethylenetriaminepentakismethylphosphonic acid)



DETAPMP

somewhat diminishes the stability of the complexes formed with alkaline-earth and transition metals, only those with the rare-earth elements constituting an exception[126].

The opposite situation is found with polyaminediphosphonic acids: for example, ethylenediaminebisisopropylphosphonic acid (EDABIP)



EDABIP

not only surpasses in efficiency of complex formation its corresponding ethylenediaminediacetic acid (EDDA), but with copper(II) even surpasses EDTA[125].

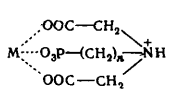
Thus the replacement of one carboxymethyl by a dihydroxylphosphinylalkyl group increases the complexing power of the compound, whereas the attachment of more than one of the latter groups to the same nitrogen atom diminishes the efficiency of complex formation. Martell and his coworkers[48] attribute this to the fact that, from steric considerations, two dihydroxyphosphinyl groups attached to one nitrogen atom cannot both take part in coordination, while their high negative charge still more impedes complex formation with cations bearing a low charge (2+). Therefore the conditions are more favourable to cations bearing a high charge. It is possible on the basis of this hypothesis to explain the high stability constants of the complexes formed by iron(III) with the compounds EDTMP, CHDATMP, and EDABIP[48,49,125] and by the rare-earth elements(III) with all the aminoalkylphosphonic acids investigated[124-127], and also the enhanced stability, even in comparison with trebly charged rare-earth elements, of the complexes of cerium(IV) with the compounds

where A = O, NH, S (OBEAIP, DETABIP, TBEAIP respectively)[100].

3. Hydrogen Complexes

A characteristic feature of organophosphorus complexones is their ability to form, besides the normal complexes, stable complexes with metal ions in the pH range preceding the dissociation of the betaine protons. These are termed "hydrogen" or "acid" complexes.

The existence of such complexes was established by Schwarzenbach et al.[41] for the complexes of aminoalkylphosphonic-diacetic acids with alkaline-earth metal ions. These workers attributed to the complexes the structure



and made special mention of the absence of a metal-nitrogen bond in such a complex.

It has since been shown[48,100,125,126] that all polyamine-polyphosphonic acids form in the acid pH range very stable hydrogen complexes with ions of transition metals and rare-earth elements, as well as with bismuth (III), arsenic(III), antimony(III), titanium(IV), tin(IV), and molybdenum(VI) (polarographic data)[128]. Even pentamethylenediaminebis-isopropylphosphonic acid (PMDABIP, A = CH_2), which is a weak complexing agent owing to the great distance between the 1-dihydroxyphosphinyl-1-methylethylamino-groups, nevertheless in the acid pH range gives complexes with rare-earth elements having stability constants[100] of the order of 10^5–10^8.

It is especially noteworthy that in several cases the acid complexes of phosphorylated polyamines are comparable in stability with the normal complexes of amino-carboxylic analogues. Thus rare-earth elements form with EDABIP acid complexes of the same order of stability as the normal complexes they form with EDDA.

Further, unlike the complexes of amino-polycarboxylic acids, the normal complexes of EDTMP and DETAPMP (ML) and their mono-, di-, and tri-protonated complexes (MHL, MH_2L, and MH_3L) are closely similar in stability[126].

Elements having a coordination number of 8 (rare-earth elements, thorium) form stable hydrogen complexes having the composition $M(H_2L)_2$.[125]

The hydrogen complexes formed by beryllium with aminepolyphosphonic acids will be discussed below.

4. Dependence of Stability of Complexes on Position of Metal in Periodic Table

(*a*) Alkaline-earth metal complexes. Amino-alkyl-mono- and -di-phosphonic acids form relatively unstable complexes with alkaline-earth metals, their stability constants not usually exceeding 100.[100,125] With acids containing four or five dihydroxyphosphinyl groups (EDTMP, CHDATMP, DETAPMP), however, the stability constants increase to $10^3(Sr^{2+})$–$10^8(Mg^{2+},Ca^{2+})$.[48,49,126]

The introduction of carboxymethyl groups tends to promote complex formation with alkaline-earth metals, and the complexes of mixed aminoalkylphosphonic–acetic acids with these metals are only slightly less stable than those of the corresponding carboxylic analogues[41,48,100,120,124,125].

(*b*) Transition-metal complexes. The introduction of one dihydroxyphosphinylmethyl group into the ethylenediamine (EDA) molecule—giving ethylenediaminemethylphosphonic acid $NH_2CH_2CH_2NHCH_2PO(OH)_2$ (EDAMP)[129]—increases the complexing power towards transition metals, but not so much (Table 5) as might have been expected from the probable closing of two chelate rings.

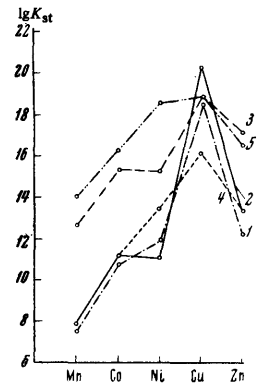
With metal ions whose 3*d*-level is almost complete, aminepolyphosphonic acids form complexes comparable in stability with those of the corresponding aminepolyacetic acids. Irving and Williams[130] established experimentally the sequence

$$Mn<Fe<Co<Ni<Cu>Zn$$

confirmed by Yatsimirskii[131] on the basis of crystal-field theory, for the stability of complexes formed by bivalent transition metals with polyamines and most of the analogues of EDTA. Although, as the accompanying diagram shows, the general variation in stability of the complexes is about the same for these compounds and for phosphorylated derivatives of polyamines, different curves are obtained in the two cases for the variation in the logarithm of the stability constant of the complex with the atomic number of the transition metal. With the phosphorylated derivatives of polyamines the nickel complexes are usually less stable than those of cobalt and zinc, differing in stability constants in the latter case always by factors of 10^2–10^3.

Table 5. Logarithms of stability constants of transition-metal complexes (metal : ligand ratio = 1 : 1).

Metal	EDAMP	EDA
Mn^{2+}	5.16	2.63
Co^{2+}	7.95	5.89
Ni^{2+}	9.62	7.66
Cu^{2+}	~14	10.66
Cd^{2+}	7.60	5.47



Graphical dependence of logarithm of stability constant for transition-metal complexes on the atomic number of the element for the complexones:
1) EDBMP; *2*) EDABIP; *3*) EDTMP; *4*) EDDA; *5*)EDTA.

An especially noteworthy feature is the considerably greater difference than usual between the stability constants of corresponding complexonates of copper and of other transition metals. The stability constants of the copper complexes of the alkylenepolyaminebisalkylphosphonic acids EDABIP, OBEAIP, and DETABIP vary between 10^{18} and 10^{20}, exceeding those of the nickel complexes by factors of 10^8–10^9,[100,125] which is quite exceptional in comparison with the complexes of polyamino-polycarboxylic acids. Whereas most transition metals form less stable complexes with the acids investigated than with EDTA, the copper(II) complex of EDABIP is more stable than the corresponding EDTA complex by a factor of 10^2.[125]

Unusual behaviour is shown by EDABIP towards iron(III). By forming a soluble complex in the pH range in which the betaine proton undergoes dissociation, iron (in fivefold excess) is not precipitated even in the presence of ten equivalents of alkali. The solution changes colour from pale yellow to wine red, gradually passing into a colloidal sol, and then into a gel[125]. This can probably be explained

by the formation in solution of a polycyclic chelate compound of polymeric type, in which cross-linkage occurs through hydroxide ions.

Stable complexes with iron(III) are formed also by EDTMP [48] and CHDATMP. [49] The extraordinarily high stability of the iron(III) complex of the latter acid in comparison with the complexes formed by other metals enabled Banks and Yerick to titrate iron in the presence of a large variety of cations (alkaline-earth metals, Al^{3+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Cu^{2+}, Ti^{4+}, Cr^{3+}, Be^{2+}, etc.)[49].

(*c*) Rare-earth metal complexes. The potential ability of aminoalkylphosphonic acids to increase their multidentate character by means of the oxygen atoms of the dihydroxyphosphinyl groups favours their formation of complexes with the rare-earth metals, which are known to be characterised by a high coordination capacity and a strong affinity for oxygen.

Alkylenepolyaminebisalkylphosphonic acids form complexes with rare-earth metals whose stability constants exceed by factors of 10^3–10^4 those for the corresponding complexes of EDDA [100,125,127]. In the case of EDBMP, which forms water-insoluble complexes, this difference would apparently be still larger, in view of the fact that even the acid complexes of this complexone with rare-earth metals are more stable than the normal complexes of EDDA. [125]

A still stronger complexing action on rare-earth metals was exhibited by EDTMP. Although in the acid pH range (up to five equivalents of alkali) it forms water-insoluble complexes having the composition $M_4(H_4L)_3$, the normal complexes, which are soluble in water at higher pH values, are far more stable than the corresponding complexes of EDTA, and are not inferior in stability to the complexes of diethylenetriaminepenta-acetic acid (DETAPA), which is regarded as the "champion" for complex formation with rare-earth metals [126]. It has been shown also that, in the presence of excess of a rare-earth element, EDTMP forms in the alkaline range soluble polynuclear complexes in which the proportions of metal to complexone are 2 : 1, whereas DETAPMP forms 3 : 1 complexes [126].

Note must be taken also of the masking power for the rare-earth metals exhibited by all the organophosphorus complexones studied [132].

(*d*) Beryllium(II) complexes. Complex formation with beryllium is especially interesting. It has been established that beryllium forms stable complexes with organophosphorus complexones, and this is most specific of the latter, distinguishing them fundamentally from their carboxylic analogues.

Potentiometric titration of mixtures of beryllium(II) and EDABIP (H_4L) in various proportions shows that, in the range preceding titration of the betaine hydrogens, homodinuclear complexes Be_2H_2L and intermediate mononuclear complexes BeH_2L are formed in solution [133].

Neither increasing the distance between the dihydroxyphosphinylalkyl groups as in PMDABIP nor replacing the middle methylene group in the latter by oxygen (OBEAIP) or sulphur(TBEAIP) makes any fundamental change in complex formation with beryllium compared with EDABIP. [134]

When carboxymethyl groups are introduced into an organophosphorus complexone, as in BPMEDDA, complexes are formed with beryllium only after two protons have been titrated. Both this and the fact that the corresponding BeH_2L and Be_2H_2L complexes are closely similar in stability to the corresponding complexes of the above diphosphonic acids probably indicate that the carboxymethyl groups are not involved in the coordination of beryllium [134]. It is interesting that this complexone masks beryllium from precipitation by hydroxides, which constitutes the first case of the masking of beryllium by a complexone [132].

The stability constants of the beryllium complexes, calculated for the monomeric compounds, are given, together with the solubility products of the insoluble complexes, in Table 6.

Table 6. Logarithms of stability constants and solubility products K_s for beryllium(II) complexes.

Complexone	BeH_2L		Be_2H_2L	
	K_s	$\lg K_{st}$	K_s	$\lg K_{st}$
EDBMP	$(2\pm1)\cdot10^{-12}$	8.76	$(3\pm1)\cdot10^{-14}$	11.4
EDABIP	—	7.65	—	11.39
PMDABIP	—	6.15	—	11.21
OBEAIP	—	7.34	—	12.46
TBEAIP	—	7.15	—	11.97
BPMEDDA	—	7.15	$(3\pm1)\cdot10^{-12}$	11.64

In the pH range corresponding to titration of the betaine hydrogens in the free acids, hydroxo-complexes BeH_2LOH and $Be_2H_2L(OH)_2$ are formed in all the cases mentioned, no complexes containing a beryllium–nitrogen bond being produced. This is confirmed also by the identity of the titration curves for beryllium with methyl-, chloromethyl-, and aminoisopropyl-phosphonic acids [135] and the high stability constants of the beryllium complexes of polymethylenediphosphonic acids not containing nitrogen atoms in the polymethylene chain (Table 7) [136].

Table 7. Solubility product and logarithms of stability constants for beryllium(II) complexes of alkylenediphosphonic acids.

Acid	BeL		Be_2L	
	K_s	$\lg K_{st}$	K_s	$\lg K_{st}$
Methylenediphosphonic	—	8.82	—	19.15
Hexamethylenediphosphonic	$(5\pm2)\cdot10^{-13}$	6.31	$(6.6\pm4.0)\cdot10^{-19}$	15.5

The fact that not all the donor atoms of a ligand take part in complex formation makes possible the coordination of another cation. In fact the formation of bimetallic heteronuclear complexes has been established in the polarographic investigation of complicated beryllium complexonate–metal ion (Ca^{2+}, Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}) systems [133]. This is confirmed also by the correlation (Table 8) between the dependence of the logarithm of the stability constant of the complex ML and that of the pH at which beryllium is precipitated from a polyheteronuclear complex on the atomic number of the second metal present in the complex. A rough calculation showed [133] that the stability constants of the polynuclear complexes exceed those of the complexes ML by factors of 10^2–10^3 (Table 8).

5. Effect of Heteroatoms on the Stability Sequence of Metal Complexes

The presence in a complexone molecule of heteroatoms—nitrogen, oxygen, sulphur—which tend to coordinate with metals, produces some selectivity with respect to certain cations. Thus for the alkaline-earth metals the relative order of stability is O > N > S, for transition metals containing almost complete *d*-orbitals it is N > S > O, and for rare-earth elements it is O > N > S.

Table 8. Logarithms of stability constants for complexes of transition metals with OBEAIP and pH for hydrolysis of beryllium from the corresponding polynuclear complexes.

Complex	M^{2+}	$\lg K_{st}$ ML	pH of hydrolysis
Be^{2+}	—	—	6.3
$BeH_2L(OH)_2$	—	—	8.3
$BeML(OH)_2$	Ca	5.1	8.2—8.3
	Mn	10.19	8.1—8.2
	Fe	10.90	7.9—8.1
	Co	11.44	7.7—7.9
	Ni	13.13	7.5—7.7
	Cu	18.33	6.4—6.6
	Zn	13.11	7.4—7.6

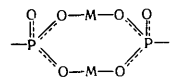
Complex formation by the phosphonic analogues of such complexones has been investigated on alkylenepolyaminebisisopropylphosphonic acids containing oxygen, a secondary amino-group, and sulphur as heteroatom (OBEAIP, DETABIP, and TBEAIP), and also on PMDABIP), in which a methylene group which is definitely incapable of complex formation acts as a quasi-heteroatom [100]. With the phosphorylated derivatives of polyamines as well, the heteroatoms were shown to coordinate to metal ions, but their effect is not so great as, and the stability sequence of the complexonates is somewhat different from, those with the polyamino-polycarboxylic acids: for the alkaline-earth metals the order is O > S > N, for the transition metals N > S > O, and for the rare-earth metals it is N > O > S. In the case of DETABIP (nitrogen as heteroatom) a large difference has also been established in the stability of the complexes from element to element in the rare-earth metals, and hydrogen complexes of more than one type are formed by the elements from gadolinium onwards.

6. Structure of the Complexes

There are still very few studies of the mechanism of coordination of metal ions by phosphorylated polyamine derivatives, the reasons for the specific character of their action, the role of the phosphonic group in complex formation, and other problems.

The structure of complexes of aminepolyphosphonic acids in which coordination of the metal by nitrogen atoms is absent (hydrogen complexes, beryllium complexes, etc.) can be explained by two alternative hypotheses—(1) formation of a four-membered ring

in which the metal ion is coordinated by two of the three oxygen atoms of the phosphonate group, and (2) formation of an eight-membered ring



in which two metal ions are coordinated with four oxygen atoms of two phosphonate groups. Let us examine these postulates in greater detail, noting that neither structure is to be regarded as universally applicable to all metal ions.

1. Four-membered rings were once regarded as unstable and of rare occurrence in the chemistry of complex compounds. However, recent investigations have shown [141-145] that such rings can be formed with metal ions not only by sulphonate, carbonate, and dithiocarbonate groups but also by nitrate, trifluoroacetate, and triazen groups. It has been concluded from these investigations that polyatomic ligands in which two chemically equivalent atoms are situated closer together than are a pair of mutually independent atoms exhibit a tendency to operate through both equivalent atoms, in such a way that the middle position of this pair is located approximately at a vertex of one of the usual coordination polyhedra (octahedron or tetrahedron) [146].

In relation to phosphonate groupings this situation could be interpreted in terms of coordination of the metal ion by two oxygen atoms in each phosphonate group, in such a way that the ligand field would have a roughly tetragonal (octahedral or tetrahedral) configuration; the oxygen atoms, however, do not lie at vertices of the corresponding polyhedron, but form a new distorted polyhedron in which the coordination number of the metal is higher than usual. It is quite difficult to say anything *a priori* concerning the possible spatial configurations which are produced in this case, probably a dodecahedron or distorted antiprism type of configuration. However, it is not excluded that in certain cases the two oxygen atoms of the phosphonate group will occupy two coordination sites in the usual way [147-149].

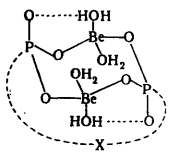
The suggested mechanism [150] provides an explanation not only for the existence and stability of the hydrogen complexes but also for several other features of complex formation by organophosphorus complexones. It suggests that, in normal complexes in which hydrogen atoms are involved in coordination, structures can be produced in several cases having additional four-membered rings, together with the usual structures in which only one oxygen atom of each phosphonate group takes part in coordination, similarly to carboxyl oxygen [151-154]. It is possible that the enhanced stability of complexes formed by phosphorylated polyamines with copper(II), lead(II), and the rare-earth metals is due to the formation of such structures strengthened by additional rings.

A very likely possibility is the formation of complexes, whose structure contains four-membered rings the phosphonate oxygens of which lie at the corners of polyhedra, with metals having a large covalent radius, e.g. uranyl UO_2^{2+} and zirconium(IV). [155,156] In fact it has recently been observed that phosphorylated polyamines exhibit special affinity for uranium in particular [157].

2. The hypothesis of eight-membered bridging rings of the type indicated above has been used by Block and his coworkers to explain the structure of the polymeric tetrahedral complexes formed by Co^{2+}, Zn^{2+}, Be^{2+}, and Cr^{3+} with dimethyl-, diphenyl-, and methylphenyl-phosphinic acids R_2POOH. [158-160] The probable existence of such structures has been confirmed by infrared spectroscopy [161-163]

and X-ray examination[164] for compounds such as the polymeric $\{[R_2PO_2]_nCo\}_n$ and the dimeric $[(C_6H_5)_2PO_2]_2 \cdot [Co(CH_3COCHCOCH_3)_2]$ [sic†].

Kabachnik et al. have suggested this type of structure for the beryllium complexes of alkylenepolyphosphonic and alkylenepolyaminebisalkylphosphonic acids[134,136]. The improved stability of such complexes in acid medium is attributed to stabilisation of the molecule as a whole by internal hydrogen bonds formed by coordinated water molecules and the phosphonate oxygen atoms in a similar manner to that suggested for phosphate complexes[165] and ammines of metal acetates[166,167]. Thus the complex Be_2H_2L (where H_4L = EDABIP, OBEAIP, TBEAIP) is probably built up in such a way that each beryllium ion is coordinated by two oxygen atoms from different phosphonate groups, while the hydrogen bonds form two additional six-membered rings:



Calculations show that the stabilising hydrogen bond should be strong, the O...O distance being around 2.5–2.6 Å.

The above discussion shows that investigation of the efficient and highly selective group of organophosphorus complexones is still far from complete. A series of questions should be studied. Thus the mechanism of complex formation by the phosphonate group and the nature of the selectivity of its action remain obscure. More complete data must be obtained on the dependence of the complexing power of aminepolyphosphonic acids on the position of a metal ion in the Periodic System, and the reasons for the departure from the order of the Irving–Williams series explained.

However, several practical applications are already being planned for this group of complexones. Because of their selective action, phosphorylated polyamines can be successfully used for the fractional determination of cations present in difficultly separable combinations. The great difference in stability of complexes of polyaminepolyphosphonic acids with transition metals and with rare-earth metals, and also the formation with the rare earths of soluble and insoluble complexes exhibiting a quite large difference in stability constants, not only enable the rare-earth elements to be separated from transition metals but also hold out the promise of separating pairs of rare earths lying close together. Complex formation by aminoalkylphosphonic acids in acid medium opens up wide possibilities in work with readily hydrolysable salts. The high stability constants of the complexes formed by several of the above complexones with copper(II) and iron(III) make them promising both for the treatment of copper and iron chloroses of plants in agriculture and for cleaning and passivating surfaces in power engineering equipment[168].

Monoesters of α-anilinobenzylphosphonic acid can be used for the extraction of metals from aqueous solutions[169]. Patents have been taken out for the use of aminoalkylphosphonic and aminoalkylphosphonous acids to soften water[23,24], to prevent the decomposition of peroxy-compounds (by combining with copper(II) ions, which catalyse the oxidation), to remove rust marks from metal structures[24], for the chelation of rare-earth and heavy metals[35,36], to prevent the precipitation of aluminium hydroxide during the etching of aluminium and its alloys[170], as nematocides and soil fungicides[60], as additives to lubricating oils[45,94], etc.

IV. BIOLOGICAL PROPERTIES

Until recently information on the biological properties of aminoalkylphosphonic acids was confined to a few disconnected publications concerned with the search for bacteriostatic preparations.

Although aminoalkylphosphonic acids can be regarded as phosphorus analogues of amino-carboxylic acids, which form part of vegetable and animal organisms, for a long time nothing was known of their occurrence in Nature. It was only in 1959 that Horiguchi and Kandatsu were able[171-172] to isolate from *Rumen protozoa* 2-aminoethylphosphonic acid $NH_2CH_2CH_2PO_3H_2$, which was given the name ciliatin‡. This was the first example of the occurrence in biological materials of a compound containing a carbon-phosphorus bond. Ciliatin and its ester with glycerol have since been detected also in bacteria of the type *Tetrahymena*[173-175], in the sea-anemone *Anthopleura elegantissima*[176], and in *Metridium dianthus*[177]. The crystal structure of ciliatin has been elucidated by Okaya[122] by X-ray structural analysis. A mechanism for the production of ciliatin in biological systems has been suggested recently by Segal[178].

In the course of the investigation of aminoarylphosphonic acids as possible analogues of sulphonamide preparations it was found that phosphanilic (*p*-aminophenylphosphonic) acid and some of its analogues possess bactericidal properties[179-184], while aminomethylphosphonic acid suppresses tobacco mosaic virus[185]. This last compound and several other aminoalkylphosphonic acids can retard the growth of the silkworm and the chick embryo, although they are not natural metabolites of these organisms[185]. It has been found also that in protein synthesis aminomethylphosphonic acid diminishes the inclusion of methionine[186]. No fundamental practical advance was made on these lines of investigation.

A systematic study of the biological properties of aminoalkylphosphonic acids was undertaken in connection with the synthesis of polyaminepolyalkylphosphonic acids and the elucidation of the specific character of their complexing properties, when possibilities were opened up for using substances of this type to treat metal poisoning in humans. Broad biological investigations of organophosphorus complexones are being conducted at the present time in the Institute of Industrial Hygiene and Occupational Diseases of the USSR Academy of Medical Sciences by one of the present Reviewers and his collaborators. It has been found[187] that derivatives of 1-amino-1-methylethylphosphonic acid, applied parenterally as the sodium salts, are tolerated in large doses by animals (mice, rats, guinea-pigs, and rabbits). Thus LD_{min} of sodium ethylenediaminebisisopropylphosphonate (the corresponding medicinal preparation is "phosphicin") is 6 g kg^{-1} for rats and mice. The absence of hypocalcaemia among the animals' symptoms, as a consequence of the low stability constant of the calcium complex, has enabled the sodium salts of these acids to be used even in large doses. Prolonged repeated injections of phosphicin did not affect the increase in weight of animals, the threshold of nervomuscular excitability to electrical stimuli, or the blood pressure, nor did they disturb the functioning of the

† The reference quoted deals with such polymeric compounds of chromium(III) which contain a $(CrOPO)_2$ bridge structure (Ed. of Translation).

‡ This name does not appear to be used in the reports in English on this material (Ed. of Translation).

kidneys or the ability of the liver to render noxious substances harmless. In animals no changes were observed in the peripheral blood. Phosphicin did not change the activity of hydrolases acting on ester bonds (EC.3. 1,.

Experiments with ^{14}C-phosphicin showed that the preparation was completely eliminated two days after parenteral introduction. After one day the urine shows its maximum activity, but a considerable proportion of the preparation is eliminated by the intestines. After ^{14}C-phosphicin has been introduced *per os*, a larger proportion of it is excreted by the intestines [188]. The effect of phosphicin on the metabolism of calcium has been examined in detail. Experiments with ^{45}Ca showed that no danger of hypocalcaemia arose on the introduction of phosphicin [188]. This distinguishes phosphicin fundamentally from polyaminepolyacetic acids, which cannot be applied as their sodium salts owing to the hypocalcaemia which they produce [189]. The relative instability of the calcium complexonates is an important property of polyaminediphosphonic acids, since, as a consequence of the high concentration of calcium in the blood, this cation competes, for a position in the complex, with any metal introduced into the organism.

The effectiveness of amino-polycarboxylic acids in the organism is determined not only by the stability of the complexonate of the metal to be eliminated but also by the ability of this metal to displace calcium from the complex. The position of equilibrium in the process of complex formation in the organism therefore depends on the relative stability constants of the complexonates of the metal and of calcium. This situation is of no fundamental significance with polyaminediphosphonic acids because of the relative instability of their calcium complexes, which has been the chief condition for the use of organophosphorus complexones in biology and medicine.

Experimental investigations have shown the usefulness of employing phosphicin to accelerate the elimination of lead from the organism [190]. It is found that lead is excreted not only by the kidneys but also to a considerable extent by the intestines, which has allowed this preparation to be applied more widely not only in the wards but perhaps also under outpatient conditions for medicinal and prophylactic purposes.

The ability of aminepolyphosphonic acids to form stable complexes with copper increases the elimination of this metal from the organism, and opens up the possibility of using them in the treatment of hepatocerebral dystrophy [191].

The formation of stable water-soluble complexes with beryllium has suggested the use of organophosphorus complexones to accelerate the elimination of this element from the organism [191-193]. Whereas amino-polycarboxylic acids have no effect on the course of acute poisoning by salts of beryllium or on its elimination from the organism, aminepolyphosphonic acids—in particular phosphicin, diethylenetriamine-*NN*″-bisisopropylphosphonic acid, and oxabisethylaminoisopropylphosphonic acid—protect animals from death on introduction of absolute lethal doses of beryllium chloride. The animals do not develop the dystrophic and necrobiotic changes in the internal organs which are characteristic of beryllium poisoning [192]. The protective effect of the complexones is explained by the formation in the organism of a non-toxic water-soluble beryllium complex which is rapidly eliminated from the organism. Experiments with $^{7}BeCl_2$ have shown that the increased excretion of beryllium from the organism results in a decrease in its content in the bones, liver, kidneys, spleen, and lungs [191-193]. The thoroughness of the eliminating effect of organophosphorus complexones is indicated also by the normalisation of the metabolic disturbances caused by beryllium. Thus phosphorylated polyamines reactivate in considerable measure the orthophosphate monoester phosphohydrolase (EC. 3.1.3.1.), and bilirubinaemia is diminished [191]. The action of phosphicin is strengthened by the simultaneous introduction of sodium nitrate, pyridoxin, and glucuronic acid [192]. The effectiveness of organophosphorus complexones in eliminating beryllium from the organism makes them promising as drugs and preventives in beryllosis, one of the most serious occupational diseases.

There are indications that diethylenetriaminepentakismethylphosphonic acid may be effective in relation to uranium [157].

The partial replacement by phosphonate groups of the carboxylate groups in a complexone molecule has been shown to improve the effectiveness of the compound obtained. Thus the introduction of bisdihydroxyphosphinylmethylethylenediaminediacetic acid into animals causes enhanced elimination of yttrium-91 and cerium-144. However, the use of compounds in which carboxylate groups have been completely replaced by phosphonate groups led to a greater accumulation of these radioactive elements in the organism than did the amino-polycarboxylic acids [194].

Data on the influence of complexing compounds on the elimination of trace elements from the organism and on the state of biocomplexes are of both theoretical and practical interest [195-198]. The possibility of complexones, including organophosphorus complexones, acting in this way is due to the high stability constants of the complexonates of copper, iron, cobalt, zinc, etc. Aminepolyphosphonic acids, when introduced into the organism, combine with trace elements and thus enter into competition with the biocomplexes of the organism, the result of this interaction depending on the strength of bonding of the trace elements with the biocomplexes. If a complexone acts on a metal whose link in the biocomplex is labile, as occurs in glycylglycinehydrolase (EC.3.4.3.1), the metal may be removed and the functions of the enzyme disturbed. In the case of the true metal enzymes, such as cytochrome $C-O_2$ oxidoreductase (EC. 1.9.3.1), and cytochrome C, the complex does not break down, as is indicated by the preservation of the haem structure [191].

Structure of Organic Oxygen Compounds of Sulphur

Yu.A.Kolesnik and V.V.Kozlov

The nature of the sulphur-oxygen bond, the geometry of molecules of the types XYSO, $XYSO_2$, XSOOH, and XSO_2OH, and the character of the intramolecular interactions in these compounds are discussed. Apart from the σ-bond between sulphur and oxygen, interaction obviously occurs by means of the $3d$-orbital of sulphur and the $2p$-orbital of oxygen ($2p$-$3d$ hybridisation). The interaction of a sulphinyl group with the substituents X and Y is not conjugation, but has an induction and electron-acceptor character.

In all oxygen compounds of sulphur the sulphonyl group has a tetrahedral structure with the sulphur atom at the centre of the tetrahedron, in good agreement both with the chemical properties and with the assignment of the modes of vibration of sulphur-oxygen bonds in infrared and Raman spectra. The position ν_{SO} of the stretching bands is affected only by change in the character and length of the sulphur-oxygen bond with variation in the electronegativity of the substituents X and Y or on passing from ionised to covalent compounds. These properties of the ν_{SO} absorption bands are explained by the highly specific character of the sulphur-oxygen vibrations. The bibliography contains 139 references.

I. INTRODUCTION

The sulphonation of organic compounds is widely used in the manufacture of many industrial products. The introduction of a sulpho-group SO_2OH into an organic molecule confers on the resulting compound several specific properties.

The chemical properties of sulpho-derivatives have been investigated in fair detail. Far less work has been done on the structure of the sulphonic acids and their derivatives, in particular on the way in which the SO_2R group interacts intramolecularly with the remainder of the molecule.

Much remains obscure in the structure of the sulpho-group itself, e.g. the character of the bonds formed by the sulphur atom, the part played by the d-orbitals of the sulphur atom in the formation of bonds, the stereochemistry of the sulpho-group, and the interaction between the sulpho-group and the rest of the molecule. There is as yet no generally accepted view on the type of electronic interaction occurring in the XSOY and XSO_2Y systems, where Y represents an organic radical and X = OH, OAlk, OAr, NR′R″, Hal, etc. Is conjugation present between the SO_2R group and the organic (in particular aromatic) radical or is this interaction different in character? Do the character and the intensity of this interaction change on passing to various derivatives of sulphonic acids? All the above questions have recently been attracting increasing attention from research workers. A study of the physicochemical properties of sulpho-compounds should obviously give an answer to these questions.

The present review covers work on the nature of sulphur–oxygen bonds and the infrared spectroscopy of oxygen compounds of sulphur.

II. GROUPS CONTAINING A SULPHUR–OXYGEN BOND

(a) Sulphur–Oxygen Bonds

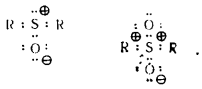
Organic compounds containing sulphur–oxygen bonds are classified as sulphoxides XSOY, sulphones XSO_2Y, sulphinic acids XSOOH, sulphonic acids XSO_2OH, and also various derivatives thereof (salts, halogeno- and amino-derivatives, esters, etc.). For a long time the nature of the sulphur–oxygen bond in these compounds was a subject of discussion, and this question cannot be regarded as finally settled even at the present time.

It can probably be supposed that the simple σ-bond between sulphur and oxygen is always supplemented by further interaction[1]. This additional bonding was shown by Cruickshank[2] to consist in interaction between the $2p$-orbital of oxygen and one of the $3d$-orbitals of the sulphur atom. In his view this interaction was universal, and could be considered as π-bonding.

It was assumed[3-5] that the sulphur–oxygen bond was a covalent double bond. The valency of sulphur would then be 4 in sulphoxides, and 6 in sulphones. This would require that the octet rule must be assumed to break down, i.e. that sulphur will be surrounded by 10 electrons in a sulphoxide, and by 12 electrons in a sulphone:

Other authors[5-7] have attributed a polar coordinate single bond to these compounds. They assumed that oxygen

was bound to sulphur only by one pair of electrons, both of which had previously belonged to the sulphur:



It was supposed that complete loss of an electron by the sulphur atom occurred, i.e. that the bond became ionic in character. In other words, the sulphur–oxygen bond was interpreted as a covalent single bond plus an ionic bond, i.e. a so called "semipolar bond". This view was still used by Suter[8] in 1948 in discussing the dipole moments of diphenyl sulphones. Such a view still exists even now[9], with the reservation that the sulphur–oxygen bond is a resonance hybrid of two structures, but nevertheless the true state is closer to a semipolar double bond than to a covalent double bond:

In some experimental papers[4,10] such a concept of the sulphur–oxygen bonds is utilised to demonstrate the chemical properties of the compounds under investigation.

In several recent papers[11–16], however, doubt has been cast on the presence of a semipolar bond. This work has been based on exact measurements of parameters of the sulphinyl group (interatomic distances, bond angles, force constants, spectral data, and certain chemical properties). A summary table of bond lengths, bond orders, force constants, and bond angles has been given in a recent paper[15].

For various compounds the length of the sulphur–oxygen bond, measured by different methods[12,17,18], varies over the range 1.39–1.55 Å. This is shorter than the length of a simple covalent bond (1.70 Å) and in many compounds is shorter than a double bond (1.49 Å), all calculated from the covalent radii for sulphur–oxygen.

For most unionised oxygen compounds of sulphur–aliphatic and aromatic sulphoxides and sulphones, sulphonic acids and their esters, and also compounds such as the halogen derivatives of sulphurous and sulphuric acids—the length of the sulphur–oxygen bond is 1.42–1.47 Å (SO_2Cl_2 1.43,[9] SO_2 1.43,[12] $(CH_3)_2SO$ 1.47,[19] and SO_2F_2 1.405 Å[20,21]). This value increases sharply on passing to ions: thus for the ions $S_2O_6^{2-}$, $S_3O_6^{2-}$, SO_4^{2-}, and $S_2O_5^{2-}$ it varies from 1.46 ($S_2O_5^{2-}$) to 1.50 Å (for the remaining ions)[9,15,20–23]. For the ion HSO_4^- the length of the S–O(H) bond is given as 1.54 Å, and that of the S=O bond as 1.46 Å.[23–25] However, crystallographic measurements for the HSO_4^- ion in $NaHSO_4.H_2O$ gave corresponding values of S–O(H) 2.613 Å and S–O 1.450 Å.[26] The maximum sulphur–oxygen bond length of 1.66 Å has been found in the compound SF_5OOSF_5,[27] and 1.64 Å in SF_5OF.[28] The probable explanation of this is that, under the influence of five fluorine atoms, which interact vigorously with the 3*d*-orbitals of sulphur, the latter take practically no part in π-bonding with the 2*p*-orbitals of oxygen[29].

The shortest sulphur–oxygen bonds are found in the molecules SO_2F_2 (1.404 Å [21]) and SOF_2 (1.412 Å [30]). No attempts were made to explain this fact, but obviously no doubt attaches to the accuracy of these results, for it has subsequently been shown[15] that the shortest sulphur–oxygen distances correspond to the highest sulphur–oxygen stretching vibrations and force constants.

Cruickshank[2] considers that the sp^3d^2 state of sulphur is actually realised in the compound SO_2F_2, where the sulphur has six octahedral σ-orbitals, while the sulphur–oxygen bond is a true double bond. The same paper shows that the order of the sulphur–oxygen bonds always exceeds 1.50 for ions (SO_3^{2-} 1.50, $CH_3SO_3^-$ 1.58, FSO_3^- 1.67). This value increases considerably for unionised compounds (CH_3SO_2OH 1.81, CH_3SO_2F 1.88, CH_3OSO_2F 1.97), which is explained[2] by the lower electronegativity of the alkyl substituents.

Force constants of the sulphur–oxygen bond have been calculated[12,31,32] for several sulphones from the spectra. Subsequent investigations have shown poor agreement between these results and more recent calculations[15]. For example, Hungarian workers[12] obtained force constants of $(14.69–14.99) \times 10^{-5}$ dyn cm^{-1} for sulphones. However, Gillespie, Robinson, et al.[15,33–35] have obtained results giving considerably smaller values (in 10^{-5} dyn cm^{-1}—SO_4^{2-} 7.1, SO_3^{2-} 3.86, HSO_4^- 8.26, H_2SO_4 8.1, 10.29, $(CH_3)_2SO_2$ 9.48, SOF_2 10.95, SO_2F_2 12.05). Values given in several papers[2,9,12,15,36] for the O–S–O bond angle usually exceed the normal tetrahedral angle (109°). The lowest value (96°) is shown by the SO_3^{2-} ion. In other ions this parameter increases ($CH_3SO_3^-$ 106°, $ClSO_3^-$ 114°). In non-ionic compounds the angle approaches 120° and above (FSO_2OH 118°, CH_3OSO_2F 120°, CH_3SO_2F 122°, $(C_6H_5)_2SO_2$ 131°).

From a comparison of numerous experimental data on the lengths, orders, and force constants of sulphur–oxygen bonds, Gillespie and Robinson conclude[15] that a direct relationship exists between bond length and force constant: with increase in the sulphur–oxygen bond length the force constant decreases. The relationship can be expressed by the equation $\lg k_{SO} = -7.41 \lg r_{SO} + 7.15$.

A similar relationship exists between bond order and force constant: with increase in the multiplicity of the bond from 1.5 to 2.0 the force constant doubles.

A non-linear relation was obtained between bond order and bond length. It is not direct[2], but is represented by a curve recalling that for bond multiplicity as a function of bond length (for the carbon–carbon bond[20]).

According to Cruickshank and Robinson[24] the constants characterising the sulphur–oxygen bond are linked by the relations

$$k_{SO} \cdot r_{SO}^{7.4} = 1.41 \times 10^7$$

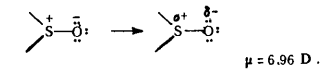
$$n_{SO} = 1.11 \times 10^{-6} \cdot k_{SO} + 0.7$$

$$r_{SO} = 1.70 - \frac{0.30}{1 + 0.46\left[\frac{2-n}{n-1}\right]}$$

$$r_{SO} = 1.69 - 0.40(n_{SO} - 1)$$

where k_{SO} is the force constant of the sulphur–oxygen bond, r_{SO} the interatomic sulphur–oxygen distance, $r_{SO}^{7.4}$ the corresponding distance for a force constant of 7.4, and n_{SO} the order of the sulphur–oxygen bond. Calculations based on these equations show satisfactory agreement with experimental values.

Calculation by means of the equation[9] for a semipolar double bond gives for the dipole moments of sulphur–oxygen bonds the value $\mu = 4.80 \times 1.45 = 6.96$ D (where 4.80×10^{-10} is the electrostatic charge on the electron, and 1.45 the experimental sulphur–oxygen distance in sulphones). This value (6.96 D) should correspond to the charge distribution



$\mu = 6.96$ D.

However, dipole moments of sulphur–oxygen bonds calculated from experimental data for certain sulphones[37] and also calculated by vector analysis[38] are considerably smaller (2.2–2.9 D), which probably indicates that a double bond is present between sulphur and oxygen.

The increase in dipole moments in the sequence

$CH_3SO_2CH_3$	$C_6H_5SO_2CH_3$	$C_6H_5SO_2C_6H_5$	p-$NH_2C_6H_4SO_2CH_3$
4.46D	4.73D	5.1D	6.09D

may constitute evidence that donor–acceptor interaction occurs between the sulphonyl group and the substituent, the sulphur acting as acceptor of electrons[13].

Several papers contain data on the dipole moments of various sulphonyl derivatives—sulphonic acids[39], sulphonyl chlorides[40,41], sulphinic acids[42].

Some workers conclude[2,9,15] that a simple σ-bond between sulphur and oxygen is supplemented by interaction between a $2p$-orbital of the oxygen atom and one of the $3d$-orbitals of the sulphur atom. This $2p-3d$ hybridisation, which is in general extremely weak, always develops, and can be regarded as π-bonding[43]. The bonding may be considerably strengthened if the electron affinity of the sulphur is increased by interaction with a strongly electronegative atom (e.g. fluorine), and also if the sulphur acquires a formal positive charge (as e.g. in a sulphonyl group). It is postulated also that the $3d$-orbitals undergo considerable compression in this type of interaction, which, of course, increases the energy of the bond.

In other words, the sulphur–oxygen bond can be regarded as in considerable measure a double bond with the electron cloud displaced towards the oxygen.

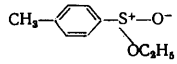
In view of the nature of the $3d$-orbitals, their overlapping with $2p$-orbitals of oxygen does not require exact agreement between the angles, as in $2p-2p$ bonding.

Similar conclusions are reached from molecular-orbital calculations of the molecules SO_2 and SO_3 and the ions SO_3^-, SO_3^{2-}, SO_4^{2-}, and $S_2O_3^{2-}$.[44,45]

(b) Geometry of the Groups XSOY, XSO_2Y, XSOOH, and XSO_2OH

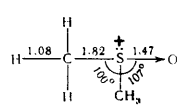
As has been shown above, it can now be regarded as proved that all cases of bond formation by sulphur involve its $3d$-orbitals. The contribution of d-orbital interaction may vary depending on the atom with which the sulphur is combined. If this atom is oxygen, the state of the sulphur atom will be s^2p^3d if surrounded by a decet of electrons, and sp^3d^2 if surrounded by a dodecet[46]. The first of these configurations corresponds to a pyramidal structure, and the second to an octahedral structure[20].

However, only one example—the sulphur hexafluoride molecule—is known of an octahedral configuration of sulphur. Such a configuration has not been found with the oxygen compounds of sulphur. Thus the study of sulphoxides, begun in 1925 by Phillips[47] on aromatic sulphoxides—ethyl toluene-p-sulphinate



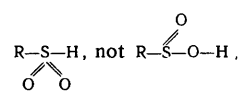
and then the work of Karrer et al.[48] showed the presence of optical isomerism in these compounds. Consequently sulphur in a sulphoxide must have a stable pyramidal structure, and may become a centre of asymmetry if all the substituents are different.

A crystallographic study of dimethyl sulphoxide[49] showed it actually to have a pyramidal structure, with the parameters



It may be supposed that in this case the nature of the bonds linking the sulphur atom will not influence the configuration. Actually, if all three bonds are semipolar σ-bonds, they will have a pyramidal p^3-distribution (the lone pair of electrons remaining in the $3s$-orbital of the sulphur[14]). If, however, the sulphur–oxygen bond is regarded as a covalent double π-bond, the bonds formed by $2p-3d$ interaction will also have a pyramidal arrangement, as Kucsman has shown[50].

Study of the vibrational spectra and of the dipole moments of sulphinic acids[42] led to the conclusion that they had the structure



In an SO_2H group sulphur is surrounded by four atoms, and the structure of the group is tetrahedral.

In sulphones, too, the structure of sulphur is close to a tetrahedron, but with considerable distortion of the bond angles. Thus for diphenyl sulphone Suter[8] gives 90° as the angle between the planes of the rings. Other workers[12,51] constructed a model of diphenyl sulphone by replacing one oxygen atom in an SO_3 group by two benzene rings, and found that one each of the two C–S and S=O bonds lies in the plane of one ring, and the other in that of the other ring. The planes of the rings are perpendicular, and the O–S–O angle is 120°. It is pointed out[12], however, that the angles may vary: for example, the O–S–O angle considerably exceeds the tetrahedral angle owing to the electrostatic repulsion between the oxygen atoms. It is assumed also that the C–S–C angle differs from 90°†. A recent work[9] gives the structure illustrated in Fig. 1 for bis-p-bromophenyl sulphone.

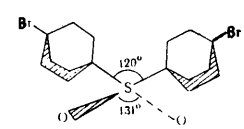


Figure 1. Diagram of molecule of bis-p-bromophenyl sulphone.

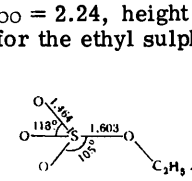
The sulpho-group in sulphonic acids and their derivatives has been assumed to have a tetrahedral structure[2,12,39,40,46,53]. However, the parameters of this pyramid are indicated only by Gur'yanova[40] for benzenesulphonyl chloride (interatomic distances), by Babaeva et al.[54] for the ion SO_3^- in Na_2SO_3 ($r_{SO} = 1.39$, $r_{OO} = 2.24$, height of pyramid 0.51 Å), and by Cruickshank[2] for the ethyl sulphate ion in potassium ethyl sulphate



Thus a tetrahedral structure, with the sulphur atom at the centre of the tetrahedron, is now generally accepted for the sulpho-group. With the polarity of the sulphur–oxygen bonds taken into account, such a structure for the

† More detailed information on the bond angles in these compounds will be found in Ref. 52.

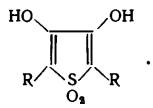
sulpho-group agrees well with the chemical properties[16], and also with the assignment of modes of vibration of sulphur–oxygen bonds in the Raman and infrared spectra[55].

(*c*) Nature of Interaction with Substituents

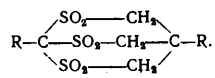
In view of the non-planar structure of the sulpho-group, it is apparently impossible to expect interaction involving conjugation of the sulpho-group with substituents. Nevertheless, it may be supposed that some interaction involving $2p-3d$ orbitals of the sulphur–oxygen bond may occur, provided that they are conveniently disposed in relation to unsaturated bonds of the substituents. There should also be some interaction of substituents transmitted through the sulphur atoms of the sulpho-group, without involving sulphur–oxygen bonds.

Both types of interaction actually occur. Thus Leandri et al.[14] showed, on the basis of the ultraviolet spectra over the range 200–300 nm for a large number of sulphoxides, that the sulphur atom is in this case in the $3sp^3$ state with one lone pair ($3s$). But besides this, weak conjugation is observed between this pair and the π-shell of unsaturated substituents. This interaction is responsible for extremely weak additional π-bonding in the sulphur–carbon(substituent) direction.

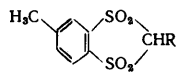
Moffitt showed[11,13] that conjugation along sulphur–oxygen bonds in sulphones is quite strongly developed when not prevented by the geometry of the molecule, e.g. in



This effect appears as a lowering of the sulphonyl frequencies in the infrared spectra and as a bathochromic shift of the bands in the ultraviolet spectra[56]. Such conjugation is also supported by results obtained by Doering[57–59], who studied the stabilising effect of the sulphonyl group on the carbanion derived from a bicyclic trisulphone of the type

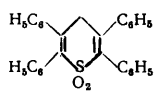


Koch and Moffitt[13] consider also that conjugation can occur in sulphones by means of a $2p$-orbital of a carbon atom (substituent), provided that these orbitals lie in the plane of the carbon–sulphur–carbon bonds. However, this is not consistent with results obtained by Jaffé[60] and Breslow[61], who studied pK_a values for the enolate ions of disulphonyl esters of the type

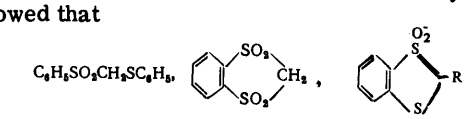


and showed that, owing to the geometrical structure of such compounds, when R = $COOC_2H_5$ [57–59] only conjugation of the type suggested by Moffitt[13] is possible. They established that there is no substantial conjugation between the $2p$-orbitals of the carbon atom and the hybrid orbitals of the sulphone.

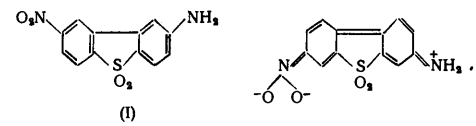
Suld and Price[62] synthesised compounds of the type



in which the "thiabenzene" ring was, in their opinion, conjugated (aromatic). This was not confirmed by Breslow[63], who showed that



have the same acidity, so that the anion is not stabilised by cyclic conjugation: i.e. it is not aromatic. Weak transmission of a conjugation effect through the sulphonyl group is suggested, even if the two rings are coplanar, by a comparison of the ultraviolet spectra of the two sulphones[9]



(I)

In compound (I) the effect of conjugation is transmitted through the sulphonyl group, whereas in the second compound it is transmitted away from this group. The ultraviolet spectrum of the second compound differs very greatly from those of (I) and of the unsubstituted sulphone.

Weak interaction of the sulphonyl group in alkyl phenyl and diphenyl sulphones is indicated also by other work[4,13,36,64–66], in which it was noted that interaction in *para*-substituted aromatic sulphones is strengthened by the introduction of electron-donor substituents. The explanation given was that the formal positive charge on the sulphur was responsible for certain of its electron-acceptor properties. The presence of a positive charge on the sulphur atom in dimethyl sulphoxide is suggested by recent spectroscopic results[67].

An assessment of the strength of interaction of the sulphonyl group from the Hammett σ-parameters[68] showed that this group possessed very little capacity for conjugation.

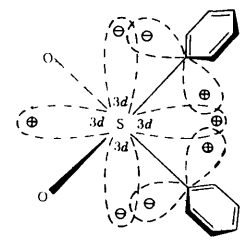


Figure 2. Scheme of electronic interaction due to $3d$-orbitals of the sulphur atom in diphenyl sulphone.

Assessing the possibility of interaction between the phenyl rings in diphenyl sulphone by means of the $3d$-orbitals of sulphur, i.e. without involving the sulphur–oxygen bonds, Price[9] points out that such interaction is quite real (Fig. 2); the two benzene rings may be non-coplanar[69]. As is evident from Fig. 2, the unsaturated orbitals of the two benzene rings—or more precisely the $2p$-orbitals of the carbon atoms—supply electrons to the free $3d$-orbitals of the sulphur, without involving the sulphur–oxygen bonds. The energy of such bonding will be slight.

In studies of the nature and strength of interaction by the sulpho-group in sulphonic acids[10,12] the authors write that "the sulpho-group (SO_2OH) does not interact with

strongly conjugated systems, such as, for example, benzene rings". This conclusion was reached from a study of the ultraviolet spectra of benzesulphonic acid. Comparison of the spectra of this acid with those of nitrobenzene, aniline, and benzoic acid showed that the SO_2OH group produces a far weaker bathochromic effect than do the nitro-, amino-, and carboxy-groups.

The vibrational structure of the absorption band is fairly well preserved in the ultraviolet spectra of substituted benzenesulphonic acids[10,64]. The authors consider that there is no conjugation between the sulpho-group and the ring, but that the sulphur exerts an electron-acceptor effect. This is demonstrated by the enhanced tendency to acylation of the amino-hydrogen atoms in the *p*-aminobenzenesulphonate ion. This occurs because the oxygen atoms of the sulpho-group in this ion carry a greater negative charge, while the positive charge on the sulphur diminishes. As a consequence, the sulphur shows less tendency to draw electrons out of the ring, which in turn weakens the displacement of the lone pair of electrons towards the ring.

To elucidate the character of the interaction between the SO_2R group and an aromatic system much information could be obtained by determining the substituent constants for the SO_2R group[70,71]. Exner[71] gives values of the induction constants σ_{ind} for a *p*-SO_2R group (SO_2O^- 0.25, SO_2NH_2 0.46, $SO_2OC_2H_5$ 0.63, SO_2Cl 0.86). It might be thought, however, that the induction constants do not reflect the actual character of the interaction, since the SO_2O^- and SO_2R groups (R = OAlk, NH_2, Hal) differ not only in the strength but also in the character of the interaction with the π-electron system of an aromatic radical.

From the above discussion it can obviously be assumed that interaction between a sulpho-group and a substituent is inductive and of electron-acceptor character rather than in the nature of conjugation. The strength of this interaction is comparatively slight. On passing to derivatives of sulphonic acids (chlorides, amides, esters) this interaction is considerably strengthened.

III. INFRARED SPECTRA OF OXYGEN COMPOUNDS OF SULPHUR

Study of the vibrational spectra of the oxygen compounds of sulphur was begun comparatively recently[18,72], at the end of the 1940s and the beginning of the 1950s. A considerable number of the papers known at the present time are still descriptive in character, and only during recent years have attempts been made to link the results of absorption spectroscopy with the structure and the properties of the oxygen compounds of sulphur. By no means all work undertaken with this aim was successful, obviously because the authors based their arguments on analogies with the carbonyl group[18]. These analogies (effect of substituents, participation in conjugation, effect of solvent) were unable, of course, to explain peculiarities observed in the infrared spectra of sulphinyl compounds, owing to the fundamental difference between these two groups both in symmetry and in electronic structure. It is now possible to link certain general features of the infrared spectra with the stereochemistry of the sulphinyl group, the nature of the substituent groups, the effect of the solvent, etc.

1. Appearance of Sulphur–Oxygen Bond in Infrared Spectra

Sulphur–oxygen bonds give strong bands in the infrared spectrum, the number of bands depending on the number of oxygen atoms attached to the sulphur. Thus the compounds XSOY give one band due to sulphur–oxygen stretching vibrations, while compounds of the type XSO_2Y give two bands. Furthermore, covalent compounds differ from ionised compounds in the position of the bands. In this way it is possible in principle to distinguish by means of the infrared spectrum the groups $\diagup$SO, $\diagdown$$SO_2$, and SO_3^-. This fact can be easily explained by considering the stereochemistry of the groups XSOY and XSO_2Y from the viewpoint of the possible vibrations of atoms in these groups. The stereochemistry of sulphur and the sulphonyl group has been discussed in the preceding Section. Here we consider only papers in which the authors discuss spatial structure directly from the viewpoint of possible modes of vibration.

The earlier work showed[18,72] that the infrared spectra of sulphoxides contain one strong band, which from its position could be assigned to a sulphur–oxygen stretching vibration (by analogy with sulphur monoxide[73]). It has since been shown[14,74] that the sulphoxide group has a quasi-tetrahedral structure with p^3d or sp^3d hybridisation. As is evident from Fig. 3, the site of one of the sulphur bonds is occupied by the orbital of the lone pair of electrons of the sulphur, and as a consequence the trigonal pyramid is extended to a tetrahedron. Such a structure, containing one oxygen atom, should, of course, have one sulphur–oxygen stretching vibration. O'Loane concluded[75] that the symmetry of the XSOY group should be *C*.

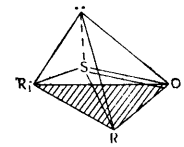

Figure 3. Structure of R_2SO group.

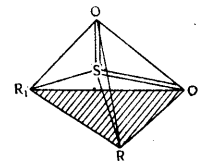

Figure 4. Structure of R_2SO_2 group

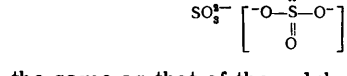
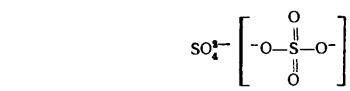
Discussion of the structure of the molecules XSO_2Y (see preceding Section) led to the conclusion that the sulphonyl group should be tetrahedral[74,76,77] (Fig. 4) or close thereto[78] both in covalent and in ionic compounds. According to Robinson[34] the spatial structure of the ion



will be the same as that of the sulphate ion



except that the position of one double bond is occupied in the sulphite ion by the lone pair of electrons of the sulphur. Consequently the modes of vibration of such ions will be identical.

These modes of vibration have been examined[79] with SO_2F_2 and the ion $CH_3OSO_2^-$ as examples[50]. The SO_2F_2 molecule has two planes of symmetry[80], one containing the two oxygen atoms, and the other the two fluorine atoms[77] (Fig. 5).

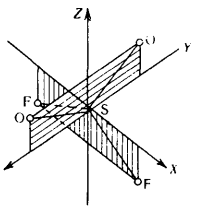


Figure 5. Diagram of SO_2F_2 molecule.

Assignment of all frequencies among types of vibrations has been made also for the simple molecules SO_3,[81] $SO_2(OH)_2$,[82,83] SO_2Cl_2,[78] and also SO_2F_2 and SO_2FCl.[84] An attempt to calculate the molecules SO_2Cl_2 and SO_2F_2 [77] was unsuccessful, for the frequencies calculated for the latter molecule did not agree with experiment. The symmetry of the group XSO_2Y is universally accepted as C_{2v},[79,80,82] and the sulphur–oxygen vibrations in such a molecule should comprise two stretching vibrations (symmetric and antisymmetric) and three deformation vibrations (twisting oscillations of sulphur–oxygen are forbidden in the infrared spectra[79]). In all a molecule having C_{2v} symmetry should describe nine normal vibrations[77], distributed among four types of symmetry:

$$C_{2v} = 4a(\nu_1; \nu_2; \nu_3; \nu_4) + a_2(\nu_5) + 2b_1(\nu_6; \nu_7) + 2b_2(\nu_8; \nu_9).$$

(*a*) Sulphur–oxygen stretching bands. Table 1[85] gives the sulphur–oxygen stretching frequencies in compounds of the type XSOY. The scatter in the results of different workers for each class of compounds does not exceed ±5 cm^{-1} from the value indicated in Table 1. It has been shown above that compounds XSO_2Y are characterised by bands due to antisymmetric and symmetric sulphur–oxygen stretching vibrations. Results for these compounds are listed in Table 2, set out in the same manner[85] as for the compounds XSOY. It is seen from Tables 1 and 2 that reliable experimental data are not available for all compounds, while certain classes of compounds have not been studied at all.

From a study of the effect of the immediate environment of an atom X in the groups $-X\overset{O}{\underset{O}{=}}$ on the X=O bonds Bellamy[86] concluded that, by analogy with carbonyl compounds[87], there should be a correlation here between the positions of the absorption bands due to the various bonds forming this group. Although it had been shown somewhat earlier, with nitro-compounds as example[88], that no satisfactory relation of such a kind is observed in these compounds, Bellamy[86] explained this by the presence of interaction between carbon–nitrogen stretching vibrations and ν_{NO_2} symmetric vibrations; furthermore, steric interactions are also possible between a substituent X and an oxygen atom in the nitro-group. Bellamy chose for investigation the compounds RSO_2R' (sulphones) and other compounds XSO_2Y (taken from Refs. 89–91). From these data a graph was plotted of the relative positions of the sulphur–oxygen stretching bands. Fig. 6 shows that the bands due to antisymmetric and symmetric sulphur–oxygen vibrations are arranged in two fairly clustered groups. The slight scatter in the values may be caused by the fact that not all the substances were examined under identical conditions, most of them being in solution, but several in the vapour state.

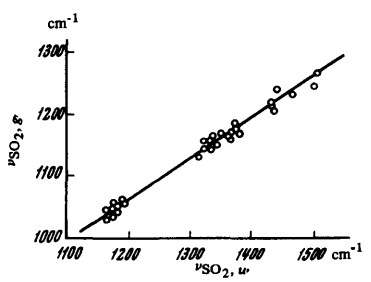

Figure 6. Relative positions of absorption bands due to symmetric and antisymmetric sulphur–oxygen stretching vibrations.

Somewhat later Robinson showed[92] that the positions of $\nu_{SO_2,g}$ and $\nu_{SO_2,u}$ are fully consistent with this relationship in other compounds of the type XSO_2Y, the ions XSO_3^- and SO_4^{2-}, and also in those cases in which the sulphonyl group is located in a ring or a chain. This correlation proved

to be very useful, since, if the position of one band in the infrared spectrum is known, the other can be found without difficulty. For this purpose the formula $\nu_u = 1.470$, $\nu_g = 359$ was proposed[86].

It has since proved possible to work either with the position of only one band[93] or with the half-sum of the bands $\frac{1}{2}(\nu_u + \nu_g)$‡, since this quantity is practically constant for all compounds[27,94]. The constancy of this parameter probably indicates that there is no or only very weak interaction between the sulphur–oxygen bonds in the compounds XSO_2Y.[15]

No systematic investigation was made into the shape or width of the sulphur–oxygen stretching bands. There are merely indications that these bands are usually symmetrical[95,96]. The band due to antisymmetric sulphur–oxygen stretching vibrations in compounds XSO_2Y is almost always broad and is often split into several maxima[97,98]. The band due to symmetric vibrations appears as a single peak (except in the case of $RSO_2NR'R''$ [99]), which is very convenient for the determination of intensities[100].

(*b*) Sulphur–oxygen deformation vibrations. Information on other modes of vibration of sulphur–oxygen bonds is still more scanty than that on the stretching vibrations, and is often less reliable. No systematic searches for these vibrations have been made. As has been shown above, among nine normal vibrations in a molecule X_2SO_2 there should be four deformation vibrations involving the sulphur–oxygen bonds—ν_3 (A_1) scissor, ν_7 (B_1) rocking, ν_9 (B_2) rocking, and ν_5 (A_2) twisting.

Table 3 shows that the majority of compounds investigated are various sulphonyl chlorides; there are far fewer representatives of sulphonic acids and their derivatives or of ions. The frequency ranges are 500–600 cm^{-1} for acid halides, 775–900 cm^{-1} for sulphonic acids and their esters, and 530–670 cm^{-1} for various ions. It is not yet possible to draw any definite conclusions from available data, either on the exact value of δ_{SO} nor, still less, on the influence of various factors on them.

Table 3. Position of bands due to deformation vibrations δ_{SO}.

* Small differences in frequency are observed with liquid and gaseous specimens.

** For compounds of the type $R(SO_2Cl)_2$ the authors indicate that the bands are split into two.

(*c*) Other bands in the spectra of compounds XSOY and XSO_2Y. Published information on the presence of other vibrations involving sulphur–oxygen bonds in the infrared spectra of oxygen compounds of sulphur is extremely scanty, and it all relates to sulphonyl chlorides. Thus for benzenesulphonyl chloride a band has been found at 800 cm^{-1} and assigned to vibrations of the S–OR group[103]. Bands at 407 or 413 cm^{-1} [78] in the $HOSO_2$. .Cl molecule and a band at 412 cm^{-1} in the $HOSO_2OH$ molecule[107] are assigned[107] to the S–OH group.

With compounds XSO_2Y a band of moderate intensity is often observed in the region of 1100 cm^{-1}. The assignment of this band is still a matter for discussion. This band in the ion SO_4^{2-} in aqueous solution and in the solid state (at 1104 and 1108 cm^{-1} respectively) is attributed by Herzberg[73] to one of the main skeletal vibrations of the tetrahedron. In sulphates $MSO_4.nH_2O$ it is located at 1105–1090 cm^{-1}.[108,109]

This band is almost always present in covalent compounds. It has frequencies of 1063–1072 cm^{-1} in propanesulphonic acid and its anhydride[110]. In sulphinic acids Detoni and Hadzi[102] found it at 1000 cm^{-1} and ascribed it to sulphur–oxygen oscillations in the appropriate structures. Their results indicate that this band is more intense in the esters than in the acids themselves. The weakening of intensity and some lowering of its frequency in the free acids are explained by intermolecular hydrogen bonding.

Study of aromatic sulphonyl chlorides showed[76,98,103] the presence of a band of moderate intensity in the range 1095–1099 cm^{-1}. It was regarded as characteristic of an aromatic chlorosulphonyl group ($ArSO_2Cl$). It has been suggested[91,111] that this band may belong either to sulphur–nitrogen vibrations in sulphonamides§ or to the first overtone of sulphonyl deformation vibrations, and it may also be due to planar carbon–hydrogen deformation vibrations.

Detoni and Hadzi[98] showed that a band always appeared at 1060–1100 cm^{-1} in a large number of compounds comprising sulphonic acids (other than ethanesulphonic acid), their esters, chlorides, and amides. This band was therefore regarded as the first overtone of an O–SO deformation vibration, analogous to the overtone of OSO in SO_2Cl.[80]

Bellamy[115], who detected this band in diphenyl sulphoxide at 1096 cm^{-1}, studied its displacements under the influence of the solvent. He assigned this band to vibrations of a phenyl ring, and explained its displacement on passing to polar solvents by the presence of Fermi resonance.

‡ This was first suggested in 1949.[18]

§ In some investigations of the infrared spectra of aromatic sulphonyl chlorides, however, this band was not observed [112,113]. Tosilini[114] assigned the frequency 829–910 cm^{-1} in compounds $RSO_2N:CH.R'$ to vibration of the sulphur–nitrogen bond.

Some part of the polar character of the sulphur–oxygen bonds is then transferred to absorption by an aromatic ring. This is supported by the fact that, in a strongly polar solvent, where the sulphur–oxygen bands undergo the greatest shifts, the intensity of the 1096 cm^{-1} band drops sharply.

Thus it is evidently still premature to draw final conclusions on the assignment of the 1100 cm^{-1} band.

2. Factors affecting Position of Sulphur–Oxygen Stretching Bands

The geometry of the groups enclosing the sulphur–oxygen bonds is of decisive importance among the various factors influencing the position of bands due to stretching vibrations of these bonds. As has been shown above, the stereochemistry of sulphur in various valency states leads to a tetrahedral or nearly tetrahedral structure for both XSOY and XSO_2Y compounds. It can therefore be assumed that the influence of both substituents and other factors on the position of these stretching bands is explained by the same causes in both classes of compounds. We shall therefore discuss all the information on the various factors for the two classes of compounds together. However, it is useful to consider covalent compounds separately from ionic compounds, since the sulphur–oxygen frequencies in the latter are far less sensitive to the various factors.

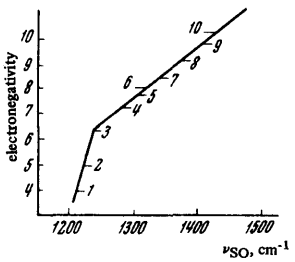

Figure 7. Correlation of electronegativity of substituents with position of sulphur–oxygen stretching bands in compounds R_2SO and R_2SO_2:
1) $(RO)_2SO$; *2*) ROSOCl; *3*) $SOCl_2$; *4*) $(RO)_2SO_2$; *5*) RSO_2OR; *6*) SOF_2; *7*) RSO_2; *8*) RSO_2Cl; *9*) SO_2Cl_2; *10*) RSO_2F.

A. Covalent Compounds

A systematic study of the influence of substituents on the position of sulphur–oxygen stretching bands must probably be regarded as starting with a paper by Bellamy and Williams[86]. On the basis of a few published data[90] and their own experimental work they showed that symmetric and antisymmetric vibrations of sulphur–oxygen bonds in compounds RSO_2R' depend on the nature of the substituent groups.

Below we shall examine the position of sulphur–oxygen stretching bands as a function of various constants of the substituents X and Y, and also the effect of the solvent.

(*a*) Effect of substituents

Electronegativity of substituents. A relation between the position of the ν_{SO_2} frequencies and the electronegativity of the substituents was first shown by Szmant and Emerson[93]. Their results (Fig. 7) indicate that the frequencies of the sulphur–oxygen bonds increase with increase in the electronegativity of the substituent Y in compounds CH_3SOY and CH_3SO_2Y (for compounds containing a sulphonyl group they plotted the antisymmetric bands along the horizontal axis, and the effective electronegativity according to Kagaraise's data[116] along the vertical axis). It is seen from Fig. 7 that the sulphonyl group is far more sensitive to variation in the electronegativity of the substituent than is the sulphoxide group $\diagdown S{-}O \diagup$.

Robinson[92] showed that, in a large number of compounds, increase in the electronegativity of the substituents is accompanied by a shift in the antisymmetric and symmetric sulphur–oxygen bands to higher frequencies (Table 4).

Table 4. Position of ν_{SO_2} bands in compounds XSO_2Y.

Group	Type of compounds	ν_{SO_2}, cm^{-1}	
		symmetric	antisymmetric
C—SO_2—F	sulphonyl fluorides	1203—1210	1401—1412
C—SO_2—Cl	sulphonyl chlorides	1169—1185	1365—1390
C—SO_2—O	sulphonic acids and esters	1165—1185	1360—1375
C—SO_2—N	sulphonamides	1152—1169	1336—1358
C—SO_2—S	thiosulphonates	1144—1154	1331—1342
C—SO_2—C	sulphones	1136—1160	1307—1334
O—SO_2—F; F—SO_2—F etc. HSO_3F		1230—1260	1445—1510
O—SO_2—Cl; $HOSO_2Cl$ etc. $S_2O_5Cl_2$		1205—1225	1408—1452
O—SO_2—O	covalent sulphates	1137—1195	1390—1415
N—SO_2—N	sulphamides	1163	1350

Thus a linear relation exists between these two parameters, the rise in the frequency ν_{SO} corresponding exactly with the increase in the electronegativity of the substituent:

$$F > OF > CF_3 > OR \simeq OH > Cl \simeq \simeq CCl_3 > SR \simeq NH_2 > Ar > R.$$

This sequence reproduces in essentials Pauling's electronegativity series[117]. The highest value of sulphur–oxygen stretching vibrations has probably been found[118] for the compound SF_5OOSF_5.

Aliphatic, aromatic, and conjugated substituents X and Y. The replacement of aliphatic by aromatic substituents in sulphoxides produces a considerable drop in the frequency ν_{SO} in non-polar solvents[96] (cm^{-1}):

CH_3SOCH_3	1069
$C_6H_5CH_2SOCH_2C_6H_5$	1056
$C_6H_5SOCH_2C_6H_5$	1054
$C_6H_5SOCH_3$	1055
$C_6H_5SOC_6H_5$	1052

Contrary to the views of Bellamy[85], the compounds XSO_2Y exhibit several differences in the position of absorption frequencies between diaryl and dialkyl sulphones. This is readily noticeable in the spectra of sulphones, but is far less readily seen in the spectra of other compounds[119] (Table 5). From Table 5 it is seen that, if the sulphonyl group is linked with two alkyl radicals, the symmetric frequencies ν_{SO_2} lie in the range 1136–1145 cm^{-1}, while in the diaryl or alkyl aryl derivatives this band has been displaced to the range 1150–1160 cm^{-1}. The antisymmetric stretching band is less sensitive, lying in both cases in the range 1312–1334 cm^{-1}.

Conjugated substituents somewhat lower the frequencies of both bands (Table 5), although not always; in the compounds $RSO_2N{:}CH.R'$ the frequencies of the sulphonyl group remained practically constant whatever the substituents R and R'.

A study[93] of the cyclic sulphites $[C]_n$ $S{=}O$ showed that the position of the bands was almost independent of whether the ring contained five, six, or seven carbon atoms.

Table 5. Effect of nature of substituent on position of ν_{SO_2} bands.

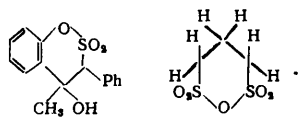
Later work has shown that the position of sulphur–oxygen stretching bands is independent of the size of the ring also in the compounds[124,110]



The infrared spectra of alkane-1-sulphonates from C_1 to C_{13} indicated no dependence of the frequency ν_{SO_2} on the length of the carbon chain. Thus the symmetric sulphur–oxygen stretching vibrations were found to be located at 1060, 1055, 1062, and 1063 cm^{-1} for C_1, C_3, C_6, and C_{12}, etc.[125]

In a study of the effect of degree of substitution at the nitrogen atom in the sulphonamide group[114] on the ν_{SO_2} frequencies it was shown that in *N*-alkylated sulphonamides the sulphur–oxygen frequencies are practically constant—ν_g = 1150–1170 cm^{-1} and ν_u = 1310–1350 cm^{-1}—and only in a quaternary sulphonamide group do they rise to 1180 and 1388 cm^{-1} respectively.

In sulphoxide complexes having the composition $[[(CH_3)_2.SO]_2M][MX_4]$ the ν_{SO} frequency was found[114] to be ~ 1000 cm^{-1} independently of the metal.

In the compounds $ArSO_2CR{:}CR'R''$ the band due to the sulphonyl group has been found[126] to depend neither on *cis–trans* isomerism nor on the nature of R, R', or R''.

The infrared spectra of twenty-seven thiosulphones $RSSO_2R'$ have been examined[127]. The properties of the sulphonyl group are unaffected by the substituent: the position of the ν_{SO_2} bands is affected neither by the nature of the radical SR nor by steric hindrance in *ortho*-substituted SAr substituents. The position of the bands due to symmetric and antisymmetric SO_2-stretching vibrations in thiosulphones $RSSO_2R'$ is analogous to that in the corresponding sulphones RSO_2R'.

An attempt has recently been made to express quantitatively the effect of substituents on the position of sulphur–oxygen stretching vibrations[94]. The formula used was

$$\frac{1}{2}(\nu_g + \nu_u) = \nu^0 + x_i \cdot x_j$$

where ν^0 = 907 cm^{-1} is a universal constant and x_i and x_j are empirical constants characterising individual substituents attached to the sulphonyl group, which were determined graphically (Fig. 8). This graph was plotted from published data, and the calculated values of x_i and x_j are given in Table 6.

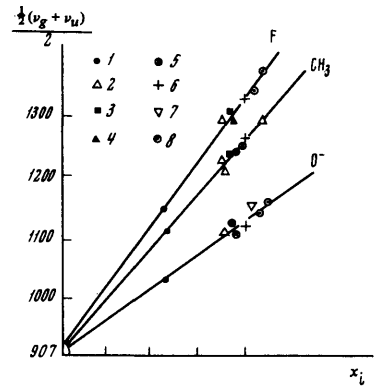


Figure 8. Explanation in text:
1) O^-; *2*) R; *3*) C_6H_5; *4*) NH_2; *5*) OR; *6*) Cl; *7*) CF_3; *8*) F.

Table 6. Values of the constants x_i and x_j for various substituents.

Substituent	x	Substituent	x
F	21.7	C_6H_5, $CH_3C_6H_4$ (*o*, *m*, *p*)	18.5
CF_3	21	Sulphonic esters	18.2
Cl	20.1	cyclo-C_6H_{11}	17.8
OR (Alk)	19.7	$-CH{=}CH_2$	17.8
OH	19.5	$-CH_2CH{=}CH_2$	17.7
NH_2	19.0	O^-	11.4

Exner combined his equation with Bellamy's equation[86], and obtained two equations from which it was possible to calculate values of ν_g and ν_u for vibrations of SO_2: ν_g = 880 + 0.810x_ix_j and ν_u = 934 + 1.190x_ix_j, the empirical constants x in these equations being given in Table 6. He considers that these empirical constants represent mainly the inductive effect of the substituents, and that adequate confirmation of this is provided by the linear relation between the Taft σ-parameter and the values of x for various substituents (Fig. 9).

Exner asserts that the quantity ν^0 = 907 cm^{-1} has a physical meaning, although the nature of this meaning is not yet known. A somewhat unexpected conclusion is that the effect of substituents on the characteristic sulphur–oxygen stretching frequencies is non-additive. Robinson's data

(Table 4 in Ref. 92) indicate strict additivity in the effect of substituents on the frequencies:

$$\begin{array}{lll} \text{C—SO}_2\text{—C} & 1136\ \text{cm}^{-1} & \\ \text{C—SO}_2\text{—F} & 1203\ \text{cm}^{-1} & \Delta\nu = 67\ \text{cm}^{-1} \\ \text{C—SO}_2\text{—O} & 1165\ \text{cm}^{-1} & \Delta\nu = 30\ \text{cm}^{-1} \\ & & \Sigma\Delta\nu = 97\ \text{cm}^{-1} \\ \text{O—SO}_2\text{—F} & 1230\ \text{cm}^{-1} & (\Delta\nu = 94\ \text{cm}^{-1}) \end{array}.$$

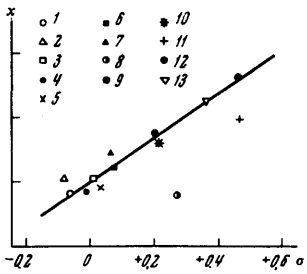

Figure 9. Explanation in text:
1) C_6H_{11}; *2*) R; *3*) $CH_2C_6H_5$; *4*) $CH_2{:}CHCH_2$; *5*) $CH_2{:}CH$; *6*) C_6H_5; *7*) NH_2; *8*) C_6H_5S; *9*) OR; *10*) OH; *11*) Cl; *12*) F; *13*) CF_3.

Table 7. Effect of solvent on the frequency ν_{SO} in dimethyl sulphoxide.

Solvent	ν_{SO}	Solvent	ν_{SO}
Cyclohexane	1083	1,2-Dichloroethane	1061
Tetrachloroethylene	1074	Dibromoethane	1061
Carbon disulphide	1070	Acetonitrile	1058
Carbon tetrachloride	1069	Nitromethane	1057
Benzene	1068	Dichloromethane	1057
Acetone	1064	Methyl chloride	1054
		Di-iodomethane	1051

(*b*) Solvent effect

The influence of solvents on the position of the ν_{SO_2} bands has been studied systematically only for the simple triatomic molecules COS and SO_2.[128] The positions of the absorption bands due to symmetric and antisymmetric stretching vibrations of sulphur dioxide have been examined in fifteen aliphatic and ten aromatic solvents. For $\nu_{SO_2,g}$ the smallest shifts (relative to the gas phase) have been found for solutions in n-hexane and in nitrobenzene (~ 6 cm^{-1}), and the largest shifts in di-iodomethane and in mesitylene (~ 11 cm^{-1}). For $\nu_{SO_2,u}$ the smallest shifts occur in n-hexane (~ 14.5 cm^{-1}) and in fluorobenzene (21 cm^{-1}), and the largest in acetone (28.5 cm^{-1}) and in mesitylene (29.5 cm^{-1}). It was established that in any solvent the shifts in the symmetric bands were always much smaller than those in the antisymmetric bands.

Relatively few data are available for more complicated compounds. As shown by Barnard et al.[18] and also by subsequent work[95,115,126,129,130], sulphoxides exhibit some displacement of the ν_{SO} band to lower frequencies in polar solvents (nitromethane) and in those capable of forming hydrogen bonds (alcohols, chloroform). This is evident in the case of dimethyl sulphoxide[27] (Table 7).

Biscarini[95] has shown that the equilibrium

$$R'R''SO + HX \rightleftarrows R'R''SO \ldots HX$$

is established in solutions of a sulphoxide in a mixture of a polar and a non-polar solvent. The compounds XSO_2Y have not been systematically studied from this point of view. The few results scattered in different papers provide no basis for generalisations: it can only be said that the ν_{SO_2} bands are displaced very slightly to lower frequencies in proton-donor solvents.

Thus the frequencies of sulphur–oxygen stretching vibrations in covalent compounds undergo substantial shifts only under the influence of change in the electronegativity of the substituents. For sulphoxides

$$\begin{array}{ll} \text{C—SO—C} & 1050\ \text{cm}^{-1} \\ \text{F—SO—F} & 1312\ \text{cm}^{-1} \end{array}$$

for sulphones, sulphonic acids, and their derivatives

$$\begin{array}{ll} \text{C—SO}_2\text{—C} & 1140\ \text{cm}^{-1} \\ & 1325\ \text{cm}^{-1} \\ \text{F—SO}_2\text{—F} & 1269\ \text{cm}^{-1} \\ & 1502\ \text{cm}^{-1} \end{array}.$$

All other factors produce far smaller displacements of the bands.

It must also be noted that the "sensitivity" of sulphonyl compounds is about half that of their carbonyl analogues[93]:

$$\begin{array}{lll} F_2CO & 1928\ \text{cm}^{-1} & \Delta\nu_{CO} = 219\ \text{cm}^{-1} \\ (RO)_2CO & 1709\ \text{cm}^{-1} & \\ F_2SO & 1312\ \text{cm}^{-1} & \\ (RO)_2SO & 1202\ \text{cm}^{-1} & \Delta\nu_{SO} = 110\ \text{cm}^{-1} \end{array}.$$

B. Ionic Compounds

Ionised compounds are characterised by a marked lowering of the sulphur–oxygen stretching frequencies: $\nu_{SO_2,g}$ = 986–1082 cm^{-1} and $\nu_{SO_2,u}$ = 1090–1218 cm^{-1}.[92] Organic and inorganic sulphites and sulphates, both in solution and in the solid state, lie within these ranges. Such a drop in frequency is usually explained by a decrease in the "double-bondedness" of the sulphur–oxygen bond. The ion $X{-}SO_2{-}O^-$ is assumed to have a tetrahedral structure[34,54,104,106,108,109,131] of symmetry C_{3v}. There are indications that the tetrahedron is not regular[108].

The influence of various factors (primarily the nature of the substituent) on the sulphur–oxygen vibrational frequency is considerably less marked in ions than in covalent compounds. Thus Haszeldine pointed out[89] that the introduction of fluorine into the anion RSO_2O^- has no effect on the position of the band due to symmetric sulphur–oxygen vibrations, while the bands due to antisymmetric vibrations are slightly raised.

Robinson has shown[92] that increasing the electronegativity of the substituent X in the ion XSO_3^- raises the symmetric bands but has no effect on the antisymmetric bands: ν_{SO_2} = 1040, 1054, 1080 cm^{-1} for HSO_4^-, $ClSO_3^-$, FSO_3^-.

Gamo[108], Ross[109], and Nakamoto[132] have shown that the bands due to stretching vibrations in crystalline hydrates of metal sulphates and in metal complexes containing the sulpho-group ($-SO_2OH$) lie in the ranges $\nu_{SO_2,g}$ = 1100–1090 cm^{-1} (doublet) and $\nu_{SO_2,u}$ = 1140–1145 cm^{-1}, being independent both of the metal in the salts and on the composition of the complex.

Ionised organic sulphonates were studied in the form of the cyclohexylamine salts by la Lau and Dahmen[104]. These workers showed that the symmetric and antisymmetric ν_{SO_2} bands lie at 1040–1050 and 1180 cm^{-1} respectively. It was found that the position of the bands did not depend on the

nature of the radical. The antisymmetric band is usually broad, and is often split into several maxima.

With regard to other regions of the infrared spectrum, Miller[105] showed that there were several bands which could be assigned to an ionised sulpho-group: SO_3^{2-} sulphite at 615–660 cm^{-1}, SO_4^{2-} sulphate at 580–670 cm^{-1}, and HSO_4^- hydrogen sulphate at 570–600 cm^{-1}. Although recent papers have been specially devoted to the infrared spectra of sulphuric acid[82,83,133–135], the assignment of bands in these spectra encounters great difficulties, primarily owing to the fact that sulphuric acid and its aqueous solutions are strongly associated. Furthermore, the spectrum of H_3O^+ (the oxonium cation) is superimposed on that of sulphuric acid itself, which also greatly increases the difficulty of assignment.

Conversion of a covalent into an ionic compound substantially lowers the frequencies of stretching vibrations[136]. This indicates that a large negative charge is delocalised on the oxygen atoms and that the sulphur–oxygen bonds are lengthened, becoming at the same time more "single" and simple. The proportion of 3*d*-orbital interaction with the sulphur atom correspondingly diminishes, and transmission of a substituent effect to the sulphur–oxygen bond in the ion is hindered.

3. Relation between Sulphur–Oxygen Stretching Frequencies and Parameters of the Sulphur–Oxygen Bond

The correlation of parameters characterising the sulphur–oxygen bond with the frequencies of sulphur–oxygen stretching vibrations forms the subject of a single paper by Gillespie and Robinson[15], in which practically all the known experimental information is assembled.

(*a*) Bond lengths and angles. These workers found a definite link (Fig. 10) between the sulphur–oxygen bond lengths determined by various methods, both for covalent and for ionic compounds, and the position of the bands due to sulphur–oxygen stretching vibrations. They regard this relation as universal, and it can be used to predict such bond lengths in molecules where direct measurement is not possible. The accuracy of a prediction is ±0.02 Å.

It has been shown also that a linear correlation exists between the O–S–O bond angles and the sulphur–oxygen stretching frequencies (Fig. 11). Gillespie and Robinson showed further that these angles can be evaluated from the equation $\nu_{SO_2,g}/\nu_{SO_2,u} = \frac{1}{2}(1 + \cos^2\alpha)/(1 + \sin^2\alpha)$, if the frequencies are known. Values showing good agreement with experiment are obtained both by calculation and by interpolation (Fig. 8).

(*b*) Force constants of sulphur–oxygen bond. Gillespie and Robinson assume that there is no interaction between the sulphur–oxygen vibrations in the $\diagdown SO_2$ group, as also with other vibrations in the molecule¶. Then the force constant can be deduced from a consideration of the sulphonyl group as a simple triatomic molecule:

$$k_{SO} = \frac{5.889 \cdot \nu_{SO_2} \cdot 10^{-2}}{\left(\frac{1}{m_S} + \frac{1}{m_O}\right)} = 0.6282\,\nu_{SO_2},$$

where m_S and m_O are the atomic weights of sulphur and oxygen. Values of k_{SO} calculated by means of this equation agree well with results obtained by other methods. These workers obtain the same relationship between the frequency ν_{SO} and the bond order as between this frequency and the bond length, since a linear relationship exists between the order and the length of a bond.

¶ However, this is not always true[115].

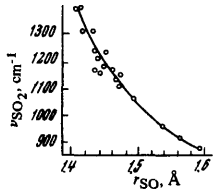

Figure 10. Correlation between position of absorption bands due to sulphur–oxygen stretching vibrations and bond length.

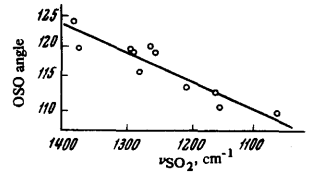

Figure 11. Correlation between sulphur–oxygen stretching frequencies and O–S–O bond angles.

Table 8. Correlation between $\nu_{SO_2,g}$ and acidity constant of sulphonic acid in sulphuric acid.

Acid	$\nu_{SO_2,g}$, cm^{-1}	K_a (25°C), mole kg^{-1}
Disulphuric	1240	0.014
Fluorosulphuric	1230	0.002
Chlorosulphuric	1209	0.001
Sulphuric	1195	—
Benzenesulphonic	1182	base
Toluene-*p*-sulphonic	1170	base

(*c*) Dissociation constants of sulphonic acids. The ν_{SO_2} vibration frequencies have been compared with the strength of the corresponding sulphonic acid, as measured by the dissociation constant of this acid in sulphuric acid[92].

It was shown that the larger is the value of K_a, the higher the frequency of the symmetric stretching vibration (Table 8). Thus the strength sequence of the various sulphonic acids relative to sulphuric acid was assessed from the SO_2-stretching frequencies to be

$$H_2S_2O_7 > FSO_3H > CF_3SO_3H > ClSO_3H < H_2SO_4 < CH_3SO_3H.$$

4. Intensity of ν_{SO_2} Bands

Very little work has been published on the intensities of the ν_{SO_2} bands. In 1961 Ghersetti[96] measured the intensity of ν_{SO} for five sulphoxides, and showed that it depended on the solvent, but did not explain this fact (Table 9). In a

non-polar solvent (carbon tetrachloride) dimethyl sulphoxide forms intermolecular dimers[67], as is shown by the changes in intensity of the 1060-cm^{-1} band. On passing to polar solvents dimethyl sulphoxide showed an increase in intensity ($10^{-4}A$), from cyclohexane 1.62 to carbon tetrachloride 1.87 and acetonitrile 1.90.

Table 9. Intensity of ν_{SO} band in some sulphoxides (dissolved in carbon tetrachloride).

Sulphoxide	ν_{SO}	$10^{-2}\epsilon^a$	$\Delta\nu_{1/2}$	$10^{-4}A$
Dimethyl	1069	7.7	15.5	1.87
Dibenzyl	1056	7.0	14.0	1.60
Benzyl phenyl	1054	8.2	10.2	1.26
Methyl phenyl	1055	7.1	9.5	1.01
Diphenyl	1052	7.8	9.0	1.00

Table 10. Intensity of $\nu_{SO_2, g}$ band in some sulphones.

Sulphone	$10^{-4}A$
Dibutyl	$1.38 \cdot 10^{-4}$
Methyl vinyl	$1.57 \cdot 10^{-4}$
Methyl phenyl	$2.1 \cdot 10^{-4}$
m-Methoxyphenyl methyl	$2.1 \cdot 10^{-4}$
p-Methoxyphenyl methyl	$3.1 \cdot 10^{-4}$

Table 11. Intensity of ν_{SO_2} stretching bands in compounds XSO_2Y.

Compounds	Stretching vibration	$10^{-2}B$	Standard deviation *s*
Sulphones	ν_{SO_2}, *g*	64.5	20.4
C—SO_2—C	ν_{SO_2}, *u*	66.5	10.7
Sulphonamides	ν_{SO_2}, *g*	91.3	18.4
C—SO_2—N	ν_{SO_2}, *u*	92.0	18.0
Sulphonic acids	ν_{SO_2}	238	50.5
C—SO_2—O	ν_{SO_2}	46.0	14.6

Five sulphones were examined by Rogers[137], who showed that the integral intensity of the ν_{SO_2} bands increases on passing to conjugated substituents (Table 10). The integral intensity of the symmetric SO_2-stretching bands can be correlated with the Taft constants (σ_{ind} and σ_R) for various sulphones[138].

Flett[100] has investigated a far larger number of compounds (Table 11). According to his results the bands are usually more intense in aromatic than in aliphatic compounds.

An attempt has been made[139] to determine sulpho-compounds quantitatively by means of the intensities of the ν_{SO_2} bands.

Hydroxyalkylphosphines and Hydroxyalkylphosphine Oxides

K.A.Petrov and V.A.Parshina

The paper discusses the condensation of phosphine and of primary and secondary phosphines with aliphatic and aromatic aldehydes and ketones, the reaction mechanisms, and the influence of the structure of the starting materials on the final products.
A detailed account is given of the chemical properties of the hydroxymethylphosphonium halides and of hydroxymethylphosphines and -phosphine oxides. Particular attention is paid to the reactions of tervalent phosphorus—oxidation, addition of sulphur, formation of quaternary phosphonium compounds with alkyl halides, alkene oxides, aldehydes, unsaturated acids, and other compounds—and also reactions at the labile hydrogen atom of the hydroxymethyl groups in hydroxymethylphosphines.
Information is given on methods for preparing organophosphorus polymers from tetrakishydroxymethylphosphonium chloride and its derivatives by the processes of polytransesterification, alcoholysis, phenolysis, and polycondensation with nitrogen-containing compounds. Problems of the practical application of the products are examined. The bibliography contains 162 references.

I. INTRODUCTION

An important place in the chemistry of organophosphorus compounds is occupied by compounds containing a coordinatively unsaturated phosphorus atom. Among them are phosphites and phosphines, by means of which it is possible to synthesise diverse derivatives containing tervalent and quinquevalent phosphorus. The Michaelis and Arbuzov reactions, which have served as foundation for numerous researches on the chemistry of organic phosphorus compounds, are based on the use of acid and normal phosphites.

The present paper gives information, widely scattered in the literature, on the condensation of phosphine and of primary and secondary phosphines with aldehydes and ketones, the chemical properties of the condensation products, and the use of hydroxymethylphosphonium halides and of hydroxymethyl-phosphines and -phosphine oxides for the synthesis of organophosphorus polymers possessing flame-resistant and ion-exchange properties, and of alkylenediphosphine oxides suitable for use as extractants in the recovery and preparation of valuable elements.

II. CONDENSATION OF PHOSPHINE AND OF PRIMARY AND SECONDARY PHOSPHINES WITH ALDEHYDES AND KETONES

Hoffmann was the first to show that phosphine reacts with formaldehyde in the presence of hydrochloric acid at 80°C in the absence of stirring with the slow formation of tetrakishydroxymethylphosphonium chloride[1,2]:

$$PH_3 + 4CH_2O + HCl \rightarrow [P(CH_2OH)_4]^+\bar{Cl}.$$

It has since been established that the reaction is best conducted with a molar ratio of formaldehyde to hydrochloric acid of 4.2 : 1 at 20°C with vigorous stirring. These conditions ensure good absorption of phosphine and its reaction with formaldehyde. The yield of tetrakishydroxymethylphosphonium chloride reaches 85–90%.[3-7]

Condensation between phosphine and formaldehyde takes place not only under the influence of acids but also in the presence of many metals of Groups II–VII or their salts, as well as in the absence of catalysts. Good results are given by the use of mercury, silver, platinum, or palladium deposited on kieselguhr or pumice[7-9]. The reaction

is usually conducted in aqueous–alcoholic and aqueous dioxan solutions at temperatures between −10° and +40°C. When phosphine is passed into aqueous formaldehyde (pH 4–8), tetrakishydroxymethylphosphonium hydroxide $(HOCH_2)_4POH$ (pH 8.5) is formed initially[8–10], and is then further treated with phosphine, without being isolated, to be converted into trishydroxymethylphosphine (pH 6.5).[9,11] This last compound is obtained also from paraformaldehyde, suspended in water or acetonitrile, and phosphine in the presence of platinum(IV) chloride at 20–35°C:[9]

$$PH_3 + CH_2O \xrightarrow{PtCl_4\ etc.} \begin{matrix} P(CH_2OH)_3 \\ [P(CH_2OH)_4]^+\,\bar{O}H \end{matrix}.$$

Interaction between phosphine and aqueous formaldehyde under a pressure of 150–300 mmHg at 40–80°C gives a good yield of tetrakishydroxymethylphosphonium hydroxide[12,13]. When paraformaldehyde is used, the reaction is conducted at 40 atm and 80–100°C in the absence of solvent or catalyst, when a high yield of trishydroxymethylphosphine is obtained[14–16].

The hydroxymethylation of phosphine can be accomplished also in the absence of pressure, by passing phosphine into heated paraformaldehyde. Under these conditions, however, the yield of trishydroxymethylphosphine is considerably diminished[17].

Tetrakishydroxymethylphosphonium chloride consists of colourless crystals of m.p. 151°C,[17] soluble in water and the lower aliphatic alcohols but insoluble in most of the usual organic solvents. Aqueous solutions of tetrakishydroxymethylphosphonium chloride have a strongly acid reaction: at 20°C a 10% solution has pH 1.92. On neutralisation to pH not exceeding 6.5 the solutions are stable on storage for a long time[18].

Tetrakishydroxymethylphosphonium hydroxide is a colourless viscous oil, sparingly soluble in water, the pH of the solution being 8.5. With an alcoholic solution of mercuric chloride it forms the complex $(HOCH_2)_4POH.HgCl_2$ melting at 140°C, which is insoluble in water and alcohol[8,10].

Trishydroxymethylphosphine is a colourless substance of m.p. 58°C, which boils with decomposition at 115°C (2.5 mmHg [13]), and possesses the characteristic odour of phosphines. It is readily soluble in water and alcohol, but does not dissolve in non-polar organic solvents. It forms yellow adducts with quinol $(HOCH_2)_3P.C_6H_4O_2$ (m.p. 160°C) and a complex with mercuric chloride $(HOCH_2)_3P.HgCl_2$ (m.p. 135°C). Unlike the simple phosphines, which possess weakly basic properties, trishydroxymethylphosphine has a slightly acid reaction in water (pH 6.5).[9,15] Trishydroxymethylphosphine can be used as intermediate in the synthesis of various organophosphorus compounds and also of insecticides, as a component of flame-resistant treatments for textiles and wood, and as an additive to lubricating oils.

In some cases phosphines reacts with other aldehydes, depending on their structure, in the same way as with formaldehyde, to form tetrakishydroxyalkylphosphonium salts, whereas in other cases more complicated compounds are formed. The peculiarity of these reactions is mostly due to transformations of unstable intermediate products of the condensation of one or two aldehyde molecules with the phosphine.

Aldehydes without branching at the α-carbon atom react similarly to formaldehyde with phosphine. It was initially supposed that, in the presence of hydrogen chloride and bromide in ether, adducts are formed containing four moles of the aldehyde together with one mole each of phosphine and the hydrogen halide, which were not isolated in pure form[19]:

$$4\,RC\begin{matrix}O\\H\end{matrix} + PH_3 \xrightarrow{HCl} \left(R{-}C\begin{matrix}O\\H\end{matrix}\right)_4 \cdot PH_3 \cdot HCl.$$

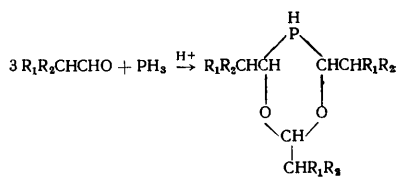
When the reaction was conducted in the presence of aqueous mineral acids (hydrochloric, hydrobromic, hydriodic, sulphuric, orthophosphoric, nitric), substances were isolated in pure form which proved to be tetrakis-1-hydroxylalkylphosphonium salts[20–23]:

$$4\,RC\begin{matrix}O\\H\end{matrix} + PH_3 \xrightarrow{HCl} \left[P\left(\begin{matrix}CH{-}R\\|\\OH\end{matrix}\right)_4\right]^+\bar{C}l$$

where R = C_{1-18} alkyl.

Good results are obtained if the aldehyde is slowly added to the reaction mixture, and organic solvents (tetrahydrofuran, butanol, dioxan) are used to increase the solubility of the phosphine and the higher aldehydes. Negative results are obtained when the reaction is conducted in the gas phase in the presence of a catalyst (aluminium silicate) at 375°C; at higher temperatures the phosphine decomposes to white phosphorus and hydrogen[20].

Aldehydes which are branched at the α-position react readily with phosphine in the presence of hydrochloric acid at room temperature, but unlike the unbranched aldehydes they form cyclic secondary phosphines having a six-membered ring. This reaction has been studied with isobutyraldehyde and 2-ethylhexanal as examples. The former gave a 75% yield of 2,4,6-tri-isopropyl-1,3-dioxa-5-phosphacyclohexane (I), and the latter a 90% yield of 2,4,6-tris-1′-ethylpentyl-1,3-dioxa-5-phosphacyclohexane (II):[20,24]



where (I) $R_1 = R_2 = CH_3$ and (II) $R_1 = C_2H_5$, $R_2 = n\text{-}C_4H_9$.

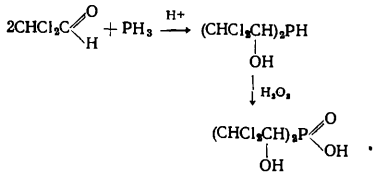
The compound (I) reacts with sulphur in benzene to form the corresponding sulphide, which possesses herbicidal activity[25]. It is assumed that the reaction involves the intermediate formation of secondary phosphines $[R_1R_2CHCH(OH)]_2PH$, which are unable to form quaternary phosphonium salts because of steric hindrance, but react with the aldehyde to give six-membered cyclic phosphines. The products have been subjected to detailed study.

Chlorinated aldehydes also react with phosphine. Chloroacetaldehyde and phosphine in the presence of hydrochloric acid (ratio 3 : 1) form an amorphous solid, which could not be isolated in pure form[20]. In the presence of a catalyst (platinum tetrachloride) it is assumed that tris-2-chloro-1-hydroxyethylphosphine is produced[26]:

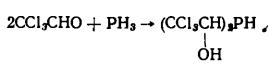
$$ClCH_2CHO + PH_3 \xrightarrow{PtCl_4} P\left(\begin{matrix}CH{-}CH_2Cl\\|\\OH\end{matrix}\right)_3.$$

Phosphine reacts with dichloroacetaldehyde in the presence of concentrated hydrochloric acid in tetrahydrofuran with the assumed formation of bis-2,2-dichloro-1-hydroxyethylphosphine, which also could not be isolated as an

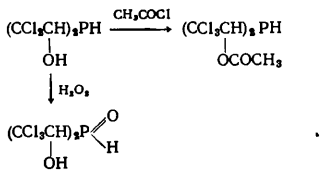
individual compound. On oxidation this product is converted into bis-2,2-dichloro-1-hydroxyethylphosphinic acid[20]:



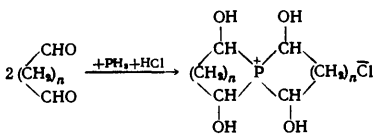
In contrast to the mono- and di-halogenated aldehydes, chloral and chloral hydrate react very vigorously with phosphine to give a 95% yield of bis-2,2,2-trichloro-1-hydroxyethylphosphine[20,27-29]:



Tris-2,2,2-trichloro-1-hydroxyethylphosphine was also obtained in this reaction[30]. On oxidation with hydrogen peroxide it yields the corresponding phosphine oxide, and on acetylation a diacetyl derivative[20]:



Dialdehydes, among which glutaraldehyde and succinaldehyde have been studied as examples, react readily with phosphine in the presence of concentrated hydrochloric acid in tetrahydrofuran at 20°C.[20] The products of this reaction are relatively stable five- and six-membered spirocyclic phosphonium salts. Glutaraldehyde gives a 65% yield of 2,2',6,6'-tetrahydroxy-1,1'-spirobiphosphanium chloride (I), and succinaldehyde a 34% yield of 2,2',5,5'-tetrahydroxy-1,1'-spirobiphospholanium chloride (II):

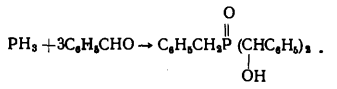


where (I) $n = 3$ and (II) $n = 2$. These spirans and their nitrogen analogues are difficultly accessible compounds.

It was originally considered that phosphine reacts with aromatic aldehydes in roughly the same way as with aliphatic aldehydes. It was supposed that the interaction of benzaldehyde and phosphine in the presence of hydrogen chloride in ethereal solution gave a crystalline adduct[19]:

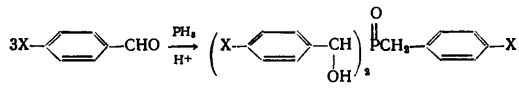
This has since been assigned the structure of tris-α-hydroxybenzylphosphine[31]:

However, the compound was then found to be benzylbis-1-hydroxybenzylphosphine oxide†, whose formation involves the transfer of oxygen from carbon to phosphorus[33,35]:



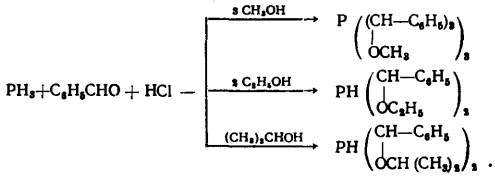
The structure of the product as an oxide is supported by many data[32,33].

Substituted aromatic aldehydes react similarly to benzaldehyde with phosphine in dioxan or tetrahydrofuran[33,35]:



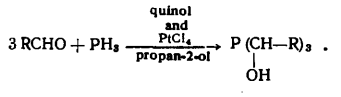
where X = Cl, Br, CH_3, C_3H_7. *p*-Nitrobenzaldehyde, *p*-hydroxybenzaldehyde, and naphthaldehyde also react with phosphine, but it has not proved possible to isolate the reaction products in pure form and establish their structure.

Benzaldehyde reacts differently with phosphine in alcoholic solution, different products being formed according to the alcohol taken[31]—tris-α-methoxybenzylphosphine in methanol, bis-α-ethoxybenzylphosphine in ethanol, and bis-α-isopropoxybenzylphosphine in propan-2-ol:



It is assumed that hemiacetals are formed in the first stage of this reaction, and these react with phosphine by a bimolecular or a termolecular mechanism[36].

Various aldehydes are able to react with phosphine in the presence of catalysts other than mineral acids to form tertiary α-hydroxy-phosphines[26], e.g.

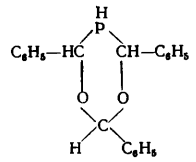


The compounds obtained, like trishydroxymethylphosphine, can be used as intermediates for organic synthesis, as insecticides, and as additives for lubricating oils.

The first attempts to promote reaction between phosphine and ketones in the presence of catalytic quantities of an acid were unsuccessful[37]. However, it has since been found that this reaction goes readily in strongly acid media.

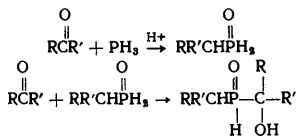
A mixture of two products—a primary phosphine oxide and a secondary 1-hydroxyalkylphosphine oxide—is obtained by the interaction of phosphine and a ketone (mixed with concentrated hydrochloric acid) in the molar proportions 1:3. Formation of the first of these products involves the transfer of oxygen from the carbonyl carbon to

† The cyclic acetal



is formed in 10–40% yield as a by-product[31,34].

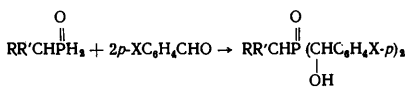
phosphorus, while the second involves the normal carbonyl addition of the ketone to the primary phosphine oxide[38,39]:



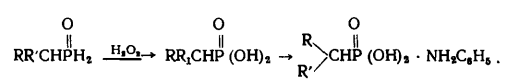
where R and R′ = alkyl, aryl.

The reaction was accomplished by passing phosphine into a solution of the ketone in concentrated hydrochloric acid at room temperature. The proportions of the products formed depends on the nature of the ketones, which can be arranged in the sequence—cyclohexanone < cyclopentanone < acetone < pentan-2-one < heptan-2-one < < pentan-3-one < acetophenone < heptan-4-one—according to increasing quantity of the primary phosphine oxide formed. The ratio of this primary product to the secondary phosphine oxide varies correspondingly from 9 : 1 with heptan-4-one to 1 : 9 with cyclohexanone, and the duration of the reaction from 30 min with cyclohexanone to 11 h with heptan-4-one; acetophenone reacts at the same rate as acetone[37].

Primary phosphine oxides, which are stable in acid solution at −80°C, have not been isolated in individual form. The presence of such compounds in the reaction mixture was proved by converting them into various derivatives. Thus treatment with aromatic aldehydes gave the corresponding tertiary bishydroxyalkylphosphine oxides:

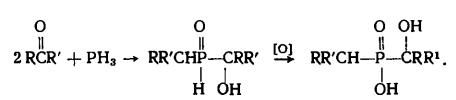


where X = H, Cl; and on oxidation the phosphonic acids were isolated (as their aniline salts):

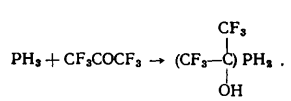


Thus the condensation of phosphines with ketones provides a convenient method for obtaining alkylphosphonic acids in which the phosphorus is bound to a secondary carbon atom.

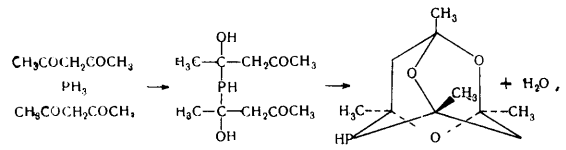
Secondary hydroxyalkylphosphine oxides have been isolated as crystalline substances from the reactions of cyclohexanone, cyclopentanone, acetone, and acetophenone with phosphine. On oxidation with nitric acid or hydrogen peroxide they gave the corresponding phosphinic acids:



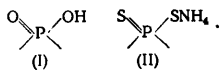
Hexafluoroacetone reacts with phosphine when heated in an autoclave to form as the sole product 2,2,2-trifluoro-1-hydroxy-1-trifluoromethylethylphosphine[40,41]:



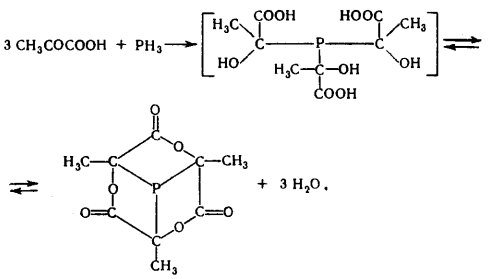
Diketones also react readily with phosphine, but heterocyclic systems are formed[42]. For example, the reaction with pentane-2,4-dione in hydrochloric acid solution has been studied, and crystalline 1,3,5,7-tetramethyl-2,4,8-trioxa-6-phosphadamantane isolated, obviously formed via an intermediate secondary phosphine:



The chemical properties of the product were typical of secondary phosphines. Oxidation with hydrogen peroxide gave the phosphinic acid (I), and treatment with sulphur and ammonium hydroxide yielded the ammonium phosphinodithioate (II)



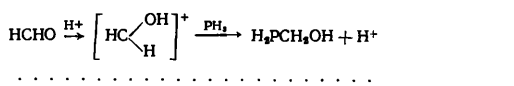
In the presence of ethereal hydrogen chloride phosphine reacts also with pyruvic acid (in the molar proportions 1 : 3) to give an almost quantitative yield of a compound $C_9H_9O_6P$, presumably with intramolecular esterification of carboxyl and hydroxyl groups present in an intermediate unstable tertiary phosphine[33]:



Thus the structure of the product represents a tricyclic system, in which three five-membered rings have fused at the phosphorus atom. The most intense absorption bands in the infrared spectrum of this compound are located near 1784 cm^{-1}, which corresponds to stretching vibrations of an ester carbonyl group, while no absorption bands are present corresponding to stretching vibrations of COOH and OH groups. The above reaction is general in character, and has been studied in a series of other acids of formula RCOCOOH, where R = C_{1-6} alkyl[43].

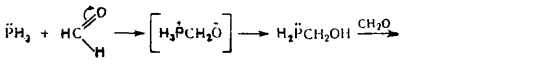
The reactions of phosphine with aldehydes and ketones yield various products depending on the starting materials, the catalysts, and the solvents. However, it is generally accepted that, whatever the final products, these reactions are very similar in their mechanism in the early stages of condensation with phosphine. Several opinions, sometimes differing only in details, are held concerning the mechanism of this reaction. According to one of them the interaction of phosphine with formaldehyde catalysed by a proton involves the initial formation of a "formaldehyde cation", which then reacts with more phosphine to give hydroxymethylphosphine and a proton. The latter again enters into reaction with formaldehyde to form the formaldehyde cation, which reacts with the hydroxymethylphosphine to give bis- and tris-hydroxymethylphosphines, and

ultimately tetrakishydroxymethylphosphonium salts or bases[44]:

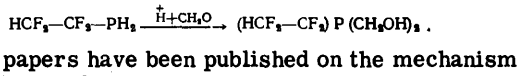


Besides this bimolecular mechanism, a termolecular reaction mechanism has been suggested, involving the initial formation of a monohydroxyalkylphosphonium salt, which is converted into a monohydroxyalkylphosphine with loss of a proton, and then into di- and tri-substituted phosphines and phosphonium salts or bases:

When condensation takes place in the absence of a catalyst, it is assumed that an intermediate phosphine—formaldehyde complex is formed, which is converted into hydroxymethylphosphine and then, by an analogous scheme, reacts with formaldehyde to form bis- and tris-hydroxymethylphosphines and tetrakishydroxymethylphosphonium hydroxide[13,15]:

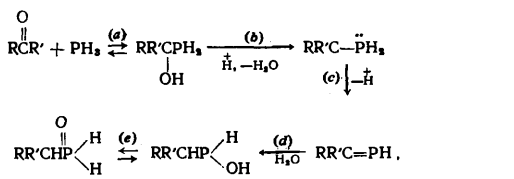


The ability of phosphine and of methyl- and dimethylphosphines to add formaldehyde is governed by the nucleophilic character of the former and the polarity of the C=O bond in the latter. The reactivity of the phosphines varies in conformity with their nucleophilic character[15] in the sequence $PH_3 < CH_3PH_2 < (CH_3)_2PH$, and when it is very low[45-49] phosphines do not react with formaldehyde in the absence of a catalyst. For example, 1,1,2,2-tetrafluoroethylphosphine, which possesses weak electron-donor power, yields with formaldehyde bishydroxymethyltetrafluoroethylphosphine only in the presence of hydrochloric acid[13]:



Several papers have been published on the mechanism of the reactions undergone by phosphine and alkylphosphines with formaldehyde; studies have been made of the kinetics, and the activation energies have been calculated[50].

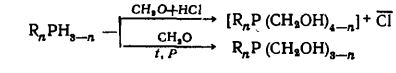
For phosphine the mechanism of the reaction, accompanied by the transfer of oxygen from carbon to phosphorus, is expressed by the scheme[37]



Phosphine first adds to the ketone as to aliphatic aldehydes (*a*). In strongly acid medium a carbonium ion is formed [*b*], which is stabilised as an intermediate compound containing a carbon–phosphorus double bond (*c*), hydration of which (*d*) yields a primary phosphine oxide (*e*).

Data have been published indicating that reactions involving the migration of oxygen from phosphorus to carbon are analogous to allyl rearrangements, and represent a general phenomenon for the series of α-substituted derivatives of tervalent phosphorus[51].

Like phosphine itself, primary and secondary phosphines react with aqueous formaldehyde in the presence of an equimolecular quantity of hydrochloric acid to form quaternary phosphonium salts[37,52-56], but when heated (to 65–100°C) with paraformaldehyde under pressure hydroxymethylphosphines are formed[13,52,57-61]:



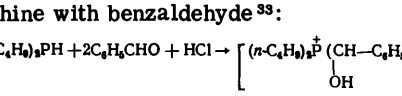
where $n = 1, 2$ and R = alkyl, aryl.

Hydroxymethylphosphonium salts are more stable towards hydrolysis[52] than are quaternary alkylhydroxymethylammonium salts, which are decomposed by water to amine hydrochlorides and formaldehyde.

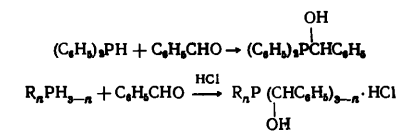
The condensation of primary and secondary phosphines with aldehydes and ketones is greatly influenced by the structure of both components. Study of the reactions of aliphatic aldehydes with phosphines (propyl-, phenyl-, and diphenyl-phosphines) has shown that, in the presence of an equimolecular quantity of hydrochloric acid, phosphonium chlorides are formed[33,37,55,62,63]:

where $n = 1, 2$, R = alkyl, aryl, and R′ = alkyl.

A quaternary phosphonium salt is formed also by dibutylphosphine with benzaldehyde[33]:



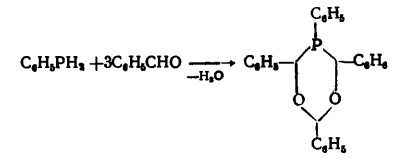
In the presence of traces of hydrochloric acid benzaldehyde condenses with diphenyl-, dicyclohexyl-, and isobutylphosphines to give tertiary phosphines[37,55,64,65] or their hydrochlorides[37]:



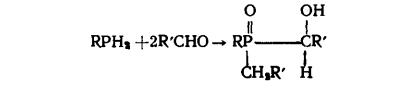
where $n = 1, 2$ and R = iso-C_4H_9, cyclo-C_6H_{11}.

Phenylphosphine forms with isobutyraldehyde the hydrochloride of a tertiary phosphine even in excess of hydrochloric acid at 20°C:[37]

With benzaldehyde in the presence of a small amount of hydrogen chloride in acetonitrile or methanol phenylphosphine gives a 59% yield of a cyclic product[37]:



In boiling strongly acid medium primary phosphines react with aromatic aldehydes, and secondary phosphines (diphenylphosphine) react with aliphatic and aromatic aldehydes, to form phosphine oxides[37]:

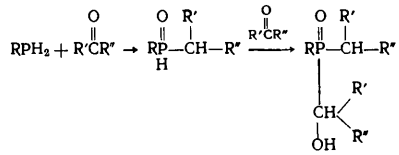


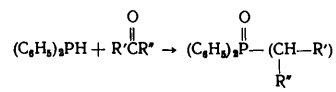
where R = alkyl, cycloalkyl, aryl and R′ = aryl, naphthyl;

$$(C_6H_5)_2PH + RCHO \rightarrow (C_6H_5)_2PCH_2R \quad (O)$$

where R = alkyl, aryl, naphthyl.

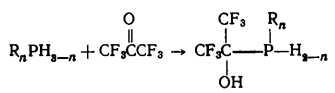
Primary and secondary aromatic phosphines react with ketones in strongly acid medium on heating to form the corresponding tertiary phosphine oxides‡ [37]:





where R = alkyl, aryl, cycloalkyl, and R′, R″ = alkyl, aryl or R′ + R″ = cycloalkyl, indol-1-yl.

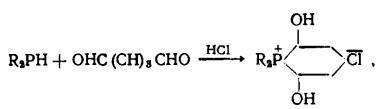
Fluorinated ketones form with primary and secondary phosphines the corresponding 1-hydroxyalkylphosphines [40,41]:



where n = 1, 2 and R = CH_3.

Several primary phosphines (isobutyl-, octyl-, phenylphosphines), on treatment with pentane-2,4-dione, give crystalline polycyclic tertiary phosphines [42].

A cyclic phosphonium salt is obtained from a dialdehyde and a secondary phosphine [66]:



Thus the reactions undergone by phosphine and phosphines with aldehydes and ketones can be divided into two groups—reactions involving normal carbonyl addition with formation of phosphines, their salts, and quaternary phosphonium bases, and reactions accompanied by migration of oxygen from carbon to phosphorus in the hydroxymethylphosphines produced initially, and leading to the synthesis of tertiary phosphine oxides.

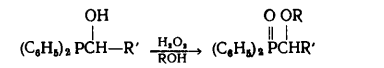
III. CHEMICAL PROPERTIES OF HYDROXYMETHYLPHOSPHONIUM HALIDES AND OF HYDROXYMETHYLPHOSPHINES AND -PHOSPHINE OXIDES

Trishydroxymethylphosphine and substituted hydroxymethylphosphines, like other compounds containing a tervalent phosphorus atom, are readily oxidised, and sulphur, and form quaternary phosphonium compounds: i.e. the chemical properties of hydroxymethylphosphines, like those of other phosphines, are determined by the presence of a coordinatively unsaturated phosphorus atom. Thus on oxidation with oxygen [52,64,67], hydrogen peroxide [13,15,37,68-71], nitric acid [67], peracetic acid [52], potassium permanganate [67], and oxides of nitrogen they are converted into phosphine oxides§.

$$R_nP(CH_2OH)_{3-n} \xrightarrow{1/2\,O_2} R_nP(O)(CH_2OH)_{3-n}$$

where n = 0–2 and R = alkyl, aryl, fluorinated alkyl, cycloalkyl.

Oxidation in alcohol yields α-alkoxyalkylphosphine oxides [37]:



where R = alkyl, aryl and R′ = naphthyl.

With sulphur trishydroxymethylphosphine and substituted hydroxymethylphosphines form phosphine sulphides [52,72,73]:

$$R_nP(CH_2OH)_{3-n} \xrightarrow{S} R_nP(S)(CH_2OH)_{3-n}$$

where n = 0–2 and R = alkyl, aryl.

Trishydroxymethylphosphine and substituted hydroxymethylphosphines react with alkyl halides and with toluene-p-sulphonic and alkyl- and aryl-phosphonic esters to form quaternary phosphonium salts [16,17,56,63,74-78]:

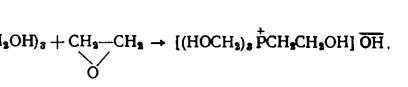
$$R_nP(CH_2OH)_{3-n} \xrightarrow{R'X} [R_nR'P(CH_2OH)_{3-n}]^+\overline{X}$$

where n = 0–2, R = alkyl, aryl, and X = halogen, anion of corresponding acid.

Trishydroxymethylphosphine is readily alkylated even in the course of formation. Thus the interaction of phosphine with formaldehyde in the presence of a catalyst (a salt of a metal in Groups II–VII) and an alkylating agent yields an alkyl(aryl)trishydroxymethylphosphonium halide [79-81]:

$$PH_3 + CH_2O + RX \rightarrow [RP(CH_2OH)_3]^+\overline{X}.$$

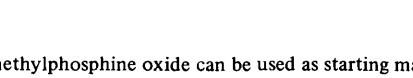
Trishydroxymethylphosphine and dialkyl(aryl)hydroxymethylphosphines react with dihalogenoalkanes, both in solution and in the absence of a solvent, to give a quantitative yield of the quaternary phosphonium salts [75,82]:



where n = 1–4, m = 0–2, R = alkyl, aryl, and X = Br, I.

Quaternary phosphonium compounds are obtained also by the interaction of trishydroxymethylphosphine with alkylene oxides [83-85] at 50–100°C in water or in an organic solvent which is miscible with water (dimethylformamide, acetonitrile, lower alcohols, ketones). Quaternary phosphonium salts are obtained in the presence of mineral or organic acids, and quaternary phosphonium hydroxides in their absence:

Quaternary phosphonium bases and salts are formed by the action of aldehydes on trishydroxymethylphosphine in the presence of water, a mineral acid, or an organic acid. Saturated and unsaturated aliphatic and aromatic aldehydes and various derivatives thereof have been studied in this reaction [10]:



Trishydroxymethylphosphine reacts with hydroxymethylated derivatives of urea to form quaternary phosphonium

‡ In the case of primary phosphines the reaction involves the addition of one or two molecules of the ketone depending on the structure of the initial phosphine and the ketone.

§ Trishydroxymethylphosphine oxide can be used as starting material for various syntheses and in flame-resistant treatments for textiles and wood.

compounds, which are recommended as intermediates in the production of flame-resistant fibre-forming plastics[86]:

$$P(CH_2OH)_3 \xrightarrow{NH_2CONH(CH_2OH)} [P(CH_2OH)_3CH_2NHCONH_2]^+\overline{OH}.$$

The action on trishydroxymethylphosphine of $\alpha\beta$-unsaturated aliphatic acids, their esters, and their amides in the presence of water and acids in a water-soluble organic solvent yields phosphorus analogues of betaines[87]:

$$P(CH_2OH)_3 \xrightarrow{CH_2=CHCOOH} \begin{matrix} \overset{+}{P}(CH_2OH)_3 \\ | \\ CH_2CH_2COO \end{matrix}.$$

Treatment of trishydroxymethylphosphine with $\alpha\beta$-unsaturated nitriles produces unstable phosphonium salts, which are able to split off hydroxymethyl groups. Thus with three moles of acrylonitrile trishydroxymethylphosphine forms tris-2-cyanoethylphosphine[88]:

$$P(CH_2OH)_3 \xrightarrow[H_2O]{CH_2=CH-CN} [(HOCH_2)_3\overset{+}{P}CH_2CH_2CN]\,\overline{OH} \xrightarrow[-(CH_2O+H_2O)]{} (HOCH_2)_3PCH_2CH_2CN$$

$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$

$$(HOCH_2)P(CH_2CH_2CN)_2 \xrightarrow[-(CH_2O+H_2O)]{CH_2=CHCN} [HOCH_2\overset{+}{P}(CH_2CH_2CN)_2]\,\overline{OH} \rightarrow P(CH_2CH_2CN)_3.$$

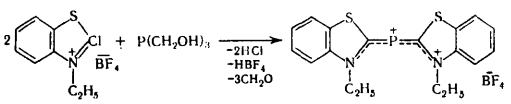
Trishydroxymethylphosphine reacts with butylsulphenyl chloride and with diethylchloramine to form quaternary phosphonium salts[89]:

$$P(CH_2OH)_3 \xrightarrow{C_4H_9SCl} \left[\begin{matrix} P(CH_2OH)_3 \\ | \\ SC_4H_9 \end{matrix}\right]^+\overline{Cl}$$

$$P(CH_2OH)_3 \xrightarrow{(C_2H_5)_2NCl} \left[\begin{matrix} P(CH_2OH)_3 \\ | \\ N(C_2H_5)_2 \end{matrix}\right]^+\overline{Cl}.$$

Quaternary phosphonium salts are recommended for use as additives in lubricating oils and as flame-resistant finishes for textiles[75], and also as pesticides and fungicides[21,23].

Trishydroxymethylphosphine has been used to prepare new coloured compounds, phosphamethincyanines, containing tervalent phosphorus having a coordination number of 2. Thus, in the presence of ethyldi-isopropylamine, 2-chloro-*N*-ethylbenzothiazole fluoroborate and trishydroxymethylphosphine gave a 45% yield of phosphamethincyanine[90]:



Other symmetrical and unsymmetrical phosphamethincyanines have been obtained in a similar manner.

Like alcohols, hydroxymethylphosphines are able to form alkoxides on treatment with metallic sodium[17]:

$$RP(CH_2OH)_2 + Na \rightarrow RP(CH_2ONa)_2 + H_2$$

where R = alkyl.

With diethylamine, hydroxymethylphosphines form aminomethylphosphines[89]:

$$R_nP(CH_2OH)_{3-n} \xrightarrow{HN(C_2H_5)_2} R_nP[CH_2N(C_2H_5)_2]_{3-n}$$

where n = 0–2 and R = alkyl. The products are able to react with compounds containing labile hydrogen[90]. Compounds of a similar type are obtained also by the action of secondary amines on tetrakishydroxymethylphosphonium chloride[91]:

$$[P(CH_2OH)_4]^+\overline{Cl} + 4HNR_2 \rightarrow (R_2NCH_2)_3P + CH_2O + R_2NH\cdot HCl$$

where R = alkyl, allyl or R_2N = morpholino; by the action of formaldehyde on phosphine and phosphines in the presence of secondary amines[92] or amides[93]:

$$R_{3-n}PH_n + nCH_2O + nHNR'_2 \rightarrow (R'_2NCH_2)_nPR_{3-n} + nH_2O$$

where n = 0–2 and R,R′ = alkyl; and also from the reaction between primary phosphines and tetraethylmethylenediamine[89]:

$$C_6H_5PH_2 + 2(C_2H_5)_2NCH_2N(C_2H_5)_2 \rightarrow C_6H_5P[CH_2N(C_2H_5)_2]_2 + 2(C_2H_5)_2NH.$$

Esters of hydroxymethylphosphines are formed by the action of acylating agents on hydroxymethylphosphines or their sodium salts[17,68]:

$$\left.\begin{matrix} R_2PCH_2OH \\ R_2PCH_2ONa \end{matrix}\right\} \xrightarrow{R'COCl} R_2P(CH_2OCOR').$$

These compounds are obtained also by the alkaline decomposition of the corresponding acylated quaternary phosphonium salts[94,95]:

$$[R_nP(CH_2OCOCH_3)_{4-n}]^+\overline{X} \xrightarrow{NaOH} R_nP(CH_2OCOCH_3)_{3-n}$$

where n = 0–2 and R = alkyl.

Cases are unknown in which ethers have been obtained directly from hydroxymethylphosphines. The alcoholysis of trischloromethylphosphine results in formation of the methylbisalkoxymethylphosphine oxide[51,96]:

$$(ClCH_2)_3P \xrightarrow[ROH]{RONa} CH_3\overset{O}{\overset{\|}{P}}(CH_2OR)_2.$$

Hydroxymethylphosphines isomerise when heated. Thus methyldicyclohexylphosphine oxide has been obtained from dicyclohexylhydroxymethylphosphine[52]:

$$(\text{cyclo-}C_6H_{11})_2PCH_2OH \xrightarrow[3\text{ h}]{240-250^\circ} (\text{cyclo-}C_6H_{11})_2\overset{O}{\overset{\|}{P}}CH_3 + (\text{cyclo-}C_6H_{11})_2PH + CH_2O$$

40.5% 49.5%

and alkylphosphine oxides from 1-hydroxyalkyldiphenylphosphines on boiling in acetic acid in the presence of toluene-*p*-sulphonic acid[62]:

$$(C_6H_5)_2\underset{\underset{OH}{|}}{PCH}-R \xrightarrow[CH_3-C_6H_4-SO_3OH]{CH_3COOH} (C_6H_5)_2\overset{O}{\overset{\|}{P}}CH_2R$$

where R = H, alkyl, phenyl.

The chemical properties of hydroxymethylphosphonium salts and bases, unlike those of hydroxymethylphosphines, are determined solely by the hydroxymethyl groups. These groups in the quaternary salts can be acylated by acid chlorides[94,95] or acid anhydrides[52]:

$$[R_nP(CH_2OH)_{4-n}]^+\overline{X} \rightarrow [R_nR(CH_2O\overset{O}{\overset{\|}{C}}R')_{4-n}]^+\overline{X}$$

where n = 0–3 and R, R′ = alkyl, aryl. They can be converted into chloromethyl groups by the action of phosphorus pentachloride[2,97] or thionyl chloride[52,54,63,97]:

$$[R_nP(CH_2OH)_{4-n}]^+\overline{Cl} \xrightarrow{SOCl_2(PCl_5)} [R_nP(CH_2Cl)_{4-n}]^+\overline{Cl}$$

where n = 0–2 and R = alkyl, aryl; or

$$[P(CH_2OH)_4]^+\overline{OH} \xrightarrow[CCl_4]{PCl_5} (ClCH_2)_4PCl^{12,13}.$$

With phenyl isocyanate hydroxymethyltriphenylphosphonium fluoroborate forms the corresponding phenylurethane[52]:

$$[(C_6H_5)_3PCH_2OH]^+\overline{BF_4} + C_6H_5NC{=}O \rightarrow [(C_6H_5)_3PCH_2O\overset{O}{\overset{\|}{C}}NHC_6H_5]^+\overline{BF_4}$$

and with diazomethane it gives methyltriphenylphosphonium fluoroborate[52]:

$$[(C_6H_5)_3PCH_2OH]^+\overline{BF_4} \xrightarrow[-CH_2O]{CH_2N_2} (C_6H_5)_3P + \{|CH_3^+\} \rightarrow [(C_6H_5)_3PCH_3]^+\overline{BF_4}\,.$$

An interesting property of hydroxymethylphosphonium halides is their tendency to split into tertiary phosphine and phosphine oxides. For example, treatment of tetrakishydroxymethylphosphonium chloride with excess of aqueous alkali yields the tertiary phosphine oxide, hydrogen, and an aldehyde:

$$P(CH_2OH)_4Cl + NaOH \rightarrow (HOCH_2)_3P{=}O + CH_2O + H_2 + NaCl\,.$$

Trishydroxymethylphosphine oxide was first isolated by Hoffmann as the tribenzoate. It has since been found that an 80% yield of the pure oxide can be obtained from tetrakishydroxymethylphosphonium chloride by the action of barium carbonate[98,99]. However, the isolation of trishydroxymethylphosphine oxide from an aqueous solution containing a metal chloride is extremely difficult, owing to its solubility in water and its sparing solubility in organic solvents. Good results have been obtained by prolonged extraction from concentrated solutions with alcohol. Trishydroxymethylphosphine oxide is obtained also by the action of lead carbonate in propan-1-ol on tetrakishydroxymethylphosphonium chloride[100].

When trishydroxymethylphosphine oxide is treated with alkalis under more severe conditions, a molecule of hydrogen is split off, and salts of phosphinic acids are formed:

$$P(O)(CH_2OH)_3 \xrightarrow{NaOH} \underset{\underset{ONa}{|}}{P(O)(CH_2OH)_2}\,.$$

Bishydroxymethylphosphinic acid can be obtained from tetrakishydroxymethylphosphonium chloride by boiling the latter with alkali or with sodium carbonate[98]:

$$(HOCH_2)_4PCl + Na_2CO_3 + 3H_2O \rightarrow 3\,(HOCH_2)_2P\!\!\underset{OH}{\overset{O}{\diagup}} + 4CH_2O + 4H_2 + 2NaCl + CO_2$$

or by heating sodium hypophosphite with paraform and then acidifying the product with an acid[101]:

$$NaH_2PO_2 + nCH_2O \rightarrow \underset{\underset{OH}{|}}{\overset{O}{\overset{\|}{P}}(CH_2OH)_2}\,.$$

Alkyltrishydroxymethylphosphonium halides are decomposed by excess of aqueous alkali with the formation of tertiary phosphine oxides. Thus treatment of propyltrishydroxymethylphosphonium chloride with barium hydroxide octahydrate at 60°C gives propylbishydroxymethylphosphine oxide[63]:

$$[C_3H_7P(CH_2OH)_3]^+\overline{Cl} \xrightarrow{Ba(OH)_2\cdot 8H_2O} \underset{\underset{O}{\|}}{C_3H_7P(CH_2OH)_2}\,.$$

Hydroxymethylphosphine oxides can be acylated by the ethyl esters[68] and by the chlorides[2,63,68,102-104] of carboxylic acids, when one, two, or three hydroxymethyl groups may react:

$$\underset{\underset{O}{\|}}{R_nP(CH_2OH)_{3-n}} \xrightarrow{RCOCl} \underset{\underset{O}{\|}}{R_nP(CH_2OCOR)_{3-n}}$$

where n = 0–2 and R = alkyl, aryl. The reaction of hydroxymethylphosphine oxides with thionyl chloride[52,63] and with phosphorus pentachloride[70] yields chloromethylphosphine oxides:

$$\underset{\underset{O}{\|}}{R_nP(CH_2OH)_{3-n}} \xrightarrow{PCl_5(SOCl_2)} \underset{\underset{O}{\|}}{R_nP(CH_2Cl)_{3-n}}$$

where n = 0–2 and R = alkyl, aryl.

Tetrakishydroxymethylphosphonium chloride and alkyl(aryl)hydroxymethylphosphonium halides are decomposed by the calculated quantities of alkali[53,62,68], alcoholic alkali[53,68], or sodium ethoxide[53] to tertiary hydroxymethylphosphines¶:

$$[R_nP(CH_2OH)_{4-n}]^+\overline{X} \xrightarrow{NaOH} R_nP(CH_2OH)_{3-n} + CH_2O + NaCl$$

where n = 0–2 and R = alkyl, aryl. The decomposition of bis-1-hydroxyalkyldiphenylphosphonium chlorides by aqueous alkalis is accompanied by side-reactions, which lower the yields of 1-hydroxyalkyldiphenylphosphines[61].

The action of tertiary amines on hydroxymethylphosphonium halides also splits off formaldehyde, to give good yields of tertiary phosphines[73,76]:

$$[R_nP(CH_2OH)_{4-n}]^+\overline{Cl} \xrightarrow[-(C_2H_5)_3N\cdot HCl]{(C_2H_5)_3N} R_nP(CH_2OH)_{3-n}$$

where n = 0–2 and R = alkyl, aryl.

The alkylation of hydroxymethylphosphines and the dealkylation of hydroxymethylphosphonium halides yield tertiary hydroxymethylphosphines and phosphines containing no hydroxymethyl groups[52,62,73,76], dialkylamides of bishydroxymethylphosphinous acid[89]:

$$[RP(CH_2OH)_3]^+\overline{X} \xrightarrow{\overline{B}} RP(CH_2OH)_2 \xrightarrow{R'X} [RR'P(CH_2OH)_2]^+\overline{X} \xrightarrow{\overline{B}}$$

$$\rightarrow RR'P(CH_2OH) \xrightarrow{R''X} [RR'R''P(CH_2OH)]^+\overline{X} \xrightarrow{\overline{B}} RR'R''P$$

where R = alkyl, aralkyl, dialkylamino and $\overline{B}$ = NaOH, $(C_2H_5)_3N$, and also diphosphines[82,107]:

$$\left[\begin{matrix} R_2\overset{+}{P}-(CH_2)_n-\overset{+}{P}R_2 \\ | \qquad\qquad | \\ CH_2OH \qquad CH_2OH \end{matrix}\right] 2\overline{X} \xrightarrow[-(2CH_2O+2NaCl)]{\text{conc. NaOH}} R_2P(CH_2)_nPR_2.$$

Tertiary amines proved to be unsuitable for the decomposition of diphosphonium salts.

Alkylenediphosphine oxides can be obtained by the oxidation of alkylenediphosphines†.

IV. PREPARATION OF PHOSPHORUS-CONTAINING POLYMERS BASED ON TETRAKISHYDROXYMETHYLPHOSPHONIUM CHLORIDE AND ITS DERIVATIVES

In contrast to phosphorus-containing insecticides, plasticisers, lubricating-oil additives, etc., organophosphorus polymers have not hitherto found wide application.

¶ The action of alkalis on chloromethylphosphonium halides similarly yields chloromethylphosphines[2,52,54,70,105]:

$$[R_nP(CH_2Cl)_{4-n}]^+\overline{X} \xrightarrow{NaOH} R_nP(CH_2Cl)_{3-n} + nCH_2O + NaCl + H_2O$$

where n = 0–2, R = alkyl, aryl, and X = Cl, BF_4. However, side-reactions are also possible, which considerably diminish the yield of tertiary phosphines. When, for example, tetrakischloromethylphosphonium chloride is boiled, methylbischloromethylphosphine oxide is formed[106]:

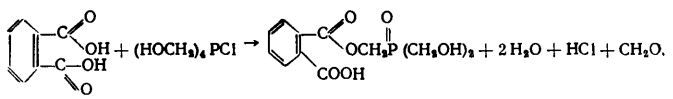
$$[P(CH_2Cl)_4]^+\overline{Cl} \xrightarrow{NaOH} \underset{\underset{O}{\|}}{CH_3P(CH_2Cl)_2}\,.$$

† Alkylenediphosphine oxides are known to be effective extractants for the recovery and separation of rare-earth metals[108-110]. Until now, however, they have been relatively difficultly accessible compounds[107,111-126].

However, available data indicate that several of them, possessing specific properties, may be of practical interest. Thus great attention is being paid to the search for phosphorus-containing polymers suitable for surface coatings on metals and for impregnating various materials in order to confer on them in some cases corrosion-resistance and in others non-flammability.

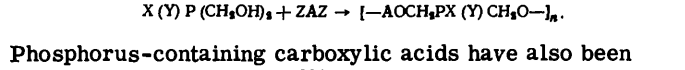
Such polymers can be obtained from tetrakishydroxymethylphosphonium chloride‡, trishydroxymethylphosphine oxide, bishydroxymethylphosphinic acid, alkyl(aryl)bishydroxymethylphosphines, and the corresponding phosphine oxides. The hydroxymethyl groups confer on these substances the properties of alcohols and aldehydes (in particular formaldehyde). Therefore they can be employed on the one hand as glycols for the preparation of polyesters (by polyesterification with dibasic acids, by the transesterification of esters, or by the alcoholysis of amides of phosphorus acids) and on the other as the phosphorus component for the production of high polymers by condensation with nitrogen-containing compounds and with phenols.

Tetrakishydroxymethylphosphonium chloride and bishydroxymethylphosphinic acid react with numerous carboxylic acids and their anhydrides to form phosphorus-containing polymers resembling alkyd resins[99,128-131]. The reaction involves the intermediate formation of monomeric substances of the following structure:



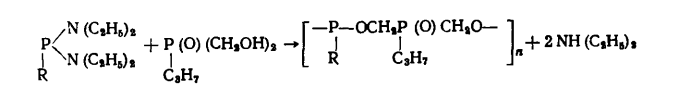
With dibasic acids the final products are fusible, transparent resins, probably of linear structure, and possessing self-extinguishability. With sebacic acid, for example, a rubberlike elastic polymer is obtained, showing good compatibility with polyethylene and conferring self-extinguishing properties on the latter; citric, succinic, phthalic, and adipic acids yield viscous liquids or brittle solids. These resins can be used for the production of corrosion-resistant films on metal surfaces.

Phosphorus-containing esters are obtained by the polycondensation of alkylbishydroxymethylphosphines and the corresponding oxides and sulphides with dicarboxylic acids or their esters, anhydrides, or chlorides[132,133]:



Phosphorus-containing carboxylic acids have also been subjected to this reaction[134].

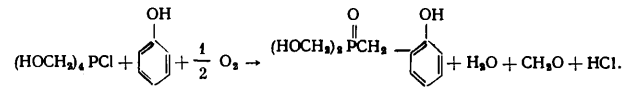
Alcoholysis of the tetraethyldiamides of methylphosphonous and phenylphosphonous acids with propylbishydroxymethylphosphine oxide gives polymers of the following type[134]:



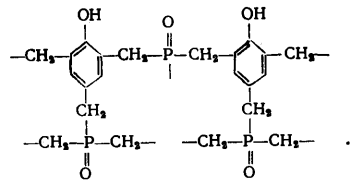
where R = alkyl, aryl. The polymers are semi-solid resinlike substances (especially those from phenylphosphonous tetraethyldiamide) having molecular weights up to 18 000. The low softening points (30–50°C) are probably due to the high phosphorus contents of the polymer molecules.

‡ When tetrakishydroxymethylphosphonium chloride is heated at 150–200°C, liquid polymers are formed which can be used for the impregnation of cellulosic materials to make them non-flammable[127].

Tetrakishydroxymethylphosphonium chloride, trishydroxymethylphosphine oxide[135], and alkylbishydroxymethylphosphines react through their hydroxy-groups with phenols, water being eliminated and phosphorus-containing polymers of linear and network structure being formed (hydroxymethyl- and bishydroxymethyl-phosphinic acids, in contrast, form not phosphorus-containing polymers but phenol–formaldehyde resins when heated with phenol[136]). Phenols containing a hydrogen atom in position 2, 4, or 6 undergo this reaction. Substituents in the phenols exert a similar influence on the condensation as in the case of the interaction of phenols with formaldehyde. Whereas the interaction of formaldehyde and phenols involves the intermediate formation of a hemiacetal[137], the condensation of tetrakishydroxymethylphosphonium chloride, trishydroxymethylphosphine oxide, and alkylbishydroxymethylphosphines with phenols obviously occurs directly at the *ortho*- and *para*-positions in the phenols, and thus bypasses the stage of semiacetal formation[131,138-143]:



The linear polycondensation products formed initially are converted into resins of complicated three-dimensional structure only when three active centres are present in the phenols employed (phenol, resorcinol, phloroglucinol)[18,140]:



If, however, the *para*-position or one of the *ortho*-positions of the phenol is occupied by a substituent, soluble, fusible resins of linear structure are formed (with *o*-bromophenol, quinol, pyrogallol, catechol)[140,144].

A more detailed study has been made of the properties of polymers based on alkylbishydroxymethylphosphines. These polymers possess ion-exchange properties in alkaline solution. For example, the polymer prepared from propylbishydroxymethylphosphine and phenol in equimolecular proportions has an ion-exchange capacity of 0.7 mg-equiv. g^{-1}.

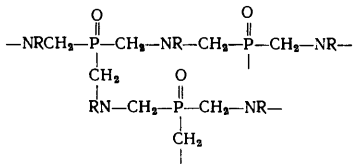
Tetrakishydroxymethylphosphonium chloride, trishydroxymethylphosphine oxide, and alkylbishydroxymethylphosphines also condense readily, with the liberation of water, with various nitrogen-containing compounds[3,131,134,138,142-158]. Linear polyaminomethylenephosphines are formed from alkylbishydroxymethylphosphines and diamines (hexamethylenediamine, *p*-phenylenediamine, benzidine, urea):

where R = alkyl and R′ = $[CH_2]_6$,

The resulting polymers (M = 42 900–54 000) are solids, mostly amorphous powders, soluble neither in acids nor in alkalis.

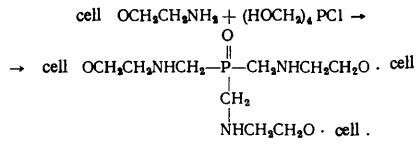
With amines (hydrazine, hydroxylamine, hexadecylamine, etc.) tetrakishydroxymethylphosphonium chloride and trishydroxymethylphosphine oxide initially form water-soluble linear products $(HOCH_2)_2POCH_2NHR$, which set on

standing in the cold for a few hours or on being heated to 100–150°C for a few minutes, to give strongly branched polymers having the structure



With ammonia and melamine tetrakishydroxymethylphosphonium chloride, trishydroxymethylphosphine oxide, and alkylbishydroxymethylphosphines form branched polymers in the form of incombustible powders, insoluble in the usual solvents.

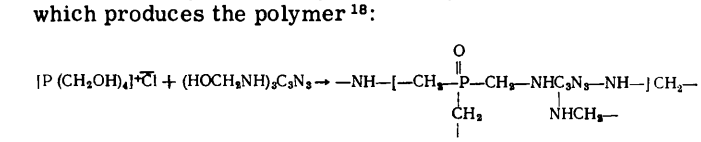
The flameproofing action of polymers obtained from tetrakishydroxymethylphosphonium chloride and amines was first discovered in a study of the properties of aminated cotton[18]. The quaternary chloride reacts with the amino-group in the aminated cotton to form a non-flammable modification of cellulose:



The phosphorus introduced into the cellulose in this way is firmly bound, and is not removed by boiling in water.

In order to confer flame-resistance on cotton without aminating it, tetrakishydroxymethylphosphonium chloride is made to react with amines, e.g. melamine, urea, thiourea, hydroxymethylmelamine. The phosphonium chloride condenses with these compounds, to form an insoluble resin on the fibre. Dicyandiamide, guanidine, melamine, and their hydroxymethyl derivatives form with tetrakishydroxymethylphosphonium chloride three-dimensional polymers, which in the cold do not dissolve in water, acids, or alkalis. The best results are obtained by condensing the quaternary chloride on the cellulosic materials with hydroxymethyl derivatives of melamine.

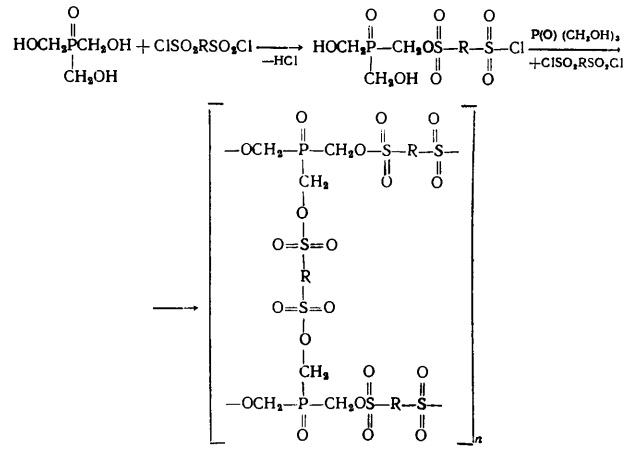
The following recipes—(1) 1868 g of tetrakishydroxymethylphosphonium chloride + 1338 g of trishydroxyethylamine + 1800 g of water; (2) 1060 g of trishydroxymethylmelamine + 1114 g of urea + 5062 g of water—have been proposed for giving cotton fabrics a non-flammable finish. Before use the two solutions are thoroughly mixed, and then applied to the fabric. The principal components of these recipes are tetrakishydroxymethylphosphonium chloride and trishydroxymethylmelamine, interaction between which produces the polymer[18]:



As a result of impregnation and a special treatment the fabric increases in weight by ~ 17%, and withstands the standard test for flame-resistance. The impregnated fabric retains its flame-resistance after 15 washes, and becomes crease-resistant and rotproof.

Copolymers obtained by the polycondensation of tetrakishydroxymethylphosphonium chloride with phenols and nitrogen compounds have also been proposed[145,159] for coating and impregnating fabrics and wood in order to confer on them non-flammable properties.

Phosphorus-containing polysulphonates are obtained by the interaction of aromatic disulphonyl chlorides with tetrakishydroxymethylphosphonium chloride, trishydroxymethylphosphine oxide, and trishydroxymethylphosphine[160]:



Tetrakishydroxymethylphosphonium chloride and trishydroxymethylphosphine oxide also find application for addition to other polymers with the aim of conferring on the latter various valuable properties, e.g. for the production of epoxide resins having improved heat-resistance[161], as modifiers in epoxide resins[156], as inhibitors of discoloration in film-forming compositions[162], etc.

Nitrosochlorination of Alkenes

P.P.Kadzyauskas and N.S.Zefirov

The reaction of nitrosochlorination has recently been attracting the attention of organic chemists, since it provides a ready means of obtaining classes of compounds which are extremely interesting from both theoretical and practical points of view. The laws governing this reaction, including the fine details of the stereochemistry and mechanism of this reaction, have not hitherto been systematised. The present review gives a detailed and systematic survey of the processes involved in nitrosochlorination and of the empirical laws of this reaction. Special attention is paid to published data on the mechanism and the stereochemistry of the reaction; nitrosochlorination is shown to possess features common to other reactions of electrophilic addition. The paper is addressed to a wide circle of organic chemists and undergraduate and postgraduate students. The list of references contains 119 items.

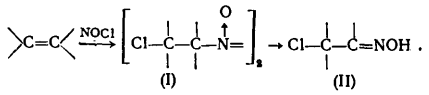
3. Mechanism and stereochemistry of the nitrosochlorination of alkenes 546
4. Anomalous products of nitrosochlorination 548

INTRODUCTION

In 1877 Tilden[1] established that nitrosyl chloride adds at a double bond to form dimeric nitrosochlorides of the type (I), which are able to isomerise to the corresponding oximes (II):



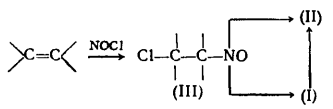
This reaction played an important part in the study of terpene compounds.

Nitrosochlorination has recently attracted the attention of chemists as a method of synthesising aziridine derivatives[2], intermediates in the synthesis of amino-sugars[3,4], amino-steroids[5-7], etc.

Several reviews have been published on methods of preparation, properties, and reactions of nitrosyl chloride[8-12]. The last review[12] covers all publications up to 1949, and fully reveals the preparative value of these reactions. During recent years, however, a large number of papers have appeared which change fundamentally our ideas on the mechanism and the stereochemistry of the nitrosochlorination of alkenes. In our survey, therefore, we have tried to summarise the general features of this reaction, while paying special attention to the stereochemistry and the mechanism of the process. We have used mainly literature which has appeared since 1950, but where necessary reference has been made to earlier work.

1. PRODUCTS OF NORMAL NITROSOCHLORINATION

Tilden[1] was the first to show that compounds containing a carbon–carbon double bond react with nitrosyl chloride usually with the formation of nitrosochlorides (III), which are dark blue oily substances. In most cases the latter are converted further into white crystalline substances—hydroxyimino-compounds (II)—or even into dimeric compounds (I). Henceforward we shall term the reaction leading to compounds of types (I), (II), or (III) normal nitrosochlorination:



It is readily seen that isomerisation to an oxime is possible only in those nitrosochlorides in which hydrogen is attached to the carbon linked to the nitroso-group.

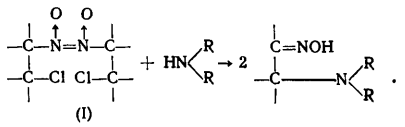
Partial conversion of (III) into (II) or into (I) can occur in the preparation of nitrosochlorides[13-16] or during their recrystallisation[17]. This explains the discrepancies in the early published data on the reaction products obtained from nitrosyl chloride and alkenes. For example, several of the compounds obtained earlier, which were regarded as hydroxyimino-compounds[15,18], have subsequently proved to be dimeric compounds[16,19].

The structure of dimeric nitrosochlorides was for a long time a matter of controversy. The work of Gowenlock[20-23] and also of Smith[24] showed that the dimerisation of nitroso-compounds involves formation of the grouping $-N(\rightarrow O)=N(\rightarrow O)-$. In such a case *syn–anti* isomerism may be expected to appear about the N=N bond even in the nitrosochlorides (in the literature on nitrosochlorination this isomerism is frequently termed *cis–trans* isomerism, although this name is evidently not accurate, and sometimes[25] incorrect terminology leads to misunderstanding).

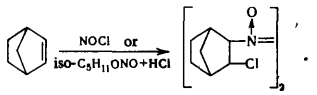
As several workers have shown, the nitrosochlorination of alkenes actually results in the formation of both *syn*- and *anti*-forms of dimeric nitrosochlorides (with respect to the N=N bond)[25-29]. In most cases the *syn*-isomers are unstable, and are readily isomerised into the *anti*-isomers. In several cases such isomerisation can occur so readily that the *syn*-isomers cannot be isolated at all[29-31].

In the molten form or in a hot solvent dimeric nitrosochlorides are in equilibrium with the monomeric form, as is indicated by the dark blue colour of the solution. After prolonged boiling, however, the hydroxyimino-compound (II) can be isolated from solutions of the dimeric nitrosochlorides[17,32,33]. The best method for obtaining oximes is probably to boil the dimeric nitrosochlorides with dilute hydrochloric acid[32,34].

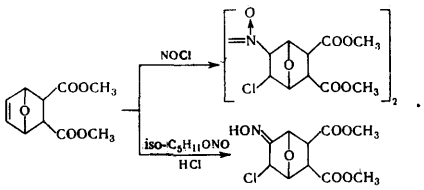
Dimeric nitrosochlorides (I) are decomposed with the formation of oximes by the action of primary or secondary amines[34-37], alkoxides[16,35], or metal phenyl sulphides[37]:



The course of the reaction is substantially influenced by the way in which nitrosochlorination is conducted. Differing results are obtained depending on whether the alkene is treated with pure nitrosyl chloride, with nitrosyl chloride contaminated with hydrogen chloride, or with isopentyl nitrite and hydrochloric acid. Thus the nitrosochlorination of norbornene and norbornadiene, both with pure nitrosyl chloride and with isopentyl nitrite and hydrochloric acid, results in the formation only of dimeric nitrosochlorides[38-40]:



In the nitrosochlorination of dimethyl 7-oxabicyclo[2,2,1]-hept-5-ene-2,3-dicarboxylate, however, pure nitrosyl chloride yields the dimer, whereas the use of isopentyl nitrite and hydrochloric acid gives the hydroxyimino-compound[32,41]:



It is seen from this example that even slight differences in the structure of the alkene strongly affect the course of the reaction.

Sometimes normal nitrosochlorination takes place only in the presence of a catalyst, such as nickel chloride, iron(II) chloride, copper(I) chloride[42], or aluminium chloride[43,44]. Thus ethylene and propene[45] do not form nitrosochlorides on reaction with nitrosyl chloride under the usual conditions of nitrosochlorination. However, good yields of the corresponding nitrosochlorides have been obtained[42] in dichloromethane or in chloroform in the presence of a catalyst (Raney nickel).

2. GENERAL FEATURES OF THE NORMAL NITROSOCHLORINATION OF ALKENES

The nitrosochlorination of unsaturated hydrocarbons shows several general features associated with the effect of substituents adjacent to the carbon–carbon double bond. Published data indicate that nitrosyl chloride adds to alkenes at the double bond more readily the more nucleophilic is this bond. Thus nitrosochlorination takes place more easily with di- and tri-substituted alkenes[13,15,16,18,27,46-51] than with monosubstituted alkenes[50-52].

It is noteworthy that the possibility and the rate of nitrosochlorination depend substantially on the position of the carbon–carbon double bond in the chain. Thus Ogloblin and his coworkers were unable to isolate crystalline dimeric nitrosochlorides by the nitrosochlorination of but-1-ene[52], pent-1-ene, hex-1-ene, hept-1-ene, or oct-1-ene[50], and only in the case of non-1-ene can stable dimeric compounds be obtained[12]. It is interesting to note that nitrosyl chloride reacts with propene at −22°C, whereas with ethylene the reaction is conducted in a nickel autoclave at +40°C.[42]

However, on treating but-2-ene[48] in contrast to but-1-ene with nitrosyl chloride, Ogloblin and Samartsev obtained a 29% yield of a crystalline dimer. Tilden and Forster[53], and subsequently also Thorne[54], isolated monomeric nitrosochlorides of hex-2-ene, hept-2-ene, oct-2-ene, and 4-methylpent-2-ene in low yields. Nevertheless, on the basis of a study of the infrared spectra, Ogloblin and Samartsev consider that pent-2-ene[27] and hex-2-ene[28] form dimeric compounds, though these are liquids.

The course of the reaction is probably unaffected by conjugation of the double bond with a benzene ring. Thus propenylbenzene forms a nitrosochloride[54], whereas allylbenzene does not react with nitrosyl chloride. Similarly, 1,3,5-trimethylstyrene does not interact with nitrosyl chloride[54], whereas 1,3,5-trimethyl-2-propenylbenzene[55] gives a crystalline nitrosochloride.

Nitrosyl chloride adds readily also to cycloalkenes to

Nitrosyl chloride adds readily also to cycloalkenes to form the normal nitrosochlorination products. For example, cyclohexene[25,26,56-60], cyclo-octene[61], cyclododecatriene[62-64], Δ^9-octahydronaphthalene[65-67], dicyclopentadiene[68], and *endo*- and *exo*-2-oxa-1,2-dihydrodicyclopentadienes[69] readily form dimeric chloro-nitroso-derivatives.

Nitrosochlorination goes still better with alkenes containing more than one alkyl substituent adjacent to the double bond. Thus 2-methylpropene[16,70] and 2-methylbut-2-ene[17,45-47,54] form with nitrosyl chloride dimeric compounds in yields of 60% and 50% respectively. 2,3,3-Trimethylbut-1-ene, 2-methylbut-1-ene, and 2-*p*-tolylpropene give yields respectively of 28%, 19%, and 9% of crystalline dimeric compounds[50]. 2,4,4-Trimethylpent-1(and 2)-enes also give good yields of dimeric nitrosochlorides[54].

A monomeric derivative was isolated from reaction of the tetrasubstituted 2,3-dimethylbut-2-ene with nitrosyl chloride[71]. In this case formation of a dimeric compound is probably made difficult by steric hindrance.

The addition of nitrosyl chloride obeys the Markovnikov rule[15,18,27,28,33,48,50,53,72-75]: the nitroso-group adds to the most hydrogenated carbon atom, which indicates that the double bond is initially attacked by the nitrosyl cation[73].

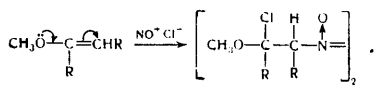
The orienting effect of n-alkyl substituents on the addition of nitrosyl chloride is the same as that of the methyl group. In the case of branched alkyl substituents the nitroso-group adds preferentially to a carbon atom attached to methyl[28], which is explained by the inductive effect of the alkyl groups. The strengthening of the orienting effect of various alkyl groups compared with that of methyl corresponds to the increase in the positive inductive effect of these groups[28], in the sequence $CH_3 < C_2H_5 < CH(CH_3)_2 < C(CH_3)_3$.

Recent kinetic investigations[76] indicate that electron-donor groups influence nitrosochlorination. The accompanying Table shows that the rate of nitrosochlorination decreases as the double bond becomes less nucleophilic.

Rate constants for the nitrosochlorination of alkenes in chloroform at 0°C.[76]

Alkene	$10^{-4}k_2$, $M^{-1}\,s^{-1}$	Alkene	$10^{-4}k_2$, $M^{-1}\,s^{-1}$
Methylallyl chloride	0.29	2,3-Dimethylbut-1-ene	20
3,3-Dimethylbut-1-ene	0.32	2-Methylpent-1-ene	23
4,4-Dimethylpent-1-ene	0.52	β-Methylstyrene	26
cis-Stilbene	0.64	Cyclohexene	29
3-Methylbut-1-ene	0.69	2-Methylpropene	30
3-Methylpent-1-ene	1.0	2-Methylbut-1-ene	33
4-Methylpent-1-ene	1.2	But-2-ene	52
But-1-ene	1.5	Hex-3-ene	66
Hex-1-ene	1.6	*cis*-Pent-2-ene	77
Oct-1-ene	1.8	*trans*-Pent-2-ene	108
Dodec-1-ene	1.8	Cycloheptene	135
trans-Stilbene	2.9	Cyclopentene	>1000
Styrene	6.5	2-Methylbut-2-ene	>1000
1,1-Diphenylethylene	9.8	2,3-Dimethylbut-2-ene	>1000
α-Methylstyrene	17	Norbornene	>1000

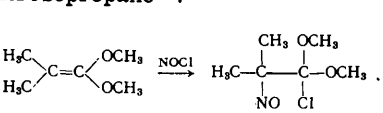
The nucleophilic character of the double bond is enhanced also in vinyl ethers owing to the effect of conjugation between the oxygen electrons and the π-electrons of the double bond. Such compounds therefore react vigorously with nitrosyl chloride[30,77]:



On the other hand, allyl methyl ether, where conjugation of this type is absent, does not form normal nitrosochlorination products[19].

Methylated and methoxylated styrenes give higher yields of the crystalline dimeric nitrosochlorides than do the unsubstituted styrenes. Thus the nitrosochlorination of α-methylstyrene[54], *p*-methylstyrene[45,56,57], *o*-methylstyrene[54], and *m*-methylstyrene[54] gave 71%, 66%, 52%, and 32% respectively of the dimers, whereas unsubstituted styrene[45,54,56,57] forms only 30% of the dimeric compound.

The nucleophilic character of the carbon–carbon double bond in the acetals of ketens is still more intensified by the electron-donor effect of the two alkoxy-groups. In this case, therefore, nitrosochlorination is rapid, and is probably immediately followed by instantaneous isomerisation of the nitrosochloride into an oxime[78]. As Ogloblin and his coworkers have shown[78], nitrosyl chloride easily interacts also with 1,1-dimethoxy-2-methylpropene, but the sole product of this reaction is 1-chloro-1,1-dimethoxy-2-methyl-2-nitrosopropane[78]:



On the other hand, electron-acceptor substituents in the α-position with respect to the double bond strongly retard nitrosochlorination[54,72,79]. Thus maleic and fumaric acids are recovered unchanged[53] from treatment with nitrosyl chloride. Similarly, crotonic and vinylacetic acids[53] also

do not react with nitrosyl chloride, but on prolonged treatment in sealed tubes are decarboxylated[44].

According to Thorne neither 5-phenylpent-4-enoic nor 6-phenylhex-5-enoic acid forms a nitrosochloride[54], although in the former case the double bond is separated from the carboxyl by two methylene groups. Published data do not indicate what is the minimum number of methylene groups necessary between the double bond and the carboxyl for reaction to occur. However, it is known that oleic acid does form a nitrosochloride[53,80].

An ester group has a similar effect. Thus Ogloblin and Semenov were unable to obtain a nitrosochloride by the action of nitrosyl chloride on methyl acrylate[81] or methyl methacrylate[44].

Chlorinated ethylenes do not form nitrosochlorides because of the strong influence of the chlorine atom[43,72,79,82,83].

The presence of a nitro-group near the double bond also prevents nitrosochlorination. Thus neither β-nitrostyrene[54] nor 2-nitropropene[83] gives a normal nitrosochlorination product.

Ogloblin and Potekhin showed[84-86] that, with αβ-unsaturated ketones, nitrosochlorination goes fairly smoothly, in spite of the presence of a strong electron-acceptor group. It is interesting that a dimer or an oxime is obtained depending on the reaction conditions or the structure of the αβ-unsaturated ketone[87,88].

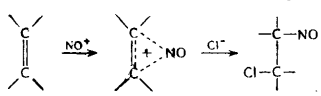
Nitrosochlorination also takes place relatively easily in the presence of a nitrile group. As Ogloblin and Semenov showed, at ordinary temperatures acrylonitrile gives β-chloro-α-hydroxyiminopropionitrile (yield 48%):[81]

$$CH_2{=}CH{-}CN \xrightarrow{NOCl} \underset{Cl}{\overset{}{CH_2{-}C{-}CN}} \underset{NOH}{\overset{}{\parallel}} .$$

3. MECHANISM AND STEREOCHEMISTRY OF THE NITROSOCHLORINATION OF ALKENES

As already stated above, the addition of nitrosyl chloride follows the Markovnikov rule, which indicates that the nitroso-group adds as an electrophilic species in the form of the nitrosyl cation.

On this Ingold[73] suggested that the reaction of nitrosyl chloride with alkenes took place according to the scheme



which is usual for electrophilic additions at a double bond. According to this, nitrosochlorination should result in the formation of *trans*-addition products. An analogous mechanism has been suggested in several other papers[30,43,54,75,77-78,89]. It must be emphasised, however, that the stereochemistry of the reaction has not been studied in any of the work on the addition of nitrosyl chloride to a double bond, with the exception of a few recent investigations[3-7,32,67].

The proposed mechanism is consistent with results for the infrared spectra[90], the electrical conductivity of the solutions[10,91-93], and isotopic exchange in liquid nitrosyl chloride[94-97], from which it follows that nitrosyl chloride dissociates according to the equation†:

$$NOCl \rightleftarrows NO^+ + Cl^- .$$

The concentration of the chloride ion and hence of the nitrosyl cation is 10^{-8} g-ion litre^{-1} at 18°C.[45]

† It must be remarked that sometimes the unjustified opinion is expressed that nitrosyl chloride dissociates into a chlorine cation and a nitrosyl anion[98].

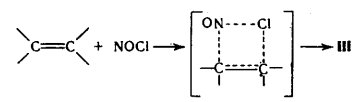
Kinetic investigations of the rate of nitrosochlorination have shown that overall it is of the second order, being of the first order with respect to each component. In the nitrosochlorination of styrene and cyclohexene in various solvents[76] the following sequence of reaction velocity

$$CH_3OH < (C_2H_5)_2O < CCl_4 < C_6H_5CH_3 \simeq n\text{-}C_7H_{16} < C_6H_5Cl < C_6H_4Cl_2 < C_6H_5CN < CH_2Cl_2 < C_6H_5NO_2 < CHCl_3$$

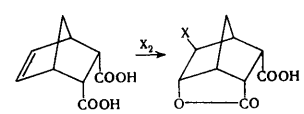
has been observed, which is difficult to explain. Unfortunately, no published data are available on the rate of reaction in liquid sulphur dioxide, where recent work[99] has shown that the course of the reaction is probably most unambiguous.

Nitrosochlorination is characterised by high entropies of activation: thus the values for styrene in chloroform and for cyclohexene are respectively −43.0 and −36.9 cal mole^{-1} deg^{-1}.[76] Unfortunately, data are lacking on the entropy of activation for nitrosochlorination in sulphur dioxide, which makes it impossible to compare the kinetic data with results of a stereochemical study (see below).

All this suggests that the transition state of the reaction is characterised by a definite and rigid orientation of the alkene and nitrosyl chloride molecules, and provides indirect evidence of the possibility of cyclic transfer of electrons, e.g. according to the scheme



There are also several experimental facts showing that nitrosochlorination does not always occur as a two-stage electrophilic addition at the double bond. It is well known that electrophilic addition to *endo*-carboxylic derivatives of norbornene involves the carboxyl and results in the formation of lactones[100,101]. For example, bromination of *endo*-adducts of diene synthesis from cyclopentadiene and maleic anhydride takes place according to the scheme

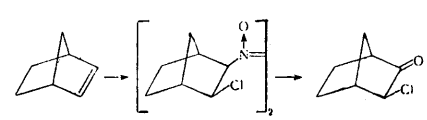


An analogous scheme is valid not only for bromination but also for the addition of mercury salts[102], 2,4-dinitrophenylsulphenyl chloride[103,104], and water[105], for opening an epoxide ring[106], etc.

Nevertheless, the interaction of *endo*-norbornenecarboxylic acid either with isopentyl nitrite and hydrochloric acid or directly with nitrosyl chloride results in the formation of dimeric nitrosochlorides, not lactones[38,67].

It should be noted that the nitrosochlorination of norbornene does not involve skeletal rearrangement of the Wagner–Meerwein type, while that of norbornadiene does not involve the second double bond[38,39].

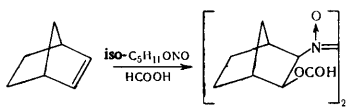
In 1964 Meinwald et al. showed that these reactions are cases of *exo-cis*-addition[67]:



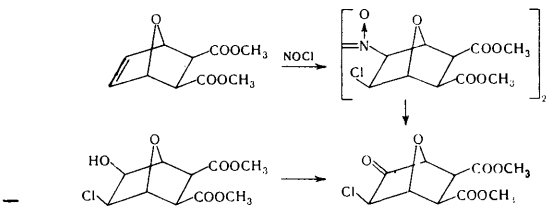
The stereochemical course of the nitrosochlorination of norbornene was elucidated by a chemical method: the dimeric nitrosochloride was converted into an *exo*-chloroketone described previously. The *cis*-configuration of the nitrosochloride of norbornene has since been confirmed by spectroscopy[3]. Miller[39] has also described the nuclear

magnetic resonance (n.m.r.) spectra, which provide unambiguous evidence of the *exo-cis*-configuration of the addition product, but he did not draw this conclusion.

It is interesting that the nitrosoformylation of norbornene[107] is also an *exo-cis*-addition:

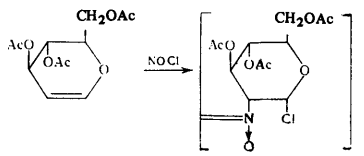


Zefirov et al. have shown[32] that the nitrosochlorination of dimethyl 7-oxabicyclo[2,2,1]hept-5-ene-2,3-dicarboxylate proceeds as an *exo-cis*-addition. This was proved by converting the dimeric nitrosochloride into a chloroketone, which was identified by comparing it with chloroketones obtained from chlorohydrins of known configuration[108]:



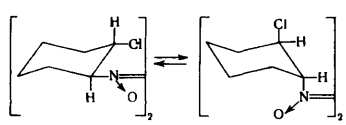
On the other hand, it has been shown in the case of hydroxymercuration[102] that the addition of weak electrophilic reagents to these bicyclic systems may lead to the formation of *cis*-addition products. Therefore it is not possible to draw general stereochemical conclusions concerning nitrosochlorination on the basis of data on the reactions of bicyclic alkenes.

The reaction of nitrosyl chloride with 3,4,6-tri-*O*-acetyl-D-glucal, 3,4-di-*O*-acetyl-D-arabinal, tri-*O*-acetyl-D-glucal, and di-*O*-acetyl-D-xylal takes place as *cis*-addition with the formation of dimeric nitrosochlorides[3,4]:



However, the stereochemical course of additions of D-glucal may also be anomalous. Thus data on the hydroxymercuration of D-glucal are contradictory: Inglis and Schwarz[109] interpret methoxymercuration as *trans*-addition, whereas results obtained by Manolopoulos et al.[110] indicate that this reaction is a *cis*-addition. The chlorination of D-glucal also takes place predominantly as *cis*-addition[3].

In this connection it is most interesting to study the stereochemistry of nitrosochlorination on simple models. Zefirov et al. have shown[111] that the reaction of cyclohexene with isopentyl nitrite and hydrochloric acid produces a dimeric nitrosochloride, which the n.m.r. spectra indicate to have a *trans*-configuration and which exists predominantly in the diequatorial form:



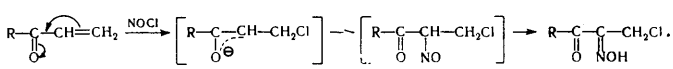
At the same time Ohno et al.[99] showed that the reaction of nitrosyl chloride with cyclohexene in liquid sulphur dioxide gives a nitrosochloride which is a *trans*-isomer. In chloroform, however, this reaction results in the formation of a dimeric nitrosochloride, to which a *cis*-configuration was attributed.

Thus the stereochemistry of nitrosochlorination depends fundamentally not only on the structure of the alkene but also on the method of preparing the nitrosochloride and on the solvent employed. The most plausible hypothesis is that the addition of nitrosyl chloride in non-polar solvents may involve an intermediate four-centre transition state. In polar solvents, however, a two-stage *trans*-addition is possible. The relative proportions of these mechanisms may depend not only on the solvent but also on the nature of the alkene, the reaction temperature, etc. It may be expected theoretically that catalysts of the aluminium chloride type will have a substantial effect on these proportions.

In 1963 Titov[43] reported the anomalous addition of nitrosyl chloride to halogenoethylenes. In order to accomplish smooth and rapid nitrosochlorination, solutions of Lewis acids (aluminium chloride, tin(IV) chloride, zinc chloride, iron(III) chloride, antimony(V) chloride) in excess of liquid nitrosyl chloride were used in this case at low temperatures. These aprotic acids form[10] with nitrosyl chloride complexes of the type $NO^+[MCl_x]^-$, which are strongly dissociated into the ions NO^+ and $[MCl_x]^-$. The use of complexes of nitrosyl chloride with Lewis acids should eliminate the possibility of a four-centre cyclic mechanism of addition of nitrosyl chloride at the double bond. Titov suggested an ionic mechanism for this process of nitrosochlorination, essentially analogous to that proposed earlier by Ingold[73].

However, data on the influence of catalysts on nitrosochlorination are contradictory. Thus Beier et al.[76] found that the use of Lewis acids produces no increase in the rate of nitrosochlorination, whereas Ogloblin and Semenov established[44] that the reaction between nitrosyl chloride and methyl methacrylate is far more rapid in the presence of aluminium chloride. Further results are evidently required, which would enable the effect of Lewis acids on nitrosochlorination to be assessed with complete clarity. Perhaps such acids will be found to accelerate the reaction only in the case of alkenes having a certain structure, in particular those containing electron-acceptor groups.

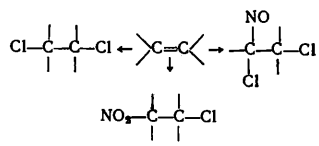
Ogloblin and Potekhin consider it possible that in several cases nitrosyl chloride adds by a nucleophilic mechanism:



Thus they showed[84] that $\alpha\beta$-unsaturated ketones form β-chloro-α-hydroxyimino-ketones very smoothly, in spite of the fact that the presence of a strongly electron-acceptor group adjacent to the double bond makes electrophilic addition difficult. Study of the reaction between nitrosyl chloride and $\alpha\beta$-unsaturated aldehydes also led the authors to the conclusion that such nucleophilic addition was possible. Thus under comparable conditions nitrosyl chloride reacts more vigorously with unsaturated aldehydes[31] than with the corresponding ketones[84]. A nucleophilic mechanism of nitrosochlorination is supported in this case by the effect of electron-donor substituents at the carbon–carbon double bond, which greatly lower the reaction velocity[31,84].

4. ANOMALOUS PRODUCTS OF NITROSOCHLORINATION

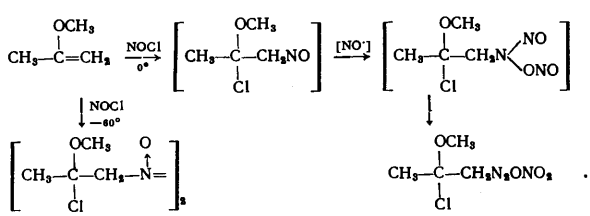
Although nitrosochlorination is widely used in synthetic practice for the preparation of chloro-nitroso- and chloro-hydroxyimino-compounds, it is nevertheless impossible in several cases to isolate the normal reaction products. The main side-processes are due to the chlorinating and oxidising action of nitrosyl chloride. The most generally occurring products of anomalous nitrosochlorination are dichlorides, dichloro-nitroso-compounds, and chloro-nitro-compounds, formed as follows:



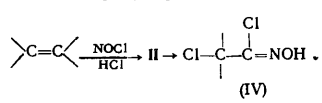
The factors determining the ratio of normal and anomalous nitrosochlorination products are extraordinarily diverse, and are often difficult to allow for exactly. Published data indicate that a substantial influence is exerted by the relative proportions of the reactants, the presence of acidic impurities in the nitrosyl chloride, the temperature of the reaction, and also the structure of the alkene. They indicate also that at elevated temperatures [33,48,81] nitration and chlorination will predominate over nitroso-chlorination.

Since in almost all cases the monomeric nitrosochlorides dimerise, Ogloblin et al. [50] explain the formation of dichloro- and nitro-chloro-derivatives in terms of the stability and the solubility of the dimeric nitrosochlorides. The formation of sparingly soluble and stable dimers would strongly diminish the yield of dichloro- and nitro-compounds; and conversely, good solubility of the dimers and ready dissociation into the monomeric forms will favour the appearance of anomalous nitrosochlorination products. These compounds are obtained by the interaction of nitrosyl chloride with the monomeric nitrosochloride of the alkene, taking place by a radical mechanism via unstable aliphatic diazo-nitrates [50].

Raising the temperature sometimes affects the formation of other reaction products in a definite manner. For example, reaction between nitrosyl chloride and 2-methoxypropene in ether at −60°C leads to formation of the nitrosochloride, whereas the same reaction at 10–15°C produces 2-chloro-2-methoxypropanediazo-nitrate, probably by a radical reaction with the monomeric nitrosochloride [30]:



As already mentioned above, in the presence of traces of hydrogen chloride the reaction of nitrosyl chloride with alkenes results in the formation of chloro-hydroxyimino-compounds [13–15,32,41]. However, cases have been observed in which chlorides of α-chlorinated hydroxamic acids can be obtained under these conditions [12–14,51,52]:



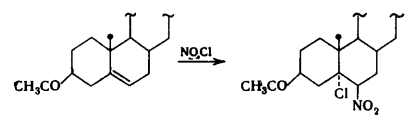
(IV)

The formation of dichloro-nitroso-compounds is obviously due to the chlorinating action of nitrosyl chloride. The interaction of oximes with this reagent results in geminal chloro-nitroso-compounds (IV) [112,113]. Therefore the formation of dichloro-nitroso-derivatives is facilitated preferentially if the reaction is conducted in the presence of excess of nitrosyl chloride. It is probable that the order in which the reactants are added plays a fundamental part in several cases.

In order that the nitrosochlorination of aliphatic alkenes should yield normal products, the double bond must have a certain nucleophilic character, and the reaction conditions must be maintained. Otherwise a complicated mixture of different addition products is formed.

In cases in which the addition of nitrosyl chloride to alkenes is difficult (i.e. in the presence of n-alk-1-enes and of alkenes containing electron-acceptor groups), the rates of chlorination and oxidation, leading to the formation of nitro-compounds, exceed the rate of addition of nitrosyl chloride, and the corresponding dichloro-compounds and chloro-nitro-compounds constitute the main products of the reaction [14,19,45,50–52,56,114–118].

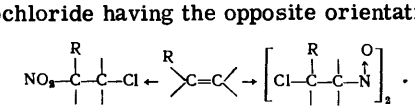
Cases are known in the literature in which chloro-nitro-compounds are formed extraordinarily readily, and are practically the sole products of the reaction [5–7]. For example, nitrosyl chloride reacts with cholesteryl acetate, the 3,17-diacetate of androst-5-ene, and 3-acetoxyandrost-5-en-17-one to form the corresponding 5-chloro-6-nitro-derivatives in high yield [5–7]:



The *trans*-diaxial positions of the chloro- and nitro-groups was established by a study of the reductive elimination of chlorine by the action of zinc dust in acetic acid [5], and also of the n.m.r. spectra [7].

Cholesteryl acetate reacts very slowly with pure nitrosyl chloride in ether at −5°C (a 53% yield of the nitrochloride was isolated after 2 months) [7]. It, however, unpurified nitrosyl chloride is used, the nitrochloride is formed quickly (in 92% yield after 5 days [5]). In the presence of nitrogen dioxide in ethereal solution the reaction is accelerated so much that the yield of the nitrochloride reaches 74% after only 2 h. This definitely indicates the possibility that this reaction is initiated by nitrogen dioxide, and in these cases the reaction probably consists in the free-radical *trans*-addition of nitryl chloride formed by the oxidation of nitrosyl chloride [12].

Such a mechanism is confirmed also by the fact that in several cases the chloro-nitro-compounds have an orientation of the nitro-group and the chlorine atom which is opposite to that to be expected for chloro-nitroso-compounds obeying Markovnikov's rule. Nevertheless, it should be noted that additions of nitryl chloride may show the opposite orientation to that observed in the reactions of nitrosyl chloride. Thus the nitrosochloride of an alkene is not the precursor of the nitrochloride of the alkene. For example, Yakubovich and Lemke [72] showed that the reaction of nitrosyl chloride with 2-methylpropene gives, together with the nitrosochloride, a small quantity of the nitrochloride having the opposite orientation:



A similar course of reaction, leading to the nitrochloride as the sole product, has been noted also by Andrianov et al.[119] in the case of 3-vinylheptamethylsiloxane:

$$2\,(CH_3)_3SiOSi(CH_3)OSi(CH_3)_3 + 2NOCl \rightarrow N_2 + Cl_2 + 2\,(CH_3)_3SiOSi(CH_3)OSi(CH_3)_3$$

The Chemistry of Azaindoles [Pyrrolo[2,3]pyridines†]

L.N.Yakhontov

The review discusses the chemical properties and the biological activity of aza-analogues of indole compounds, i.e. substances containing fused pyridine and pyrrole systems.
The interest taken in azaindole derivatives is due on the one hand to the ever broadening application during recent years of the principle of building up aza-analogues of biologically active substances (purines, pyrimidines, steroids, etc.) as bases in the search for new medicinal preparations, and on the other hand to the appearance in such systems of characteristic chemical properties, indicating a redistribution of electron density caused by the interaction of the "π-electron-deficient" and "π-electron-excessive" rings involved in the fusion.
The above problems are fully reflected in the review. Considerable attention is paid to discussing the chemical peculiarities of azaindoles associated with the presence in the fused systems of rings which have directly opposite displacements of π-electrons relative to carbon atoms, describing the features of lactam-lactim and amino-imino tautomerism in azaindole and azaindoline systems, and also examining routes and methods for introducing substituents both into the pyridine and into the pyrrole parts of the molecule. Exhaustive consideration is given to data on the biological activity of azaindoles. A special section is concerned with the choice of methods for building up azaindole systems and the characteristics of ring-closure in azaindoles compared with indoles.
The review covers all information available in the world's literature on the chemistry and the biological activity of azaindoles. The list of references comprises 159 items.

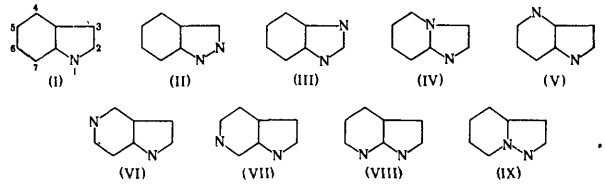
I. INTRODUCTION

In recent years the search for new medicinal preparations has been based with increasing frequency on the possible similarity or antagonism of the pharmacological action of biologically important compounds and their aza-analogues, substances in which one or more carbon atoms have been replaced by nitrogen.

Investigation of aza-analogues of pyrimidine and purine bases has enabled substances exhibiting considerable tumorstatic activity[6,7] to be obtained in the series of azaguanines[1], azauracils[2,3], azacytosines[4], and azathymines[5]. It has been established that aza-analogues of purine and pyrimidine bases, subjected in the organism to the processes of ribosidation and phosphorylation, become powerful inhibitors of several successive steps in the biosynthesis of pyrimidine nucleotides. Thus 6-azacytosine is converted in the tumour cells of Ehrlich's ascitic cancer into 6-azacytidine 5'-phosphate, which is an orotidylic acid decarboxylase inhibitor[4]. An analogous enzymic conversion product of 6-azauracil—6-azauridine monophosphate—blocks orotic acid decarboxylase, and interferes with the synthesis of uridylic acid[8,9].

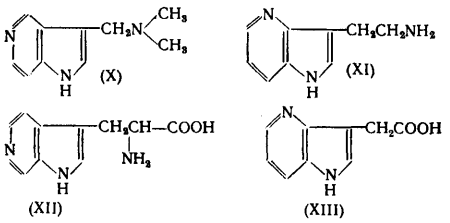
Study of the aza-analogues of steroid hormones[10-16] has brought to light compounds of interest not only from the point of view of their hormonal activity. This makes understandable the interest shown by chemists and biologists in the investigation of azaindoles, the simplest aza-analogues of the physiologically important indole compounds.

All products in which one of the carbon atoms of the indole ring (I) has been replaced by nitrogen are formally azaindoles. However, such a broad interpretation, adopted by several authors[17], includes in this class substances which are extremely diverse in chemical properties—pyrrolopyridines (V)–(VIII), benzimidazoles (III), indazoles (II), pyrimidazoles (IV), and pyrazolopyrimidines (IX):

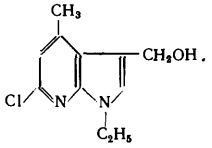


It appears advisable to restrict the concept of "azaindoles" by retaining this name only for products in which one of the atoms not common to the two rings in the indole molecule has been replaced by nitrogen (V)–(VIII), without, in contrast to Adler and Albert[18-20], regarding benzimidazole (III) and indazole (II) as azaindoles.

The nomenclature of the azaindoles is based on the principles used in constructing the names of indole compounds. The most widely used is addition of the position of the aza-substituent to the name of the corresponding indole derivative—4-azaindole (V), 5-azaindole (VI), 6-azaindole (VII), 7-azaindole (VIII), 5-azagramine (X), 4-azatryptamine (XI), 6-azatryptophan (XII), 4-azaindol-3-ylacetic acid (XIII), 6-chloro-1-ethyl-4-methyl-7-azaindol-3-ylmethanol (XIV), etc.:



† Although the "aza" system of nomenclature should strictly be based on the corresponding homocyclic compounds, the Reviewer's nomenclature has been followed in the Translation, especially as he discusses his choice of nomenclature in the Introduction (Ed. of Translation).

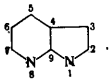


(XIV)

This most widely used principle of nomenclature is adopted in the present review.

It should be noted, however, that other terms of azaindole compounds are met in the literature. Azaindoles are most often named as diaza-analogues of indane[21-23], e.g. 1,4-diazaindane (V), 1,6-diazaindane (VII), etc. In American journals azaindoles are not infrequently considered to be derivatives of pyrrolopyridines[24-27], e.g. 1*H*-pyrrolo[2,3-*b*]pyridine (VIII), 1*H*-pyrrolo[3,2-*c*]pyridine (VI), etc.‡. An analogous nomenclature is found also in German papers[28], e.g. pyrrolo(2,3 : 2'3')pyridine (VIII).

In earlier papers azaindoles were termed pyrindoles[29,30]. Besides the above numbering of the rings, e.g. 7-pyrindole (VIII)[29], another system was also used, according to which the compound (VIII) was termed 8-pyrindole[31]:



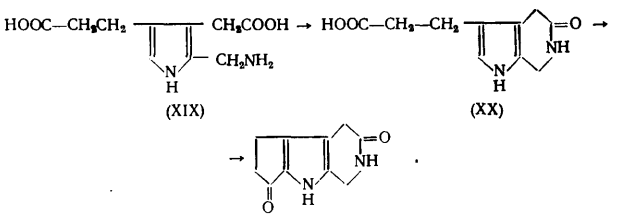
Quite often trivial names are used—harmyrine for 6-azaindole, and apoharmine for its 7-methyl derivative—reflecting the historical relation between 6-azaindoles and the harmine group of alkaloids.

II. METHODS OF PREPARING AZAINDOLES

1. Naturally Occurring Azaindoles

Most azaindole derivatives are synthetic products. The only naturally occurring unsubstituted azaindole which has yet been found is 7-azaindole, discovered in 1943 by Kruber[28] in the lepidine fraction of coal-tar. Nevertheless, the bicyclic 6-azaindole system is widely distributed as part of the fused polycyclic structures of various groups of alkaloids—yohimbine, canthine, harmine, corynanthine—alstonine, sarpagine–ajmaline, etc. Since such fused systems are not discussed in the present paper, we merely mention them, referring readers who are interested to specialised reviews on the chemistry of the alkaloids[32-35].

Derivatives of 6-azaindole are of definite value also in the chemistry of porphobilinogen (XIX), an intermediate in the biosynthesis of porphyrins[36]. A key compound in the study of the structure of porphobilinogen[37-39] was its lactam (XX)[40], a derivative of tetrahydro-oxo-6-azaindole. Conversion of porphobilinogen (XIX) into the lactam (XX) followed by closure of the five-membered ketone ring enabled the position and the nature of the side-chains in (XIX) to be determined[40]:



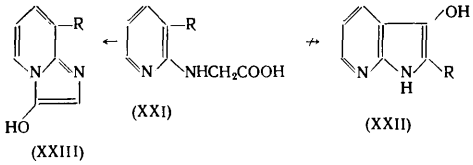
(XIX) (XX)

‡ The preceding examples in this paragraph are consistent with the recommendations of the International Union of Pure and Applied Chemistry (Ed. of Translation).

2. Features of the Synthesis of Azaindole Systems

Synthetic investigations in the azaindole series began in connection with the modification of indigoid dyes, when the idea arose of synthesising pyridine analogues of indigo, and publications appeared on a "new class of indigoid dyes", which were "pyrindole" derivatives. The key reaction in these syntheses was the cyclisation of substituted pyrid-2-ylaminoacetic acids (XXI) into the corresponding 7-azaindoxyls[41,42].

However, further research showed[43-45] that the course of this reaction in the pyridine series was different from that found in benzene derivatives. Ideas on the structure of the bicyclic pyridine product, based solely on analogies with indole derivatives, proved to be erroneous. Actually, cyclisation of the substituted pyrid-2-ylaminoacetic acids (XXI) led to the formation not of 7-azaindoxyls (XXII) but of compounds of the pyrimidazole series (XXIII):

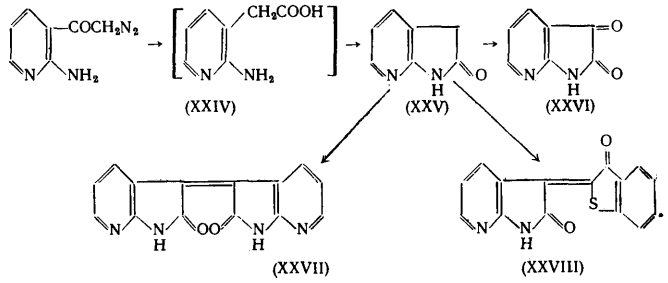


(XXIII) (XXI) (XXII)

where R = H, COOH.

Nor did subsequent work on the cyclisation of 4-carboxymethylamino-2,6-dimethylpyridine-3-carboxylic acid lead to azaindigoid dyes[46].

It was only in 1941 that Kägi[29] was able to obtain 7-azaoxindole (XXV) by the cyclisation of 2-aminopyrid-3-ylacetic acid (XXIV) and accomplish the conversion of (XXV) into 7-azaisatin (XXVI) and 7-azaindigoid vat dyes (XXVII) and (XXVIII). These researches have been further developed by the synthesis of 4-, 5-, and 6-azaindigos[47]:



(XXIV) (XXV) (XXVI) (XXVII) (XXVIII)

The initial failures to synthesise azaindigoid dyes were not fortuitous, and are of considerable interest for the chemistry of the azaindoles. In contrast to compounds of the benzene series, in which electrophilic substitutions occur comparatively readily, analogous reactions are accomplished with great difficulty in the pyridine ring, where the electron-acceptor properties of the cyclic nitrogen atom diminish the electron density on the carbon atoms. Furthermore, pyridine derivatives contain a ring nitrogen enriched with electrons, which easily acts as a nucleophilic centre in an addition reaction, and in the case of 2-aminopyridine derivatives also in nucleophilic substitution (with migration of the reaction centre).

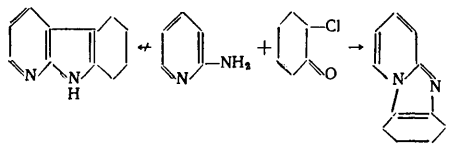
The peculiarities in the closing of azaindole compared with indole rings are due to these two factors—the lower electron density on the ring carbon atoms and the presence of a heteroatom having increased electron density.

The above method for obtaining indoxyls, and also the numerous reactions (Fischer, Harley-Mason, Reissert, Bischler–Napieralski, Pictet, Pomeranz–Fritsch reactions, etc.), which are widely used for synthesising various

heterocyclic systems from benzene derivatives, necessarily pass through a stage of electrophilic substitution in the benzene ring.

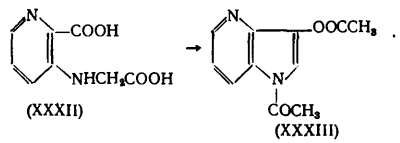
An analogous electrophilic substitution at a carbon atom is always more difficult and requires severe conditions on passing to the corresponding pyridine derivatives[48]. Furthermore, the competing process at the pyridine nitrogen becomes in several cases the main reaction, and prevents the use for preparing azaindoles of synthetic methods which have been widely and successfully employed in the chemistry of indole compounds.

Disregard of the peculiarities of the pyridine molecule in comparison with the benzene molecule led to errors not only in studying the cyclisation of pyrid-2-ylaminoacetic acid but also in several other cases. For example, a patent was applied for[49] in 1930 claiming the preparation of 9,10,11,12-tetrahydro-α-carboline (XXIX) by the reaction of 2-aminopyridine (XXX) with 2-chlorocyclohexanone. Later workers have shown[50] that the product of this reaction is not (XXIX) but 6,7,8,9-tetrahydropyrido[1,2-a]-benzimidazole (XXXI):



(XXIX) (XXX) (XXXI)

Thus in this case the reaction follows the general path of interaction between α-halogeno-carbonyl compounds and 2-aminopyridine discovered by Chichibabin[51]. A pyrimidazole derivative was probably formed also in the cyclisation of 2-carboxymethylaminopyridine-3-carboxylic acid described by Willette[52]. The analogous process of cyclisation of 2-carboxypyrid-3-ylaminoacetic acid (XXXII) yielded 1-acetyl-4-azaindol-3-yl acetate (XXXIII)[52]:



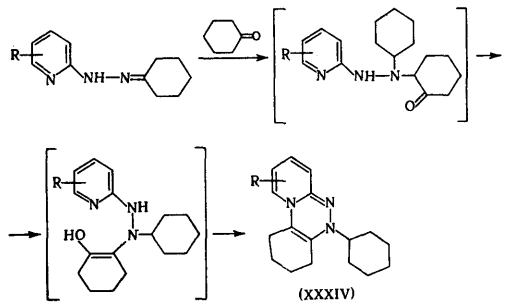
(XXXII) (XXXIII)

3. Application of the Fischer Reaction

The peculiar features of the chemical behaviour of pyridine compounds noted above have been responsible for the restricted application in the azaindole series of one of the most general methods for synthesising various indole compounds, the Fischer reaction. While going easily and smoothly with various arylhydrazones[53-55], this reaction does not usually give positive results with pyridyl- and quinolyl-hydrazones[21,22,56-60]. Successful synthesis of azaindoles by the Fischer method could be accomplished only from the pyridylhydrazones of a few ketones—cyclohexanone[58-60], 3-methylbutan-2-one[21,22], desoxybenzoin[60,61], cyclopentanone[62], indan-1-one[62], and α-tetralone[62].

A study of condensing agents has shown that in all cases considerably more severe conditions are required for the cyclisation of pyrid-2-ylhydrazones than for that of the corresponding arylhydrazones[63]. For example, catalytic quantities of zinc chloride or copper(I) chloride, which with cyclohexanone phenylhydrazone ensure that the Fischer reaction shall occur normally from 180°C,[64,65] enable only the original compound to be isolated in the case of the pyrid-2-ylhydrazone even at 240°C.[66] The Fischer cyclisation of pyrid-2-ylhydrazones is difficult even when boron trifluoride is used as catalyst. Only the application of strong mineral and arenesulphonic acids has made it possible to accomplish the conversion of cyclohexanone pyrid-2-ylhydrazones into 5,6,7,8-tetrahydro-α-carbolines in yields up to 98%.[67] Electron-donor substituents in the 5- and 6-positions of the pyridine ring, by increasing the electron density on the third carbon atom, facilitate the reaction, whereas electron-acceptor substituents hinder the process[66].

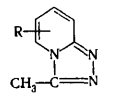
Nevertheless, it has been shown[63] that the cyclisation of cyclohexanone pyrid-2-ylhydrazones in the presence of hydrochloric acid, and also with an acetic-acid solution of the boron trifluoride–ether complex, involves "anomalous" reactions caused by the nucleophilic character of the nitrogen of the pyridine ring. The "anomalous" products of cyclisation in hydrochloric acid which have been isolated[63] are 9-cyclohexyl-5,6,7,8,9,12-hexahydro-9,10,12-triazaphenanthrene derivatives (XXXIV), the mechanism of whose formation can be written



(XXXIV)

In strongly acid medium the initial hydrazone is partly hydrolysed with the formation of cyclohexanone, which, by means of the reactive methylene group, adds at the C=N bond of the hydrazone. Subsequent enolisation of the ketone and elimination of water are facilitated by formation of the energetically favourable dihydro-1,2,10-triazanaphthalene system. Such a mechanism for the process is supported by the fact that the yield of (XXXIV) is more than trebled by the addition of an equimolecular quantity of cyclohexanone to the reaction mixture.

The "anomalous" course of the Fischer reaction in an acetic-acid solution of the boron trifluoride–ether complex is also due to acid hydrolysis. The pyrid-2-ylhydrazines which are thus obtained are acylated by the acetic acid, with further cyclisation of the acetyl derivatives into 3-methyl-1,2,9-triazaindenes (XXXV)[66]:

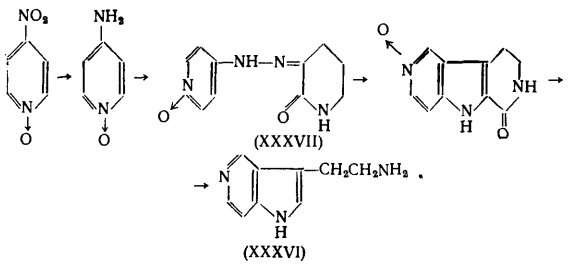


(XXXV)

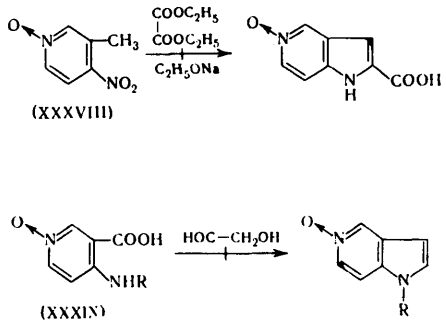
The above "anomalous" reactions are general in character, and are repeated with various substituted pyrid-2-ylhydrazones of cyclohexanone (R = H, 5-CH_3, 6-CH_3, 5-Cl, 5-Br, etc.)[66,67].

Since it has been established that the cyclisation of pyrid-2-ylhydrazones can be influenced by introducing substituents into the pyridine ring[66], it is worth looking into the Fischer synthesis of azaindoles from 6-chloropyrid-3-ylhydrazones of acetone and propionaldehyde[68], and also the successful application of the scheme of Abramovich and Shapiro for preparing 5-azatryptamine (XXXVI) from

the $N_{(1')}$-oxide of 2,3-dioxopiperidine 3-pyrid-4'-yl-hydrazone (XXXVII)[69]:



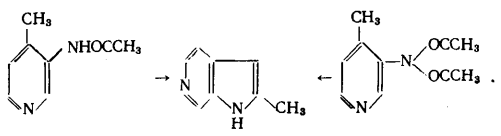
These results are especially interesting because attempts to synthesise 5-azaindole derivatives from the *N*-oxide of 3-methyl-4-nitropyridine (XXXVIII) by the Reissert reaction and from the $N_{(1')}$-oxide of 4-methyl(or phenyl)aminonicotinic acid (XXXIX) by the Harley-Mason reaction were unsuccessful[70]:



where R = CH_3, C_6H_5.

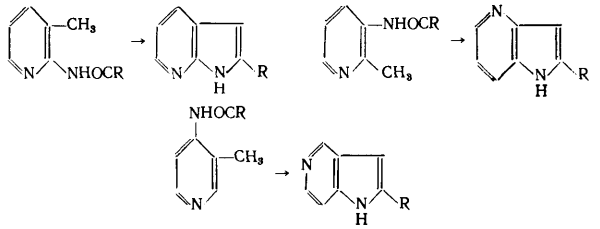
4. Application of the Madelung Reaction

Among methods which are widely used in the chemistry of indole, the Madelung synthesis[71] has found the widest application for the preparation of azaindole compounds. In 1927 Koenigs and Fulde[30] used this reaction to prepare the first synthetic azaindole derivative, 2-methyl-6-azaindole, a yield of 23% being obtained by the cyclisation of 3-acetamido-4-methylpyridine in the presence of sodium ethoxide. Somewhat better yields (up to 40%) were achieved from the corresponding 3-diacetylamino-4-picoline[25]:



It has proved impossible to convert the corresponding 3-formamido-derivative into unsubstituted 6-azaindole[30]. In all other cases formamidopyridines are poorer starting materials for azaindoles than are aminopyridines acylated by other acids.

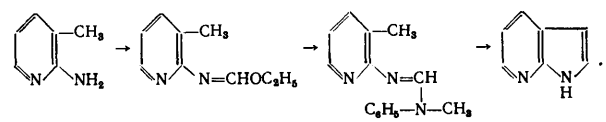
The Madelung method was later used for the synthesis of 4-, 5-, and 7-azaindole derivatives[72,73]:



The best results (yield 20%) were obtained in the case of 4-azaindole, while the yield of 7-azaindole was 3%, and unsubstituted 5-azaindole could not be synthesised by this method. The cyclisation of 4-acetamido-3-picoline to 2-methyl-5-azaindole took place with a yield of only ~ 1%. The same method enabled 5-methyl-4-azaindole (yield 12%) to be synthesised from 3-acetamido-2,6-lutidines, as well as the corresponding 2-methyl and 2-phenyl derivatives (yields 55% and 67% respectively)[23,74], while from 3-acylamino-4-picolines 12–24% yields were obtained of 2-phenyl-, 2-pyrid-2'-yl-, and 2-pyrid-4'-yl-6-azaindoles[75].

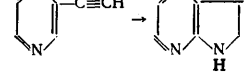
Further improvement of the Madelung reaction involved the use of sodium anilide and potassium formate as condensing agents[76], which enabled the yield of 7-azaindole at the cyclisation stage to be increased to 51%.[77] Rather lower yields (13–38%) are obtained for 4-, 5-, and 6-methyl-7-azaindoles[78]. Unfortunately, this modification of the Madelung reaction did not give favourable results for the 5- and 6-azaindoles. Conversion of 4-formamido-3-picoline in the presence of sodium anilide into a 21% yield of 5-azaindole[79] could not subsequently be repeated[24,25]. Published data[20,25] on the possibility of obtaining 4-azaindole by this method are also contradictory.

An interesting modification of the Madelung method was described in 1965 by a group of American workers[80], who showed that the best results are obtained by cyclising not formamidopicolines but the corresponding formamidine derivatives:



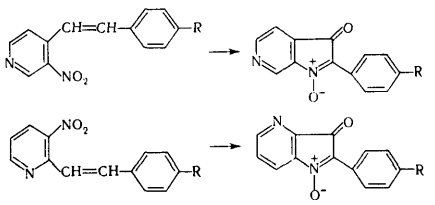
This procedure gives yields, based on the initial aminopicolines, of 70%, 37%, and 6% respectively of 7-, 5-, and 4-azaindoles.

It is worth noting the synthesis, recently published by Reisch[81,82], of unsubstituted 7-azaindole from 3-ethynylpyridine and sodamide, the yield being 54%:



The 2-amino-3-ethynylpyridine formed by the Chichibabin reaction in the course of the synthesis is immediately cyclised to 7-azaindole. A fundamental defect of this method is the relative inaccessibility of the initial 3-ethynylpyridines[83–85]. As Kost et al.[85] have shown, the preparation of 3-ethylnylpyridines from 3-vinylpyridines via the dihalogeno-derivatives is usually accompanied by the formation of 3-1'-alkoxyvinylpyridines as a side-reaction. In some cases the production of acetylenic derivatives of the pyridine series is so unsatisfactory that the method of synthesis via 3-ethynylpyridines loses its practical value.

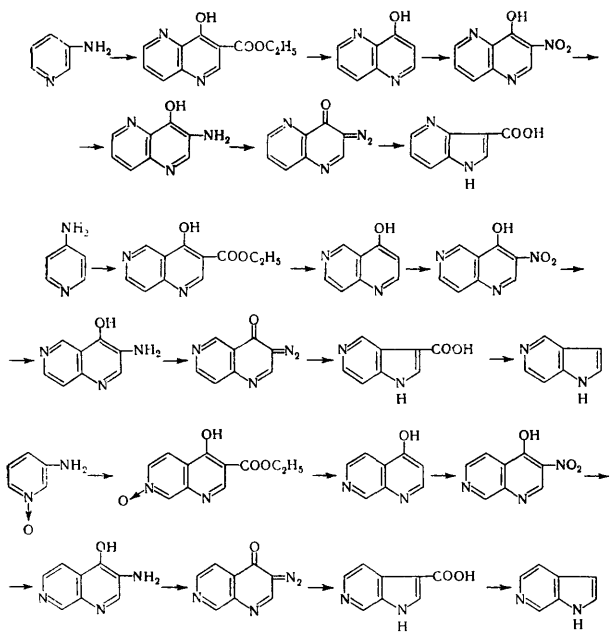
For example, Hooper et al.[75] intended to synthesise 1-hydroxy-3-oxo-4(and 6)-azaindolines from 3-nitro-2-(and 4)-styrylpyridines via the corresponding phenylethynyl derivatives. However, failures in obtaining the initial ethynyl compounds forced them to reject this scheme. The use of Splitter and Calvin's method[86] in this case enabled 2-aryl-1-hydroxy-3-oxo-4(and 6)-azaindolines to be obtained by the ultraviolet irradiation of substituted 3-nitro-2(and 4)-styrylpyridines[75]:

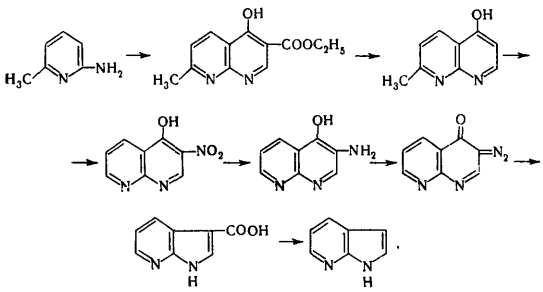


where R = $N(CH_3)_2$, OH.

5. Synthesis of Azaindoles by Süs and Möller's Method

An original photochemical method for preparing azaindoles from 3-diazo-3,4-dihydro-4-oxonaphthyridine isomers was described by Süs and Möller[87-89]. The starting materials used for the preparation of 4- and 5-azaindoles were respectively 3- and 4-aminopyridines, which were converted into 4-hydroxynaphthyridine-3-carboxylic esters by condensation with ethoxymethylenemalonic ester[90]. Subsequent stages consisted in saponification of the ester, decarboxylation, nitration, reduction of the nitro-group, and diazotisation of the 3-amino-4-hydroxynaphthyridines[87-89]. In the case of 6-azaindoles[88] the starting material for the preparation of 1,7-naphthyridine derivatives had to be 3-aminopyridine *N*-oxide, since unoxidised 3-aminopyridine could be converted only into substituted 1,5-naphthyridine[91]. In the preparation of 7-azaindole[89] 2-amino-6-methylpyridine was treated with ethoxymethylenemalonic ester; 2-aminopyridine which is not substituted in the 6-position forms in this case a pyrido[1,2-*a*]pyrimidine derivative, owing to cyclisation of the pyridine ring at the nitrogen atom[91]:



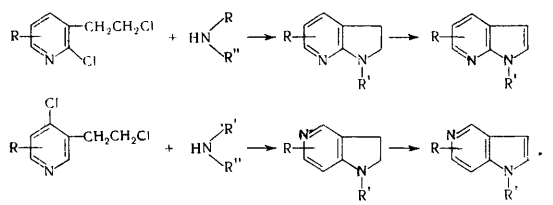


Photochemical ring contraction in the 3-diazo-3,4-dihydro-4-oxo-derivatives of the isomeric 1,5-, 1,6-, 1,7-, and 1,8-naphthyridines yields respectively the 4-, 5-, 6-, and 7-azaindole-3-carboxylic acids. With the exception of 4-azaindole-3-carboxylic acid, these are readily decarboxylated to isomeric azaindoles[87-89].

In spite of the multistage character of the process, it has proved valuable in the preparation of unsubstituted azaindoles. However, the comparatively severe reaction conditions restrict its use for obtaining azaindoles containing functional substituents.

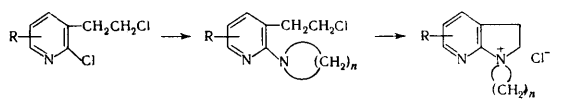
6. Syntheses of Azaindolines from 2(and 4)-Chloro-3-2'-chloroethylpyridines

A general method for synthesising various derivatives of 5- and 7-azaindoles[66,92-101] is to treat 3-2'-chloroethylpyridines containing halogen in position 2 or 4 with ammonia or a primary or secondary amine. The resulting azaindolines lose two hydrogen atoms on dehydrogenation, and are converted into the substituted azaindoles:



The reaction between 2(or 4)-chloro-3-2'-chloroethylpyridine and a secondary amine involves a novel type of pyrroline ring-closure accompanied by *N*-dealkylation. The reaction begins with replacement of the 2(or 4)-chlorine atom by the radical of the secondary amine, which is followed by cyclisation with formation of a quaternary azaindolinium salt, and this splits off alkyl halide, being thereby converted into a 1-alkyl(or aryl)-7-azaindoline.

The use of cyclic secondary amines (piperidine and pyrrolidine), by breaking up the process, permitted observation of the two successive stages—replacement of chlorine in the 2-position of the pyridine ring by the residue of the secondary amine, and subsequent cyclisation with the formation of spiro-7-azaindolinium compounds[102]—the reactions terminating at the latter stage, since in this case the quaternary 7-azaindolinium salt is unable to split off alkyl halide:



where n = 4, 5.

Study of the factors governing the ease of formation of 7-azaindoline derivatives by the above procedure indicates that the first stage of the reaction—replacement of the chlorine atom in the pyridine ring by the residue of the

secondary amine—is fundamentally influenced by the reactivity of the attacking nucleophilic agent, the lability of the halogen under attack, and also the competition of side-reactions. A decisive factor in the concluding stage of the synthesis is the ease of rupture of the carbon–nitrogen bonds in the quaternary azaindolinium derivative.

If steric factors are disregarded, increasing the basic strength of the secondary amine facilitates reaction with 2-chloro-3-2′-chloroethylpyridines and the formation of 7-azaindoline derivatives; secondary processes are facilitated at the same time. Thus, for example, *N*-substituted anilines ($pK_a < 6$) react with 2,6-dichloro-3-2′-chloroethyl-4-methylpyridine (trichlorocollidine) only at 190°C,[92,94] whereas aliphatic secondary amines ($pK_a > 9$) react similarly at only 80–140°C.[92] Nevertheless, 1-arylazaindolines are obtained from reactions with *N*-substituted anilines invariably in high yields, sometimes close to theoretical. The presence of electron-acceptor substituents in the *para*-position of *N*-alkylanilines hinders the reaction, whereas electron-donor groups facilitate the process[97].

When aliphatic secondary amines are used, formation of azaindolines is accompanied by that of secondary products[92,103], primarily derivatives of 2-chloro-3-vinylpyridine. Raising the temperature accelerates both processes—replacement of the 2-chlorine by the radical of the amine, which increases the yield of azaindoline derivative, and elimination of hydrogen chloride from the side-chain, which shifts the reaction towards the 2-chloro-3-vinylpyridine—the rate of the second process increasing more rapidly than that of the first with rise in temperature.

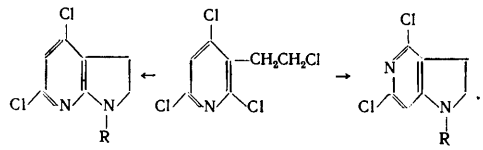
In the case of diphenylamine interaction with trichlorocollidine begins only at 300°C, the product being not an azaindoline derivative but 2-chloro-6-diphenylamino-4-methyl-3-vinylpyridine[92]. This course of the reaction is due not only to the low basic strength of the aromatic secondary amine (pK_a 0.9) but also to steric hindrance. The influence of steric factors appears also in other cases of reaction between 2-chloro-3-2′-chloroethylpyridines and secondary amines. For example, the ease of formation of azaindolines varies inversely with the length of the alkyl chain in the secondary amine[92]. Reactions with homologous dialkylamines or *N*-alkylanilines at the same temperatures reveal an increase in the yield of azaindoline derivatives as the alkyl chain becomes shorter[92,94].

The question of the relative reactivity of different electrophilic centres in substituted 2-chloro-3-2′-chloroethylpyridines towards amines has been examined most generally in the case of 2,6-dichloro-3-2′-chloroethyl-4-methylpyridine (trichlorocollidine), study of whose reactions with various nucleophilic agents has shown[104] that the chlorine in the side-chain of this compound is easily eliminated as hydrogen chloride and is very resistant to nucleophilic substitution.

Of the two ring chlorine atoms, that in position 2 is the more mobile, while nucleophilic attack at position 6 plays no important part, except where reaction at position 2 is sterically hindered[103]. As a consequence, only 1-substituted 6-chloro-7-azaindolines are formed at temperatures up to 270°C with various secondary aliphatic and aliphatic–aromatic amines, as also with *N*-alkyl(and aralkyl)anilines. The chlorine atom in position 6 is retained even in the presence of large excesses of secondary amines.

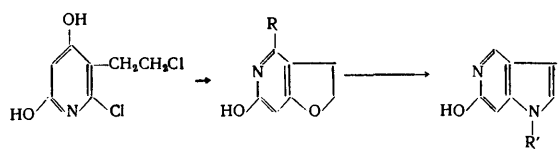
Further rise in temperature levels off the difference in reactivity between the halogen atoms in positions 1 and 6. At 300°C, for example, trichlorocollidine and *N*-methylaniline form no longer 6-chloro-4-methyl-1-phenyl-7-azaindoline but 4-methyl-1-phenyl-6-phenylamino-7-azaindoline[94]. It is interesting that in this case the *N*-dealkylation involved in closure of the pyrroline ring is accompanied by *N*-dealkylation of the 6-substituent. Since the product of the reaction of 6-chloro-4-methyl-1-phenyl-7-azaindoline with *N*-methylaniline, also occurring at 300°C, is 4-methyl-6-*N*-methyl-*N*-phenylamino-1-phenyl-7-azaindoline, not the corresponding *N*-desmethyl derivative, it can be assumed that replacement of the 6-chlorine by the amine residue in the high-temperature reaction of trichlorocollidine with *N*-methylaniline takes place either before or during, but not after, closure of the pyrroline ring[94].

The synthesis of azaindolines is considerably influenced by substituents in the initial 2-chloro-3-2′-chloroethylpyridines, which produce definite quantitative and in several cases even qualitative differences in the course of the reaction[66,92,93,97,98]. 2,4,6-Trichloro-3-2′-chloroethylpyridine undergoes two competing reactions with amines, with the formation of 5- and 7-azaindolines[96]:



The use of 2,4-dichloro-5-2′-chloroethylpyridine opened up the possibility of the directed synthesis of 5-azaindoline derivatives[66].

Dehydrohalogenation with closure of a dihydrofuran ring takes place extraordinarily easily in the case of 2-chloro-3-2′-chloroethyl-4,6-dihydroxypyridine, which opens new routes to the preparation of the hitherto difficultly accessible bicyclic 1-oxa-5-azaindane system[66]. Derivatives of this system on treatment with amines are readily converted into the corresponding 5-azaindoles[66]:



where R = Cl, H.

Further study of ways of synthesising azaindoline derivatives showed that not only 2-chloro-3-2′-chloroethylpyridines but also the corresponding 2-chloro-3-2′-hydroxyethyl and 2-chloro-3-2′-methoxyethyl-pyridines could react with secondary amines[105]. In this case, however, azaindoline derivatives could be synthesised only at higher temperatures (300–350°C). The mechanism of the formation of azaindolines from these 3-2′-hydroxy- and 3-2′-methoxy-ethylpyridines is probably analogous to that obtaining in the case of the 2-chloro-3-2′-chloroethylpyridines. The differences in reaction conditions are probably connected with the influence of the substituents in the side-chain (methoxy, hydroxy, chloro) on the lability of the 2-halogen atom. Transmission of the inductive effect of substituents through a chain of two carbon atoms and a pyridine ring can be observed also in other cases[105].

The final stage in the formation of 1-substituted 7-azaindolines from 2-chloro-3-2′-chloroethylpyridines and secondary amines is dealkylation of the quaternary azaindoline derivative. In the case of symmetrical secondary amines *N*-dealkylation is practically unambiguous: detachment of the alkyl (aralkyl) group is energetically more favourable than cleavage of the pyrroline ring. With unsymmetrical secondary amines which carbon–nitrogen bond undergoes cleavage in the quaternary azaindolinium

derivative is determined by the relative strengths of the bonds linking the substituents to the nitrogen atom: benzyl groups are more readily detached than are alkyl groups, and the latter considerably more easily than aryl groups[66].

The alkyl (or aralkyl) chloride which is eliminated in the process of dealkylation reacts under the given conditions with excess of the secondary amine, converting it into a tertiary amine. The corresponding tertiary amines have been detected and determined quantitatively by gas–liquid chromatography, after which samples were isolated[66].

7. Dehydrogenation of Azaindolines

Various methods of dehydrogenation have been used to convert azaindolines into the corresponding azaindoles. In the case of 1-alkyl(aryl)-7-azaindolines the most general method proved to be boiling with chloranil in xylene[93-97]. In most cases the reactions go smoothly with yields of 45–91%.

Dehydrogenation is facilitated by the presence of a 6-methoxy-group in the azaindoline molecule. With 4,6-dichloro- and 1-aryl-6-chloro-7-azaindolines, on the other hand, the oxidising potential of chloranil is inadequate, and a stronger oxidant, 2,3-dichloro-5,6-dicyanobenzoquinone, is required to convert such compounds into the azaindoles[96].

The process of dehydrogenation is considerably affected by the nature of the substituent attached to the pyrroline nitrogen. The introduction of an electron-acceptor substituent into position 1 of the azaindoline molecule hinders dehydrogenation, while the process is facilitated by an electron-donor substituent[66]. In the case of such strong electron-acceptor residues as acyl groups, dehydrogenation takes place neither on boiling with chloranil in xylene nor on heating with sulphur or with selenium to 240–300°C.[95]

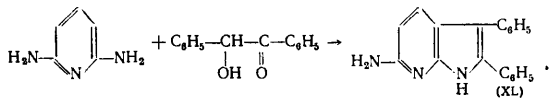
On passing from indolines and azaindolines to their *N*-sodio-derivatives (more accurately anions), when the electron density on the pyrroline nitrogen is greatly increased, the reduction potentials of the compounds rise markedly, and even air is a sufficiently strong oxidant to convert these substances into the corresponding indoles and azaindoles[106]. The dehydrogenation of indolines and azaindolines is accomplished in this case by treating their solutions in liquid ammonia with sodium in the presence of air. Separate experiments have shown that dehydrogenation does not take place in the absence of atmospheric oxygen[107].

Other strong bases—sodium hydride, sodamide, caustic soda—can be used instead of sodium. The yield of dehydrogenation products then varies directly with the strength of the base: with sodium hydride the extent of the process is about 80–85%, roughly the same as with metallic sodium, with sodamide 50–55%, with caustic soda 30–35%, and with sodium carbonate only traces of dehydrogenation products are formed[107]. Liquid ammonia is a convenient solvent for this reaction, and although the process goes also when indolines and azaindolines are treated with sodium in boiling toluene, formation of the corresponding anions is difficult under the conditions of a heterogeneous reaction, and the yields of dehydrogenation products are diminished.

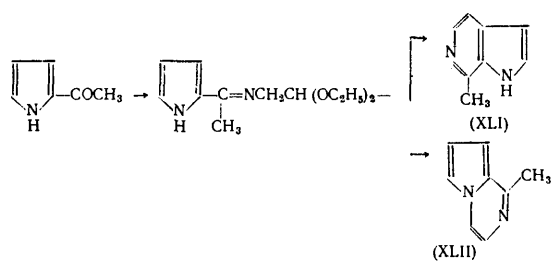
The possibility of combining into one stage, by the method which has been developed, the dehydrogenation of azaindoline derivatives with dehalogenation, and also the elimination of *N*-acyl and *N*-benzyl protective groups, is of considerable preparative interest[106].

8. Other Methods of Synthesising Azaindoles

Apart from the more or less general methods for obtaining azaindoles described above, syntheses have been published which are applicable only to individual compounds of this type. For example, formation of 6-amino-2,3-diphenyl-7-azaindole (XL) in 89% yield was observed on the reaction of 2,6-diaminopyridine and its hydrochloride with benzoin[26]. Unfortunately, this example proved to be unique, and in no case could azaindole compounds be isolated by the reaction of 2,6-diaminopyridine with other hydroxy-ketones:



Apoharmine (XLI) was synthesised[108,109] from 2-acetylpyrrole by the Pomeranz–Fritsch reaction:

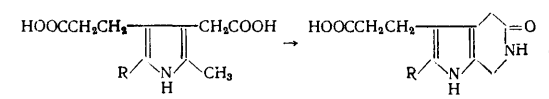


However, cyclisation of the 2-*N*-(2,2-diethoxyethyl)acetimidoylpyrrole went unexpectedly: together with (XLI), the stable yield of which did not exceed 5%, the formation was observed of a substituted 5,8-diazaindene (XLII). In the analogous synthesis from the corresponding 2-formidoyl derivative, the pyrrolopyrazine derivative was practically the only product of the reaction.

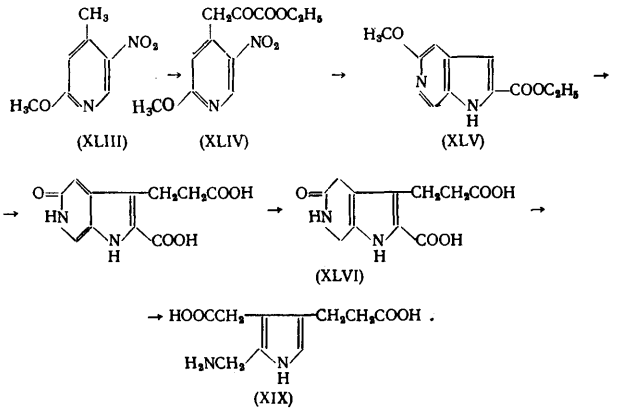
Low yields (1–7%) of 7-azaindole derivatives were obtained, accompanied by other compounds, by Johnson and his coworkers by treating diethyl 4-cyano-4,5-dihydro-2,7-dimethylazepine-3,6-dicarboxylate with silver nitrate[110] and by the reaction of potassium cyanide with dimethyl 4-chloromethyl-1,4-dihydro-1,2,6-trimethylpyridine-3,5-dicarboxylate[111].

The cyclisation of amino-carboxylic acids of the pyridine or pyrrole series to the corresponding lactams has occupied a definite place in the synthesis of azaindoles. As noted above, 7-azaoxindole was prepared from 2-aminopyrid-3-ylacetic acid by this method[29]. However, the poor accessibility of other aminopyridylacetic acids has not permitted the isomeric 4-, 5-, and 6-azaoxindoles to be synthesised[24,60].

3-Carboxyethyl-4-carboxymethyl-5-methylpyrroles, both substituted and unsubstituted in position 2, were used as starting materials in the synthesis of lactams of porphobilinogen and its analogues[112-115]. The 5-methyl group in these compounds was converted into aminomethyl either via the aldehyde, oxime, and nitrile[113,114] or via bromomethyl. Cyclisation of the substituted 5-aminomethyl-4-carboxymethylpyrroles was brought about by heating in acetic anhydride. The products of the synthesis were various 2-substituted 4,5,6,7-tetrahydro-5-oxo-6-azaindol-3-ylpropionic acids:

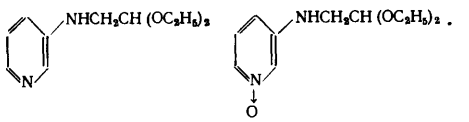


An interesting synthesis of porphobilinogen from 2-methoxy-5-nitro-4-methylpyridine (XLIII), proposed in 1965,[116] is based on Claisen condensation of the latter with oxalic ester followed by reductive cyclisation of the product (XLIV). Saponification of the methoxy-group in the resulting ethyl 5-methoxy-6-azaindole-2-carboxylate (XLV), introduction of a carboxyethyl group in position 3, and reduction of the pyridine ring with palladium gave the lactam of porphobilinogen-2-carboxylic acid (XLVI). Saponification of the lactam and decarboxylation enabled porphobilinogen (XIX) to be synthesised in an overall yield throughout the synthesis of 19%:



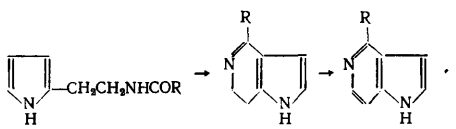
Methods of synthesising (XIX) suggested previously[112-115] gave yields not exceeding 2%.

Experiments on the cyclisation with polyphosphoric acid of 3-*N'*-diethoxyethylaminopyridines and their *N*-oxides, made by analogy with the synthesis of benzothiophens from aryl 2,2-dimethoxyethyl sulphides[117,118], did not give positive results in the case of azaindoles[25]:



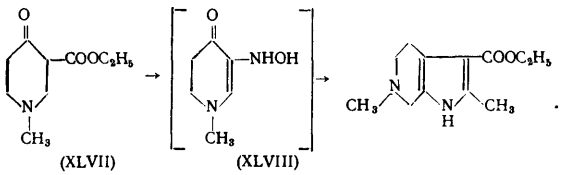
Attempts to cyclise 4-acetamido-3-bromopyridine to the corresponding 5-azaindole derivative[79] by the method of Hrutford and Bunnett[119] were also unsuccessful.

More interesting results have been obtained by synthesising 5-azaindole derivatives from acylated 2-2'-aminoethylpyrroles[120] by the Bischler–Napieralski reaction:

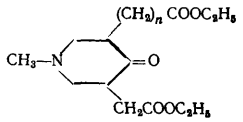


The acetyl and benzoyl derivatives were cyclised to the 4-methyl- and 4-phenyl-6,7-dihydro-5-azaindoles in yields of 18% and 24% respectively[27]. 2-*N'*-Formamido- and 2-*N'*-(3,4-dimethoxyphenylacetamido)-ethylpyrroles could not be converted into 5-azaindole derivatives[27].

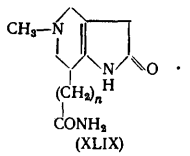
The synthesis of certain partly hydrogenated 6-azaindoles was accomplished by means of the reaction of ethyl 1-methyl-4-oxopiperidine-3-carboxylate (XLVII) with sodium nitrite, followed by reductive cyclisation of the 3-hydroxyimino-1-methyl-4-oxopiperidine (XLVIII) with acetoacetic ester[121]:



The cyclisation of other 1-methyl-4-oxopiperidines of general formula



by the action of ammonia has enabled several new 7-substituted 4,5,6,7-tetrahydro-5-methyl-5-azaoxindoles (XLIX) to be obtained, these existing in the oxo-form[122]:



III. CHEMICAL PROPERTIES OF AZAINDOLES

1. Chemical Peculiarities of Azaindoles due to Fusion of π-Electron-deficient and π-Electron-excessive Heterocycles in a Bicyclic System

A characteristic feature of azaindoles is that their fused bicyclic system is formed by two nitrogenous heteroaromatic rings with directly opposite displacement of the π-electrons inside each ring—the "π-electron-deficient" (in Albert's terminology[123]) pyridine ring and the "π-electron-excessive" pyrrole ring—and it is therefore interesting to examine the interaction of π-electron systems of this type and compare the chemical properties of azaindoles with those of the corresponding derivatives of pyridine, pyrrole, and indole.

Papers on the chemistry of the azaindoles have repeatedly noted their differences from indole compounds. In comparison with the latter, azaindoles have higher melting points[20], better aqueous solubility[20], and stability in acid and alkaline media[28,124], they do not give with a pine splint the colour reaction characteristic of indoles[30,73], and they exhibit more intense fluorescence[19].

Study of the basic strengths of unsaturated azaindoles revealed that three of them (4-, 5-, and 6-azaindoles) are stronger bases than is quinoline (pK_a 4.94), while 7-azaindole has a considerably smaller ionisation constant[20] (see Table 1).

The peculiarities of the 7-azaindole molecule in this case are due to the inductive effect on the 7-nitrogen atom of the closely placed 1-nitrogen[20]. An analogous effect is observed in benzimidazole (pK_a 5.53) and still more in indazole (1.22). Furthermore, the resonance contribution of *o*-quinonoid forms in 4- and 7-azaindoles is smaller than is that of *p*-quinonoid forms in 5- and 6-azaindoles, as a consequence of which the two former azaindoles have a lower pK_a value than have the latter isomers[20]. A

theoretical examination of the factors influencing the pK_a has enabled steric hindrance to be rejected in the case of 7-azaindole, since such hindrance would not be greater than in quinoline.

The ionisation constants of methylated 7-azaindoles[78], as was to be expected, are larger than that of unsubstituted 7-azaindole, diminishing in the sequence 4-, 6-, and 5-methyl-7-azaindoles (pK_a 5.23, 5.18, and 4.91 respectively).

Table 1.

Compound	M.p., °C	pK_a	λ_{max}, nm (lgε), in water
Indole	52	<1	273—278, 288(3.79+3.78; 3.69)
4-Azaindole	127	6.94	292 (3.92)
5-Azaindole	112	8.26	265.273 (3.59; 3.50)
6-Azaindole	135	7.95	260.291 (3.59; 3.68)
7-Azaindole	105	4.59	290 (3.91)

Examination of a large amount of information on the transmission of the effect of 1- and 6-substituents on the ability of 7-azaindoles and 7-azaindolines to undergo protonation at the nitrogen atom has shown[66,125] that a single aromatic system is present in 7-azaindoles, whereas in 7-azaindolines the effect of a substituent in the 1-position correlates well with the Taft induction constant for non-aromatic compounds. The application of correlation methods has enabled cross correlation equations to be obtained: for 1- and 6-substituted 7-azaindolines $-pK_a = -5.43 + 1.29\sigma^* + 8.0\sigma_i$, where σ^* and σ_i are the constants of substituents present in positions 1 and 6 respectively; and for 1- and 6-substituted 7-azaindoles $-pK_a = -3.80 + 8.57\sigma_{i\Sigma}$, where $\sigma_{i\Sigma}$ is the total constant of the substituents in positions 1 and 6.[66,125]

Table 2.

Compound	τ_1	τ_2	τ_3	τ_4	τ_5	τ_6	τ_7	$J_{1,2}$	$J_{1,3}$
Indole	—0.12	2.73	3.55	2.45	3.00	2.92	2.60	2.5	2.
7-Azaindole	—	2.53	3.52	2.04	2.95	1.73	—	—	—
	$J_{1,4}$	$J_{2,3}$	$J_{3,7}$	$J_{4,5}$	$J_{4,6}$	$J_{4,7}$	$J_{5,6}$	$J_{5,7}$	$J_{6,7}$
Indole	0.8	3.1	0.7	7.8	1.2	0.9	7.0	1.2	8.0
7-Azaindole	—	3.4	—	7.7	1.5	—	4.7	—	—

The good agreement between pK_a-values calculated by means of the correlation equations and those found experimentally shows that, in the case of 1- and 6-substituted 7-azaindoles and 7-azaindolines, the ionisation constants are influenced mainly by the induction effect of the substituents. A considerably smaller part is played by direct conjugation (except in 4-methyl-1-*p*-nitrophenyl-7-azaindole) and also by steric factors in these cases[66].

A special investigation[126] has been made of the nuclear magnetic resonance spectra of several heteroaromatic systems, including indole and 7-azaindole. However, this was confined to measurement of the proton chemical shifts and the spin–spin interaction constants, no attempt being made to characterise the distribution of electron density in azaindole systems (Table 2).

In order to examine theoretically the mutual influence of conjugated π-electron-deficient and π-electron-excessive rings in a fused system, the 7-azaindole[127] and indole[127,128] molecules have been calculated to the Hückel π-electron approximation. The results are presented in the form of tables (Table 3) and molecular diagrams (that of pyridine[129] is given for comparison):

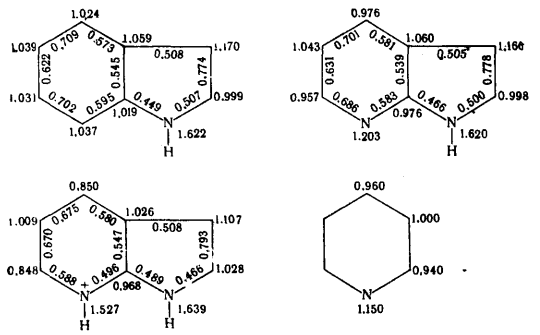


Table 3.

Compound	Vacant levels		Occupied levels		Total energy of π-electrons	Delocalisation energy	Resonance energy
Indole	—2.158	—1.179	0.534	1.280			
	—1.500	—0.853	0.796	1.669	13.399	11.399	3.399
				2.420

				2.455			
7-Azaindolinium cation	—2.012	—1.044	0.742	1.603			
	—1.336	—0.481	1.022	2.174	16.944	11.844	—
				2.932			

From the distribution of effective charges it has been shown[127] that in the carbon portion of the 7-azaindole electrophilic substitutions should occur most readily at position 3, and nucleophilic substitutions at positions 4 and 6.

Comparison of the molecular diagrams of pyridine and 7-azaindole indicates[127] that, owing to the redistribution of charges in the 7-azaindole molecule, increased electron density is present at positions 4 and 6 compared with the corresponding positions 4 and 2 in the pyridine ring. This provides an explanation of the difficulty of nucleophilic substitutions in 7-azaindoles.

Chemical experiment has confirmed[66] that in 7-azaindole electrophilic substitution takes place most readily at position 3, while the sites of nucleophilic attack are the 4- and 6-carbon atoms. 7-Azaindole derivatives exhibit considerably less tendency to nucleophilic substitution in

comparison not only with pyridines but also with 7-azaindolines. For example[95], when 6-chloro-4-methyl-7-azaindole is treated with such a strong nucleophilic reagent as the methoxide ion, replacement of chlorine by methoxyl is only 39% complete even at 300°C. The analogous reaction with 6-chloro-4-methyl-7-azaindoline was more than 70% complete at 190°C, while the chlorine atom in 2-chloropyridine was replaced by the methoxy-group at only 70°C. 4-Methylpyridine reacts with *m*-nitrobenzaldehyde to give a 73% yield of *m*-nitrostilbazole, and the yield of styryl derivative when *m*-nitrobenzaldehyde is condensed under the same conditions with 1-butyl-4-methyl-7-azaindoline is 26%, while 1-butyl-4-methyl-7-azaindole does not react with aldehydes over a wide range of temperatures[93]. Nor have positive results been obtained from experiments[130] on the direct introduction of an amino-group into the 7-azaindole molecule in the presence of sodamide by the Chichibabin reaction, which is so characteristic of the pyridine series.

Electrophilic substitutions (the Mannich and Vilsmeier reactions, cyanomethylation, nitration, and bromination) are more difficult in position 3 of 7-azaindole derivatives than in the indole series. Groups present in positions 1 and 6 have a considerable effect here[66,131]. The ease of occurrence of these reactions increases, for example, on passing from 6-methoxy-7-azaindoles through the 6-unsubstituted compounds to 6-chloro-7-azaindoles[131], approaching in the last case analogous reactions in the indole series. The introduction of electron-acceptor groups into position 1 of the azaindole molecule hinders electrophilic substitutions in position 3, whereas electron-donor groups facilitate the process.

Substituents in positions 1 and 6 affect electrophilic substitution not only owing to change in the electron density at position 3 of the azaindole molecule but also because the ability of 7-azaindoles to be protonated at the pyridine nitrogen is changed[66,127]. The production, under the conditions of electrophilic substitutions, of forms in which the nitrogen atom is protonated leads to a general positive charge on the molecule and an associated redistribution of π-electron density, which, of course, hinders electrophilic attacks at position 3. This agrees well with calculation of the protonated form of 7-azaindole—the 7-azaindolinium cation[127].

2. Lactam–Lactim and Amino–Imino Tautomerism in 7-Azaindoles and 7-Azaindolines

Interesting results related to the interaction of the two nitrogen atoms in the 7-azaindole system have been obtained in a study of the lactam–lactim and amino–imino tautomerism of 6-hydroxy-7-azaindoles and also of 6-hydroxy-, 6-amino-, and 6-acylamino-7-azaindolines[66,132]. In contrast to other α(or γ)-hydroxy-*N*-heteroaromatic compounds, no sufficiently complete displacement of the tautomeric equilibrium towards the lactam takes place in 6-hydroxy-7-azaindoles and 6-hydroxy-7-azaindolines. In solutions comparable quantities of the two tautomers are observed, and ultraviolet and infrared spectroscopy permit the influence of the polarity of the solvent, and also the nature of the substituents attached to nitrogen in the five-membered ring, on the position of the lactam–lactim tautomeric equilibrium to be clearly traced[66].

With 6-hydroxy-4-methyl-7-azaindoline in dioxan solution 88% of the lactim form is observed, dilution with alcohol diminishes the content of the lactim, and in absolute alcohol the compound is almost completely converted into the lactam form. In the case of 1-butyl-6-hydroxy-4-methyl-7-azaindoline such conversion is already achieved in the range dioxan : alcohol (9 : 1)–alcohol : water (3 : 1). 6-Hydroxy-4-methyl-1-phenyl-7-azaindoline contains 88% of the lactim form even in a 1 : 1 mixture of alcohol and dioxan, while sufficiently complete conversion to the lactam form is accomplished only in water containing 2% of alcohol.

The presence of the two tautomeric forms of 6-hydroxy-7-azaindolines together is confirmed by the infrared spectra in dilute carbon-tetrachloride solutions, where both the carbonyl bands of the lactam form at 1630–1645 cm^{-1} and the absorption at 3580–3582 cm^{-1} characteristic of hydroxy-stretching vibrations of the lactim form are clearly developed.

The decrease in electron density on the 7-nitrogen on passing from pyridines through 7-azaindolines to 7-azaindoles is made evident in a further shift in the lactam–lactim tautomeric equilibrium towards the lactim forms in 6-hydroxy-7-azaindoles compared with 6-hydroxy-7-azaindolines[133]. Ultraviolet spectroscopic data indicate that in 6-hydroxy-4-methyl-1-phenyl-7-azaindole, for example, the tautomeric equilibrium is shifted so far towards the lactim form that considerable quantities of the lactim remain even in strongly polar solutions (in water containing 2% of alcohol). In this case neither in the crystals nor in dioxan solution can lactam groups be detected by infrared spectroscopy, and only in carbon tetrachloride, where the dielectric constant is higher than in dioxan, is a weak band at 1642 cm^{-1} due to the lactam carbonyl apparent together with the intense band at 3580 cm^{-1} characteristic of the hydroxy-group of the lactim form[133].

6-Hydroxy-derivatives of 7-azaindole and 7-azaindoline are distinguished from other α-hydroxy-*N*-heteroaromatic compounds not only in the position of the lactam–lactim tautomeric equilibrium but also in their chemical properties. For example, methylation with dimethyl sulphate in alkaline aqueous medium gives high yields not of *N*-methyl but only of *O*-methyl derivatives[66].

Investigation of the amino–imino tautomerism of 6-amino-4-methyl-1-phenyl-7-azaindoline and its $N_{(6)}$-acyl (acetyl, trichloroacetyl, and toluene-*p*-sulphonyl) derivatives by ultraviolet and infrared spectroscopy has shown that in this case the equilibrium is practically completely displaced towards the amino-forms, and even acylation with toluene-*p*-sulphonic acid does not lead to an appreciable shift in the tautomeric equilibrium towards the imino-form, in contrast to what happens with other *N*-heteroaromatic amines[66].

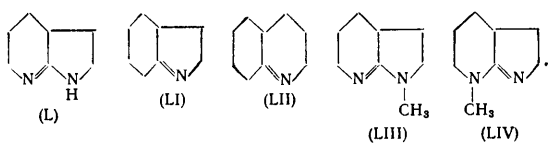
3. Substituted Azaindoles and Reduction of the Azaindole Ring

Synthetic investigations based on azaindole compounds developed by analogy with the chemistry of indole and pyridine. The various reactions were applied mainly to derivatives of 7-azaindole. Like the various pyridine bases, 7-azaindole forms salts (hydrochloride, picrate) and quaternary derivatives involving the nitrogen atom in the six-membered ring[28,124]; as in indole, the pyrrole nitrogen can be acylated and alkylated[95,124].

The hydrogenation of 7-azaindole by means of a nickel catalyst in decalin at 200°C and 118 atm yields 7-azaindoline[28]. 2-Amino-3-ethylpyridine was isolated as a side-product, and at higher temperatures became the chief product[134]. Analogous cleavage of the five-membered ring during hydrogenation at high temperatures is

observed also in the indole series[135]. 2-Alkyl-7-azaindoles are reduced under the same conditions with marked resinification, and satisfactory yields of 2-methyl- and 2-ethyl-7-azaindolines are obtained only with a copper–chromium catalyst[72]. Attempts to reduce ethyl 7-azaindole-1-carboxylate under mild conditions[134] did not yield positive results, unlike analogous experiments with other ethyl pyrrole-1-carboxylates[136].

The hydrogenation of 7-azaindole at room temperature and atmospheric pressure with a platinum catalyst yielded Δ^7-hexahydro-7-azaindole (L), whose structure was established by a comparative analysis of the characteristic C=N stretching frequencies in the infrared spectra of (L) and a series of analogous compounds[134]. It was shown[137–139] that in $\Delta^{8(1)}$-hexahydroindole (LI) the C=N stretching vibrations have a frequency of 1647 cm^{-1}, while the analogous C=N bond in $\Delta^{9(1)}$-octahydroquinoline (LII) is characterised by a frequency of 1658 cm^{-1}. The hexahydro-derivative of 7-azaindole investigated had an absorption band at 1652 cm^{-1}, while the hexahydro-derivatives (LIII) and (LIV) obtained by the reduction of 1- and 7-methyl-7-azaindole absorbed at 1657 and 1615 cm^{-1} respectively:



All these data indicate that, when 7-azaindole is hydrogenated in the presence of a platinum catalyst, the double bond in position 7(8) in the six-membered ring remains unreduced[134].

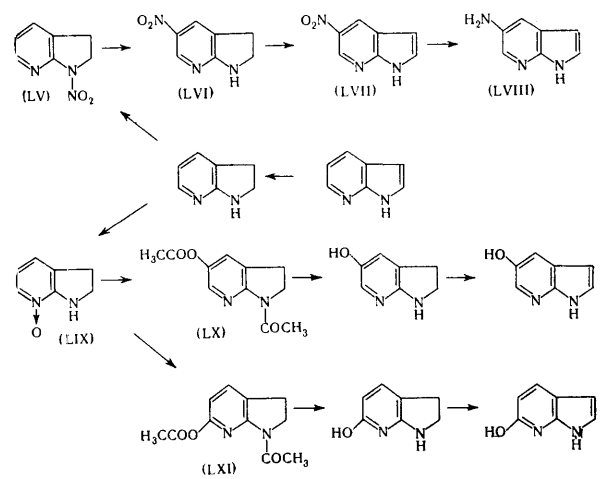
In contrast to 7-azaindole, the isomeric 5-azaindole could not be reduced in the presence of a platinum catalyst in acid medium[79].

When the 7-azaindole ring contains a 3-hydroxyimino-group, however, formation of 7-azaindoline derivatives is observed even in the presence of lithium tetrahydroaluminate[140].

4. Introduction of Substituents into the Pyridine Ring of Azaindoles

The conversion of 7-azaindoles into 7-azaindolines and the processes described above for dehydrogenating azaindoline derivatives have enabled a trial to be made in this series of compounds of an elegant method which has been widely used by Terent'ev, Preobrazhenskaya, and their coworkers in the chemistry of indole[141–144]. The method consists essentially in reducing indole or a derivative thereof to an indoline, which is an aromatic amine and hence capable of the usual reactions in the benzene ring. After the introduction of a substituent, the indoline is dehydrogenated, and the corresponding *Bz*-substituted indole is obtained.

This procedure has been used to introduce substituents at position 5 in 7-azaindole[130]. The 1-nitro-derivative (LV), obtained by nitrating 7-azaindoline, could be converted by thermal rearrangement into 5-nitro-7-azaindoline (LVI). The latter was dehydrogenated over palladium to 5-nitro-7-azaindole (LVII), from which 5-amino-7-azaindole (LVIII) was obtained by reduction. Another reaction used for the preparation of *Py*-substituted 7-azaindoles was rearrangement of the $N_{(7)}$-oxide of 7-azaindoline (LIX) in the presence of acetic anhydride. The rearrangement occurred unambiguously, and the corresponding 5- and 6-hydroxy-7-azaindolines were obtained as the *NO*-diacetyl derivatives (LX) and (LXI) in yields of 19% and 31%:[130]



In view of this, the directed synthesis of *Py*-substituted azaindoles[66] is more promising than the introduction of functional groups into unsubstituted azaindole structures.

5. Introduction of Substituents into the Pyrrole Ring of Azaindoles

Most work has been done on the preparation of 3-substituted 7-azaindoles. The 7-azaindoles are converted by the Mannich reaction into azagramines[66,77,131,145], the position of the 3-dimethylaminomethyl group in which has been confirmed by synthesis[77]. The nitration[66,77,131], bromination[66,131,146], and cyanomethylation[131] of 7-azaindoles have been described. The Vilsmeier reaction has proved a convenient general method for introducing a 3-formyl group into the 7-azaindole molecule[131,145,147]. The influence of the distribution of electron density and the nature of the substituents in 7-azaindoles on the above electrophilic substitution reactions has been considered above.

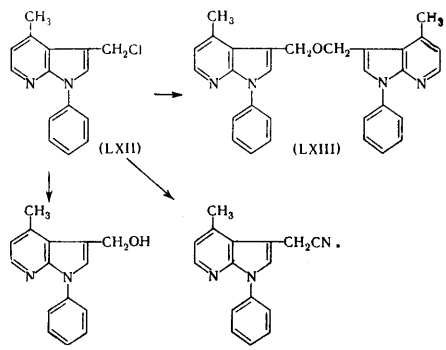
In the 5-azaindole series, in contrast to the 7-azaindoles, nitration, bromination, and other reactions did not give positive results. For example, various modifications of the Mannich reaction did not yield 5-azagramine[79]. Nor was it possible to synthesise[79] products of the reaction of 5-azaindole with piperidinomethylformamidomalonic ester by the method developed for the corresponding indole compounds[148]. Yet 2,5-dimethyl-4-azaindole undergoes electrophilic substitution at position 3 comparatively easily (even more readily than does 7-azaindole), which provided a method for preparing 2,5-dimethyl-4-azaindoles containing bromine, a nitro-group, formyl, and other substituents in position 3.[23] Information is lacking in the literature on the introduction of substituents into the ring of 6-azaindole.

The above peculiarities in the distribution of electron density in 7-azaindole govern not only the character of electrophilic substitution at position 3 but also the reactivity of substituents already present. For example, 3-bromo-7-azaindole, unlike analogous 3-bromoindoles, does not react with various nucleophilic reagents[146]. 7-Azagramine and its derivatives proved to be considerably weaker alkylating agents than the analogous gramines[145,146].

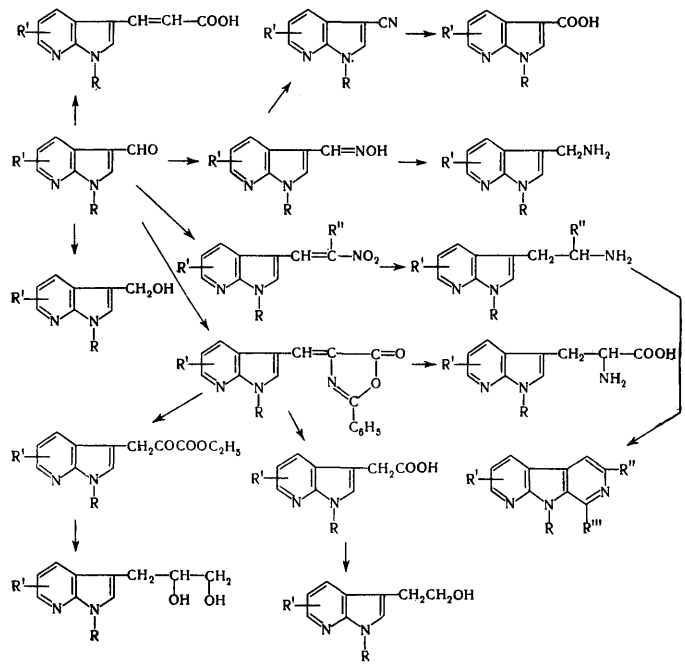
Although reaction of 7-azagramine with acetamidomalonic ester converts it into 7-azatryptophan[77], with malonic ester into 7-azaindol-3-ylpropionic acid[146], and with hydrocyanic acid into 7-azaindol-3-ylacetonitrile, syntheses based on 7-azagramines present certain difficulties. For example, even boiling unsubstituted 7-azagramine with hydrocyanic acid for many (64) hours does not raise the yield of 7-azaindol-3-ylacetonitrile above 49%.[146] Still lower yields were obtained in the analogous reaction with nitromalonic ester[146], and also in the reaction of substituted 7-azagramines with hydrocyanic acid[145].

In this connection considerable preparative interest attaches to 3-formyl-7-azaindoles[145,147] and the 3-chloromethyl-7-azaindoles which can be readily obtained from the former via the 3-hydroxymethyl derivatives[145]. The chlorine atom in the second series of compounds is allylic in character and is extremely labile. For example, it is replaced by hydroxyl even when the compound is dissolved in water, and can be titrated alkalimetrically[145].

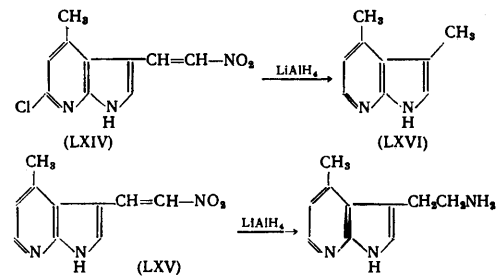
It is interesting that when, for example, 3-chloromethyl-4-methyl-1-phenyl-7-azaindole (LXII) is treated with potassium cyanide in 80% aqueous alcohol, bis-4-methyl-1-phenyl-7-azaindol-3-ylmethyl ether (LXIII) is formed in theoretical yield[145]. The cyano-group can be introduced only by the use of acetone cyanohydrin under anhydrous conditions[140]:



Comparison of various synthetic methods shows that the best results in the preparation of 3-aminomethyl derivatives are obtained by reducing the oximes of the corresponding 3-formyl-7-azaindoles with zinc in hydrochloric acid[140]. The most convenient method for the synthesis of 3-2'-aminoalkyl-7-azaindoles is to condense the 3-formyl derivatives with the nitroalkanes and then reduce with lithium tetrahydroaluminate in boiling tetrahydrofuran[66,101,107,140,149,150]. Other methods of synthesis, investigated by analogy with indole compounds (from 7-azagramines or 3-chloromethyl-7-azaindoles via the nitriles, cyanomethylation of azaindoles followed by reduction, from 3-formyl-7-azaindoles via the azlactones and amides of 7-azaindol-3-ylacetic acids), gave no advantages over these methods[66,151].



The course of the reaction of 6-chloro-4-methyl-3(2'-nitrovinyl)7-azaindole (LXIV) with lithium tetrahydroaluminate is unexpected: unlike the normal reduction of the dehalogenated compound (LXV), the reaction is accompanied by rupture of a carbon–carbon bond with formation of 4-methyl-7-azaskatole (LXVI)[150]:



The conversion of 3-formyl-7-azaindole into 3-cyano-7-azaindole by the action of nitropropane, ammonium phosphate, and acetic anhydride is interesting[152]. The mechanism of these reactions has not yet been studied.

The best method for obtaining 7-azaindol-3-ylacetic acids has proved to be from 3-formyl-7-azaindoles via the corresponding azalactones[66], for 7-azaindole-3-carboxylic acid from 3-formyl-7-azaindole via its oxime and 1-acetyl-3-cyano-7-azaindole[146], for 7-azaindol-3-ylacrylic acids from 3-formyl-7-azaindoles by the Knoevenagel and Wittig–Horner reactions[145], and for 7-azatryptophan derivatives by reducing the azlactones with hydriodic acid in the presence of phosphorus[66].

The reduction of 3-formyl-7-azaindoles and of 7-azaindol-3-yl-acetic and -pyruvic esters with complex metal hydrides provides a route for obtaining 3-hydroxymethyl[145], 3-2′-hydroxyethyl[66], and 3-(2,3-dihydroxypropyl)[145] derivatives of 7-azaindoles.

Acylation of 3-aminoalkyl-7-azaindoles followed by cyclodehydration yields derivatives of the new tricyclic system 1,7,9-triazafluorene[153]. Besides the fully aromatic triazafluorenes, the corresponding dihydro- and tetrahydro-derivatives have also been described[153].

IV. BIOLOGICAL ACTIVITY OF AZAINDOLE COMPOUNDS

Published information on the biological activity of azaindole compounds is still very sparse, and relates mainly to derivatives of 7-azaindole. It is interesting to note that the study of unsubstituted azaindoles led to the conclusion that there was no correlation between their pharmacological properties and such physicochemical characteristics as their ionisation constants, percentage ionisation at pH 7.4, or distribution in the ether–water system[18].

The examination of biological activity showed that in several properties competitive relations existed between indole and azaindole derivatives. For example, experiments with *Neurospora crassa* established that 7-azaindole inhibited the conversion of indole into tryptophan[154]. 7-Azatryptophan retards the assimilation of tryptophan by *Tetrahymena pyriformis*[155], and replaces tryptophan in reaction with the protein of the bacterium *Escherichia coli* and the bacteriophage T2,[156] by blocking the formation of carbamoyl-transferase and D-serine-deaminase[157]. It has been reported[18] that unsubstituted 7-azaindole, unlike indole, causes depression of the central nervous system, adynamia, and weakening of the smooth musculature in small laboratory animals. Another series of parameters established the similarity in the biological action of indole and azaindole compounds. For example, 7-azaindol-3-ylacetic acid proved to be a powerful plant growth hormone[158], similar to heteroauxin, and *laevo*-12-azadeserpidine[159] exhibited reserpinelike activity characteristic of natural deserpidine.

Nevertheless, as the investigations of S. S. Liberman (in M. D. Mashkovskii's laboratory in the All-Union Chemical–Pharmaceutical Scientific Research Institute) have shown[66], in several cases more complicated relationships than competing or similar activities were exhibited in the biological actions of indole and azaindole compounds. For example, in an experiment substituted 3-aminomethyl derivatives of 7-azaindole act similarly to tryptamine, and substituted aza-analogues of tryptamine exert a central depressive effect on the tone of the skeletal musculature, slow down motor activity, and produce a prolonged hypothermic effect. A pronounced hypotensive action, associated with the effect on the central nervous system, is possessed by aminoalkyl derivatives of 7-azaindole containing a longer aminoalkyl chain. Thus replacement of the 7-methine group in the indole ring by a nitrogen atom leads in several cases to the appearance of new pharmacological characteristics, sharply distinguishing azaindoles from analogous derivatives of indole.

Chromatographic Resolution of Racemates on Dissymmetric† Sorbents

S.V.Rogozhin and V.A.Davankov

The review discusses the use of natural sorbents (proteins, carbohydrates, and optically active quartz) and also artificial dissymmetric sorbents (based on silica gel and activated carbon) for the chromatography of racemates. Gas chromatography is very effective for the separation of diastereomers, but is less suitable for the direct separation of optical isomers. On the other hand, dissymmetric ion-exchange sorbents, which are considered in detail in the review, may find wider practical application. The list of references contains 197 items.

I. INTRODUCTION

In connection with the vigorous development of research on the production of synthetic medicines, animal feeds, and food products, the problem of resolving various racemic compounds into optically active components has now become urgent. Chemical synthesis produces a racemic mixture of enantiomorphs, but usually only one form can be used for biological purposes.

A foreign dissymmetric agent is necessary for the resolution of a racemic compound‡. Use can be made of differences between the enantiomorphs in—(1) interaction with a dissymmetric environment (sorption on dissymmetric phases, diffusion through a medium containing dissymmetric centres, dissolution in optically active solvents, interaction with circularly polarised radiation or with polarised elementary particles, etc.); (2) rate of chemical interaction with optically active substances, and physical and chemical properties of pairs of diastereomers formed as a result of such interaction; and (3) interaction with a

† The term dissymmetric is to be applied to sorbents containing dissymmetric structural units possessing optical activity of definite sign (positive or negative). We recall that a structure is said to be dissymmetric if it contains no rotation-reflection axis of symmetry (an axis rotation about which, followed by reflection in a plane perpendicular to the axis, yields a structure identical with the original structure). Dissymmetry of structure is the necessary and sufficient condition for the appearance of optical activity in a substance. In determining the dissymmetric character of a molecule it is necessary to take into account all the conformations which the molecule can adopt under the given conditions. The selective absorption by a dissymmetric sorbent of one of the enantiomorphs of a racemate is to be termed stereoselective sorption.

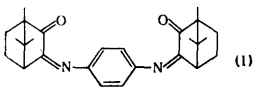
‡ The "spontaneous" resolution of racemates during crystallisation generally requires the introduction of a seed of an optically active substance.

living cell or its enzymes, which are capable of selectively assimilating or modifying one of the enantiomorphs of the racemic mixture.

Among all the methods enumerated[1], the resolution of racemates by chromatography on a dissymmetric sorbent is favourably distinguished by the theoretical possibility of quantitatively isolating both components of the racemate in optically pure form even if the dissymmetric sorbent used does not possess 100% optical purity[2]. This fact, coupled with the well known merits of the chromatographic method, suggests that the chromatographic resolution of racemates is quite promising for use on an industrial scale.

The possibility of resolving racemic compounds by stereoselective sorption of one of the enantiomorphs on a dissymmetric sorbent was first suggested by Willstätter in 1904.[3] By simulating dyeing processes for animal fibres, he tried unsuccessfully to detect the appearance of optical activity in a solution of a racemic alkaloid (tropacocaine, atropine, homatropine) in contact with the fibres. In such a case optical activity in the solution would have indicated preferential sorption of one of the enantiomorphs on the fibres. A difference in the sorbability of the optical isomers of a dye on wool was detected only in 1919 by Porter, first colorimetrically[4] and then by a polarimetric method[5].

In 1938 Henderson and Rule[6] first applied Tswett's chromatographic method to the resolution of racemic *NN'*-bis-2-oxoborn-3-ylidene-*p*-phenylenediamine



(I)

on a (+)–lactose column. In this case, the resolution of the racemate was due to the differing stabilities of the labile diastereomeric adducts formed with the enantiomorphs on the surface of the sorbent. The chromatographic method enabled these small differences in sorbability of the enantiomorphs to be clearly revealed, and showed the suitability of chromatography for the partial resolution of racemates.

Much research has been done during recent years on the problem of stereoselective sorption, these investigations having been partly surveyed in several review papers[7-14]. Therefore, while giving a full bibliography on these questions, we have discussed in greater detail only the most recent work in this field, and also the general features of the stereoselective sorption and the chromatography of racemates.

II. CHROMATOGRAPHY OF RACEMATES ON NATURAL AND INORGANIC DISSYMMETRIC SORBENTS

Natural proteins constituted the first dissymmetric sorbent used in studying the stereoselective sorption of enantiomorphs. In several cases some difference was confirmed in the sorbability of the enantiomorphs of racemic azo-dyes on the proteins of wool[4,5,15,16] or a difference in sorbability between the racemate and one of the enantiomorphs[17,18]. However, the effect observed under conditions of static sorption was extremely small, and the results obtained[4,5,15,16] could not be repeated on more careful checking[18-20]. Several workers report the absence of stereoselectivity in the sorption of azo-dyes on wool[20-22].

It was only in 1941 that Martin and Kuhn[23] demonstrated a separation of enantiomorphs sufficient for accurate observation in the case of mandelic acid, using an original device having a moving endless wool top. The optical activity observed in the acid solution in these experiments reached −0.35° and +1.0° at opposite ends of the apparatus.

A more detailed study of the sorption of racemic α-hydroxy-acids on wool was made during the 1950s by Bradley and his coworkers[8,24-28], who reached the conclusion[24,26] that an important part in this process is played by the free basic groups of L-lysine and L-arginine, which are present in considerable quantities in wool (the exchange capacity of wool with respect to acids reaches 0.45 mg-equiv. g^{-1}). This is supported by the sharp decrease in adsorption and in degree of resolution of mandelic acid when wool is used whose basic groups have previously been blocked by the radicals of some other acid[28]. It is indicated also by the inability of silk, which contains only minute quantities of diamino-carboxylic acids, to sorb selectively the enantiomorphs of racemic acids[17,18,22,24].

By studying the separation on wool of the isomers of a large number of racemic α-substituted glycollic acids

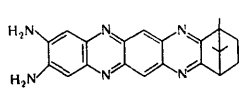
Bradley showed[24,26-28] that substituents R which are too large promote non-selective adsorption, and thus impair resolution of the racemic acid. Thus on passing in α-substituted glycollic acids from phenyl, substituted phenyl, and naphthyl radicals to *p*-hexadecyloxyphenyl and anthr-9-yl radicals the degree of separation of the isomeric acids is appreciably diminished. These facts make clear the reason for the failure of earlier attempts to detect the selective sorption of the large molecules of azo-dyes[18,20,21].

According to Bradley, important factors for the development of the selective sorption of α-hydroxy-acid enantiomorphs on wool are the presence of a free carboxyl and of an aromatic ring in the α-position[26,27].

It is interesting that, in all cases studied by Bradley[8,24-28] and by other workers[5,23,29], the dextrorotatory isomers of α-arylglycollic acids were more strongly retained by wool than were the laevorotatory isomers. It may be supposed that L-mandelic acid and its analogues containing substituted phenyl radicals and even other aromatic and heterocyclic substituents in place of the phenyl radical will possess a greater affinity for wool protein. Thus the accumulation and systematisation of experimental data on the chromatography of racemates may lead to the establishment of empirical rules for the assignment of dissymmetric compounds to known configurational series.

Slight selectivity of sorption for racemic azo-dyes[30], and to a greater extent for tryptophan[31], was observed with proteins of the serum albumin type. In contrast to mandelic acid[8], no separation of the enantiomorphs of α-bromopropionic acid was observed on casein[32].

There are indications of the non-selective sorption of the product (II) of the interaction of tetra-aminophenazine with camphorquinone isomers on protein tissues of living organisms[33].



(II)

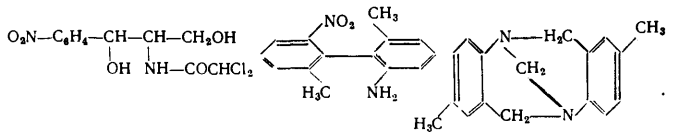
Grubhofer and Schleith[34] made successful use of a product obtained by coupling a protein with diazotised poly-*p*-aminostyrene for the partial resolution of racemic alanine.

Natural carbohydrates (lactose, cellulose, starch, sucrose) have been used in a considerable amount of work on the resolution of racemates. Carbohydrates contain no functional groups capable of electrolytic dissociation in

neutral media, and therefore the resolution of racemates on them is a consequence of intermolecular forces, an important part in these processes probably being played by hydrogen bonds.

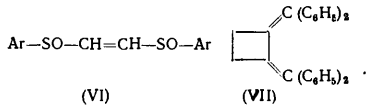
It has already been mentioned above that the chromatographic method was first used for the resolution of *NN'*-bis-2-oxoborn-3-ylidene-*p*-phenylenediamine (I) on a (+)-*lactose* column[6]. The resolving effect was very considerable. When the initial fractions of the eluate, enriched with the laevorotatory enantiomorph, were repeatedly passed through the column, the optically pure isomer was isolated after four cycles[19].

Lactose columns have been used for the partial separation of the isomers of chloromycetin (III)[35] and 1-amino-6,6'-dimethyl-1'-nitrobiphenyl (IV)[36], as well as Tröger's base (V)[37], which could not be resolved by other methods owing to its instability in acid media. The use of (+)-tartaric acid columns and those containing its potassium hydrogen salt gave a smaller effect[37].



(III) (IV) (V)

The molecules (IV) and (V) contain no asymmetric carbon atoms, their dissymmetry being due in the former to the non-coplanarity of the molecule and in the latter to the asymmetry of the rigid pyramidal structure of tervalent nitrogen attached to three different substituents. The similar pyramidal structure of sulphoxides is responsible for the existence of enantiomers in the *cis*- and *trans*-forms of 1,2-bisarylsulphoxyethylenes (VI), which also have been separated by means of (+)-lactose[38].



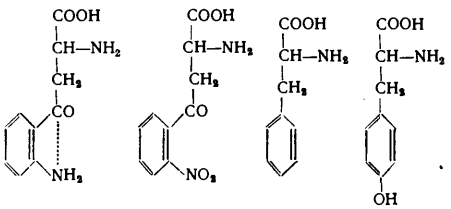
(VI) (VII)

Partial resolution on (+)-lactose has been observed with racemic lysine, its methyl ester and dihydrochloride, proline, tryptophan, glutamic acid[39], quaternary arsonium salts[40], and also the trisacetylacetonates of chromium and cobalt[41], yttrium and gadolinium[42], but not of iron, gallium, and indium[41]. Failure attended attempts to resolve the racemates of 1,2-bisdiphenylmethylenecyclobutane (VII) and its analogues[43], although the molecules of these compounds are non-coplanar.

In contrast to calcium (+)-tartrate, emulsin, maltose, glucose, and sucrose, (+)-lactose is able to resolve *m*-naphth-2'-ylazomandelic acid[21]. In some cases lactose can nevertheless be replaced by sucrose[39].

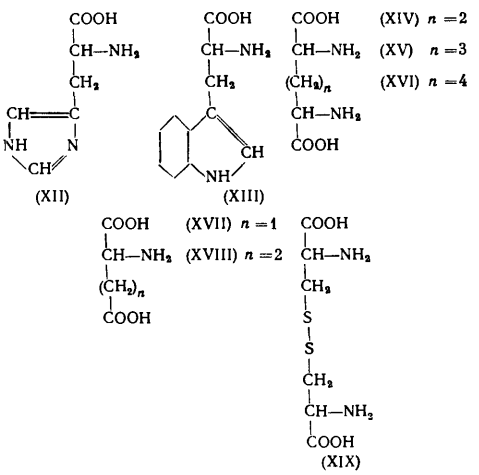
During the 1950s considerable progress was made in the resolution of racemates by chromatography on *cellulose* (paper). The first attempts to resolve racemic sugars were unsuccessful[44]. It was then found that preliminary treatment of the paper with (+)-camphorsulphonic acid[45] enabled the enantiomorphs of phenylglycine to be separated. In the presence of (+)-tartaric acid the isomers of 1-benzylamino-2-naphthol[46] and phenylalanine[47] are separated on paper. Some Japanese workers have subsequently found[48-51] that tyrosine, glutamic acid, and especially well tyrosine-3-sulphonic acid are resolved into two components even in the absence of foreign optically active substances. It was concluded that the reason was selective adsorption of the enantiomorphs on the paper, which was soon confirmed by the resolution of several other racemic amino-acids—kynurenine[52,53], α-hydroxytryptophan[54], tryptophan[52,55,56], histidine[56,57]—although Fujisawa[52] found that tyrosine (see, however, Refs. 49 and 50), leucine, phenylalanine, *N*-benzoyltyrosine, acetyltryptophan, and phenylalanine-*p*-sulphonic acid are not resolved on paper. In this connection it should be noted that the first worker to observe the resolution of a racemate by paper chromatography was obviously Dent[58], who as early as 1948 described the unexpected splitting of chromatographic spots of aspartic and glutamic acids.

An important contribution to elucidating the fundamental laws governing the resolution of racemates by paper chromatography was made by the work of Dalgliesh[59-61], who concluded that paper chromatography did not involve partition chromatography, as had previously been assumed[62], but represented a method of adsorption chromatography. Hydrogen bonds play an important part in the process of adsorption.



(VIII) (IX) (X) (XI)

Dalgliesh observed that racemic kynurenine (VIII) and 3-hydroxykynurenine[59] are successfully resolved on paper, but kynurenine which has been acetylated at either of the amino-groups, and also α-amino-β-benzoylpropionic acid and its *o*-nitro-derivative (IX), are not resolved[59,60]. Among phenylalanine (X) derivatives the 2,3-diol and the 2-methyl-3,4-diol are resolved, but phenylalanine itself, its 3,4-diol and 5-methyl-3,4-diol, and also tyrosine (XI) are not resolved (see, however, Refs. 49 and 50, which report partial resolution of tyrosine in the presence of amines). From these results Dalgliesh concludes that, for successful resolution of the racemate of an amino-acid, its molecule should contain a free carboxyl and a free amino-group. A planar aromatic ring having a small *ortho*-substituent can serve as third functional group to ensure three-point adsorption. The presence of a hydrogen bond between the amino-group and carbonyl in the kynurenine molecule (VIII) provides also a planar ring system in the β-position. However, whereas the L-series of isomers are more strongly sorbed among phenylalanine and tryptophan derivatives, the opposite situation is found for kynurenine derivatives.



(XII) (XIII) (XIV) $n=2$ (XV) $n=3$ (XVI) $n=4$ (XVII) $n=1$ (XVIII) $n=2$ (XIX)

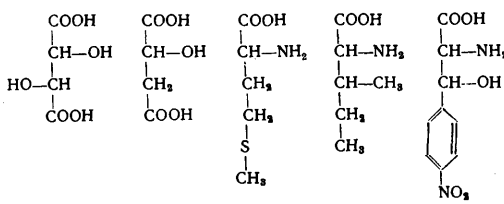
Dalgliesh's rules concerning three-point sorption are only approximate. They are consistent with the above resolution of histidine (XII) and tryptophan (XIII), but they cannot explain the fact that, among the dihydroxy-derivatives of phenylalanine, the 2,3-, 2,4-, 2,5-, and 3,5-diols are resolved, while the 3,4- and 2,6-isomers are not resolved[61,63]. Furthermore, it is obvious that the presence of an aromatic ring is not essential, since resolution on paper is observed for racemic $\alpha\delta$-diaminoadipic (XIV), $\alpha\epsilon$-diaminopimelic (XV), and $\alpha\zeta$-diaminoazelaic (XVI) acids[64], as well as partial resolution of aspartic (XVII)[58] and glutamic (XVIII) acids[48-51,58] and of cystine (XIX)[65].

A detailed study of the effect of the conditions of chromatography on the degree of resolution of racemic amino-acids has shown[65] that the best medium is 90% aqueous methanol without any addition of electrolytes. It has been found also that the separation of the enantiomorphs is appreciably improved by lowering the temperature to +2° and −15°C, a fact which was not explained[65]. Lowering the temperature to +4°C has an analogous effect also in the thin-layer chromatography of tryptophan and its derivatives on cellulose[66].

Partial resolution on paper has been reported for racemic catechin and epicatechin[67], complex cobalt(III) salts of glycine, alanine, and oxalic acid[68], pteridines[69], and also several alkaloids of the berberine[70,71]. Alessandro and Caldarera[72] described the resolution of the racemates of several physiologically active amines of the adrenaline group, but these results could not be repeated by other workers[73].

Chromatography on cellulose can be conducted also on a preparative scale in columns[67,69,71], but the degree of separation of the enantiomorphs then drops sharply[67,71].

The successful work of Krebs and his collaborators[74-82] has added yet another carbohydrate, *starch*, to the store of natural dissymmetric sorbents suitable for the resolution of racemates. This sorbent has proved capable of partly resolving into fractions having opposite optical rotation a large number of dissymmetric complex salts of cobalt and chromium containing two or three bidentate ligands such as glycine, dithiocarbamic acid, *p*-methylaminophenol, ethylenediamine, oxalic acid, etc.[74-77]. The resolution of these complexes was more effective on starch than on lactose, cellulose, sucrose, or wool[75,77].

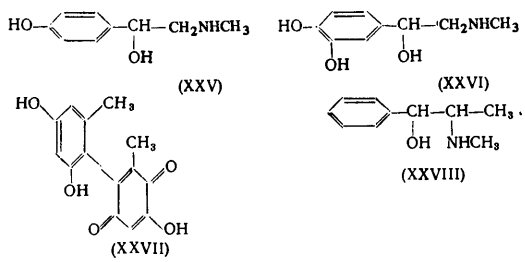


(XX) (XXI) (XXII) (XXIII) (XXIV)

Among organic substances the racemates of racemic acid (XX), malic acid (XXI) (optical purity 8%), and aspartic acid (XVII) (13%) are resolved on starch, but alanine, phenylalanine (X), methionine (XXII), isoleucine (XXIII), tryptophan (XIII), and β-hydroxy-β-*p*-nitrophenylalanine (XXIV) are not resolved[78-80]. These results agree well with Dalgliesh's rule on three-point adsorption established for paper chromatography. However, Krebs considers it valid only for flexible aliphatic molecules. The resolution of mandelic acid (optical purity 64.5%), phenylglycine (42%), phenylchloroacetic acid (50%), *O*-alkyl and *O*-acyl derivatives of mandelic acid, and also its esters shows that, with all these aromatic compounds having rigid molecules, the presence of two or even one functional group capable of forming hydrogen bonds with the hydroxyls of the starch is sufficient for successful resolution. Krebs regards molecular rigidity as the decisive condition for the successful resolution of isomers of such compounds[78-82]. This can be artificially increased by introducing additional bulky groups. Thus alanine, valine, and isoleucine are not resolved on starch, but their benzoyl derivatives are resolved. To resolve phenylalanine it proved sufficient to introduce into its molecule an acetyl or even a formyl group.

Krebs made the interesting observation that the best medium for chromatography on starch was water. The use of water–alcohol mixtures always diminishes the efficiency of the separation of isomers[78-80]. This fact has been confirmed by other investigators[83].

Ohara and his coworkers[84-86] have pointed out that, in all pairs of enantiomorphs of mandelic acid and its derivatives, the D-series of isomers—D(−)-mandelic acid $C_6H_5CH(OH)COOH$, (−)-methyl ester of D-mandelic acid, D(+)-acetylmandelic acid, D(+)-β-phenyl-lactic acid $C_6H_5CH_2CH(OH)COOH$, D(−)-tropic acid $C_6H_5CH(CH_2OH)COOH$—are the more weakly sorbed on starch. In the chromatography of atrolactic acid $C_6H_5C(OH)(CH_3)COOH$, on the other hand, the L(+)-isomer is eluted first. In view of this, these workers conclude that either the generally accepted assignment of (+)-atrolactic acid to the L-series is incorrect or else starch begins to develop a greater affinity for isomers of the D-series—not of the L-series—on passing from mandelic to atrolactic acid[85]. The latter hypothesis seems to us entirely plausible, because in mandelic acid and its derivatives the smallest substituent attached to the asymmetric carbon atom is a hydrogen atom, whereas in atrolactic acid the smallest substituent is a hydroxy-group. This marked change in molecular structure is fully able to explain the reversal in the order of sorption of these compounds.



(XXV) (XXVI) (XXVII) (XXVIII)

Partial resolution on starch has been reported for trichloroacetyl derivatives of α-amino-acids[83], phenylglycine[87], sympathol (XXV), adrenaline (XXVI), Henrich's quinone (XXVII)[88], and allylethylmethylphenylphosphonium bromide[89].

Reference has been made[90] to the possibility of resolving ephedrine (XXVIII) and 1-phenylethylamine by means of a copolymer of styrene and maleic acid which has been treated with thionyl chloride and then with glucose.

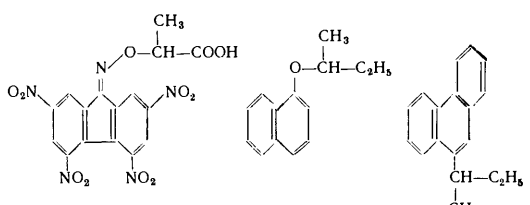
Finely ground crystals of *optically active quartz*, among inorganic dissymmetric sorbents, have been used for resolving racemates. Quartz is inert towards *m*-naphth-2′-ylazomandelic acid[19], *NN′*-bis-2-oxoborn-3-ylidene-*p*-phenylenediamine[6,19], and quaternary phosphonium salts[89], but several racemic complexes have been separated by means of quartz into fractions having opposite rotations. A partial separation has been effected of the oxahedral complex salts of cobalt(III) and chromium(III) with two or three bidentate ligands such as ethylenediamine, dimethylglyoxime, oxalate[91-96], and pentane-2,4-dione[97], and with

hexadentate ethylenediaminetetra-acetate[98], the tetrahedral complex of beryllium with benzoylacetone[99], and also potassium dinitro-*N*-methyl-*N*-ethylglycineplatinate[100] containing an asymmetric nitrogen atom.

Very little selectivity has been detected, during sorption on optically active quartz, of racemates of such neutral compounds as butan-2-ol[101], cyclic hydroperoxides[102], and quaternary arsonium salts[40,103]. The use[104] of this property of quartz for establishing molecular dissymmetry in compounds has been proposed. It has also been suggested[105] that the stereoselectivity of sorption can be determined by measuring the quantities of isomers sorbed from the vapour phase.

Sodium chlorate, like quartz, is able to form enantiomorphous optically active crystals. This property has been used by Ferroni and Cini[106] for the partial resolution of beryllium bisbenzoylacetonate. These workers report the possibility of resolving this complex directly on a commercial aggregate of sodium chlorate, which is a mechanical mixture of enantiomorphous crystals. They explain this phenomenon by the non-equivalent sorption of (+)- and (−)-forms of the complex on the corresponding forms of the crystals, which appears to us doubtful.

Methods have been described for preparing *silica gels* capable of the stereoselective sorption of optical enantiomorphs. Such silica gels contain "imprints" of the molecules of an optically active isomer of a substance which had been present in the reaction mixture during formation of the gel and then removed by extraction[107]. The presence of these "imprints" is due to the greater sorption capacity of the gel for the same isomer of this substance or of a structurally related substance than for their enantiomorphs. Thus silica gels have been prepared in the presence of optically active mandelic acid, (+)-camphorsulphonic acid[107,108], quinine and its enantiomorph quinidine[109], and also by hydrolysing optically active tetrakis-2-methylbutoxysilane, tetramenthyloxysilane, and tetrabornyloxysilane[110]. A silica gel containing "imprints" of quinine possessed greater affinity for quinine, cinchonidine, and other alkaloids of the same steric series than did silica gel having "imprints" of quinidine[109]. The selectivity of such sorbents falls with time.



(XXIX) (XXX) (XXXI)

Ordinary silica gel can also be given the properties of a stereoselective sorbent, by impregnating it with a solution of (+)-α-(2,4,5,7-tetranitrofluoren-9-ylideneaminooxy)propionic acid (XXIX). Racemates of esters and ethers, e.g. 1-s-butoxynaphthalene (XXX)[111], and even of hydrocarbons such as 9-s-butylphenanthrene (XXXI)[112] can be partly resolved on such a sorbent. In this case the adsorbent and adsorbate molecules form adducts of the picrate type, with the aromatic rings arranged parallel.

Aluminium oxide modified with optically active alanine, lactose, glucose, tartaric acid, sodium glutamate, menthan-3-ol, and fenchone was used by Karagounis[113,114], which enabled him to observe the weak resolution of mandelic acid, phenylglycine, camphor, etc.[114]. However, he was unable to resolve the free biphenylnaphth-1-ylphenylmethyl radical on these sorbents or on several other sorbents, undoubtedly owing to its planar structure[113].

Carbon modified with alkaloids has been used to separate the isomers of mandelic acid[115], and aluminium oxide modified with (+)-tartaric acid for separating chromium and cobalt acetylacetonates[97].

Thus, beginning in the 1920s, a large number of attempts have been made to resolve various racemic compounds on naturally occurring dissymmetric sorbents (proteins, carbohydrates, and optically active quartz) and also on silica gel, aluminium oxide, and activated carbon modified with optically active substances. The best results were obtained by using carbohydrates. In several cases it was possible to achieve quantitative resolution of a racemate by paper chromatography. However, on passing from purely analytical chromatography to the preparative separation of enantiomorphs on cellulose columns, the degree of separation fell sharply. On (+)-lactose and starch columns it has sometimes been possible to obtain fractions of isomers of optical purity ~ 50%, but an immense excess of the sorbent had to be used.

III. RESOLUTION OF RACEMATES BY GAS CHROMATOGRAPHY

Attempts have been made during recent years to apply the method of gas chromatography to the resolution of racemates.

The considerable advances made in the separation of various diastereomeric pairs by gas–liquid chromatography[116–135] have enabled highly sensitive methods to be developed for determining the degree of optical purity of optically active compounds, based on chromatography of the diastereomers formed by coupling these compounds with some other dissymmetric compound[130,131,135]. These methods have proved to be far more accurate than traditional measurements of specific rotation. The rapidity of an analysis and the great reliability of the results have permitted the use of gas–liquid chromatography for solving such complex problems as, for example, racemisation in peptide synthesis[136,137].

Here, however, we are more interested in direct separation of the components of a racemate by gas chromatography on an optically active phase. The first results in this field were obtained in 1959 by Karagounis and Lippold[138], who used (−)-ethyl tartrate or starch as adsorbent, and observed slight splitting of the peaks corresponding to racemic butan-2-ol, 2-bromobutane, ethyl α-bromobutyrate, and α-bromopropionic acid. However, in 1962 Japanese workers reported[84] that they were unable to repeat Karagounis' experiments on the separation of butan-2-ol by gas chromatography on columns containing starch, (−)-ethyl tartrate, or other optically active sorbents. Goldberg and Ross[139] also reported unsuccessful attempts to separate butan-2-ol, 2-chlorobutane, and 2-bromobutane on starch, (+)-1-methylheptyl sebacate, and methyl (+)-tartrate. They were unable to establish even partial separation of the enantiomorphs by measuring the optical activity of the fractions obtained by a preparative method of gas–liquid chromatography. Here these workers showed—what is extremely important—that racemisation of the optically active components does not take place under

analytical conditions. A paper[140] on the gas-chromatographic separation of the n-pentyl esters of *N*-acetyl-α-amino-acids on L-glutamic acid and sodium L-glutamate also does not report the splitting of peaks due to racemic compounds.

A detailed investigation of the possibility of separating by gas chromatography fifteen different racemates (carbohydrates, alcohols, alkyl halides, alkenes) on a series of optically active phases (sucrose octapropionate, heptamethylsucrose, menthyl stearate, and poly(propylene oxide)) was made by Goeckner[141]. In no single experiment was he able to observe splitting of the chromatographic peaks, in spite of his varying the temperature and the speed of the carrier gas between wide limits.

Nevertheless, Karagounis published a second paper[142] on the resolution of racemates by gas-adsorption chromatography on starch, sucrose, camphor-β-sulphonic acid, sorbitol, and (+)-trisethylenediaminecobalt(III) chloride, and also by gas–liquid partition chromatography on the optically active phases—(+)-dipentyl phthalate, ethyl (+)-tartrate, (+)-heptamethylsucrose, and (+)-heptamethyllactose—the racemates used being *trans*-1,2-dichlorohexafluorocyclobutane, 2-methoxybutane, and 3-hydroxybutan-2-one. In all cases the degree of separation of the enantiomorphs was extremely small. Nevertheless, in the preparative chromatography of *N*-methylpiperidine on sucrose two fractions of volume 0.3 and 0.5 ml were isolated, their optical rotations being respectively +0.100° and −0.120°.

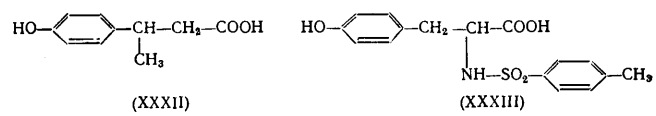
Complete separation of the isomers of racemic esters of the *N*-trifluoroacetyl derivatives of valine, alanine, and isoleucine was achieved only in 1966,[143] a capillary column of efficiency 75 000 theoretical plates being used. The optically active phase was the dodecyl ester of *N*-trifluoroacetyl-L-isoleucine. It was established that the degree of separation of the enantiomorphs increased with increase in the size of the alcoholic radical in the ester of the amino-acid. However, this was accompanied by an increase in the retention time, which reached 300–400 min, with almost complete blurring of the chromatographic zones. Besides this, the high temperature of the experiment (210°C) casts doubt on the lasting configurational stability either of the optically active phase or of the compounds undergoing separation.

Thus available information suggests that gas chromatography holds little promise for the resolution of racemates. On the other hand, the chromatography of diastereomers may prove of inestimable value as a rapid and accurate method of analysis.

The ineffectiveness of gas chromatography for the separation of optical isomers is explained, in our opinion, by the high temperature necessary for the analysis. The stereoselectivity of the sorption of enantiomorphs is determined by the difference in their energies of interaction with the dissymmetric phase. This interaction is characterised by weak intermolecular forces (induction, dispersion forces, hydrogen bonds, etc.), the effect of which falls rapidly with rise in temperature. Attempts to strengthen this interaction by introducing additional polar or bulky groups inevitably entail a rise in the boiling point of the racemate, and hence in the temperature of the chromatographic process. This difficulty cannot be removed within the limits of gas chromatography, but it does not arise in liquid chromatography. Such an explanation is consistent with the increase in degree of separation of enantiomorphous amino-acids noted above[65,66] with drop in the temperature of their chromatography on paper. The influence of temperature should appear especially clearly in paper chromatography, since here the process of sorption is not complicated by the temperature-dependent process of diffusion.

IV. DISSYMMETRIC ION-EXCHANGE SORBENTS§

In order to resolve racemic alcohols Macbeth and his coworkers[144] esterified them with dicarboxylic acids, and then prepared diastereomeric salts of the resulting acid esters with optically active alkaloids, an example being brucine 1-methylheptyl phthalate. Instead of the usual crystallisation, however, these workers successfully used a chromatographic method to separate the diastereomeric salts on a column filled with brucine. Although separation of the diastereomers takes place here mainly as a consequence of the difference in their solubilities in the solvent mixture employed, these workers correctly pointed out the theoretical possibility of ion-exchange reactions between the acid component of the salt and the brucine. This enabled them to propose the possibility of resolving racemates by means of synthetic dissymmetric ion-exchangers.



(XXXII) (XXXIII)

In 1952 Bunnett and Marks[145,146] synthesised dissymmetric ion-exchangers by the polycondensation of formaldehyde with optically active (+)-β-*p*-hydroxyphenylbutyric acid (XXXII) or *N*-toluene-*p*-sulphonyl-L-tyrosine (XXXIII). They showed in separate experiments that these compounds undergo no considerable racemisation under the conditions of polycondensation. However, all attempts to resolve racemic amines (*N*-methylpiperidine, 1-phenylethylamine, and γ-dimethylamino-αα-diphenylvaleronitrile) by means of these ion-exchangers in water and in ethanol were unsuccessful. Yet the accuracy of the measurements would have enabled even a slight (3%) enrichment of the eluate with one of the enantiomorphs to be detected. Discussing their results, Bunnett and Marks reject the possibility of the resolution of racemates by means of ion-exchangers containing in the macromolecule considerable aliphatic portions and only one ionogenic group for interaction with the ions of the substance to be separated.

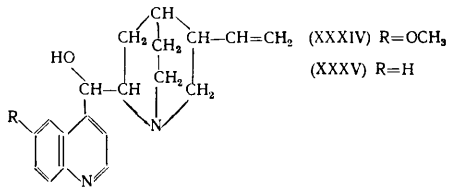
Failure attended an attempt to separate the isomers of mandelic acid on an anion-exchanger obtained by detaching the acetyl groups from the D-glucosamine units in the chitin macromolecule[147].

The successful resolution of racemic mandelic acid on a dissymmetric anion-exchange resin was first reported by Grubhofer and Schleith[34,148]. They converted the carboxyls in the cation-exchange resin Amberlite XE 64 (polyacrylic acid) into chlorocarbonyl groups, and esterified them with the secondary alcoholic groups of quinine (XXXIV). The exchange capacity of the resulting anion-exchange resin was low, 0.7 mg-equiv. g^{-1}. The isomers of mandelic acid did not separate on a column of the anion-exchange resin in aqueous and alcoholic media. On passing a 0.036 *N* solution of the acid in chloroform through the column, however, the percentage optical purity of the first

§ It has already been mentioned that naturally occurring proteins, e.g. wool, also contain ionogenic groups, which, perhaps, play an important part in the processes of sorption and chromatography.

few fractions, containing 4, 7, 16, 26, 34, and 43 micromoles of the acid, was found to be 100, 70, 44, 34, 31, and 30 respectively. The great defect of this exchanger is partial hydrolysis of the ester bonds even during its regeneration.

Krebs confirmed[80] Grubhofer and Schleith's results and used their anion-exchange resin to resolve complex salts of cobalt[77].



(XXXIV) R=OCH₃
(XXXV) R=H

Grubhofer's work was repeated by Klabunovskii[149], who also used quinine and the carboxylate cation-exchange resin KMG as starting materials. It is true that the maximum degree of enrichment with mandelic acid reached only 39% in his experiments, and was zero on the quite similar anion-exchange resin containing cinchonidine (XXXV). Attempts to employ an analogous anion-exchange resin with optically active ephedrine (XXVIII) were also unsuccessful.

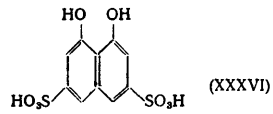
In 1959 Tsuboyama and Yanagita[150] described a dissymmetric anion-exchange resin of a different type: a styrene–divinylbenzene copolymer was subjected to chloromethylation and then to amination with (–)-1-phenylethylamine, which resulted in the introduction of secondary amino-groups into the copolymer. The capacity of the resulting anion-exchange resin was extremely small (0.43 mg-equiv. g^{-1}). On a column containing 10 g of this exchanger (4.3 millimoles) was sorbed 100 mg (0.66 millimole) of racemic mandelic acid, which was then eluted with 0.2 *N* aqueous ammonia. The resulting chromatogram consisted of two completely separate peaks, which were not equal in size. These workers state that the mandelic acid fraction corresponding to the second peak, and containing about 25% of the initial quantity of acid, consists of the practically pure dextrorotatory isomer. No explanation is given for the inequality of the chromatographic peaks.

We have tried to repeat Tsuboyama and Yanagita's results. However, no resolution of mandelic acid could be detected[2] on the high-capacity anion-exchange resin (3.36 mg-equiv. g^{-1}) which we have synthesised. The exchanger showed poor swelling in aqueous media, and retained practically no mandelic acid.

American workers have also been unable[151] to repeat the results of this work. Since Tsuboyama and Yanagita have published no further investigations on the chromatography of racemates, their results[150] must obviously be regarded as erroneous. Nevertheless, they aroused great interest in the ion-exchange chromatography of racemates.

A possible way of synthesising dissymmetric ion-exchangers is the polycondensation of optically active compounds containing basic or acidic groups. This method was used by Khromov-Borisov and Kozhevnikov[152], who effected the polycondensation of L-tyrosine with formaldehyde. They obtained insoluble polymers, since tyrosine reacted not only at the aromatic ring but also at the amino-groups, between which methylene bridges $NHCH_2NH$ or dimethyleneoxy-bridges $NHCH_2OCH_2NH$ were formed. The ability of the resulting exchangers to resolve racemates was not tested.

This was done by Losse et al.[153], who effected the polycondensation of formaldehyde with L-tyrosine in the presence of chromotropic acid



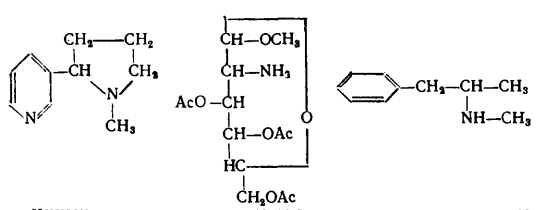
(XXXVI)

resorcinol, or *m*-toluidine. As a result, acidic or basic groups predominated in the polycondensate. The exchangers were tested for their ability to resolve racemic amino-acids—ornithine, lysine, valine, and glutamic and aspartic acids—for which purpose 1 g of the amino-acid in 10 ml of water (in the case of valine and the amino-dicarboxylic acids this could be assumed to be a suspension of the amino-acid in water) was sorbed on a column containing the exchanger, and eluted with 0.1 *N* hydrochloric acid or with water. In all cases the L-isomer of the amino-acid could be isolated from the eluate with an optical purity of 20–50%. The best results were given by the polymer obtained in the presence of resorcinol. The efficiency of separation of the isomers increased to a certain level with increase in the tyrosine content of the exchanger.

Another route has since been proposed for the synthesis of a dissymmetric cation-exchange resin containing residues of an optically active amino-acid[154]: cross-linked polyacrylic acid (Amberlite IRC-50) was converted into its acid chloride, and then treated with excess of L-aspartic or L-glutamic acid in boiling pyridine. The cation-exchange resins obtained in this way are capable of partly resolving racemates of diamino-carboxylic acids. By chromatographing lysine, for example, the D-isomer was isolated with an optical purity of 17%.

Analogous cation-exchange resins have been obtained by the radical polymerisation of optically active *N*-acryloyl-α-amino-acids or their esters[155]. In the latter case the carboxyl of the amino-acid is freed by heating the polymer with an acid (partial detachment of the amino-acid itself, bound to the polymer chain by an amide bond, is unavoidable).

A number of publications have described the synthesis of dissymmetric anion-exchange resins by the amination of chloromethylated styrene copolymers by means of various optically active amines, most often alkaloids. Thus Oda et al.[156] synthesised strongly basic anion-exchange resins, by using brucine and quinine. When a solution of mandelic acid was passed through a column containing the exchanger based on brucine, a fraction of the acid of optical purity 27% was isolated.



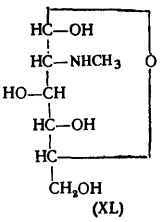
(XXXVII) (XXXVIII) (XXXIX)

Trochimczuk, Rabek, and Morawiec report an analogous synthesis of anion-exchange resins containing as dissymmetric components 1-phenylethylamine[157], cinchonidine (XXXV), nicotine (XXXVII), and ephedrine (XXVIII)[158,159]. Tsuboyama[160] used 3,4,6-triacetyl-1-methyl-D-glucosamine (XXXVIII) for the same purposes, and Selegny[161] has employed (–)-deoxyephedrine (XXXIX).

Lott and Rieman[151] used the laevorotatory isomer of *NN*-dimethyl-1-phenylethylamine for the amination of a

chloromethylated copolymer of styrene with divinylbenzene, and showed that the strongly basic anion-exchange resin formed possessed a greater affinity for (−)-mandelic acid than for its enantiomorph. Calculations based on a series of experiments with this exchanger indicate that a chromatographic column 2.3 km long would be required for complete separation of the isomers of mandelic acid.

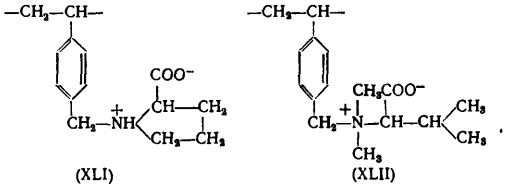
A patent[162] for the synthesis of ion-exchange resins based on cross-linked chloromethylated styrene copolymers proposes the use of a wide range of optically active amines and alkaloids—1-phenylethylamine, strychnine, ephedrine, *N*-methylglucosamine



(XL)

and also amino-carboxylic and amino-sulphonic acids or their esters.

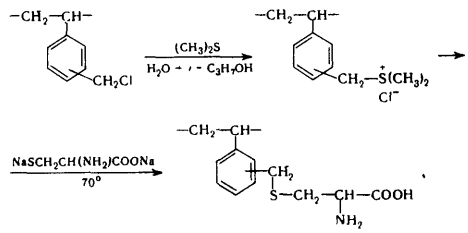
A series of dissymmetric ion-exchange sorbents based on α-amino-acids and copolymers of styrene with divinylbenzene has been synthesised by Davankov et al.[2,163,164]. Highly active bromo- and iodo-methylated copolymers were used for the synthesis, which enabled them to be aminated under mild conditions with amino-acids and their derivatives. Proline and *NN*-dimethylvaline readily undergo this reaction, forming amphoteric ion-exchange resins containing the units (XLI) and (XLII)



(XLI) (XLII)

It is advisable to use other α-amino-acids in the form of amides. Their interaction with halogenomethylated copolymers gives anion-exchange resins which can be converted into amphoteric exchangers by acid hydrolysis of the amide groups. Exchangers based on L-valineamide, L-leucineamide, and L-leucine have been prepared in this way. Chromatography of mandelic acid on these sorbents led to the isolation of small fractions of the optically pure dextrorotatory isomer of the acid. The isomers of proline undergo separation when its aqueous solution is run through a column of an exchanger based on L-proline.

Roberts and Haigh[165] synthesised an exchanger containing residues of optically active cysteine bound to a styrene copolymer by means of a sulphide bond:



The product possessed weak resolving power for racemic methionine.

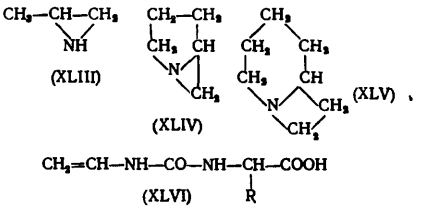
Papers by Manecke and his coworkers on the synthesis and examination of enzymatically active resins[166-168] have described nitrated copolymers of acrylic acid with its *m*-fluoroanilide, which, in virtue of the presence of a labile fluorine atom, could be combined with various enzymes or amines, in particular ephedrine. The anion-exchange resin obtained with L-ephedrine retained (+)-mandelic acid more firmly during chromatography, while the enantiomorph of the acid was eluted from the chromatographic column with optical densities up to 52.7%.[167]

Japanese workers[169] prepared a dissymmetric sorbent by the action of epichlorohydrin on chitosan, a product of the alkaline hydrolysis of chitin comprising oligomers of D-glucosamine. The sorbent obtained exhibited only very slight ability to resolve mandelic acid.

The use of carboxycellulose has been proposed[170] for the resolution of propylenediamine, and the product of the interaction of alkali cellulose with (−)-epoxypropyldeoxyephedrine for resolving racemic α-hydroxy-acids[171].

Attempts to resolve racemates by means of products of the reaction of poly-*p*-lithiumstyrene with nicotine, camphor, and camphorsulphonic acid have been unsuccessful[172].

Among the large number of optically active polymers which have been synthesised during recent years (for reviews see Refs. 173–175), a series of polyelectrolytes have been described which could in principle serve as foundation for dissymmetric ion-exchangers. Among them are the optically active polymers of 2-methylaziridine (XLIII),[176] 1-azabicyclo[3,1,0]hexane (XLIV),[177] and conidine (XLV).[178]



(XLIII) (XLIV) (XLV)

(XLVI)

Besides polypeptides (reviews[179,180]) we must include here polymers containing α-amino-acid fragments linked to the polymer chain by amide bonds at the amino-groups[181-183] or by ester bonds at the carboxy-groups[184], and also polymers of *N*-(vinylcarbamoyl)-L-amino-acids (XLVI)[185]. (Ionogenic groups in the polymers described in Refs. 182 and 184 can be freed by splitting off the protective groups.)

From our point of view the practical application of stereoselective sorption on a dissymmetric ion-exchanger is complicated by the fact that, in contrast to such sorbents as quartz, wool, starch, and cellulose, where we are dealing with dissymmetric active centres rigidly fixed on a solid surface, ion-exchangers when functioning have mobile solvated polymer chains. On the one hand, this tends to hinder formation of an adduct with the molecule undergoing sorption, which makes it necessary to impose specially rigorous requirements on the active centres of such a sorbent. On the other hand, it ensures that the sorbent shall operate throughout its bulk, which is shown in a considerably larger exchange capacity of the exchangers in comparison with other sorbents. This property makes dissymmetric ion-exchangers quite promising for the preparative resolution of racemates.

In our opinion the most suitable for these purposes are chromatographic systems having continuous circulation of the separable mixture through one or more columns. The initial and final fractions of a chromatographic zone are automatically withdrawn, and fresh portions of the mixture

are introduced into the middle of the zone, during each cycle. Such systems make even minute separation effects appreciable[186-188].

In connection with this problem it is interesting to mention the work of Toy et al.[189,190], who, foreseeing the need in the near future to convert amino-acids of the D-series into L-amino-acids, have synthesised resins which effect racemisation of optically active α-amino-acids. The desired isomer could be isolated from the racemic mixture, and the less valuable enantiomorph again subjected to racemisation. The process of racemisation is catalysed by resins containing units of the salicylaldehyde type, at pH 10.5 in the presence of copper ions.

Dissymmetric ion-exchangers can be used not only for the resolution of racemates but also as catalysts in asymmetric organic synthesis. This aspect of their application is shown by the work of Tsuboyama[160,191], who conducted a cyanohydrin synthesis in the presence of optically active polyisobutylethyleneimine

 (XLVII).

The benzaldehyde cyanohydrin (mandelonitrile) obtained in this way was laevorotatory, its optical purity reaching 11–19%. If a proportion of the amino-groups in the polymer were treated with isocyanate, the resulting polymer would catalyse the formation of the dextrorotatory cyanohydrin[191]. This phenomenon was explained by supposing that asymmetric catalysis was determined in this case not so much by the configuration of the asymmetric carbon as by the conformation of the whole polymer chain, which changed on passing from amine to amide nitrogen atoms in the chain.

Finally, dissymmetric sorbents may find application also in elucidating the mechanisms of chemical reactions and establishing the three-dimensional structure of compounds. Quite often only partial resolution of a racemate by a chromatographic method is sufficient for this purpose[91,100,192].

In conclusion we note the appearance of the first communications on the chromatographic *resolution of polymers*, containing asymmetric carbon atoms in the main chain[193,194] or in side-chains[195,196], into fractions of opposite rotation. Thus the separation of the crystalline polymer of 2-methyloxiran by means of polymeric (–)-menthyl glycidyl ether[193], and also by means of components containing sucrose, menthol, or borneol[194], has shown that the polymer consists mainly of enantiomorphous chains, and is not a stereo-block-copolymer. The analogous separation of poly-4-methylhex-1-ene adsorbed on optically active stereoregular poly-3-methylpent-1-ene[195] suggests that the polymerisation of racemic alkenes can be conducted not only as a stereospecific but also as a stereoselective process. Such separation of polymers differs, of course, from the chromatography of racemates of substances of low molecular weight in the fact that the polymeric product must in general be regarded not as a racemic mixture of enantiomeric chains but as a mixture of diastereomers[197]. It is noteworthy that, in contrast to poly-4-methylhex-1-ene, the monomeric analogue of its chain unit, 3-methylhexane, is not resolved on poly-3-methylpent-1-ene[196].

Gas-chromatographic Methods for Studying the Kinetics of Liquid-phase Reactions

V.G.Berezkin

A brief account is given of the main features of chemical reactions occurring in the stationary liquid phase in gas-chromatographic columns during the pulsed injection of the sample. Attention is paid mainly to the use of direct and indirect pulse methods of gas chromatography for determining the kinetic characteristics of reactions in the liquid phase.
The advantages and limitations of these methods are analysed. A promising future is shown for the wide application of pulse gas-chromatographic methods for the experimental study of the kinetics of liquid-phase reactions.

I. INTRODUCTION

Advances in the study of one of the main problems of modern chemistry—kinetics and the reactivity of chemical compounds—are governed in considerable measure by the development of new physicochemical methods and their wide practical incorporation in scientific investigations. Considerable progress in the study of the quantitative aspects of chemical reactions is due in particular to the wide use of gas-chromatographic methods in kinetic investigations [1,2].

Study of the composition of the reaction mixture is one of the most important tasks in experimental kinetic research. Although various physicochemical and chemical methods are employed to solve this problem, the most widely used techniques for analysing complicated multicomponent mixtures of volatile compounds are gas-chromatographic methods.

The simplest application of gas-chromatographic methods in research on kinetics consists in periodically withdrawing a sample of the reaction mixture from the reaction vessel, and then analysing it by gas chromatography. This is the mode of use adopted in most kinetic investigations.

An important characteristic of the chromatographic method is the possibility of studying the kinetics of a complicated chemical reaction at low degrees of conversion (under "pure" conditions), when the influence of the reaction products on the kinetics is negligible [3,4].

The first work on the application of gas chromatography to studying chemical kinetics by withdrawing and analysing samples of the reaction mixture was done during 1954–1956, [5-10] i.e. at the very start of the wide entry of gas chromatography into research practice. Gas chromatography is extensively used for studying the kinetics and the mechanism of chemical reactions because it possesses the following characteristics as an analytical method: (1) separation of the compounds under analysis is highly efficient (1000–5000 theoretical plates for packed columns, (20–100) × 10^3 theoretical plates for capillary columns); (2) the use of highly sensitive detectors enables small amounts of the reaction mixture (1–10 μl) to be employed for analysis, and the amount of component to be determined may be 0.01 mg for a catharometer and 10^{-4}–10^{-5} mg for a flame-ionisation detector; (3) the duration of an analysis is short, usually varying from a few minutes to several dozen minutes; and (4) standard chromatographic equipment is used for the separation.

In some studies of chemical conversion products, gas chromatography is used as a method of preparation, the compounds which are isolated on a preparative chromatograph being identified by other physicochemical methods [11]. Special mention must be made of the great opportunities for using gas chromatography in the analysis of radioactive and stable isotopes [12-15], which considerably extends the range of application of the method in kinetic investigations [12]. Methods have now been worked out for analysing the isotopes of hydrogen [14-18], the isotopes of oxygen [19], deuteriated methanes [20] and ethanes [21], and other labelled compounds [18].

By withdrawal of a sample from the reaction mixture and subsequent analysis, the gas-chromatography and the chemical process under investigation are isolated from one another, the former being used only as an efficient method of analysis. This method of applying gas chromatography to kinetics is by no means always the best, its wide use often being limited by several experimental difficulties: (1) kinetic investigations require the use as starting materials of pure compounds, and the amount of substance necessary for a kinetic experiment is often several grammes; (2) practical operation of the method is relatively simple only for slow reactions, rapid reactions requiring special methods to "freeze" the process; (3) gas chromatography can be used only to study the kinetics of reactions involving volatile components; and (4) the study of reactions occurring in viscous media is restricted by the difficulties involved in withdrawing the sample to be analysed and introducing it into the chromatograph.

Fundamentally new possibilities in studying the kinetics of reactions are opened up by pulse chromatographic methods, in which a plug of a volatile compound is injected into the carrier gas at the inlet to the reaction column, and the reaction occurring therein is assessed from the conversion or the retention time of the compound. In pulse methods the chemical reaction and the analysis are organically combined into a single method.

Two ways of applying pulse kinetic methods have been described, differing in the relation between the size of the plug of volatile reactant and the length of the active layer

in the reaction vessel. In the most widely used modification the plug is considerably smaller than the length of the layer, and in the other it considerably exceeds the length of the reaction vessel[22,23]. In the second variant there is practically no separation of the substances into individual zones along the layer. This method can be regarded as a microvariant of the usual flow technique for studying chemical reactions in a reaction vessel. We may mention also the possibility of using in kinetic investigations the method of reactant plugs, when reaction takes place in the reaction column between two plugs of volatile compounds, introduced successively into the column and moving along the reaction vessel at different speeds. In the literature the application of this method has been described only for analytical purposes[24].

In the kinetic study of reactions between a liquid and a volatile reactant (gas), investigation of the process under conditions of kinetic control is of especial interest. Various methods—e.g. vigorous shaking of the liquid phase in contact with the gaseous phase[25], bubbling the gas rapidly through the liquid[1], producing a thin layer of the liquid phase on the walls of the reaction vessel[26]—are used to accelerate diffusion processes in kinetic investigations of liquid-phase reactions in liquid–gas systems. When the reaction is conducted in a chromatographic reaction column, one of the reactants (the stationary liquid phase) is distributed as a thin layer (a few microns thick) on the surface of a macroporous inert carrier of surface 1–2 $m^2 g^{-1}$. On the assumption that blurring of the chromatographic zone is governed by the rate of mass exchange between gas and stationary liquid phase, the kinetic coefficient can be estimated by means of the relation[27] $\beta = 2\alpha/H$, in which α is the linear velocity of the carrier gas, and H the height equivalent to a theoretical plate. In practice we frequently have $\alpha \simeq 4$ cm s^{-1} and $H \simeq 0.2$ cm, so that $\beta \simeq 40$ s^{-1}. Thus it is probable that liquid-phase reactions having a rate constant $k \leqslant 1$ s^{-1} can be studied under kinetic conditions in a chromatographic reaction vessel.

Oxidation of an oil or other non-volatile product under the conditions of a chromatographic experiment, the liquid being applied as a thin layer to an appropriate porous carrier (glass, salt, metal), may be of interest for the rapid assessment of the working properties of technical products[28].

Pulse gas-chromatographic methods have been developed most widely and in greatest detail for the investigation of heterogeneous catalytic reactions. In several cases the results obtained can be used directly to examine the kinetics of liquid-phase reactions, for which gas-chromatographic methods are employed to a considerably smaller extent. Therefore the present review considers also work on the application of pulse gas-chromatographic methods to heterogeneous catalytic reactions where the results are of fundamental interest and can be used in studying liquid-phase reactions.

II. MAIN FEATURES OF CHEMICAL REACTIONS IN CHROMATOGRAPHIC COLUMNS

The pulse method was first suggested and employed by Kokes et al.[12] for the investigation of catalytic processes. Pulse chromatographic methods not only are more convenient and effective experimentally, but also provide fundamentally new opportunities for studying the kinetics and the mechanism of reactions.

A great contribution to the development of methods of reaction gas chromatography was made by Roginskii, Yanovskii, Gaziev, and their coworkers, who were the first to direct attention to the characteristics of chemical reactions occurring in chromatographic reaction vessels[29-35]. They showed that the kinetics of reactions occurring in chromatographic reaction columns are often so unusual that it is necessary in several cases to consider a special chromatographic régime of reactions, which differs fundamentally from the static and dynamic régimes.

For a reaction of the type $A \rightleftharpoons B + C$ with a pulsed supply of substance A to the reaction column, for example, the substances B and C are continuously generated and separated from A and from one another in zone A (the compounds A, B, and C move at different speeds along the reaction column), and form characteristic "peaks" outside the zone of the reactant A. Separation of reactant and products makes it possible to conduct the reversible reaction in one preferred direction, and to obtain yields of the desired product which considerably exceed the equilibrium yields under static conditions, etc. Under chromatographic conditions the chemical reaction takes place simultaneously (in conjunction) with chromatographic separation of reactants and products, which results in the process having the following characteristics: (1) owing to the separation it is mainly the initial reactant which is present in the reaction zone; (2) reversible reactions (e.g. of the type $A \rightleftharpoons B + C$) can be conducted predominantly in one direction, which enables yields to be obtained exceeding the equilibrium yields under static conditions; (3) the selectivity of the process is increased, the temperature of the reaction is lowered, side-reactions are eliminated, etc.; (4) the kinetic laws are simplified (e.g. the reaction zone contains practically no products which could act as poisons or promoters); and (5) new possibilities are opened up for studying the initial stages in the operation of a catalyst and for detecting intermediate products which are unstable under the reaction conditions[36].

If reaction of the initial volatile reactant is regarded as taking place in a system of coordinates moving at the speed of the reactant plug maximum in the reaction column, the reaction can be considered to occur in an open system in which the concentration of the initial volatile reactant continuously diminishes, and from which the reaction products are continuously removed (the rate of escape of the reaction products from the system is proportional to the difference between the velocities of the initial component and of the reaction products in the reaction column under the given experimental conditions). Reactions in open systems have several special characteristics[37]. In the present case an open reaction vessel of size proportional to the peak width of the initial reactant cannot be regarded as providing ideal mixing, since considerable concentration gradients of the reactants exist along its length. All this hinders an exact mathematical description of chemical reactions whose rate depends on the concentration of the products and the state of the catalyst.

Several specific physicochemical effects may occur during interaction between a solid catalyst and gases of variable composition, which are accompanied by a fundamental change in the results of the chemical process[38]. Continuous and pulsed supply of reactants produce different operating conditions for the catalyst, which may lead also to different results. In a study of the kinetics of the dehydrogenation of methanol[39], for example, similar results were obtained by the two methods. However, different kinetic parameters have been found[40] for the hydrogenation of acetone under conditions of pulsed and continuous reactant supply. Interesting results on the kinetics of the dehydrocyclisation of iso-octane and the hydrogenolysis of

mono- and di-alkylcyclopentanes have been obtained[41] by both methods, and a rational physical explanation is given of the observed differences for several types of reaction.

The above features of chemical reactions under pulse conditions are, of course, valid not only for catalytic but also for liquid-phase reactions. It must be emphasised only that, for the relatively wider range of liquid-phase chemical reactions, conducting the reactions in a chromatographic reaction column produces no change in the kinetics, as often occurs in the more complicated heterogeneous catalytic reactions.

In the case of slow irreversible reactions occurring in chromatographic columns, the zones of initial reactant and reaction products formed are now determined both by the chromatographic and by the kinetic characteristics of all the components in the reaction. For the reaction A → B, for example, the shapes of the zones due to the initial compound and to the product vary as a result of two processes—(1) ordinary chromatographic blurring during movement of the zone along the column, and (2) chemical reaction, during which the concentration of the initial compound in the chromatographic zone diminishes, while that of the reaction product increases.

Quantitative aspects of the formation of zones were discussed for the reaction A → B by Kallen and Heilbronner[42] on the basis of the theory of theoretical plates[43,44] within the framework of non-ideal linear chromatography. Equations were obtained[42] for the chromatographic zones of both the initial reactant compound and the product formed.

Let us examine the variation in concentration in the chromatographic zone of the initial reactant under conditions of equilibrium linear gas chromatography, caused by the action of longitudinal blurring factors. For a first-order reaction the initial equation can be written

$$\rho_G\frac{\partial c}{\partial t}+\alpha\rho_G\frac{\partial c}{\partial x}+\rho_L\frac{\partial a}{\partial t}+\rho_L k_L a=D^*\rho_G\frac{\partial^2 c}{\partial x^2} \qquad (1)$$

where ρ_G and ρ_L are the fractions of gaseous and liquid phases in a cross-section of the column, D^* is the quasi-diffusion coefficient of longitudinal migration, and k_L is the first-order reaction rate constant in the liquid phase.

In view of the linear relation between the concentration in the liquid phase a and that in the gas phase c, we eliminate the variable a from Eqn. (1):

$$\frac{\partial c}{\partial t}+v\frac{\partial c}{\partial x}+k_{eff}\cdot c=D_{eff}\frac{\partial^2 c}{\partial x^2}, \qquad (2)$$

where

$$v=\frac{\alpha}{1+\Gamma\dfrac{\rho_L}{\rho_G}}. \qquad (3)$$

$$k_{eff}=\frac{k_L}{\dfrac{\rho_G}{\rho_L}\cdot\dfrac{1}{\Gamma}+1} \quad (4) \qquad D_{eff}=\frac{D^*}{1+\Gamma\dfrac{\rho_L}{\rho_G}}. \qquad (5)$$

If no reaction occurs, $k_L = 0$, and Eqn. (1) becomes

$$\frac{\partial\tilde{c}}{\partial t}+v\frac{\partial\tilde{c}}{\partial x}=D_{eff}\frac{\partial^2\tilde{c}}{\partial z^2}. \qquad (6)$$

The solution of this equation is[27]

$$\tilde{c}=\frac{c_0}{\sqrt{4\pi D_{eff}\,t}}\exp\left[-\frac{(x-vt)^2}{4D_{eff}\,t}\right]. \qquad (7)$$

We shall seek a solution of Eqn. (1) in the form

$$c=f(t)\cdot\tilde{c}. \qquad (8)$$

Substituting Eqn. (8) in (1), and taking into account Eqn. (6), we obtain for $f(t)$

$$-\frac{df}{dz}=k_{eff}\cdot f(t). \qquad (9)$$

Hence an approximate solution of Eqn. (1) is

$$c=\frac{c_0}{\sqrt{4\pi D_{eff}\cdot t}}\exp-\left[\frac{(x-vt)^2}{4D_{eff}\,t}+k_{eff}\,t\right]. \qquad (10)$$

Analysis of this equation shows that the retention time of the zone maximum and the temporal width of the zone vary somewhat as a consequence of the chemical reaction. However, for the usual conditions of a chromatographic experiment and slow chemical reactions, this variation is small.

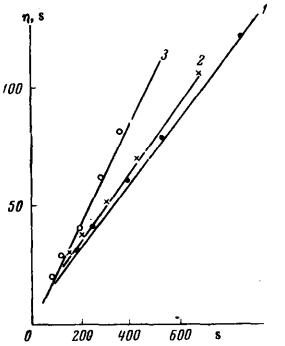

Figure 1. Dependence of peak width η on retention time for a mixture of hydrocarbons (in order of their elution from the column)—isopentane, pent-1-ene, isoprene, *cis*-piperylene, n-heptane— in a column (450 x 0.4 cm) containing as sorbent 10% of tritolyl phosphate and maleic anhydride (4:1) on a diatomite support at 70°C, with different velocities (ml min^{-1}) of the carrier gas: *1*) 31; *2*) 42; *3*) 65.

An experimental study has been made[45] of the blurring of the chromatographic zone of a reacting compound under the actual (non-equilibrium) conditions of gas–liquid chromatography. In order to ascertain whether this blurring is specific, the dependence of the peak width η on the residence time t in the column was determined simultaneously for the peaks due to a non-reactant and to a reactant[46]. It was supposed that, if the point (η_r, t_r) for the reactant did not lie on the $\eta = \eta(t)$ "calibration" curve obtained for non-reactant compounds, the specific blurring of the peak due to the chemical reaction could be estimated quantitatively; otherwise, it could be concluded that the reaction had no specific effect on the blurring of the chromatographic peak. Fig. 1 shows the dependence of peak width η on retention time for various hydrocarbons and various velocities of the carrier gas (31–65 ml min^{-1}). No specific blurring of the zone representing a reactant compound (isoprene) was detected (for constants of 5–16 $M^{-1}\,h^{-1}$ and degrees of conversion of 30–70%).

Roginskii and Rozental'[47] obtained a solution for the more general case in which a first-order homogeneous reaction in the gas phase and a heterogeneous catalytic reaction, of the first order with respect to the surface concentration of adsorbed reactant, occur simultaneously in the chromatographic reaction vessel. In this case the

reactant concentration distribution along the column should satisfy the set of equations

$$\frac{\partial p}{\partial t}+\frac{\partial a}{\partial t}+u\frac{\partial p}{\partial x}+k_1 p+k_2 a=0$$
$$\frac{\partial a}{\partial t}=k_3 p-(k_2+k_4)a, \qquad (11)$$

where p is the number of reactant molecules per unit volume of the gas phase (which is proportional to the partial pressure of the reactant gas), x is the distance along the column from the point of entry of the gas into the column, a is the number of adsorbed reactant molecules per unit volume of the gas phase, u is the linear velocity of the carrier gas in the column, and k_1, k_2, k_3, and k_4 are the rate constants of the homogeneous reaction, the heterogeneous catalytic reaction, adsorption, and desorption respectively.

If the chemical reaction takes place in a film of the stationary liquid phase, the above set of equations and the consequent solution can be extended to reactions in gas–liquid chromatography, provided that $k_3=\beta$ and $k_4=\beta/\Gamma$, where β is the kinetic coefficient and $\Gamma=a/p$.

The partial pressure of the reactant gas before entering the column is a known function of time $\psi(t)$, with $\psi(t)=0$ at $t=0$ and $t\geqslant t_e$. At the inlet to the column $\psi(t)=p(x,t)$ at $x=0$.

If the time required to introduce the reactant gas into the reaction column t_e is close to zero, the solution obtained for the chromatographic zone of the reactant at $t-x/u\gg t_e$ was

$$p(x,t)=\frac{2xm_0k_3k_4\exp\left[(k_3-k_1-k_2+k_4)\frac{x}{u}-(k_3-k_4)tJ_1(z)\right.}{uz}, \qquad (12)$$

where

$$z=2\sqrt{k_3\cdot k_4\frac{x}{u}\left(t-\frac{x}{u}\right)}$$

m_0 is the initial quantity of reactant gas, and $J_1(z)$ is the first-order Bessel function of the first kind in an imaginary variable. For large values of the variable we have

$$J_1(z)=e^z/\sqrt{2\pi z}\ .$$

For values of x which satisfy the condition $x/u>3k_3k_4(k_2+k_4)$ the retention time of the reactant compound is given by the formula[47,48]

$$t_{max}=\frac{x}{u}+\frac{k_3\cdot k_4x}{2u(k_3+k_4)^2}\left[1+\sqrt{1-\frac{3u(k_3+k_4)}{k_3\cdot k_4x}}\right]. \qquad (13)$$

This equation shows that a homogeneous reaction does not affect the retention time.

A more general solution for the mean residence time of reactant molecules in a chromatographic reaction vessel and for the dispersion of the chromatographic zone has been obtained by Denisova and Rozental'[49]. These workers, in discussing first-order chemical reactions under pulse conditions, take into account the diffusion of gas molecules, and show that diffusion combined with the chemical reaction diminishes the mean residence time of unchanged molecules in the reaction vessel and also the width of the peak.

The characteristic kinetic laws for reactions of different orders ($n\neq 1$) under conditions of pulse chromatography were first examined by Gaziev et al.[50] On the assumption that reaction occurs under conditions of ideal linear chromatography, they examined the diminution in concentration of the initial reactant for reactions of zero, first, and second orders and for pulses having different forms. In the case of a first-order reaction the degree of conversion was unaffected by the shape of the pulse, but for zero- and second-order reactions it does depend on the form of the pulse at the inlet to the reaction vessel.

The fact that the degree of conversion is independent of the form of the pulse for a first-order reaction under conditions of gas-chromatographic separation has received experimental confirmation[51], in which the degree of conversion of butadiene by reaction with maleic anhydride was determined from the areas of the peaks due to the reactant compound and from the heights of multistage peaks. In Fig. 2 the heights of the chromatographic zones (steps) preceding and following the reaction vessel (h_1/h_2) are plotted along the horizontal axis, and the ratio of the areas of the peaks (S_1/S_2) along the vertical axis. It is seen that the same results are obtained in the two cases: i.e. the form of the pulse does not affect the degree of conversion. In the study of first-order reactions, therefore, the degree of conversion can be measured by the ratio of peak areas, which is more convenient in practice.

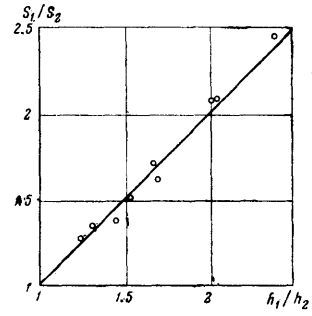

Figure 2. Dependence of S_1/S_2 on h_1/h_2 for butadiene at temperatures of 55.5°, 60°, and 74°C.

The field of application of the pulse gas-chromatographic method to liquid-phase reactions is considerably extended by using as a second reactant (the stationary liquid phase or a solution of a non-volatile component in it) a substance having a measurable vapour pressure at the temperature of the experiment. When the experiment is conducted under steady-state conditions, the loss of volatile substance from the column must be balanced by establishing the same concentration of this substance in the flow of carrier gas before the sample inlet. In this case reaction will take place in two phases—liquid and gaseous—and it is interesting to examine methods for determining separately the reaction rate constants in them. Assuming that the rates of chemical reaction can be described in both phases by a first-order equation, and that the reaction is kinetically controlled, let us examine the variation in the quantity of volatile substance (plug) resulting from passage through the reaction vessel, which is actually measured in an experiment. We remember that the superposition principle is satisfied (Eqn. 1):

$$W=\frac{dm}{dt}=\frac{dm_G}{dt}+\frac{dm_L}{dt}=F\rho_G\int_0^L w\,dx+F\rho_L\int_0^L w\,dx \qquad (14)$$

in which

$$w=k_G c_B^l c \qquad (15)$$

$$w=k_L a_B^n a \qquad (16)$$

$$a=\Gamma c \qquad (17)$$

where k_G and k_L are the reaction rate constants in gas and liquid phases respectively, c and a are the corresponding concentrations of the volatile component, c_B and a_B are those of the second, less volatile component (practically constant under the experimental conditions), F is the cross-sectional area of the column, and ρ_G and ρ_L are the fractions of gas and liquid phases in the cross-section of the column. Let us rearrange Eqn. (14) to give

$$W = F[k_G\rho_G c_B^l + k_L a_B^n \Gamma\rho_L]\int_0^L cdx. \quad (18)$$

The total quantity of volatile component in the column satisfies the relation

$$\int_0^L cdx = \frac{m}{F(\rho_G + \Gamma\rho_L)} \quad (19)$$

and consequently

$$\frac{dm}{dt} = \frac{k_G\rho_G c_B^l + k_L a_B^n \Gamma\rho_L}{\rho_G + \Gamma\rho_L} \cdot m = k_{eff} \cdot m \quad (20)$$

where

$$k_{eff} = \frac{k_G\rho_G c_B^l + k_L\Gamma\rho_L a_B^n}{\rho_G + \Gamma\rho_L}. \quad (21)$$

Equation (20) is analogous to the differential rate equation for a first-order reaction.

Since, when detectors are used in the range of the linear scale, the quantity of substance is directly proportional to their area on the chromatogram, it follows that

$$\ln\frac{m_0}{m} = \ln\frac{S_0}{S} = k_{eff}\,t \quad (22)$$

where S_0 and S are the areas of the peak due to the volatile reactant on the chromatogram in the absence of the reaction vessel and after passing through it.

Let us make a more detailed examination of the equation for k_{eff}, having written it in the somewhat different form

$$k_{eff} = \frac{k_G\rho_G c_B^l/\rho_L + k_L\Gamma a_B^n}{\rho_G/\rho_L}. \quad (23)$$

All the terms in Eqn. (23) other than the rate constants can be determined. The separate determination of k_G and k_L requires that measurements should be made with different reaction vessels, characterised, for example, by different proportions of liquid and gaseous phases.

For stationary phases (reactants) which are either completely or nearly non-volatile, we note that $a_B \gg c_B$, and the first term in the numerator of Eqn. (21) can be neglected, so that

$$k_{eff} = \frac{k_L a_B^n}{\rho_G/\rho_L \cdot 1/\Gamma + 1}. \quad (24)$$

According to Ref. 27, we have

$$\rho_G/\rho_L \cdot \frac{1}{\Gamma} = \frac{t_0}{t_{corr}} \quad (25)$$

in which t_0 is the dead time of the reaction column and t_{corr} is the corrected retention time; therefore

$$\ln\frac{S_0}{S} = k_L a_B^n t_{corr}. \quad (26)$$

In the other extreme case, in which reaction takes place solely in the gas phase, and a flow of carrier gas containing a constant concentration of one reactant passes through a tube containing no sorbent, we find that

$$\ln\frac{S_0}{S} = k_G c_B^l t. \quad (27)$$

The theory of reversible chemical reactions of the type $A \rightleftharpoons B + C$ occurring under conditions of ideal linear chromatography in a column has been discussed by Magee [52]. A theoretical investigation of the effect of reaction velocity on the retention time and the form of the eluted peak has been made by Klinkenberg [53] for reactions of the type $A \rightleftharpoons B$. A closely related problem has also been analysed [54].

III. CHIEF EXPERIMENTAL METHODS FOR STUDYING THE KINETICS OF LIQUID-PHASE REACTIONS

The variation in concentration (quantity) of the components of a reaction can be studied by direct and indirect methods. In direct pulse chromatographic methods the rate of a chemical reaction is assessed from a direct determination of the quantity of a reacting component, and in indirect methods from the dependence of the retention parameters of unreactive components on the composition (quantity) of the reaction mixture used as the stationary liquid phase.

Table 1. Various forms of pulse gas-chromatographic methods for studying the kinetics of chemical reactions.

Reactants volatile	One reactant volatile, others non-volatile	All reactants non-volatile
1. Two volatile components enter reaction column together. Method has been used to study the kinetics of catalytic reactions [55]. 2. One component injected as plugs into reaction column, while the second enters the reaction vessel continuously in the stream of carrier gas. Method suggested in Ref. 50. 3. Plug of one component injected into reaction column, and after a definite time interval a plug of the second component. Reaction occurs during the time in which the second overtakes the first component in the reaction column.	4. Volatile component injected into column in plugs, while non-volatile compounds used as stationary liquid phase, either directly [56] or as solution in non-volatile solvent [51]. 5. Volatile component introduced continuously into column, while non-volatile components used as stationary liquid phase. Into the reaction column are periodically injected plugs of a standard mixture of non-reactants, the variation in whose retention times indicates the composition of stationary liquid phase (indirect method) [58].	6. Starting materials used as stationary phase in reaction column. Plugs of mixture of standard non-reactants periodically injected into column, the variation in their retention times indicating the variation in composition of the stationary liquid phase resulting from reaction (proposed [58] indirect method).

Pulse chromatographic methods of kinetic investigation are applicable to various chemical reactions, but the choice of the optimum method depends on the state of aggregation and the volatility of the reaction components, as well as on the type of reaction. Some of the main modifications of the method for reactions of the type $A + B + \ldots \rightarrow C + D + \ldots$ are listed in Table 1. It can be seen that pulse gas-chromatographic methods can be successfully applied to a wide range of reactions, the components of which are in various states of aggregation. It must be stressed that Table 1 indicates only the chief variants: for example, it does not reflect experimental methods of using volatile products to study the kinetics of non-volatile compounds, which are especially promising for the kinetic examination of the degradation of polymers.

The arrangement of the kinetic chromatographic apparatus is varied depending on the method of kinetic study and the type of reaction. Table 2 gives some of the principal block diagrams. Switching devices (valves, multiway taps, etc.) are not shown in these diagrams.

Table 2 illustrates four main types of scheme, differing in the relative arrangement of chromatographic column and reaction vessel. When it is necessary to work with labelled atoms, these schemes must be supplemented by detectors to record the labelled compounds (e.g. Geiger counters).

Table 2. Some fundamental block schemes for studying the kinetics of chemical reactions.

Chromatographic schemes	Characteristics of scheme
1	Simple chromatographic scheme. Column is also reaction vessel.
2.1, 2.2, 2.3, 2.4	Reaction vessel preceded by chromatographic column, which is used to obtain a plug of the pure reactant. Trap used if necessary to constrict plug of initial volatile reactant. Column and reaction vessel may be located in different thermostats. The most universal scheme of this type is 2.4.
3.1, 3.2	Reaction vessel followed by column to separate initial reactants and reaction products.
4	Combined scheme, enabling pure substances to be obtained before entering the reaction vessel, and substances to be analysed after leaving it.

○ 1 ⋀⋀⋀ 2 □ 3 △ 4 ⊠ 5 ● 6

Conventional symbols: *1*) device for injecting sample; *2*) chromatographic column; *3*) detector having two measuring cells; *4*) measuring unit with pen-recorder; *5*) reaction vessel; *6*) trap.

In the design of chromatographic apparatus for kinetic studies account must be taken of the following possibilities in conducting an experiment—(1) "preparative" (in analytical quantities, of the order of milligrammes and fractions of a milligramme) chromatographic production of the pure initial reactant, (2) mixing of one initial reactant with others, (3) injection of the reaction mixture as a sharp plug (instantaneous introduction) or as a rectangular pulse of finite duration (step), or else continuous introduction of one or more reactants into the reaction vessel, (4) chromatographic separation of the reaction products and determination of their concentration both before and after the reaction, and (5) stabilisation of the reaction conditions (temperature, rate of flow of carrier gas, etc.).

An important advantage of direct pulse gas-chromatographic methods for studying the kinetics of liquid-phase reactions is the possibility of using impure substances as starting materials, these being separated from impurities by chromatography immediately before the reaction. This increases both the reliability and the universality of the method. Rephrasing Ostwald's well known statement, we can say that pulse chromatographic methods enable accurate results to be obtained when using contaminated starting materials.

It may be noted that kinetic chromatographic equipment can be assembled very quickly by using standard parts (thermostats, detectors, columns, measuring devices, etc.) of gas chromatographs.

IV. DIRECT PULSED CHROMATOGRAPHIC METHODS FOR STUDYING THE KINETICS OF LIQUID-PHASE REACTIONS

A direct method for the kinetic study of liquid-phase reactions was first used by Gil-Av and Herzberg-Minzly in investigating the reaction of conjugated dienes with chloromaleic anhydride[56]. A plug of the diene was introduced into the flow of carrier gas before the latter entered the reaction column (dimensions 200 × 0.4 cm) containing the chloromaleic anhydride. It was shown that the reaction was not controlled by diffusion, and corresponded to a first-order kinetic equation. From measurements of the rate constants at two temperatures (25° and 40°C) the activation energy was found to be 17.2 and 15 kcal mole^{-1} for *trans*-penta-1,3-diene and isoprene respectively, these values agreeing with published data.

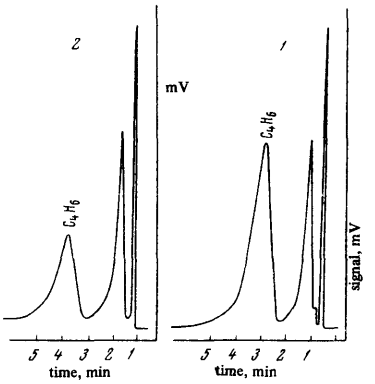

Figure 3. Chromatograms of butadiene:
1) preceding the reaction vessel; *2*) following the reaction vessel.

This method has been developed[51] to determine the order of reaction with respect to a second, non-volatile component and the rate constant of a bimolecular reaction. Scheme 2.2 in Table 2 was used for the experimental work, in which the kinetics of the reaction between dienes and maleic anhydride was studied. Fig. 3 shows as example the chromatograms of butadiene before and after reaction with maleic anhydride. The peaks eluted from the column before the butadiene are due to air and butenes present as impurities in the butadiene. The second component in the reaction—maleic anhydride—was deposited on brick as a solution in tritolyl phosphate saturated at 45°C. This choice of solvent had the aims of—(1) extending the temperature range of the reaction (since the melting point of maleic anhydride is 55°C, so that it cannot be used as a reactant in the liquid phase below this temperature), (2) increasing the retention time and hence the period of contact of the reactants, and (3) investigating the kinetics of the reaction with respect to the non-volatile component, i.e. maleic anhydride.

The kinetic measurements were made at a constant concentration of maleic anhydride, which exceeded by factors of 10^2–10^4 that of the volatile component, butadiene. Not more than 0.02% of the maleic anhydride reacted during one experiment. Reaction in the gas phase had no appreciable effect on the observed results. Kruglikova and the Reviewer have shown that, for this reaction at 69°C, $k_G\rho_G c_B/k_L\Gamma\rho_L a_B \simeq 10^{-4}$, so that the gas-phase reaction can be disregarded.

Degree of conversion was determined from the change in the areas of the chromatographic peaks preceding and following the reaction vessel. The slight blurring which occurs when the plug of the substances passes through the reaction vessel should not affect the results, since with a first-order reaction the relative conversion does not depend on the form of the plug. The bimolecular rate constant was calculated by means of Eqn. (26), the concentration a_B being varied [57]. This equation was used to determine the kinetic characteristics of the Diels–Alder reaction of butadiene, isoprene, and penta-1,3-diene with maleic anhydride. Under the given conditions these reactions are practically irreversible [59].

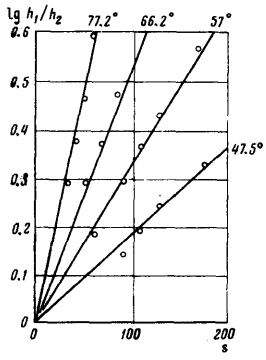

Figure 4. Dependence of logarithm of degree of conversion of butadiene on time of reaction at various temperatures.

Fig. 4 shows the dependence of the logarithm of the degree of conversion of butadiene on its contact time with maleic anhydride at various temperatures. The contact time of the reactants was calculated as the difference between the retention times of the diene preceding and following the reaction vessel, with the dead time of the latter taken into account. The straight lines obtained confirm that, with a constant concentration of maleic anhydride, the reaction obeys a first-order equation with respect to the diene.

The order of the reaction with respect to maleic anhydride can also be determined by this method. For this purpose different concentrations of maleic anhydride in tritolyl phosphate were used in a series of experiments, and the logarithm of the maleic anhydride concentration $\lg c_{MA}$ was plotted against $\lg y$, where $y = \lg(S_0/St_{corr})$. Fig. 5 illustrates this relationship for the reactions of maleic anhydride with butadiene and with isoprene. The slopes of these straight lines show that the order of the reaction with respect to maleic anhydride differs slightly from unity (slightly greater with butadiene, and slightly less than unity with isoprene), which is probably due to the influence of the solvent used.

The activation energies of the reactions were determined graphically from the linear dependence of the logarithm of the rate constant on the reciprocal of the temperature. Activation energies were evaluated by this method for the reactions of butadiene, isoprene, and piperylene with maleic anhydride. Table 3 gives values determined by the pulse chromatographic method for the rate constants and the activation energies of these reactions, and includes for comparison available published values of the activation energies calculated from the quantity of diene remaining unchanged, as in the case of a second-order reaction [60]. The rate constants differ somewhat from the published values, but are of the same order of magnitude, while the activation energies for butadiene and isoprene are practically identical with the published values. The results in Table 3 are mean values for whole series of experiments. Individual values of the constants do not differ from their mean value by more than 10%. Thus rate constants and activation energies for bimolecular reactions can be determined quite accurately by the pulse chromatographic method.

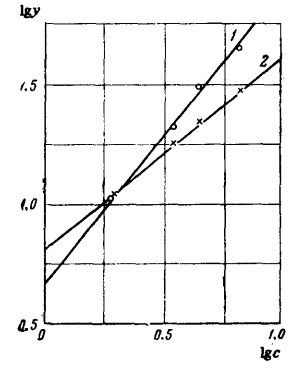

Figure 5. Dependence of $\lg y$ on $\lg c$ for: *1*) butadiene; *2*) isoprene.

Table 3. Rate constants and activation energies for reactions of dienes with maleic anhydride.

Diene	Reaction rate constants k, $M^{-1}\,h^{-1}$, at temperatures (°C)									Activation energy, kcal mole^{-1}	
	47.5	49	51.3	57	59.6	60.5	66	68.3	69.6	77	found	Ref. 60
Butadiene	1.55			2.8			4.7			7.9	12±0.8	11.7±0.8
Isoprene		5.75			11.0			16.9			12.1±1	12.2
Piperylene			8.5			12.4			16.7		8.1	—

The rate constants of these reactions can be determined on chromatographic apparatus having a single detector if the reactant concentration is measured relative to an unreactive reference substance introduced into the mixture:

$$k_L = \frac{2.3 \lg \dfrac{S_{01}/S_{1ref}}{S_{02}/S_{2ref}}}{c_B^n t_{L\,corr}} \qquad (28)$$

where S_{01}/S_{1ref} is the ratio of the areas of the chromatographic peaks for the diene and the reference material on the column (in the absence of the reaction vessel), and S_{02}/S_{2ref} is the corresponding ratio when a reaction column

is used. Rate constants obtained by this method for the reaction of isoprene with maleic anhydride are practically identical with results obtained by other methods.

Pulse methods can be applied also to studying the kinetics of isotopic exchange. They have been used[61] to produce deuterium-labelled compounds (ketones containing a labile hydrogen atom) on a semi-preparative scale. The compound labelled with deuterium was formed during passage of a plug of the volatile compound through a gas–liquid chromatographic column filled with Gaschrom Z (100–120 mesh) which had been coated with 10% Carbowax 6000 and 10% potassium deuteroxide KOD. The column (3 m long) was used for the semi-preparative production of deuterated compounds after the initial injection of 0.3 ml of D_2O and stabilisation for a few hours. A table is given[61] indicating the conditions of deuterium exchange and the degree of exchange.

A pulse chromatographic method has been used also to study the kinetics of the esterification with acetic anhydride of various alcohols having high boiling points[62]. The volatile reactant (acetic anhydride) entered the reaction vessel in the form of a plug, while the non-volatile reactant (the alcohol) was present in the reaction column as the stationary liquid phase. In contrast to the application of the pulse method to diene syntheses, in the esterification of an alcohol with acetic anhydride one of the reaction products (acetic acid) is eluted from the reaction column after the initial component (acetic anhydride).

The reaction vessel used was a chromatographic column of size 100 × 0.4 cm. The non-volatile alcohol was deposited on fluorinated plastic A (1 : 10 by weight). The purity of the initial alcohols was checked chromatographically. Esterification of the alcohols was studied over the temperature range 80–130°C, since the rate of esterification is small at lower temperatures, and at higher temperatures the alcohols begin to volatilise appreciably from the column.

Table 4. Kinetic characteristics of the esterification of alcohols with acetic anhydride.

Reactant	Rate constants		Activation energy, kcal mole^{-1}
	first order k_I, min^{-1}	second order k_{II}, M^{-1} h^{-1}	
Dodecan-1-ol	1.12*	14.8*	17
Hexadecan-1-ol	0.73**	12.9**	19
Heptadecan-9-ol	0.099**	1.9**	24
Cyclododecanol	0.22**	3.0**	15
7-Methyltridecan-7-ol	0.041*	0.65*	23

* At 104°C. ** At 100.7°C.

A mixture of acetic anhydride and the reference material (benzene) was introduced as plugs into the chromatographic reaction column, where the test alcohol was used as the stationary liquid phase. Different degrees of absorption of the acetic anhydride were obtained by varying the speed of the carrier gas. The time of contact of the reactants was determined as the difference between the retention time of the acetic anhydride and the dead time of the reaction column.

The first-order rate constants with respect to acetic anhydride were determined by the method of least squares from the linear dependence of $\lg(S_0/S_{ref})$ on the period of contact.

Table 4 shows that primary alcohols have the highest esterification rate constants, while tertiary alcohols are esterified much more slowly under the same conditions, secondary alcohols occupying an intermediate position with respect to their reactivity. The activation energies of these reactions were determined from the temperature dependence of the rate constants, and are included in Table 4.

The above examples indicate the promising future for the wide application of direct pulse methods in the kinetic study of liquid-phase reactions.

V. INDIRECT PULSED CHROMATOGRAPHIC METHODS FOR STUDYING THE KINETICS OF CHEMICAL REACTIONS

The above methods for studying the kinetics of liquid-phase reactions cannot be used with reactions involving only compounds which are non-volatile or which are unstable at high temperatures, i.e. compounds for which direct gas-chromatographic analysis is impossible under the reaction conditions. However, analysis is often a complicated problem for such systems.

A new form of gas chromatography—inverse gas chromatography—has been used to study the kinetics of chemical reactions in such systems[63,64]. In contrast to the usual form of development chromatography, the substance to be analysed is the stationary liquid phase, and a mixture of known standard compounds of various types is separated on it. In inverse chromatography the substances and mixtures under analysis (stationary liquid phases) are characterised mainly by the retention parameters of the components of the standard mixture. The stationary phase (test compound) is characterised by a spectrum of retention parameters of the standard compounds. The method can be applied both for group identification and for determining the quantitative composition of simple mixtures[63,64].

In a proposed method[58] for studying chemical kinetics, the reaction occurs in the chromatographic column, and the reaction mixture is used as stationary liquid phase for a standard mixture of non-reactants. Variation in the composition of the reaction mixture with time is checked by periodic measurement of the elution characteristics (e.g. the relative retention times) of the non-reactants. Thus determination of the composition of the reaction mixture is based on a relation of the type

$$c_i = f(\tau_j) \qquad (29)$$

where c_i is the concentration of one of the components in the reaction mixture, and τ_j is the relative retention time of a standard non-reactive compound. The inverse relation $\tau_j = \psi(c_i)$ has been studied by several investigators in connection with the problem of using binary mixed liquid phases for separating complicated mixtures of volatile compounds[65–68].

Results given in most of the papers indicate a linear relation between the relative retention parameter and the concentration of one of the components in the binary stationary phase. In general, however, this relation must be regarded as non-linear, which was correctly pointed out in Ref. 68.

If some physical property (in the present case the retention time τ) is proportional to the concentration of a substance in the reaction mixture, we have

$$\tau = \tau_\infty + (\tau_0 - \tau_\infty)\frac{c}{c_0} \qquad (30)$$

where τ, τ_0, and τ_∞ are the retention times of some substance on the reaction mixture (the stationary liquid phase)

respectively at time t, at the start of the reaction, and when the reaction is complete. In this case the kinetic equation for a unidirectional first-order reaction can be written[37]

$$k = \frac{2.3}{t} \lg \frac{\tau_0 - \tau_\infty}{\tau_t - \tau_\infty} \quad . \qquad (31)$$

The indirect pulse method of studying kinetics has several advantages: it does not require the removal of samples, and only small amounts of the test substances are needed, of the order of a few milligrammes in the case of capillary columns; it can be used to investigate the kinetics of reactions in systems which cannot be analysed chromatographically because of thermal instability or non-volatility; and it enables kinetic investigations to be made in various systems—solid–liquid, liquid–liquid, liquid–gas—and also for various catalytic reactions.

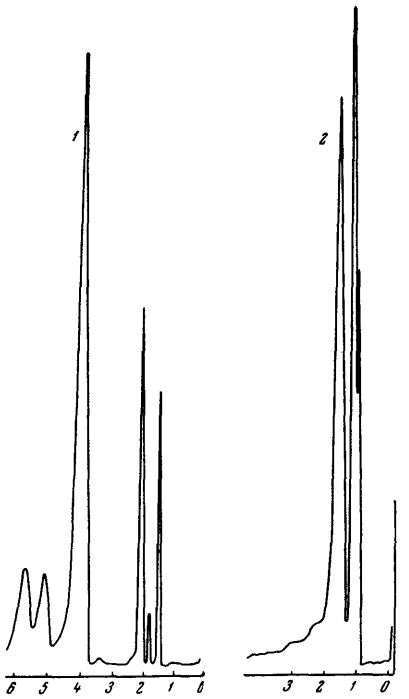

Figure 6. Chromatograms of standard mixture of butenes on: *1*) original benzaldehyde; *2*) completely oxidised benzaldehyde.

An example of the use of this method is the kinetic investigation of the oxidation of benzaldehyde to benzoic acid. The usual chromatographic apparatus was used for the kinetic study[69]. Air was passed at a rate of 30 ml min^{-1}, to act both as oxidant and as carrier gas, through a chromatographic column (200 × 0.4 cm) filled with diatomaceous brick on which had been deposited benzaldehyde (40%). Since the oxidation of benzaldehyde is catalysed by traces of heavy metals, the brick had first been impregnated with a solution of copper sulphate (0.1%). The benzaldehyde had been applied to the brick from acetone solution in an atmosphere of nitrogen freed from oxygen. The standard mixture comprised ethane, propene, but-1-ene, and but-2-ene, since these compounds were characterised by different retention times on benzaldehyde and benzoic acid. The procedure consisted in obtaining chromatograms of the standard mixture on the reaction mixture (benzaldehyde + benzoic acid) after definite intervals of time. The retention times of the compounds changed as the benzaldehyde was oxidised.

Chromatograms obtained on the original benzaldehyde and on the completely oxidised compound show (Fig. 6) a marked change in the retention times. At 0°C the concentration of benzoic acid in benzaldehyde corresponding to saturation is 7%, so that the composition of the liquid phase then remains practically constant during the oxidation, while the quantity of benzaldehyde (stationary liquid phase) decreases. During oxidation the corrected retention times vary in direct proportion to the content of benzaldehyde in the column. Therefore Eqn. (31) can be used in processing the experimental results, on the assumption that the kinetics of the oxidation of benzaldehyde to benzoic acid in the presence of oxygen corresponds formally to a first-order equation. The effective rate constant calculated by means of Eqn. (31) is 4.7×10^{-3} min^{-1}.

The results of the proposed method for studying the kinetics of the oxidation of benzaldehyde have been compared with those obtained by oxidation in a bubbler reaction vessel. These gave an oxidation rate constant of 4.6×10^{-3} min^{-1}. Thus the proposed chromatographic method of studying reaction kinetics gives results in good agreement with those obtained by a method of bulk oxidation.

The method under discussion can be applied not only to binary systems: in the case of multicomponent systems it is possible to select volatile compounds whose retention times would be greatly dependent on the content of individual components in the liquid phase.

---o0o---

In conclusion we may note that the development of pulse gas-chromatographic methods is far from complete. An especially interesting application, it seems to us, is their development for study of the mechanism of liquid-phase reactions and of the effect of the medium on the rates of chemical changes. However, the experience which has now accumulated is sufficient for the wide application of pulse methods in the practical investigation of various liquid-phase reactions.

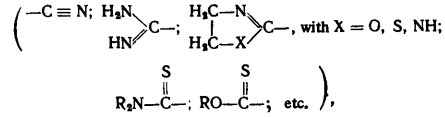
Rearrangements Connected with the Migration of Acyl and Certain Other Groups

L.V.Pavlova and F.Yu.Rachinskii

This review surveys instances of the migration of groups sensitive to nucleophilic attack (structures exhibiting the C=O, C=S, or C= N bonds) between two nucleophilic groups (NH_2, OH, and SH). Intramolecular rearrangements connected with the migration of acyl groups in acylated amino-phenols, amino-alcohols, polyhydric alcohols and phenols, diamines, thioglycols, amino-thiophenols, and amino-thiols are considered. The rearrangements take place by a common mechanism through the stage of formation of unstable cyclic compounds. Apart from the migration of acyl residues, instances of the rearrangements associated with migration of other groups which proceed by an analogous mechanism are surveyed in the article. Such rearrangements



are not only of theoretical interest but are also of great importance for preparative practice.

I. INTRODUCTION

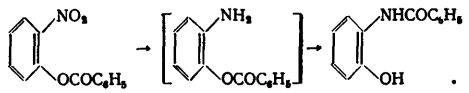
As long ago as the start of the XXth century several investigators observed examples of intramolecular rearrangements connected with the migration of acyl groups from an oxygen atom to a nitrogen atom in acylated amino-phenols; from oxygen at a secondary carbon atom to oxygen at a primary carbon atom in acyl derivatives of polyhydric alcohols, etc. Instances of N ⇌ O and S → N migrations of acyl groups in acylated amino-alcohols and amino-thiols are especially frequent. It was found later that migration between two nucleophilic groups (H_2N, OH, SH) is undergone not just by acyl but also by other groups sensitive to nucleophilic attack.

Such rearrangements are not just of theoretical interest as their mechanism is still not completely clear; they are also of great practical importance. In several instances these rearrangements formed the basis of the development of simple methods of synthesising complicated compounds, particularly *N*-substituted amino-thiols, guanidinoalkanthiols, and other compounds.

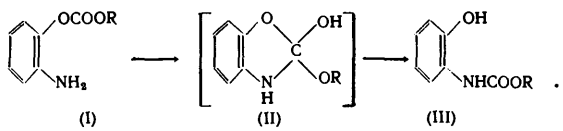
In this connection we thought it desirable to summarise the published data, both our own and those of other authors, assuming that a review of the intramolecular migration of acyl and other groups could prove useful for organic chemists.

II. MIGRATION OF AN ACYL GROUP IN ACYLATED AMINO-PHENOLS AND AMINO-ALCOHOLS

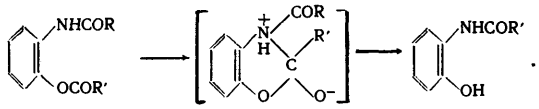
The investigations of Böttcher[1], Einhorn[2], and Auwers[3-5] showed that esters of *o*-amino-phenols and *o*-hydroxybenzylamines are very unstable and immediately after their formation they rearrange into the corresponding amides as a result of the migration of the acyl group from the oxygen atom to the nitrogen atom. Thus, in the reduction of *o*-nitrophenyl benzoate *N*-benzoyl-*o*-aminophenol was obtained as a result of the O → N rearrangement[1,3]:



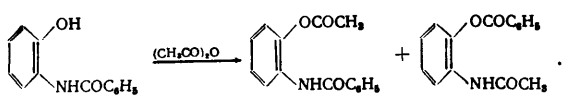
The analogous O → N migration of the alkoxycarbonyl group was observed in an example of the conversion of the *o*-aminophenyl alkyl carbonates (I) into the *o*-hydroxyphenylurethanes (III). The latter are obtained either in the reduction of *o*-nitrophenyl alkyl carbonates[6-8] or when aqueous solutions of the hydrochlorides of *o*-aminophenyl alkyl carbonates are kept for a long time[6-9]. It is suggested[6,8] that the rearrangement of (I) into (III) proceeds through the stage of the formation of an unstable cyclic compound (II):



The migration of acid residues from oxygen to nitrogen also takes place in the partial hydrolysis of *ON*-diacyl derivatives of *o*-amino-phenols[10-14]. Probably here also the rearrangement proceeds through the stage of formation of an intermediate ring[14]:



Moreover, examples are known of intramolecular migrations of acyl groups from a nitrogen atom to an oxygen atom for acylated *N*-alkoxycarbonyls[15-17] and *N*-acyl derivatives[11,18-30] of *o*-amino-phenol. For example, in the acylation of *N*-benzoyl-*o*-aminophenol with acetic anhydride as a result of the N → O migration of acyl groups a mixture of diacyl derivatives was isolated[31]:

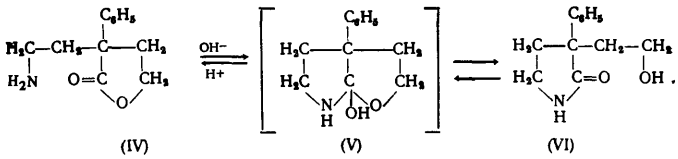


Rearrangements connected with the migration of acyl groups were also observed in a series of derivatives of aliphatic amino-alcohols[32-54]. It was found that in an alkaline medium aminoalkyl benzoates are converted into hydroxyalkylamides[33]:

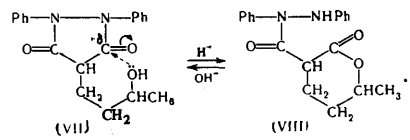
In an acid medium hydroxyalkylamides are in turn converted into *O*-acyl derivatives of amino-alcohols[33-38] as a result of the N → O conversion of the acyl group:

The reversibility of the migration of the acyl group (O ⇌ N) was also observed in the acyl derivatives of 2-amino-1-(naphth-2-yl)ethanol[45], 2-amino-1-phenylpropanol[40], and certain other amino-alcohols[46-54].

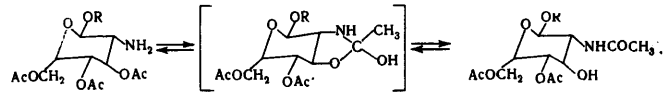
Walton and Green[55] consider that a similar reversible N ⇌ O migration of an acyl group also occurs in the example which they studied of the mutual conversion of 2-(2-aminoethyl)-2-phenyl-γ-butyrolactone (IV) into 3-(2-hydroxyethyl)-3-phenyl-2-pyrrolidone (VI). The authors assume that the formation of the intermediate cyclic compound (V) is possible:



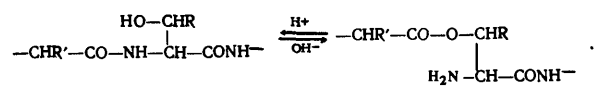
An analogous reversible N ⇌ O rearrangement was observed[56] in the conversion of pyrazolidinediones (VII) into lactones (VIII):



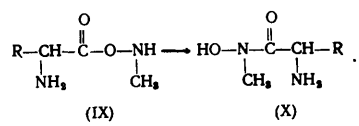
Instances of the N → O and O → N migration of acyl groups were also observed in a series of amino-sugar derivatives[57-63]:



The rearrangements connected with N → O and O → N migrations of the acyl groups were also observed in the residues of serine, threonine, and other amino-acids of proteins[62-85], the usual *N*-peptide bond being converted into an *O*-peptide bond:

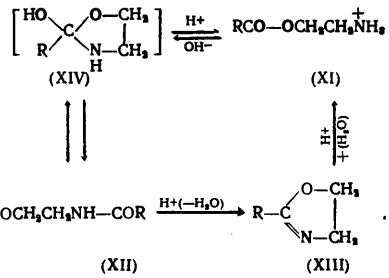


Probably such an O → N migration of an acyl group also occurs in the conversion of the hydrochloride of *O*-(2-aminoacyl)-*N*-methylhydroxylamine (IX) into the corresponding hydroxamic acid (X) when the solution is heated or left to stand for a long time[86]:



Phillips and Baltzly[87] give, as a possible mechanism of the migration of acyl groups, a scheme for the reversible

conversion of aminoalkyl esters (XI) into hydroxyalkylamides (XII):



These authors think that the oxazoline (XIII) is an intermediate in the N → O migration of an acyl group in a strongly acid medium. This is quite probable, since on the one hand oxazolines are formed[88-91] from hydroxyalkylamides (XII) and on the other hand they are readily converted[92-94] into salts of amino-esters (XI) in an acid medium.

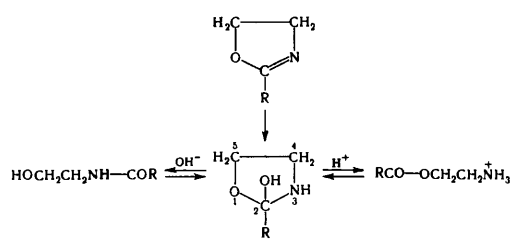
Phillips and Baltzly[87] succeeded in separating and identifying the oxazoline (XIII) in the rearrangement of the hydroxyamide (XII) into the amino-ester (XI). However, they think that the oxazoline (XIII), which is relatively stable in an alkaline medium, cannot be the intermediate cyclic compound in the O → N migration of an acyl group—a process which is observable only in an alkaline medium. This circumstance served as the basis for assuming that in an alkaline medium the change of (XI) into (XII) proceeds through the intermediate hydroxyoxazolidine (XIV) whereas in acid the conversion of (XII) into (XI) proceeds through the oxazoline[35,36,87], which was subsequently confirmed by kinetic studies of Porter and coworkers[95].

These authors found that for partly neutralised solutions of 2-methyloxazoline (XIII; R = CH_3), initially (XIII) is converted into an amino-ester (XI), which is, in turn, gradually converted into the hydroxyamide (XII). If it is assumed that the conversion of *O*-acetylethanolamine (XI; R = CH_3) into an *N*-acetyl derivative (XII; R = CH_3) proceeds through an oxazoline (XI) ⇌ (XIII) ⇌ (XII), then the *O*-acetylethanolamine (XI) can accumulate in the system.

On comparing the rate constants of these conversions it was found that the *N*-acetylethanolamine (XII) is formed more rapidly from the *O*-acetyl derivative (XI) than the latter from the oxazoline (XIII). The results obtained show that (XIII) cannot be an intermediate in the conversion of (XI) into (XII).

Kinetic investigations of similar acyl migrations carried out by other investigators[96-98] showed that the intermediate in both the O → N and the N → O migrations of acyl groups is hydroxyoxazolidine (XIV).

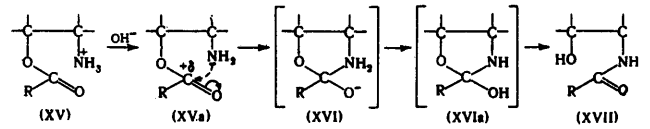
This conclusion agrees with the works of the study of the opening of the oxazoline ring[96,99,100]. Under the action of acid reagents the latter forms an amino-ester, and under the action of alkaline reagents, a hydroxy-amide. Furthermore, the breaking of the oxazoline ring is accompanied by the intermediate formation of a hydroxyoxazolidine, and the hydroxyl group in position 2 can lose a proton with opening of the ring in either the 1–2 or the 2–3 positions:



In an acid medium the bond in the 2–3 position is broken, owing to the C–N bond being more readily polarised than the C–O bond. On the other hand, in neutral or alkaline media the ring is broken in position 1–2 since the C–O bond is then more polarisable.

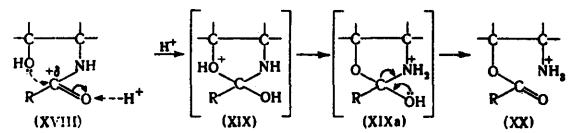
Phillips and Baltzly[87] mainly consider the structure of the intermediate cyclic compounds in reversible N ⇌ O migrations of the acyl groups. This served as a reason for other authors to express their hypotheses about possible mechanisms of such migrations.

Welsh[101,102] and Fodor and Kiss[103] consider that for the O → N migration of acyl groups the mechanism of the rearrangement can be represented by the scheme:



On the carbon atom of the carbonyl group of the amino-ester (XV) there is a certain positive charge as a result of the displacement of the electron cloud in the direction towards the oxygen atom of the carbonyl group, which exhibits a great affinity for the electron. Under the influence of hydroxyl ions (an alkaline medium) the salt of the amino-ester is converted into a base and the unshared electron pair of the nitrogen atom attacks the electron deficient carbonyl group, as a result of which a cyclic intermediate compound (XVI) is formed. The migration of a proton from nitrogen to the carbonyl oxygen gives structure (XVIa), in which as a result of alkaline hydrolysis the ester bond is broken and the hydroxyamide (XVII) is formed.

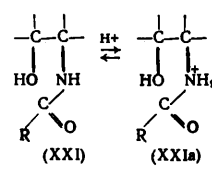
For the N → O migration of an acyl group the mechanism of the rearrangement can, according to Welsh[101,102], be represented by the scheme:



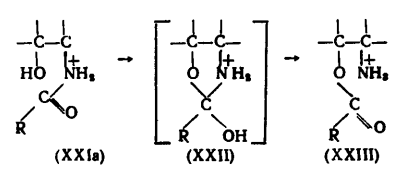
According to this scheme a proton is added to the carbonyl oxygen of compound (XVIII) and the intermediate unstable cyclic compounds (XIX) and (XIXa) are formed owing to interaction of the protonated carbonyl group with the alcoholic hydroxyl.

An analogous mechanism was almost simultaneously advanced to explain the migration of acyl groups in the formation of a mixture of *NO*-diacyl derivatives of *o*-aminophenol[31].

A somewhat different mechanism for the N → O migration of acyl groups, according to which the movement of the acyl groups takes place in two stages, was proposed by Fodor and Kiss[104]:



(1)



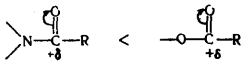
(2)

The first stage is the formation in a strongly acidic medium of the unstable salt of an *N*-acylamide (XXIa). The second stage is the formation of an intermediate cyclic compound (XXII), which then is stabilised by the breaking of the C–N bond owing to its greater polarisability in an acid medium with formation of a salt of an *O*-acylhydroxyamine (XXIII).

Starting from the above ideas on the possible mechanism of the N → O migration of acyl groups, it can be concluded that the rate of this rearrangement should increase with the hydrogen ion concentration. This was confirmed experimentally by Fodor and Kiss[105].

The influence of the pH of the medium on the degree of the O → N migration of an acyl group was also studied. It appeared that the degree of conversion of *O*-acyl derivatives of amino-alcohols into *N*-acyl derivatives increases with the pH of the medium[87,95,101,102,106]. For example, the conversion of 2-aminoethyl benzoate into an amide is complete at pH ~ 10; at pH 8 the degree of conversion reaches 20%, whereas at pH ≤ 7.5 the formation of the amide is hardly observed. A study of the reaction kinetics of the conversion of *O*-acetylethanolamine into the corresponding amide confirmed that with increase in the pH of the medium the rate of the rearrangement also increases[95].

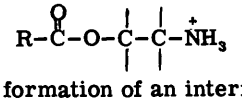
A noteworthy feature is that the N → O migration of an acyl group takes place only partly and at a low rate, whereas the O → N migration is instantaneous and almost quantitative[87,107,108]. This is evidently connected with the difference in the electronegativities of nitrogen and oxygen. As the electronegativity of nitrogen is less than that of oxygen the positive charge (+δ) on the carbon atom of the carbonyl group bonded with a nitrogen atom will be less than for a carbonyl group bonded with an oxygen atom:



This can probably explain why the rate of formation of an intermediate cyclic compound during the rearrangement of an *O*-acyl derivative of an amino-alcohol is greater than for the rearrangement of an *N*-acyl derivative.

Taking into account that the approach of a proton to oxygen or of a hydroxide ion to a carbonyl-carbon increases the electron displacement, it could be expected that the N → O and O → N migrations of an acyl group in acylated amino-alcohols will take place in both acid and alkaline media. However, the experimental results show that O → N migration takes place only in an alkaline medium and the N → O migration in acid, which agrees with the above mechanism of O ⇌ N migration[88,98,101–105], which assumes the formation of an intermediate cyclic compound.

The migration of an acyl group from oxygen to nitrogen in acylated amino-alcohols takes place only in an alkaline medium, since in an acid medium the amino-group exists in the form of the ammonium ion:



and therefore the formation of an intermediate ring is impossible.

With an *N*-acyl derivative of an amino-alcohol the N → O migration in an alkaline medium cannot proceed, since under these conditions the free electron pair of the nitrogen atom probably removes the positive charge on the carbon atom of the carbonyl group, making impossible the formation of an intermediate cyclic compound. This explains the stability of the hydroxyamides in an alkaline medium and of the amino-esters in acid.

The formation of an intermediate ring in N ⇌ O rearrangements is confirmed also by experimental results on the effect on this process of the mutual arrangement of the hydroxy- and amino-groups in the acylated amino-alcohols. Thus, N → O migration of an acetyl group is observed in the benzoylation of *o*-*N*-acetylaminophenol but is not observed for the *p*-isomer[29]; O → N migrations of the acyl group in acylated amino-alcohols of the general formula $RCOO[CH_2]_nNH_2$ only take place when $n = 2$ or 3, that is, under conditions when the closing of five- or six-membered rings is possible[33].

The migration of an acyl group in acyl derivatives of 1,2-amino-alcohols is also considerably affected by substituents at the carbon atoms[103,106–120].

For the acyl derivatives of the amino-alcohols $H_2N–CHR–CHR'–OH$, where R = R' = H, the free rotation around a C–C bond is not reflected on the acyl migration, but on introducing substituents which restrict free rotation the migration is naturally hindered and made more complicated.

In the acylated diastereoisomers of 1,2-amino-alcohols (*cis*- and *threo*-, *trans*- and *erythro*-) one observes the same rate of migration of acyl groups. As might have been expected, the similarity in the position of the functional groups (NH_2 and OH) should facilitate the formation of an intermediate ring, and consequently, a more rapid migration of acyl groups, which found confirmation in a series of studies[106–120].

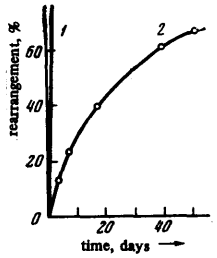


Figure 1. Rate of N → O rearrangement in 0.115 *N* alcoholic HCl solution:
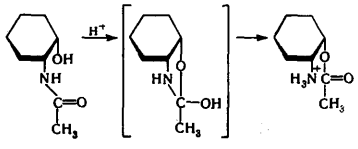
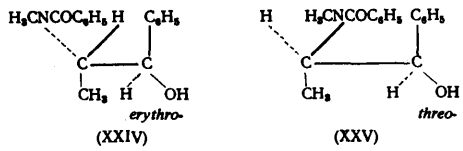
1) *N*-benzoyl-ψ-ephedrine; *2*) *N*-benzoylephedrine.

For example, the rate of N → O migration of an acyl group in the *cis*- and *trans*-forms of *dl*-acetamidocyclohexanol are different; the *cis*-form rearranges 5–6 times more rapidly than the *trans*-form[114]:



It was also shown that the rate of the N → O migration of the benzoyl group in *N*-benzoylephedrine (XXIV) and *N*-benzoyl-ψ-ephedrine (XXV) differ considerably under the same conditions[101,107], as Fig. 1 shows.



The examples given above show that unlike the rapid migration of acyl groups in acylated 1,2-amino-alcohols having *cis*- and *threo*-forms in the analogous compounds of *trans*- and *erythro*-forms the rearrangement is extremely slow[111-116] and is accelerated only on raising the temperature[104,105]. Thus, the *N*-benzoyl derivative of *trans*-aminocyclohexanol undergoes hardly any rearrangement at room temperature, whereas in a sealed tube at 100°C an *O*-benzoyl derivative is formed in 48–50% yield after 2 h.

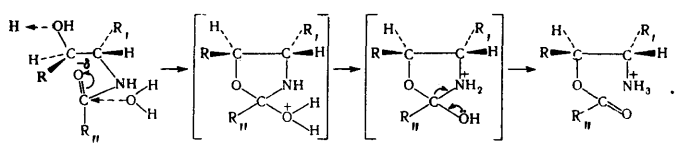
By making use of the difference in the rate of migration of acyl groups in diastereoisomers, the configuration of amino-alcohols can be established[101-116,121-126].

To separate the stereoisomers, Fodor proposed[110,111,115] to treat a mixture of the *N*-acyl derivatives of *threo*- and *erythro*-forms of amino-alcohols with hydrochloric acid at room temperature. Here the *N*-derivatives of the *threo*-forms are rapidly and almost quantitatively rearranged into *O*-derivatives as a result of the N → O migration of acyl groups, whereas the *N*-derivatives of the *erythro*-forms are unchanged under these conditions. The *O*-acyl derivatives of the *threo*-forms which are produced are readily soluble in aqueous hydrochloric acid and hence are easily separated from the *N*-acyl derivatives of the *erythro*-forms.

Fodor also noted[110] that the prolonged holding of *N*-benzoylephedrine (*erythro*-form) in alcoholic HCl brings about its partial conversion into *O*-benzoyl-ψ-ephedrine (*threo*-form). An analogous change in the configuration as a result of the migration of acyl groups was also observed by Welsh[101,102] on treating *N*-acyl-ψ-ephedrine with hot alcoholic HCl; only *O*-acyl-ψ-ephedrine is obtained, whereas the products of the acyl migration of *N*-acetylephedrine are the *O*-acetylephedrine and a large proportion of *O*-acetyl-ψ-ephedrine. It appears that the migration of an acyl group can proceed in two directions: with retention of the configuration of the amino-alcohol (*R*-mechanism) and with change in configuration (*I*-mechanism).

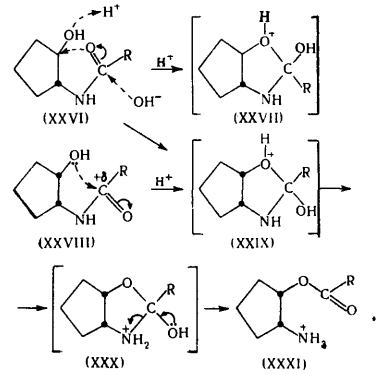
The migration of an acyl group (N → O) in acylated 1,2-amino-alcohols with a linear structure usually proceeds with retention of the configuration[103,104,109,114,115] and only in exceptional instances and severe experimental conditions is the rearrangement accompanied by a change in configuration[101,102,105,110,113,114].

The *I* mechanism of the rearrangement can be represented by the scheme[101,102]:



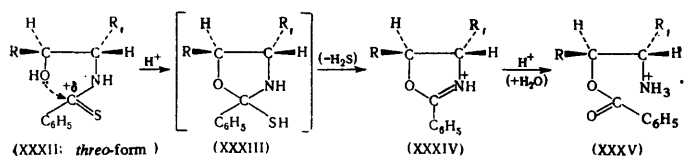
According to this scheme complete inversion at the carbon takes place as a result of the approach of the carbonyl oxygen to the asymmetric carbon atom simultaneously with the attack by the proton at the hydroxyl oxygen.

The migration of an acyl group (N → O) with inversion is observed also in a series of acylated alicyclic amino-alcohols[121]. Thus under the action of hydrogen chloride *cis*-*N*-acetylated amino-alcohols are converted into *cis*-*O*-acetyl derivatives, whereas the *trans*-derivatives are not rearranged under these conditions. However, under severe conditions (boiling, long treatment with HCl) *trans*-*N*-acetyl derivatives are converted into *cis*-*O*-acetyl derivatives, but the rearrangement is accompanied by a change in configuration:



In the *cis*-isomer (XXVIII) the N → O migration of an acyl group takes place readily, since the intermediate compound (XXIX) is formed without strain. In the *trans*-isomer (XXVI) rearrangement with retention of configuration is prevented by steric factors. The intermediate compound (XXVII) is structurally strained and is obtained from the amide of the *trans*-isomer (XXVI) with great difficulty, therefore the migration of an acyl group leading to the *trans*-ester is very difficult. Although in compound (XXVI) in the N → O migration of an acyl group the removal of a hydroxyl after the scheme of the *I* mechanism requires more severe conditions the formation of the intermediate compound (XXIX) may be more rapid than that of (XXVII).

As confirmation of the proposed mechanisms of N → O migration of an acyl group both with retention of the configuration and with inversion there is the work on the replacement of an acyl group by a thioacyl[127]. For the *threo*-epimers of *N*-thiobenzoyl derivatives of amino-alcohols studied by Farkaš and Sicher[127] the replacement of the acyl group as might have been expected, proceeds by the *R* mechanism:

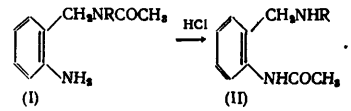


2-Mercapto-2-phenyloxazolidine (XXXIII) is formed as the intermediate cyclic compound and is stabilised in the form of 2-phenyloxazoline (XXXIV) which is readily converted in an acid medium into an amino-ester salt (XXXV). Therefore on heating with alcoholic HCl the *N*-thiobenzoyl derivatives of *threo*-isomers of 1,2-amino-alcohols were isolated as the hydrochlorides of amino-esters; the formation of aminothioesters was not observed.

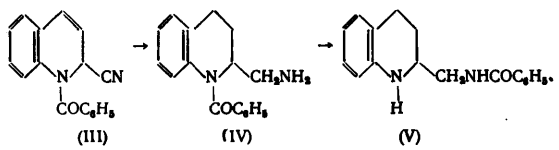
As already reported for *erythro*-epimers N → O migration of acyl groups can take place by either an *R* mechanism or with inversion (*I* mechanism). It is known[88,101,102,128,129] that the *I* mechanism presumes nucleophilic attack of the oxygen atom of the carbonyl group at the β-carbon atom. Since sulphur is more nucleophilic than oxygen the replacement of an acyl group by thioacyl should facilitate for *erythro*-epimers the reaction by an *I* mechanism, which was also confirmed in the study by Farkaš and Sicher[127].

III. MIGRATION OF AN ACYL GROUP IN ACYLATED DIAMINES

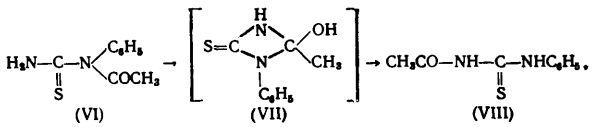
At the end of the last century Widman[130] noted that the 2-acetamidomethylaniline (I) is converted into 2'-(aminomethyl)acetanilide (II) on treatment with hydrochloric acid:



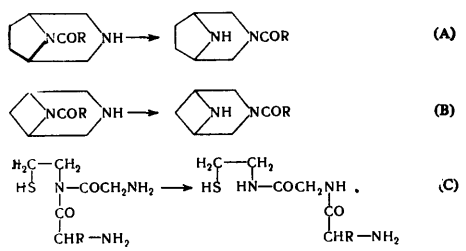
The analogous N → N' migration of the acyl group was also observed in the reduction of 1-benzoyl-2-cyano-1,2-dihydroquinoline (III). As a result of the reaction 2-(benzamidomethyl)tetrahydroquinoline (V) was isolated. The authors[131-133] suggested that initially 2-aminomethyl-1-benzoyltetrahydroquinoline (IV) is formed, which then undergoes rearrangement accompanied by the N → N' migration of an acyl group:



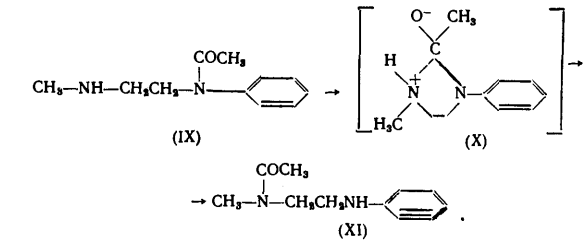
The rearrangement described by Wheeler[134] of the unsymmetrical *N*-acyl derivatives of thiourea (VI) in isomeric symmetrical derivatives (VIII) is also probably connected with the N → N' migration of acyl groups taking place through the stage of formation of an intermediate unstable ring (VII):



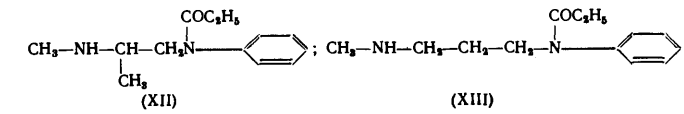
Subsequently an example of the N → N' migration of acyl groups was observed in the derivatives of ethylenediamine[135], triazines[136], aminoalkylanilines[137], 3,8-diazabicyclo[3,2,1]octane (A),[138] 3,9-diaza-bicyclo[3,3,1]nonane (B),[139] and also *N*-aminoacylated amino-thiols (C):[140-142]



It was suggested[137-142] that the N → N' migration of acyl groups proceeds by a mechanism similar to the analogous N → O migration in acylated amino-alcohols. Thus *N*-(2-anilinoethyl)-*N*-methylacetamide (XI) was isolated from the distillation of *N*-(2-methylaminoethyl)acetanilide (IX). In the opinion of Wright and coworkers[137] (XI) is obtained as a result of the intramolecular rearrangement of (IX), which passes through the stage of formation of the unstable intermediate five-membered ring (X):



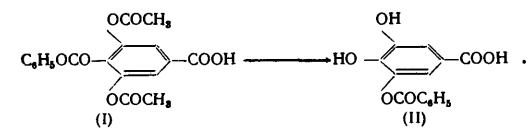
As was shown[137], the rate of rearrangement depends on the structure of the initial compounds, which confirms the mechanism of the N → N' migration through a stage of formation of an intermediate ring. Compound (IX), which contains two methylene groups between nitrogen atoms, rearranges readily on distillation (90–130°C). *N*-(2-Methylaminopropyl)propioanilide (XII) is more stable and on distillation is rearranged to only a slight extent, but the rate of rearrangement is considerably increased at 175–185°C. This fact can probably be explained by steric hindrance in the formation of an intermediate ring. *N*-(3-Methylaminopropyl)propionanilide (XIII), in which the N → N' migration of an acyl group should take place through the stage of formation of an intermediate six-membered ring, is fairly stable and is only partly rearranged at temperatures > 200°C:



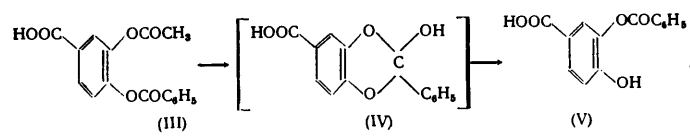
IV. MIGRATION OF AN ACYL GROUP IN ACYLATED POLYHYDRIC ALCOHOLS AND PHENOLS

The migration of acyl groups has also been noted in a series of acylated polyhydric phenols and alcohols.

Thus, in the hydrolysis of 3,5-diacetyl-4-benzoylgallic acid (I), both in acid and in aqueous solutions of weak bases, 3-benzoylgallic acid (II) is formed[143]:

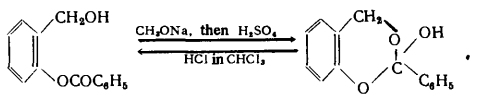


In the treatment of 3-acetyl-4-benzoylprotocatechuic acid (III) with bases or acids, 3-benzoylprotocatechuic acid (V) was isolated[144]. Fischer[144] thinks that this O → O' migration of an acyl group proceeds through the intermediate cyclic compound (IV):



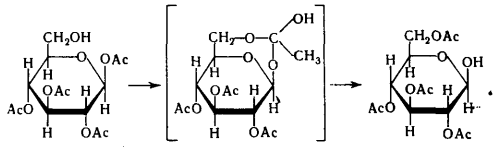
The possibility of the existence of an intermediate cyclic compound of type (IV) was shown by Helferich and Liesen[145]

by the example of 2-benzoyloxybenzyl alcohol (benzoylsaligenin), which was isolated in two desmotropic forms—open (VI) and cyclic (VII), capable of mutual interconversion:



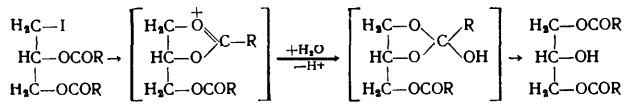
(VI) (VII)

The migration of acid residues (O → O′) is also observed for acyl derivatives of glucose[146-154]. In the given example the rearrangement proceeds through the stage of formation of an intermediate ring[152-154]:



A similar O → O′ rearrangement of acyl groups was observed in the preparation of mixed esters of glycerol[155] and in the saponification of triglycerides[156]. For example, in the action of silver nitrite on alcoholic solutions of αβ-di-(*p*-nitrobenzoyl)-α′-iodohydrin or αβ-distearyl-α′-iodohydrin with the aim of obtaining diesters of glycerol containing a free alcoholic group in the α′-position αα′-di-(*p*-nitrobenzoyl)- and αα′-distearyl-glycerols with a free hydroxyl group in the β position were isolated.

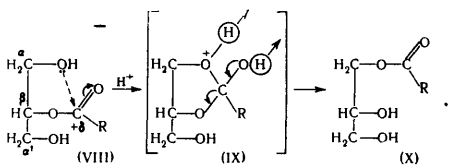
In these instances, according to Winstein and Buckles[157] migration of an acyl group also proceeds through intermediate cyclic compounds:



where R = *p*-$NO_2C_6H_4$, $C_{17}H_{35}$.

According to Fischer[143,144,155], the mechanism of migration of acyl groups in polyhydric alcohols is connected with the intramolecular interaction of and OH groups with the formation of an intermediate cyclic compound, which then opens with the migration of a hydrogen atom.

The mechanism of the O → O′ migration of acyl groups in polyhydric alcohols was considered in greater detail by Doerschuk[158], who proposed the following scheme:



(VIII) (IX) (X)

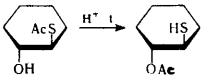
For the carbonyl group the partial shift of an electron pair to the side of the more electronegative oxygen atom and the consequent appearance of some positive charge on the carbon atom of the carbonyl group is characteristic. The electron pair of the oxygen atom of the hydroxyl group attacks the electron deficient carbonyl group (VIII); during this an intermediate cyclic compound (IX) is formed which is cleaved at the C–O bond in the β-position owing to its easier polarisability, forming (X).

On assuming such a mechanism for the O → O′ migration of an acyl group the rate of rearrangement should be influenced by the degree of polarisation of the carbonyl group and consequently also the magnitude of the positive charge on the carbonyl carbon, which is due to the influence of the pH of the medium and the nature of the acyl group. In experiment this in fact was confirmed[159,160]. For example, glyceryl β-monopalmitate in alcoholic 0.5 *N* HCl at room temperature is completely converted into the α-isomer in 24 h, whereas in more dilute solutions (0.005 *N*) rearrangement does not take place[159]. The benzoyl group migrates slowly[158] or not at all[160] owing to the effect of conjugation, leading to some filling of the electron deficiency on the carbonyl carbon. On the other hand, the rearrangement proceeds rapidly for the acetyl group. This is especially noticeable for the example of the β-trichloroacetyl group with a clearly expressed positive charge on the carbonyl-carbon[156].

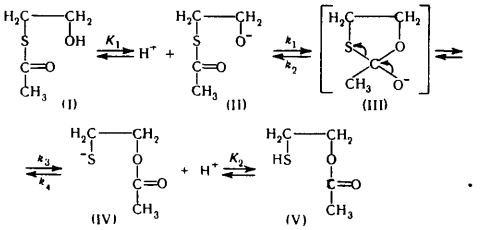
Proof of the intramolecular mechanism of the O → O′ migration of the acyl group was given by the results[158] on the rearrangement of glyceryl β-monopalmitate in an acid medium in the presence of labelled 1-^{14}C glycerol. As a result of this reaction α-monopalmitate free from ^{14}C was isolated.

V. MIGRATION OF AN ACYL GROUP IN ACYLATED THIOGLYCOLS AND THIOGLYCEROLS

In thioglycols[161-166] and thioglycerols[167] the S → O migration of an acyl group is observed in neutral and alkaline media, and under severe conditions also in an acid medium[168]. For example, on long heating in an acid medium *trans*-2-acetylthiocyclohexanol is converted into *trans*-O-acetyl-2-thiocyclohexanol:



As a result of Martin and Hedrick's investigations[166] it is suggested that the S → O migration of acyl groups can be represented by the scheme:



(I) (II) (III) (IV) (V)

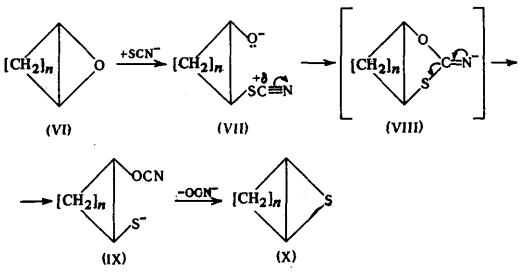
where K_1 and K_2 are the acid ionisation constants and k_1–k_4 the rate constants for cyclisation and breaking of the C–O and C–S bonds respectively.

As for the acyl derivatives of amino-alcohols[87,97,98] and polyhydric alcohols[155,157] the migration of acyl groups in acylated thioglycols proceeds through the formation of an unstable intermediate cyclic compound (III) which is opened at the site of the most easily polarisable bond, depending on the pH. It has been shown that the migration of an acyl group from sulphur to oxygen takes place only in neutral or alkaline media; the reversible O → S migration was not observed here. According to Martin[166], the stage of cyclisation precedes the ionisation of acyl derivatives of thioglycols with the formation of a thiolate ion (IV) or an alkoxide ion (II), which naturally is possible in alkaline or neutral media. The formation of a cyclic intermediate compound (III), as for O ⇌ N, N → N′, O → O′ migrations is also connected with the intramolecular interaction of a carbonyl carbon with a hydroxyl oxygen, in the example of (II), or with sulphur—for (IV). Since nucleophilic properties are

expressed more strongly by sulphur than by oxygen the formation of intermediate ring (III) from the thiolate ion (IV) should be faster than the formation of (III) from (II), which is confirmed by the ratio of the rates of these reactions ($k_1/k_4 = 1/20$). However, a study of reaction rates showed that the ratio $k_2/k_3 \simeq 10^{-10}$, that is, the rate of opening of ring (III) with the formation of the S-acyl derivative (I) is so low that the process proceeds in the main with the formation of the *O*-acyl derivative (V).

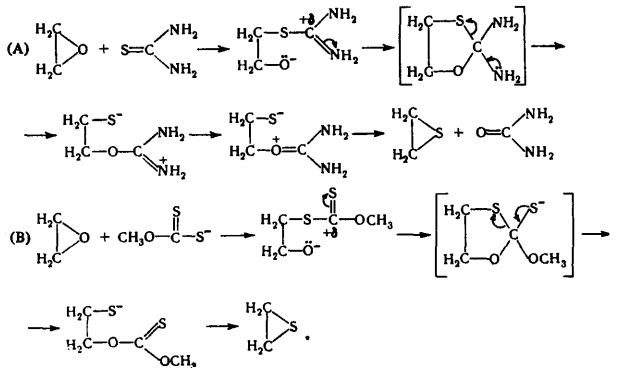
The migration of an acyl group was also studied in the $CH_3COS[CH_2]_nOH$ series where $n = 2, 3, 4$. As might be expected, in accordance with the assumption concerning the formation of an intermediate cyclic compound, the migration of acyl groups takes place rapidly for $n = 2$, more slowly for $n = 3$, and hardly at all at $n = 4$. It was found that the rate of the S → O migration in *S*-acetylmercaptoethanol is approximately 30 times as great as the rate of the analogous change in propyl compounds[165].

Intramolecular rearrangements can occur as a result of the S → O migration not only of acyl[161-166] but also of other groups. Thus the formation of alkylene sulphides (X) in the reaction of alkylene oxides (VI) with thiocyanates[163,169-173] is connected with the migration of CN groups from the sulphur atom to the oxygen atom:



The intermediate cyclic compound (VIII) was isolated[172] as a *p*-nitrobenzoyl derivative.

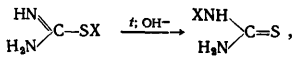
The formation of alkylene sulphides in the interaction of alkylene oxides with thiourea[169,174] or with methyl xanthates[174] must be considered as a reaction in which there is an S → O migration of amidine (A) or thiomethoxycarbonyl (B) groups:



VI. MIGRATION OF AN ACYL GROUP IN ACYLATED AMINO-THIOPHENOLS AND AMINO-THIOLS

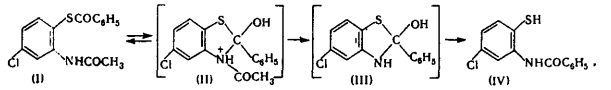
Rearrangements which are accompanied by the migration of acyl groups from a sulphur atom to a nitrogen atom were first observed for *S*-acyl derivatives of thiourea[175-178] and diacyl derivatives of *o*-amino-thiophenols[179].

It was noted that *S*-acyl[175-177] and *S*-alkoxycarbonyl derivatives[178] of thiourea are converted into the corresponding *N*-derivatives of thiourea on heating or basification:



where X = COR or COOR.

In the alkaline hydrolysis of 2-acetamido-4-chlorophenylthiobenzoate (I) 2-benzoylamino-4-chlorothiophenol (IV) was isolated and characterised. By analogy with the acyl migration in acylated amino-phenols[14] it can be assumed that here an S → N migration is accompanied by the formation of intermediate unstable cyclic compounds (II) and (III):



An analogous S → N migration of acyl groups in a series of aliphatic compounds containing sulphur and nitrogen, leading to *N*-substituted amino-alkanethiols was first reported by Baddiley and Thain[180] in 1951 by the example of *S*-acetylmercaptoethylamine; the latter gradually forms a thiol in aqueous solution. A freshly prepared solution of *S*-acetyl-2-mercaptoethylamine shows initially a negative reaction for the SH group but after as little as 5 min the proportion of SH groups becomes appreciable.

The formation of thiol can here be assumed to be the result of the following processes.

(a) Hydrolysis of the *S*-acyl derivative with the formation of an amino-thiol and an acid:

$$CH_3COSCH_2CH_2NH_2 + H_2O \rightarrow CH_3COOH + HSCH_2CH_2NH_2.$$

(b) Migration of the acyl group from the sulphur atom to the nitrogen atom, that is, as a result of "reacylation":

$$CH_3COSCH_2CH_2NH_2 \rightarrow HSCH_2CH_2NHCOCH_3.$$

Subsequent investigations cast light on the mechanism of conversion of an *S*-acyl derivative of 2-mercaptoethylamine.

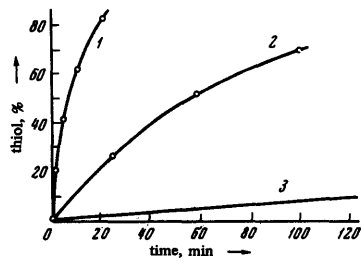


Figure 2. Rate of conversion of S-acetyl-2-mercaptoethylamine into a thiol as a function of the pH of the solution: *1*) pH 5; *2*) pH 4; *3*) 1 *N* HCl.

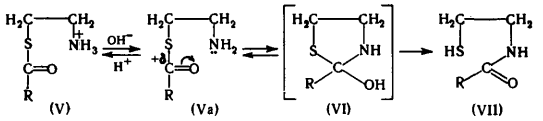
Wieland and Bokelmann[181] found that *S*-acetyl-2-mercaptoethylamine is extremely stable in 2 *N* HCl, and the formation of free thiol is not observed under these conditions. With decrease in the acidity of the solution (pH ≃ 4) the reaction at the SH group becomes positive and a gradual rise in thiol concentration is observed (Fig. 2). The main products of the conversion of *S*-acetyl-2-mercaptoethylamine in neutral and weakly acidic media were

N-acetyl-2-mercaptoethylamine and 2-methylthiazoline-Δ^2; 2-mercaptoethylamine, a possible hydrolysis product, was not observed even by a chromatographic method[181].

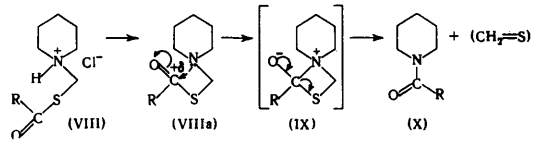
Experimental results[180-182] and kinetic studies[98,166,183,184] suggest that the conversion of *S*-acyl derivatives of amino-thiols (V) in neutral and weakly alkaline media proceeds as a result of an intramolecular S → N migration of an acyl group through the stage of formation of an intermediate cyclic compound (VI) according to the scheme:



(V) (Va) (VI) (VII)

In strongly acid media where the concentration of free amino-groups is insignificant owing to the formation of ammonium ions (V), the rate of this conversion should be low. With increase in pH the concentration of free amino-groups increases (Va), and consequently there is an increase in the rate of "reacylation".

The formation of an intermediate cyclic compound of the type of (VI) found confirmation in the studies of Smissman and Sorenson[185] and others[186]. Thus on distilling the free base 1-piperidinomethyl thioacetate (VIIIa), 1-acetylpiperidine (X) was obtained. The mechanism of this transformation can be represented as follows:



(VIII) (VIIIa) (IX) (X)

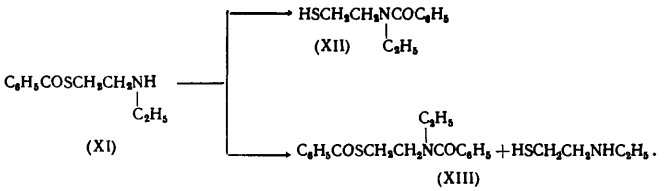
An investigation of the rate of "reacylation" of *S*-acetyl-2-mercaptoethylamine showed that at pH 4 and 5 the reaction is unimolecular[181] but at pH > 5 it becomes bimolecular[98,183,184]. However, it is difficult to explain such a marked change in the order of reaction for so slight a change in pH.

As well as the pH of the medium, the nature of the acyl group at the sulphur atom also affects the rate of migration of the acyl groups in amino-thiols, also in both the O → O′ and the O → N migrations. For example, *S*-benzoyl-2-mercaptoethylamine is converted into the thiol at one-tenth the rate of the conversion of the *S*-acetyl derivative[181].

Since the migration of acyl groups proceeds through the formation of an intermediate cyclic compound, it is quite natural for rearrangement to occur only for amino-thiols containing a primary or secondary amino-group. Compounds which contain a tertiary amino-group do not rearrange and in aqueous solution can only be hydrolysed with the formation of a free thiol. Thus *S*-acetyl-2-dimethylaminoethyl mercaptan undergoes partial hydrolysis at pH 7–8 and in 1 h forms ~ 17% SH groups titratable by iodine as a result of this[181].

In studying the migration of acyl groups in *S*-acetyl derivatives of amino-alkanethiols of general formula $CH_3COS[CH_2]_nNH_2$ (with $n = 3$, 4, 6, or 10), it was found that at pH ~ 7.0 apart from *S*-acetyl-2-mercaptoethylamine ($n = 2$), only *S*-acetyl-3-mercaptopropylamine ($n = 3$) is rearranged at a measurable rate[182]. On comparing the rate of reacylation of the β- and γ-*S*-acetyl derivatives of amino-thiols the γ derivative is rearranged at one-hundredth the rate of the β-substituted derivative. This agrees with the finding that the formation of an intermediate five-membered cyclic compound from the *S*-acetyl-2-mercaptoethylamine ($n = 2$) takes place 70 times more rapidly than the formation of the corresponding six-membered ring from *S*-acetyl-3-mercaptopropylamine[183]. The higher homologues of *S*-acetyl-ω-aminoalkanethiols ($n = 4$, 6, 10) cannot undergo rearrangement and their deacylation is possible only as a result of hydrolysis, the rate of which increases with the pH[182].

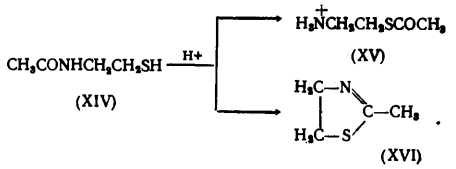
Certain other instances of S → N migration of acyl groups are also known. Thus in an attempt to isolate the free base of 2-ethylaminoethyl thiobenzoate (XI) from its hydrobromide, Stirling[187] obtained a product of S → N migration—*N*-benzoyl-2-ethylaminoethanethiol (XII); in addition to that an *NS*-dibenzoyl derivative (XIII) was also isolated from the reaction products; its formation can be explained by the reaction of the amido-thiol (XII), obtained as a result of S → N rearrangement, with the amino-ester (XI):



(XI) (XII) (XIII)

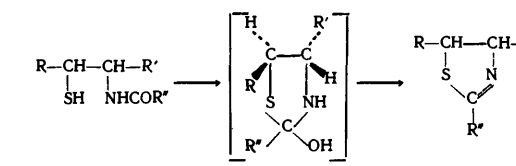
Rearrangements associated with the S → N migration of acyl and alkoxycarbonyl groups was also observed for *S*-derivatives of cysteine[188,189], peptides[190], ephedrine[191], and 2-mercaptoethylamine and acylated amino-acids[140-142,192,193].

It must be pointed out that very little information has been published on the N → S migration of acyl groups in an acid medium. Martin and coworkers[183] found that *N*-acetyl-2-mercaptoethylamine (XIV) in an acid medium forms mainly 2-methylthiazoline-Δ^2 (XVI), together with a little *S*-acetyl-2-mercaptoethylamine (XV), which was identified only spectrophotometrically:

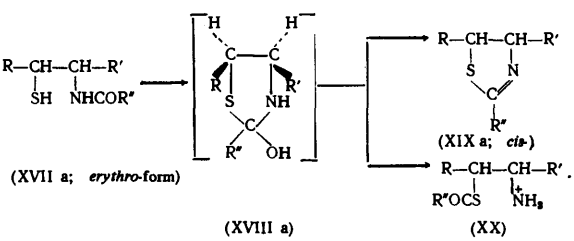


(XIV) (XV) (XVI)

An instance of N → S migration of an acyl group in an acid medium was also observed by Sicher and Svoboda[194,195] in studying the cyclisation of epimers of *N*-acyl derivatives of acyclic 1,2-amino-thiols (*threo*- and *erythro*-forms). The first stage of reaction for both epimers (XVII, XVIIa) is the formation of an unstable 2-hydroxythiazolidine intermediate derivative (XVIII, XVIIIa):



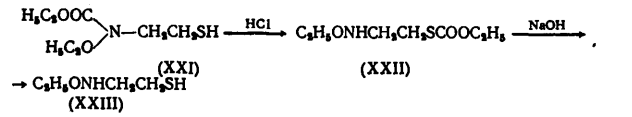
(XVII; *threo*-form) (XVIII) (XIX; *trans*-)



(XVII a; *erythro*-form) (XVIII a) (XIX a; *cis*-) (XX)

For the *threo*-epimer (XVII) the intermediate ring (XVIII) in an acid medium is converted exclusively into Δ^2-thiazoline derivative (XIX), where the substituents R and R' at the carbon atoms are in the *trans*-position, that is, the formation of (XIX) does not lead to approach of the substituents. For the *erythro*-epimer (XVIIa) the product of the N → S migration of the acyl group is formed–*S*-acylaminoalkanethiol (XX), since the formation of (XVIIIa) from (XVIIa) leads to the approach of the substituents R and R', and the thiazoline ring (XIXa) is structurally strained. As a result of this there is opening of the hydroxythiazolidine intermediate ring (XVIIIa) at the C–N bond, and the acyl group migrates from the nitrogen atom to the sulphur atom.

An example of an N → S migration of an ethoxycarbonyl group has also been described[196]. In the treatment of 2-(*N*-ethoxy-*N*-ethoxycarbonylamino)ethyl mercaptan (XXI) with dilute hydrochloric acid the formation of the thiol carbonate (XXII) was observed; this was then converted by alkaline hydrolysis into the thiol (XXIII):



From what has been said above it follows that the migration of acyl groups in acylated amino-alcohols and amino-thiols proceeds by a similar mechanism. In the first stage of the process, whether in acid or in alkaline media, an intermediate unstable cyclic compound (hydroxyoxazolidine) for amino-alcohols and hydroxythiazolidine for amino-thiols) is formed. In the second stage this intermediate cyclic compound is converted, depending on the pH of the medium, into various final products.

A comparative study of the rate of migration of acyl groups in acylated derivatives of amino-alcohols and amino-thiols showed that the rate of the S → N migration is greater than that of the O → N migration[97]. Moreover it is known that the formation of a hydroxyoxazolidine as an intermediate compound in the rearrangement of *O*-acyl derivatives of amino-alcohols takes place 140 times more rapidly than the formation of hydroxythiazolidine from amino-thiols[97].

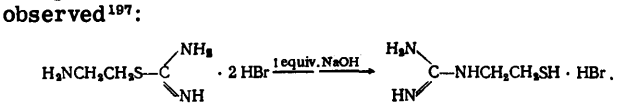
This is probably influenced by the fact that a positive charge on the carbon atom of the carbonyl group connected with the oxygen atom is greater than that at the carbon atom of a carbonyl group connected with a sulphur atom.

It can be suggested that owing to this effect the rate of O → N migration should be greater than the rate of S → N migration. But since the subsequent opening of the hydroxythiazolidine ring in an alkaline medium, leading to the formation of an *N*-acyl derivative of the amino-thiol takes place much more rapidly than the opening of the hydroxyoxazolidine[97], in the end the rate of the S → N rearrangement is greater.

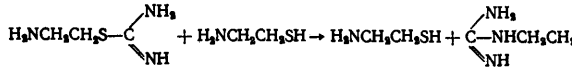
VII. REARRANGEMENT OF AMINOALKYL DERIVATIVES OF ISOTHIOUREA AND ISOSELENOUREA

Rearrangements similar to the S → N migration of acyl groups in acylated amino-thiols are also observed in a series of aminoalkyl substituted isothioureas[197–204].

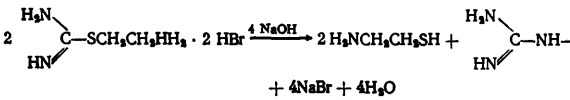
Thus during the neutralisation of an aqueous solution of a salt of *S*-2-aminoethylisothiourea with one equivalent of alkali (pH ≃ 7.0) the formation of 2-mercaptoethylguanidine is observed[197]:



Initially attempts were made to explain the mechanism of such a conversion by the known reactions for the aminolysis of *S*-substituted thioureas, leading to the formation of guanidine derivatives[205,206]:



But here the aminolysis should precede the hydrolytic splitting of the C–S bond in 2-aminoethylisothiourea with the formation of 2-mercaptoethylamine; this is possible only at pH > 10 and elevated temperature:

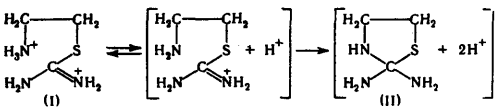


In studying the stability of aqueous solutions of *S*-2-aminoethylisothiourea at various pH, Khym and coworkers[199] found that this compound does not change at room temperature in 0.2 *N* HCl in 14 days. At pH ≃ 3.5, *S*-2-aminoethylisothiourea in aqueous solution is completely converted into 2-aminothiazoline and an ammonium salt after four days. At somewhat higher pH (~ 4.5) in addition to 2-aminothiazoline, 2-mercaptoethylguanidine is also observed. In neutral or weakly alkaline medium this isothiuronium compound is instantaneously and completely converted into 2-mercaptoethylguanidine. In a strongly alkaline medium the reaction for the formation of a guanidine derivative competes with the reaction for the formation of 2-mercaptoethylamine as a result of the hydrolytic splitting of the isothiuronium salt, and consequently both 2-mercaptoethylguanidine and 2-mercaptoethylamine are observed in the solution together.

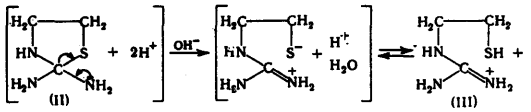
The above authors gave the name "transguanidation" to the conversion of the isothiouronium compounds into guanidine and thiazoline derivatives[199], as it is a special case of intramolecular S → N rearrangement.

The mechanism of this rearrangement is explained as follows: *S*-2-aminoethyl isothiourea (I) can exist in an unstable cyclic form (II) which is produced as a result of nucleophilic attack by the β-amino-group on the thiourea residue. This unstable intermediate cyclic compound (II) is subsequently converted either into 2-mercaptoethylguanidine (III) or into 2-aminothiazoline (IV), depending upon the reaction medium: according to the following scheme:

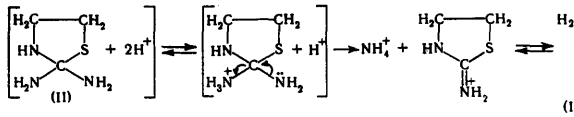
A. Formation of an unstable intermediate ring:



B. Stabilisation of intermediate ring (II) at pH ≃ 7.0:



C. Stabilisation of ring (II) at pH ≃ 3.5:



In neutral or weakly alkaline media cleavage of ring (II) occurs with formation of 2-mercaptoethylguanidine (III)

since at a low proton concentration the uncharged amino-group facilitates migration of the electrons of the neighbouring C–S bond to the sulphur atom, which in this way leads to breaking of this C–S bond and formation of (III).

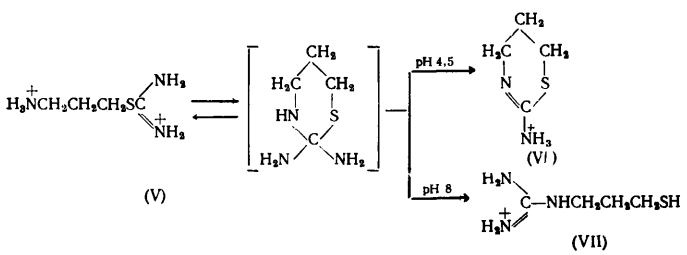
In a weakly acid medium as a result of addition of a proton to one of the amino-groups electrons of the C–N bond are displaced, an ammonium ion is lost, and 2-aminothiazoline (IV) is formed.

Confirmation of the "transguanidation" reaction scheme, which proceeds with formation of an intermediate cyclic compound, was also obtained by Rachinskii and Slavachevskaya[207], who studied the rate of conversion of *S*-2-aminoethylisothiuronium into 2-aminothiazoline in aqueous solution at pH ~ 3.5.

In addition the authors[207] showed that the reaction of "transguanidation" can be used to obtain a series of guanidinoalkanethiols and the corresponding disulphides.

In studying the behaviour of various *S*-substituted thioureas in aqueous solutions it was observed that in neutral or weakly alkaline media there is a sharp difference in the rate of formation of the thiol depending on the structure of the isothiuronium salts[207]. Aminoalkylisothiuronium compounds, which contain a primary or secondary amino-group in the β or γ position at pH ~ 7.5 are converted almost instantaneously and quantitatively into the thiol, whereas the analogous compounds with a tertiary amino-group do not form a thiol under these conditions.

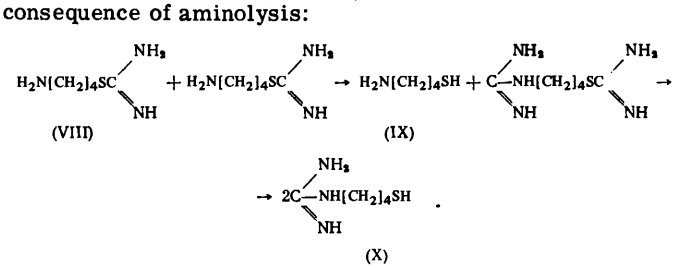
In addition it has been noted that *S*-3-aminopropylisothiourea (V) undergoes rearrangement at a higher pH than *S*-2-aminoethylisothiourea[201]. Thus the optimal conditions for the quantitative conversion of (V) into 2-aminopenthiazoline (VI) are pH 4.5 and for rearrangement into 3-mercaptopropylguanidine (VII), pH 8.



(V) (VI) (VII)

With lengthening of the carbon chain between the amino-groups and the thiourea residue naturally the formation of the unstable intermediate ring (II) is hindered and the degree of rearrangement is decreased[201,207].

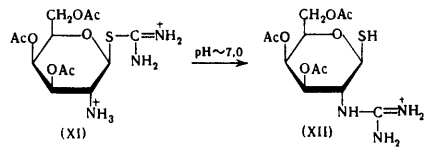
The difficulty of forming a seven-membered intermediate cyclic compound explains why the salt of *S*-4-aminobutylthiourea (VIII) is stable in aqueous solution at pH 7. However, on standing for several days at pH 9.2, a mixture of 4-mercaptobutylamine (IX) and 4-mercaptobutylguanidine (X) is formed, which, as has been shown[201] is the consequence of aminolysis:



(VIII) (IX) (X)

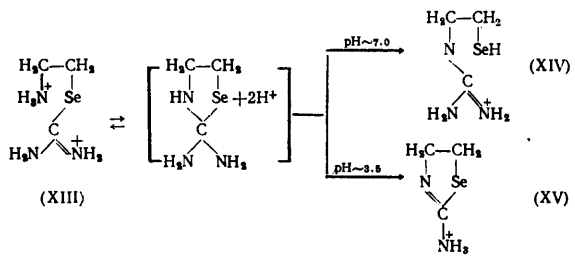
The introduction of alkyl substituents to the nitrogen atoms of amino-groups of the thiourea residue has no effect on the rearrangement of *S*-aminoalkylisothiouronium salts[201,208–210]. However, the presence of alkyl substituents at the nitrogen atoms of the amido-groups decreases the degree of "transguanidation". *S*-aminoalkyl-substituted thioureas, which contain one substituent at the nitrogen atom of the amido-group undergo rearrangement more easily than those which contain two substituents[208–210].

"Transguanidation" is also observed in a series of isothiuronium derivatives of hydrocarbons. Thus Wolfrom and coworkers[211,212] showed that at pH ≃ 7 the salt 2-(3,4,6-tri-*O*-acetyl-2-amino-2-desoxy-2-D-galactopyranosyl)-2-isothiourea (XI) is converted into the corresponding guanidinothiol (XII) by the scheme:



(XI) (XII)

In recent years information has also been published[208–210,213] about the analogous rearrangement of derivatives of isoselenourea. At pH ~ 7.0, 2-aminoethylisoselenourea (XIII) is converted into 2-guanidoethylselenol (XIV) but at pH ~ 3.5 2-aminoselenazoline (XV) is formed, that is, the reaction of "transguanidation" takes place by the usual scheme:



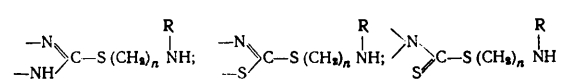
(XIII) (XIV) (XV)

The "transguanidation" rules, found by the examples of aminoalkyl-substituted isothioureas[201,207], extend also to the corresponding derivatives of isoselenourea[208–210]. The relative rate of rearrangement of the isothiuronium compounds and their selenium analogues were studied spectrophotometrically. It was found[208–210] that 2- and 3-aminoalkyl derivatives of isoselenourea undergo rearrangement much more rapidly than the corresponding thio-analogues. It was also observed[208–210] that aminoalkyl substituted isoselenoureas which contain a tertiary amino-group are, unlike the corresponding S analogues, capable of undergoing partial hydrolysis in a neutral medium, which is evidently explained by the C–Se bond being weaker than the C–S bond.

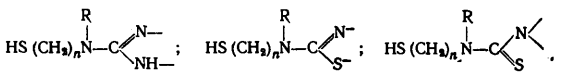
We assume that "transguanidation" can be considered as an instance of S → N (or Se → N) migration of an amidine group which takes place by the same mechanism as the migration of acyl groups in acylated amino-thiols.

VIII. REARRANGEMENT OF CERTAIN AMINOALKYL SULPHIDES

Naturally it was suggested that *S*-aminoalkyl derivatives of compounds which contain elements structurally similar to thiourea:

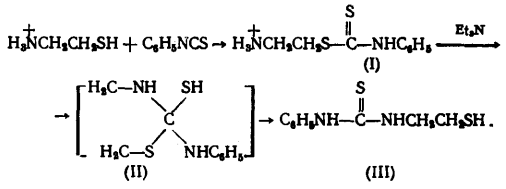


can also rearrange with formation of the corresponding *N*-substituted aminoalkane thiols:



Such rearrangements, which take place by the mechanism of S → N migration of acyl groups in the series of acylated amino-thiols, were also observed in *S*-aminoalkyl-substituted dithiocarbamates[214,215], xanthic[216] and trithiocarbonic[217] acids.

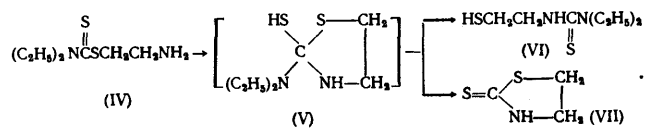
Thus, in the treatment of salts *S*-(2-aminoethyl)-*N*-phenyldithiocarbamate (I), obtained by the reaction of salts of 2-mercaptoethylamine with phenyl isothiocyanate, 1-(2-mercaptoethyl)-3-phenyl-2-thiourea (III) was liberated by one equivalent of a weak base[214]:



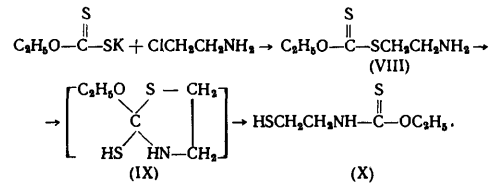
This rearrangement is a particular example of an S → N migration of a thiocarbamyl group and is also associated with the formation of an unstable thiazolidine ring (II).

Pustoshkin and Rachinskii[215] found that *S*-aminoethyl derivatives of diethyl dithiocarbamate undergo an analogous rearrangement in an alkaline medium. The reaction of sodium diethyldithiocarbamate with 2-chloroethylamine was first studied by Postovskii[218], who showed that the main product of the reaction is *S*-2-aminoethyldiethyldithiocarbamate (IV). Somewhat later Johnstone and Gallagher[219] noted, in repeating this work, that besides the compound (IV) another unidentified reaction product is also formed in large amount. This led Pustoshkin and Rachinskii to investigate the reaction in greater detail. As a result it was found that in an alkaline medium not only *S*-2-aminoethyldiethyldithiocarbamate (IV) is formed, but also a product of S → N rearrangement (VI) which does not exhibit salt-forming properties, is titrated by iodine, is readily oxidised by atmospheric oxygen and gives isothiuronium compounds with halogenoalkylamines.

It is natural to assume that here an intramolecular rearrangement of (IV) proceeds through the stage of formation of an unstable intermediate ring (V), which, depending on the conditions, is stabilised either in the form of an *NN'*-substituted thiourea (VI) by breaking of a C–S bond or as a 2-thiazolidinethione (VII) by loss of an amine molecule:



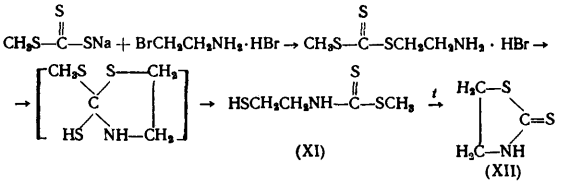
A rearrangement connected with S → N migration was also observed in a series of *S*-β(γ)-aminoalkyl derivatives of the ethyl xanthate[216]. The reaction of potassium xanthate with β-chloroethylamine in alcoholic solution at room temperature gave the ethyl *N*-2-mercaptoethyl monothiocarbamate (X), which is formed as a result of the rearrangement of *S*-2-aminoethylxanthate (VIII):



It has been shown[216] that the "transguanidation" rules are also retained here: the formation of the derivatives of ethyl monothiocarbamate was observed only when potassium xanthate reacts with halogenoalkylamines with a primary or secondary amino-group. Only the *S*-aminoalkyl xanthate is obtained for halogenoalkylamines with a tertiary amino-group or with a long carbon chain, when the formation of intermediate ring (IX) is hindered.

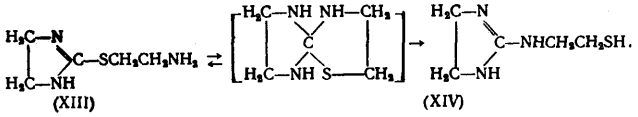
Here also the rearrangement can be regarded as S → N migration of a thioethoxycarbonyl group, taking place by the same mechanism as in derivatives of thioglycol[174].

An analogous S → N rearrangement was also observed in *S*-β(γ)-aminoalkyl-substituted esters of trithiocarbonic acids[217]. The reaction of sodium methyl trithiocarbonate with 2-bromoethylamine at low temperature gives methyl *N*-(2-mercaptoethyl) dithiocarbamate (XI), which is converted into 2-thiazolidinethione (XII) on heating:



Papers have recently appeared on the possibility of an S → N rearrangement in a series of *S*-aminoalkyl derivatives of certain heterocycles.

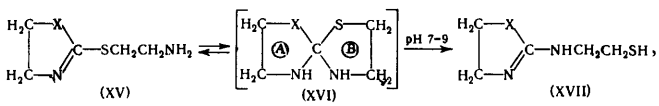
Khym and coworkers[201] showed that 2-(2-aminoethylmercapto)imidazoline (XIII) stable in 0.2 *N* HCl, at pH ~ 7.0, is converted into 2-(2-mercaptoethylamino)imidazoline (XIV) to the extent of 70% in 10 min, but the product of the rearrangement was not isolated and was only characterised chromatographically. In Khym's opinion the rearrangement proceeds thus:



Pavlova and coworkers[209,210,220] investigated the rearrangement of a considerable number of *S*-aminoalkyl derivatives of 2-mercaptoimidazoline containing primary, secondary, and tertiary amino-groups, over a wide range of pH. According to their results the conversion of these substances into *N*-substituted amino-thiols proceeds in accordance with the general mechanism of S → N rearrangement. They isolated the products of the rearrangement and characterised them as disulphides, whose structures were demonstrated by countersynthesis.

Subsequently an analogous rearrangement was studied by the example of the rearrangement of *S*-2(3)-aminoalkyl

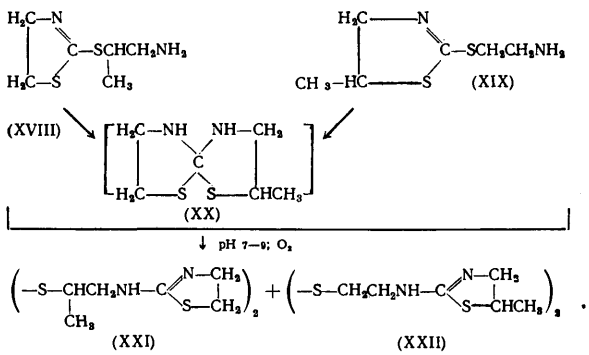
derivatives of 2-mercaptothiazoline [209,210,220,221] and 2-mercapto-oxazoline [222] into the corresponding thiols:



(XV) (XVI) (XVII)

where X = S, O.

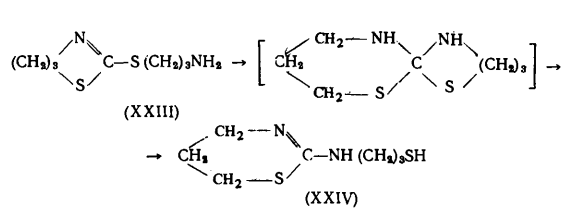
The assumption that the rearrangement of 2-(2-aminoethylmercapto)thiazoline (XV; X = S) proceeds with formation of an unstable intermediate bicyclic compound (XVI; X = S) naturally leads to the question as to which ring of the compound (XVI; X = S) is opened—that newly formed (B) or the original one (A)? To determine this, Pavlova and Rachinskii [210] obtained 2-(2-aminoisopropylmercapto)thiazoline (XVIII) and 2-(2-aminoethylmercapto)-5-methylthiazoline (XIX). It can be suggested that in the S → N rearrangement of these compounds the same intermediate bicyclic compound (XX) should be formed, in which the breaking of a C–S bond can proceed with the same probability in any ring of the compound (XX) and then the production of a mixture of the products (XXI) and (XXII) should be expected:



(XVIII) (XIX) (XX) (XXI) (XXII)

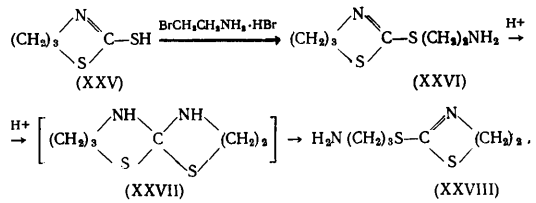
However, it was found [210] that the only product of the rearrangement of (XVIII) is 2-(2-thiazolinylamino)isopropylmercaptan, isolated as the disulphide (XXI) and for (XIX) bis-{β-[2-(5-methyl)thiazolinylamino]ethyl} disulphide (XXII). The results obtained suggest that the rearrangement of *S*-aminoalkyl derivatives of 2-mercaptothiazoline (and other heterocycles) does not proceed through the formation of the bicyclic intermediate spirane compound, but through a transition state.

Later Clapp and coworkers [223] studied the conversion of 2-(3-aminopropylthio)penthiazine (XXIII) into 2-(3-mercaptopropylamino)penthiazine (XXIV) in an alkaline medium:



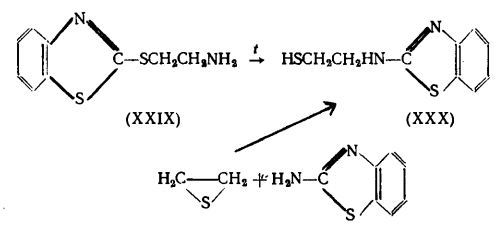
(XXIII) (XXIV)

At the same time, in the reaction of 2-thiopenthiazine (XXV) with 2-bromoethylammonium chloride instead of the expected 2-(2-aminoethylthio)penthiazine dihydrobromide (XXVI) the authors isolated 2-(3-aminopropylthio)thiazoline (XXVIII). It was suggested that the formation of (XXVIII) is the result of the rearrangement of (XXVI) in an acid medium through the intermediate compound (XXVII):



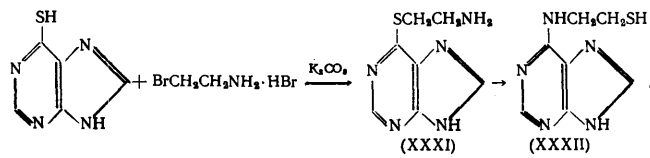
(XXV) (XXVI) (XXVII) (XXVIII)

In an attempt to bring about the rearrangement of *S*-2-aminoethyl derivatives of 2-mercaptobenzimidazole and 2-mercaptobenzthiazole it was found that these compounds do not form a thiol at pH 7–9 and room temperature [224]. Probably the difficulty of rearrangement is connected with a decrease in the positive charge on the $C_{(2)}$ carbon atom as a result of the influence of the double bond of the imidazole or thiazole ring. The results agree with the fact that in the reaction of 2-mercaptothiazole with halogenoalkylamines in an alkaline medium the corresponding *S*-aminoalkyl derivatives are obtained, and not the thiols, as the possible products of the rearrangement [225]. However, Manolov [226] succeeded in effecting the thermal rearrangement of 2-(2-aminoethylmercapto)benzthiazole (XXIX) into 2-(benzthiazol-2-ylamine)ethanethiol (XXX). The conversion of (XXIX) into (XXX) was carried out as follows: the base (XXIX) was heated in an atmosphere of nitrogen at 160°C for 1 h. The thiol (XXX) isolated as a result of the rearrangement of (XXIX) was shown chromatographically to be identical with the thiol obtained by the countersynthesis:



(XXIX) (XXX)

Johnston and Gallagher [227] observed the S → N rearrangement for derivatives of 6-mercaptopurine. In an attempt to obtain 6-(2-aminoethylthio)purine by the reaction of 6-mercaptopurine with 2-bromoethylammonium bromide in the presence of potassium carbonate, unchanged 6-mercaptopurine, β-purin-6-ylaminoethanthiol (XXXII), and the corresponding disulphide were isolated; the expected 6-(2-aminoethylthio)purine (XXXI) was not. As the authors proposed [227] (XXXI) is formed initially and in an alkaline medium it rearranged into β-purin-6-ylaminoethanethiol (XXXII):

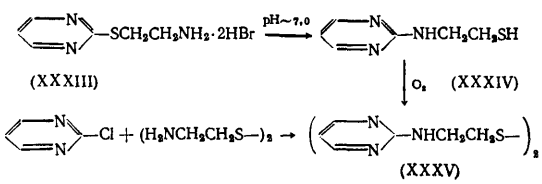


(XXXI) (XXXII)

Later a similar rearrangement was also described for *S*-aminoethyl derivatives of 8-mercapto- and 2-mercaptoadenine and also 8-mercaptocaffeine [228].

It was also found [210] that 2-(2-aminoethyl)mercaptopyrimidine (XXXIII) is rearranged into the corresponding *N*-substituted aminothiol (XXXIV) in neutral and slightly alkaline media. The product of the rearrangement, isolated

as a disulphide (XXXV), was identical with the product obtained by countersynthesis:



The rules for the S → N migration were studied in greater detail[209,210] by the example of the rearrangement of *S*-aminoalkyl-substituted 2-mercapto-4,6-diaminopyrimidine.

---o0o---

We think that the results given above about the rearrangements associated with the intramolecular migration of acyl and other groups represent a generalisation of instances of the migration of groups sensitive to nucleophilic attack (structures which include the bonds C=O, C=S, or C=N) between two nucleophilic groups (H_2N, OH, SH). The study of the rules and limits of application of these rearrangements as well as being of general theoretical interest, opens a path to the synthesis of new organic compounds.

Thermal Decomposition of Aliphatic Nitro-compounds

G.M.Nazin, G.B.Manelis, and F.I.Dubovitskii

Two mechanisms of decomposition of nitro-compounds are discussed: molecular, when a molecule of HNO_2 is detached and the corresponding alkene is formed, and free-radical, in which the reaction starts with the breaking of the C–N bond. Study of the reactions of the first type is of considerable interest in the light of the general theory of elimination reactions in the gas phase. The radical decomposition of nitroalkanes is characterised by high values of the pre-exponential factors. The activation energy in this instance equals the energy for breaking the bond. Secondary reactions have little influence on the rate of radical decomposition of *gem*-polynitroalkanes, therefore the study of the kinetics of the decomposition can be an effective method of determining the energy for the breaking of the C–N bond in these compounds. Bibliography of 48 references.

I. INTRODUCTION

The investigation of the kinetics of the reactions of thermal decomposition of aliphatic nitro-compounds began in the middle of the 1930s, when the first paper on the decomposition of nitromethane appeared[1], and several papers were published[2,3] which dealt with the thermal decomposition of chloropicrin. The mononitroalkanes nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane were the chief subjects of further investigations; these account for about three-quarters of all the work completed up till now. These four compounds were thoroughly studied by various authors in the period from 1950 to 1959, and the main features of their decomposition mechanisms were found. Considerably less attention has been paid to the polynitro-compounds. A quantitative study of the reactions during the decomposition of substances in this class was begun in 1962 and completed for only two compounds: 2,2-dinitropropane[4] and hexanitroethane[5]. Despite the comparatively small number of substances studied and the incompleteness of some of the studies, the results obtained are of considerable interest for the solution of a series of scientific and technical problems and merit careful examination.

The explanation of the mechanism of decomposition of nitro-compounds is inseparably connected with such problems as the determination of the energy of breaking of the C–N bond (and also bonds of another type) in substances of various structures, of finding the heats of formation of nitroalkyl free radicals, the conversion of free radicals in systems containing NO and NO_2, the influence of the state of aggregation and of the solvent on the radical reactions, topochemical processes in molecular crystals, and various other problems where the decomposition of nitro-compounds can serve as a model. A series of peculiarities of the reactions in the decomposition of nitro-compounds, for example, the possibility of decomposition by two competing mechanisms—radical and molecular—the dependence of these mechanisms on the structure of the molecule and the experimental conditions, and the existence of high pre-exponential factors in the radical decomposition are of undoubted interest to the theory of unimolecular reactions.

Among the technical problems which were responsible for the practical value of a study of the decomposition of nitro-compounds and to a certain extent stimulated these studies there is above all the industrial synthesis of mononitroalkanes by the vapour-phase nitration of hydrocarbons with nitrogen dioxide or nitric acid[6,7] and also the possibility of using certain nitroalkanes as additives to fuels for air-breathing and rocket engines[8].

The establishment of the detailed mechanism of the decomposition of any nitro-compound and the determination of the rate constants of the separate stages would have definite value in considering problems in the theory of combustion of liquid monopropellents.

A general introduction to the conditions and results of the studies of the reactions in the decomposition of nitro-compounds is given in Table 1.

In addition to Table 1, we note that the decomposition of all the substances except hexanitroethane was studied in the gas phase and in every instance the reaction obeyed a first-order law. Despite the simplicity of the formal kinetic laws there are often serious discrepancies between the results of different authors in determining the rate constants and for the choice of reliable quantities it is necessary to compare all the data. This is even more true of the treatment of the decomposition mechanism. A consideration of the accumulated material shows certain general features, inherent in the decomposition reactions of nitro-compounds, which in turn promote a better understanding of the mechanism of decomposition of other substances.

In connection with what has been stated above, in this review all the experimental data will be briefly examined, the mechanisms for the decomposition of nitro-compounds will be judged from various viewpoints, and the problems which we consider to be of greatest interest for further investigations will be emphasised.

Table 1. Some information about the reactions in the decomposition of the nitro-compounds.

II. DECOMPOSITION OF MONONITRO-COMPOUNDS

1. Nitromethane

Taylor and Vesselovsky, who first investigated the kinetics of thermal decomposition of nitromethane[1], found that under static conditions at initial vapour pressures of P_0 = 27–198 mmHg the reaction obeys a first-order equation and is homogeneous (the increase in the ratio of the surface to the volume of the reaction vessel by a factor of 6.3 has no influence on the initial rate of reaction). By distillation of the reaction products a small fraction with b.p. 84°C was isolated; this b.p. corresponds with that of formaldehyde oxime, an isomer of nitrosomethane. From this it was supposed that the first stage of the decomposition of nitromethane is the loss of oxygen from the nitro-group:

$$CH_3NO_2 \rightarrow CH_3NO + O\,. \qquad (1)$$

However, in an analysis of Taylor and Vesselovsky's experimental results Cottrell and coworkers noted[11] that the rate constant for the decomposition of nitromethane depends on the pressure, decreasing systematically with decrease in P_0. A more careful study of the decomposition of nitromethane, made by Cottrell and coworkers[10,11] by a manometric method, showed that the reaction is indeed homogeneous but the rate constant ceases to depend on the pressure only at an initial pressure $P_0 > 200$ mmHg.

In this connection criticism must be directed at both Taylor and Vesselovsky's results and those of Frejacquens[9], who determined the activation energy for the decomposition of nitromethane and the influence of other gases on the rate of this reaction at $P_0 = 4-40$ mmHg.

The activation energy found by Cottrell, 53.6 kcal mole^{-1}, was considerably less than that of Taylor (61 kcal mole^{-1}) and is in good agreement with the thermochemically determined energy for the dissociation of the C–N bond in CH_3NO_2†. This was an important point in support of a mechanism with primary breaking of the C–N bond. Cottrell's approximate thermochemical calculation[11] showed that $D(CH_3NO-O) \geqslant 73$ kcal mole^{-1}—that is, approximately the same value as $D(NO-O)$—and hence reaction (1) seems improbable.

A semiquantitative analysis of the decomposition products was made with the aid of various methods (infrared and mass spectroscopy, gas analysis). The main products were H_2O, CO, and CH_4 (Table 2). In addition small amounts of CO_2, N_2O, C_2H_4, and C_2H_6 were detected.

From these results, Cottrell proposed the following scheme for the decomposition of nitromethane[11]:

$$CH_3NO_2 \rightarrow CH_3 + NO_2 , \quad (2)$$

$$CH_3 + CH_3NO_2 \rightarrow CH_4 + CH_2NO_2 , \quad (3)$$

$$CH_2NO_2 + NO_2 \rightarrow CH_2O + NO + NO_2 , \quad (4)$$

$$CH_2O + NO_2 \rightarrow CO + NO + H_2O , \quad (5)$$

$$CH_3 + CH_3 \rightarrow C_2H_6 . \quad (6)$$

Table 2. Composition of the products (in mole fractions) in the initial stages of the decomposition of nitromethane at various pressures.

The possibility of the following reactions was also noted:

$$CH_2NO_2 \rightarrow CH_2O + NO , \quad (7)$$

$$CH_3 + NO \rightarrow CH_3NO \rightarrow HCN + H_2O . \quad (8)$$

After Cottrell's work, Hillenbrandt and Kilpatrik[12] studied the decomposition of nitromethane in a flow system.

Nitrogen saturated with water vapour was used as the carrier gas, and reproducible results were obtained by this procedure. The nitromethane was analysed polarographically. Formaldehyde (hydroxylamine method), methane, carbon monoxide, and nitrogen monoxide (adsorption gas analysis) were determined in the products. The rate of decomposition in the stream is independent of the changes in the nitromethane concentration for mole fractions between 0.06 and 0.18. The parameters of the Arrhenius equation are close to those obtained by Cottrell (Table 1). However, unlike Cottrell's results, a large proportion of formaldehyde was found in the decomposition products. The yield of formaldehyde per mole nitromethane was 0.5 mole in the initial stages at 420°C and reached 0.9 mole at 473°C. With increase in the extent of the conversion the yield of formaldehyde decreases, reaching a constant value of 0.4 mole at 473°C and 0.2 mole at 420°C. According to Cottrell's scheme, even allowing for reaction (7) the yield of formaldehyde cannot be $> 50\%$. Hillenbrandt and Kilpatrik suggested that the reaction proceeds at least partly by an intramolecular rearrangement:

$$CH_3NO_2 \rightarrow CH_2O + HNO . \quad (9)$$

The low concentration of formaldehyde in Cottrell's static experiments was explained by reaction (5), which proceeds very slowly at temperatures > 200°C.[29]

Hillenbrandt and Kilpatrik's conclusions were criticised by Gray and coworkers[14]. These authors investigated the kinetics of the decomposition of nitromethane, also under flow conditions (but at a lower concentration of nitromethane in the mixture), and determined the formaldehyde by reaction with dimedon; they found that the yield of formaldehyde is considerably less than had been claimed[12]. For example, at 447°C and a contact time of 1.1 s (extent of conversion 13%) the yield of formaldehyde was 16%. Gray considers that in the earlier work[12] there were two sources of error in determining the yield of formaldehyde: (1) the accuracy in calculating the $[CH_2O]/[CH_3NO_2]$ ratio decreases with decrease in the extent of decomposition; (2) it is possible that in the analysis the sum of the formaldehyde and formaldehyde oxime (obtained by isomerisation of nitrosomethane) was determined.

By use of metallic mirrors, Gray established that active free radicals are formed in the decomposition of nitromethane. He therefore supports Cottrell's viewpoint concerning the radical nature of the decomposition of nitromethane.

The formation of nitrosomethane (which under static conditions is converted into hydrogen cyanide and water) during the decomposition of nitromethane was proved convincingly by Müller, who studied the decomposition at 355°C in the range of pressures 12.2–20 atm. The reaction was studied by an ampoule method with mass spectrometric analysis of the nitromethane and the decomposition products. It was found that, in addition to nitric oxide and water, hydrogen cyanide is formed, its yield increasing with the pressure (Table 2). For comparison with Cottrell's results an experiment was run at 418°C and $P_0 = 158$ mmHg. Table 2, which gives these results, shows clearly that in addition to the products noted by Cottrell (CH_4, CO, NO, CO_2, H_2O) hydrogen cyanide and nitrogen are formed in comparatively large quantities.

To explain the large yield of hydrogen cyanide Müller suggested that the decomposition of nitromethane proceeds not solely by the Cottrell mechanism but partly by reaction (1) proposed by Taylor; the part played by this reaction increases with the pressure.

However, this conclusion was not convincing and has been criticised by Makovky and Gruenwald[16]. By using

† Three values for the heat of formation of nitromethane in the gas phase have been published: 17.8,[26] 12.35,[27] and 13.1[28] kcal mole^{-1}. The use of the last two values, obtained subsequently and evidently more accurate, gives for D(C–N) the values 52.0 and 52.7 kcal mole^{-1} respectively.

mass spectrometric analysis these authors found that the rate of decomposition of nitromethane at $P_0 > 1$ atm depends weakly on pressure, but the value of the activation energy determined at a pressure of 40 atm agrees well with Cottrell and Hillenbrandt's results (Table 1). The dependence on pressure of the hydrogen cyanide yield was confirmed and, furthermore, it was shown that its formation is facilitated by addition of nitric oxide to the nitromethane.

Makovky and Gruenwald consider that all these results are explained by Cottrell's scheme and the formation of hydrogen cyanide follows from reaction (8). The primary stage of this reaction—the formation of nitrosomethane—is termolecular and its rate depends more strongly on pressure than the rates of competing processes (3) and (10)‡:

$$CH_3 + NO_2 \rightarrow CH_3O + NO\ , \qquad (10)$$

which also explains the increase in the yield of hydrogen cyanide with increase in pressure.

From the material considered clearly Cottrell's scheme gives a satisfactory explanation for both the observed activation energy and the composition of the decomposition products. Therefore it can be considered correct in both features.

Additional information about secondary processes which take place during the decomposition of nitromethane can be obtained on considering the effect on the rate of this reaction of adding certain gases.

It was found[15,16] that the addition of NO_2 greatly retards the decomposition of nitromethane. Makovky explains this fact by the reversibility of reaction (2). As has been shown[30,31] in studies of the reactions of the methyl radical with nitrogen dioxide, this interaction takes place in two ways. The first leads to recombination:

$$CH_3 + NO_2 \rightarrow CH_3NO_2 \qquad (11)$$

and the second, to oxidation by Eqn. (10). Here $k_{10} \simeq 2k_{11}$.[30,32] In the decomposition of nitromethane the methyl radical not only reacts with nitrogen dioxide but also undergoes conversion by reaction (8) and possibly (3). A considerable yield of methane, especially at low pressures and in the initial stages, does not allow this reaction to be ruled out although with considerable concentrations of nitrogen dioxide and monoxide its role will be small. If it is assumed that the methyl radical is consumed only in reactions (3), (6), (10), and (11), then for the rate of decomposition of nitromethane under conditions when the concentration of methyl radical is stationary we obtain the expression§

$$-\frac{d[CH_3NO_2]}{dt} = k_3[CH_3NO_2]\left\{1 - \frac{k_{11}[NO_2] - k_3[CH_3NO_2]}{(k_{10}+k_{11})[NO_2] + k_7[NO] + k_3[CH_3NO_2]}\right\}. \qquad (12)$$

With a large excess of nitrogen dioxide the rate constant is $k_2[1 - k_{11}/(k_{10} + k_{11})]$ and if it is assumed that $k_{10} = 2k_{11}$ the rate can be expected to be ~ 30% less. As a matter of fact, the addition of 36–37% nitrogen dioxide reduces the rate of decomposition by approximately half[16]. This fact shows the presence of some other reactions of radicals with the nitromethane which are inhibited by additions of nitrogen dioxide. It should be noted that in studies of the decomposition of nitromethane the possibility of reaction (10) and the fate of the methoxy-radical have not been considered at all. This radical is undoubtedly formed in the decomposition of nitromethane and its recombination with nitrogen monoxide and dioxide hardly occurs at the temperatures of the experiments. Possibly the methoxy-radical is destroyed by the reactions:

$$CH_3O + NO \rightarrow CH_2O + HNO\ , \qquad (13)$$

$$CH_3O + NO_2 \rightarrow CH_2O + HNO_2\ , \qquad (14)$$

which also explains the absence of methanol in the decomposition products. Observations concerning the retarding action of nitrogen dioxide were made at temperatures not above 355°C, when it does not react directly with nitromethane. At higher temperatures the accelerating influence of nitrogen dioxide is observed. Thus Schay and coworkers[17] found, in studying the influence of nitrogen dioxide and nitric acid on the decomposition of nitromethane at 430°C with a contact time of 1–2 s, that both substances increase the rate of decomposition and at a concentration ratio of $NO_2 : CH_3NO_2 = 17 : 1$ the formation of polynitro-compounds is observed. These facts are explained by the reactions:

$$NO_2 + CH_3NO_2 \rightarrow HNO_2 + CH_2NO_2\ ,$$

$$NO_2 + CH_2NO_2 \rightarrow CH_2(NO_2)_2\ .$$

According to Eqn. (12) the addition of nitric oxide to nitromethane should accelerate the decomposition at $k_{11}[NO_2] > k_3[CH_3NO_2]$ and decrease the rate under the opposite conditions. Some observations[11,15,16] show that the addition of nitric oxide in amounts up to 10% to nitromethane does not alter the rate but at higher concentrations nitric oxide retards the decomposition. This fact can be taken as confirmation of the correctness of Cottrell's conclusion concerning reaction (3) in the scheme of decomposition of nitromethane.

Investigations by several authors[14–16] showed that the addition of oxygen accelerates the decomposition of nitromethane. For example, at 330°C and $P_0 = 40$ atm the addition of 8–35% oxygen increases the rate of decomposition by 20–25%.[15] The forward reaction of oxygen with nitromethane under these conditions is improbable, since oxygen is less active in reactions at the C–H bond than is nitrogen dioxide, for which the reaction with nitromethane is not observed. Possibly the oxygen affects the decomposition through the $CH_3OO^{\cdot}$ radical, which is formed in the reaction of oxygen with the methyl radical. The reaction of this radical with nitrogen monoxide and dioxide requires an activation energy. It is therefore comparatively long-lived and can react with nitromethane:

$$CH_3O\dot{O} + CH_3NO_2 \rightarrow CH_3OOH + CH_2NO_2\cdot . \qquad (15)$$

The decrease in the yield of hydrogen cyanide observed on adding oxygen[15] is indirect proof of the reaction of oxygen with methyl radicals.

The decomposition of nitromethane at high temperatures (872–1157°C) was studied by Bradley[18] with the aid of the shock tube method. The reaction was carried out in a mixture with argon (1 : 9) at pressures of 6–10 mmHg with analysis of the products every 50–100 μs on a time-of-flight mass spectrometer. The stoichiometry of the reaction corresponds to the equation:

$$2CH_3NO_2 \rightarrow CH_4 + CO + H_2O + 2NO\ .$$

The yields of methanol and formaldehyde are very small. The decrease in nitromethane equals the rate of formation of the products. Throughout the whole temperature range of the reaction the first-order equation is obeyed but the activation energy decreases as the temperature is raised, the mean value being 13 ± 7 kcal mole^{-1}.

‡Reaction (10) is not taken into account in Cottrell's scheme.

§ For k_7 read k_8 in Eqn. 12 (Ed. of Translation).

To explain these factors a mechanism was proposed which includes two successive excitations of the nitromethane molecules. However, before a definite conclusion can be drawn about the decomposition paths for nitromethane which are new in principle it is necessary to be convinced that the experiments were made in the range where the rate constants of the unimolecular reaction are independent of pressure.

The catalytic decomposition of nitromethane into various oxides was described by Makovky[32,33], who found that the decomposition is catalysed only by oxides which are basic. Evidently, the formation of *aci*-forms of nitromethane in layers adsorbed on oxides plays a part. The compounds can be arranged in the following order of catalytic activity:

$$Cr_2O_3>ThO_2>ZnO>MnO_2>CaO>Co_2O_3>TiO_2>PbO>MgO>$$
$$>CdO>HgO>Fe_2O_3>Al_2O_3>CuO>CeO_2>SbO_2>$$
$$V_2O_5, WO_3, CrO_3, MoO_3, SiO_2, P_2O_5$$

(the last does not act below 350°C). The decomposition of nitromethane over chromium oxide has been studied in most detail[22]. This catalyst has a very great effect on both the rate of decomposition (see Table 1) and the composition of the decomposition products, among which large proportions of ammonium hydrogen carbonate have been observed.

2. Nitroethane, 1-Nitropropane, and 2-Nitropropane

In distinction from nitromethane, the decomposition of which starts with rupture of the C–N bond, the decomposition of remaining mononitroalkanes that have been studied takes place (at least, at temperatures up to 450°C) by a unimolecular mechanism with elimination of nitric acid and formation of the corresponding alkene:

$$-\overset{H}{\underset{}{C}}-\overset{NO_2}{\underset{}{C}}- \rightarrow >C=C< + HNO_2. \qquad (16)$$

This mechanism was first proposed by Cottrell[19] in studying the decomposition of nitroethane and 1-nitropropane under static conditions. On using a manometric method, Cottrell found that the decomposition of nitroethane proceeds according to a first-order equation and is independent of the pressure at $P_0 > 30$ mmHg. The activation energy (~ 47 kcal mole^{-1}) was considerably below the dissociation energy of the C–N bond in this compound (56 kcal mole^{-1}) which can be evaluated from thermochemical data[26,28]. Infrared spectroscopy showed the presence in the products of CO_2 (~ 18%), NO (~ 45%), and C_2H_4 (~ 36%).

On the basis of these results Cottrell also proposed reaction (16), that is, a mechanism analogous to the molecular decomposition of alkyl halides[34]. This mechanism was disputed by Gray and coworkers[14]. The contradiction was resolved in the detailed studies by Wilde[20,21].

Gray investigated the kinetics of decomposition of nitroethane in flow at temperatures higher than in Cottrell's experiments. The mole fraction of nitroethane in helium was 4×10^{-4}–5×10^{-3}. Polarographic determination of the nitroethane was used to observe the reactions. CH_2O (by dimedon), NO_2 (Griess reaction), CO_2, NO, C_2H_4, C_2H_6 (adsorption analysis) were determined in the decomposition products. CO, CH_4, and N_2 were determined by the mass spectrometric method. The results of the analyses gave the following overall equation for the decomposition of nitromethane at 477°C:

$$C_2H_5NO_2 = 0.4\,C_2H_4 + 0.03\,C_2H_6 + 0.367\,CH_4 + 0.22\,CH_2O + 0.483\,CO + 0.07\,CO_2 + 0.657\,H_2O + 0.29\,N_2 + 0.08\,NO_2 + 0.34\,NO\,.$$

Gray found the activation energy to be 39 kcal mole^{-1}, even lower (and, as further investigation showed, more correct) than that of Cottrell. By the metallic mirror method Gray found that the decomposition of nitroethane at temperatures above 500°C is accompanied by the formation of free radicals. At the same time the artificial introduction of methyl radical (formed in the decomposition of di-t-butyl peroxide) depresses the decomposition temperature of nitroethane by a hundred degrees. One of the main products in this is formaldehyde. On the basis of these facts Gray proposed the following scheme for the decomposition of nitroethane:

$$C_2H_5NO_2 \rightarrow C_2H_5 + NO_2\,, \qquad (17)$$
$$C_2H_5 + NO_2 \rightarrow C_2H_5NO_2\,, \qquad (18)$$
$$C_2H_5 + NO_2 \rightarrow C_2H_5O + NO\,, \qquad (19)$$
$$C_2H_5O \rightarrow CH_2O + CH_3\,, \qquad (20)$$
$$C_2H_5O \rightarrow CH_3CHO + H\,, \qquad (21)$$
$$CH_3CHO \rightarrow CH_4 + CO\,, \qquad (22)$$
$$CH_3 + RH \rightarrow CH_4 + R\,, \qquad (23)$$
$$CH_3 + NO \rightarrow CH_3NOH \rightarrow HCN + H_2O\,. \qquad (8)$$

The formation of ethylene is explained by the reaction

$$C_2H_5 \rightarrow C_2H_4 + H \qquad (24)$$

and partly by the occurrence of process (16). Furthermore, Gray assumes reaction of methyl radicals with nitroethane, which he thinks leads to the low value of the activation energy.

Wilde[20,21] carried out a detailed investigation of the decomposition of nitroethane in flow and under static conditions. In the first instance the method used was analogous to that employed by Hillenbrandt for nitromethane[12]. At a total pressure of 750 mmHg the rate of decomposition is independent of the composition of the $C_2H_5NO_2$–N_2 mixture. Nitroethane, acetaldehyde, and formaldehyde were determined polarographically, ethylene and nitrogen monoxide by chemical methods. It was shown that the main products (in the temperature range 414–442°C) are ethylene and nitric oxide. Hydrogen cyanide, water, and a little nitrogen dioxide were also observed, and at 442°C, methane and carbon monoxide. The discrepancy with Cottrell's results is explained by the fact that hydrogen cyanide, formaldehyde, and acetaldehyde are decomposed and oxidised under static conditions, giving, in particular, carbon dioxide. The activation energy determined for 412–442°C was 41.4 ± 1.1 kcal mole^{-1}. The inclusion of a point at 453°C gave the value 46.8 ± 3 kcal mole^{-1}, with much greater error.

Wilde also studied the decomposition of nitroethane under static conditions at lower temperatures (see Table 1), with analysis of the nitroethane by infrared spectroscopy. The temperature dependence of the rate constants obtained both under static and flow conditions (up to 442°C) are well described by a single Arrhenius' equation $k = 10^{10.83} \exp(-39\,700/RT)$ s^{-1}, with an activation energy almost equal to that determined by Gray. The same activation energy was found by Geiseler and Reinhardt[7] under flow conditions at 380–470°C.

Wilde considers that the high yield of ethylene combined with the low activation energy can be explained only within the framework of the Cottrell molecular mechanism, which (at least, up to 450°C) is the predominant path for the decomposition of nitroethane. Actually not one of the schemes including the primary decomposition of nitroethane at the C–N bond with subsequent formation of ethylene by the reaction:

$$C_2H_5 + NO_2 \rightarrow C_2H_4 + HNO_2 , \quad (25)$$

or

$$C_2H_5NO_2 \rightarrow C_2H_4NO_2 + HNO_2 , \quad (26)$$

$$C_2H_4NO_2 \rightarrow C_2H_4 + NO_2 , \quad (27)$$

can explain the low activation energy.

The low value of the pre-exponential factor ($\sim 10^{11}$ s^{-1}) also agrees well with this mechanism, as the most frequent reason for a low pre-exponential factors is[35,36] the formation of a cyclic transition state in which one or more internal rotational degrees of freedom are inhibited.

The existence of free radicals, observed by Gray at temperatures above 500°C and the formation of such products as CH_2O, CH_3CHO, HCN, CH_4, CO, and CO_2 cannot be explained without reference to free-radical processes. Wilde therefore suggests that part of the nitroethane decomposes by a radical mechanism (Gray's scheme), the fraction of which rises with the temperature. From Wilde's results, the decomposition at the C–N bond begins to affect significantly the total reaction rate for the decomposition at ~ 450°C. Consequently, at temperatures above 450°C a change in the mechanism of decomposition of nitroethane should occur.

To check this conclusion, Wilde investigated the decomposition of nitroethane at 400–525°C under flow conditions at contact times of 0.1–1 s.[21] Despite the high accuracy of the experiments it was found that the reaction obeys the first-order equation and the activation energy is 60.6 ± 5 kcal, that is, close to the energy of dissociation of the C–N bond in nitroethane. The same products were found qualitatively as were observed at low temperatures: ethylene, nitrogen monoxide, and formaldehyde.

Wilde considers that the high activation energy can be explained either within the framework of a non-chain radical decomposition:

$$C_2H_5NO_2 \rightarrow C_2H_5 + NO_2 , \quad (17)$$

$$C_2H_5 + NO_2 \rightarrow C_2H_5O + NO. \quad (19)$$

$$C_2H_5O \rightarrow CH_3 + CH_2O , \quad (20)$$

$$CH_3 + NO \rightarrow HCN + H_2O , \quad (8)$$

$$C_2H_5 + NO_2 \rightarrow C_2H_4 + HNO_2 , \quad (25)$$

$$2HNO_2 \rightarrow H_2O + NO + NO_2 , \quad (28)$$

or by a chain process:

$$C_2H_5NO_2 \rightarrow C_2H_5 + NO_2 , \quad (17)$$

$$C_2H_5NO_2 + NO_2 \rightarrow C_2H_4NO_2 + HNO_2 , \quad (26)$$

$$C_2H_4NO_2 \rightarrow C_2H_4 + NO_2 , \quad (27)$$

for binary chain breaking (bimolecular decomposition of nitrogen dioxide or reaction of nitrogen dioxide with ethylene) should have an activation energy of ~ 50–55 kcal $mole^{-1}$.

A high value of the pre-exponential factor A found by experiment ($10^{17\pm1}$ s^{-1}) agrees best with a non-chain mechanism. Change of the molecular path of the decomposition to a radical one leading to a higher activation energy unavoidably suggests the existence of high values of A for stage (17). This conclusion can be easily correlated with theory[35–37] if it is assumed that in nitroethane rotation around the C–N bond is hindered. Many examples have shown that high pre-exponential factors in unimolecular reactions are observed when the initial state of the molecule has restricted internal rotational motion, which is freed in the formation of the transition complex. When a calculation was made (decomposition of C_2H_6 and N_2O_4) it was shown that replacement of the torsional vibrations by free internal rotation alone cannot give the experimentally observable increase in activation entropy and it is necessary to assume that a significant part is played by other types of motion (pronounced weakening of the deformation vibrations or even free three-dimensional rotation of the radicals in the activated molecule). Nitroethane is evidently not excluded from the general rule and the presence of a high pre-exponential factor in its decomposition is completely natural.

Similarly increased values of A can be expected for reactions of radical decomposition of any nitro-compounds having restricted rotation around the C–N bond.

The possible difference of 5–6 orders of magnitude between the pre-exponential factors of molecular and radical decompositions ensures successful competition for the latter at 400–450°C, even when the activation energy is 15–20 kcal $mole^{-1}$ greater than in molecular cleavage. In this connection a more careful study of the decomposition of nitroethane and other mononitro-compounds at high temperatures which would ensure the predominance of a radical mechanism, merits attention.

The decomposition of 1- and 2-nitropropanes at temperatures below 450°C proceeds as for nitroethane, according to a molecular mechanism[20]. The chief products are propene and nitrogen monoxide. The activation energy for the decomposition of 2-nitropropane is 39 kcal, and the pre-exponential factor has the diminished value of 10^{11} s^{-1}. 1-Nitropropane is characterised by a higher activation energy (Table 1) and the normal value of the pre-exponential factor. The last fact led Wilde to reject the mechanism of simple molecular elimination. Instead of it he advanced the hypothesis of the primary rearrangement of nitropropane with the formation of the *aci*-form:

$$CH_3CH_2CH_2NO_2 \rightarrow CH_3CH_2CH{=}NOOH ,$$

which is also the active species in the decomposition. Such explanation, in turn, seems improbable and hence the problem of the difference in the pre-exponential factor of 1-nitropropane from the corresponding values for the nitroethane and 2-nitropropane remains unsolved.

2-Nitropropane was studied in greater detail than 1-nitropropane. The rate of decomposition of this substance was determined by three methods—under static conditions using the yield of propene[23] and the change in total pressure[9], and also in flow from the decomposition of 2-nitropropane itself[20]. All three methods gave the same result (Table 1). Complete analysis of the decomposition products, carried out by Smith and Calvert[23] with the aid of mass spectrometry and gas chromatography, showed the considerable part played by side-processes in this reaction. At degrees of decomposition from 4 to 55% it was found that propene, nitric oxide, and water are formed in approximately equivalent amounts and constitute 65–75% of the total quantity of products. Acetone, acetonitrile, and formaldehyde amounted to 25–15% and various nitroalkane hydrocarbons, carbon monoxide and dioxide, to ~ 10%. The addition of propene did not affect and the addition of nitric oxide increases the rate of decomposition and alters the composition of the products (the

yield of nitroalkanes and acetonitrile is increased). The addition of nitrogen dioxide at 250°C did not affect the decomposition rate. Increasing the S/V ratio 100 times (by packing the vessel with glass wool) leads to a considerable increase in the rate and a rise in the yields of acetone, acetonitrile, and water. The ratio C_3H_6/NO is almost independent of the experimental conditions. The yield of propene does not alter on adding nitric oxide or propene itself nor on altering S/V. These facts show the formation of propene by the reaction:

$$(CH_3)_2CHNO_2 \rightarrow CH_3CH=CH_2 + HNO_2 .$$

As regards other carbonaceous products their production is explained by the occurrence of side-reactions, which occur because of the presence of the hydroxyl radical:

$$HNO_2 \rightarrow OH + NO \quad (29)$$

$$OH + CH_3CHNO_2CH_3 \rightarrow H_2O + CH_3\dot{C}NO_2CH_3 \quad (30)$$

$$OH + CH_3CHNO_2CH_3 \rightarrow H_2O + CH_3CHNO_2\dot{C}H_2 \quad (31)$$

$$CH_3\dot{C}NO_2CH_3 \rightarrow CH_3COCH_3 + NO \quad (32)$$

$$CH_3CHNO_2\dot{C}H_2 \rightarrow CH_3CHNO + CH_2O \quad (33)$$

$$CH_3CHNO_2\dot{C}H_2 \rightarrow CH_3CH=CH_2 + NO_2 \quad (34)$$

$$CH_3CHNO \rightarrow CH_3CNOH \quad (35)$$

$$CH_3CNOH + NO \rightarrow CH_3CN + HNO_2 . \quad (36)$$

The ratio CH_3CN/CH_3COCH_3 increases with the temperature, as reaction (31) has a higher activation energy than (30).

The weak link in the above scheme is reaction (29). The decomposition of nitric acid according to Eqn. (29) requires an activation energy of 48 kcal mole^{-1} and evidently cannot compete with reaction (28). Moreover, the assumption that the decomposition of nitrous acid initiates side-processes in the molecular decomposition of nitroalkanes cannot explain two features—the influence of the surface on the rate and the comparatively high yield of the products of radical origin at low temperatures—which distinguish 2-nitropropane from nitroethane and 1-nitropropane.

It is possible that in the decomposition of 2-nitropropane, because of its considerable acidity, a significant part is played by processes (decomposition of ionised form and reaction with nitric oxide) taking place in layers adsorbed on the surface.

In connection with the molecular mechanism of decomposition of mononitroalkanes a consideration of these reactions from the standpoint of the general theoretical concepts of gas phase eliminations merits attention. The most significant achievement in this region is the introduction of the concept of quasiheterolytic reactions in the gas phase[34,38]. It was shown[34] that in a series of gas-phase reactions just the same effect of substituents on the rate is observed as in ionic reactions of elimination or substitution, taking place in polar solvents. Hence the conclusion was drawn that the transition state of such gas-phase reactions has a polar nature and the internal supply of electrons is the main factor which determines the decomposition rate. In quantity and direction of the action of the substituents two types of quasiheterolytic reactions are distinguished. Reactions of the first type, which include the elimination of hydrogen halides from alkyl halides, are similar to S_N1 and $E1$ liquid-phase reactions; the reactions of the second type, represented by the elimination of alkenes from esters and alkyl vinyl ethers, are analogous to $E2$ reactions. Judging by the relative rates (Table 3) the decomposition of mononitroalkanes, at least in the quantitative respect, differs strongly from other eliminations in the gas phase. Nevertheless, from the standpoint of the polar nature of these reactions the nature of the change in activation energy in the series $C_2H_5NO_2$, n-$C_3H_7NO_2$, iso-$C_3H_7NO_2$ (39.7, 47.7, and 39.0 kcal mole^{-1} respectively) can be explained qualitatively. The value of the potential barrier for the detachment of HNO_2 from nitroalkanes $\epsilon_0 = E - Q$ (E is the activation energy, Q the heat of the process) varies symbathically with such properties as acidity or chemical shift of α-protons in the NMR spectra (Table 4), that is, it reflects the real change in the distribution of electron density in the molecule¶.

Table 3. Relative rates of reaction eliminations in the gas phase[34].

R	RCl	RBr	RNO_2^*	ROAc	HCO_2R	$ROCH{-}CH_2$
C_2H_5	1	1	1	1	1	1
n-C_3H_7	3.9	3.3	0.5	—	—	—
iso-C_3H_7	223	280	2.8	26	20	17

* The rates for the nitroalkanes were calculated from Wilde's results[20]. The temperatures of comparison were selected as for the alkyl halides[34].

Table 4. Correlation of the values of E and ϵ_0 with change in acidity and the chemical shift on the α-hydrogen atom.

Formula	E, kcal mole^{-1} (Ref.20)	Q^*, kcal mole^{-1}	ϵ_0, kcal mole^{-1}	pK	Chemical shift of α-H (in τ units) (Ref.42)
$C_2H_5NO_2$	41.4	16.1	25.3	8.49[39]	5.62
n-$C_3H_7NO_2$	47.7	14.6	33.1	8.98[40]	5.70
iso-$C_3H_7NO_2$	39.0	18.8	20.2	7.675[39]	5.42

* Data for the calculation taken from Refs.26 and 28.

The limited information does not allow more definite conclusions to be drawn about the nature of the molecular decomposition of mononitroalkanes, but undoubtedly these substances, being comparatively convenient for experimental investigation and exhibiting a great variety of structures, will merit attention as model compounds for studying gas-phase eliminations.

3. Chloropicrin

The first qualitative observation of the decomposition of chloropicrin CCl_3NO_2 was made in 1919 by Gardner and Fox[43]; on boiling (112°C), chloropicrin slowly decomposes into carbonyl chloride and nitrosyl chloride. In 1935 Rădulescu and Zamfirescu[3], using the method of titration of chloropicrin with permanganate, established the first order of the reaction for the decomposition and determined the rate constants at 130–160°C. Later[23] these results were used to estimate the activation energy, 40 kcal mole^{-1}.

¶ The reaction of nitrogen dioxide with an alkyl residue is evidently not limited solely to an induction mechanism. This is shown, for example, by the fine effects in the change in acidity of mono- and di-nitroalkanes[39-41]. It is easy to see that in the RX series, where X = Cl or Br (and the interaction of X with R is purely inductive), a linear relation is observed between ϵ_0 and Taft's induction constant σ^* of the group R.

In their detailed investigation of the decomposition of chloropicrin[23] Steacie and Smith found, with the aid of a manometric method, that the reaction proceeds homogeneously and is independent of P_0 in the range 60–200 mmHg. The decomposition products are carbonyl chloride, nitrosyl chloride, chlorine, and nitric oxide, the relative proportions of the last three compounds being close to equilibrium. Starting from these results a mechanism was proposed for the decomposition which included intramolecular rearrangement.

$$CCl_3NO_2 \rightarrow Cl_2CO + NOCl\,, \quad (37)$$

$$NOCl \rightleftarrows NO + {}^1/_2 Cl_2\,. \quad (38)$$

As, however, equilibrium (38) is established slowly (in the decomposition of chloropicrin to the extent of 50% there is 1% decomposition of the nitrosyl chloride at 160°C), to explain the observed composition of the products it was suggested that in stage (37) the activated molecule (NOCl*) is formed; this is rapidly decomposed into NO and Cl.

An analogous mechanism with primary decomposition of chloropicrin into carbonyl chloride, chlorine, and nitric oxide was proposed by Ashmore and Norrish[24].

In 1955, Gray[25] expressed the opinion that the decomposition of chloropicrin proceeds by a free radical mechanism and the first stage is the breaking of the C–N bond.

Gray's scheme:

$$CCl_3NO_2 \rightarrow CCl_3 + NO_2\,, \quad (39)$$

$$CCl_3 + NO_2 \rightarrow [CCl_3ONO] \rightarrow CCl_3O + NO\,, \quad (40)$$

$$CCl_3O \rightarrow Cl_2CO + Cl\,, \quad (41)$$

$$Cl + NO \rightleftarrows NOCl\,, \quad (42)$$

$$2Cl + M \rightarrow Cl_2 + M\,, \quad (43)$$

agree with all the experimental facts. The low value of the dissociation energy of the C–N bond, the value of which, according to the scheme, equals the activation energy of the decomposition can be attributed to the influence of three chlorine atoms[25]. In methane derivatives the introduction of electronegative substituents usually decreases the strength of the bonds[44]. This conclusion is indirectly confirmed by the force constant and frequency of the vibrations of the C–N bond in chloropicrin as compared with nitromethane (842 and 917 cm^{-1} respectively[45]).

The most convincing proof of the radical mechanism of the decomposition of chloropicrin gives an anomalously high value of its pre-exponential factor (Table 1). Only within the framework of the radical decomposition does this fact find a natural explanation (see p. 608). In rearrangements which include a cyclic transition state the pre-exponential factor can have only a normal or a low value.

Hence the replacement of hydrogen atoms in nitromethane by chlorine leads to a singificant decrease in the strength of the C–N bond and correspondingly to a very pronounced increase in the rate of decomposition. The mechanism of the first stage here remains unchanged but the secondary reactions in the case of chloropicrin are appreciably simpler and do not affect the initial state.

III. POLYNITRO-COMPOUNDS

Two of the polynitro-compounds (PNC) studied—2,2-dinitropropane (DNP)[4] and hexanitroethane (HNE)[5]—differ considerably in structure, decomposition rates, and the conditions under which their decomposition rates were studied. For these substances completely different mechanisms were proposed: breaking of the C–N bond and a chain process for DNP, and the formation of biradicals for HNE. Here, however, a situation analogous to that with chloropicrin is repeated. On closer examination it becomes almost certain that both substances have the same mechanism and decompose by a non-chain radical path with primary breaking of the C–N bond. Here the activation energy equals D(C–N).

1. 2,2-Dinitropropane

Fluornoy[4] studied the decomposition of DNP at 175–210°C by the ampoule method with mass spectroscopic analysis of the decomposition products. There are three initial products: acetone, nitric oxide, and nitrogen dioxide, which are formed in equivalent proportions. On increasing the extent of the decomposition the nitrogen dioxide concentration decreases rapidly (which is explained by its reaction with acetone) and carbon monoxide and dioxide and water appear. The rapid oxidation of acetone directly by nitrogen dioxide at temperatures above 100°C was shown in special experiments. At 2.3% decomposition the yield of nitrogen dioxide amounted to 75 mole % from the DNP and at 7.6% decomposition almost all the nitrogen of the products was found as nitric oxide. The decomposition of DNP proceeds homogeneously and the nature of the surface does not affect the reaction. The first-order rate constant is $3.2 \times 10^{18} \exp(-50\,500/RT)\ s^{-1}$.

Fluornoy considers that the decomposition of DNP starts with the breaking of the C–N bond, the strength of which should be less than in mononitro-compounds. The 2-nitropropyl radical formed in the first stage is converted into acetone, either on reaction with NO_2 with the intermediate formation of a nitro-nitrite:

$$(CH_3)_2\dot{C}NO_2 + NO_2 \rightarrow \left[O_2N{-}\overset{CH_3}{\underset{CH_3}{C}}{-}ONO \right] \rightarrow NO_2 + (CH_3)_2 + CO + NO \quad (44)$$

or intramolecularly according to (32), as Smith and Calvert assume (see p. 609). The direct unimolecular rearrangement of DNP into the nitro-nitrite is thought by Flournoy to be impossible owing to steric hindrance.

To explain the high pre-exponential factor, Flournoy suggested that in parallel with Eqn. (44) there is a reaction of the 2-nitropropyl radical directly with DNP:

$$(CH_3)_2\dot{C}NO_2 + (CH_3)_2C(NO_2)_2 \rightarrow (CH_3)_2C(NO_2)(ONO) + (CH_3)_2\dot{C}NO_2 \quad (45)$$

and hence the chain decomposition of the latter is effected. However, in the light of contemporary theory which allows the high value of A to be explained within the framework of a mechanism with breaking of a single bond (as occurs for nitromethane and chloropicrin) the hypothesis about chains is superfluous. Reaction (45) is evidently thermoneutral [$D(C{-}NO_2) \simeq D(C{-}ONO)$ [25]] and its activation energy should be not less than 10 kcal $mole^{-1}$. It is not known whether the 2-nitropropyl radical is removed by reaction with nitric oxide, but in the initial stages when there is a considerable concentration of nitrogen dioxide, reaction (45) cannot compete with (44) and the occurrence of the chain process is impossible.

We note that a high yield of acetone allows a molecular path for the decomposition of DNP to be excluded. Hence the change from mono- to *gem*-di-nitro-radicals is accompanied by a change in mechanism. The endothermicity of the reaction for loss of nitrous acid on going from 2-nitropropane to DNP can only decrease and even if it is assumed that the activation energy of the molecular decomposition is 15 kcal $mole^{-1}$ less than the strength of the

C–N bond (and the radical mechanism is affected only because of the high activation entropy), then $E \geqslant 35$ kcal mole^{-1} and the value of ϵ_0 (see p. 609) will be greater or equal to ϵ_0 for 2-nitropropane. The weakening of the C–N bond and the greater mobility of the β-hydrogen atom in *gem*-dinitro-compounds[46] should facilitate an increase in ϵ_0. As this does not take place, it can be assumed that the drop in electron density at the nitro-groups exerts an opposite effect and compensates the first two effects. A study of the decomposition of nitroalkanes of the type $RCH_2CH(NO_2)_2$ and $RCH_2C(NO_2)_3$ offers a further possibility of solving the problem of the competition of molecular and radical mechanisms.

2. Hexanitroethane

HNE is a strong oxidant and reacts with organic compounds of almost all classes[47]. Exceptions are hydrocarbons with branched chains and substances with a high concentration of halogens. A quantitative study of the decomposition was undertaken[5] for solid HNE and for dilute solutions (2×10^{-2}–4×10^{-2} M) in carbon tetrachloride, chloroform, perfluorokerosene, n-heptane, and cyclohexane. The reactions were observed by three methods: from the change in intensity of the absorption bands in the infrared spectra at 6.10 and 6.17 μm, from the yield of nitric oxide and dioxide, determined titrometrically, and manometrically from the increase in pressure of the decomposition products. All three methods give the same results. Tables 1 and 5 give the results on decomposition rates.

The agreement of the rates for decomposition in carbon tetrachloride, chloroform, and perfluorokerosene show the inertness of these solvents in relation to HNE. Hence the activation parameters found in carbon tetrachloride characterise the unimolecular decomposition of HNE. The decomposition in n-heptane and cyclohexane is considerably faster (and with a lower activation energy) than in inert solvents. This result is explained by the formation between HNE and the solvent of unstable molecular compounds of the charge-transfer complex type. Undoubtedly the aliphatic HNC exhibit electron acceptor properties, the strength of which increases with saturation of the molecule with nitro-groups. The idea of complex formation as a first stage in the interaction with different donors can play an important part in the study of the compatibility of PNC with other substances.

The decomposition of the HNE in the solid state proceeds more slowly than in inert solvents. The ratio of the constants k_{diss}/k_{solid} at 85°C is, according to Marshall and coworkers[5], 3.5; according to other results it is significantly greater, 56 (see Table 5). It should be noted that the accuracy of the determination of k_{solid} in this study[5] is somewhat doubtful. Thus the authors of this work write that the solid-state decomposition of HNE obeys a first-order equation. However, it is known that topochemical reactions never obey a first-order law and the reaction has to be accompanied by acceleration[48]. In this study[5] no information is given about the kinetics of the initial stage of the decomposition of HNE. Possibly acceleration of the reaction takes place in this stage and the value of k_{solid} corresponding to the initial rates will be less than that calculated[5]. Another reason for the differences in the available data can be the difference in the physical state and purity of the HNE specimens. The agreement of the activation energy in the decomposition of HNE in inert solvents and in the solid state suggests (by analogy with other instances[48] of the decomposition of solid organic substances) that the decomposition of HNE proceeds at places where there is pronounced strain in the ideal crystal lattice (surface micro-blocks, dissimilar type of defects) and the rate of reaction depends on the fraction of the molecules found at these points.

As noted by Marshall and coworkers[5], HNE itself is a fine model for investigating the regularity of the reactions of thermal decomposition of molecular crystals. The decomposition of HNE proceeds with an appreciable rate in the range of temperatures far from the melting point and is not accompanied by the formation of a liquid phase and condensed products, which could affect the reaction, by dissolving HNE or forming a new crystalline phase.

Table 5. Comparison of the rate constants (s^{-1}) for the decomposition of hexanitroethane in the solid state and in solutions.

t, °C	Solvent						
	without solvent	without solvent*	CCl_4	$CHCl_3$	perfluoro-kerosene	n-heptane	cyclo-hexane
85	$6.41 \cdot 10^{-6}$	$4 \cdot 10^{-7}$	$2.24 \cdot 10^{-5}$	$2.43 \cdot 10^{-5}$	—	$7.35 \cdot 10^{-5}$	$1.53 \cdot 10^{-4}$
100	$6.79 \cdot 10^{-5}$	$3.55 \cdot 10^{-6}$	$2.22 \cdot 10^{-4}$	—	$2.03 \cdot 10^{-4}$	$3.46 \cdot 10^{-4}$	$5.68 \cdot 10^{-4}$

* Private communication of Rosen cited in Ref.5.

The final products of the decomposition of HNE are nitrogen oxides and carbon oxides. Their composition corresponds approximately to the equation:

$$HNE \rightarrow 3NO_2 + NO + N_2O + 2CO_2,$$

and the rate of formation equals the rate of decomposition of HNE. The absence of information on the structure of the intermediate products does not permit any judgement about the secondary reactions, as a result of which the HNE molecule is destroyed. As possible primary stages of the decomposition two processes were proposed, including the simultaneous breaking of two nitro-groups

$$HNE \rightarrow (O_2N)_2\dot{C}-\dot{C}(NO_2)_2 + 2NO_2 \quad (46)$$

$$HNE \rightarrow (O_2N)_3C-\dot{C}(NO_2) + 2NO_2, \quad (47)$$

since the decomposition of the molecule into three species could explain the high values of the activation entropy. However, reactions (46) and (47) are no less than 10 kcal mole^{-1} more endothermic than the simple breaking of a single bond

$$HNE \rightarrow (O_2N)_3C\dot{C}(NO_2)_2 + NO_2 \quad (48)$$

and their occurrence is possible only for a considerably greater (by at least four orders of magnitude) pre-exponential factor. All this suggests that reaction (48) is the most probable primary act of decomposition of HNE. A conclusive solution of the problem is possible only on studying and comparing the decomposition of other PNC and determining the energy of the C–N bond in polynitro-derivatives of methane and ethane.

The problem of finding the energies of breaking of C–N bonds in aliphatic PNC has real prospects of solution in the study of thermal decompositions and makes it desirable to carry out further work to explain the mechanism of the decomposition of typical representatives of PNC of various structures. In experimental respects a study of these reactions should evidently not present great difficulty, since it can be expected that characteristic signs of the decomposition processes are general for DNP and HNE: the

combination of comparatively low activation energies with high pre-exponential factors, and in consequence the moderate decomposition temperatures at which nitrogen monoxide and dioxide found in the reaction products do not react with the initial components, do not inhibit chain processes, ensuring the unimolecularity of the process even under static conditions, the speed of the secondary reactions and the possibility of using a manometric method, is retained also for other nitro-compounds with a geminal distribution of the nitro-groups.

Catalysis of Isotope Exchange in Molecular Oxygen and Its Application to the Study of Catalysts

G.K.Boreskov and L.A.Kasatkina

Problems related to the kinetics and mechanism of isotope exchange in molecular oxygen on solid catalysts are reviewed. Experimental data on the homomolecular exchange of oxygen on oxides and metals are reported. The relationship between the catalytic activity of oxides towards oxygen exchange and their activity towards other oxidation reactions is discussed. It is pointed out that studies of isotope exchange reactions of molecular oxygen should prove useful in elucidating the nature of intermediate entities during the interaction of oxygen with a catalyst surface. The activity towards exchange can be used as a characteristic of general oxygen reactivity, and rules for the choice of oxidation catalysts can be based on it.

I. INTRODUCTION

The exchange of atoms between oxygen molecules (homomolecular isotope exchange)

$$^{16}O_2 + {}^{18}O_2 = 2{}^{16}O{}^{18}O \qquad (1)$$

is the simplest chemical reaction which oxygen can undergo. This provides a very convenient model reaction for investigating the rules which control the choice of catalysts, since it is not accompanied by changes in the chemical composition of the reaction mixture. The features of the homomolecular isotope exchange reactions provide information on the nature of the oxygen bond on the catalyst surface and can be useful in explaining the mechanism of catalytic oxidation reactions. The analogous isotope exchange reaction in molecular hydrogen has been the object of a large number of investigations, and has played an important role in elucidating the mechanism of catalytic hydrogenation reactions.

Studies of homomolecular exchange in oxygen began relatively recently. The first results for this reaction on magnesium and zinc oxides[1] were published by Winter as recently as 1954; this paper was followed by a paper relating to some other oxides[2]. The early results were reviewed by Winter[3], and compared with data on the rate of isotope exchange between molecular oxygen and the oxygen from the oxides, the rate of adsorption and the catalytic activity towards the oxidation of CO and the decomposition of N_2O. In later years, a great deal of work on homomolecular exchange in oxygen was published by Soviet scientists[4-32]. Foreign workers also are active in this field[33-37].

The present review attempts to generalise the results obtained so far and to consider the various possible relationships between the activity of catalysts towards homomolecular oxygen exchange and their activity towards other oxidation reactions, involving the transfer of oxygen atoms between reactant molecules.

II. KINETICS OF ISOTOPE EXCHANGE IN MOLECULAR OXYGEN

1. Method of Investigation

The course of reaction (1) is monitored mass-spectrometrically from the change in the intensity ratio of the peaks corresponding to masses 32 ($^{16}O_2$), 34 ($^{16}O^{18}O$), and 36 ($^{18}O_2$). Winter[3] worked with a static system, taking a continuous leak of a very small fraction of the reaction mixture to the mass spectrometer tube through a fine capillary. Some workers have sampled the gas for isotopic analysis at intervals, by means of ampoules removed from the apparatus and transferred to the mass spectrometer. To avoid the possibility of diffusion-controlled steps at high rates of exchange it is desirable to work with a circulating system[6].

Isotope exchange in molecular oxygen has been studied mainly on oxides[1-4,6-10,33,34], and less extensively on metals[4,5,11,20-22,35,36]. With oxides, exchange between molecular oxygen and oxygen from the oxide is possible as well as homomolecular exchange. In most of the work on the isotope exchange of molecular oxygen on oxides, conditions were such that the concentrations of ^{18}O in the solid (α_s) and in the gas (α) were equal. Some workers[9,19,28,34] studied exchange in molecular oxygen under conditions of simultaneous isotope exchange between the oxygen in the oxide and in the gas phase.

2. Kinetics of Isotope Exchange in Molecular Oxygen in the Absence of Isotope Exchange with the Catalyst

The kinetics of homomolecular oxygen exchange are described in this case ($\alpha_s = \alpha$) by a first-order equation. For

example, the change in the concentration of $^{16}O^{18}O$ molecules is

$$\frac{dC_{34}}{d\tau} = Z\frac{S}{N_g}(C_{34}^* - C_{34}) = k(C_{34}^* - C_{34}) \quad (2)$$

where Z is the total number of oxygen molecules, whatever their isotopic composition, which exchange atoms per unit time and unit catalyst surface, in molecules cm^{-2} s^{-1}; N_g is the total number of oxygen molecules in the gas phase; S is the surface area of the catalyst in cm^2; τ is time in s; C_{34}^* and C_{34} are the fractional numbers of $^{16}O^{18}O$ molecules at equilibrium and at time τ respectively. Integration of Eqn. (2) gives

$$k = \frac{1}{\tau}\ln\frac{C_{34}^* - C_{34}^0}{C_{34}^* - C_{34}} \quad (2a)$$

where C_{34}^0 is the fraction of $^{16}O^{18}O$ molecules at zero time.

Eqn. (2) is valid for any exchange mechanism[38]. The influence of the mechanism is manifest only in the dependence of the total number Z of exchanges upon the oxygen pressure P_{O_2} and the temperature T.

3. Kinetics of Exchange in Molecular Oxygen with Simultaneous Isotope Exchange with the Oxygen of the Catalyst

To elucidate the details of the exchange mechanism, it is often helpful to measure simultaneously the rates of exchange in molecular oxygen and of isotope exchange with the oxygen of the catalyst. In this case $\alpha \neq \alpha_s$, and the kinetics of the exchange become more complex.

Isotope exchange with the oxygen of the catalyst (for example, an oxide) includes dissociative adsorption with formation of adsorbed atoms or atomic ions, exchange of these adsorbed species with oxygen ions from the oxide, and desorption in the form of molecules[7].

The change in concentration of ^{18}O in the gas phase due to exchange with the oxygen of the catalyst is described by the equation

$$-\frac{d\alpha}{d\tau} = R\frac{S}{N_g}(\alpha - \alpha_s) = R'(\alpha - \alpha_s) \quad (3)$$

or, in the integral form,

$$R' = \frac{N_s}{N_g + N_s}\frac{1}{\tau}\ln\frac{\alpha^0 - \alpha^*}{\alpha - \alpha^*} \quad (3a)$$

Here R is the total number of exchanges between oxygen from the oxide and oxygen in the gas phase, in molecules cm^{-2} s^{-1}; N_s is the amount of accessible oxygen in the oxide (number of molecules); α^0, α^*, and α are the fractional amounts of ^{18}O at zero time, at equilibrium, and at time τ respectively.

The kinetics of exchange in molecular oxygen occurring simultaneously with isotope exchange with the oxygen of the catalyst have been considered in detail by Musykantov and coworkers[18]. Three kinetically different variants are possible.

1. Isotope exchange in molecular oxygen [reaction (1)] occurs without involving the oxygen of the catalyst. In this case $d\alpha/d\tau = 0$, and the change in concentration of $^{16}O^{18}O$ molecules is described by Eqn. (2).

2. Exchange in molecular oxygen involves one atom of oxygen from the catalyst. In this case

$$-\frac{d\alpha}{d\tau} = {}^1/_2 k_2(\alpha - \alpha_s) \quad (4)$$

and

$$\frac{dC_{34}}{d\tau} = k_2[\alpha(1-\alpha_s) + \alpha_s(1-\alpha) - C_{34}]. \quad (5)$$

3. Exchange in molecular oxygen involves two atoms of oxygen from the catalyst. In this case

$$-\frac{d\alpha}{d\tau} = k_3(\alpha - \alpha_s) \quad (6)$$

and

$$\frac{dC_{34}}{d\tau} = k_3[2\alpha_s(1-\alpha_s) - C_{34}]. \quad (7)$$

If the exchange occurs by all three mechanisms at the same time,

$$-\frac{d\alpha}{d\tau} = \left(\frac{k_2}{2} + k_3\right)(\alpha - \alpha_s) = R'(\alpha - \alpha_s) \quad (8)$$

$$\frac{dC_{34}}{d\tau} = k_1[2\alpha(1-\alpha) - C_{34}] + k_2[\alpha(1-\alpha_s) + \alpha_T(1-\alpha) - C_{34}] + k_3[2\alpha_s(1-\alpha_s) - C_{34}] \quad (9)$$

where $k_1 = Z_1S/N_g$, $k_2 = Z_2S/N_g$, $k_3 = Z_3S/N_g$, and Z_1, Z_2, Z_3 are the numbers of oxygen molecules (molecules cm^{-2} s^{-1}) which exchange atoms by the corresponding mechanisms.

Eqn. (9) can be recast[18] by inserting the value of α_s from Eqn. (8) and introducing the new variable

$$y = 2\alpha(1-\alpha) - C_{34} = C_{34}^* - C_{34}.$$

The physical significance of this variable is that of a driving force for the isotope exchange between oxygen molecules. In the absence of isotope exchange with the oxygen of the catalyst, the fractional change in the number of molecules would be proportional to y.

With this substitution, Eqn. (9) can be written in the form

$$\frac{dy}{d\tau} = -ky + \varphi\left(\frac{d\alpha}{d\tau}\right)^2 \quad (10)$$

where

$$\varphi = \frac{8k_3}{(k_2 + 2k_3)^2} \text{ and } k = k_1 + k_2 + k_3.$$

To solve the resulting system of differential equations we must know the variation of α_s with time of exchange. This variation can be quite complicated, because it is determined not only by the rate of exchange of surface oxygen atoms from the catalyst but also by the rate of diffusion of atoms which have been exchanged into the bulk of the catalyst. In its general form, the problem is soluble only in some special cases[18].

Generally speaking, the exchange constants k_1, k_2, k_3 can be evaluated by means of the differential equations (8) and (9) from experimentally found values of $d\alpha/d\tau$ and $dC_{34}/d\tau$ at different times. Reliable results can be obtained in this way only from a large number of measurements, which must be of the highest precision.

To characterise the role of the individual mechanisms, it is desirable to work with catalyst samples containing very small amounts of ^{18}O, whilst ensuring a high total concentration of this isotope in the molecular oxygen. Fig.1 shows the curves for the change in isotopic composition of the molecular oxygen, assuming different exchange mechanisms, for the case of $\alpha_s \ll \alpha$. If the concentration of the ^{18}O isotope in the enriched oxygen (from which the reaction mixture is prepared by dilution with ordinary oxygen) is in excess of 50%, we have $\alpha^0 > C_{34}^0$ at zero time. Hence it

is possible to identify the predominant exchange mechanism by the following qualitative rules:

a) if $\left(\frac{d\alpha}{d\tau}\right)_{\tau=0} = 0$, and $\left(\frac{dC_{34}}{d\tau}\right)_{\tau=0} > 0$, exchange occurs by mechanism *1*;

b) if $\left(\frac{d\alpha}{d\tau}\right)_{\tau=0} < 0$, and $\left(\frac{dC_{34}}{d\tau}\right)_{\tau=0} > 0$, mechanism *2* predominates;

c) if $\left(\frac{d\alpha}{d\tau}\right)_{\tau=0} < 0$, and $\left(\frac{dC_{34}}{d\tau}\right)_{\tau=0} < 0$, exchange occurs by mechanism *3*.

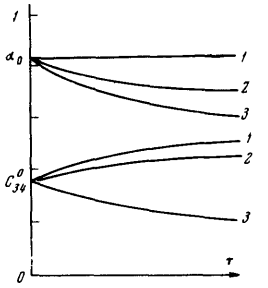

Figure 1. Change in isotopic composition of molecular oxygen for the different mechanisms of exchange. The numbers on the curves denote the exchange mechanism

Evidence for the third mechanism is provided also by a change in the ratio of the isotopic oxygen molecules (initially in homomolecular equilibrium) during exchange with oxygen from the oxide. If the exchange involves only the second mechanism ($k_3 = 0$), the homomolecular exchange equilibrium

$$\beta = \frac{C^2_{34}}{C_{32}\ C_{36}} = 4$$

will not be disturbed. Thus, if $k_3 = 0$, it follows that $\varphi = 0$, and from Eqn. (10) $dy/d\tau = 0$ under homomolecular equilibrium ($y = 0$).

Non-constancy of β during exchange is evidence that the exchange is occurring by the third mechanism.

All these conclusions involve the assumption of a uniform catalyst surface in respect of oxygen exchange. If the surface is not uniform, the constants k_1, k_2, and k_3 will vary from point to point on the surface. However, since exchange in this case will be confined to the most active regions of the surface, we can evaluate approximate exchange constants for these regions from experimental data for very small values of τ and $\alpha_s \ll \alpha$.

III. EXPERIMENTAL DATA ON ISOTOPE EXCHANGE IN MOLECULAR OXYGEN ON SOLID CATALYSTS

1. Catalytic Activity of Oxides

The influence of the conditions of pretreatment of oxides on their catalytic activity towards homomolecular oxygen exchange was first pointed out in Winter's review[3]. More recent work[14,16,24,29,31,33] has shown that in some cases the activity is greatly increased by a preliminary vacuum activation at high temperature, whereas oxygen treatment at high temperatures causes a sharp fall in activity. Some oxides showed differences in activity of several orders after different treatments. Since the change in activity caused by pretreatment under different conditions is evidently associated with a change in the oxygen content, it is desirable to compare the catalytic activity of the various oxides under two different headings: samples which have been treated in oxygen at a temperature high enough to ensure equilibrium composition of the surface layer, and samples having a non-equilibrium oxygen concentration in the surface layer.

2. Oxides with Equilibrium Oxygen Concentration in the Surface Layer

The main results (published since 1958) on the catalytic activity of oxides of equilibrium composition towards the isotope exchange reaction in molecular oxygen are summarised in Table 1. For comparison, the activity of platinum is also given in the Table.

Table 1. Kinetic characteristics of homomolecular exchange reactions of O_2 on various catalysts

* For MgO and γ-Al_2O_3 at 300°C and 10 mmHg, for the rare-earth oxides at 370°C and 20 mmHg, for the other catalysts at 300°C and 40 mmHg.

The oxides examined usually had a steady activity towards homomolecular exchange in oxygen, with the exception of NiO and CuO whose activity gradually fell to a stable value in 1–2 days[8]. Evidently, the conditions of treatment adopted had failed to ensure an equilibrium oxygen content in the surface layer of these oxides, and the achievement of phase equilibrium continued during the measurements of homomolecular oxygen exchange. The values listed in Table 1 refer to the stable activity of these oxides. The temperature dependence of the rate of exchange for a

series of oxides of the fourth period of the Periodic Table is shown in Fig. 2.

Some of the data listed in Table 1 differ from the results obtained by other workers. Thus, the rate of exchange observed by Winter[2] on NiO (from the carbonate) was approximately 100 times lower, and the activation energy was higher (35 kcal mole^{-1}). These discrepancies are probably due to different amounts of excess oxygen in the samples.

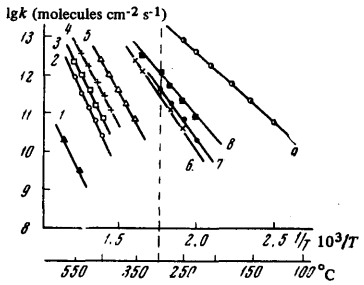

Figure 2. Temperature dependence of the rate of exchange of molecular oxygen on the oxides of metals from the fourth period: *1*) TiO_2; *2*) V_2O_5; *3*) Cr_2O_3; *4*) ZnO; *5*) Fe_2O_3; *6*) CuO; *7*) NiO; *8*) MnO_2; *9*) Co_3O_4.

The rate of exchange on Fe_2O_3 according to Winter[2] is close to the value given in Table 1, but the activation energy (19.2 kcal mole^{-1}) and the kinetic order with respect to oxygen (~ 1) are substantially different. According to Sazonov and coworkers[31], the activity of CeO_2 is approximately 40 times lower, and that of Gd_2O_3 4–8 times higher than Minachev and Antoshin's values[28], the activation energies being 31 and 10 kcal mole^{-1} respectively. These differences may be associated with the preparative conditions of the oxides. Sazonov and coworkers[27] studied the exchange in molecular oxygen on neodymium oxide, and found that the activity can vary by about an order of magnitude depending on the preparation and treatment conditions of the catalyst ($E = 30$ kcal mole^{-1}). The effect of the activation conditions on the catalytic activity towards homomolecular oxygen exchange, associated with a change in the oxygen content of the oxide, has been reported also for manganese dioxide[23].

Isotope exchange in molecular oxygen on oxides with an equilibrium oxygen concentration in the surface layer takes place in the temperature range where the surface oxygen has sufficient mobility and is able to exchange with the gas phase.

As regards their behaviour towards isotope exchange with the gas phase, the oxides investigated can be classified into the following groups.

1. Oxides in which the whole of the oxygen is equivalent. (The mobility of the oxygen in the lattice is greater than the rate of exchange with the gas phase.) This group includes V_2O_5,[39,40] CeO_2 [41] (oxygen diffusion in the CeO_2 lattice begins to affect the rate of exchange only above 440°C)[31], and MoO_3.

2. Oxides in which the surface oxygen has uniform mobility but exchange with the underlying layers of lattice oxygen is diffusion-limited. This group includes Fe_2O_3,[8,42] ZnO, Cr_2O_3,[8] Al_2O_3,[24] and the rare-earth oxides[41].

3. Oxides in which the surface oxygen is non-uniform towards isotope exchange with the gas phase. These are MnO_2,[42,43] Co_3O_4, NiO, and CuO.[8,42]

As an example, Fig. 3 shows the variation in the exchange rate as the fraction of exchangeable oxygen on the surface of MnO_2 is increased[23]. It is interesting to note that higher activation temperatures, which increase the activity of manganese dioxide towards oxygen isotope exchange, decrease the degree of non-uniformity of the surface oxygen. On raising the temperature of exchange the non-uniformity of the surface oxygen decreases.

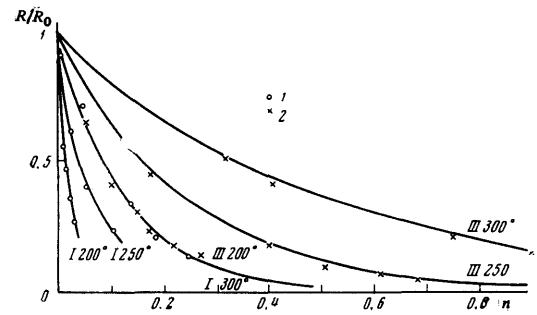

Figure 3. Decrease in the rate of exchange between O_2 and manganese dioxide with increase in the fraction of surface oxygen exchanged. The heat treatment temperatures were 350°C for preparation *I* (points *1*) and 550°C for preparation *III* (points *2*).

The NiO preparation investigated by Keier[44] showed uniformity of the surface oxygen, in contrast to the findings of other workers[8,42].

Winter[3] had noticed that on Cr_2O_3, NiO, and Fe_2O_3 the rates of exchange in molecular oxygen (Z) and of isotope exchange with the oxygen of the oxide (R) are closely similar. Subsequent work confirmed[8] that this behaviour is characteristic of all the oxides in which the equilibrium oxygen concentration is present. Results obtained[8] for transition metal oxides of the fourth period are listed in Table 2. The identity of the rates for the processes under discussion is particularly striking with the oxides in which the surface oxygen is uniform for isotope exchange with the gas phase (V_2O_5, Cr_2O_3, ZnO, Fe_2O_3). With these oxides the experimental values of the heteromolecular and homomolecular exchange rates agree within the limits of the inequality $R \leqslant Z \leqslant 2R$.

The rates of the exchange processes are more difficult to compare when the surface oxygen of the oxide is non-uniform and the rate of isotope exchange is lowered by confining the reaction to a monolayer. In this case the rate of exchange in molecular oxygen should coincide with the maximum initial rate of isotope exchange with the surface oxygen of the catalyst. Fig. 4 shows experimental results, obtained[23] on MnO_2, which support this argument. With Co_3O_4 a reliable determination of the initial rate of heteroexchange proved impossible.

Satisfactory agreement between the rates of hetero- and homo-molecular exchange was obtained also for the oxides CeO_2, Cd_2O_3, and Nd_2O_3.[27,31]

Several workers have examined the effect of various additives known to influence the semiconducting properties of the oxides on the rate of isotopic oxygen exchange.

Winter[2] studied oxygen exchange on NiO containing oxides of lithium, silver, and tungsten, and observed a rather weak correlation between the nature of the added oxide and the resulting change in rate. This may have been due to incomplete dissolution of the dopant at the low firing temperature used (650°C). According to Keier[44], the addition of 0.8 at. % of Li to NiO increased the exchange rate by a factor of 7–8 whilst the electrical conductivity rose by 5 orders of magnitude. The effect of the temperature at which the impurities are added to NiO was investigated by Gorgoraki and coworkers[29], who found that Li and In impurities added to NiO at 800°C had practically no effect on the activation energy: with the addition of lithium the reaction rate increases, but with the addition of indium it remains practically unaffected. Increasing the firing temperature of the preparation containing indium from 800° to 1200°C led to a sharp drop in reaction rate, possibly as a result of more complete dissolution of the impurity. Raising the firing temperature of pure NiO from 800° to 1200°C causes a slight drop in rate and an increase in the apparent activation energy of the exchange reaction.

Table 2. Comparison between rates of exchange in molecular oxygen and rates of isotope exchange with the oxygen of the oxide.

Oxide	Temp., °C	Rate of exchange, molecules $cm^{-2}\ s^{-1} \times 10^{-11}$	
		in molecular oxygen	with the oxygen of the oxide
V_2O_5	550	13.6	13.1
	550	2.4	1.7
Cr_2O_3	525	16.7	16.7
	400	0.31	0.63
ZnO	500	29.0	15.0
Fe_2O_3	400	6.8	4.7
NiO	300	6.8	6.8
CuO	300	5.7	4.7
MnO_2	300	21.0	25.0
	250	3.2	3.1

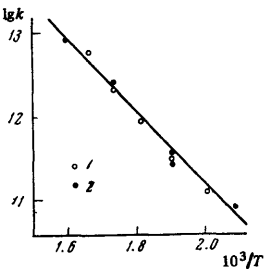

Figure 4. Comparison of the rates of exchange in molecular oxygen with the initial rates of exchange between O_2 and MnO_2: *1*) exchange in molecular oxygen; *2*) exchange with the oxygen of the oxide.

Gorgoraki and coworkers[12,13,45] studied the effect of Li, Ga, and In impurities on the activity of ZnO. Additions of lithium were found to increase the activity, whereas indium and gallium additions lowered it.

Margolis and Kiselev[5] studied the effect of adding the oxides Cr_2O_3, Bi_2O_3, and Li_2O to copper oxide.

Alkali metal sulphates are used as promoters in a variety of industrial vanadium catalysts[46]. Studies of the effect of alkali metal salts on the activity of V_2O_5 towards the isotope exchange of oxygen have shown that the mobility of oxygen in vanadium pentoxide is appreciably raised by alkali metal compounds[6,34,47-49]. As in the case of V_2O_5, volume diffusion of oxygen in the bulk of the promoted catalysts is much faster than the surface exchange. It is interesting to note that the promoted samples show very fast oxygen exchange not only of the vanadium pentoxide, but also of the impurity, whereas the oxygen of alkali metal salts does not in any way exchange with molecular oxygen under comparable conditions. The rates of hetero- and homo-molecular oxygen exchange on promoted vanadium pentoxide catalysts were found to be very similar[6].

Kasatkina and Antoshin[15] studied the isotope exchange between O_2 and CO_2 molecules and the heteroexchange of MnO_2 with O_2 and CO_2 on manganese dioxide which had been activated in a vacuum at 350°C. They found that the exchange of oxygen atoms between CO_2 molecules on the surface of manganese dioxide is much faster than reaction (1). The oxygen of MnO_2 proved to be very non-uniform towards exchange with CO_2: the first experimental points were obtained at extents of exchange of 8–16% of a monolayer, at which the rate of exchange is several times lower than the maximum. Later work from the same laboratory[23] showed that the rate of exchange of CO_2 with MnO_2, like the rate of exchange of O_2 within the limits of a monolayer, decreases exponentially as the extent of exchange increases. The initial rates of exchange of oxygen between CO_2 and MnO_2 calculated from the exponential law were identical to the rate of isotope exchange in molecular CO_2. The rate of isotope exchange between O_2 and CO_2 was much lower than the rate of isotope exchange between CO_2 and MnO_2, and was somewhat lower than (but of the same order as) the rate of exchange between O_2 and MnO_2. These results justify the conclusion that exchange between O_2 and CO_2 occurs through the exchange of these gases with the oxygen of the manganese dioxide surface, and that the exchange of molecular oxygen is the rate-limiting step.

Kiyoura[50] subsequently arrived at the same conclusions by studying the exchange between O_2 and CO_2 on the oxides TiO_2, V_2O_5, Cr_2O_3, Fe_2O_3, NiO, MnO_2, and Co_3O_4 at 150–600°C. On all these oxides the rate of exchange decreased in the sequence: CO_2–oxide > O_2–oxide > O_2–CO_2 (on the oxide).

Exchange between CO_2 and O_2 was observed only when exchange between molecular oxygen and the oxide was possible.

3. Basic Features of Exchange in Molecular Oxygen on Oxide Catalysts with Equilibrium Oxygen Content

a. Exchange mechanism. In view of the close similarity between the rates of homomolecular oxygen exchange and of isotopic exchange with the oxygen of the oxide, we may conclude that the simplest catalytic reaction—isotope exchange in molecular oxygen—occurs with participation of the oxygen from oxides with an equilibrium oxygen content. If the oxide has a uniform surface, the whole of the surface oxygen takes part in the reaction, but if the oxide surface is non-uniform, only the most active ("mobile") oxygen atoms are involved. Hence, of the possible exchange mechanisms discussed above, mechanism *1* is excluded for oxides with an equilibrium oxygen content. It is harder to establish whether isotope exchange in molecular oxygen occurs on these oxides by mechanism *2* or

by mechanism *3*, that is, whether one or two oxygen atoms from the catalyst are involved. The problem may be solved using an analysis of the exchange kinetics for the various mechanisms given above (p. 614).

Dzisyak and coworkers[8] have established qualitatively, from the time-changes of the quantity C_{34}/C_{36}, that exchange on V_2O_5 and on V_2O_5 doped with alkali metal sulphates occurs mainly with the participation of two oxygen atoms from the catalyst. Jiru and Novakova[34] independently reached the same conclusion for those catalysts.

Muzykantov and coworkers[19] quantitatively assessed the rates of exchange on V_2O_5 by different mechanisms by studying the exchange between V_2O_5 and oxygen of normal isotopic composition ($y_0 = 0$). They observed the change in the value of y with time of exchange (Fig. 5*a*), and found that y goes through a maximum when plotted against τ. By measuring $dy/d\tau$ at $\tau = 0$ and y_{max} from the experimental curves, the values of k_3 and k can be calculated[18]. Thus, substituting into Eqn. (10) the value of $d\alpha/d\tau$ from Eqn. (3), and assuming $y_0 = 0$, we obtain

$$k_3 = \frac{\left(\frac{dy}{d\tau}\right)_{\tau=0}}{2(\alpha^0 - \alpha^*)^2}\left(\frac{N_s}{N_g + N_s}\right)^2.$$

At the maximum, $dy/d\tau = 0$, and

$$k = \frac{\left(\frac{dy}{d\tau}\right)_{\tau=0}}{y_{max}\, e^{2r\tau}}, \text{where } r = \frac{N_g + N_s}{N_g N_s} SR.$$

Table 3. Homomolecular exchange of oxygen with simultaneous heteromolecular exchange between O_2 and V_2O_5.

Temperature, °C	p_{O_2}, mmHg	y_{max}, %	τ_{max}, min	R, molecules cm^{-2} s^{-1}	Z_3, molecules cm^{-2} s^{-1}	Z_3/Z
450	11	—	—	$4.6\cdot10^8$	$4.6\cdot10^8$	—
462	11	—	—	$1.1\cdot10^9$	$1.1\cdot10^9$	—
475	11	5.5	620±40	$1.9\cdot10^9$	$1.9\cdot10^9$	0.9—1.0
483	11	5.3	400±30	$2.5\cdot10^9$	$2.4\cdot10^9$	0.7—0.8
500	11	5.5	200±20	$5.1\cdot10^9$	$5.1\cdot10^9$	0.9—1.0
500	31	5.5	400±30	$7.8\cdot10^9$	$7.8\cdot10^9$	0.9—1.0
500	46	5.4	470±30	$9.6\cdot10^9$	$9.6\cdot10^9$	0.9—1.0

The results of this work are set out in Table 3. We can see that $Z_3 = R = Z$, i.e. $Z_2 = 0$ and $Z_1 = 0$, and therefore the exchange between molecular oxygen and the oxygen of vanadium pentoxide consists in the replacement of two atoms from the gas-phase molecule undergoing exchange by two atoms from the surface layer of the oxide. The observed rate of exchange is equal to the rate of the reversible surface dissociation of the oxide with formation of molecular oxygen.

Minachev and Antoshin[28] also observed, for all the oxides of the rare-earth elements except thulium and lutetium oxides, a departure from equilibrium in the gas phase during exchange with oxygen of equilibrium isotopic composition. Therefore, on these oxides also, exchange in molecular oxygen mainly involves two atoms of oxygen from the oxide in the elementary exchange act. The values of R, calculated for various oxides from the variation of α with τ, and of k_3, from data on the variation of y with τ during exchange on the same oxides (Fig. 5*b*), are very similar.

An unambiguous choice between mechanisms *2* and *3* cannot yet be made for the majority of oxides, due to lack of sufficiently accurate data. However, the similarity between the rates of exchange in molecular oxygen and of isotope exchange with the oxygen of the oxide is evidence that exchange on oxides of equilibrium oxygen content involves the participation of oxygen from the oxide, and therefore the rate of exchange should be a function of the energy and of the nature of the oxygen bond in the surface layer of the oxide.

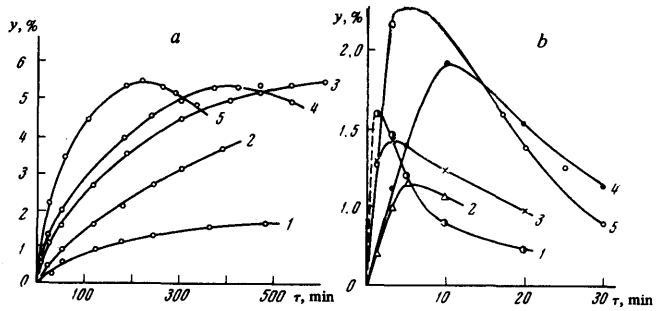

Figure 5. Variation of the quantity y with time of exchange; *a*) on V_2O_5 at 11 mmHg oxygen pressure, temperature (°C):
1) 450; *2*) 463; *3*) 475; *4*) 483; *5*) 500;
b) on rare-earth oxide at 370°C and 40 mmHg:
1) Nd_2O_3; *2*) Ho_2O_3; *3*) Dy_2O_3; *4*) CeO_2; *5*) CeO_2 (420°C).

b. Relationship between the catalytic activity towards exchange in molecular oxygen and other properties of the oxide. The oxygen bond energy in the surface layer of the oxide is uniquely determined by the electronic structure of the metal atom. Unfortunately, neither computational nor experimental methods of determining this energy are yet available. If, as a very rough approximation, the heat of formation per oxygen atom computed from thermodynamic data is used, the activation energy for the exchange reaction on oxides of metals from the fourth period is found to change monotonically with this quantity (see Fig. 6). The optimum bond energy corresponds to cobalt oxide, whereas in copper oxide the bond energy is apparently below the optimum.

On this basis, the study of oxides of metals from the fourth period can be divided into two groups. The oxides of the first group, including TiO_2, V_2O_5, Cr_2O_3, Fe_2O_3, and ZnO are characterised by a high bond energy, relatively low activity, and high activation energy for the exchange reaction. The kinetic order of the reaction with respect to oxygen is 0.6–0.8; the surface oxygen is uniform. All these oxides (except Cr_2O_3) are weakly semiconducting (*n*-type). The conductivity of chromic oxide is not yet clearly characterised: according to some measurements, this oxide exhibits *p*-type semiconductor properties after heat treatment in oxygen. For most of the oxides in this group, the number of electrons in the 3*d* shell of the cations corresponds to the most stable configuration: 0 for TiO_2 and V_2O_5, 5 for Fe_2O_3, and 10 for ZnO.

The second group comprises the oxides of lower oxygen bond energy: Co_3O_4, NiO, CuO, and MnO_2. On these oxides the exchange is fast, and is characterised by a low activation energy and a low pre-exponential factor. The order of the reaction is 0.3–0.4. The surface oxygen is not energetically uniform. The oxides of the second group,

on the whole, are *p*-type semiconductors of relatively high conductivity. The number of electrons in the 3*d* shell of the cations is 3 for MnO_2, 7 and 8 for Co_3O_4, 8 for NiO, and 9 for CuO.

The more active the oxide, the lower are the observed activation energy and pre-exponential factor. On going from the most active catalyst (Co_3O_4) to the relatively inactive V_2O_5, the activation energy increases by 30 kcal mole^{-1}, and the pre-exponential term increases by more than 4 orders of magnitude.

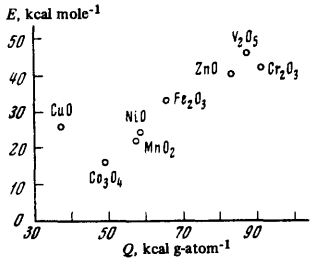

Figure 6. Correlation between the activation energy (E) for oxygen exchange on the oxides of fourth period metals and the heat of formation (Q) of the oxide referred to 1 g-atom of oxygen.

Winter noted breaks in the linear Arrhenius plots for the isotope exchange of oxygen with MgO [51] and ZnO [52], and for the homomolecular oxygen exchange on Cr_2O_3 [2] and on NiO from $Ni(NO_3)_2$.[3] These breaks correspond to a substantial decrease in activation energy at high temperatures. In our work[8], no such decrease in activation energy could be observed in the high-temperature region. Possibly, the drop in activation energy observed by Winter at high rates of exchange may have arisen from the onset of diffusional control, which was excluded in our work[8] by forced circulation of the reaction mixture.

Assuming that the rate-limiting step in the exchange is oxygen sorption (over the entire surface of the oxide), and that the active sorption complex is delocalised, the theory of absolute reaction rates[53] leads to the following value of the pre-exponential factor

$$k_0 = C_g \sqrt{\frac{kT}{2\pi m}}$$

where C_g is the concentration of sorbed molecules (cm^{-3}), k is Boltzmann's constant, and m is the mass of the molecule (grammes).

The maximum possible value of k_0 for the conditions corresponding to the data in Table 1 is 10^{22} molecules cm^{-2} s^{-1}. If the activated complex on the surface is localised, the theoretical value of the pre-exponential factor decreases. The loss of the translational degrees of freedom for motion along the surface and of the rotational degrees of freedom of the active complex lowers the theoretical value of k_0 by almost five orders of magnitude.

If desorption (again, over the entire surface) is rate-limiting, the maximum theoretical value of the pre-exponential factor rises to 10^{28} molecules cm^{-2} s^{-1}.

The experimental results listed in Table 1 show that the pre-exponential factor for the oxides of the first group is much greater than the maximum possible value for the rate of adsorption. Hence, we must conclude that the observed activation energy for the exchange is much higher than the activation energy for adsorption, and approaches the activation energy for desorption. Thus, for V_2O_5 the true activation energy for adsorption should be lower than the observed activation energy for exchange by at least 10 kcal mole^{-1}, in order to bring the value of k_0 below the theoretical maximum. This means that the surface of these oxides is effectively covered by oxygen, and oxygen removal is the rate-limiting step. This argument is supported by the fact that the rate of exchange on V_2O_5 was found to be approximately equal to the experimentally observed desorption rate.

In oxides of the second group the surface is, apparently, largely free to adsorb oxygen, and the observed activation energy for exchange is close to the true activation energy for sorption. The low value of the pre-exponential factor (as compared with the theoretical maximum) is probably the result of non-equivalence of the surface oxygen on these oxides. The degree of non-uniformity of the surface oxygen increases in the order $CuO < NiO < MnO_2 < Co_3O_4$. Hence it must be assumed that exchange in molecular oxygen occurs only on part of the surface of these oxides, the fraction of the surface involved being smaller, the greater the degree of non-uniformity. This explains the decrease in the pre-exponential factor on going from CuO to Co_3O_4. Low k_0 values may also arise from localisation of the active oxygen sorption complex.

These ideas on the relationship between the rate of exchange in molecular oxygen and the oxygen bond energy on the surface of the oxide can also be applied to the action of promoters in vanadium pentoxide. The addition of alkali metal sulphates to V_2O_5 leads to the formation of compounds close in composition to $V_2O_5.M_2SO_4$ and soluble in the excess of vanadium pentoxide. The oxygen bond energy in the resulting solid solutions is lowered, and therefore the activation energy decreases and the rate of exchange in molecular oxygen increases. The mobility of the oxygen increases, depending on the alkali metal, from lithium to caesium: in other words, the oxygen bond energy in a series of promoted catalysts changes monotonically with the atomic number of the alkali metal. As shown in Fig. 7, the rate and the activation energy of exchange on vanadium pentoxide promoted by alkali metal sulphates vary in the same sense as the electronegativity[54] of the alkali metal atom.

From Minachev and Antoshin's data[28], the change in the mobility of oxygen in the rare-earth oxide family is similar in character to the change in energy of the oxygen bond in the oxides. Inspection of Table 1 shows that the pre-exponential factor for these oxides is less than 10^{22} (with the exception of CeO_2). With CeO_2, the rate-limiting step in the exchange is apparently oxygen sorption over the entire surface of the oxide. The non-stoichiometric oxides of praseodymium and terbium, characterised by high concentrations of oxygen defects in the lattice, are the most active. Under exchange conditions all these oxides (except CeO_2) are *p*-type semiconductors.

c. Activity towards isotopic exchange of oxygen and semiconducting properties of oxides. During isotope exchange on oxides with equilibrium oxygen content, mutual transformations of molecular oxygen and atomic oxygen ions, involving electron transfer, must take place. Therefore, the electronic work function can be one of the terms which define the value of the activation energy for the exchange reaction. It is interesting

to establish whether a relationship exists between the catalytic activity towards isotope exchange in oxygen and the electronic work function. Experimental results[9] for a series of transition metal oxides are given in Table 4.

The activity was characterised by the rate of exchange at 300°C, and the work function by the contact potential difference between the oxide and gold[55]. The data of Table 4 suggest the lack of a simple correlation between catalytic activity and work function. For comparable values of the work function the catalytic activities of some oxides differ by five orders of magnitude, and for the same activity the work function can vary by more than 1 eV. It follows that the change in work function between different oxides is neither the only nor the main factor which determines the catalytic activity.

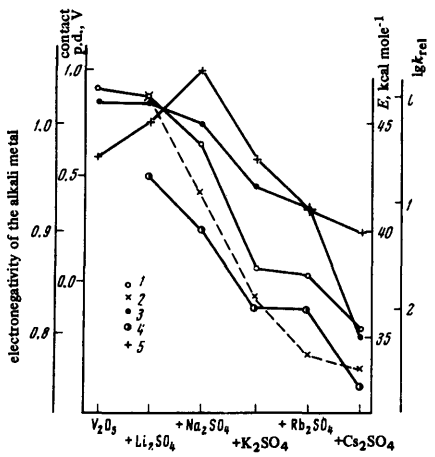

Figure 7. Activity of vanadium pentoxide promoted by alkali metal sulphates:
1) logarithm of the relative rate of exchange in molecular oxygen ($\lg k_{rel}$); *2*) logarithm of the relative rate of oxidation of SO_2 ($\lg k_{rel}$); *3*) activation energy of exchange (E); *4*) electronegativity of the alkali metal atom; *5*) electronic work function (contact p.d.).

Table 4. Catalytic activity and electronic work function of the oxides of metals of the fourth period.

Oxide	Contact potential difference against gold, V	Exchange rate at 300°C, molecules $cm^{-2}\ s^{-1} \times 10^{-10}$
TiO_2	−1.36	0.0002
V_2O_5	−0.75	0.001
Cr_2O_3	−0.10	0.0061
Fe_2O_3	−0.74	0.94
Co_3O_4	−0.13	5200
NiO	+1.02	68
CuO	−0.03	70
ZnO	0.0	0.037

In promoted oxides, also, the electronic work function bears no simple relationship to the catalytic activity towards oxygen exchange. Thus, the addition of 0.5 at. % of lithium or gallium to zinc oxide has the same effect on the work function (which is lowered in both cases), but the catalytic activity of zinc oxide is increased by a factor of 4 by the addition of lithium and is decreased by a factor of 5 by the addition of gallium[12].

Addition of alkali metal sulphates to vanadium pentoxide raises both the catalytic activity and the electrical conductivity[48]. Promotion with the sulphates of different alkali metals does not correlate with the change in electronic work function (see Fig. 7). Addition of 0.1 M potassium sulphate to vanadium pentoxide increases 50-fold the rate of isotope exchange in oxygen, but has no significant effect on the electronic work function.

4. Catalytic Activity of Oxides with Non-equilibrium Oxygen Content

Many workers[14,16,24,29-31,33] have found that the activity towards homomolecular oxygen exchange is very considerably increased by preliminary activation of the oxides in a vacuum. The effect was first noted on zinc oxide. Samples of zinc oxide which have been heated in oxygen before measurements of their catalytic activity show appreciable activity only at temperatures above 400°C. At 450°C, and 40 mmHg oxygen pressure, $Z = 4.8 \times 10^{11}$ molecules $cm^{-2}\ s^{-1}$.

Winter[1] studied the activity of ZnO after vacuum activation for 16 h at 630°C, the oxygen being admitted after the sample had been cooled to the temperature of the experiment. Under these conditions, exchange in molecular oxygen is detectable even at 120°C, and at 215°C the rate of exchange reached 8×10^9 molecules $cm^{-2}\ s^{-1}$. Barry and Stone[33] obtained even more striking results: one of their zinc oxide preparations had an activity of 8.1×10^{11} molecules $cm^{-2}\ s^{-1}$ at −193°C.

A detailed investigation of the low-temperature activity of zinc oxide[16] has shown that exchange on freshly activated preparations proceeds to equilibrium almost instantaneously at 25° and −194°C, but even after 2–2.5 min the rate of exchange drops to a measurable level (5.7×10^{13} at 25° and 4.34×10^{10} molecules $cm^{-2}\ s^{-1}$ at −194°C). After 5–8 h operation in oxygen at room temperature the rate of exchange becomes immeasurably low.

Exchange on copper oxide vacuum-activated at 400°C occurs with initial rates too high for accurate measurement between 0° and −78°C. Cuprous oxide heated in vacuum at 400°C is active towards isotope exchange in molecular oxygen over the wide temperature range between −196° and +200°C: at all temperatures the rate of exchange decreases with time, reaching a constant value after 20–60 min. The initial rate of exchange at 25°C is 1.5×10^{12} molecules $cm^{-2}\ s^{-1}$.

The rate of exchange on NiO [14,29] was 1.2×10^{13} molecules $cm^{-2}\ s^{-1}$ immediately after activation, decreasing by about a factor of 3 after 27 h.

Manganese dioxide[30] baked in vacuum at 350°C shows a stable activity over a fairly long period in the temperature range from −78° to +50°C. The rate of exchange at 25°C on MnO_2 is 2.1×10^{12} molecules $cm^{-2}\ s^{-1}$. The activation energy in this temperature region is 3.7 kcal $mole^{-1}$, the kinetic order with respect to oxygen is 0.64. From 50°C upwards the rate of exchange decreases appreciably with time, eventually reaching the value typical of manganese dioxide stored in oxygen. The decrease in exchange rate is faster at higher temperatures. The temperature dependence of the rate of exchange on MnO_2 is shown in Fig. 8*a*.

The deactivation of these oxides in oxygen at low temperatures is reversible: repeated vacuum activation at high temperatures fully restores the low-temperature activity. Exchange at high temperatures on ZnO produces an irreversible deactivation of the catalyst towards exchange at low temperatures[16]. The low-temperature ac-

tivity of MnO_2 is fully restored by vacuum activation irrespective of the deactivation temperature[30]. In the case of CuO, further activation after high-temperature exchange produces a decrease in the rate of exchange at low temperatures, i.e. the activity is not fully recovered.

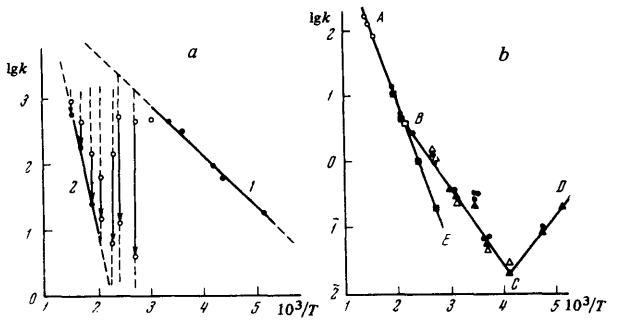

Figure 8. Temperature variation of the exchange rate in molecular oxygen; *a*) on MnO_2: *1*) with non-equilibrium oxygen content; *2*) with equilibrium oxygen content (open circles) and stable activity (filled circles), the unstable activity depending on the time of exposure of the catalyst to oxygen; *b*) on Gd_2O_3; *AE* high-temperature exchange on the oxide heated in oxygen, *BC* and *CD* low-temperature exchange on the oxide heated in a vacuum.

These results suggest the possibility of exchange by two different mechanisms, depending on the bond strength of the adsorbed oxygen to the oxide surface. Low-temperature exchange occurs only on catalysts which have been activated in a vacuum, i.e. under conditions when the oxide surface is strongly depleted of oxygen. This exchange does not involve participation of oxygen from the oxide: there is no isotopic exchange of oxygen between the oxide and the gas at low temperatures. Weakly adsorbed oxygen is probably involved. Exchange rates are high, and the activation energy low. Weakly adsorbed oxygen becomes more firmly bound, in time, to the surface of a vacuum-baked catalyst. This is accompanied by a decrease in the activity towards exchange by the low-temperature mechanism. The deactivation process is slow at low temperatures and fast at high temperatures. Therefore, the activity observed at high temperatures (even immediately after activation) corresponds to an oxide of surface composition close to—if not equal to—the equilibrium oxygen content. Under these conditions, isotope exchange between oxygen from the oxide and the gas takes place in parallel with homomolecular exchange. The rates of these processes are similar, and in this case the exchange in molecular oxygen proceeds through exchange with the oxide lattice. In the transition region of temperatures it is obviously possible, depending on the time of storage of the catalyst in oxygen, to observe homomolecular exchange at rates close to the rates characteristic of the low-temperature mechanism, or alternatively at rates close to those characteristic of the high-temperature mechanism.

The oxides of the rare-earth elements also show a low-temperature activity[31]. It is interesting to note that below 200°C the catalytic activity of gadolinium oxide heated in vacuum at 700°C for 4 h and rapidly cooled to room temperature remained stable even after prolonged storage (100 h) in oxygen at 20°C. The reproducibility of the measurements was adequate over the whole temperature range from −78° to +200°C and in both directions of temperature change. The low-temperature catalytic activity of the oxide began to change only after the catalyst had been heated in oxygen above 200°C, i.e. concurrently with the onset of isotope exchange between the gas phase and oxygen from the oxide. The temperature dependence of the activity of gadolinium oxide towards the isotope exchange of oxygen is illustrated in Fig. 8*b*. The presence of a break in the Arrhenius plot shows that the exchange can occur by different mechanisms, and the "negative" activation energy is evidence that the rate of exchange in the region *CD* is determined by the concentration of adsorbed oxygen, which increases with decrease of temperature.

Some interesting results have been obtained for γ-Al_2O_3.[17,24] The sample was prepared by thermal decomposition of the hydroxide followed by 10 h baking in air at 700°C. Exchange in molecular oxygen began at 350°C on a sample freshly prepared in this way. Vacuum treatment raised the activity of the catalyst, the effect increasing with temperature. Under these conditions, exchange was observed at temperatures as low as −78°C. The initial rates of exchange at 25°C and 10 mmHg oxygen pressure for various activation temperatures are tabulated below;

t, °C	300	350	400	450	500	600
Z_0, molecules $cm^{-2}\,s^{-1}$	0	$2\cdot10^{10}$	$3.5\cdot10^{10}$	$\sim10^{11}$	$5\cdot10^{11}$	$>10^{12}$

In an oxygen atmosphere the low-temperature activity of a vacuum baked sample decreases, rapidly at first and then slowly, reaching a stable value after 2–3 days: the rate is then 2–3 orders of magnitude less than the initial rate. Studies of the effects of temperature of heat treatment and of poisoning by water vapour on the activity of γ-Al_2O_3 lead to the conclusion that the active centres include sites remaining on the surface after removal of the OH groups[24].

Isotope exchange of molecular oxygen with oxygen from the oxide becomes appreciable in this case at a temperature of ~ 350°C, which is the same as the minimum activation temperature of γ-Al_2O_3 for low-temperature exchange in molecular oxygen, but the rate of hetero-exchange is approximately two orders of magnitude lower than the rate of homomolecular exchange. The whole of the oxygen on the surface of γ-Al_2O_3 takes part in hetero-exchange, whereas the active regions for homomolecular exchange occupy only a small fraction of the surface. These localised areas differ from the surface oxygen atoms which take part in exchange, as shown by the different response of the rates of hetero- and homo-molecular exchange to the conditions of pretreatment. Thus, increasing the degree of dehydration of γ-Al_2O_3 raises the rate of homomolecular exchange much more drastically than the rate of hetero-exchange, whereas oxygen treatment decreases the rate of homomolecular exchange but increases the rate of hetero-exchange[56].

Since there is no departure from homomolecular equilibrium following isotope exchange between molecular oxygen and the oxygen of γ-Al_2O_3 (i.e. $y = 0$), we conclude that hetero-exchange in this case involves the replacement of one atom from an adsorbed oxygen molecule by one oxygen atom from the surface layer of the oxide. A quantitative treatment of the experimental results for isotope exchange at 450°C indicates the following relative amounts of the various types of exchange: $k_1 = 0.95$, $k_2 = 0.05$, $k_3 = 0$.[24]

In every case, the high activity of the oxides at low temperatures arises from the formation of chemical defects at the oxide surface. In most cases these defects result from the loss of oxygen, and disappear after high-temperature treatment in oxygen. On γ-Al_2O_3 the active regions

can be of at least two types[56]: the first are formed by the loss of oxygen from the surface layer of the lattice during high-temperature treatment in a vacuum, and are poisoned by oxygen; the second are formed by the extensive dehydration of the surface during high-temperature treatment in a vacuum and in oxygen alike, and are stable to oxygen treatment but are rapidly poisoned by water vapour.

Isotope exchange of molecular oxygen on oxides which are active at low temperatures is not accompanied by isotope exchange with the oxygen of the oxide. This means that under these conditions the exchange does not involve the participation of oxygen from the oxide surface, i.e. the exchange proceeds exclusively by the first mechanism. It may take the form of dissociative adsorption and desorption, or the formation on the surface of a triatomic or tetratomic activated complex from one or two oxygen molecules. There are as yet no data on which to base a choice between these variants.

5. Catalytic Activity of Metals towards Molecular Oxygen Exchange

The isotope exchange of oxygen on metals was first investigated by Margolis[4]. Exchange was observed at 320°C on platinum after prolonged oxygen treatment at 300–400°C, and at 220°C on silver.

Margolis and Kiselev[5] examined the effect of chloride and iodide impurities in silver. On increasing the chloride concentration from 0.0015 to 0.015%, i.e. by a factor of 10, the rate of exchange fell by a factor of 3. Addition of iodine increased the rate of exchange of molecular oxygen.

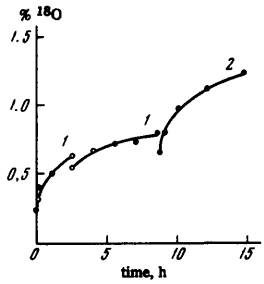

Figure 9. Isotopic exchange of molecular oxygen with oxygen adsorbed on platinum:
1) 200°C; *2*) 250°C.

Khasin and Boreskov[11] studied isotope exchange in oxygen on platinum films prepared by evaporation of platinum in a vacuum. The adsorption of oxygen on the freshly prepared films was measured at first, and found to include a fast stage and very slow stage. At 20°C the fast adsorption reached a coverage of 0.6×10^{15} atoms cm^{-2}, i.e. about half a monolayer, and at 250°C the amount of fast adsorption was in excess of a monolayer. Slow adsorption of oxygen took place throughout the experiment. The total amount of oxygen sorbed before starting the exchange experiments was 2–4 monolayers.

Even at 200°C the homomolecular exchange of oxygen on a platinum film occurs at a measurable rate. The activation energy of the exchange is 16.5 ± 1.5 kcal $mole^{-1}$. The kinetic order of the exchange reaction with respect to oxygen is close to 0.5.

The same films were used to study the exchange between adsorbed and molecular oxygen. Oxygen enriched with the heavy isotope (38% ^{18}O) was first adsorbed, the reaction vessel was filled with oxygen of normal isotopic composition, and the concentration of ^{18}O in the gas phase was monitored. The results are shown in Fig. 9. The discontinuities in the curve are due to the addition of natural oxygen to maintain the desired pressure, since the pressure is continually lowered by the removal of samples for analysis. The shape of the curves indicates a sharp decrease in exchange rate at low extents of exchange (below 0.1 of a monolayer), pointing to non-uniformity of the adsorbed oxygen.

The rate of exchange in molecular oxygen is the same as the maximum rate of exchange with adsorbed oxygen. The activation energy for exchange with adsorbed oxygen at an extent of exchange of 0.15 of a monolayer amounts to 28 ± 3 kcal $mole^{-1}$. Assuming appreciable non-uniformity of the adsorbed oxygen, the change in activation energy ΔE for the exchange with time τ can be calculated from the equation[57,58]

$$\Delta E = 2.3RT\,\Delta \lg \tau .$$

Fig. 10 shows the variation of the change in activation energy for exchange, measured in this way, with the extent of exchange x, defined as the fraction of a monolayer of adsorbed oxygen which has come to isotopic equilibrium with the gas phase. The dashed part of the curve is the extrapolation to $x = 0$. The results obtained justify the conclusion that oxygen adsorbed on a platinum film is non-uniform, and that the activation energy attending its exchange increases by 6 kcal $mole^{-1}$ over 25% of a monolayer. On the regions where homomolecular exchange takes place, the heat of adsorption of oxygen is ~ 13 kcal $mole^{-1}$, increasing to 28 kcal $mole^{-1}$ over 25% of a monolayer.

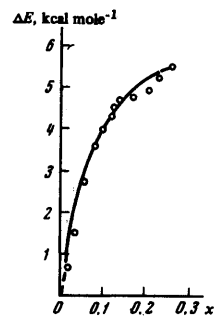

Figure 10. Change in the activation energy E for exchange of oxygen adsorbed on a platinum film with the extent of exchange x.

The exchange reaction in molecular oxygen occurs preferentially at zones which constitute ~ 3% of the total surface area of the platinum film. The higher rate of exchange of molecular oxygen found in this work (as compared with the results of Margolis[4]) is probably due to higher purity of the surface of the platinum film.

Subsequently[20–22], the homomolecular exchange of oxygen was studied on films of silver, palladium, and gold. It was shown that the rate of isotope exchange on palladium films is substantially decreased by oxidation of the metal,

pointing to a strengthening of the bond between adsorbed oxygen and the surface. Oxygen adsorbed on palladium films is energetically non-uniform. The bulk of this oxygen is barely mobile at 250°C, and is bound to the surface more firmly than in the case of silver. However, a very small fraction of the surface oxygen (< 2% of a monolayer) is very reactive towards exchange and plays a major role in the homomolecular isotope exchange reaction.

Oxygen adsorbed by a silver film at temperatures ≤ 200°C, and not exposed to higher temperatures, is uniformly accessible to exchange with gaseous oxygen at 200°C, suggesting that this oxygen is energetically uniform and has a high mobility. At 250°C part of this oxygen is transferred to a state which does not take part in exchange at 200°C: this state is characterised by a stronger bond to the silver.

Homomolecular exchange in oxygen on a gold film was negligible at 350° and 400°C.[22]

Comparative data for platinum, palladium, and silver are listed in Table 5. The difference in the interaction of oxygen with platinum and palladium surfaces on the one hand, and with silver surfaces on the other hand, evidently stems from the presence of *d*-orbitals in the first two metals, which can take part in bond formation with oxygen, whereas these orbitals are absent in silver[22].

Table 5. Comparison of the state of oxygen on films of platinum, palladium, and silver.

Metal	Rate of exchange at 250°C, Z^*, molecules $cm^{-2}\ s^{-1}$	Fraction of the surface involved in exchange, x	$\frac{Z}{x}$	Heat of adsorption of oxygen, kcal mole^{-1}	Activation energy of exchange, kcal mole^{-1}	Kinetic order with respect to oxygen
Pt	$7.83\cdot10^{12}$	~0.03	$\sim1.96\cdot10^{14}$	13	16±2	0.5
Pd	$4.22\cdot10^{11}$	<0.02	$>2.11\cdot10^{13}$	—	27—32	0.3
Ag	$2.41\cdot10^{12}$	~1	$\sim2.41\cdot10^{12}$	13	29—34	0.3

* Values of Z obtained at 0.5 mmHg oxygen pressure on Pt, 0.1 mmHg on Pd and Ag.

Sandler and Durigon[35] studied the homomolecular exchange and adsorption of oxygen on spongy silver, and found that at 160–180°C the chemisorption of oxygen is partially reversible, the rate of desorption being equal to the rate of exchange. They propose the existence of two forms of bond between chemisorbed oxygen and a silver surface. Increasing the amount of strongly bound oxygen lowers the rate of desorption, but does not affect the activation energy for desorption (32.5 kcal mole^{-1}). Fast diffusion and exchange occur over the whole of the surface, but only the oxygen less firmly bound to the surface is desorbed.

IV. RELATIONSHIP BETWEEN THE CATALYTIC ACTIVITY OF OXIDES TOWARDS OXYGEN EXCHANGE AND THEIR ACTIVITY TOWARDS OTHER OXIDATION REACTIONS

In the previous Sections we have shown that the catalytic activity of oxides and of oxygen-saturated metals towards the isotopic exchange of molecular oxygen is essentially determined by the energy of the bond between oxygen and the surface layer of the catalyst. It is natural to suppose that the oxygen bond energy may also be the key factor in other oxidation reactions taking place on these catalysts with the participation of oxygen.

It is interesting, therefore, to examine the catalytic activity of oxides towards these processes. The data chosen to be discussed here were confined to oxides with an equilibrium oxygen content. Accordingly, we select, for comparison, data on oxidation reactions taking place in an oxidising medium (i.e. with an excess of oxygen in the reaction mixture). It would have been very interesting to establish to what extent oxides with a non-equilibrium oxygen content, which show low-temperature activity towards oxygen exchange, can accelerate other oxidation reactions, but the available experimental material is insufficient for this purpose.

1. Catalytic Oxidation of Hydrogen

This reaction was studied by Popovskii and Boreskov[59] on the actual oxide samples used[8] to investigate isotopic exchange in molecular oxygen. The experiments were made by a stationary–circulation method[60], which allowed the reaction rate to be measured directly in the presence of a large excess of oxygen. The data for manganese dioxide are taken from the work of Bruns[61]. Complete consistency was found between the activity of transition metal oxides of the fourth period towards homomolecular oxygen exchange and towards the oxidation of hydrogen (curves *1* and *2* of Fig. 11). Consistency between changes in catalytic activity towards oxygen exchange and towards the oxidation of hydrogen is found also for vanadium catalysts promoted by alkali metal sulphates[48].

2. Oxidation of Carbon Monoxide

The very extensive literature on the activity of various oxides towards the oxidation of CO was reviewed by Krylov[62]. A statistical treatment was applied in an attempt to allow for the reliability of the various data by appropriate weighting factors. The relative activities of the oxides of the fourth period were found to be

MnO_2	Co_3O_4	NiO	CuO	ZnO	TiO_2	Fe_2O_3	V_2O_5	Cr_2O_3
310	200	100	83	22	18	16	11	11

This activity sequence with respect to the oxidation of CO is very close to the sequence found for the oxygen isotope exchange.

Stone[63] arrived at the following sequence of catalytic activities for the oxides by analysing published data on the oxidation of CO

$$CoO > NiO > MnO_2 \text{ from } 0° \text{ to } 150°C$$
$$CuO > Fe_2O_3 > ZnO > TiO_2 > Cr_2O_3 > V_2O_5 \text{ from } 150° \text{ to } 400°C$$

Again, the oxides of cobalt, nickel, manganese, and copper are the most active.

3. Complete Oxidation of Hydrocarbons

The results of a study of the activity of various catalysts towards the oxidation of methane in a flow–circulation apparatus are shown as curve *3* of Fig. 11. The change in specific catalytic activity for the series of fourth period oxides is similar to the change observed in the homomolecular exchange of oxygen. The same conclusion is reached if the comparison is made with the results of Gerald and

Horvatisch[65], who established the following activity sequence for the various catalysts

$$Co_3O_4 > MnO_2 > Pt > NiO > CuO > Cr_2O_3 > Fe_2O_3 > ZnO .$$

Stein and coworkers[66] made a systematic study of the activity of a large number of oxides towards the complete oxidation of hydrocarbons with five and six carbon atoms. The most active was Co_3O_4; a high activity was noted in most cases with manganese and nickel oxides; the lowest activity was shown by zinc oxide and vanadium pentoxide.

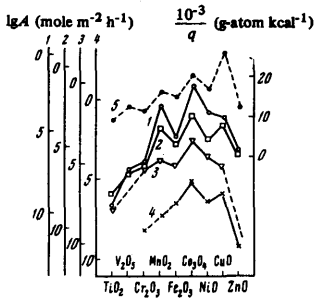

Figure 11. Specific catalytic activity of the oxides of metals from the fourth period towards oxidation reactions:
1) homomolecular oxygen isotope exchange; *2*) oxidation of hydrogen; *3*) oxidation of methane; *4*) decomposition of nitric oxide; *5*) reciprocal heats of formation of the oxides referred to 1 g-atom of oxygen.

Minachev and coworkers[67] studied the activity of the rare-earth oxides towards the complete oxidation of propene. They point out that the activity of these oxides appears in the temperature range corresponding to appreciable mobility of the surface oxygen[41]. A comparison of the extent of conversion of propene to CO_2 and of the rate of exchange of O_2 with the oxygen of the rare-earth oxides reveals a definite correspondence between these characteristics. The change in activity as a function of the atomic number of the element corresponds to the classification of these oxides into the cerium and the yttrium subgroups, both for oxygen exchange and for the oxidation of propene.

4. Oxidation of Ammonia

Kurin and Zakharov[68] found that the activity of the oxides of fourth period metals towards the high-pressure oxidation of ammonia decreases in the following order:

$$Co_3O_4 > MnO_2 > Cr_2O_3 > CuO > NiO > Fe_2O_3 > ZnO > TiO_2 .$$

Except for the position of chromium oxide, this series is very similar to the corresponding series for the isotope exchange reaction in oxygen.

5. Decomposition of Nitric Oxide

Curve *4* of Fig. 11 shows the relative catalytic activities of the oxides of the elements of the fourth period towards the decomposition of NO, measured in a static circulation apparatus[69]. MnO_2 and CuO were found to be unstable under the conditions of the reaction. The activity of the other oxides varies in the same sense as their activity towards homomolecular oxygen exchange.

6. Oxidation of Sulphur Dioxide

The activities of the various oxides towards this reaction cannot be compared, because most of them are converted into inactive sulphates under the conditions of the reaction. The only exception is vanadium pentoxide, whose activity is significantly increased by promotion with alkali metal sulphates.

As Fig. 7 shows, the catalytic activity of vanadium catalysts containing alkali metal sulphates varies in the same sense for isotope exchange in molecular oxygen and for the oxidation of sulphur dioxide.

---o0o---

In spite of occasional discrepancies, not surprising in view of differences in sample preparation, purity, and experimental conditions, the examples considered undoubtedly show that the activity of oxides towards exchange in molecular oxygen is characteristic also of their activity towards various other oxidation reactions. In many cases, as for example in the oxidation of hydrogen, the correlation between the specific catalytic activities towards oxygen exchange and towards the oxidation reaction on the various catalysts is so striking that a common rate-limiting step for the two reactions can be postulated. For the hydrogen oxidation and the molecular oxygen exchange reactions this limiting step could be the chemisorption of oxygen. However, the activation energy and the kinetic order with respect to oxygen[9,59,70] of the oxygen exchange and the hydrogen oxidation reactions are quite different. Hence we must reject the hypothesis of a common rate-limiting step. The only possible conclusion is that although the rate-limiting steps of the two reactions are different, the catalytic activity depends on one and the same property of the oxides, which varies along the series of catalysts considered. It is natural to suppose that this property must be the bond energy between the oxygen and the surface layer of the oxide. In isotope exchange reactions this quantity determines the activation energy for adsorption and desorption of oxygen, and in the oxidation of hydrogen it determines the activation energy for the interaction of hydrogen with the oxygen on the oxide surface. In a similar way, the activation energy for the interaction of the reducing agent with the oxygen on the surface of the oxide can be determined as for other oxidation reactions by the binding energy of the oxygen on the surface layer of the oxide.

Thus, the binding energy of the oxygen is one of the basic factors controlling the activity of oxides towards oxidation reactions. However, the rate of isotope exchange in molecular oxygen, readily measured experimentally, can be a convenient quantitative criterion of the reactivity of the oxygen on the surface of an oxide.

Nevertheless, the prediction of the catalytic efficiency for oxidation reactions remains a complicated problem, since the simple dependence on the reactivity of the surface oxygen may be masked by the influence of numerous other factors. Thus, the catalytic activity may be limited by the stability of the oxide phase under the conditions of the catalytic reaction: an example of this behaviour is the oxidation of SO_2, discussed above, in which the activity of most oxides is extremely low because of their conversion into sulphates. If the Co_3O_4 phase had been more stable than cobalt sulphate under the conditions of the reactions,

cobalt catalysts would probably have been much more active than vanadium catalysts towards the oxidation of SO_2.

A complicated dependence on the reactivity of the surface oxygen can be expected also for partial oxidation reactions, in which the yield of the desired product is determined by the relative rates of a number of competitive and consecutive reactions.

In some cases the interaction between the material to be oxidised and the catalyst (chemisorption) can be the limiting step, instead of the subsequent reaction with the oxygen on the catalyst surface. The possibility that some oxidation reactions may proceed by interaction between the reducing agent and molecular oxygen cannot be excluded. This possibility has been examined in detail by Margolis[71]. In the latter two cases the correlation with the reactivity of the oxygen on the oxide surface may be very weak or altogether absent.

Lastly, even if the interaction with the oxygen on the oxide surface is the rate-limiting step, the simple correlation with the reactivity may be obscured by the decrease in the concentration of surface oxygen brought about by the reaction itself: this effect can have a profound influence on the properties of the surface oxygen. To a greater or lesser extent, this complication can be expected in all cases. It may be avoided, however, by measuring the reactivity of the oxygen on the oxide surface during the actual oxidation reaction.

In spite of the many complicating factors listed above, the bond energy of the oxygen in the surface layer of the oxide can be used as the basis for a generalisation of the experimental data and for the choice of catalysts for reactions involving the transfer of oxygen atoms between reactant molecules.

V. PARTICIPATION OF OXYGEN FROM OXIDE CATALYSTS IN OXIDATION REACTIONS

Transition metal oxides have found wide applications as the active components of oxidation catalysts. To explain the mechanism of oxidation reactions, involving the transfer of oxygen between molecules of the reacting materials, it is important to establish whether the oxygen of the catalyst plays a direct part in these transfers.

One possible assumption is that the oxygen to be added to the reducing component is taken from the surface layer of the crystal lattice of the catalyst, the oxygen loss in this layer being continuously replenished by the second component (capable of giving up oxygen). It must be stressed that these elementary processes of oxygen loss and oxygen addition involve no phase changes in the catalyst.

A second variant of the mechanism is based on the assumption that the transfer of oxygen from the oxidising to the reducing component takes place without intermediate conversion of the oxygen into an anion on the surface layer of the catalyst lattice. The energy and nature of the intermediate formed between the oxygen and the catalyst in this case are quite different from those of the oxygen bond in the oxide.

When comparing these variants, we should not try to reach a general conclusion. The correctness of one or other of the above assumptions depends on the nature of the catalyst, the nature of the reactants, and the conditions of the reaction. The discussion given in this review of the simplest oxidation reaction—isotope exchange in molecular oxygen—provides a good illustration of the state of affairs. With oxides which have been treated in oxygen at high temperatures, and whose surface layer therefore has acquired the equilibrium composition for the particular oxygen pressure, the rate of exchange in molecular oxygen is always the same as the rate of isotope exchange with the oxygen of the catalyst surface. This is evidence that the first of the above variants of the mechanism applies to this reaction. The form of the intermediate in the reaction between oxygen and the catalyst coincides, in this case, with the form of the oxygen bond in the surface layer of the oxide (or is so close to it that fast transitions between them are possible). The existence of other forms of atomically bound oxygen is unlikely under these conditions, and in any case the rate of formation of such structures should be considerably lower than the rate of binding of the oxygen in the surface layer of the oxide, since the exchange of molecular oxygen would otherwise take place through this form and its rate would be higher than the rate of exchange with oxygen.

On the other hand, oxides with a non-equilibrium oxygen content in the surface layer, prepared by a special heat treatment and active towards exchange at relatively low temperatures, give a rate of exchange in molecular oxygen considerably in excess of the rate of exchange with the oxygen of the oxide. This proves beyond doubt the correctness of the second variant of the mechanism.

These results can be of use also in identifying the mechanism of more complex oxidation reactions. The rate of exchange of molecular oxygen is characteristic of the rate of binding of oxygen by the catalyst. If the oxidation reaction takes place through the same intermediate form, produced by the interaction of oxygen with the catalyst, this step will be common to the two reactions. Simple comparison of the rates is not sufficient, however, to identify the mechanism of the oxidation reaction.

Because of the reaction with the component to be oxidised, the concentration of oxygen in the surface layer of the oxide under the conditions of the oxidation reaction may be lower—and the rate of binding of oxygen may therefore be significantly higher—than under conditions of exchange of molecular oxygen on oxides with an equilibrium oxygen content. Therefore, a rate of oxidation higher than the rate of exchange for the same temperature and oxygen pressure does not preclude oxidation through interaction with the oxygen of the oxide. Direct measurements of the rate of transfer of oxygen from the oxide to the reaction products are needed. These measurements are possible in principle (by introducing the heavy oxygen isotope into the oxide composition), but unambiguous conclusions are not always possible because of complicating factors.

Most of the work has been on the oxidation of carbon monoxide on manganese dioxide, copper oxide, and some other oxides. The first investigations[72,73] led to the conclusion that the oxygen of the oxide catalysts takes part in the reaction. On the other hand, Vainshtein and Turovskii[74,75] failed to observe a significant change in the isotopic composition of the catalyst after oxidising CO on MnO_2 and CuO enriched with ^{18}O. The sensitivity of the method would have allowed ~ 5% exchange of the oxygen of the catalyst to be detected, corresponding to several monolayers. The authors suggested, on the evidence of stepwise oxidation experiments on reduced oxides by successive additions of oxygen of different isotopic composition, that the mobility of oxygen in their oxides was high enough to ensure a uniform isotopic composition in the bulk and on the surface under the conditions of the experiment. However, direct measurements of the mobility of oxygen in MnO_2 [43] and CuO [42] have shown that the oxygen has no significant mobility in these oxides under the conditions of the CO oxidation experiments. Therefore, the work of Vainshtein and Turovskii, which showed that oxygen from the

bulk of the oxides does not take part in the oxidation of CO on MnO_2 and CuO, leaves unresolved the question of whether the oxygen on the surface of the catalyst (and, more to the point, the most active part of this oxygen) takes part in the reaction.

Winter[76] studied the mechanism of the oxidation of CO on NiO and Cr_2O_3 and concluded that only a small fraction (no more than 2.5%) of the surface oxygen of the catalyst was involved. With Cu_2O, however, between 10 and 40% of the surface oxygen took part in the reaction, the fraction increasing at higher reaction temperatures.

Popovskii and coworkers[77], in their work on the participation of oxygen from the surface of Co_3O_4 in the oxidation of hydrogen at 75°C, found that between 2 and 20% reacted if the sample had been activated at 400°C, whereas between 13 and 39% of the surface oxygen reacted on a sample which had been merely evacuated at 75°C. The low precision of these measurements is due to the need to apply corrections for the exchange of oxygen isotopes between the catalyst and the water vapour formed by the reaction.

Roiter and coworkers studied the participation in oxidation reactions of the oxygen of vanadium pentoxide with the help of ^{18}O. In the oxidation of naphthalene[78] on ^{18}O-enriched vanadium pentoxide the concentration of this isotope in the catalyst did not decrease within the limits of the measurement accuracy (~ 10%). If the whole of the oxygen used in the oxidation of naphthalene had been taken from the surface of the vanadium pentoxide, with complete mixing of the oxygen within the catalyst, the final concentration of ^{18}O in the vanadium pentoxide should have been 10–30% lower than the initial concentration. The authors concluded that the oxygen of vanadium pentoxide does not take part in the oxidation of naphthalene. This conclusion cannot be accepted unreservedly in view of the low mobility of oxygen within vanadium pentoxide crystals, inferred from the large departure from first order of the exchange kinetics in water vapour[40] at these temperatures (340–390°C).

In the oxidation of sulphur dioxide on ^{18}O-enriched vanadium pentoxide[79] the concentration of this isotope was found to decrease, but by no more than after oxygen exchange under the same conditions. If oxygen from the V_2O_5 surface had been involved in the oxidation of SO_2, the loss of ^{18}O from the catalyst should have been accelerated by the reaction. At the higher experimental temperatures of this work (500–610°C) inadequate mobility of the oxygen from the catalyst ceases to be an obstacle. The result of Kasatkina and Shustov[80] do not support these conclusions: these workers showed that SO_3 exchanges with the oxygen of vanadium pentoxide at a rate well in excess of the rate of oxidation of sulphur dioxide. This observation adds further complexity to the problem of the participation of oxygen from the oxide in the reaction.

Roiter and Yuza[70] made separate measurements of the rates of reduction of vanadium pentoxide by hydrogen and of oxidation by oxygen, and by comparing the results with the rate of the catalytic oxidation of hydrogen on V_2O_5 they concluded that the oxygen of vanadium pentoxide does not enter into the catalytic reaction.

All these researches enable us to conclude with some confidence that oxygen from the bulk of the oxides does not take part in catalytic oxidation reactions. This conclusion is in keeping with the general proposition that reactions involving a phase transformation cannot be invoked as stages of a catalytic process. The problem of whether oxygen from the surface of the oxides is involved in catalytic oxidation is more difficult to resolve. For the oxidation of CO and H_2 on NiO, CuO, and Co_3O_4 we believe that the bulk of the evidence points to participation of some—the most active part—of the oxygen on the oxide surface. This conclusion is supported not only by direct experimental data but also by the similarity between the relative activities of the various oxides towards these reactions on the one hand and towards exchange in molecular oxygen on the other hand. For the latter reaction it has been established that oxygen from the surface of the oxides is involved, and that oxygen sorption on the surface of these oxides cannot occur at significant rates to give an atomic form, which has bonding substantially different from the oxygen bond in the surface layer of the crystal lattice of the oxide. The last conclusion follows from the equality of the rates of exchange in molecular oxygen and of isotope exchange with the oxygen of the oxide.

It is possible, however, that at lower temperatures and when the surface layer of the oxide shows large departures from its equilibrium oxygen composition, the oxidation will occur through some other form of chemisorbed oxygen, as is the case in the exchange of molecular oxygen on specially activated oxides.

Data on the catalytic oxidation reactions on vanadium pentoxide are still too scanty for unambiguous conclusions. It is possible that the rate of sorption of oxygen and the form of the oxygen bond to the catalyst are substantially altered by the simultaneous adsorption of the compound to be oxidised. This argument, put forward by Roiter[81], is particularly relevant when the adsorption of oxygen and of the oxidisable species is accompanied by electron transfers in opposite directions. There is experimental evidence of a positive effect on the rate of adsorption by preliminary adsorption of another material[82,83].

An extension of the study of the participation of oxygen from the oxides in oxidation reactions, to include a wider range of oxide catalysts and of reactions, would undoubtedly be of interest.

---o0o---

Studies of the catalysis of isotope exchange in molecular oxygen began relatively recently, and have so far been confined to a limited number of catalysts and a relatively narrow range of reaction conditions. Nonetheless, the results obtained justify the hope that this reaction will prove to be a useful method of studying the mechanism of oxidation reactions, and particularly convenient for characterising the intermediate forms in the interaction between oxygen and solid catalysts.

The most important result obtained so far is the conclusion that exchange in molecular oxygen on the one hand, and isotope exchange with the oxygen of the catalyst (in the case of oxides with an equilibrium oxygen concentration in the surface layer) on the other hand, proceed at equal rates. This equality of rates points to the participation of oxygen from the catalyst in exchange reactions, and also suggests that the oxygen chemisorbed by oxides has the same (or nearly the same) bond energy as the oxygen of the surface layer of the oxide crystal lattice. Hence, the rate of exchange of molecular oxygen can serve as a general characteristic of the reactivity of the oxygen, and can be a useful guide to the rules for the choice of catalysts for oxidation reactions.

The surface oxygen of catalytically active oxides is non-uniform, the degree of non-uniformity being greater, the more active the oxide. There is no simple relationship between the catalytic activity towards exchange and the electronic work function of oxides.

Under the conditions leading to isotope exchange on metals (Pt, Pd, Ag), considerable sorption of oxygen in the surface layer of the metal (equivalent to several monolayers) is observed. In this form, the metals behave very much like oxides towards the catalysis of exchange in molecular oxygen. Platinum is very similar to the most active oxide (Co_3O_4) in the values of the activation energy and of the absolute rate of exchange, and in the nature of the non-uniformity.

The high catalytic activity towards oxygen exchange at low temperatures shown by oxides which have been subjected to strong activation in a vacuum is extremely interesting. The low-temperature activity is short-lived, particularly at high temperatures, and is evidently caused by the departure from equilibrium composition of the oxide brought about by the activation. Isotope exchange with the oxygen of the oxide does not occur under these conditions. Homomolecular exchange on oxides activated in this way involves special intermediate forms of interaction between the oxygen and the catalyst. Studies of the possible role of these forms in the catalysis of oxidation reactions are highly desirable.

The Electron Spin Resonance Method in Photochemistry

V.E.Kholmogorov

The electron spin resonance (ESR) method is, at the moment, one of the most sensitive physical methods of detecting, identifying, and studying free radicals, ion-radicals, and molecules in the triplet state formed during photochemical reactions. In this review, the use of the ESR method in studies of photodecomposition and photoionisation reactions of simple and of complex compounds is discussed on the basis of results obtained by Soviet and foreign workers. It is concluded that the ESR method will prove to be a powerful physical method of investigation of photochemical systems only if used in conjunction with other methods (in particular, optical spectroscopy).

I. INTRODUCTION

For many years, chemical analysis of the final reaction products has been the most widely used method of investigating the mechanism of photochemical reactions. Knowing the products, one can surmise the nature of the intermediate stages. Methods of separation and of analysis of the reaction products have reached an advanced level of development. For the identification of products, chemists can call on methods such as chromatography, mass spectroscopic analysis, and tracer methods. It is well known that excited states, ions, and free radicals play a key role in photochemical change. If the optical absorption or luminescence spectra of these intermediate states are known, direct identification using the ultraviolet, visible, or infrared bands is possible in principle. However, this approach is often precluded by the extremely short lifetimes of photochemical reaction intermediates.

The difficulty was resolved by Norrish and Porter's publication in 1948 of the impulse photoexcitation method[1] for photo-active systems, in conjunction with fast spectrophotometric measurements, known as the flash spectroscopic or flash photolysis method. Furthermore, studies of the primary stages of photoreactions using the spectra of frozen solutions and mixtures exposed to radiation have increased in scope during the last twenty years. A programme of spectroscopic investigations of chemical reactions at low temperatures was started by Terenin[2,3] as early as in 1940: this was the first attempt to stabilise the intermediates of photochemical reactions in matrices. Subsequently, Lewis and Kasha[4] discovered, in their study of the mechanism of phosphorescence in organic compounds, that free radicals and ion-radicals formed during illumination can be stabilised in rigid, glassy solutions at low temperatures. The main difficulty in this work, pointed out by Frank and Rabinowitch[5], is that the primary products of the photoreaction are often prevented from escaping from their "cage" by the viscosity of the glassy solution, and therefore recombine. On the other hand, the glassy solution must have sufficient rigidity to prevent the active products from diffusing and taking part in secondary, dark reactions. Mixtures of hydrocarbons, alcohols, and ethers at low temperatures are ideal for the purpose: the viscosity of the medium can be controlled either by changing the composition or by changing the temperature of these mixtures.

However, it is sometimes impossible to resolve the optical absorption bands of individual intermediates in photochemical reactions, because they are masked by the absorption bands in the spectrum of the photochemical system due to some of the compounds present in the experimental mixture. If the optical spectrum of the ion or free radical is not known, identification is generally not possible.

Fortunately, photochemical reaction intermediates such as free radicals, ion-radicals, and molecules excited to the triplet state have one important physical property in common: they are paramagnetic due to the presence of unpaired electrons[6]. This makes possible their detection and identification by the electron spin resonance (ESR) method, discovered in 1944 in the Soviet Union by Zavoiskii[7]. Several excellent reviews and monographs on the theoretical and practical aspects of ESR have already been published[8-11], and it is unnecessary therefore to discuss the method in detail. We shall only remark that at the present time this is one of the most sensitive physical methods of detection, identification, and study of free radicals, ion-radicals, and molecules in the triplet (phosphorescent) state.

Hundreds of papers on studies of elementary photoprocesses by the ESR method have been published in the last ten years. As an illustration of the potentialities of the ESR method in photochemistry, we shall consider only a few of these original papers.

The writer has not attempted a detailed analysis of the results quoted in the literature, nor has he concerned himself with matters of purely physical interest. The main emphasis of this review will be a systematic treatment of photochemical investigations by the ESR method. An attempt has been made to preserve the chronological order of the work discussed.

Terenin[12] has given an excellent account of the physical processes underlying the conversion of radiant energy in photochemical systems, and a diagram of the most important photochemical reactions. Following this diagram, we shall classify the photochemical work by the ESR method published up to the time of writing (1966) into the following main photochemical reactions: (1) photodecomposition (photolysis into radicals, photolysis into ions or photoionisation); (2) phototransfer of electrons (photooxidation, photodissociative electron addition); (3) photosensitisation (photosensitised reduction, photosensitised decomposition).

A section on the detection and study by ESR of the triplet (phosphorescent) states of organic compounds has not been included in this review, in spite of its great interest. The omission was deliberate, in order to avoid overloading the article with material which is principally of interest to physicists.

In the main section of this review, we shall discuss the photochemical decomposition of molecules into free radicals and photoionisation processes, investigation by the ESR method.

The first step in any photochemical reaction is the absorption of light by one or more of the components of the photosensitive system under study. Four types of absorption band must be distinguished.

1. Strong ($\lg\epsilon = 3-4$) bands arising from π,π^* absorption in aromatic compounds. These usually occur above 250 mμm, and in conjugated aromatic compounds (dyes) they lie in the visible region of the spectrum. These bands are sharp, and are associated with the transition of one electron from the uppermost filled molecular π-orbital of the ground state to a free non-bonding π^*-orbital of higher energy.

2. Less strong ($\lg\epsilon = 2$) n,π^* absorption bands of heterocyclic compounds, usually in the long-wave part of the absorption spectrum, due to the transition of one of the unshared n-electrons from the hetero-atoms (N, O, S) from a non-bonding $2p$-orbital localised on these atoms to a non-bonding π^* molecular orbital.

3. Strong ($\lg\epsilon = 3-4$), differ σ,σ^* absorption bands of saturated hydrocarbons, found in the ultraviolet region below 200 mμm, due to the transition of an electron from an atomic, bonding σ-orbital to an excited, non-bonding σ^*-orbital (unstable state).

4. Diffuse, long-wave ($\lambda < 260$ mμm) absorption bands from aliphatic alcohols, ethers, amines, alkyl halides, etc. due to the transition of an n-electron to an excited σ^* atomic orbital.

The reactivity of the molecules is determined by the nature of the electronic state, defined by the multiplicity of the state[12] and by the type of electronic transition leading to this state[13-17].

It is known[12] that molecules can exist in the singlet unexcited (ground) state S_0, in a singlet excited state S_1^*, in the lowest (ground) triplet state T_0, and in a triplet excited state T^*. The excited electronic states S_1^*, T_0, and T^* can arise from π,π^*, n,π^*, σ,σ^*, and n,σ^* electronic transitions occurring under the influence of light. The position in energy of these states determines to a large extent the spectral characteristics (absorption and luminescence spectra) and the photochemical properties of the molecules[13-17]. As a rule, the molecules which take part in chemical reactions are not in a singlet S_1^* state, but in the long-lived T_0 state, to which the molecules are transferred by internal conversion[12].

Data on the photochemical action of short-ultraviolet light, which excites the σ,σ^* and n,σ^* transitions in molecules, are so far limited to the photodecomposition and photoionisation reactions of simple molecules in the gas phase, studied by the luminescence of the ejected radicals[18,19] and more recently by flash-photolysis[20] and mass-spectrometrically[21].

However, light absorption is a necessary but not a sufficient condition for the occurrence of a photochemical reaction. After light absorption, a compound does not invariably undergo chemical change, because the excited molecule can undergo physical deactivation processes which involve no chemical conversion[12]. Depending on the spectral composition of the exciting light, the temperature of the medium, and intermolecular interactions, different photoprocesses can take place in a photosensitive reaction system.

The presence of the energy from an absorbed photon in the molecule can manifest itself in several ways. It can: (1) be stored as potential energy of the electronically excited state and either be transferred to another molecule by collision or by exchange or inductive-resonance intermolecular interactions, or else it can be radiated in the form of luminescence; (2) it can be dissipated as heat in a chain of collisions; (3) it can be converted into intramolecular energy of the molecule.

The third way is particularly interesting to photochemists, since under suitable conditions it can lead to dissociation of the molecule into free radicals and ion-radicals. The breaking of chemical bonds in a compound under the influence of light (the photodecomposition reaction) is one of the most direct methods of preparing free radicals.

Since the free radicals formed in most photochemical reactions are very active and undergo secondary chemical interactions, various methods of stabilisation are necessary to enable them to be studied by the ESR method. In the earliest work (1954) on the study of elementary photoprocesses by the ESR method[22,23] the intermediate photoproducts were stabilised in viscous media (in polymer films at room temperature and in frozen solutions). Subsequently, the preferred technique has been the low-temperature stabilisation of the active products in solid solutions.

II. ESR STUDIES OF PHOTODECOMPOSITION REACTIONS

The work of Terenin[18,19], Lewis[24], and Porter[25,26], has produced a substantial fund of spectroscopic data on the photodecomposition of various compounds, which has been responsible for the success of the ESR method. The earliest ESR work was mostly confined to photoreactions whose mechanism had been made clear by the previous work, so that the identification of intermediates involved no difficulties and was a clear proof of the correctness of earlier conclusions.

The first ESR spectra of free radicals formed by ultraviolet irradiation and stabilised in frozen solutions at 77° and 96°K were obtained by Ingram and coworkers[23], who repeated the experiments of Norman and Porter[25] on the photodecomposition of various compounds under the influence of ultraviolet light. Free radical formation was detected by irradiating solid solutions of ethyl iodide, toluene, benzylamine, benzyl chloride, and benzene with light of $\lambda = 254$ mμm. Free radicals appeared also after irradiation of a 40% solution of hydrogen peroxide in water and of the chlorides of oxalato-complexes of tervalent iron in ether–water–alcohol mixtures. The measurements were made on an unsatisfactory ESR apparatus and did not allow accurate identification of the paramagnetic products because the ESR spectra did not show a well resolved hyperfine structure. The photochemical formation of two different free radicals from a single molecule further complicated the identification of the ESR spectra obtained. It was found that the most definite results were obtained from the photodecomposition of hydrogen peroxide by the reaction $H_2O_2 \xrightarrow{h\nu} 2\dot{O}H$. However, more recent work has shown[27-32] that in concentrated aqueous solutions of H_2O_2 ($c > 10^{-2}$ M) the observed ESR spectrum is not due to free OH radicals but to $H\dot{O}_2$ radicals formed by the dark reaction $\dot{O}H + H_2O_2 \rightarrow H\dot{O}_2 + H_2O$.

The doublet ESR spectrum of the $\dot{O}H$ radical could be observed only by irradiating dilute aqueous solutions of H_2O_2 (10^{-2} M or less).[33,34] Stabilisation of the $\dot{O}H$ radical was achieved by minimising the rate of the dark reaction in a dilute solution.

The search for specimens containing active free radicals in measurable concentrations led to the development of the matrix isolation method for these radicals[35]. Solid H_2, Ar, Kr, and CH_4 proved to be suitably inert matrices for stabilising simple free radicals produced photochemically.

1. Photolysis of Simple Compounds

Foner and Cochran[36-38] published a series of researches on the preparation and stabilisation of simple free radicals in these matrices at 4.2°K by ultraviolet irradiation of low-molecular compounds. The source of ultraviolet light was a radio-frequency discharge in a hydrogen tube with a window transparent to ultraviolet (lithium fluoride down to 100 mμm, sapphire to 145 mμm, quartz to 180 mμm, Vycor to 240 mμm). The mixture under study, consisting of the photosensitive material and the matrix gas, was deposited on a sapphire rod at 4.2°K and irradiated with ultraviolet during or after the cooling period, and it was then examined by ESR. Foner and coworkers[38] were able to observe the ESR spectrum of free $\dot{N}H_2$ radicals (triplet of triplets) and $\dot{N}D_2$ radicals (triplet of quintets), produced by photodecomposition in ultraviolet light of 0.5% NH_3 or ND_3 in an Ar matrix at 4.2°K, thus confirming the scheme for the photodecomposition of ammonia first established by Terenin and Neuimin[18]:

$$NH_3 + h\nu \rightarrow \dot{N}H_2 + \dot{H}$$

Some interesting anomalies were observed in the ESR spectrum of the $\dot{N}H_2$ and $\dot{N}D_2$ radicals: whereas the ratio of the hyperfine interaction constants (a_H, a_D) for $\dot{H}$ and $\dot{D}$ is accurately equal to the ratio of the g-factors for their nuclei (6.514), the corresponding constant for nitrogen (a_N) increases only by 15% on going from $\dot{N}H_2$ and $\dot{N}D_2$. The effect is probably associated with differences in the zero-point vibrations of these molecules.

The same workers[36] observed the ESR spectra of hydrogen atoms after ultraviolet irradiation of 1% hydriodic acid in an Ar matrix at 4.2°K. Instead of a single doublet ($I_H = \frac{1}{2}$) with a splitting of 508 Oe, the known ESR spectrum of hydrogen atoms, they found three doublets one of which accurately coincided with the known spectrum.

It is interesting to note that the ESR spectrum of hydrogen atoms obtained by the photodecomposition of water ($H_2O + h\nu \rightarrow \dot{O}H + \dot{H}$) in solid argon at 4.2°K consists of two doublets[39]. The separation of the inner doublets was 507.9 Oe, which is commonly found for condensed $\dot{H}$ atoms and corresponds to a hyperfine splitting constant a_H 0.46% lower than the value for the free hydrogen atom. For the outer doublets the splitting was 516.1 Oe, corresponding to an a_H value 1.5% higher than the free H atom value. As in the previous case, these results were interpreted theoretically[40] as evidence for the penetration of $\dot{H}$ atoms into the available octahedral holes of the face-centred cubic lattice of crystalline argon. Phenomena associated with the capture of $\dot{H}$ atoms at various positions in the

lattice were observed also with krypton and xenon at 4.2°K.

The formation of $\dot{C}H_3$ and $\dot{C}D_3$ radicals was observed by Cochran and coworkers[37] during ultraviolet irradiation of CH_3I and CD_4 respectively in Ar at 4.2°K. The ESR spectrum of the free $\dot{C}H_3$ radical was a quartet of lines with a splitting of 22.9 Oe, $g = 2.0024$, and relative intensities of the components 1 : 3 : 3 : 1, pointing to interaction of the unpaired electron with the protons of three equivalent hydrogen atoms. The $\dot{C}D_3$ radical had a seven-component ESR spectrum ($I_D = 1$) with intensity ratios 1 : 3 : 6 : 7 : 6 : 3 : 1. As was to be expected, the separation of the components of the ESR spectrum was less for the $\dot{C}D_3$ radical than for the $\dot{C}H_3$ radical as required by the ratio of the nuclear g-factors for D and H.

When more complex radicals are trapped in an argon matrix we can no longer average all anisotropic interactions by assuming free rotation in the solid matrix at 4.2°K. With the ethyl radical $CH_3\dot{C}H_2$, obtained by Cochran and coworkers[36] by ultraviolet irradiation of solid 1% ethyl iodide (C_2H_5I) solution in argon at 4.2°K, the ESR spectrum consists of a quartet ($a\beta = 26.3$ Oe) of relatively sharp lines each of which is split into a triplet ($a\beta = 18.5$ Oe) with relatively broad outer components. The sharpness of the lines suggests that the $C_\alpha H_2$ group is free to rotate about the $C_\beta C_\alpha$ bond. The outer lines of each triplet correspond to parallel orientation of the spins of the α-hydrogens, which creates additional magnetic anisotropy. It is not averaged by internal rotations, and therefore line broadening occurs.

Photodecomposition of 1% n-propyl iodide in solid Ar at 4.2°K gave a three-component ESR spectrum for the n-propyl radical C_3H_7. In order to identify the protons responsible for the hyperfine splitting, n-propyl iodide deuterated in the α and β positions was photodecomposed ($CH_3CH_2CD_2I$ and $CH_3CD_2CH_2I$). The authors concluded[36] that the observed ESR spectrum of the n-propyl radical can be explained by assuming that the main contribution to the hyperfine splitting comes from the protons of the two equivalent β-hydrogens.

Cochran and coworkers[39] decomposed SiH_4 by ultraviolet light in Ar at 4.2°K, and obtained an ESR spectrum for the $\dot{S}iH_3$ radicals stabilised under these conditions. The spectrum consisted of a quartet of lines, like that of the $\dot{C}H_3$ radical, but with a somewhat larger separation between the components.

Hayon and Saito[41] used the ESR method to investigate the photodecomposition of HNO_3 in degassed and frozen (77°K) aqueous solutions, for which the following reaction scheme had been proposed[42]:

$$HNO_3 \xrightarrow{h\nu} \dot{O}H + \dot{N}O_2;\ \dot{O}H + HNO_3 \rightarrow H_2O + \dot{N}O_3 .$$

When samples of 0.1, 1.0, and 5.0 M HNO_3 are irradiated with light of $\lambda = 254$ mμm, the solid solution at 77°K develops a blue colour. The ESR spectrum of these coloured samples consisted of the well known[43-48] three-component signal of the $\dot{N}O_2$ radical ($g_\perp = 2.0055$; $g_\parallel = 1.9927$; $A/h = 160$ MHz; $B/h = -8$ MHz), the singlet line of the $\dot{N}O_3$ radical ($\bar{g} = 2.018 \pm 0.001$ and $\Delta H = 10$ Oe), and an additional singlet line with $g = 2.003$. It is interesting to note that yellow light ($\lambda > 480$ mμm) bleaches the samples and leads to the disappearance of the signal with $g = 2.018$. It is known[49-52] that the $\dot{N}O_3$ radical has three absorption bands in the region of 500–700 mμm ($\epsilon = 3000 \pm 1000$ litre mole^{-1} cm^{-1} at $\lambda = 662$ mμm). From energy considerations, the photodecomposition of $\dot{N}O_3$ can be expected to occur by two paths:

$$\dot{N}O_3 \xrightarrow{\lambda > 624\ m\mu m} \dot{N}O + O_2;\ \dot{N}O_3 \xrightarrow{\lambda < 570\ m\mu m} \dot{N}O_2 + \dot{O}.$$

Indeed, the signal of the $\dot{N}O_2$ radical and the singlet line with $g = 2.003$ which had been tentatively assigned to the $\dot{N}O$ radical became more intense in the ESR spectrum after irradiation of the coloured samples with yellow light.

2. Secondary Reactions of Photogenerated Simple Free Radicals

The photochemical formation of simple free radicals in solid matrices at low temperatures is, as stated above, one of the standard methods of investigating primary photoprocesses. The problem of the secondary reactions and subsequent photoconversions of the free radicals at low temperatures is highly relevant on the one hand to the preservation of these radicals by appropriate stabilisation and on the other hand to the realisation of low-temperature reactions involving these radicals.

Pimentel and coworkers[53] observed, in their study of the photodecomposition of HI in solid CO at 20°K, the infrared spectrum of the formyl radical HĊO, apparently produced by the chemical reaction between atomic hydrogen and molecules of the solid matrix according to the scheme

$$HI \xrightarrow{h\nu} \dot{H} + \dot{I};\ \dot{H} + C{=}O \rightarrow H{-}\dot{C}{=}O .$$

Cochran and coworkers[54] showed by the ESR method that the HCO radical is formed in this system even at 4.2°K.

However, this is not the only reaction which can take place at these very low temperatures. It is known that irradiation with vacuum ultraviolet light of 1% HCN in solid argon produces, in addition to the CN radical, a weak ESR signal from the $H_2\dot{C}N$ radical (a triplet of triplets), formed by a secondary dark reaction involving atomic hydrogen:

$$\dot{H} + H{-}C{\equiv}N \rightarrow H_2C{=}\dot{N}.$$

The activity of atomic hydrogen at 4.2°K is demonstrated also by an experiment in which HI mixed with 10% of HCN was photodecomposed in argon at 4.2°K under the influence of light ($\lambda = 254$ mμm). The ESR spectrum of the $H_2\dot{C}N$ free radical, formed by the above scheme, was again observed.

The ESR spectrum of the amino free radical ($\dot{N}H_2$) was observed by Coope and coworkers[55] in the products of the photodecomposition of hydrazoic acid (HN_3) in a krypton matrix at 4.2°K. The first product of the photodecomposition of hydrazoic acid was shown, by a study[56-58] of the optical absorption spectra of the products, to be the imino radical $\dot{N}H$. The $\dot{N}H_2$ radical can be formed by the secondary reaction

$$\dot{N}H + HN_3 \rightarrow \dot{N}H_2 + N_3.$$

In fact, the products of the photodecomposition of hydrazoic acid showed a broad, strong singlet line with $g \simeq 2$, identified as the ESR spectrum of the imino radical, on which the weak nine-component spectrum of the $\dot{N}H_2$ radical was superimposed[38].

As was stated at the beginning of the article, the intermediate products in the photodecomposition of H_2O_2 are $\dot{O}H$ radicals, which are chemically active at 77°K and can extract a labile hydrogen atom from neighbouring molecules of the medium, forming $H\dot{O}_2$ hydroperoxy radicals. Sergeeev and coworkers[32,59-62] have demonstrated the special role of phase transformations in the matrix in determining the reactions of the $\dot{O}H$ and $H\dot{O}_2$ radicals at low temperatures. Depending on the rate at which a 25% aqueous solution of H_2O_2 is cooled, a crystalline or a

glassy phase can be obtained at 77°K. When the samples are irradiated with ultraviolet light, $H\dot{O}_2$ radicals are formed. The destruction of these radicals in a glassy phase does not begin until 143°K, and is complete at 158°K. For aqueous solutions of H_2O_2 this temperature is the glass–crystal phase transition point. The destruction of the $H\dot{O}_2$ radicals is probably caused by the increased mobility of the molecules during the phase transition. In crystalline samples there is no destruction of the radicals at 158°K. On raising the temperature from 163° to 183°K a stepwise disappearance of the radicals was observed, corresponding to the loss of a definite fraction of the radicals at a number of specific temperatures. Complete destruction of the radicals does not occur until the temperature reaches 220°K, the melting point of the eutectic mixture.

A similar type of destruction of the radicals was observed by the same authors for the phase transition point at 103°K in their work on the photolysis of H_2S frozen at 77°K.

More recently, several interesting features of the photolysis of dilute aqueous solutions of H_2O_2 have been reported. Thus, at H_2O_2 concentrations below 10^{-3} M the ESR spectrum consists of the combined signals from the $\dot{O}H$ and $H\dot{O}_2$ radicals[33,34]. On increasing the time of irradiation the ESR signal from $H\dot{O}_2$ decreases. The observed change in the concentration of the radicals can be explained by the following series of reactions:

$$H_2O_2 \xrightarrow{h\nu} 2\dot{O}H$$
$$\dot{O}H + H_2O_2 \rightarrow H_2O + H\dot{O}_2$$
$$H\dot{O}_2 \xrightarrow{h\nu} \dot{H} + O_2 \cdot$$

It is usually assumed that the formation of the hydroperoxy ($H\dot{O}_2$) radicals is due to the diffusion of $\dot{O}H$ at 77°K during the dark period. However, Sergeev and coworkers consider[61] that diffusion of $\dot{O}H$ in ice at 77°K is unlikely, and they explain the formation of $H\dot{O}_2$ in dilute aqueous solutions of H_2O_2 by postulating migration of the free valency along the system of hydrogen bonds

$$\begin{array}{ccccccccccccc} O\cdots(H-O\cdots H-O)_n\cdots H-O & \rightarrow & O-H\cdots(O-H\cdots O-H)_n\cdots O \\ | & & | & & | & & | & & | & & | & & | \\ H & & H & & H & & O-H & & H & & H & & O-H \end{array}.$$

According to this scheme, any disturbance of the hydrogen bond structure should lead to stabilisation of the $\dot{O}H$ radical. Stabilisation of this radical can therefore be expected in solutions with a high concentration of H_2O_2. This expectation was confirmed[62], but not in a pure aqueous solution: addition of sodium perchlorate (8 M) was necessary to destroy the hydrogen bond structure of the water. Ultraviolet irradiation of such a solution produced ESR signals from the $\dot{O}H$ radical. In the absence of sodium perchlorate, photodecomposition of aqueous solutions of H_2O_2 produced only $H\dot{O}_2$ radicals. This is a clear confirmation of the proposed migration of free valencies along the system of hydrogen bonds.

The chemical activity of hydroxyl radicals produced by the photodecomposition of hydrogen peroxide at 77°K or 96°K was successfully applied by Ingram and coworkers[63-69] to the preparation of free radicals from various aliphatic alcohols and saturated hydrocarbons. The ESR spectra obtained by ultraviolet irradiation (λ = 365 or 254 mμm) of frozen hydrogen peroxide solutions (10^{-1}–10^{-6} M) in various readily oxidisable solvents were due to free radicals of the solvent molecules which had been dehydrogenated by the free hydroxyl. Thus, the reaction of $\dot{O}H$ with methanol[65] at 96°K produces an ESR spectrum consisting of three components with an intensity ratio of 1 : 2 : 1, showing that the hyperfine structure of the ESR spectrum arises from the interaction of an unpaired electron with the protons of two equivalent hydrogen atoms and is due to the $\dot{C}H_2OH$ radical. Several characteristic ESR spectra for various alcohols were obtained in this way, ranging from methanol to n-hexanol (including some secondary and tertiary alcohols). Using deuterated alcohols it was shown that the $\dot{O}H$ radical removes the α-hydrogen from the alkyl group and that the proton of the hydroxyl group of the alcohol does not interact with the unpaired electron of the radical.

Shelimov and coworkers[70,71] studied by the ESR method the kinetics of the accumulation, disappearance, and transformation of the radicals formed by ultraviolet irradiation of dilute H_2O_2 solutions in CH_3OH and C_2H_5OH at 77°K. When solutions of H_2O_2 in CH_3OH at 77°K are irradiated with light from a SVDSh-250 mercury lamp ($\lambda < 320$ mμm), an ESR spectrum appears after a few minutes, and is found to consist of the combination of the spectra of two free radicals: $\dot{C}H_3$ and $H\dot{C}O$.[70] Under prolonged irradiation the concentration of these radicals reach a limiting value. When the light is removed the form of the ESR spectrum begins to change: the intensity of the lines from the $\dot{C}H_3$ radical decreases, and at the same time the three-line ESR signal of the $\dot{C}H_2OH$ radical appears in the spectrum and begins to grow. After a second exposure to light the concentration of $\dot{C}H_2OH$ falls off quickly, with a corresponding increase in the concentration of CH_3 radicals. Meanwhile, the concentration of $H\dot{C}O$ remains practically unchanged. It should be noted that a kinetic picture very similar to the above was obtained when a solution of C_6H_6 in CH_3OH was irradiated at 77°K. The photochemical behaviour of these systems can be described by the following scheme:

$$H_2O_2 \xrightarrow{h\nu} 2\dot{O}H$$
$$(C_6H_6 \xrightarrow{h\nu} C_6H_6{}^*)$$
$$\dot{O}H\,(C_6H_6{}^*) + CH_3OH \rightarrow H_2O\,(C_6H_6 + \dot{H}) + \dot{C}H_2OH$$
$$\dot{C}H_2OH \xrightarrow{h\nu} :CH_2 + \dot{O}H \xrightarrow{+CH_3OH} \dot{C}H_3 + 2\dot{C}H_2OH + H_2O$$
$$\searrow H\dot{C}O + H_2$$
$$\dot{C}H_3 + CH_3OH \rightarrow CH_4 + \dot{C}H_2OH\,.$$

The formyl radical ($H\dot{C}O$) is known to have absorption bands in the visible region of the spectrum[72]. If the irradiation is repeated with light of $\lambda > 320$ mμm, a very fast decrease in the concentration of the $H\dot{C}O$ radical is observed, due to the photodecomposition of this radical with formation of the $\dot{C}H_2OH$ radical according to the scheme

$$H\dot{C}O \xrightarrow{h\nu} \dot{H} + CO;$$
$$\dot{H} + CH_3OH \rightarrow H_2 + \dot{C}H_2OH.$$

After the concentration of $H\dot{C}O$ radicals has fallen to zero the concentration of $\dot{C}H_2OH$ no longer increases. A mass spectroscopic analysis of the gaseous products of the photodecomposition of H_2O_2 in CH_3OH detected H_2 (57%), CO (26%), and CH_4 (17%).

It follows from this sequence of experimentally identified elementary steps that a photochemical system irradiated with the unfiltered light from a SVDSh-250 mercury lamp will undergo a peculiar type of chain reaction involving the decomposition of methanol at 77°K with photochemical acts of chain initiation and branching and with some chain propagation steps.

Shelimov and coworkers[71] also investigated by ESR the kinetics of the accumulation, disappearance, and mutual conversion of the radicals formed during irradiation by ultraviolet light (λ = 240 mμm) of H_2O_2 or C_6H_6 solutions

in ethanol at 77°K. The solutions were thoroughly degassed before photodecomposition. As in the case of the methanolic solutions discussed above, the form of the ESR spectra and all the kinetic characteristics were the same for the two solutes. The formation of the following radicals was recorded: $\dot{C}_2H_5$, $\dot{C}H_3$, $CH_3\dot{C}HOH$, and $CH_3CH_2\dot{O}$. It was shown that under the action of ultraviolet light of specific wavelengths ($\lambda > 360$ mμm) the alcoholic radicals $CH_3\dot{C}HOH$ decompose with formation of alkyl radicals ($\dot{C}_2H_5$ and $\dot{C}H_3$). When the light is removed, a gradual disappearance of the alkyl radicals is observed at 77°K, accompanied by the appearance of the radicals $CH_3\dot{C}HOH$ and $CH_3CH_2\dot{O}$ (singlet ESR line, $\Delta H = 14$ Oe). It is found that the $CH_3CH_2\dot{O}$ radicals isomerise under the action of light with $\lambda > 360$ mμm to give $CH_3\dot{C}HOH$ radicals. From mass spectroscopic data, the main gaseous products of the photodecomposition of H_2O_2 solutions in C_2H_5OH are CO (23%), CH_4 (19%), and H_2 (58%). Evidently, a very important stage in their formation is the decomposition of the alcoholic radicals under the influence of light to give alkyl radicals.

Mal'tsev and Petrov[73,74] have shown that the ESR spectra of the photodecomposition products of hydrogen peroxide in tertiary alcohols of general formula $R(CH_3)_2COH$, where $R = CH_3$, C_2H_5, $CH_2{=}CH$, $HC{\equiv}C$, consist of a combination of components associated with the alcoholic radical $R(CH_3)C(\dot{C}H_2)OH$ and the CH_3 radical. The formation of t-butanol radicals during photodecomposition of hydrogen peroxide in this alcohol had previously been reported by Ingram and coworkers[63] and by Symons and coworkers[68]. Mal'tsev's paper describes[74] the mechanism of the photoprocesses occurring in solid solutions of H_2O_2 in tertiary alcohols taking trimethylmethanol as an example. The ESR spectrum obtained after irradiation with the unfiltered light from a DRSh-500 mercury lamp contains 7 lines which can be assigned as a triplet for the alcoholic radical and a quartet for the methyl radical. Storage of the sample, after irradiation at 77°K, for 60–70 h in the dark is accompanied by gradual disappearance of the components of the quartet and growth of the triplet. When a frozen solution of H_2O_2 in trimethylmethanol is irradiated with light of wavelength 340–390 mμm the ESR signal consists of the triplet only. However, the quartet spectrum of the CH_3 radical appears after further irradiation, with light of $\lambda < 320$ mμm, of a solution in which the concentration of alcoholic radicals (triplet ESR spectrum) is below the maximum. The following reaction scheme can be proposed for this system:

$$H_2O_2 \xrightarrow{u.v.} 2\dot{O}H$$

$$(CH_3)_3COH + \dot{O}H \rightarrow (CH_3)_3C(\dot{C}H_2)OH + HOH$$

$$(CH_3)_3C(\dot{C}H_2)OH \xrightarrow{u.v.} \dot{C}H_3 + CH_3\overset{\|}{C}CH_3 \,.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad O$$

But the authors[74] suggest the following mechanism

$$(CH_3)_3COH + \dot{O}H \rightarrow (CH_3)_3C\dot{O} + HOH$$

$$(CH_3)_3C\dot{O} \xrightarrow{u.v.} \dot{C}H_3 + CH_3\overset{\|}{C}CH_3 \,.$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad O$$

on the grounds that appreciable concentrations of methyl radicals appeared only in samples which after storage in the dark at 77°K showed a singlet ESR line in the centre of the spectrum, tentatively ascribed to the radical $(CH_3)_3C\dot{O}$.[75] The authors postulate that the penultimate reaction is caused by "hot" OH radicals which appear only under the influence of ultraviolet light with $\lambda < 340$ mμm.

Quite recently, Livingston and Zeldes[76] have used the ESR method to study the reaction of photogenerated ȮH radicals with alcohols in the temperature range from −70° to +60°C. Using a concentrated beam of ultraviolet light, they irradiated a flow of alcohol containing 1% of H_2O_2 in the cavity of their radio-frequency spectrometer. This technique allowed them to produce measurable steady-state concentrations of short-lived radicals. In the absence of dissolved oxygen the main reaction products were the radicals formed by the removal of the α-hydrogen from a molecule of the alcohol by the hydroxyl radical. The RĊHOH radicals, where R = H, CH_3, C_2H_5, C_3H_7, $(CH_3)_2CH$, and C_6H_5, had hyperfine splitting constants a_α in the range 14.7–17.4 Oe, and $g = 2.00298$–2.00334. For the alcoholic radicals with β-hydrogens, $a_\beta = 20.0$–22.2 Oe. The ring protons of the benzyl alcohol free radicals were found to be non-equivalent. Removal of the α-hydrogen from allyl alcohol by a free hydroxyl produces two geometrically isomeric free radicals of the alcohol.

Norman and Porter[77] found that solutions of iodine in ether–isopentane–ethanol (EPA) mixtures at 77°K are decolorised by visible light. When the irradiated solutions are allowed to warm up, the colour of the iodine is restored, indicating stabilisation of iodine atoms at 77°K. Filseth and Willard[78] investigated the processes involved in the bleaching of these solutions, and possible chemical reactions between iodine and saturated solvent molecules, by applying optical spectroscopy and ESR to solutions of iodine in EPA, and also in ethanol, ether, and isopropanol at 90° and 77°K before and after irradiation (AN-6-1000 W), and also after thawing the system to room temperature. Spectrophotometric measurements on solutions irradiated at 90°K showed strong absorption at 291 and 358 mμm, due to tri-iodide, which disappeared at room temperature whilst the absorption bands of molecular iodine reappeared. The ESR spectra of iodine solutions irradiated at 77°K indicate that the iodine atoms produced by the photodissociation of molecular iodine can extract an α-hydrogen atom from the solvent molecule with formation of alcoholic radicals. Hydrogen removal by an iodine atom in the ground state has a low probability at 77°K, because the process is endothermic and requires an energy of the order of 20–30 kcal. The most probable reaction mechanism is the following

$$I_2(^1\Sigma_g) \xrightarrow{h\nu} I_2(^3\Pi) \rightarrow \dot{I}(^2P_{3/2}) + \dot{I}(^2P_{1/2})$$

$$\dot{I}(^2P_{1/2}) + RH \rightarrow HI + \dot{R}$$

$$\dot{I} + I_2 \rightarrow I_2 \cdots \dot{I}$$

$$I_2 \cdots \dot{I} + \dot{I} \rightarrow 2I_2 \,.$$

In order to arrive at a more complete understanding of low-temperature reactions of the type $\dot{X} + RH \rightarrow \dot{R} + HX$, where X is a halogen atom, and to explain the features of the photodecomposition of mixtures of halogens and aliphatic organic compounds, Sergeev and coworkers[62] studied the formation of free radicals during ultraviolet irradiation of mixtures of bromine (or chlorine) with various hydrocarbons and alcohols at 77°K. These included chlorine and bromine mixtures with iso-octane, isopentane, pentane, and cyclohexane. Radicals were formed only in the mixtures with chlorine when irradiation was with ultraviolet light of $\lambda > 280$ mμm. From the number of components of the hyperfine structure and their separation, the ESR spectra can be assigned to radicals of the type $(CH_3)_2\text{–}\dot{C}\text{–}CH_2\text{–}CH_3$ and $\dot{C}_6H_{11}$, formed by the reaction

$$Cl_2 + RH \xrightarrow{h\nu} 2\dot{C}l + RH \rightarrow HCl + \dot{R} \,.$$

The absence of radicals in the Br_2 mixtures can be ascribed to the strong endothermicity of these reactions, which do not readily occur at 77°K.

Ultraviolet irradiation ($\lambda > 280$ mμ) of mixtures of chlorine or bromine with methanol, ethanol, and isopropanol produced complex ESR signals, consisting of several free radical spectra superimposed. These radicals were formed by secondary photodissociation of the radicals formed in the primary process. Essentially, the processes observed in the photodecomposition of H_2O_2 in alcohols occur also in these systems. However, the activation energy of the reaction $\dot{B}r + RH_\alpha OH \rightarrow HBr + \dot{R}OH$ is ~ 9 kcal mole^{-1} in the case of methanol[79], and therefore the removal of an α-hydrogen atom from a molecule of the alcohol has a low probability at 77°K. According to Sergeev[62,80], the formation of organic free radicals in the alcohol–halogen system involves molecular charge-transfer complexes between the halogen and the oxygen of the alcohol formed in the condensation, which alter, the absorption spectrum of the system. The following mechanism is proposed for the formation of the radicals: light absorption causes excitation of the complex and transfer of an electron from the oxygen of the alcohol to the bromine, followed by the formation of the $R\dot{H}O$ radical which isomerises to $\dot{R}OH$ under the influence of light.

3. Photolysis of Complex Organic Compounds

Piette and Landgraf[75] have successfully applied the ESR method to studies of the photodecomposition of primary, secondary, and tertiary butyl hydroperoxides of structure R–O–O–H, where R = $CH_3CH_2CH_2CH_2$ (primary), $CH_3CH_2\dot{C}HCH_3$ (secondary), and $-C(CH_3)_3$ (tertiary). The source of ultraviolet light was a medium-pressure mercury lamp (N85S3). From energy considerations, breaking of the O–O bond with formation of alkoxy and hydroxyl radicals could be expected under the influence of light. For the alkoxy radical $R\dot{O}$, the density of the unpaired electron can be expected to have a low value on the α-protons and a negligible value on the β-protons, because of the influence of the oxygen atom. Hence, the ESR spectrum of these radicals should show a triplet, a doublet, and a singlet for primary, secondary, and tertiary butyl hydroperoxide respectively. In all cases the hyperfine splitting constant a_H should lie between 2 and 3 Oe. Piette found a triplet ESR signal after light irradiation of primary butyl hydroperoxide, a doublet with secondary butyl hydroperoxide, and a singlet with the tertiary compound, the splitting being 3.5 and 2.8 Oe respectively. Thus, it was shown that the photodecomposition of butyl hydroperoxides goes through the formation of alkoxy radicals. The ESR spectrum of the hydroxyl radical $\dot{O}H$ was not detected, probably because of its short lifetime.

Piette[81] studied the photodecomposition of simple aliphatic alcohols during irradiation with unfiltered ultraviolet light. Irradiation of methanol at 77°K gave an ESR signal consisting of two superimposed spectra: a quartet of lines from the $\dot{C}H_3$ methyl radical and a doublet of lines with a splitting of about 120 Oe from the $H\dot{C}O$ radical. On irradiation of methanol which had been deuterated in the hydroxyl position (CH_3OD), the ESR signal was the same as with ordinary methanol. Irradiation of CD_3OH led to the appearance of a seven-line spectrum from the $\dot{C}D_3$ radical and an unresolved multiplet. The doublet with a splitting of 120 Oe was not obtained in this case. Irradiation of ethanol gave rise to a complicated ESR spectrum. As shown by Sullivan and Koski[82–84], and by Shelimov and coworkers[70,71], these free radicals stabilised at 77°K are the result of interdependent, complex photochemical reactions of alcohols, so that primary photoprocesses in these materials can be assessed only by spectral and kinetic studies at different temperatures.

Maas and Volman[85] studied the action of ultraviolet light on various pure allyl alcohols (allyl alcohol, but-2-en-1-ol, but-1-en-3-ol) at 77°K, and found that the primary photochemical act for these compounds is the breaking of the C–O bond with formation of the corresponding allylic hydrocarbon free radicals. These radicals are stable at 77°K. However, at higher temperatures (100–130°K) hydroxy-allyl radicals appear with the allyl hydrocarbon radicals: they are formed by the removal of an α-hydrogen from the alcohol by the active hydroxyl radical produced in the primary photochemical act (photodissociation of the C–O bond).

Ultraviolet irradiation of 2-hydroxy-2-methylbut-1-ene, which does not contain α-hydrogen, gives rise to the ESR spectra of the $\dot{C}H_3$ and $R\dot{C}H_2$ radicals, probably formed in the primary process.

Poole and Anderson[86] reported the observation of the ESR spectra of radicals, stable at 77°K, formed by ultraviolet irradiation of normal and branched unsaturated hydrocarbons (alkenes). Their light source was a high-pressure mercury lamp (GE-BH6), producing a flux of 16.9 W steradian^{-1} in the photochemically active wavelength range (250–380 mμ). The following compounds were irradiated with ultraviolet: methylacetylene (propyne), pent-2-ene (2-amylene), hex-1-ene and hex-2-ene, hept-2-ene, oct-1-ene and oct-2-ene, and also 3-ethylpent-2-ene, 3-methylbut-2-ene, 2,4,4-trimethylpent-2-ene, 4-methylpent-2-ene, and 2,6-dimethylhept-3-ene. The model used to interpret the observed ESR spectra assumed the absorption of a photochemically active photon by the chromophoric group of the molecule, followed by dissociation into two fragments. The light fragment (hydrogen atom, or methyl radical), being able to diffuse at 77°K, reacts with neighbouring species. The heavy fragment is stabilised at 77°K and is responsible for the ESR signal in every case. The hyperfine structure of the ESR signal results from the interaction of the unpaired electron with the protons of the hydrogen atoms in the α and β positions. However, Anderson and Beasley[87] subsequently showed that the appearance of free radicals in ultraviolet-irradiated alkenes is initiated by the photodecomposition of organic peroxides[88] present as impurities in the alkenes used for the investigation:

a)
$$ROOH \xrightarrow{h\nu} R\dot{O} + \dot{O}H$$
$$R\dot{O} + R'H \rightarrow ROH + \dot{R}'$$
$$\dot{O}H + R'H \rightarrow HOH + \dot{R}'$$

b)
$$R\dot{O} + C{=}C{-}C{-}R' \rightarrow RO{-}C{-}\dot{C}{-}C{-}R'$$
$$\dot{O}H + C{=}C{-}C{-}R' \rightarrow HO{-}C{-}\dot{C}{-}C{-}R' .$$

Kuwata and Hirota[89] investigated the photodecomposition of organic ketones (acetone and benzophenone) by the ESR method. Several types of free radical could have been expected[90] in the photodissociation of acetone, namely

$$CH_3COCH_3 \xrightarrow{h\nu} CH_3\dot{C}O + \dot{C}H_3$$
$$CH_3\dot{C}O \xrightarrow{h\nu} \dot{C}H_3 + CO .$$

However, several hours' irradiation of pure acetone with ultraviolet light at 77°K did not produce a detectable amount of free radicals. A single ESR line with ΔH = 30 Oe and g = 2.003 was observed by irradiating a solution

of acetone in alcohol or in EPA mixture (ether–isopentane–alcohol), but the authors were unable to identify the radical responsible for this line. A singlet ESR spectrum (ΔH = 23–24 Oe, g = 2.003) was obtained after ultraviolet irradiation of pure benzophenone or a solution of benzophenone in ethanol or EPA at 77°K. As in the previous case, it was not possible to identify the free radicals.

In a recent investigation by Pukhal'skaya and coworkers[91] on the photoconversions of radicals in γ-irradiated frozen acetone, the photodissociation of acetone frozen at 77°K and of a 50% aqueous solution of acetone were also examined in control experiments. The light source was a DRSh-500 super-high pressure mercury lamp. The ESR signal obtained consisted of two superimposed spectra: the spectrum of the $\dot{C}H_3$ radical (a quartet of lines with intensity ratio 1 : 3 : 3 : 1) and that of the acetyl radical $CH_3C\dot{O}$ (singlet line). The authors point out that the rate of appearance of $\dot{C}H_3$ radicals, assessed from the initial portion of the kinetic curve for the accumulation of these radicals during illumination, is higher by a factor of two than the rate of appearance of acetyl radicals: this seems to be further confirmation of the generally accepted scheme for the photodecomposition of acetone. The assignment of the singlet in the ESR spectrum to the acetyl radical raises some doubt. The unpaired electron of the $CH_3\dot{C}O$ radical can interact with the protons of three methyl hydrogens, leading to an ESR spectrum consisting of four equidistant components with a binomial intensity distribution, 1 : 3 : 3 : 1. Such a spectrum was in fact obtained by Morton and Falconer[92] in the photodecomposition of biacetyl $(CH_3CO)_2$ at 77°K in a vacuum using a low-pressure mercury lamp. After 90 min irradiation the spectrum consisted of two superimposed quartets, one of which had a hyperfine splitting of 66 ± 5 MHz and g = 2.0027 ± 0.0008 and could be assigned to the methyl radical, the second having 47 ± 5 MHz and g = 2.0055 ± 0.0008 and arising, according to the authors, from the acetyl radical. The signal from the methyl radical fell in intensity by a factor of 2 in 15 min after the irradiation ceased; on the other hand, the signal from the acetyl radical did not change in the dark at 77°K, but on raising the temperature to 140°K it rapidly disappeared without changing shape. The authors point out that the initial concentration of methyl radicals was about 5 times higher than the concentration of acetyl radicals, which can be explained by two photoreactions occurring consecutively:

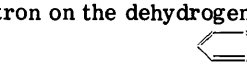
$$CH_3COCOCH_3 \xrightarrow{h\nu} 2CH_3\dot{C}O$$

$$CH_3\dot{C}O \xrightarrow{h\nu} \dot{C}H_3 + CO.$$

The formation of methane by the photodissociation of methyl iodide and of azomethane in a hydrocarbon solvent[50] at 77°K also suggested that the abstraction of a hydrogen atom by a methyl radical by the reaction $\dot{C}H_3 + RH \rightarrow CH_4 + \dot{R}$ proceeds at appreciable rates at low temperatures. To confirm the accepted views on this type of reaction, Varbanskaya and coworkers[93] made an ESR study of the photodissociation of azomethane and methyl iodide, and also of acetone and acetaldehyde in methylcyclohexane at 77°K under the influence of ultraviolet light of various wavelengths. In the first two cases the ESR spectrum showed the methylcyclohexyl radical ($\dot{R}$), formed by the removal of a hydrogen atom by a $\dot{C}H_3$ free radical from the methylcyclohexane molecule. Four narrow components of different intensity with a splitting of ~ 23 Oe and intensity ratio 1 : 3 : 3 : 1 can be resolved in the ESR spectrum, pointing to the formation and stabilisation of methyl radicals under these conditions. The results justify the conclusion that methyl radicals are undoubtedly formed during the photolysis of CH_3I and $CH_3N_2CH_3$ in the solid phase at 77°K: depending on the wavelength of the active light, they can recombine immediately after formation in the "cage" or they can enter into replacement reactions, or again they can be stabilised and emerge from the cage. It was found that methyl radicals formed by the photodissociation of methyl iodide at 77°K retain their activity also towards unsaturated compounds of the olefin type. These radicals can either add on to olefins at the double bond or they can extract a hydrogen atom from the methylene group, leading to the formation of alkyl or allyl radicals respectively, as can be verified by the ESR method[94].

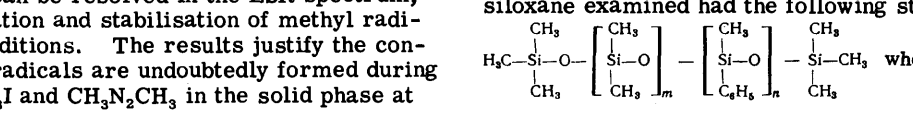
Bielski and Timmons[95] studied the photodecomposition of aliphatic nitro-compounds (nitromethane, methyl nitrite, tetranitromethane) at 77°K. Brief irradiation (from 5 s to several minutes) of these compounds with ultraviolet light from a GE-BH6 high-pressure lamp or a low-pressure lamp led to the appearance of complex ESR signals corresponding to a number of superimposed ESR spectra from different radicals. In particular, after irradiation of a solution of nitromethane in water or in CCl_4 the observed ESR signal can be interpreted, in accordance with the photoreaction scheme $CH_3NO_2 \xrightarrow{h\nu} \dot{C}H_3 + \dot{N}O_2$, as the combination of a quartet of narrow lines from the $\dot{C}H_3$ radical and a triplet of asymmetric lines from the $\dot{N}O_2$ radical. When the solution temperature is raised from 77 to 193°K the methyl radical spectrum disappears and only the $\dot{N}O_2$ radical spectrum remains. A poorly resolved ESR signal was obtained from photodecomposition of methyl nitrite (CH_3ONO). According to the photodissociation scheme proposed by Gray and Style[96], $CH_3ONO \xrightarrow{h\nu} CH_3\dot{O} + \dot{N}O$, the ESR spectrum of the methoxyl group and of $\dot{N}O$ would have been expected. Indeed, the central singlet line can be assigned to the methoxy radical[82]. However, when the temperature of the sample is raised to 193°K, there only remains the ESR spectrum characteristic of the $\dot{N}O_2$ radical, whose appearance is difficult to explain. The photodecomposition of tetranitromethane at 77°K invariably led, irrespectively of the matrix (water, or methanol), to a single ESR spectrum: that of the $\dot{N}O_2$ radical, whose formation can be described by the scheme $C(NO_2)_4 \xrightarrow{h\nu} \dot{C}(NO_2)_3 + \dot{N}O_2$. No spectrum was obtained from the $\dot{C}(NO_2)_3$ radical, probably because of strong interaction with the matrix.

The action of ultraviolet light (SVDSh-1000) on alkylphenylacetylenes (methylphenylacetylene, deuteromethylphenylacetylene, ethylphenylacetylene) produces an intense ESR spectrum pointing to the localisation of the unpaired electron on the dehydrogenated alkyl group[97]:



Irradiation of dialkylacetylenes (R–C≡C–R) produces complicated ESR spectra, probably due to the interaction of the unpaired electron with all the protons of the alkyl groups as a result of the delocalisation of this electron over the whole of the molecule. Thus, in compounds of the type of R–C≡C–Ar and R–C≡C–R (R = CH_3, C_2H_5), the formation of free radicals is due to the photo-removal of a hydrogen atom from the alkyl groups of the substituted acetylenes.

Voevodskii, and Bubnov and coworkers[98,99], have successfully applied the ESR method to the characterisation of the elementary processes of formation and of reaction of free radicals in irradiated organosilicon compounds (polyphenylmethylsiloxane, silazanes). The polyphenylmethylsiloxane examined had the following structure[98]:



where m = 18–20, n = 5–7.

Ultraviolet irradiation of this compound with condensed light from a DRSh-500 super-high pressure mercury lamp at 77°K produces a well resolved ESR spectrum in which two groups of lines with hyperfine structure can be distinguished: (1) a quadruplet with a splitting of 24 ± 0.5 Oe and intensity ratio 1 : 3 : 3 : 1, and 2) a triplet with a splitting of 21 ± 0.5 Oe and intensity ratio 1 : 2 : 1. On the basis of these findings, the authors conclude that ultraviolet irradiation of polyphenylmethylsiloxane gives rise to the radicals $\dot{C}H_3$ and $-O-\overset{\overset{CH_2}{|}}{\underset{\underset{R}{|}}{Si}}-O$, where R = CH_3, C_6H_5. On interrupting the irradiation the spectrum of the methyl radical gradually disappears, with a simultaneous increase in the intensity of the spectrum of the second radical according to the scheme

$$\dot{C}H_3 + R-CH_3 \xrightarrow{k_1} CH_4 + R-\dot{C}H_2 \quad (k_1 = 3.5 \cdot 10^{-6}\ s^{-1})$$

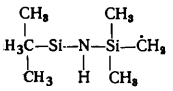
$$\dot{C}H_3 + \dot{C}H_3 \xrightarrow{k_2} C_2H_6 \quad (k_2 = 1.2 \cdot 10^{-21}\ cm^3\ s^{-1}) .$$

In addition to methyl radicals, irradiation should produce radicals with an unpaired electron on the silicon atom, $-\dot{Si}-$. Since these are not manifest in the ESR spectrum, it can be suggested that they disappear under the conditions of the experiment by a fast process whose mechanism is not clear. The kinetics of the accumulation of free radicals were studied as a function of the intensity (I) of the incident light. At low intensities of incident light the initial rate of accumulation of CH_3 radicals was found to be proportional to I^2, and the initial rate of formation of $R-\overset{\overset{O}{|}}{\underset{\underset{O}{|}}{Si}}-\dot{C}H_2$ radicals was proportional to I over the whole of the experimental range of ultraviolet light intensities. This led to the conclusion that the formation of one methyl radical requires the successive (two-stage) absorption of two photons. The absorption of the first photon ($\lambda \leqslant$ 300 mμm) breaks the $\rangle Si-CH_3$ bond, but the radical remains within the "cage". Only the absorption of a second photon ($\lambda \geqslant$ 350 mμm) results in the appearance of a free $\dot{C}H_3$ radical.

However, the formation of $R-\overset{\overset{O}{|}}{\underset{\underset{O}{|}}{Si}}-\dot{C}H_2$ radicals can apparently occur also by direct removal of a hydrogen atom from the methyl group following the absorption of a quantum of ultraviolet light by the polyphenylmethylsiloxane molecule.

In keeping with the results obtained by the ESR method, a mass spectrometric analysis of the gaseous end-products of the photodecomposition of polyphenylmethylsiloxane found 70% of methane, 5% of ethane, and 25% of hydrogen.

The ESR method has been used in conjunction with a mass spectrometric analysis of the gaseous end-products also to investigate the photoreactions of the following silazanes: (1) hexamethyldisilazane $(CH_3)_3SiNHSi(CH_3)_3$; (2) hexamethylcyclotrisilazane $[(CH_3)_2SiNH]_3$; (3) octamethylcyclotetrasilazane $[(CH_3)_2SiNH]_4$; (4) trimethylcyclotrimethylsilazane $[(CH_3)HSiNCH_3]_3$; (5) tetramethylcyclotetramethylsilazane $[(CH_3)HSiNCH_3]_4$. These compounds show remarkable absorption in the wavelength region below 300 mμm. Ultraviolet illumination of compound (1) at 77°K gives a well resolved ESR signal consisting of seven hyperfine structure lines from two superimposed ESR spectra: a quadruplet with a splitting of 24 ± 0.5 Oe ($\dot{C}H_3$) and a triplet with a splitting 21 ± 0.5 Oe from the radical



The ESR results justify the assertion that photolysis of compound (1) at 77°K follows essentially the same path as the photolysis of polyphenylmethylsiloxane, i.e.

$$M \xrightarrow{h\nu} \begin{cases} \rightarrow \equiv \dot{Si} + \dot{C}H_3 \\ \rightarrow \dot{H} + R\dot{C}H_2 \end{cases}$$

$$\dot{H} + M^{**} \rightarrow H_2 + R\dot{C}H_2$$

$$\dot{C}H_3 + M \rightarrow CH_4 + R\dot{C}H_2$$

$$\dot{C}H_3 + \dot{C}H_3 \rightarrow C_2H_6 .$$

Components from the radicals $\dot{C}H_3$ and $R\dot{C}H_2$ can be found also in the ESR spectra of compounds (2) and (3) irradiated with ultraviolet light at 77°K. However, the ESR spectrum is distorted by the presence of a broad, asymmetric line from the peroxy radical produced by a reaction between the molecular oxygen entrained in the structure of these compounds and the radicals formed by irradiation. Ultraviolet irradiation of compound (4) gives an ESR signal consisting of a broad symmetrical line superimposed on a triplet with a splitting of 21 ± 0.5 Oe from the $R-\dot{C}H_2$ radical. The singlet line is apparently due to the formation under the influence of ultraviolet of a radical with an unpaired electron on the silicon atom[100]. These results showing the type of photogenerated free radicals, combined with data on the composition of the gaseous photolysis products, allow the following scheme to be put forward for the radical processes in compound (4):

$$M \xrightarrow{h\nu_1,\ I_a} \dot{H} + \rangle\dot{Si}$$

$$\dot{H} + M \xrightarrow{k_1} H_2 + R\dot{C}H_2$$

$$\dot{H} + R\dot{C}H_2 \rightarrow M$$

$$\rangle\dot{Si} + \dot{Si}\langle \rightarrow \rangle Si-Si\langle$$

$$M \xrightarrow{h\nu_1,\ \beta I_a} \dot{C}H_3 + \rangle\dot{Si}$$

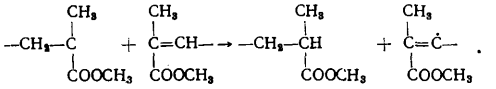
$$\dot{C}H_3 + M \rightarrow CH_4 + R\dot{C}H_2 .$$

Ultraviolet irradiation of compound (5) gave rise to an ESR spectrum similar to the previous one, its only distinguishing feature being that the singlet signal was significantly stronger than in compound (4). From the kinetics of the accumulation of free radicals, in conjunction with the composition of the gaseous products of the photodecomposition of (5), it was concluded that under the influence of ultraviolet light compound (5) undergoes the same processes as compound (4), but the breaking of the $\rangle Si-C$ and $\rangle Si-H$ bonds is more efficient, and the rate of reaction of $\dot{H}$ with silazane (5) is greater. This conclusion is in keeping with chemical considerations of the decreased stability of cyclosilazanes with increase in molecular chain length.

The photodecomposition of the hydroperoxide of atactic polypropene was investigated by Ershov[101] using the ESR method. This worker attempted a quantitative assessment of the rate of photodecomposition of the hydroperoxide obtained by thermal oxidation of polypropene, to give a concentration of hydroperoxide groups of 0.5–1 mole kg^{-1}. The sample (~ 0.05 g) of polypropene hydroperoxide, in a vacuum of 10^{-2} mmHg, was irradiated at 77°K in the cavity

of the radio-frequency spectrometer with filtered light from a DRSh-1000 mercury lamp. Formation of free radicals began immediately after the beginning of irradiation. The ESR signal is asymmetric ($g = 2.0047$, $\Delta H \simeq 60$ Oe) and consists of the ESR spectra of hydrocarbon radicals resulting from the isomerisation of alkoxy radicals superimposed on the spectra of peroxy radicals[102]. The rate of production of radicals, measured by the linear portion of the kinetic curve, is 4 times higher for irradiation with $\lambda < 300$ mμm than with $\lambda > 300$ mμm, and amounts to 6×10^{14} radicals min^{-1}. Thus, the hydroperoxide of atactic polypropene is decomposed at a significant rate not only by short-wave radiation but by longer-wave radiation as well. It is suggested that the high rate of decomposition of the hydroperoxide and of accumulation of radicals under the influence of light of $\lambda > 300$ mμm, i.e. in the region where the hydroperoxide absorbs very weakly, is due to the high quantum yield of this photoreaction.

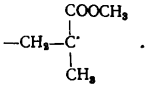
As has already been stated, free-radical concentrations during photoreactions in the liquid phase are minimal, and their detection lies at the very limit of performance of modern ESR radio-frequency spectrometers. However, ESR has been used with success[103-196] to study photoreactions in media which are very viscous at ordinary temperatures, as for example in the late stages of photopolymerisation. We shall discuss, as an illustration, the results obtained by Bresler and coworkers[106] in their ESR study of the photoinitiated polymerisation of methyl methacrylate (MMA), vinyl acetate (VA), and methacrylic acid (MAA). Photopolymerisation was induced both directly inside the cavity and externally, using PRK-4 lamps as the light source. When photopolymerisation was carried out outside the cavity of the radio-frequency spectrometer, the bulb containing the sample was placed in a quartz tube through which water from an ultrathermostat was circulated. Attempts to detect PMMA macroradicals in the early stages of photopolymerisation inside the cavity were unsuccessful because of the low sensitivity of the apparatus. Beyond about 50% conversion in the photopolymerisation of MMA and VA at 300°K, formation of a considerable number of macroradicals with a five-line ESR spectrum was observed (intensity ratio of the components 1 : 4 : 6 : 4 : 1, splitting 26 Oe). If the photoinitiation of the polymerisation is stopped at 60–80% conversion, the polymerisation effectively ceases. Most of the macroradicals under these conditions remain stable, and can undergo neither recombination nor monomer addition at room temperature. The ESR spectrum of the PMAA macroradicals is in no way different from the corresponding spectrum of the PMMA macroradicals. Since the polymer formed by the polymerisation of MAA is precipitated, the accumulation of macroradicals, captured by the gel being deposited, is not surprising[103,104]. The observed ESR spectra relate in the main to "captured" radicals, whose concentration is only indirectly related to the kinetics of the photopolymerisation process. The accumulation of "captured" radicals in homogeneous systems at relatively early stages of polymerisation stresses the inadequacy of the generally held views on the kinetics of the growth and disappearance of macroradicals. Evidently, a considerable proportion of the macroradicals is relatively stable because of the difficulty of access to the reactive centre deep within the tangle formed by the macromolecule. An important factor in this "capture" of macroradicals is whether the monomer is a good solvent or a poor solvent for the polymer. Hence, not all polymers "capture" macroradicals to the same extent. Furthermore, the higher the molecular weight, the more likely is the reactive centre to be screened by the polymer tangle. An attempt was made to study the fate of the radicals captured in PMMA after completion of the polymerisation: even at 330°K the ESR spectrum of a low-molecular-weight polymer changed quite rapidly, and the original five-component spectrum was replaced by a four-component spectrum with a 1 : 3 : 3 : 1 intensity ratio. This spectrum points to the appearance of a new radical in which the unpaired electron interacts not with four equivalent protons (as in the original radical) but with three. The rearrangement of the ESR spectrum is ascribed[106] to the ability of the macroradicals to capture a labile hydrogen atom at 330°K by the reaction



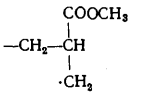
The ESR spectra in PMAA and PVA disappeared instantaneously on crossing the glass transition point.

However, the possibility must be considered that the initial ESR spectra were due to radicals formed by the photodecomposition of the resulting polymer rather than to radicals appearing during photopolymerisation.

Sorin and Tsaregradskii[107] have reported a study by ESR and optical spectroscopy of the photodegradation of PMMA at 77° and 300°K. By using molecular spectroscopy it was shown[108,109] that CO_2, CO, H_2, CH_3OH, methyl formate, etc. are produced when PMMA is irradiated with ultraviolet. It was also found that the photodegradation of PMMA is accompanied by a decrease in molecular weight, formation of monomer, and a decrease in strength. There is no doubt that photodegradation is accompanied by the appearance of intermediate free-radical products. In fact, irradiation of PMMA with the light of a DRSh-500 mercury lamp or with the filtered light (BS type filters) of a DKSSh-1000 xenon lamp produces free radicals whose ESR signal is the combination of a quintet and a quartet of lines of relative intensities 1 : 4 : 6 : 4 : 1 and 1 : 3 : 3 : 1 respectively. These radicals are stable and persist for several months. It has been shown that the first spectrum is produced by the radicals



For the second type of radical, the authors proposed the structure



arising from the first when the free valency on the carbon of the polymer chain captures a proton from the methyl group. It is found experimentally that the relative intensities of the quintet and the quartet are functions of the temperature and of the spectral composition of the active light: the intensity of the quartet decreases with rise in temperature and at 290°K only the quintet remains; the quartet is not formed when irradiation is with light of $\lambda \geq 340$ mμm, but it appears on subsequent irradiation with unfiltered light. Thus, the second (quartet) ESR signal could alternatively be assigned to the $\dot{C}H_3$ radical, formed in the primary act of short-wave ultraviolet irradiation.

4. Photodecomposition of Adsorbed Organic Compounds

The formation and stabilisation of active intermediate products on the surface is of enormous importance in heterogeneous catalysis. These intermediate products could be free radicals and ion-radicals. The first systematic study of adsorption by spectral methods is due to Terenin[110-113]. Under his direction, methods were developed for investigating adsorbed molecules and also the surface properties and the catalytic properties of adsorbents from visible, ultraviolet, and infrared absorption spectra. In recent years, the ESR method has been successfully applied to the study of the properties of adsorbed free radicals and of the nature of their interaction with the surface. In particular, the possibility of low-temperature stabilisation, on a silica gel surface, of active radicals such as atomic hydrogen and alkyl radicals has been demonstrated.

Kazanskii and coworkers[114,115] described a photochemical procedure for preparing and stabilising methyl radicals at 77°K from methyl iodide, adsorbed in a vacuum from the vapour onto the surface of silica gel. After irradiating this system for 4–6 h at 77°K with ultraviolet light (from a PRK-7 lamp), they observed the ESR spectrum of adsorbed methyl ($\dot{C}H_3$) radicals, consisting of four hyperfine structure components of half-width 1–2 Oe, splitting 23.3 Oe, and an unusual distribution of the intensity of the individual components (1 : 8.5 : 13 : 2.5 instead of 1 : 3 : 3 : 1). This is ascribed to the fact that adsorption of a methyl radical on the surface of silica gel causes the loss of two rotational degrees of freedom because of the coupling of the unpaired electron to the adsorbent. Only one axis of rotation remains, around the orbital of the unpaired p-electron. This rotation produces incomplete averaging of the anisotropic hyperfine and spin–orbital interaction, and therefore the ESR spectrum adopts an asymmetric form with a non-binomial distribution of component intensities[114]. The intensity of the signal does not alter on keeping the specimen for several hours at liquid nitrogen temperature. A decrease in intensity of the spectrum becomes noticeable 5 min after allowing the sample to warm up to −130°C. The spectrum has not completely disappeared after 30 min storage at −40°C. Hence it is evident that methyl radicals adsorbed on the surface of silica gel have a relatively high stability, well in excess of the stability of alkyl radicals in frozen solutions. These results show that quite active radicals prepared by photodecomposition of adsorbed compounds can be stabilised on the surface of solids. Furthermore, the results also show that the ESR method can give fairly detailed information on the geometry of the bond between adsorbed radicals and the surface, and on the type of motion of the radicals.

Tolkachev and coworkers[116] used the method (proposed by Kazanskii and Pariiskii) of photodecomposition of molecules adsorbed on a silica gel surface in order to stabilise and detect, at 77°K, benzyl radicals ($C_6H_5\dot{C}H_2$) produced by ultraviolet irradiation of benzyl chloride[98,104]. Theoretical calculations of the density distribution of the unpaired electron in the benzyl radical have been published[117,118]. The first experimental attempts at observing the hyperfine structure of the ESR spectrum of this radical in solid hydrocarbon glasses were unsuccessful[23]. In the more recent work[116] the benzyl chloride was adsorbed from the vapour phase, in a vacuum, on the surface of silica gel (of specific surface area 300 $m^2\ g^{-1}$) at room temperature, and was then irradiated with ultraviolet light from a PRK-7 high-pressure mercury lamp for 2–4 h at 77°K. The resulting ESR spectrum consisted of a triplet with a separation of 16.5 ± 1 Oe between the components. Each of the components was further split into a quadruplet with a constant spacing of 5.5 ± 0.5 Oe between its components. The triplet in this spectrum was due to the interaction between the unpaired electron and the protons of the $-\dot{C}H_2$ group. The low value of the splitting on the protons of the methylene group (16.5 instead of 23 Oe) suggests delocalisation of the unpaired electron into the π-system of the ring, and this is confirmed by the splitting of each component of the triplet into a quadruplet, due to interaction of the unpaired electron with three protons of equivalent hydrogen atoms of the ring. The agreement between experimental results and theoretical calculations is evidence that the spectrum was correctly interpreted. As in the previous case, no ESR spectrum could be obtained from the halogen atoms ($\dot{C}l$).

5. Photo-ejection of an Electron (Photoionisation)

Photoionisation is the extraction of an electron, under the influence of light, from a photoexcited molecule into a vacuum or into a medium, accompanied by free existence or capture of the photoemitted electron in the medium (trapping, solvation, etc.). Terenin[12] treats the photoionisation of organic molecules as a special case of the photodecomposition reaction: the photodissociation of the compound into oppositely charged ions (a molecular cation and an electron). However, the photoionisation reaction is often considered to be[119,120] the primary, elementary act of the oxidation–reduction process[121]. The term elementary photo-oxidation usually refers to the removal of an electron from a photoexcited molecule (the oxidisable component) to another molecule (the oxidising agent or electron acceptor), which has a positive electron affinity. The photo-oxidation of one compound is invariably accompanied by the reduction of another compound (the oxidiser). The mechanism and the energetics of the photoionisation and the elementary photo-oxidation process are quite different: this defines their individual roles and allows us to discuss the photo-extraction of an electron independently of oxidation–reduction photoreactions.

The removal of an electron under the influence of light (i.e. the photoelectric effect) has long been known for aromatic molecules in the solid state and in solution. The emission of an electron by light from organic molecules in the condensed phase was clearly demonstrated for the first time by Lewis and coworkers[119,120] by a spectroscopic investigation. It has also been known for a long time that the vapours of anthracene, diphenylmethane, aniline, diphenylamine, and α-naphthylamine show electrical conductivity under the influence of short ultraviolet light[122-124]. Terenin and Vilesov[125,126] have recently developed a powerful mass-spectrometric method of studying the photoionisation of vapours of aromatic compounds (including dyes) which enables the critical energy for the photoremoval of an electron in a vacuum to be determined with high precision.

Lewis and coworkers[119,120], and more recently Linschitz and coworkers[127], observed, in their spectroscopic investigations, coloured products from the interaction of near ultraviolet with frozen solutions at 90°K in EPA (a mixture of alcohol, isopentane, and ether in the ratio of 2 : 5 : 5 by volume) of various colourless aromatic compounds: amines, phenols, and the leuco-forms of dyes. The colouration of the solutions upon irradiation was caused by the photo-extraction of an electron from the colourless

aromatic compound with formation of a positively charged molecular radical-ion, for example

$$(C_6H_5)_3\dot{N} \xrightarrow{h\nu} (C_6H_5)_3\dot{N}^+ + e\,.$$

An analogous process occurs during the photo-extraction of an electron from aromatic compounds containing N, O, and S atoms, which have unshared electron pairs. The electron split off by the light remains trapped in the solid solution at 90°K. However, even a small temperature rise allows the medium to lose its rigidity and the trapped electron to recombine with the ion. Photoionisation of molecules can be induced also at ordinary temperatures by using a medium (such as boric acid glass, or polymers†) rigid enough to trap the photo-extracted electrons for an appreciable time. Since one of the products of the electron photo-extraction reaction is an unstable molecular ion with an unpaired electron and therefore paramagnetic, such a product can in principle be detected by the ESR method in the condensed phase.

Bijl and Rose-Innes[22] were among the first to apply the ESR method to the study of photo-processes in organic compounds, and in particular to the study of photoionisation. Their experimental materials were aromatic diamines, which are readily oxidised by light: tetramethyl-*p*-phenylenediamine (Wurster's base) and *p*-phenylenediamine. To stabilise the resulting radical-ions a, polymeric medium [poly(methyl methacrylate)] having a glassy state at ordinary temperatures was used instead of a low-temperature hydrocarbon glass. After 5 min irradiation with ultraviolet light from a high-pressure mercury lamp the film developed a brown and greyish-green colour accompanied by the appearance of an ESR signal consisting of a single line with $g = 2.001 \pm 0.002$. The paramagnetic product stabilised in this way survived for several months at room temperature. It is known[119] that the cation-radical of tetramethyl-*p*-phenylenediamine (Wurster's Blue) has absorption bands at 630, 580, 520, and 500 mμm, and therefore has a blue colour. Since the product obtained in these experiments is brown in colour, it may be assumed not to be the cation-radical of the diamine, but rather a free radical resulting from the interaction of that cation-radical with the medium.

Bennema and coworkers[130] made a detailed study of the formation of coloured photo-products by the ultraviolet irradiation of various aromatic hydrocarbons in boric acid glasses. Solid, glassy solutions of the following hydrocarbons in boric acid were irradiated: biphenyl, phenanthrene, terphenylene, tetracene, pyrene, perylene, and coronene. In every case the authors observed the formation of coloured products whose optical absorption and ESR spectra indicated the presence of singly charged, positive molecular ions of the corresponding hydrocarbons, produced by photoionisation. On heating the coloured glasses the colour disappeared, with simultaneous emission of the characteristic recombination phosphorescence of the particular hydrocarbon molecule.

Hoijtink and Zandstra[131] exposed to ultraviolet light methyltetrahydrofuran solutions of the negative ions of aromatic hydrocarbons in a vacuum at 77°K, and obtained spectroscopic evidence of their photoionisation:

$$M^{2-} \xrightarrow{h\nu} M^- + e;\ M^- \xrightarrow{h\nu} M + e\,.$$

† Electron photo-extraction has recently been observed in the flash-irradiation of a liquid solution of triphenylamine in hexane[128] and of diphenylamine and triphenylamine in electron-acceptor solvents like CCl_4, $CHCl_3$, and CH_2Cl_2 at 300°K,[129] by the appearance of a short-lived (10^{-4} s) optical absorption spectrum due to the corresponding radical cation.

In the first experiments, no evidence could be found of capture of the ejected electrons by the alkali metal cation (Na^+) or by the solvent matrix. However, on repeating the experiments including ESR, visible, and infrared spectroscopy of the irradiated solutions, van Voorst and Hoijtink[132] obtained clear proof of the capture of the ejected electrons in the holes of the network of the frozen matrix. As in the earlier experiments, negative ions were obtained by treating a 3-methyltetrahydrofuran solution of the appropriate aromatic hydrocarbon (tetracene, perylene, pyrene) with an alkali metal in a vacuum:

$$M + X \rightarrow M^- + X^+;\ M^- + X \rightarrow M^{2-} + X^+;\ (X = \text{Li, Na, K})\,.$$

After irradiation at 77°K, with light corresponding to their absorption bands, the optical absorption spectra of the frozen solutions of singly and doubly charged ions of the solution changed to those of uncharged and singly charged ions respectively. At the same time, an absorption band ($\epsilon = 3-4 \times 10^4$) appeared in the infrared region at 1300 mμm, accompanied by a singlet ESR line with $g = 2.002$ and $\Delta H = 4.5$ Oe, increasing with duration of exposure to the photoionisation process. On thawing the glassy solution, or under the influence of visible light ($330 < \lambda < 600$ mμm), the infrared band disappears, and the initial spectra of the negative ions are re-established. These results imply that the phototransfer of an electron is a reversible process in a solid solution. The minimum quantum energy (2 eV) needed to inhibit the infrared band can be identified with the depth of the trap in which the ejected electron is captured. Since both the shape and the position of the infrared band and of the ESR signal are independent of the nature of the aromatic hydrocarbon and of the alkali metal ion, the author concludes that these signals are due to unpaired electrons trapped in holes of the matrix at 77°K.

The photoionisation of aminoacids and proteins at low temperatures was first investigated by the ESR method by Allen and Ingram[133], who attempted to obtain unpaired electrons by ultraviolet irradiation ($\lambda = 365$, 254 mμm) of four amino-acids (tyrosine, methionine, cystine, and leucine) and four proteins (insulin, insulin with protamine, ox albumen, and egg albumen). All preparations were examined as aqueous solutions or suspensions at 96°K. The experimental results obtained led the authors to the conclusion that radicals are formed by ultraviolet irradiation of proteins and amino-acids, photoionisation of the starting compounds being involved in the primary process. Relatively little has been published on free-radical states in amino-acids and proteins. The first papers on this topic by Grossweiner[134,135] appeared after the development of the techniques of flash photolysis and fast spectroscopy, which allow short-lived radical-ion intermediates to be studied in solutions of aromatic hydrocarbons. Studies of low-temperature thermoluminescence in ultraviolet-irradiated aqueous solutions of aromatic amino-acids and proteins allowed to warm up from 77° to 110°K led Vladimirov and Roshchupkin[136] to ascribe the effect to the recombination of two intermediate products of the first step of the photochemical reaction.

By using the ESR method to study the primary photochemical processes in amino-acids and proteins, Azizova[137-140] was able to investigate the paramagnetic species resulting from ultraviolet irradiation and to give a convincing account of the photoionisation of the biologically important compounds being examined. Ultraviolet irradiation of aromatic amino-acids in the crystalline state at 77°K produces a singlet ESR signal with a *g*-factor close to the free-electron value and $\Delta H = 16$ Oe (tyrosine, tryptophan) or 20 Oe (phenylalanine). A singlet ESR

signal with $\Delta H = 13$ Oe appears in ultraviolet-irradiated glycyltyrosine and glycyltryptophan. Subsequent irradiation of the amino-acids with light of $\lambda = 320-700$ mμm, or a rise in temperature to 300°K of the ultraviolet-irradiated sample, produces a 1.5–2-fold decrease in the intensity of the singlet ESR signal. Irradiation with ultraviolet light of aqueous solutions of aromatic amino-acids (tryptophan, tyrosine) at 77°K causes photoionisation, accompanied by the appearance of positive radical-ions of the amino-acids and of electrons trapped in the medium. The evidence for this is a singlet ESR signal with $\Delta H = 20$ Oe and a g-factor close to the free-electron value, which is suppressed by light of $\lambda = 320-700$ mμm or by heating the sample. The paramagnetic centres which absorb light in this region and disappear on heating are hydrated electrons. Ultraviolet irradiation of water solutions of proteins at 77°K also causes photoionisation of the aromatic amino-acid residues and decomposition of the sulphur-containing amino-acid residues. Hélène and coworkers[141] observed, in aqueous solutions of purine, adenosine, and guanosine at 77°K, the formation under ultraviolet irradiation of a singlet ESR signal by the photoreaction

$$Pu \xrightarrow{h\nu} Pu^{+} + e$$

The singlet ESR signal consists, strictly, of a signal from the Pu^{+} radical-cation and a signal from the hydrated electron. The latter can be set free from the "traps" in the ice lattice under the influence of visible light of $\lambda < 450$ mμm, and this is manifest (as in the previous work of Azizova and coworkers) by a decrease in the amplitude of the ESR signal. The electrons set free by the light can be captured by Pu^{+} ions or by neutral Pu molecules, which have a high electron affinity[142]. A theoretical calculation of the ionisation energy of π-electrons gives a value of the order of 8 eV for nucleic acid bases[143]. The energy quantum of the active photon ($\lambda = 254$ mμm) corresponds to 5 eV and cannot produce photoionisation of these molecules. The energy of the triplet state in purine, adenosine, and guanosine is close to 3.4 eV. Assuming a two-photon mechanism for the photoionisation of nucleic acid bases, as suggested by the authors[141], an ionisation potential of the order of 8 eV can be attained by the absorption of the second photon ($\lambda = 254$ mμm) by the triplet molecule of the base (3.4 + 5 = 8.4 eV).

The possibility of a two-quantum process of this kind for the ionisation of aromatic compounds in solid solutions at 77°K was first proposed in 1963 by Terenin and the present writer[144,145]. Since then, the two-photon mechanism of the photoionisation of aromatic compounds has been convincingly demonstrated in a number of instances[146-154].

---o0o---

The purpose of this review has been to give a systematic and ordered account of the very numerous photochemical investigations in which the ESR method has been used to throw light on the paths followed by photodecomposition reactions. Most of the photochemical processes had been previously investigated spectrophotometrically. The EST method, on the other hand, had been used mainly to confirm various photodissociation mechanisms. In a number of instances the ESR method has given new and original results. It must be stressed, however, that the successful application of the ESR method in photochemical investigations requires a sound knowledge of the spectral properties of photochemically active systems, a keen appreciation of possible photoprocesses in these media, including secondary processes, and skilful experimentation (choice of medium, temperature, light source, etc.). The ESR method will become a powerful physical method of investigation only if used in conjunction with other methods, and in particular with optical spectroscopy and mass-spectroscopic analysis.

Application of the Ferromagnetic Resonance Method in the Study of Heterogeneous Catalysts

A.A.Slinkin

The main features of the ferromagnetic resonance method are discussed in the context of the study of heterogeneous catalysts. Results obtained by this method are examined, and possible future developments are pointed out.

CONTENTS

I. Introduction 643
II. The ferromagnetic resonance method 643
III. Experimental work on the application of the ferromagnetic resonance method to the study of catalysts 649

I. INTRODUCTION

A detailed knowledge of the physical properties and structure of real catalysts is one of the prerequisites for the development of a theory of heterogeneous catalysis able to pave the way to the synthesis of catalysts of prescribed chemical composition and structure, leading to the development of new chemical processes and to the improvement of existing ones. Unfortunately, and in spite of the large number of catalysts used in industry and in laboratories, this information is lacking in most cases. Only during the last 10–15 years, as a result of the application of various physical methods, has some progress been possible in this direction. The study of a real, multicomponent heterogeneous catalyst by physical methods is a very complex problem. A catalyst of this type contains a very large number of defects, frequently of unknown nature. In these circumstances, quantitative interpretation of the results of physical measurements becomes very difficult, and quantitative calculations are ambiguous. The position is made worse by the change in both the number and the nature of the defects induced by the catalytic reaction itself. A study of these systems would be meaningless to a solid-state physicist concerned with studies at the single-crystal level. Yet, we are forced to work with these materials if we wish to inquire into the nature of heterogeneous catalysis.

At the moment, the only way out of the dilemma is to examine a given catalyst by the greatest possible number of physical methods which, by cross-checking and complementing each other, can offer a fuller understanding of the real physical structure of heterogeneous catalysts. Therefore, the use of any physical method which can reveal new facets in the study of catalyst structure is highly desirable. Accordingly, this review will deal with the ferromagnetic resonance method and its application to the study of various nickel catalysts.

II. THE FERROMAGNETIC RESONANCE METHOD

1. General Remarks

Static magnetic methods have been applied for a number of years to the study of catalysts [1-5], with valuable results for both paramagnetic and ferromagnetic catalysts. The application of static magnetic methods (i.e. the measurement of magnetic properties in constant fields) to the analysis of the structure and valency characteristics of paramagnetic ions depends essentially on the use of the Langevin equation and Curie's law.

In paramagnetic materials the magnetic moments of the ions, atoms, or molecules are pointing in all directions in space with equal probability, and the total magnetic moment is zero. When such a material is placed in a magnetic field the magnetic moments become oriented along the field, and the number of moments oriented with the field becomes greater than the number oriented against the field. As a result, the material becomes magnetised, and we observe a positive magnetic susceptibility.

Noting that the magnetic moments in a paramagnetic material immersed in a magnetic field of intensity H are experiencing simultaneously the randomising effect of thermal motion and the orienting effects of the field, Langevin obtained a formula relating the magnetisation to the field strength (H) and to the absolute temperature (T):

$$\sigma = \sigma_0 \left[\coth \frac{\mu H}{kT} - \frac{kT}{\mu H} \right], \qquad (1)$$

where σ is the magnetisation per unit weight of the material, σ_0 the limiting magnetisation per unit weight (saturation magnetisation), μ the magnetic moment of the ion, atom, or molecule, H the field strength in Oersteds, k Boltzmann's constant, and T the absolute temperature.

Fig. 1 shows the variation of the Langevin function with the value of the parameter $\mu H/kT$. It is obvious that the function tends to saturate at high values of H (i.e. tends to the value σ_0). However, with paramagnetic materials fields in excess of 10^6 Oe, which are inaccessible in practice, are needed to reach the saturation region, i.e. to obtain values of $\mu H/kT > 1$. The only way to obtain a Langevin curve covering a significant range of the parameter $\mu H/kT$ with paramagnetic materials is to work at low temperatures and relatively high field strengths. Thus, at $T \simeq 1°K$ and $H \simeq 10^4$ Oe, $\mu H/kT \simeq 1$. More commonly, at room temperature and fields of the order of 10^3 Oe, the value is

$$\mu H/kT = \frac{0.93 \cdot 10^{-20} \cdot 10^4}{1.38 \cdot 10^{-16} \cdot 300} \simeq 0.02, \text{ i.e. } \mu H \ll kT.$$

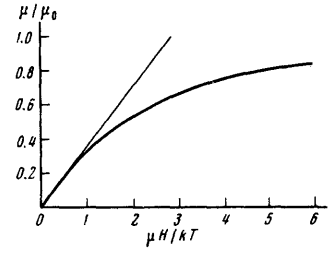

Figure 1. Dependence of the relative magnetic moment μ/μ_0 upon the parameter $\mu H/kT$.

In this case we can expand the Langevin function into a series for small values of the parameter $\mu H/kT$, and retain only the first term of the expansion, giving

$$\sigma = \sigma_0 \frac{\mu H}{3kT} \qquad (2)$$

which is the tangent to the curve of Fig. 1, or

$$\sigma = N\mu \frac{\mu H}{3kT},$$

where N is the number of magnetic particles of magnetic moment μ in 1 g of the material.

$$\chi = \frac{\sigma}{H} = \frac{N\mu^2}{3kT} \quad \text{or} \quad \chi T = C \qquad (3)$$

is Curie's law, where χ is the magnetic susceptibility.

Thus, we obtain Curie's law, where the Curie constant $C = \frac{N\mu^2}{3k}$. However, it must be stressed that Langevin obtained his formula on the assumption that: 1) we are dealing with a gas of paramagnetic particles, and 2) the magnetic moments of the particles are not mutually interacting. In practice, however, plots of $\frac{1}{\chi}$ against T do not pass through the origin as required by formula (3), and χ is found to vary with temperature by the more complicated law

$$\chi = \frac{C}{T - \Delta} \qquad (4)$$

(the Curie–Weiss law), where Δ can be either positive or negative.

This deviation from Curie's law arises from the interaction of the magnetic moments of neighbouring particles, and the constant Δ (Weiss's constant) characterises the magnitude of this interaction in the simplest cases. Nevertheless, the forces between neighbouring ions, atoms, or molecules in paramagnetic materials are not very large, and their magnetic susceptibilities are negligible.

In addition to the static magnetic methods of investigating paramagnetic catalysts, the methods of microwave spectroscopy have come to the fore in recent years, and in particular the electron paramagnetic or electron spin resonance (ESR) method. Details of the method and of the results obtained in studies of heterogeneous catalysts have been discussed elsewhere[6,7]. The resonance conditions for the ESR method are given in the form

$$h\nu = g\mu_B H_0$$

where h is Planck's constant, ν the frequency of the radiation absorbed, g the spectroscopic splitting factor, μ_B is the Bohr magneton, and H_0 the external magnetic field.

We can recast this formula in terms of angular Bohr frequencies:

$$h\nu = \hbar\omega_{res} = g\mu_B H_0, \text{ or}$$
$$\omega_{res} = \gamma H_0, \qquad (5)$$

where

$$\omega_{res} = 2\pi\nu; \quad \gamma = \frac{g\mu_B}{\hbar}, \text{ and } \hbar = \frac{h}{2\pi}.$$

In general, and like the static magnetic susceptibility method, the ESR method when applied to the study of paramagnetic materials relates to the spin and orbital moments of isolated particles (for example, highly dilute solid solutions of paramagnetic ions in a diamagnetic matrix), or alternatively to the relatively weak interactions of the magnetic moments of neighbouring particles.

A situation different in principle is observed in studies of resonance phenomena in ferromagnetics[8]. Because of the very strong exchange interaction between atoms in a ferromagnetic crystal, the magnetic moments of neighbouring atoms are oriented parallel to each other even in the absence of a field, and the application of a field produces gigantic values of the magnetisation (10^4–10^5 times higher than in paramagnetics). The magnetisation process will be considered in more detail in the following sections. The existence of strong exchange interactions, and various other effects, in ferromagnetic substances makes the interpretation of ferromagnetic resonance spectra in polydisperse systems much harder than the interpretation of ESR spectra. Thus, formula (5) must be written, for the case of ferromagnetic resonance, in the form

$$\omega_{res} = \gamma H_{eff}, \qquad (6)$$

where $H_{eff} = H_0 + H'$, and H' is some additional field whose value depends on the nature of the specimen, the experimental conditions, the shape of the particles, the presence of defects, and so on. Failure to allow for this additional field can lead to serious errors, particularly in the determination of the g-factor.

We shall now discuss the main factors which determine the resonance conditions in ferromagnetics, and on the basis of this analysis we shall review the work on the study of catalysts by this method.

2. Influence of Crystallographic Magnetic Anisotropy on the Resonance Frequency and on ΔH

The *magnetic crystallographic anisotropy* effect is one of the most important factors which determine the resonance frequency, and the line width (ΔH) of ferromagnetic resonance, in studies of polydisperse systems. Basically, the nature of the effect is as follows. Let us consider the magnetisation of single crystals of Ni, Fe, and Co as a function of the applied external field and its orientation with respect to the crystal axes. As Fig. 2 shows, an axis along which the crystal can most easily be magnetised exists in these crystals (as also in other ferromagnetics). For example, for Ni this axis is the [111] axis or body diagonal of the cube. The major planes of a cubic crystal and the directions of the corresponding axes are shown in Fig. 3.

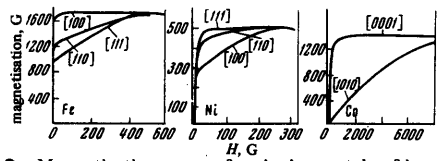

Figure 2. Magnetisation curves for single crystals of iron, nickel, and cobalt.

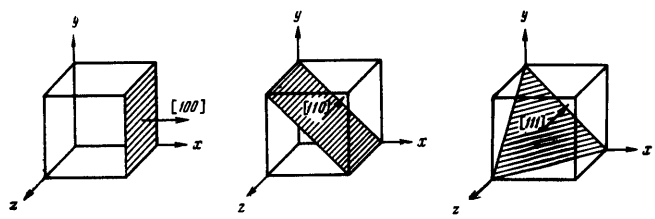

Figure 3. Main crystal planes and axes in a cubic crystal.

How does magnetisation of a magnetically anisotropic crystal occur? If the external magnetic field is parallel to the easy magnetisation axis, the crystal is magnetised practically to saturation in very small fields. If, on the other hand, the direction of magnetisation by the external field is at a definite angle to the easy magnetisation axis, a greater expenditure of energy is required to magnetise the crystal to saturation, and therefore saturation is reached at higher magnetic fields. The physical explanation of the existence of magnetic anisotropy depends on spin–orbital interactions in the crystal. An atom (or ion) in the crystal experiences crystal fields having a definite symmetry, which lead to the removal of orbital degeneracy and therefore to an anisotropic distribution of orbital magnetic moments. The spin magnetic moments (which are mainly responsible for ferromagnetism) are affected by this anisotropic distribution through spin–orbital coupling.

The magnetic anisotropy energy is expressed by the magnetic anisotropy constants, which are strongly temperature dependent. Fig. 4 shows the temperature variation of the first magnetic anisotropy constants (K_1) of Ni, Fe, and Co. It can be seen that the magnetic anisotropy constant is greatest for Co, and that the constants for Ni and Fe are relatively lower. The most striking feature of the temperature dependence of K_1 for nickel is a rapid decrease with increase of temperature, the constant K_1 almost vanishing at 100°. [Unless stated otherwise, all temperatures are in °C (Ed. of Translation).]

How are the conditions for ferromagnetic resonance affected by these peculiarities of the magnetisation of ferromagnetic crystals? It is obvious that if the magnetic

field H_0 is applied in the direction of the axis of easy magnetisation the anisotropy energy will be a minimum. For the case of an Ni single crystal, in which $K_1 < 0$, it has been shown[9] that when $\Theta = 0°$ (difficult magnetisation axis, [100]) we have

$$\frac{\omega_{res}}{\gamma} = H_0 - \frac{2(K_1)}{\sigma_0}, \qquad (7)$$

where σ_0 is the saturation magnetisation and K_1 is the anisotropy constant.

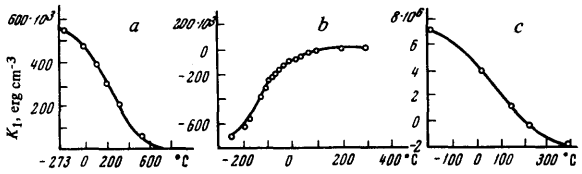

Figure 4. Temperature dependence of the first anisotropy constant (K_1):
a) Fe; *b*) Ni; *c*) Co.

When $\Theta = 54°44'$ (easy magnetisation axis, [111])

$$\frac{\omega_{res}}{\gamma} = H_0 + \frac{4}{3}\frac{(K_1)}{\sigma_0}, \qquad (8)$$

In these formulae the constant external field H_0 together with the additional field resulting from anisotropy,

$$2\frac{(K_1)}{\sigma_0} \quad \text{or} \quad \frac{4}{3}\frac{(K_1)}{\sigma_0},$$

constitute the effective field H_{eff} used in formula (6). Thus, with single crystals it is possible to find H_{eff} and to calculate ω_{res} by experimentally varying the angle between the direction of H_0 and the crystal axes.

In studies of real catalysts we are not dealing with single crystals. One commonly deals with Ni microcrystals in a diamagnetic or paramagnetic matrix ($Ni-Al_2O_3$, $Ni-SiO_2$, $Ni-Cr_2O_3$, etc.) or with highly disperse nickel powders (Raney nickel). In these systems the Ni crystallites have arbitrary orientations of the easy magnetisation axis with respect to the direction of the external field H_0, resulting in a range of resonance fields (at a fixed value of ω) for the various Ni crystallites. This causes significant line broadening, and often produces asymmetry in the shape of the line and a shift of the g-factor. This is one of the forms which non-uniform magnetisation of the sample can take.

Obviously, if $K_1 = 0$ and no other sources of non-uniform magnetisation are present, it follows from formulae (7) and (8) that $H_{eff} = H_0$, and formula (5) can be applied. From this formula, which is characteristic for paramagnetic resonance, the g-factor can be accurately calculated. Hence, the only way of avoiding the magnetic anisotropy effect in studies of polydisperse catalysts is to measure the ferromagnetic resonance at high temperatures, when $K_1 \simeq 0$ and the g-factor can be calculated by formula (5).

3. Influence of Shape Anisotropy on the Resonance Frequency and ΔH

In addition to the non-uniformity of magnetisation due to magnetic crystallographic anisotropy, the true internal magnetic field H_{eff} in a ferromagnetic sample differs from the external magnetic field H_0 through the influence of the geometrical shape of the sample. The physical basis of this effect can be explained as follows. If a sample having a high magnetisation is placed in the uniform external field H_0, magnetic charges giving rise to a formal magnetic field H_e in opposition to the external field H_0 are generated on the surface of the specimen (Fig. 5). This field, called the demagnetising field, is proportional to the magnetisation of the specimen:

$$H_e = -N\sigma_0, \qquad (9)$$

where N is the demagnetisation factor.

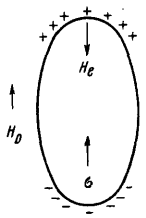

Figure 5. Formation of the demagnetising field H_e.

Hence, the field experienced by the specimen is not H_0 but a field H_{eff} given by

$$H_{eff} = H_0 - N\sigma_0 = H_0 - N\chi H,$$

whence

$$H_{eff} = \frac{1}{1+\chi N} H_0.$$

Since ferromagnetics have very high χ values, the field H_{eff} can differ very substantially from H_0. Strictly speaking, formula (9) is applicable only to ellipsoidal specimens of other shapes. The factor N in formula (9) is the total demagnetisation factor, but it is more convenient to consider factors of the form N_x, N_y, and N_z along the principal semi-axes of the ellipsoid l_x, l_y, and l_z. The relationship between N_x, N_y, and N_z is

$$N_x + N_y + N_z = 4\pi.$$

Allowing for the demagnetising effect of the surface, Kittell obtained the following formula for the resonance frequency

$$\frac{\omega_{res}}{\gamma} = \sqrt{[H_0 + (N_x - N_z)\sigma_0][H_0 + (N_y - N_z)\sigma_0]} \qquad (10)$$

showing that the resonance condition depends on the shape of the specimen and on σ_0. Thus, if we are considering a specimen whose shape is an ellipsoid of revolution about the z-axis ($l_x = l_y = l_\perp$; $l_z = l_\parallel$), it follows that $N_x = N_y = N_\perp$ and $N_z = N_\parallel$, so that formula (10) becomes

$$\omega_{res} = \gamma(H_0 - \sigma_0 \Delta N), \quad \text{and} \quad \Delta N = N_\parallel - N_\perp.$$

A graphical expression for the dependence of the shape anisotropy factor ΔN on the ratio of the longitudinal to the radial axes of the ellipsoid $\left(n = \frac{l_\parallel}{l_\perp}\right)$ can be obtained[9] (see Fig. 6).

If follows from the graph that only in the case of a sphere ($n = 1$) does the effect of shape anisotropy on the resonance condition vanish, leading to formula (5), i.e.

$$\omega_{res} = \gamma H_0.$$

The shape of the sample has a very substantial effect on the value of the applied field corresponding to resonance. Thus, for iron (with $\sigma_0 = 1700$ G), the following resonance fields have been observed[9] using specimens of different shape (frequency 10^4 MHz, $\lambda \simeq 3$ cm).

Sphere	$H_{res} \simeq 3570$ Oe
Disk∥	$H_{res} \simeq 530$ Oe
Cylinder⊥	$H_{res} \simeq 12500$ Oe
Disk⊥	$H_{res} \simeq 26800$ Oe.

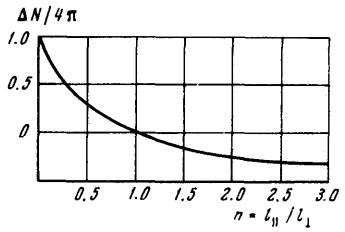

Figure 6. Variation of the difference between the longitudinal and the radial demagnetisation factor of an ellipsoid of revolution with the ratio of the half-axes.

Since a catalyst may contain particles of widely different shape, line broadening can occur through the increased range of resonance fields. However, unlike the broadening caused by magnetic crystallographic anisotropy, this type of broadening should be relatively insensitive to the measurement temperature, since the distribution of particle shapes during measurements of the temperature dependence of line width should remain essentially constant (provided that sintering is not taking place). Extremely interesting in this context is an attempt[10] to investigate the shape of ferromagnetic cobalt particles from the shape of the line. The ferromagnetic resonance of a polycrystalline Co–Cu alloy containing 2% of Co was measured as a function of aging at high temperatures. The calculated shapes of the resonance curve for disordered assemblies of plates, spheres, and rods are shown in Fig. 7*a*. Inspection of the shape of the resonance curves with increasing time and temperature of heat treatment (Fig. 7, *b*–*d*) shows that the particles are almost spherical in the original alloy, but they become larger and plate-like during aging. Thus, the shape of the ferromagnetic particle can be inferred from the features of the resonance curve if due allowance is made for all the other factors which influence the trend of the curve.

4. Domain Structure, Superparamagnetism, and Relaxation Processes

We have already noted the presence in ferromagnetics of strong exchange interactions as a result of which the magnetic moments of the atoms take up parallel directions. We shall now examine in greater detail the magnetisation of ferromagnetic substances. Generally speaking, a ferromagnetic could be expected to be fully magnetised at temperatures below the Curie point even in the absence of a field. Such, however, is not the case, and the modern theory of ferromagnetism offers the following explanation. Consider a ferromagnetic single crystal which has become spontaneously magnetised to saturation in the absence of an external field (Fig. 8*a*). This crystallite can be treated as a permanent magnet, giving rise to a surrounding magnetic field containing an appreciable amount of magnetic energy. However, any system must tend towards a state of minimum free energy. Can this happen in our case? Evidently, if the ferromagnetic crystallite is broken into a number of regions such that the total magnetisation in each pair of neighbouring regions points in opposite directions, the volume occupied by the external magnetic field and the energy of the field will decrease as the number of these regions increases (Figs. 8*b* and 8*c*). A region having only one direction of magnetisation, i.e. a region magnetised to saturation, is called a *domain*. This type of domain structure in ferromagnetic materials results in the magnetic moments at the boundaries between neighbouring domains being oriented in different directions. However, a state in which the magnetic moments are oriented in the same direction is energetically favourable in ferromagnetics. Therefore, energy must be expended to produce opposing orientations of the magnetic moments in the boundary region between domains. This energy is termed the *energy of the domain wall* †. Thus, the fragmentation of a ferromagnetic crystallite into domains involves both a decrease in the energy of the magnetic field outside the crystal and an expenditure of energy in the formation of domain walls. Hence, domain formation will continue until the energy required to form an additional domain becomes equal to the decrease in energy of the magnetic field outside the crystal.

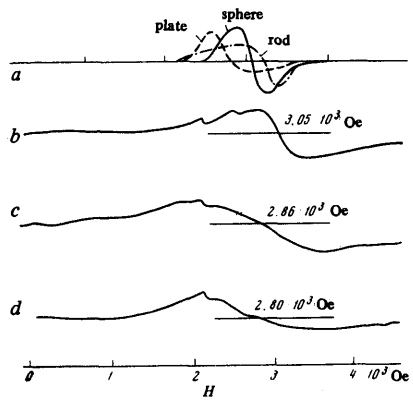

Figure 7. Theoretical and experimental ferromagnetic resonance lines for a Co–Cu (2% Co) alloy[10];
a) theoretical shape of the curve for particles of various shapes;
b) 30 min aging at 600°, average size of Co particles 25 Å;
c) 15 h aging at 600°, average size of Co particles 65 Å;
d) 20 min aging at 800°, average size of Co particles 300 Å.

Fig. 9 is a schematic representation of the magnetisation of a ferromagnetic crystal including its domain structure. In a real crystal the magnetisations of adjacent domains are oppositely oriented, and the total magnetisation is zero (Fig. 9*a*). Upon the application of an external magnetic field, the domains which happen to be magnetised in the

† The inversion of the direction of the magnetic moment at the boundary between domains does not occur abruptly, i.e. within the limits of one atomic layer, but gradually, and it involves hundreds of atomic layers. Therefore the thickness of the boundary wall can be as large as several hundred Ångstroms.

direction of the external field grow at the expense of other domains with a less favourably oriented magnetisation, leading to a movement of the domain walls (Fig. 9*b*). This process is accompanied by an increase in magnetisation. In small magnetic fields the displacement of the domain walls is reversible, and the magnetisation returns to zero when the field is removed. A much more complex situation obtains when large magnetic fields are used. Real crystals invariably contain defects, dislocations, impurities, etc. When a moving domain wall meets one of these defects its progress becomes uneven, discontinuous, and accompanied by a loss of magnetisation energy. As a result, this part of the curve becomes irreversible. Lastly, in large fields, when some domains have already grown at the expense of others and the magnetisation of the former is directed along the field, there are some residual domains whose magnetisation does not coincide with the direction of the applied field (Fig. 9*c*). Larger fields are needed to coerce the magnetic moments of these domains into the direction of the external magnetic field. The overall magnetisation curve is shown in Fig. 10.

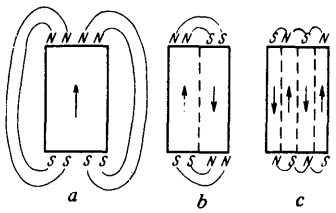

Figure 8. Formation of a domain structure.

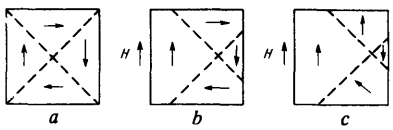

Figure 9. Magnetisation of a ferromagnetic with participation of the domain structure.

So far we have been concerned with a single crystal of a ferromagnetic material subdivided into domains. Real ferromagnetic materials are not usually monocrystalline (particularly in the case of ferromagnetic catalysts), but rather an assembly of a large number of crystallites of various sizes. According to its size, each crystallite is divided into a larger or smaller number of domains. The structure of a real ferromagnetic of this type is shown in Fig. 11. It is evident that its magnetisation can be treated in the same way as that of a single crystal, as was done above.

The domain structure of the specimen can influence the character of the ferromagnetic resonance[9]. In all the formulae given above it has been assumed that the specimen is magnetised to saturation, i.e. consits of a *single* ferromagnetic region of arbitrary magnetisation. Indeed, in the majority of ferromagnetic resonance experiments (including studies on catalysts) this condition is satisfied, because very high magnetic fields are used (several thousand Oersted). Allowance for the domain structure is essential in work with weak fields, when saturation magnetisation may not be achieved, leading to non-uniformity of magnetisation and therefore to line broadening and to a shift in the g-factor.

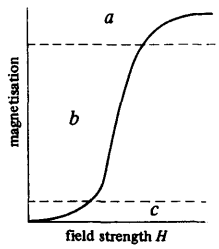

Figure 10. Characteristic magnetisation curve of a ferromagnetic: *a*) rotation processes; *b*) irreversible motion of domain walls; *c*) reversible motion of domain walls.

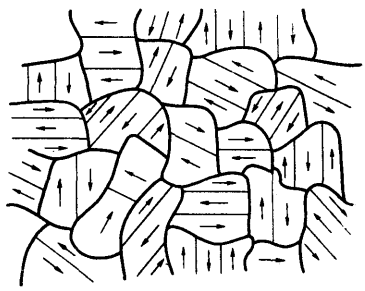

Figure 11. Microstructure of a non-magnetised polycrystalline ferromagnetic.

Let us consider the effect on the magnetic properties of the particles of size significantly less than the domain size. A one-domain particle, like a single crystal, has an axis of easy magnetisation, and the total magnetic moment of the particle in the absence of a field is oriented along the axis of easy magnetisation. Because of the large exchange interactions, the magnetic moments of neighbouring atoms have parallel orientations, and thermal motion cannot destroy the orientation of the resulting magnetic moment in the domain. When the size of the magnetic particles is drastically reduced the situation can be reached when $kT > K_1V$, where K_1 is the anisotropy constant and V is the volume of the particle. In this case the total magnetic moment of the particle will respond to thermal fluctuations, which will be opposed by the external magnetic field. Thus, the behaviour of the total magnetic moment of a small ferromagnetic particle is not unlike that of paramagnetic ions or molecules. Therefore, the temperature dependence of the magnetisation of these particles can be formally described by the Langevin equation (1), with the only difference that in Eqn. (1) μ is the magnetic moment of the paramagnetic ion, atom, or molecule, whereas in the present case μ is the magnetic moment of the particle, equal to $\mu_i n$ where μ_i is the magnetic moment at saturation of the ferromagnetic (0.6 μ_B for Ni) and n is the number of atoms in the particle. In contrast to classical paramagnetic

particles, the magnetic moment of these very small ferromagnetic crystals is thousands of times greater, and therefore Bean[10,11] has proposed the term "superparamagnetism" for this effect in ferromagnetics.

Since the magnetisation of these particles is formally described by the Langevin equation, the size of the particles can be calculated from the results of magnetic measurements. If the thermal energy is much greater than the energy of the interaction between the magnetic moment and the field, i.e. $kT \gg \mu H$, we have

$$\frac{\sigma}{\sigma_0} = \frac{\mu_{Ni} n H}{3kT}.$$

This equation is fully identical to Eqn. (2). If σ/σ_0 and H are known, we can determine $\mu_{Ni}n$, whence n, and therefore also the particle size, can be calculated.

The problem of the particle size determination of finely divided ferromagnetics, and the thermodynamic study of their magnetic properties, have already been discussed in detail[4,5]. We shall briefly consider these questions to arrive at a better understanding of ferromagnetic resonance in systems of small ferromagnetic particles.

Exchange forces, leading to narrower resonance lines, and dipole–dipole (magnetic) forces, leading to line broadening, are present in both paramagnetic and ferromagnetic substances. However, exchange interaction is very much stronger in ferromagnetics than in paramagnetics[12], and therefore quite narrow resonance lines (400–600 Oe) can be obtained with fairly coarse ferromagnetic particles. For iron single crystals lines as narrow as 40–60 Oe are possible. The situation is quite different with "superparamagnetic" particles of 10–15 Å dimensions. As stated above, thermal motion in these particles imposes a fluctuation on the total magnetic moment, the magnetisation of the particles is greatly reduced, and the Curie point is abnormally low[5,13]. All these phenomena arise from the decreased exchange interaction in particles of this type. As a result, resonance lines can become extremely broad and practically undectable (due to dipole–dipole broadening) in catalysts with a low content of ferromagnetic supported on a carrier of large surface area (Ni–SiO_2, Ni–Al_2O_3, etc.) and therefore consisting of small particles. In these cases the ferromagnetic resonance signal can be developed by sintering the catalyst, which increases the particle size of the ferromagnetic.

However, the dependence of the width of the resonance line on the disperseness of the ferromagnetic is a complex problem, and relevant data in the area of catalyst studies are practically non-existent. Some work in this general area has been done on ferromagnetic resonance in thin layers[14]. Fig. 12 shows the effect of the thickness of a Co film on the width of the ferromagnetic resonance line. The steep rise of ΔH at film thicknesses below 500 Å is ascribed to structural non-uniformity of the thin layers, implying non-uniformity of magnetisation and consequent line broadening. However, the results of studies of ferromagnetic resonance in thin layers (Ni, Co, Fe) cannot be directly applied to catalysts of the ferromagnetic metal–carrier type.

There is yet another effect tending to produce non-uniform magnetisation and a broadening of the absorption line in work with metallic ferromagnetics: the so-called "skin effect". This effect arises from the finite (1000–10 000 Å) depth of penetration of a high-frequency field in metals, resulting in non-uniform magnetisation in depth of the crystal. In studies of catalysts this effect can be ignored in most cases, because ferromagnetic crystals on a carrier are usually much smaller than the range of thicknesses quoted above.

The temperature dependence of the width of the ferromagnetic resonance line in ferromagnetic metals is also very interesting. For these materials (and in particular for Ni) ΔH remains practically constant between room temperature and the temperature of liquid helium, and increases steeply on approaching the Curie point[15] (Fig. 13).

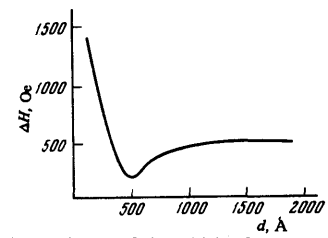

Figure 12. Dependence of the width of the resonance curve on the thickness of thin films of Co.

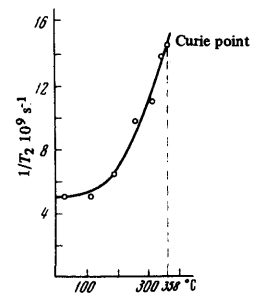

Figure 13. Dependence of relaxation frequency $1/T_2$ (proportional to the line width) on temperature, for Ni.

In this section we have considered various factors which influence the width of the ferromagnetic resonance line and the g-factor. If it were possible to exclude all the effects tending to broaden the distort the absorption curve, one could arrive at the true line width determined only by the relaxation processes in the ferromagnetic. The characterisation of the relaxation processes actually responsible for the width of the true absorption line is a complicated problem which has not yet been fully resolved[16]. An important consideration is the fact that electron–spin relaxation through the conduction electrons in a metal may be the most important of the various relaxation processes available to ferromagnetic metals and capable of giving rise to a resonance line of finite width. If such is the case, it should be possible to change the ferromagnetic resonance conditions and thus attempt to explain, for example, the interaction between metal and carrier, by somehow changing the concentration of conduction electrons in a ferromagnetic crystal whilst keeping constant all the other parameters which influence ΔH.

III. EXPERIMENTAL WORK ON THE APPLICATION OF THE FERROMAGNETIC RESONANCE METHOD TO THE STUDY OF CATALYSTS

1. Study of Hydrogen Chemisorption

Various investigations of the chemisorption of hydrogen on Ni by magnetic methods have been reviewed by Selwood [4]. Magnetic methods can be applied to the study of chemisorption processes only when the ratio of the number of surface atoms to the number of atoms in the bulk is not too small (~ 0.6). This condition is satisfied for Ni crystals of less than 50 Å dimensions, i.e. for crystals which behave magnetically as superparamagnetics.

This size of Ni crystals is necessary also in studies of chemisorption by the ferromagnetic resonance method. The best catalyst from this point of view is Ni supported on SiO_2 or an alumina–silica, because Ni crystals of 10–50 Å size can be produced on these carriers. These were, indeed, the catalysts used by Selwood [17] to study the chemisorption of H_2 by the ferromagnetic resonance method. Catalysts containing 1–50% of Ni were prepared by saturating SiO_2 with a solution of $Ni(NO_3)_2$, followed by drying and reduction at 350°. The hydrogen chemisorbed during the reduction process was pumped off at 350°. The ferromagnetic resonance spectrum was recorded before and after exposure to hydrogen. Catalysts containing 10% Ni were examined in greatest detail: their ferromagnetic resonance spectrum before and after adsorption of hydrogen is reproduced in Fig. 14. The line width is unaffected (within experimental

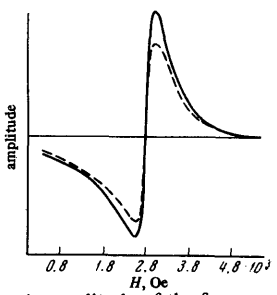

Figure 14. Change in amplitude of the ferromagnetic resonance line during adsorption of H_2 on Ni-SiO_2.[17] Continuous line—before adsorption; dashed line—after adsorption.

error) by the exposure to hydrogen, and remains at 470 ± 30 Oe, but the amplitude of the signal decreases by 15–25%. The g-factor, equal to 2.22, is also unaffected by the admission of hydrogen. As expected, the decrease in amplitude was a function of the particle size of the Ni. Thus, with a commerical catalyst of average Ni particle size 40 Å the decrease in amplitude was only 6%, and for the catalyst described above containing 10% Ni and having an average Ni particle size of 15 Å the decrease in amplitude was ~18%. Selwood showed that the decrease in amplitude was linearly related to the amount of hydrogen chemisorbed. Thus, the ferromagnetic resonance method qualitatively confirms the results obtained by static or low-frequency magnetic methods. However, Selwood points out that the main advantage of the ferromagnetic resonance method as compared with other magnetic methods is its very high sensitivity. He assumed that very small Ni crystals can be obtained by using catalysts with a low Ni content, and that these crystals will contain an extremely large number of surface Ni atoms, thus giving an enhanced change in the intensity of the ferromagnetic resonance signal.

Unfortunately, the sensitivity of the ferromagnetic resonance method is not such a simple problem. For measurements on catalysts containing relatively coarse Ni particles (>200 Å), the ferromagnetic resonance method offers no advantage over static magnetic methods of measuring the amount of ferromagnetic phase. If the concentration of Ni on the surface is decreased at the same time as the particle size, the sensitivity of the ferromagnetic resonance method does not increase, but actually decreases. We have already pointed out that low concentrations of small Ni particles on the surface produce a drastic broadening of the ferromagnetic resonance line due to the effect of dipole–dipole interaction. This substantial line broadening associated with low Ni concentrations on the carrier has in fact been observed in studies of Ni catalysts on charcoal [18]; the effect results in a loss of sensitivity, and imposes a limit on the application of the method to systems of this type. Furthermore, very small amounts of material (0.1–10 mg) are used for plotting ferromagnetic resonance spectra: quantitative adsorption data cannot be obtained under these conditions. Hence, there is no justification at the moment for the belief that the ferromagnetic resonance method is more sensitive in hydrogen chemisorption studies than the low-frequency permeameter method, which can accept large amounts of material (up to 10 g) and has an acceptable sensitivity. The real advantage of the ferromagnetic resonance method over other magnetic methods is the potential access to new information, in principle, on the structure and properties of Ni in catalysts, information which cannot be obtained by other methods.

A paper by Loy and Noddings [19] also describes a study of the interaction between Ni and hydrogen. These workers investigated the catalyst $NiCa_3(PO_4)_6$, used in the dehydrogenation of butene to butadiene. The interaction between hydrogen and the catalyst was analysed in two ways: 1) from the dependence of the amplitude of the ferromagnetic resonance signal upon the temperature of exposure of the catalyst to hydrogen, and 2) by saturation of the Ni with hydrogen at high temperatures, followed by desorption of the hydrogen at the same temperature.

The first method involved the following experimental procedure. The catalyst pellet was reduced for 15 min at the desired temperature, and the ferromagnetic resonance spectrum was recorded at room temperature. The specimen was next oxidised at the reduction temperature and the spectrum was again recorded. This oxidation–reduction cycle was repeated on the same pellet over the temperature range 400–800°.

In the second method the catalyst was reduced in a stream of hydrogen at 1100° for 30 min, the ferromagnetic resonance spectrum was measured, the hydrogen was pumped off at 1100° for 1.5 h, and the spectrum was again measured.

Fig. 15*a* shows the ferromagnetic resonance spectrum after an oxidation–reduction cycle by the first method. The line width for the reduced catalyst is 720 Oe, and $g = 2.2$. No signal is obtained after oxidation. The change in the relative intensity of the ferromagnetic resonance signal as a function of the temperature of hydrogen treatment is shown in Fig. 16. The authors interpret this behaviour by postulating the occurrence of two processes.

1. Catalysts reduced below 670° contain metallic Ni, produced by the reduction of Ni^{2+}, in an amount which increases with increase of reduction temperature, accompanied by a corresponding increase in the intensity of the ferromagnetic resonance signal.

2. Reduction of the catalyst above 670° leads to a decrease in signal intensity, due to the decreased magnetisation of the Ni following hydride formation in the bulk or on the surface of the Ni crystals.

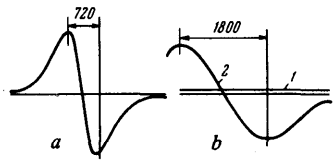

Figure 15. Resonance absorption curve for a nickel–calcium phosphate catalyst:
a) reduced at 680°; *b*) reduced at 1100° (*1*) and degassed at 1100° (*2*).

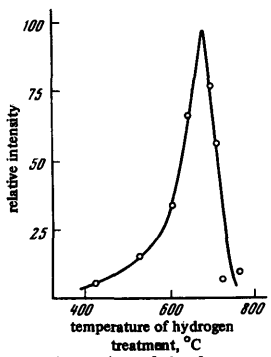

Figure 16. Relative intensity of the ferromagnetic resonance signal of a nickel–calcium phosphate catalyst as a function of the temperature of reduction.

Fig. 15*b* shows the ferromagnetic resonance spectra of a catalyst reduced at 1100° and degassed at 1100°. The reduced catalyst does not give a signal, but the outgassed catalyst gives a broad line ($\Delta H = 1800$ Oe) with $g = 2.55$. The authors suggest that reduction at 1100°C produces the diamagnetic nickel hydride, which is decomposed by evacuation at 1100° with regeneration of metallic nickel, which gives a ferromagnetic resonance signal. Thus, the conditions for the interaction of Ni with hydrogen chosen in this work are quite different from those of Selwood's work, in which hydrogen chemisorption was studied. Obviously, in Loy and Noddings' work nickel hydrides are formed, i.e. there is formation of bulk chemical compounds. Furthermore, at the high heat treatment temperatures used in this work sintering of the metallic nickel must be substantial, and yet the authors ignore this process in their subsequent discussion (analysed below).

2. Study of the Shape of Nickel Particles and of the Structure of Nickel Catalysts

The earliest application of the ferromagnetic resonance method was in a study of the structure of nickel catalysts prepared by the decomposition of Ni formate in sunflower oil in a stream of hydrogen[20]. X-Ray diffraction and magnetic studies of the catalysts were used to complement the ferromagnetic resonance spectra. It was shown that the *g*-factor calculated without applying corrections for the crystallographic magnetic anisotropy and for shape anisotropy was 2.22, i.e. the particles were spherical. In contrast to the behaviour of Raney nickel catalysts,[21] dehydrogenation does not increase the magnetisation and the intensity of the ferromagnetic resonance signal: on the contrary, it is accompanied by fragmentation (the particle size falling from 100 to 50 Å) and by a decrease in magnetisation (from 7.2 to 0.30). The dehydrogenated catalyst has a very labile structure consisting of finely divided Ni (width of the ferromagnetic resonance line 300 Oe), which undergoes extensive sintering at moderate temperatures.

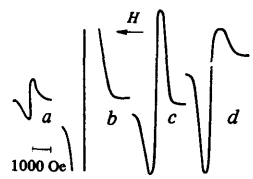

Figure 17. Ferromagnetic resonance spectra of heat treated nickel formate catalysts:
a) starting catalyst; *b*) catalyst sintered in air for 2 h at 300° (at the same amplification); *c*) catalyst sintered in vacuum for 4 h at 300°; *d*) catalyst sintered in air for 4 h at 300°C.

Fig. 17 shows the ferromagnetic resonance spectra of the formate catalyst, dehydrogenated by nitrobenzene, for various conditions of heat treatment. It is evident that sintering the catalyst in air at 300° (Fig. 17*b*) produces a sharp increase in the intensity of the signal. This is due to the fact that with a very labile and "loose" catalyst structure the growth of Ni particles, accompanied by an increase in magnetisation, is much faster than the oxidation of Ni to NiO. Typically, sintering the catalyst in a vacuum or in the air causes substantial line broadening (from 300 to 900 Oe), increase of particle size (from 50 to 200 Å), and increase of magnetisation (from 0.3 to 14.0), but sintering in the air additionally gives a sharply asymmetric line (Fig. 17*d*). As stated above, these processes are determined by non-uniform magnetisation of the sample (due to magnetic anisotropy, shape anisotropy, NiO impurities), which increases with increase of the Ni particle size.

Gasumura and Abe[22] have reported a study of the ferromagnetic resonance spectra of two Raney nickel catalysts, prepared by leaching a melt containing 49% Ni and vacuum heat treatment (10^{-3} mmHg) for 2 h at 70° and 300°. The catalyst prepared at 70° was active towards hydrogenation and had a magnetisation of 11.0; that treated at 300° was inactive with a magnetisation of 27.0. The ferromagnetic resonance spectra of both catalysts are shown in Figs. 18*a* and 18*b*. The line asymmetry of the catalyst heated at 70° is not due to anisotropy of the *g*-factor, as stated by the authors, but to shape anisotropy (see Fig. 7) or to magnetic

anisotropy. The question can be resolved by measuring the temperature dependence of the asymmetry coefficient of the line. In this case the asymmetry of the line is evidently associated with shape anisotropy, since sintering of the catalyst gives a symmetrical line with $g = 2.22$ (Fig. 18*b*). The increased magnetisation on sintering is due mainly to growth of the Ni particles, and not to the evolution of hydrogen. The lower catalytic activity of the catalyst heated at 300° evidently has the same explanation.

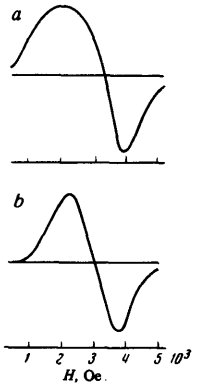

Figure 18. Ferromagnetic resonance spectra of Raney nickel catalysts[22]:
a) catalyst heated in vacuum at 70°C, $g = 2.09$; *b*) catalyst heated in vacuum at 300°C, $g = 2.22$.

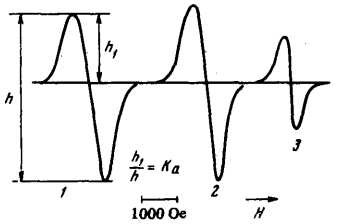

Figure 19. Temperature variation of the asymmetry coefficient (K_a) of the line for Ni–ZnO catalysts (49.5% Ni):
1) 20°; *2*) 100°; *3*) 220°C.

A similar increase in the symmetry of the line with a tendency of the *g*-factor towards the value 2.20 (characteristic of spherical particles), and increased magnetisation, was observed during the sintering of Ni prepared by chemical reduction with sodium hypophosphite[23]. A study has been reported[24] of the temperature dependence of the asymmetry coefficient of the ferromagnetic resonance line for Ni–ZnO catalysts. The results are given in Table 1 and Fig. 19. It can be seen that the line becomes more symmetrical as the measurement temperature is raised. Thus, the asymmetry of the ferromagnetic resonance line in this case is not due to shape anisotropy of the particles (since there is no sintering of the catalyst during the measurements) but to a steep temperature dependence of the Ni anisotropy constant (see Fig. 4), and hence to a decreased non-uniformity of magnetisation at higher measurement temperatures. It is obvious, therefore, that the existence of line asymmetry can be interpreted only as an indication

Table 1. Variation of the asymmetry coefficient of the ferromagnetic resonance line (K_a) with measurement temperature

of the presence of non-uniform magnetisation, but not of the origin of the non-uniformity. The underlying causes can only be established by a detailed study of the specimen using different methods, and in particular by observing the temperature variation of the shape of the ferromagnetic resonance line.

3. Interaction Between Ni Particles in Catalysts According to Ferromagnetic Resonance Data

The problem of the interactions within Ni particles and between particles was formulated on the basis of ferromagnetic resonance data by Loy and Noddings[19]. These workers measured the temperature dependence of the amplitude of the ferromagnetic resonance signal, and obtained the results summarised in Fig. 20. A curve of this

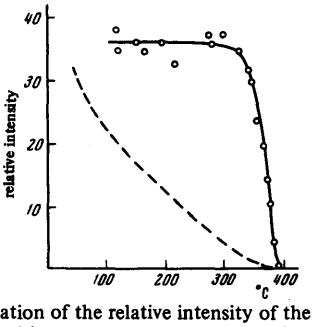

Figure 20. Variation of the relative intensity of the ferromagnetic resonance signal with measurement temperature for a nickel–calcium phosphate catalyst[19]. The dashed curve shows the shape of the thermomagnetic curve for finely divided nickel.

shape for the change in magnetisation with temperature is characteristic of coarsely divided Ni, but the authors state that coarse Ni particles could not have been present in their catalysts because the magnetisation disappears completely under the appropriate conditions in the presence of hydrogen, indicating[17] that the Ni particles must be very finely divided. But finely divided Ni particles should have a low Curie point (not 358°, as suggested by Fig. 20), and their thermomagnetic curve should have the shape of the dashed line in Fig. 20. Loy and Noddings explain these

anomalies by postulating that resonance methods measure transitions in individual domains, whereas static measurements encompass the whole particle including inter-domain interactions. In small particles this interaction is distorted by thermal energy, leading to abnormally low Curie points. The authors consider that the particle size and the influence of thermal vibrations are reflected only by the line width, and not by the Curie point. However, this explanation seems to be physically unsound for the following reasons.

1. There is not justification at all for associating the loss of magnetisation on exposing the catalyst to hydrogen at temperatures as high as 800–1100° with the presence of small particles. At those temperatures the interaction of hydrogen with nickel ceases to be a surface chemisorption effect, and involves the whole mass of the particle in formation of a bulk hydride phase, as the authors themselves point out. Obviously, as soon as the loss of magnetisation can be ascribed to the formation of a bulk phase of nickel hydride, it is no longer necessary to consider only very small nickel particles, and the same process can occur with coarse nickel crystals.

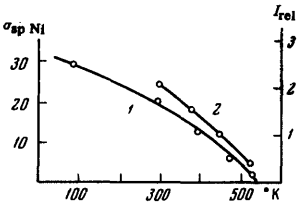

Figure 21. Temperature dependence of the saturation magnetisation (*1*) and of the relative intensity of the ferromagnetic resonance signal (*2*) for a Ni-ZnO catalyst (20.3% Ni).

2. With very small Ni crystals—complete demagnetisation under the influence of hydrogen is theoretically possible for a particle size < 10 Å—the concept of domains and domain boundaries (see Section II,4) loses physical significance, because such particles are not subdivided into domains. Therefore, the suggestion that in these particles the transitions within domains are characterised by resonance methods whilst static methods include interactions between domains is not physically justified. Both static and resonance methods should give the same type of change of magnetisation with temperature. This was actually demonstrated by the present writer [24] for an Ni–ZnO catalyst. Curve *1* of Fig. 21 was obtained from static measurements, and curve *2* shows the relative change of the integral intensity of the ferromagnetic resonance signal. It is evident that the two curves have entirely similar trends, i.e. that the presence of fine Ni particles in the catalyst is manifest in both static and resonance methods. The influence of various factors on the line width has already been treated in detail in previous Sections. Measurements on a single catalyst at a single temperature usually provide very little information on the underlying causes of the observed line width.

Data on the temperature dependence of the line width for a series of Ni–ZnO catalysts are set out in Table 2. All the catalysts show a characteristic decrease in line width with increase of temperature, and an increased line symmetry (Table 1). It follows that additional line broadening is due to magnetic crystallographic anisotropy rather than to shape anisotropy of the particles. The higher the measurement temperature, the lower is the magnetic anisotropy constant (see Fig. 4), and the less substantial is the line broadening due to this factor. As already pointed out above, from the point of view of magnetic anisotropy the line width is relatively insensitive to temperature until it begins to rise steeply on approaching the Curie point. Therefore, the opposite change of ΔH with temperature for Ni–ZnO catalysts must be ascribed to magnetic crystallographic anisotropy, and this effect should not be ignored in work with powdered materials.

Table 2. Variation of the width (ΔH) of the ferromagnetic resonance line with measurement temperature.

Concn. of Ni, wt.%, allowing for incomplete reduction	Catalyst reduced from oxides: temperature dependence of ΔH, Oe				ΔH, Oe after sintering*
	20°	100°	220°	−196°	
5.6	780	690	660	—	1700
8.8	780	720	660	1170	1320
14.3	750	660	660	1260	960
39.8	1050	780	660	1620	1350
49.5	1600	1250	680	1740	1800
51.0	1440	1080	690	3500	1860
77.3	2340	2040	1380	—	—

* Sintering in vacuum (10^{-5} mmHg) for 12 h at 410°C.

Since the line width measured at 220° is practically constant in catalysts containing 5.6–51% Ni (Table 2), the width is evidently determined by strong exchange interactions within the particles (particle size 400 Å) and relatively weak interactions between particles. Sintering of the catalysts causes increased magnetisation, growth of the Ni particles, and therefore also a greater influence of the anisotropy effect ($K_1 V \gg kT$) and considerable line broadening (Table 2). Simultaneously decreasing the size of the Ni particles on the carrier and their concentration produces considerable line broadening [18], obviously through dipole–dipole interaction. However, in the presence of a large number of fine Ni particles very close to each other the state of affairs can be quite different. Thus, with Ni particles prepared by decomposition of nickel formate in oil and having dimensions of the order of 40 Å, the line width was found [20] to be only 300 Oe. This value is even lower than the value reported [25] for colloidal Ni particles. Obviously, with high densities of small ferromagnetic particles in close proximity the dipole–dipole broadening is masked by the exchange interactions which tend to sharpen the line. Characteristically, the line width for this catalyst does not change on going to −196°, i.e. it is not determined by spin–lattice relaxation and magnetic anisotropy: it may be close to the true line width characteristic of the material.

Ni–Al_2O_3 catalysts have been investigated by Rubinshtein and coworkers [26]. Even small (5 wt.%) additions of Al_2O_3 enable a symmetrical ferromagnetic resonance signal to be observed ($g = 2.2$, $\Delta H = 1400$ Oe). Pure Ni under the same reduction conditions (350°C) gives a line so broad as to be almost impossible to plot (Figs. 22*a* and 22*b*). Reduction of the same catalyst at 450°C produces some line broadening ($\Delta H = 1550$ Oe) and above all an increase of the *g*-factor to 2.8. This is due to slight sintering of the Ni crystals, and to the associated increase in the non-uniformity of magnetisation, leading to line broadening

and a change in the g-factor. The effect is entirely analogous to the result obtained[19] for a nickel–calcium phosphate catalyst reduced at 1100°, and is further confirmation of the sintering processes which Ni undergoes at these temperatures. The major effect of small additions of Al_2O_3 on the ferromagnetic resonance spectrum of Ni is explained by a substantial increase in the disperseness of the nickel (60–100 Å). The structure of the catalyst may be depicted as Ni particles (60–100 Å in size) separated by thin layers of Al_2O_3. This structure is very stable towards sintering and very resistant to oxidation because of the slow diffusion of O_2 to the Ni particles, as shown by Rubinshtein and coworkers[26].

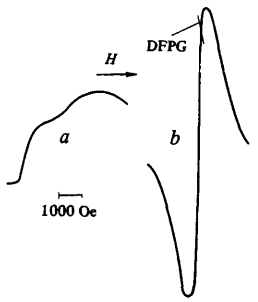

Figure 22. Ferromagnetic resonance lines for Ni and Ni–Al_2O_3 catalysts:
a) pure Ni; *b*) Ni–Al_2O_3 (~5% Al_2O_3).

We shall now briefly discuss the determination of the concentration of Ni, and its magnetisation, from ferromagnetic resonance data. Loy and Noddings[19] have computed the number of Ni atoms and the approximate domain size by comparing the area under the ferromagnetic resonance curve with the area under the curve of a *paramagnetic standard* ($MnSO_4.H_2O$). This procedure is, of course, physically quite unsatisfactory for quantitative calculations, because a ferromagnetic with the same number of atoms as a paramagnetic is subject to exchange forces giving rise to enormously greater values of the magnetisation. Even more unsatisfactory is the method proposed by Fasman[27], in which the relative integral intensities of ferromagnetic resonance lines are calculated by the formula $I = A(\Delta H)^2$, where A is the amplitude of the second derivative and ΔH is the line width. This formula is analysed, and the conditions under which it can be applied are discussed, in Refs. 6 and 28. It is used to calculate the concentration of unpaired spins in paramagnetic materials, by reference to a standard, in the case of *symmetrical lines*. For asymmetric lines the use of this formula is inadmissible, because it leads to considerable errors. The saturation magnetisation has been evaluated from ferromagnetic resonance data[9] by means of the formula

$$\mu''_{res}\,\Delta H = 4\pi\sigma_0$$

where μ''_{res} is the imaginary part of the dynamic permeability under resonance conditions, ΔH is the line width, and σ_0 is the saturation magnetisation of the sample.

Calculation of the change in relative intensity requires a double integration of the absorption line (when plotted in the form of the first derivative), followed by measurement of the area under the curve, which is proportional to the magnetisation.

As regards the quantitative determination of Ni in the catalysts, the problem is very much complicated by the fact that for a given number of Ni atoms in the sample the magnetisation (or area under the absorption curve) will be strongly dependent on the size of the particles formed by the Ni atoms. Therefore, each catalyst sample requires its own standard with the same size distribution of Ni particles. It is very difficult, of course, to fulfil this condition.

4. Interaction of the Metal with the Carrier

In recent years, the study of the structure and of the catalytic activity of supported metal catalysts has attracted increasing interest, and the problem has become a key one in catalysis. An important aspect of this problem is whether direct electronic interaction is present between the carrier and the metal, and whether the catalytic activity is thereby affected. Various workers have shown[29–32] that doping of the carriers (Al_2O_3, ZnO, MgO) with different cations (Li^+, Ga^{3+}) which affect their electrical conductivity produced a change in the catalytic activity of the deposited nickel. We shall not attempt a detailed analysis of these researches, and we shall consider only the physical effect which underlies these observations.

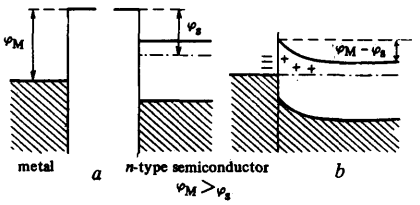

Figure 23. Energy level diagram for the contact between a metal and an n-type semiconductor:
a) before contact; *b*) after contact.

The physical effect is based on phenomena at the metal–semiconductor interface. Assume an n-type semiconductor of work function φ_s and a metal of work function φ_M, such that $\varphi_M > \varphi_s$ (see Fig. 23*a*). If the metal is brought into contact with the semiconductor, electrons from the semiconductor (at a higher chemical potential) will be transferred to the metal until the chemical potentials in the metal and the semiconductor are equal. As a result, the layer of semiconductor adjacent to the metal becomes depleted of current carriers and positively charged, and the metal layer becomes negatively charged. At the boundary, a potential barrier is formed (Fig. 23*b*): this barrier plays an essential role in rectifying contacts. An analogous model can be set up for the case of a metal deposited on a p-type semiconductor. This transfer of electrons to the metal from the semiconductor (metal–n-type semiconductor boundary, $\varphi_M > \varphi_s$) or to the semiconductor from the metal (metal–p-type semiconductor boundary, $\varphi_M < \varphi_s$) is invoked by the authors of these papers to account for the change in catalytic activity of the Ni deposited on variously doped

carriers. And yet, the reality of this transfer in catalysts has not so far been demonstrated. Can the ferromagnetic resonance method be applied to the solution of this problem? We have already pointed out that the true line width is determined by the interaction between the ferromagnetic system of electrons and the conduction electrons. Hence, if the metal is depleted or enriched of electrons, the relaxation time (and therefore also the line width) can be expected to change. Thus, the experiment consists in determining changes in line width for Ni deposited on carriers having different electrical properties. However, such an experiment is very difficult to realise, because (as stated above) the line width in systems of the catalyst type is not determined exclusively by relaxation processes. The experiment requires that the Ni on the various carriers should have: 1) an identical size distribution of Ni particles; 2) identical particle shape, so as to exclude shape anisotropy; 3) identical and preferably low concentration of Ni on the carrier, so as to avoid interaction between Ni particles.

The measurements should be made at high temperatures, in order to avoid line broadening through magnetic crystallographic anisotropy. The Ni particles should have the greatest possible degree of disperseness, but such as to allow resonance to be observed, since the effect will be most pronounced in this case. Of course, it will not be easy to fulfil all these conditions, but qualitatively new information on the structure of metallic catalysts on carriers can be expected from work of this type.

---o0o---

The ferromagnetic resonance method has recently begun to be applied to the study of ferromagnetic catalysts in parallel with the various magnetic methods of investigating paramagnetic and ferromagnetic catalysts. The method is capable in principle of producing qualitatively new information on the properties of ferromagnetic catalysts, which cannot readily be obtained by other methods: 1) on the interactions within and between ferromagnetic particles; 2) on the structure of ferromagnetic catalysts and its dependence on various influences; 3) on the interaction between the catalyst and various adsorbents; 4) on the shape of the ferromagnetic particles; 5) on the nature of the interaction between the ferromagnetic metal and the carrier.

We may hope that extensive application of this method will result in an even closer approach to an understanding of the structure of real catalysts and to the development of a modern theory of catalysis.

Oxidation of Benzene

E.T.Enisov and D.I.Metelitsa

The review gives a systematic account of studies on the oxidation of benzene by different methods—with oxygen in the gas phase, with Fenton's reagent in aqueous solution, under the action of light and penetrating radiation, and also catalytic oxidation in aqueous solution. Particular attention has been paid to the mechanism of the oxidation of benzene; the main experimental evidence for individual mechanisms is discussed and unlikely schemes are criticised. Kinetic data and the mechanism of the catalytic oxidation of benzene to phenol with oxygen in aqueous solution in the presence of iron and copper ions which follows from them are discussed in detail. The bibliography incorporates 120 references.

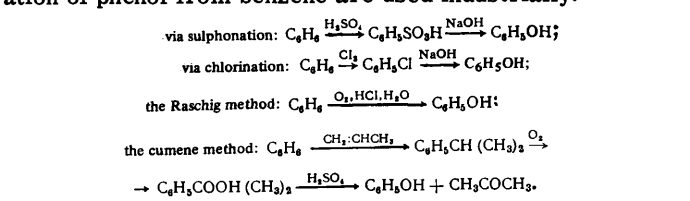
I. INTRODUCTION

Benzene differs sharply from other hydrocarbons by its high stability with respect to oxidation, which is due to its structure. Hydrocarbons are known to be oxidised by a free-radical mechanism, the reaction including a stage involving the homolytic abstraction of a hydrogen atom. The high stability of the C–H bond in benzene (102 kcal mole^{-1}) is one of the reasons for its stability. No less important is another factor, namely the major role played in the oxidation of hydrocarbons by hydroperoxides, which break down into free radicals and initiate further chain oxidation. The corresponding hydroperoxide is not known for benzene and attempts to synthesise it have proved unsuccessful, and it appears that it does not exist as a stable molecular compound. The absence of a hydroperoxide as the species initiating the reaction does not favour rapid oxidation. Finally, it is very significant that the oxidation of benzene yields phenol and products of its further oxidation, which behave as inhibitors of chain reactions involving the oxidation of hydrocarbons. All these factors explain the stability of benzene with respect to oxidation.

The oxidation of benzene to phenol is of practical importance. Nowadays the following methods for the preparation of phenol from benzene are used industrially:



These procedures, including the cumene method which is the most economical, consist of many stages. Therefore the development of an effective single-stage process is important. As will be seen from the present review, under certain conditions it is possible to oxidise benzene to phenol with a fairly high yield. The theoretical possibility of oxidising benzene to phenol under mild conditions is a consequence of the existence of enzymes which can, for example, oxidise phenylalanine to tyrosine.

II. GAS-PHASE OXIDATION OF BENZENE

The first studies on the oxidation of benzene with molecular oxygen in the gas phase were performed in the 1920's. The gas-phase oxidation of benzene takes place at 500–700°C.[1-31] The oxidation yields phenol, resins, carbon monoxide, and carbon dioxide. At these high temperatures the oxidation of benzene is accompanied by its cracking on the wall of the reaction vessel. Glass packing favours the cracking process[27]. As a result of cracking, low-molecular hydrocarbons (methane, ethylene, acetylene, etc.) are formed together with the oxidation products[19,20,27]. In a number of investigations homogeneous catalysts, such as hydrogen chloride, nitrogen dioxide, and iodine were used. As an example, one may quote the experiments with iodine in which the introduction of 0.02% of iodine into air at 604°C increased the yield of phenol from 40.4% (without iodine) to 56.5% with respect to unreacted benzene[12]. In order to accelerate the oxidation of benzene, atomic oxygen obtained in an electric discharge has also been used[13,21,22]. The oxidation of benzene has been stimulated by readily

oxidisable organic compounds: cyclohexane, cyclohexanol, cyclohexanone, n-hexane, aniline, cyclohexene, etc.[15,23,28].

Photochemical oxidation of benzene at room temperature leads to the formation of phenol and a peroxide[24]. The phenol undergoes further photochemical decomposition.

The heterogeneous oxidation of benzene to maleic anhydride on vanadium pentoxide is an industrial method. The rate-limiting stage of this process is the heterogeneous oxidation of benzene to phenol, which is then rapidly oxidised to quinone and the latter is oxidised to maleic anhydride[8]. Table 1 gives the benzene oxidation conditions and the yields of phenol obtained in a number of the most interesting studies.

Table 1. Oxidation of benzene.

Oxidation conditions	Oxidation products	Yield of phenol, %	References
Benzene–air mixture, 300–500°C	phenol, biphenyl, maleic and formic acids	0.5—1.0 by weight	19,20
Benzene–air, 520–685°C, column without packing	phenol, resins, CO, CO_2, CH_4	20—26	27
Benzene–air, packed column	phenol, resins, CO, CO_2, CH_4, C_2H_2	16—18	
$O_2 + N_2$ + benzene, 660°C	phenol, resins	30	14
Atomic oxygen + benzene, 180–230°C		4.5—27	22
Atomic oxygen + benzene	phenol, biphenyl, CO, CO_2	43	13
Benzene–air, I_2(0.02%), 604°C	phenol, biphenyl	56.5	12
5% O_2 + benzene, 400–500°C	phenol, resins	to 75	5
Chromium, molybdenum, vanadium, and tantalum oxides			
Benzene–air, V_2O_5, 316°C	phenol, maleic acid	1.9	16
Benzene + cyclohexane (10%), 585°C		62	23
Benzene + readily oxidisable organic substances, 400°C	phenol, CO, CO_2, resins, CH_4, C_2H_2	20—26	28
Benzene + cyclohexane (0.2–0.3%), 449°C		30	15

The kinetics of the gas-phase oxidation of benzene were investigated by Ioffe[26–30] and Norrish et al.[31] The kinetic curves for the disappearance of benzene and the accumulation of phenol have the S-shape characteristics of auto-oxidation processes. In the initial period the reaction kinetics are described by the following equation: conversion = const. $\times e^{\varphi t}$, where φ = const. $\times e^{-32\,000/T}$ at 660–685°C for $(C_6H_6):(O_2) = 2:1$.[30] It is suggested that the acceleration of the reaction occurs as a result of the oxidation of side products such as methane, ethylene, etc.[30] The following mechanism has been proposed for the initial stage of the oxidation[30,31]:

$$C_6H_6 + O_2 \rightarrow C_6H_5^{\cdot} + HO_2^{\cdot},$$
$$C_6H_5^{\cdot} + O_2 \rightarrow C_6H_5OO^{\cdot},$$
$$C_6H_5OO^{\cdot} + C_6H_6 \rightarrow C_6H_5O^{\cdot} + C_6H_5OH,$$
$$C_6H_5O^{\cdot} + C_6H_6 \rightarrow C_6H_5OH + C_6H_5^{\cdot},$$
$$C_6H_5^{\cdot} + C_6H_5^{\cdot} \rightarrow C_6H_5{-}C_6H_5.$$

The available experimental data are still insufficient to decide whether this mechanism of the gas-phase oxidation at high temperatures should be accepted or rejected. One can only note that the reaction of phenoxy-radicals with benzene is endothermic to the extent of 17 kcal mole^{-1} and should be extremely slow. The reactions of phenoxy-radicals with O_2, benzene ("addition"), and phenyl radicals should be faster.

Phenol is an intermediate and undergoes further oxidation. The oxidation of phenol was investigated by Ioffe at 650°C and a mechanism was proposed for the oxidation of phenol in the presence of benzene (RH is benzene)[26]:

$$C_6H_5OH + R^{\cdot} \rightarrow C_6H_4OH^{\cdot} + RH,$$
$$C_6H_4OH^{\cdot} + O_2 \rightarrow HOC_6H_4OO^{\cdot},$$
$$HOC_6H_4OO^{\cdot} + RH \rightarrow HOC_6H_4OH + RO^{\cdot},$$
$$C_6H_4OH^{\cdot} + R^{\cdot} \rightarrow RC_6H_4OH.$$

In this mechanism the first reaction, the removal of H from the C–H bond in phenol, is doubtful. The weakest bond in the phenol molecule is O–H and this should in fact be the point of attack by the radical on the phenol molecule which yields a phenoxy-radical.

III. OXIDATION OF BENZENE WITH FENTON'S REAGENT

Fenton's reagent (aqueous solution of ferrous sulphate and hydrogen peroxide) is a source of hydroxy-radicals and is used for the oxidation of organic compounds[32–45]. In the absence of a substance undergoing oxidation, hydrogen peroxide breaks down as a result of the following reactions[41,45]:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^{\cdot} + OH^{-},$$
$$Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + HO_2^{\cdot} + H^{+},$$
$$Fe^{2+} + HO^{\cdot} \rightarrow Fe^{3+} + OH^{-},$$
$$Fe^{3+} + HO_2^{\cdot} \rightarrow Fe^{2+} + O_2 + H^{+},$$
$$HO^{\cdot} + H_2O_2 \rightarrow H_2O + HO_2^{\cdot},$$
$$Fe^{2+} + HO_2^{\cdot} \rightarrow Fe^{3+} + HO_2^{-} \overset{H^+}{\rightleftarrows} H_2O_2.$$
