The ability of phosphorus, aluminium, and iron chlorides etc. to stabilise linear chlorophosphazenes is sometimes used in the preparation of chlorophosphazenes by the ammonolysis of PCl_5. The ammonolysis was carried out in the presence of these chlorides [77,78] or even in the presence of metals [79–81] which form chlorides during ammonolysis.

The mechanisms of the thermal and catalytic polymerisation are thus very similar, especially at the chain growth stage--in every instance this is the process of growth of a polymeric ion.

Among other methods of polymerisation mention must be made of attempted solid-phase polymerisation of HCP and OCP. [82,83] Although radiation polymerisation of HCP does not take place [49–51], irradiation of the solid trimer with 50 kV X-rays at 40–120°C leads to the formation of a polymer [83]. However, the rate of polymerisation is low and reaches a maximal value of 0.8% h^{-1} at the melting point of HCP. By the action of γ-radiation for 300 h and a dose of 10^6–10^7 roentgen a degree of conversion of HCP into polymer of ~ 15% could be reached, which decreases in the presence of water, oxygen, solvent, and even OCP. [82] Unlike HCP the tetrameric chloride is not polymerised under the action of X-rays and γ-radiation. This difference in their capability for radiation polymerisation is evidently connected with the structural features of HCP (the greater capability of HCP for polymerisation was noted earlier [41]) and agree well with the calculated heat of polymerisation [61]. The identity of the polymers obtained by thermal and radiation polymerisation of HCP has been noted [82]. In the common solid-phase polymerisation of isomorphous HCP and hexabromocyclotriphosphazotriene the rate of polymerisation is lower than during their separate polymerisation [84].

It should be noted that in the determination of the quantitative rules for the polymerisation of cyclic chlorophosphazenes there are significant differences in the results of different authors (Table 2) even when the polymerisation is carried out under identical conditions. This characterises the complexity of the process of polymerisation of cyclochlorophosphazenes and the influence of many factors on this process.

Assuming that the most accurate values of the activation energy for the polymerisation of trimeric cyclochlorophosphazene is 27.3 kcal $mole^{-1}$ [66] and that for depolymerisation is 26 kcal $mole^{-1}$, [42] Paddock [10] considers that their difference accurately corresponds to the molar heat of polymerisation of HCP (1.39 kcal $mole^{-1}$), determined by differential thermal analysis [61].

There have been some reports of the polymerisation of oily homologues of chlorophosphazenes which also form chlorophosphazene rubber when heated above 130°C. [18,85,86] However, in estimating their polymerisation tendency it is necessary to take into account that these homologues can contain higher cyclic chlorophosphazenes with terminal NH groups [85] capable of polycondensation with liberation of HCl [86] and also that partial hydrolysis by small quantities of water with the formation of high-molecular-weight compounds in which the chlorophosphazene blocks are linked by P–O–P bonds can occur [85,87]. Linear polychlorophosphazenes with terminal ionic groups of the $\ldots P^+Cl_3.An^-$ type are thermally stable; their molecular weight does not change up to the depolymerisation temperature (although destruction processes with participation of terminal groups can occur in it). If these linear chlorophosphazenes have a low molecular weight and are not capable of being cyclised they are stable to temperatures above 500°C. [77]

Table 2. Results of the kinetic investigations of the polymerisation of hexachlorocyclotriphosphazotriene and depolymerisation of polydichlorophosphazene.

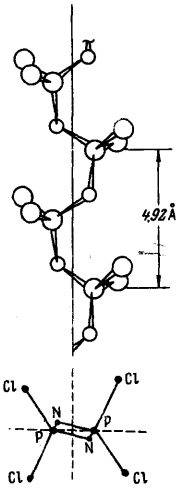
Process	Temp., °C	Kinetic order of reaction	Activation energy, kcal $mole^{-1}$	Reference
Polymerisation in the absence of air	250—300	2	42	41
Depolymerisation (traces of oxygen)	250—500	1	26	42
Polymerisation in benzene in the presence of various catalysts	210	1	—	52
Polymerisation in the presence of benzoic acid	200—210	1	27.3	66
Polymerisation in a block	240—255	2	57	67
Polymerisation in the presence of benzoic acid and sodium benzoate	235	1	—	67
Polymerisation in a block	250—300	1	51	47

An original method for obtaining linear polychlorophosphazenes was developed by Yakubovich and coworkers [88–90]. Heating low-molecular-weight linear compounds of the type $Cl[PNCl_2]_n$–$P(O)Cl_2$ and $R[PNCl_2]_n$–$P(O)Cl_2$ (where R is Cl, OR, or other groups and $n \geq 1$) at 150–200°C leads to the release of $POCl_3$ and the formation of a linear chlorophosphazene polymer of the general formula $P_XN_XCl_{2X}$ - mR_m free from lateral intermolecular bonds which are present in the polymers obtainable by thermal polymerisation of cyclochlorophosphazenes.

Since the hydrolytic stability of polychlorophosphazene is low, an attempt was made to improve it by various additions and modifiers, for example, silicone rubber, barium and tin stearates, and other salts [91] and also by carrying out the polymerisation of HCP in the presence of 2,6-di-t-butyl-*p*-cresol [92]; although in the last instance the hydrolytic stability of the polychlorophosphazene was increased ten times it was still unsatisfactory. The molecular weight of the linear polychlorophosphazenes was determined by various methods: by osmometry and viscometry [39–42], by viscometry and light scattering [93], and also from the temperature dependence of the elasticity modulus [35,36]. A comparison of the values of the osmometric and viscosimetric measurements made by Patat and coworkers [39,41] gave the following relation for solutions of polychlorophosphazenes in toluene: $[\eta] = 0.165 \times 10^{-4} M^{0.69}$. The values of the molecular weights of the polychlorophosphazene calculated by this formula were [41] ~ 10^6. Later [93] in an investigation of polychlorophosphazene isolated by precipitation into several fractions other values of the coefficients K and α in the equation $[\eta] = KM^{\alpha}$ were found for this polymer: in toluene $K = 3.89 \times 10^{-3}$ and $\alpha = 0.71$; in chloroform $K = 1.32 \times 10^{-1}$ and $\alpha = 0.56$. The difference between the values of the constants and those found earlier [99,41]

were explained[99] by the polydispersity of the products which Patat and coworkers had used. Nevertheless the absolute values of the molecular weights of the polychlorophosphazenes found by various authors agree satisfactorily and are ~ 10^5.

X-Ray diffraction studies of the polychlorophosphazene[94] suggested that its macromolecules do not have a spiral structure[27] but are almost planar. The conformation of the chain (see Figure) of the polychlorophosphazene is characterised by angles of rotation around the P–N and N–P bonds of 156° and 4° respectively, which is close to a *cis*-planar conformation. The identity period is 4.92 Å and includes two $PNCl_2$ links; the bond angles are PNP = 127° and NPN = 119° the length of the P–N bond is 1.74 Å.



Space model of a linear polychlorophosphazene.

Other halogenocyclophosphazenes are also capable of thermal polymerisation. At 250°C or over bromocyclophosphazenes form elastomeric products[95-97] which when heated subsequently form a brittle solid substance stable to the action of acids and alkalis. Polyfluorophosphazenes[98,99] form cyclofluorophosphazenes on heating above 300°C.

Of the other methods for making polyhalogenophosphazenes mention must be made of the "azide" method, which is being greatly developed. Thus, by heating PBr_3 with sodium azide at 170°C in the absence of a solvent, Herring[100] obtained polybromophosphazene:

$$PBr_3 + NaN_3 \xrightarrow{-NaBr} Br_2PN_3 \xrightarrow{-N_2} 1/n\,[-PNBr_2-]_n,$$

which forms an elastomer when heated to 200°C.

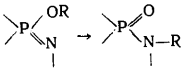
2. Polyorganophosphazenes

The chemical inertness of the P–C, P–O–C, and other bonds and above all their hydrolytic stability suggests that thermostable and chemically stable polyorganophosphazenes with these bonds in the side-chain can be obtained.

Two synthetic paths for such high-molecular-weight polymers are possible in principle: polymerisation of cyclic organophosphazenes and the replacement of the halogens in the polyhalogenophosphazenes by corresponding groups.

Polymerisation of cyclo-organophosphazenes. Most of the investigations in this field relate to attempts to polymerise alkyl, aryl, alkoxy, and aryloxy-cyclophosphazenes. Lipkin tried to convert the most accessible and easily obtainable in high yields of the alkoxy- and aryloxy-cyclophosphazenes into linear polymers[101]. By heating the products of the condensation of cyclochlorophosphazenes with phenoxides, alkoxides, and their thio-analogues, Lipkin obtained water-resistant polymers insoluble in organic solvents. Braun[102] repeated Lipkin's experiments but was unable to isolate pure products. When the aryloxyphosphazenes he had obtained were heated above 320°C their viscosity increased, they lost their solubility, but their composition did not change. Braun suggested that here polymerisation of cycloaryloxyphosphazenes took place with the formation of linear polymers.

Study of the thermal polymerisation of alkyloxy- and aryloxy-cyclophosphazenes in air and in nitrogen at 150–350°C showed that under these conditions low-molecular-weight polymers are formed[103]. Many authors[3] have noted the resinification and formation of polymeric products when alkoxycyclophosphazenes are heated in a vacuum, but it was found later[104] that the formation of polymers on heating alkoxycyclophosphazenes is due to side-reactions connected with the insufficient purity of the monomers. Shaw and coworkers[105-107] showed that at 200°C and above cyclic alkoxyphosphazenes undergo the phosphazene–phosphazane rearrangement:



but here there is no polymerisation as a result of the opening of the phosphazene ring, as occurs with halogenocyclophosphazenes. This is also characteristic for cyclophosphazenes with alkyl and aryl substituents at the phosphorus atom.

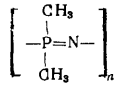
One of the first attempts at the polymerisation of the aryl-cyclophosphazenes was made by Bode and coworkers[108,109]: heating $(C_6H_5)_4P_3N_3Cl_2$, $(C_6H_5)_2P_3N_3Cl_4$ and $(C_6H_5)_6P_4N_4$ at 250–300°C for several hours leads, in their opinion, to the formation of polymers, but these polymers do not exhibit rubber-like properties. However, detailed investigation of the thermal polymerisation of $(C_6H_5)_6P_4N_4$ in the temperature range from 320° to 500°C showed[110] that there is hardly any polymerisation but a mixture of lower cyclic phenylphosphazenes is formed. The cyclic $(CH_3)_6P_3N_3$ and $(CH_3)_8P_4N_4$,[111] and $(C_2H_5)_6P_3N_3$ and $(C_2H_5)_8P_4N_4$[112] also do not polymerise on heating but start to decompose at 350–400°C. Similar results are also obtained in the polymerisation of the isopropyl- and phenyl-phosphazenes in air and in nitrogen[113].

Only two instances are at present known of the formation of high polymers from substituted cyclophosphazenes: at 150°C the trimeric and tetrameric isothiocyanate cyclophosphazenes form rubbery polymers[114-116]; tris-(*o*-phenylenedioxy)cyclotriphosphazatriene and tris-(2,2-dioxybiphenyl)cyclotriphosphazatriene also polymerise on heating[117,119].

Gimblett[53] thinks that the ability of thioisocyanatocyclophosphazenes to polymerise is due to the possibility of the ionisation of the P–NCS bond. However, as was correctly noted by Shaw and coworkers[120], both polymerisation as a result of the breaking of the phosphazene rings and also polymerisation with participation of thioisocyanato-groups

are possible here and it is still not yet known which of these two processes actually takes place. The same can also be said in respect of tris-(*o*-phenylenedioxy)- and tris-(2,2-dioxybiphenyl)-cyclotriphosphazotrienes: in addition to the polymerisation of the phosphazene rings[119] opening of the five-membered heterocycles is also possible and this can lead to the formation of polymers constructed from compounds with oxyaromatic units of substituted phosphazene structures.

Hence the direct thermal polymerisation of organocyclophosphazenes cannot yet be used for obtaining the corresponding homopolyphosphazenes. The catalytic polymerisation of these compounds shows greater promise. Rice and coworkers[121] heated a mixture of $(CH_3)_2P(NH_2)_2Cl$ and NH_4Cl and obtained the polymer



with a molecular weight of ~ 12 000, together with the corresponding trimer and tetramer. They suggest that the polymer is formed by the proton-catalysed polymerisation of cyclic phosphazenes. Polydimethylphosphazene is a crystalline polymer stable on heating to 300°C.[121]

It can be assumed that in the future the ionic polymerisation of many organocyclophosphazenes will be effected.

Synthesis of polyorganophosphazenes from polyhalogenophosphazenes. The reactivity of the halogens in the polyhalogenophosphazenes allows them to be readily replaced by various radicals.

The first attempt in this direction was made in 1948 when, by the action of alcohols in the presence of pyridine on polychlorophosphazenes with a polymerisation coefficient of 200, Goldschmidt and Dishon[122] obtained the corresponding polyalkoxy-derivatives, however, not all the chlorine was replaced, the proportion of alkoxy-groups was low and could not be increased by replacing the alcohol–pyridine mixture by alkoxides. Becke-Goering and Koch[85] obtained the corresponding polymethoxyphosphazene by the action of sodium methoxide on a linear chlorophosphazene oligomer with a polymerisation coefficient of 11. High-molecular-weight organo-oxyphosphazenes have been obtained by the action on polychlorophosphazenes of a mixture of alcohols and pyridine[123-126], alkoxides of alcohols and phenoxides[127-130], glycols or alkoxides of glycols[131,132].

The alcoholysis of polydichlorophosphazene favours its dissolution[125] or swelling[127] in an inert solvent. Under these conditions 93–95% of the chlorine atoms could be replaced by alkoxy-groups and polyalkoxyphosphazenes stable to hydrolysis obtained. The action of solutions of alkoxides or phenoxides in alcohol and also of amines[133] on polychlorophosphazene in benzene[129] gave the corresponding polyalkoxy-, aryloxy-, and amino-phosphazenes with high molecular weights. It was found that the process is not accompanied by appreciable destruction of the main chain of the initial polychlorophosphazene (see Table 3). X-Ray structural investigation of oriented linear alkoxy- or aryloxy-phosphazenes showed the identity period of their chains to be 4.8–4.92 Å, on the basis of which they were assigned a planar zig-zag structure[129]. With the aim of obtaining polymers which were more inert chemically, fluorinated[125-127,130,134] or chlorinated[124,128] alcohols were used for the alcoholysis of the polychlorophosphazenes, and polyalkoxyphosphazenes can be obtained by polyreesterification of the lower alkoxy-derivatives[125]. All the alkoxy-, aryloxy, and aminophosphazene polymers prepared exhibit comparatively low thermal stability—at 150–200°C and above they rapidly undergo destruction with the formation of low-molecular-weight linear and cyclic oligomers[129].

The greater ability of the high-molecular-weight organophosphazenes to undergo depolymerisation in comparison with the polychlorophosphazenes was related by Allcock[119,135] to the structure of the chain and the increase in the intramolecular interaction on replacing chlorine by larger organic radicals, which makes the cyclic compounds more stable thermodynamically. However, it is possible that the high flexibility and polarity of the bonds of the polyphosphazene chains[27] can also facilitate the destruction of the macromolecule and the formation of cyclophosphazenes, owing to the intramolecular redistribution of bonds, analogous to that observed in polyorganosiloxanes[64].

Polydimethylphosphazene could also be obtained by the action of CH_3MgBr or CH_3Li on polychlorophosphazene[136].

Table 3.

Elementary unit of the polymer	Mol. wt. $\times 10^{-3}$	T_c, °C	Solvent
$PN(OC_2H_5)_2$	2 000	—84	ethanol
$PN(OCH_2CF_3)_2$	1 700	—66	ketones
$PN(OC_6H_5)_2$	3 700	—8	benzene
$PN(OCH_3)_2$	640	—76	methanol
$PN(NHC_6H_5)_2$	1 650	91	benzene
$PN[N(CH_3)_2]_2$	363	—4	aqueous solution of acid
$PN(NC_5H_{10})_2$	697	19	benzene

Other methods of making polyorganophosphazenes. Methods of obtaining polyorganophosphazenes are known which are based on the use of alkali metal azides. This method was first proposed for obtaining chlorophenyl[100] and perfluoromethyl[137] polyphosphazenes and then extended also to phenyl polyphosphazenes[138,139]:

$$R_2PX + MN_3 \rightarrow [R_2PN_3] \rightarrow 1/n\,[-R_2P=N-]_n + N_2.$$

When R = CF_3 only a polymeric, solid, waxy product with a softening point of 95°C and good resistance to strong acids and oxidants is formed[137]. When R = CH_3 lower cyclic homologues are mainly formed.

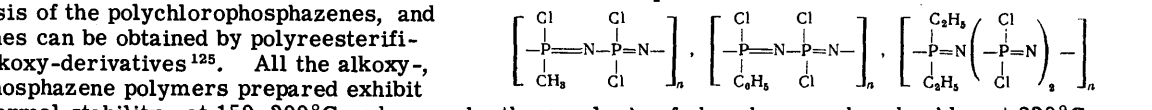
Linear oligomeric fluorine-containing organophosphazenes with yields of up to 40% (remainder: cyclic phosphazenes) are formed by the following reaction[140]:

$$R_2PNH_2 + Cl_2 \rightarrow R_2PCl_2(NH_2) \xrightarrow{R'_3N} 1/n\,[-R_2P=N-]_n + R'_3N \cdot HCl.$$

The polyfluoromethylphosphazene obtained by this method is similar to those made by the azide method[137]. By heating hydrazinophosphines at 200°C mixed polyarylaminoalkylphosphazenes of the formula:

were obtained[141].

Yakubovich and coworkers[142] obtained insoluble polymers of the composition



by the pyrolysis of phosphazene phosphoxides at 220°C.

IV. HETEROPOLYPHOSPHAZENES

In this class of polyphosphazenes we put the polymers which contain a main chain of phosphazene groups or structures linked by various organic, organoelemental, or inorganic radicals and groups of atoms:

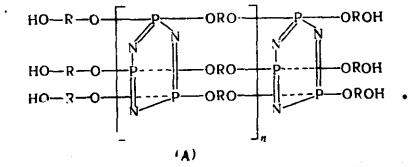
where E is alkylene, arylene, oxyalkyleneoxy, or oxyaryleneoxy radicals, residues of amines, diamines, the –NH– and O–B– groups, etc.

1. Polymers with  Bonds in the Main Chain

This type of heteropolyphosphazenes obtained on the basis of cyclic and linear halogenophosphazenes and polyoxy-compounds is one of the most promising polymers in practical respects, similar in structure to phenolic resins but differing from them by higher thermal stability and fire resistance.

Three methods for obtaining such polymers are now known[143]: the reaction of chlorophosphazenes with dihydricphenols[144-147], with phenoxides of diphenols[148,149] and the polyre-esterification of alkoxyphosphazenes with polyhydric phenols[150-152].

Although the reaction of chlorophosphazenes with alcohols and phenols has long been known[3], the preparation of polymers based on chlorophosphazenes and polyhydric phenols was first patented by Redfarn in 1957[144]. This method involved heating (at 170–190°C) a mixture of crystalline chlorophosphazenes, predominantly the trimer and tetramer, with resorcinol, hydroquinone, 2,2-di-(4-hydroxyphenyl)propane and other aromatic polyhydroxy-compounds, amounting to 75–100% of the weight of the chlorophosphazenes. The process was accompanied by the release of HCl and the formation of a resin capable of solidifying when heated with paraform or hexamethylenetetramine. However, the resins thus formed have low solubility owing to the high functionality of the original chlorophosphazenes; furthermore, the high temperature of the process facilitates the partial destruction of the phosphazene rings in these resins by the action of the HCl liberated. These drawbacks could be avoided by carrying out the polycondensation of the initial substances in organic solvents at temperatures below 130°C in the presence of acceptors of HCl—tertiary amines[145-146]. The use of an excess of dihydricphenols and their restricted solubility in the reaction mixture leads to gradual successive replacement of the chlorine atoms in the cyclochlorophosphazenes and the formation of resins predominantly containing structure of the type (for HCP):



(A)

However, these resins nevertheless contain up to 10% residual chlorine and are often sparingly soluble. The molecular weight of the soluble resins varies within the range 10 000–15 000; they are freed from traces of tertiary amines by precipitation with aqueous solutions of acids[153] and harden when heated with substances which are donors of formaldehyde[154] or in the presence of organosilicon or organotin hardeners[155].

An investigation of the reaction of HCP with dihydricphenols[143,147,156-158], made with the aim of finding the optimal conditions for the formation of polymers based on them showed that when pure the initial substances hardly react below 180°C whether in the melt or in organic solvents. Appreciable reaction starts above 190°C and its rate depends significantly on the polarity of the medium which also affects the composition and structure of the reaction products when the reaction is carried out in the presence of tertiary amines[143,156-158].

The order and rate constants of the reaction of equimolecular amounts of HCP and dihydricphenols were determined and it was assumed that both without catalysts and in the presence of tertiary amines the reaction is unimolecular with heterolysis of the P–Cl bond[157]. This assumption agrees well with the formation of pyridine complexes of HCP and $SnCl_4$ [56] and of phosphazenepyridinium salts[55].

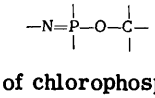
Bispentachlorocyclotriphosphazetrienes—the simplest homologues of the polyphosphazenes being considered—were isolated from the products of the reaction of equimolecular amounts of HCP and dihydricphenols by liquid absorption chromatography and characterised[159]. Their study allowed some conclusions to be drawn concerning their mode of formation[157,158].

To obtain only soluble resins, equimolecular amounts of cyclochlorophosphazenes and dihydricphenols were made to react and then the chlorine atoms left in the oligomers were replaced by various groups of atoms and radicals[160,161].

For the same purpose the functionality of the initial substances can be reduced by using monohydric phenols instead of the dihydricphenols[162] or by replacing some of the chlorine atoms in the original cyclochlorophosphazenes by inert phenyl[163-165] or phenoxy[166,167] radicals. Thus linear polymers with a softening point of 110–120°C and molecular weight of ~ 12 000 are obtained by heating dichlorohexaphenylcyclotetraphosphazotetraene and resorcinol in a vacuum at 310°C; when hydroquinone is used under the same conditions the molecular weight of the polymer is 5000.[163] Polymers of higher molecular weight were obtained from the same cyclophosphazene and 4,4-dihydroxydiphenyl oxide; the molecular weight of the polymer before purification was 42 000 when the reaction was effected in a melt and 115 000 when in a solvent; the molecular weights of the other fractions exceeded 250 000–500 000.[164]

Yokoyama and coworkers[168] repeated Redfarn's experiments[144] and also obtained resins insoluble in most solvents. The use of 2,6-bishydroxymethyl-*p*-cresol[169,170] leads to the formation of polymers similar to those described above. It was found that up to 200°C only the hydroxymethyl groups react with cyclochlorophosphazenes[169] but above 200°C the phenolic OH groups also start to react; homocondensation of the hydroxymethyl groups does not occur[170].

The release of HCl and the presence in the resinous products of some residual chlorine are the principal drawbacks of the method of making the heteropolyphosphazenes with



bonds by the reaction of chlorophosphazenes with polyhydroxycompounds. These drawbacks can be circumvented by the use instead of chlorophosphazenes of their alkoxy-derivatives[150-152]. The kinetics of the polyre-esterification of hexabutoxycyclotriphosphazotriene with diphenols was investigated and it was shown that the polymers thus formed are analogous to those synthesised from cyclochlorophosphazenes[152].

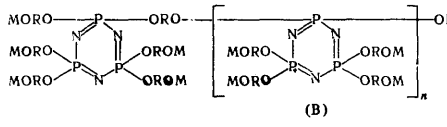
Instead of the completely substituted alkoxycyclophosphazenes, phosphazene compounds of the general formula

$$[PN(OR)_m(OH)_{2-m}]_n,$$

where $m \leqslant 2$, n is an integer $\geqslant 3$, and R = CH_3, C_2H_5, or C_4H_9, which are made by the alcoholysis of cyclochlorophosphazenes with lower alcohols, also react with diphenols. When these phosphazenes condense with dihydroxy-compounds water-soluble polymers are formed[171] which contain OH groups connected with phosphorus atoms. Such polymers can also be obtained by the hydrolysis of resins with cyclic phosphazene structures which contain residual P–Cl bonds[172,173].

An extremely promising method for obtaining polyphosphazene polymers with

bonds is by the reaction of chlorophosphazenes with phenoxides of polyhydric phenols[148,149], which are distinguished by a high rate even at comparatively low temperatures. Thus the reaction of HCP with the diphenoxide of 2,2-di-(4-hydroxyphenyl)propane dispersed in dioxan or ethyl methyl ketone ends after 2–4 h and leads to the formation of soluble and insoluble resins of type A (p. 67). When HCP reacts with an excess of diphenoxide in a medium which is a solvent for both the initial components (in alcohols) then polymers of type (B) are formed[149] (M = Na or K):

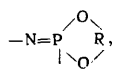


(B)

After the replacement of the phenoxide groups in these products by OH groups resins analogous to those of the phenol formaldehyde type are formed. The reaction of cyclochlorophosphazenes with diphenoxides is accelerated in the presence of pyridine or NaI.[174]

The resins of type (B) and also of type (A) readily harden when heated substances which are donors of formaldehyde; they are also convenient materials for modification or for preparing other polymers based upon them. Thus resin of type (A)[146] is used for the modification of butadiene–acrylonitrile copolymer[175] and resin (B) with phenoxide groups is readily epoxidised with epihalogenohydrins and forms epoxide phosphazene resins[176]. The latter were also obtained by the epoxidation of hexahydroxyarylene-hydroxycyclophosphazotrienes[177,178] (which are synthesised from the monophenoxides of dihydric phenols and HCP[179]) or on using the glycidyl ester of HCP;[180] nevertheless the attempt to obtain such esters by the epoxidation of allylhydroxyphosphazenes with peracetic acid was unsuccessful[181].

In the reaction of cyclochlorophosphazenes with dihydroxy-compounds (especially with glycols), in addition to the polymeric products, substances with a spirane structure are formed with a phosphorus atom in the alcoholic groups:



and partial dehydration of the glycols also takes place[182]. Thus in the reaction of *o*-diphenols (particularly pyrocatechol) with HCP or OCP in tetrahydrofuran in the presence of $(C_2H_5)_3N$[183] or in pyridine[184] a certain proportion of tris- or tetrakis-(*o*-phenylenedioxy)cyclophosphazenes is formed. It is interesting that these substances are capable of forming inclusion compounds with the molecules of various substances[185].

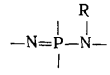
Other cyclic esters were synthesised from HCP and OCP with diphenols such as 2,2-dihydroxybiphenyl, toluene-2,3-dithiol, and 2,3-dihydroxynaphthalene[117].

The ability to form rings is much greater in the reaction of cyclochlorophosphazenes with glycols and other polyfunctional aliphatic compounds[186,187]. An increase in the [chain length of the] aliphatic radical between the OH-groups of glycol decreases the probability of the formation of spirane structures. This is especially noticeable in polyalkylene glycols[188–191]; when these are used polymeric products which can be employed in the production of polyurethane foams are formed[189–191]. This same effect is obtained when part of the chlorine in the initial cyclochlorophosphazenes is replaced by phenoxy-groups[192] or by perfluoroalkylphenol residues[193]. When glycols or amino-alcohols are used ring closure can proceed at different phosphorus atoms of the cyclophosphazene[194].

Phosphazene polymers based on aromatic polyhydroxy-compounds exhibit high thermal stability and fire resistance: they withstand long heating in air at 300°C[195] and can be heated to 500° for a short time[171]; in several instances destruction begins with breakdown of the phosphazene cyclic structures[164]; these polymers are also stable to attack by various chemical agents[145].

2. Heteropolyphosphazenes with –N=P(–)–N Bonds in the Main Chain

Polymers with



bonds in the main chain of the macromolecules (R = H or an organic radical) are obtained from chlorophosphazenes and ammonia or organic amines. The simplest representative of this class of polyphosphazenes—phospham—was first obtained by passing ammonia over molten HCP or by heating HCP with NH_4Cl.[196]

In investigating the ammonolysis of chlorophosphazenes Moureu and Rocquet[197] showed that on heating the prepared aminophosphazenes the irreversible loss of ammonia takes place and a polymeric product is formed—phospham:

$$[PNCl_2]_n + 4n\,NH_3 \xrightarrow[-2n\,NH_4Cl]{} [PN(NH_2)_2]_n \xrightarrow[2n\,NH_3]{} [PNNH]_n.$$

Phospham is an infusible powder which in the early stages of its formation can be dissolved in water; it is thermally stable up to 550–600°C and is converted into $(PN)_x$ on heating above 800°C. To accelerate the formation of phospham pyrolysis of aminophosphazenes is effected in the presence of NH_4Cl with passage of dry HCl.[198]

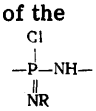
Audrieth and Sowerby[199,200] studied the formation of phospham from cycloaminophosphazenes by a thermogravimetric method. They found that the phosphams which are formed cannot be characterised by starting from the size of the phosphazene ring from which they were obtained. X-Ray structural investigations showed that the phosphams are amorphous substances and Steger[201] was unable to determine by infrared spectroscopy whether the size of the phosphazene rings was unchanged. He concluded that the phosphams are constructed from a disordered array of phosphazo-groups connected by –N= and –NH–structural elements.

The more detailed investigations of Miller and Shaw[202] showed that the formation of phospham in the pyrolysis of pure $P_3N_3(NH_2)_6$ and $P_4N_4(NH_2)_8$ in an atmosphere of nitrogen occurs at ~ 300°C; this was shown by the loss in weight and the composition of the residue. The loss in weight was measured during the heating of phospham to 1000°C; however, the formation of phosphorus nitrides $(P_3N_5)_y$ and $(PN)_x$ was not observed, a difference from previous reports[203]. Often the material of the crucible in which the pyrolysis of the aminophosphazenes was carried out reacted with the reaction mixture[204]. The retention of the phosphazene ring in the formation of phospham from aminocyclophosphazenes is proved by the fact that the phospham obtained from $P_3N_3(NH_2)_6$ has a lower density than the product made from $P_4N_4(NH_2)_8$.[202]. The preparation of a foam based on phospham has also been described[205].

Deammonolysis has been used to obtain organo-substituted phosphams; thus polymers stable above 300°C were obtained by the pyrolysis of compounds of the general formula $P_3N_3R_x(NH_2)_{6-x}$, where R is an organic radical which can be fluorinated and $x \geqslant 3$.[206,207] Polymers with greater thermal stability were obtained by heating phenylaminocyclophosphazenes[208-210] above 300°C with a residual pressure of 10^{-3}–10^{-4} mmHg.

Organo-substituted phosphams were also synthesised by the reaction of chlorophosphazenes with amines. Aniline and HCP or OCP were used most frequently for this; in pyrolysis of the anilidocyclophosphazenes formed by the reaction of these substances aniline is released and phenylphosphams are formed[211]. The latter can again be converted into the original cyclic structures by heating with aniline which is impossible with unsubstituted phospham[202]. Phenylphospham is also formed on heating anilidochlorophosphazenes, obtainable in the non-polar replacement of chlorine in the initial chlorophosphazenes by aniline residues[212]. The formation of polymers from chlorophosphazenes and butylamine has also been reported[213].

Thermostable and fire-resistant polymers are obtained by the reaction of a mixture of crystalline chlorophosphazenes and acetaldehyde[102,214,215]. The process is accompanied by the liberation of HCl and CH_3COCl and, as has been shown[102], proceeds through the formation of cyclic products $(PNNC_6H_5)_n$ with their subsequent thermal polymerisation into a linear polymer. Similar polymers are formed in the reaction of chlorophosphazenes with diphenylurea and other amides[102]. It should be noted that an attempt to prepare the same polymers by ammonolysis of trichlorophosphazo-compounds $RN{=}PCl_3$ was unsuccessful[216]; instead polymers of the



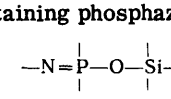
type were obtained; these decompose above 200°C with the formation of anilinium chloride.

The preparation of phosphazene polymers based on chlorophosphazenes and organic diamines has been described[164,217,218]. For this it is usual to employ a mixture of crystalline chlorophosphazenes in which some of the chlorine atoms can be replaced by inert organic radicals. But here the formation of cyclic spirane structures is also possible especially if the initial diamine contains an alkylene radical with 2–4 carbon atoms between the amino-groups[219-220].

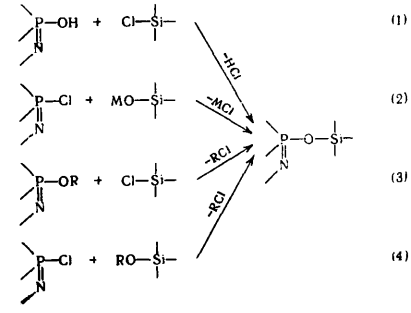
Water-soluble polymers with  bonds in the main chain are evidently also formed when linear chlorophosphazenes are treated with methanol and ammonia simultaneously[221,222].

3. Polyelementophosphazenes

In recent years there have been reports of the synthesis of heteropolyphosphazenes containing silicon, boron, germanium, and other elements. Many of the investigations relate to silicon-containing phosphazenes with



bonds in the main chain. There are four methods for making such polymers:



where M is an alkali metal or hydrogen, R = alkyl, and X is halogen.

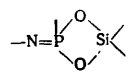
The first syntheses of silicon-containing polyphosphazenes by reaction (1) were effected in 1958–59. Dumont[223-225], who used the reaction of triphenyldihydroxychlorocyclotriphosphazotriene with diorganodichlorosilanes. The high thermal and hydrolytic stability of the polymers obtained was noted. Instead of the dihydroxyphosphazene derivative the tri-functional monomer $P_3N_3(OC_6H_5)_3(OH)_3$ can also be used[226]; this leads to the production of three-dimensional polymers or those capable of hardening.

To obtain siloxyphosphazene polymers of similar type by reaction (2), diphenylsilanediol and linear or cyclic chlorophosphazenes were used[227-229]. With the more reactive linear chlorophosphazenes the reaction takes place under milder conditions and leads to the formation of thermostable polymers[227], which can be used for preparing asbestosplastics[228]. However, in every instance the condensation of diphenylsilanediol with chlorophosphazenes is accompanied by side-reactions of homocondensation of dihydroxysilane and hydrolysis of chlorophosphazenes or of the semiproducts with water liberated in the condensation of dihydroxysilane. Therefore the polymers obtainable by reaction (2) contain a P–OH bond and also considerable amounts of water-soluble polymetaphosphimic acids[229]. The fraction of such side-reactions does not decrease on using acceptors (for example, quinoline). This is evidently due to the fact that the chlorophosphazene–tertiary amine systems are strong dehydrating agents[8].

It was therefore desirable to replace diphenylsilanediol by its siloxane, which is incapable of homocondensation, and thus exclude the appearance of water in the reaction mixture. However, it was shown[230] for monosiloxides and monosilanols that their reaction with hexachlorocyclotriphosphazotriene proceeds by scheme (2) but is considerably more complex and leads to the opening of the phosphazene ring and the formation of a mixture of low-molecular weight products, including disiloxanes. It was suggested that under certain conditions the polysiloxanes can react with the chlorophosphazenes with breaking of the Si–O–Si bond[230]. Thus, by heating hexaethyldisiloxane and HCP at 240°C in an ampoule for 6 h an oligomeric liquid and a solid insoluble polymer containing silicon and phosphorus were obtained[231].

A method for obtaining organosiloxyphosphazene polymers which is new in principle consists in the interaction of cyclic or linear alkoxyphosphazenes with organohalogenosilanes[232]. Its advantages are the high rate of reaction under comparatively mild conditions for carrying it out and the absence of side-reactions.

An investigation of the kinetics of this reaction in the case of hexabutoxycyclotriphosphazotriene and triorganohalogenosilanes[233] suggested that the process proceeds with heterolysis of the silicon–halogen bond and attack by the silicone cation at the oxygen atom of the alkoxyphosphazene. Under our conditions the formation of the organosiloxyphosphazene polymers on the basis of diphenyldichlorosilane and phenyltrichlorosilane[226] a marked decrease in the molecular weight of the polymeric products was noted owing to the partial formation of cyclic spirane structures of the type[226,234]:

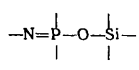


[226, 234].

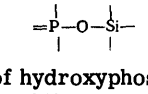
The formation of the latter can be prevented by starting from triphenoxytrialkoxycyclotriphosphazotrienes in which the phenoxy-groups do not react with chlorosilanes: it was then possible to obtain polymers which are three-dimensional or capable of subsequent hardening. Siloxyphosphazene polymers are also obtained by the reaction of cyclochlorophosphazenes with organoethoxysilanes[235].

It was found by differential thermal analysis and isothermal heating that the organosiloxyphosphazene polymers obtainable by reaction (3) start to decompose appreciably at 200°C as a result of the splitting off of the residual alkoxy-groups, whereas the thermal destruction of the main chain begins above 300°C.

Dumont's report[223,224] of the high hydrolytic stability of the phosphazene polymers with



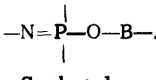
bonds was subsequently not confirmed. An investigation of the hydrolytic stability of the oligomeric and hardened organosiloxyphosphazene polymers showed that they are rather readily decomposed by water at the



bonds with formation of hydroxyphosphazenes and hydroxysilanes or the products of their homocondensation[226,234].

Silicon-containing phosphazene polymers of greater stability to hydrolysis can be obtained by the reaction of alkoxyphosphazenes with halogenoalkylsilanes[236].

Boron-containing phosphazene polymers of various types[237–239] and in particular with



bonds are interesting. Such polymers are obtained by the reaction of boric and organoboric acids with HCP and its alkoxy-derivatives[237] or by the condensation of boric acid (and other inorganic acids) with cyclic acids of alkoxyphosphazenes of the general formula

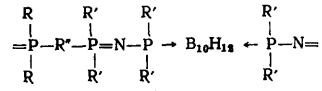
$$[PN(OR)_x(OH)_{2-x}]_n,$$

where $n = 3$ or 4 and $x \leqslant 2$.[238] On using the normal[237] and acid[238] alkoxyphosphazenes the proton-catalysed semiire-esterification of them by the boric and organoboric acids takes place accompanied by the loss of the corresponding alcohol.

In the direct reaction of HCP and boric acids the reaction takes place only in the presence of tertiary amines and leads to the formation in 50–70% yield of an infusible and insoluble polymeric product which is distinguished, according to differential thermal analysis, by high thermal stability (the loss in weight at 600°C is less than 20%) but by ready hydrolysis with boiling water.

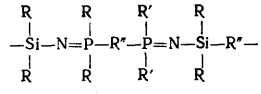
Hydrolytically stable boron-containing phosphazene polymers with a high softening point are obtained by the reaction of bis(azidodiarylphosphino)decaborane with such diphosphines as bis(diphenylphosphino)ethane, 1,4-bis(diphenylphosphino)benzene, etc.[239]

A process which can be effected by heating the initial substances in inert solvents and is accompanied by the liberation of nitrogen leads to the formation of polymers constructed from alternating units of the type



(where R and R′ are aryl and R″ is alkylene or arylene). Organoelemental polymers of the same type are synthesised by the reaction of the sodium derivative of decaborane with $P_3N_3Br_6$.[240]

The basis of a method for making an extensive class of heterochain element-containing phosphazene polymers is the reaction of phosphines with organoelemental azides[241]. In the reaction of the corresponding diphosphites and organoelemental diazides liquid phosphazene polymers of the type



are obtained, where R and R′ are alkyl or aryl and R″ is alkylene or arylene. These polymers are of interest as hydraulic liquids and lubricants or modifying additives for these materials[242–244].

4. Other Heteropolyphosphazenes

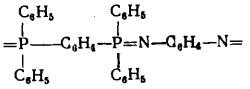
Many polyphosphazenes are known the macromolecules of which contain bonds different from those considered above. Thus resins analogous to the melaminoaldehydes are synthesised by the reaction of aminocyclophosphazenes and aldehydes at 60–80°C and pH 7–11.[245] Phosphazene-containing ureas and polyureas obtained by the reaction of aminocyclophosphazenes and aldehydes at 60°–80° and pH 7–11.[245] Phosphazene-containing ureas and polyureas are obtained by the reaction of $P_3N_3Cl_4(NH_2)_2$ with polyisocyanates[246]; however, this process is much more complex than the simple interaction of H_2N groups with isocyanato-groups[247]. $P_3N_3[N(CH_3)_2]_4(NH_2)_2$ is more reactive with isocyanates; this compound readily forms a urea derivative but in reaction with 2,4-toluene di-isocyanate in any ratio only two molecules of diaminocyclophosphazene are added to one molecule of di-isocyanate and products of higher molecular weight are not formed[247]. Urea derivatives can also be obtained from isocyanatocyclophosphazenes and amines[248]; when glycols are used phosphazene-containing polyurethanes are obtained[249].

Polyphosphazene products are also made by the reaction of HCP with guanidine urea, guanylurea, and other amides[250]. Phosphazene analogues of polycarbonates, formed in the phosgenation of hydroxycyclophosphazenes have been described[251] although the phosgenation products may have a more complex structure, since the reaction of

chlorocyclophosphazenes with organic acids and their salts leads to the breaking of the phosphazene rings[68].

Phosphazene polymers with P–O–P bonds in the main chain are obtained by heating a mixture of $P_3N_3R_4Cl_2$ and $P_3N_3R_4(OC_2H_5)_2$ (R = C_6H_5 or OC_6H_5); the process is accompanied by the release of ethyl chloride and the formation of thermostable products[252-254]. Polyphosphazenes with such bonds are formed in the heat treatment of alkoxyphosphazenes at 150–350°C [255] and also in the condensation of chlorocyclophosphazenes with alkyl phosphates, which is accompanied by the release of an alkyl halide and the formation of polymers stable to 500°C.[256]

A polymer with the structural units



and which softens at 150–200°C is obtained by the reaction of 1,4-bis(diphenylphosphino)benzene and 1,4-diazobenzene[257].

V. POLYMERS WITH PHOSPHAZENE GROUPS IN THE SIDE-CHAIN

Dishon[258] was the first to report the polymerisation of the allyl ester of cyclotriphosphazene into a viscous oil. Later[259] emulsions were obtained from unsaturated ethers of cyclophosphazenes. Infusible and insoluble polymers are formed in the polymerisation of dimethylamino- and phenylallyloxycyclotriphosphazatrienes in the presence of benzoyl peroxide[260]. In several studies it was found that triallyloxy-derivatives of phosphazenes are not polymerised at room temperature for 2 years and the ability to be sublimed in a vacuum up to 160°C is retained[261]. The polymerisation of butoxy- and phenoxy-allyloxycyclophosphazenes and also their copolymerisation with methyl methacrylate were investigated. The copolymers obtained did not exhibit high thermal stability[181]. Allyloxycyclophosphazenes and styrene were copolymerised at 70°C in the presence of benzoyl peroxide and the dinitrile of azoisobutyric acid. The determination of the copolymerisation constants allowed a conclusion to be drawn about the high activity of styrene; however, allyloxycyclophosphazene is more active than other allyl compounds[262]. Thermoplastic polymers and copolymers were obtained based on allylaminocyclophosphazenes. These polymers form stable films with good adhesion and, according to the thermogravimetric analysis, their loss in weight in air at 1000°C is 65%.[263,264]

VI. USES OF POLYPHOSPHAZENES

In contemporary literature, particularly patents and advertisements, there are two main trends in the practical use of phosphazene polymers: the use of homo- and hetero-polyphosphazenes as a basis for the preparation of stuffing plates [box? (Ed. of Translation)] coated with elastomers, etc., and the use of polyphosphazenes for modifying organic polymers and other materials to improve their thermal stability and fire resistance[265].

Use of polyphosphazenes as thermally stable and fire resistant materials. Comparatively long ago an attempt was made to use the thermal stability and fire resistance of polychlorophosphazene, by increasing its hydrolytic stability by replacing chlorine atoms by other atoms and groups. One of the variants of this exchange is based on the observed capability of polydichlorophosphazenes, during their formation in the thermal polymerisation of cyclochlorophosphazenes, to be bonded chemically with various silicate materials[266,267]. On this basis elastic electrical insulating coatings[268,269] and semiceramic products stable up to 500–600°C were prepared[270].

However, organophosphazene polymers are used most frequently for this purpose. The first attempts in this direction were made by Lipkin[101]. The products of the condensation of cyclochlorophosphazenes with polyhydroxyaromatic compounds have the greatest practical value[144-146,254]. Thus the polyhydroxyaryloxyphosphazenes obtainable by the method described in a patent[144] are recommended for use as adhesives, impregnating compositions, and prepared press articles. The same polymers which can be made in the presence of tertiary amines[146] are used as coatings on glass, ceramics, and metals; these coatings are distinguished by high shock resistance, resistance to solvents, acids, and alkalis. On hardening these polymers by heating at 244°C with 10% hexamethylenetetramine and a pressure of 176 kgf cm^{-2}; pressings are obtained with a tensile strength of 422, a bending strength of 703, and a compressive strength of 3160 kgf cm^{-2}.[145] Asbestoplastics from polyhydroxyaryleneoxyphosphazenes obtainable by a patented method[171] have a bending strength of 1600–1700 kgf cm^{-2} but after treatment at 500°C for 50 h it fell to no more than a half of this[271]. The same phosphazene binding agent is also used in making abrasive materials[272]. The products of the condensation of cyclochlorophosphazenes with polyhydroxyaromatic compounds, which are analogous in structure to phenolic resins but surpass them in thermal stability and also the products of the deammonolysis of phenyl(phenoxy)aminocyclophosphazenes[205-207] are undoubtedly some of the most promising phosphazene polymers in a practical respect.

Use of polyphosphazenes as modifiers of organic plastics. Additions of polyphosphazenes to organic polymers (phenolic, polyester, epoxy, and other resins) are made for the increasing the fire resistance and thermal stability of the latter. Polychlorophosphazenes[273-275] and the products of their amination or alcoholysis[276] are used for this purpose; for modification, polyphosphazenes with –OH, NH–, and other functional groups are more convenient to use. Thus, aminophosphazenes react readily with epoxy resins, forming modified products[277]. Fire-resistant polyurethane foams are obtained by using for the OH-containing component the products of the condensation of chlorocyclophosphazenes with glycols[188-191] and also by the introduction of polyphosphazenes with NHR groups into the mixture of components used for making polyurethanes[278].

Aziridinyl derivatives of polyphosphazenes are used as modifying hardeners for polyester compositions[279] and the products of the condensation of chlorocyclophosphanes and diphenols are modified with butadieneacrylonitrile copolymers[175]. Studies of the use of chlorophosphazene oligomers as catalysts for the polymerisation of organocyclosiloxanes have been described[280,281]. Copolymers of polychlorophosphazene with styrene and acrylonitrile have been obtained[282].

Alkoxypolyphosphazenes have been proposed for use as plasticisers for lacquers and cellulose films[122-123]. Polyphosphazenes of various types are widely used for conferring fire resistance on cellulose and other polymeric materials. Studies have been published[283-287] on the conferment of fire resistance on viscose silk, cotton, cotton fabrics, and on the improvement of the water and oil-resistance

of textile articles[288]. Hydroxymethylphosphazenes[285], water-soluble phosphams[289,290], condensation products of chlorophosphazenes with urea and chloroaniline[286], and the products from treating linear chlorophosphazenes with ammonia and methanol[222] are usually employed for this purpose. Polymethoxyphosphazenes[291] and lattices obtainable by the polymerisation of unsaturated bromo-containing alkoxycyclophosphazenes[259] are also used for improving the fire resistance of textiles.

Ion-exchange resins based on polychlorophosphazene[292], copolymers of unsaturated phosphazene derivatives with vinyl monomers[263,264], compositions based on phosphazene oligomers and polyacrylonitrile[293] and copolymers of acrylonitrile with HCP[294] have been synthesised.

Polychlorophosphazenes are used as activators for the hardening of polysiloxanes[295,296] and catalysts of the polymerisation of tetrahydrofuran[297]. Organo-substituted polyphosphazenes can be used for obtaining films, fibres, coatings, etc.[298]

Undoubtedly, in the near future many more possibilities for using polyphosphazenes of various types will appear; this is facilitated to no small extent by both the high thermal stability and other valuable properties of the polyphosphazenes and also their availability.

New Contribution to the Development of Organoelementary and Organic Chemistry

R.Kh.Freidlina, M.I.Kabachnik, and V.V.Korshak

CONTENTS

I. Introduction 684
II. Organometallic compounds of transition metals 685
1. Metallocene and arene compounds of iron (ferrocene) 685
2. Carbonyls and organometallic derivatives of metal carbonyls 687
3. Heteropolymetallic derivatives of metal carbonyls 688
4. Organometallic compounds of titanium, zirconium, and hafnium 691
III. Organometallic compounds of non-transition metals and problems of conjugation, dual reactivity, and tautomerism 691
IV. Investigations on organic compounds 692
1. Investigations on β-substituted vinyl ketones 692
2. Onium compounds 694

I. INTRODUCTION

Twenty years ago, in a review of the achievements of the chemistry of organoelementary compounds, it was necessary to begin by defining the concept of "organoelementary chemistry", to formulate the region embraced by this science, and to specify its borderline position between organic and inorganic chemistry. Nowadays there is no need of this: organoelementary chemistry has become firmly established as a large and important branch of chemistry, covering a multiplicity of types of compounds, possessing numerous and well developed synthetic methods, specific reactions, and laws of reactivity, and having found diverse and important practical applications—from organoelementary medicinals, the industrial manufacture of which constitutes a typical example of fine organic synthesis, to organoelementary polymeric materials, combustion regulators, agricultural chemicals, and many other products of large-scale, so called heavy organic synthesis.

Organoelementary chemistry occupied a strong position in the development of general and theoretical aspects of chemistry, by providing extremely convenient materials for study by theoreticians and experimentalists. Not only in the USSR, which contains the first Institute of Organoelementary Compounds to be founded in the world, but also in other countries institutes and major laboratories appeared, specialising in the study of organoelementary chemistry, and publication of an international journal on the chemistry of organometallic compounds was started, while more than half the papers in the "Journal of General Chemistry" were devoted to organoelementary compounds.

An outstanding part in this birth and vigorous development of organoelementary chemistry as an independent branch of science was played by A. N. Nesmeyanov, in whose works and those of his many pupils organoelementary and especially organometallic chemistry found its greatest development. Ten years ago we gave in this journal a brief review of Nesmeyanov's scientific activities [1]. While referring readers to this review, in the present paper we shall concentrate our attention on the results of investigations made during recent years.

Nesmeyanov had an unusually broad range of scientific interests. He and his school undertook the leading fundamental researches in several fields of organometallic, organoelementary, and organic chemistry.

In spite of the diversity of subjects investigated by Nesmeyanov, they show a profound inner relationship in the logic with which the questions were posed and with which the investigation was developed. As example we may point to the logical and methodological connection existing between his diazo-method (1929) and his synthesis in 1955 of diarylchloronium salts, which greatly enriched one of the oldest branches of organic chemistry, that of chlorinated organic compounds. Just as at one time the diazo-method, originally proposed for synthesising organomercury compounds, was then developed by him in a comprehensive series of researches, leading to methods for the synthesis of organic compounds of several non-transition elements, so the "onium" synthesis was extended to the preparation of aromatic and heterocyclic diarylchloronium, diarylbromonium, triaryloxonium, sulphoxonium, and completely aromatic ammonium salts.

A profound inner connection exists between such apparently remote lines of research by Nesmeyanov as the investigation of β(and α)-substituted organometallic compounds (quasi-complex compounds), β-chlorovinyl ketones, and the tautomerism and dual reactivity of organic and organometallic compounds.

Using the popular definition of academics as romantics and classicists, we can say that Nesmeyanov is a romantic in the breadth of his interests and in his thirst for new discoveries, and a classicist in the accuracy of the expanded interests, the depth and comprehensiveness with which he works out problems.

During the past ten to fifteen years Nesmeyanov and his students have conducted researches in several completely new fields. Examples are the comprehensive and extraordinarily intensive investigation of organometallic compounds of transition metals, the discovery and investigation of the phenomenon of metallotropy, and the already mentioned investigations of onium and β-chlorovinyl compounds. He initiated and directed researches on synthetic foodstuffs, this work being reviewed in the present issue by V. M. Belikov, R. V. Golovnya, S. V. Rogozhin, G. L. Slonimskii, and B. V. Tolstoguzov.

A brief survey is given below of some new investigations by Nesmeyanov in the chemistry of organometallic compounds of transition and non-transition metals and on general aspects of organic chemistry.

II. ORGANOMETALLIC COMPOUNDS OF TRANSITION METALS

The past two decades have seen a vigorous growth of research on the organic compounds of transition metals. Not so very long—twenty years—ago it was considered that the transition metals did not form organometallic compounds. The few substances of this type then known, such as tetramethylplatinum, were regarded as a typical, exceptions to the rule. Nevertheless, an extremely characteristic feature of transition metals was the formation of numerous complex compounds of the Werner type, which had been widely studied in the chemistry of inorganic complexes and metal carbonyls, these forming a very peculiar, isolated "island" of chemical compounds marked off from the "continents" of inorganic and organic substances.

Fundamental changes have occurred in this field during recent years. Transition metals have been found to be capable of forming exceptionally numerous organometallic compounds of sandwich type, as well as π- and σ-complexes, which are sometimes extremely stable, as e.g. ferrocene, on the basis of which it has proved possible to construct new families of organic derivatives—not only metal–hydrocarbons but also halogeno-derivatives, alcohols, aldehydes, ketones, nitro- and amino-derivatives, carboxylic and organoelementary acids, and many others—a vast region of mixed structures, including sandwiches, π-complexes, and carbonyls, being found also between inorganic complex compounds and the new organic derivatives of transition metals. The carbonyl "island" has proved to form part of an immense new "mainland".

The chemistry of organic compounds of transition metals has proved exceptionally rich in new types of chemical bond, new laws, and new reactions. The Soviet school of organometallic chemists, with Nesmeyanov at its head, has made an exceptionally important contribution to the development of this field.

1. Metallocene and Arene Compounds of Iron (Ferrocene)

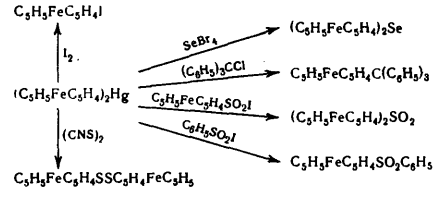
The main theme of this work was at first the development of the chemistry of ferrocene [2]. Nesmeyanov and his pupils have now carried out wide researches on the organic compounds of a large group of transition metals—iron, cobalt, manganese, rhenium, chromium, molybdenum, tungsten, vanadium, niobium, tantalum, titanium, zirconium, hafnium—and certain other elements.

In investigating ferrocene and its derivatives, Nesmeyanov and his coworkers solved a large group of general problems in this branch of chemistry. Examples are the determination of the reactivity of ferrocene compounds as non-benzenoid aromatic systems, the establishment of specific differences in the reactivity of ferrocene and aromatic benzenoid compounds, rules of orientation in substitution reactions in ferrocene and its derivatives, the magnitude of polar effects in the reactions of ferrocene compounds, the polar characteristics of the ferrocenyl group as a substituent, the effect of ferrocenyl on the stability of adjacent cationic, radical, and anionic centres, electronic effects in the ferrocene series, the development of methods for demonstrating the structure of ferrocene derivatives, and the transition from ferrocene to compounds of other types. The list of problems can easily be extended.

In the solution of these problems Nesmeyanov made wide use of the whole available range of chemical, physical, and physicochemical methods of investigation. Only a brief survey of some of the results obtained can, of course, be given in this paper.

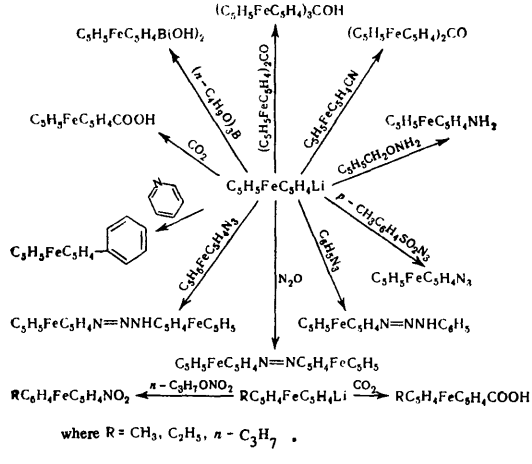
In order to solve the problems it was first necessary to develop synthetic methods for, and examine the chemical reactions of, various derivatives of ferrocene. At the start of this series of investigations only a single substitution in the cyclopentadienyl ring of ferrocene was known, this being the reaction with acid halides and anhydrides to form ketones [3]. Since the classical electrophilic substitution reactions—halogenation, nitration, sulphonation, etc.—are difficult in the ferrocene series (because of the ease of oxidation of ferrocene), Fischer and Jira [4] spoke against an analogy between ferrocene and aromatic compounds.

Scheme 1



In the very first paper of this series, Nesmeyanov and his coworkers [5] showed this view to be incorrect, by effecting the mercuration of ferrocene with mercury acetate and its metallation with butyl-lithium. Mercury and lithium derivatives of ferrocene have since been widely used in the preparation of other ferrocene compounds (Scheme 1). In particular it has proved possible for the first time, with mercury derivatives of ferrocene as starting material, to obtain halogenated derivatives [6], and ferrocenylamine from ferrocenyl-lithium [7] (Scheme 2).

Scheme 2



The lithium compounds can be converted into carboxylic and boronic acids, ketones, alcohols, amines, azides, and nitro-, azo-, and diazamino-derivatives of the ferrocene series (Scheme 2).

The direct alkylation of ferrocene [8,9] by alkyl halides and alkenes in the presence of aluminium chloride was accomplished by Nesmeyanov and Kochetkova during 1956–1958. Introduction of the first alkyl group into the ferrocene molecule favours further alkylation. Nesmeyanov et al. have since shown by gas–liquid chromatography that

all possible isomeric di- and tri-alkylated ferrocenes are thus formed [10-12]. Use of a mixture of anhydrous aluminium chloride and lithium tetrahydroaluminate increases the yield so greatly that alkylation becomes a method for preparing certain homologues of ferrocene.

Study of the absorption spectra of monoalkylated and heteroannular dialkylated ferrocenes and comparison with those of the corresponding acyl derivatives have permitted an assignment of the absorption bands of ferrocene itself [10-12]. The agreement of the change in the spectra predicted theoretically (by calculation based on the molecular orbital method to the Hückel approximation) on passing from ferrocene to its substituted derivatives with the experimental data has confirmed the correctness of this assignment [13].

Investigation of the nuclear magnetic resonance spectra of homologues of ferrocene containing primary, secondary, and tertiary alkyl groups indicates hyperconjugation of the alkyl substituent with a cyclopentadienyl ring of the ferrocene system [14].

Nesmeyanov and his students have discovered many new reactions—acylation [15,16], sulphonation [17], phosphorylation [18]—of electrophilic substitution. Together with Kursanov, Setkina, and their coworkers a study was made of the deuteriation of ferrocene and its substituted derivatives [19-23]. Investigations have been made of the nucleophilic substitution of halogen in ferrocenyl halides [24-26], of radical substitution—arylation by aromatic diazo-compounds [5,7,27]—and many other reactions [2,28], e.g. the condensation of ferrocene with aldehydes [29].

o-Carboxybenzoylferrocene undergoes reactions of a peculiar type [30-33]. By ring–chain tautomerisation in its cyclic form it exhibits several reactions of the α-ferrocenylcarbonium ion, e.g. extremely readily occurring nucleophilic substitutions initiated by acids. The ferrocene analogue of anthraquinone—"ferrocoanthraquinone"—has been obtained by a series of transformations of the "open" acyclic form of *o*-carboxybenzoylferrocene.

Nesmeyanov, Vil'chevskaya, Kochetkova, and their coworkers accomplished the phosphorylation of ferrocene with phosphorus trichloride, obtaining triferrocenylphosphine oxide. This reaction has considerable value for alkyl, aralkyl, and aryl derivatives of ferrocene. The peculiar behaviour of these compounds towards nucleophilic and electrophilic reagents distinguishes them from the corresponding aromatic and aliphatic organophosphorus compounds [34,35].

The investigation by Nesmeyanov, Sazonova, and Drozd of ferrocenylboronic acids has proved extremely fruitful for synthetic purposes [36-40]. In particular, monochloro- and 1,1′-dichloro-ferrocene were obtained for the first time by replacement of the $B(OH)_2$ group in these acids, and hydroxy- and amino-ferrocenes have been prepared by the same method (Scheme 3).

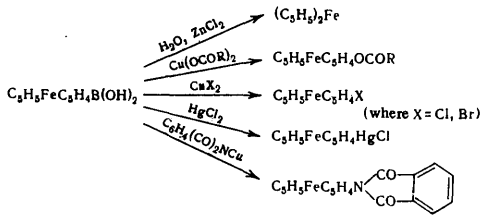
The synthesis of chlorinated ferrocenes made it possible to obtain various compounds by a nucleophilic substitution of the chlorine by other groups. It was shown [24,25,41,42] that the halogen in halogenated ferrocenes is easily exchanged in the presence of copper salts; amino- and hydroxy-derivatives of ferrocene, as well as azides, nitriles, and other derivatives, have been obtained in this way (Scheme 4).

Without attempting to exhaust all the methods of preparing ferrocene compounds developed by Nesmeyanov and his students, we may mention a series of papers on preparations involving the use of *NNN*-trialkylammonium derivatives of ferrocene (Scheme 5) (together with Perevalova, Shilovtseva, Ustynyuk, et al. [43-48])

A specific "ricochet" substitution (cyanation) involving iron has been discovered [49-51]. Ferricinium salts (or ferrocene in the presence of aluminium chloride) on treatment with hydrocyanic acid yield ferrocenecarbonitrile:

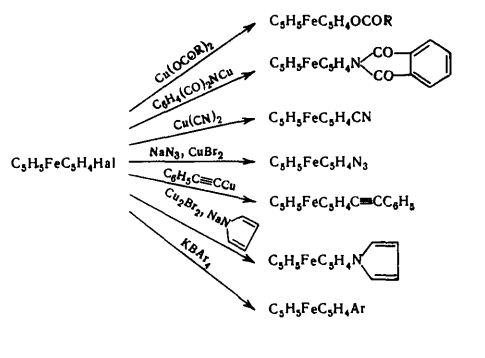
$$(C_5H_5)_2Fe \xrightarrow[FeCl_3]{HCN} C_5H_5FeC_5H_4CN\ .$$

Scheme 3

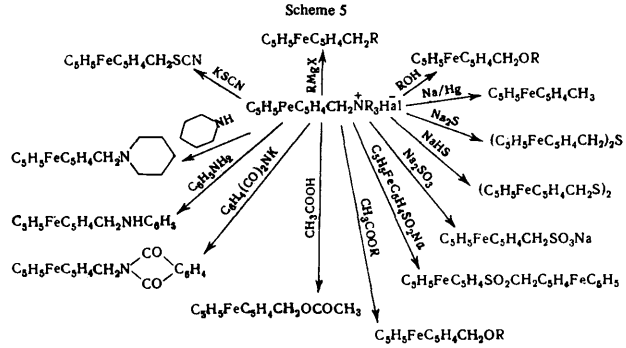


This is not a bimolecular nucleophilic substitution, since it does not obey the rules of orientation for nucleophilic substitution. Thus electron-acceptor substituents (*p*-nitrophenyl, phenylsulphonyl, acetyl, and chloro-, bromo-, cyano-, and nitro-groups) make cyanation more difficult and favour the formation of heteroannular isomers [50]. The cyanide anion probably first attacks the iron atom of the ferricinium cation with liberation of the proton from the hydrocyanic acid molecule (the pH of the medium decreases). The cyano-group then migrates into the five-membered ring with simultaneous reduction of the iron.

Scheme 4



Scheme 5



Representatives of the principal types of compounds of the ferrocene series have been obtained by the above reactions and several others, in most cases the mechanism of

their formation (electrophilic, nucleophilic, radical substitution) has been established, and their chemical properties have been studied.

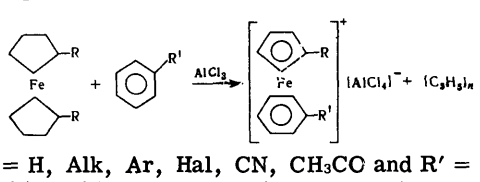
The reactions of many functional derivatives of ferrocene are analogous to those of the corresponding aromatic compounds. Several fundamental differences in chemical reactivity have been observed between ferrocene compounds and their aromatic analogues. Thus the former are incapable of the typical rearrangements of aromatic compounds: azoferrocene, for example, cannot undergo the benzidine rearrangement[52], and the allyl ether of ferrocenol is unable to rearrange into allylferrocenol[53]. This is explained by the inability of the ferrocene ring system to transmit *T*-effects requiring quinoid transition states.

A series of papers by Nesmeyanov, Gubin, and Perevalova has been devoted to electronic effects in ferrocene compounds[54–57]. The formal oxidation potentials of a large number of derivatives of ferrocene[54,55], the dissociation constants of acids and phenols, and the basic dissociation constants of amines of the ferrocene series[56] have been determined, and the infrared and ultraviolet spectra of several substituted ferrocenes studied. The application of correlation equations to an analysis of the results revealed the difference between the interaction of substituents with the phenyl and with the ferrocenyl ring systems, and enabled ferrocenyl to be characterised as a substituent[57].

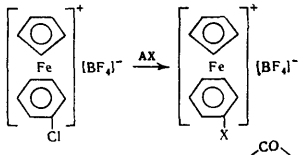
Both in the ferrocene system and in the benzene ring a ferrocenyl substituent exhibits electron-donor properties, the effect of the ferrocenyl being determined by the combination of a strong positive inductive effect with a fairly weak positive conjugative effect.

The effect of ferrocenyl on the stability of a neighbouring cationic centre is consistent with the above description of ferrocenyl as a substituent: it stabilises a neighbouring carbonium centre, carbonium salts containing ferrocenyl residues in the α-position being extremely stable[58,59]. The triferrocenylmethyl cation is also stable at room temperature[60].

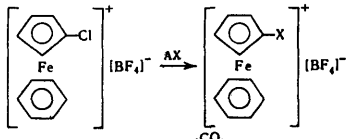
A remarkable type of ligand exchange was discovered in ferrocene by Nesmeyanov and Vol'kenau[61,62]. When ferrocene interacts with benzene and its derivatives in the presence of aluminium chloride, one five-membered ring is exchanged for an arene ring with the formation of arenecyclopentadienyl derivatives of iron:



where R = H, Alk, Ar, Hal, CN, CH_3CO and R′ = H, Alk, Ar, Hal, OAlk, OAr, CH_3, CH_3CONH. The effect on this reaction of substituent groups both in the ferrocene and in the arene has been investigated. The reactivity of the arenecyclopentadienyl compounds of iron thus made available has been studied. In particular, the replacement of halogen in the five-membered and six-membered rings by other groups has been investigated:



where X = OAlk, OAr, SAr, SAlk, C_6H_4(CO)(CO)N, NH_2, NHK, $C_5H_{10}N$; A = Na, K, H



where X = OAlk, C_6H_5S, C_6H_4(CO)(CO)N, NH_2, NHC_6H_{11}, $C_5H_{10}N$.
A = Na, K, H

2. Carbonyls and Organometallic Derivatives of Metal Carbonyls

In a long series of papers Nesmeyanov, Anisimov, Kolobova, Makarov, Pasynskii, and Ioganson have elaborated methods for the synthesis of organometallic compounds of manganese, rhenium, niobium, tantalum, vanadium, and several other transition metals, and have studied their chemical reactions, physicochemical properties, comparative reactivity, the nature of the bond, the mutual influence of groups, and many other aspects of their chemistry[63,64].

Mixed compounds have been investigated, in which the metal is bound to cyclopentadienyl and carbonyl groups, as well as aromatic derivatives of manganese and rhenium carbonyls containing a metal–carbon σ-bond, and polymetallic derivatives of molybdenum and tungsten carbonyls containing a direct metal–metal bond with elements of Group IVb.

A method has been developed for the synthesis of cyclopentadienyl derivatives of carbonyls of metals in Group VII:[63,64]

$$C_5H_5Na + ClM(CO)_5 \rightarrow C_5H_5M(CO)_3 + 2CO + NaCl$$

where M = Mn, Re.

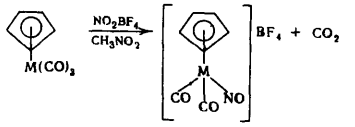
The acylation[65], mercuration[65], chloromethylation[65], phosphorylation[65], and deuteriation of tricarbonylcyclopentadienylmanganese (TCCM) and to some extent of its homologues[66–68] have been accomplished, as well as the deuteriation[66–68], sulphonation[69], and mercuration[69] of tricarbonylcyclopentadienylrhenium (TCCR). The cyclopentadienyl derivatives of Group VII metals have been shown to resemble ferrocene in possessing aromatic properties, the above rhenium compound being less active in electrophilic substitutions, but more active in protophilic substitutions, than is the corresponding manganese derivative.

It has been discovered[70,71] that the ring in TCCM and TCCR can be metallated.

The transformations of the lithium, mercury, and chloroderivatives of TCCM and TCCR have been studied[70,71]. Methods have been worked out for synthesising various compounds containing in the cyclopentadiene ring such groups as COOH, NH_2, $B(OH)_2$, HgCl, Cl, Br, RCO, and many others. These reactions are set out in Scheme 6.

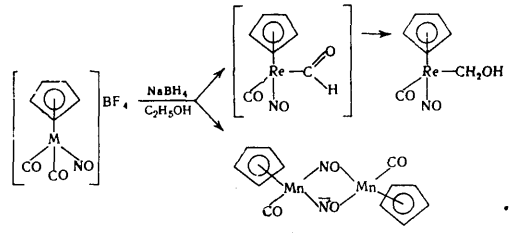
The chloromethylation of TCCM and the chemical reactions of the chloromethyl derivatives have been studied[65].

TCCM and TCCR react in very peculiar fashion with nitryl tetrafluoroborate. Instead of the expected nitration of the ring the reaction involves simultaneous oxidation–reduction and ligand exchange with the formation of nitrosyl complexes:

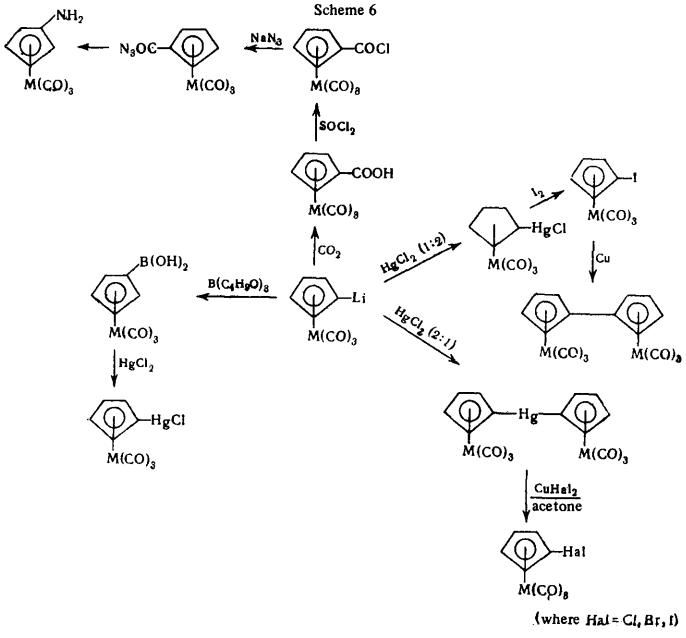


(where M = Mn, Re)

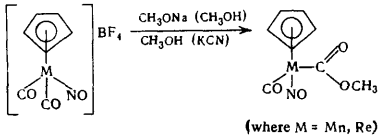
Several differences in chemical behaviour have been established between the cyclopentadienyl–carbonyl complexes of manganese and of rhenium. When the fluoroborate complexes are reduced with sodium tetrahydroborate in ethanol, the manganese derivative yields a dimeric product, but the rhenium analogue gives an alcohol:



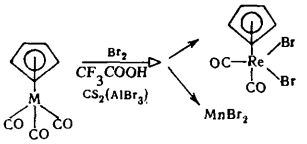
Scheme 6



The action on the fluoroborate complexes of a sodium alkoxide in methanol, or of methanol in the presence of potassium cyanide, results in esters (reaction at the carbonyl group):

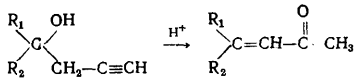


Bromination under conditions of electrophilic substitution goes in different ways with TCCR and TCCM:



The chemical behaviour of ketones of TCCM has been investigated. Reduction of the ketones [72], hydration of the carbonyls, and interaction of the former with Grignard and Iotsich reagents have been accomplished, and the rearrangement of tertiary α-acetylenic alcohols has been studied [73,74].

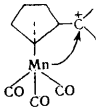
The rearrangement of β-acetylenic alcohols has been discovered [75]:



where R_1 = TCCM, $C_5H_4FeC_5H_5$ and R_2 = CH_3, C_2H_5, C_6H_5.

Ketones of TCCM on treatment with bromine yield α-bromoketones [76]. A study has been made of the mobility of halogen in the α-position with respect to the carbonyl group in nucleophilic substitutions and condensations.

The TCCM residue is more efficient than phenyl in stabilising an adjacent carbonium centre. Yet it also surpasses phenyl in reactions involving a neighbouring α-anionic centre. Thus a TCCM residue possesses stronger negative and positive mesomeric effects than does phenyl. Its stronger positive mesomeric effect (+M) is obviously due to the part played by the electronic environment of manganese in stabilising the α-carbonium centre:



Investigation of TCCM, TCCR, and their derivatives by physical methods (infrared, nuclear magnetic resonance, nuclear quadrupole resonance spectra, etc.) has enabled differences in the fine structure of the manganese and rhenium compounds to be formulated (relative electron density of the cyclopentadienyl rings, order of the metal–carbonyl bond, etc.).

The reactions of the carbonyl–cyclopentadienyl complexes of vanadium, niobium, and tantalum with p- and π-donor ligands have been examined [77], and new types of complexes of these metals obtained containing cyclopentadienyl, carbonyl, and substituted acetylenic groups. For example, products of the successive incorporation of one, two, and three diphenylacetylene molecules with one niobium atom have been isolated, the final product being hexaphenylbenzene. This process can be regarded as a model of the trimerisation of acetylenic hydrocarbons on complexes of transition metals.

Methods have been worked out for preparing derivatives of manganese and rhenium carbonyls containing metal–carbon σ-bonds [78], of the types $XC_6H_4COM(CO)_5$ and $XC_6H_4M(CO)_5$, where X is a substituent in the aromatic ring. The way in which the electronic effect of the substituent X in these compounds is transmitted via the metal atom to the carbonyl groups has been examined by various physical methods [79].

3. Heteropolymetallic Derivatives of Metal Carbonyls

It is well known that, unlike π-complexes of transition metals, the organic σ-derivatives are unstable if they contain no other stabilising ligands. When ligands (CO, π-C_5H_5, etc.) capable of accepting electron density from the metal into vacant π-orbitals are introduced into the coordination sphere of the metal atom, the metal–carbon σ-bond is considerably stabilised. The preparation of several stable organic σ-derivatives of metal carbonyls has opened up the possibility of synthesising stable compounds containing σ-bonds between atoms of transition metals and of elements in Group IVb other than carbon.

The researches of Nesmeyanov and his students showed that compounds containing covalent bonds between atoms of

transition metals and of Group IVb elements can be obtained by several methods—(1) exchange interaction of salts of metal carbonyls with organic halides of silicon, germanium, tin, or lead [80-93], e.g.

$$R_3MX + NaRe(CO)_5 \rightarrow R_3MRe(CO)_5$$
$$R_2MX_2 + 2NaMo(CO)_3C_5H_5 \rightarrow R_2M[Mo(CO)_3C_5H_5]_2$$
$$RMX_3 + 3NaCo(CO)_4 \rightarrow RM[Co(CO)_4]_3$$
$$SnX_4 + 4NaFe(CO)_2C_5H_5 \rightarrow Sn[Fe(CO)_2C_5H_5]_4$$

where M = Si, Ge, Sn, Pb, R = Alk, Ar, and X = Cl, Br.

(2) Reactions involving "insertion" of germanium dichloride at metal–halogen bonds [84]:

$$Cl-Fe(CO)_2C_5H_5 + GeCl_2 \xrightarrow{\text{dioxan}} Cl_3Ge-Fe(CO)_2C_5H_5$$
$$Cl-M'(CO)_3C_5H_5 + GeCl_2 \rightarrow Cl_3Ge-M'(CO)_3C_5H_5$$

where M′ = Mo, W; or at a metal–carbon bond:

$$R-Fe(CO)_2C_5H_5 + GeCl_2 \xrightarrow{\text{dioxan}} RCl_2Ge-Fe(CO)_2C_5H_5$$

where R = CH_3, C_2H_5, n-C_3H_7, iso-C_3H_7, $C_6H_5CH_2$. It is also possible for germanium dichloride to be inserted into metal–metal bonds under mild conditions:

$$C_6H_5(OC)_2Fe_2 + GeCl_2 \xrightarrow[\text{dioxan}]{} Cl_2Ge[Fe(CO_2)C_5H_5]_2 .$$

Insertions of tin dihalides into dinuclear carbonyls in which the two parts are linked by a direct metal–metal bond, e.g. $[C_6H_5(CO)_3M']_2$ (M′ = Mo, W) or $M'_2(CO)_{10}$(M′ = Mn, Re), takes place at high temperatures or on ultraviolet irradiation:

$$M'_2(CO)_{10} + SnCl_2 \rightarrow Cl_2Sn[M'(CO)_5]_2$$
$$[C_5H_5(CO)_3M']_2 + SnCl_2 \rightarrow Cl_2Sn[M'(CO)_3C_5H_5]_2 .$$

With molybdenum and tungsten derivatives, compounds containing one metal–carbonyl group, such as $Cl_3SnM'(CO)_3C_5H_5$, have been isolated together with the above insertion products.

(3) Trichlorogermyl derivatives of the carbonyls of molybdenum, tungsten, iron, and manganese have been obtained by reaction between trichlorogermane and the corresponding carbonyl halides [85,86]:

$$ClMn(CO)_5 + Cl_3GeH \rightarrow Cl_3GeMn(CO)_5 + HCl .$$

(4) Compounds containing bonds between cobalt and a Group IVb element have been prepared also directly from octacarbonyldicobalt and organic halides of germanium, tin, or lead [87]:

$$R_nMX_{4-n} + Co_2(CO)_8 \rightarrow R_nX_nM[Co(CO)_4]_{4-m-n}$$

where R = Alk, Ar, n = 1–3, m = 2–0, and M = Ge, Sn, Pb. The number of carbonylcobalt groups linked directly to the atom of the non-transition element is determined by the ratio of the reactants, but does not exceed three.

The methods enumerated above have been used to obtain many new compounds containing atoms of Group IVb elements together with 1–6 identical or differing atoms of transition metals.

Derivatives, containing a metal–metal σ-bond, of Group IVb elements and metal carbonyls are mostly crystalline substances, soluble in the usual organic solvents, and insoluble in water. A considerable proportion of them are coloured, varying from pale yellow to red.

In the solid state compounds containing metal–metal bonds (with the exception of certain derivatives of cobalt) are stable to the action of oxygen and atmospheric moisture. Depending on the nature of the transition metal the thermal and oxidative stability of the complexes increases in the sequence

$$Co < Cr < Mo < W < Mn < Re < Fe .$$

The most stable compounds are those containing a tin–transition metal bond. Derivatives containing germanium and especially lead atoms are less stable. Among compounds containing transition metal–silicon bonds derivatives of carbonyls of Group VII metals (manganese, rhenium) are the most stable, withstanding prolonged heating (at 160–170°C for 35 h) without appreciable decomposition. As the number of carbonylmetal groups combined with the non-transition metals increases, the thermal and oxidative stability diminishes. Derivatives containing three or four metal atoms, of the types $R_2M[M'(CO)_mL]_2$ and $RM[M'(CO)_mL]_3$, are the least stable. Tetrametallic derivatives have been obtained mainly with tin and silicon.

The chemical properties of compounds containing metal–metal bonds with two or more metal-bound fragments depend in considerable measure on the nature of the stabilising ligands, the electronegativity of the substituents combined with the non-transition metals, and several other factors.

Three types of reaction—at metal–metal, metal–carbon, and metal–carbonyl group bonds—are possible with compounds of the given type, containing R–M–M′–CO bonds, where R = Alk, Ar, Hal. The action of halogens, halogen hydrides, hydrohalic acids, and several other reagents has been investigated.

The reactions of derivatives containing two metal atoms are specific, depending on the conditions, the nature of the transition metal, and the ligands attached to it.

The action of chlorine or bromine on tin derivatives of manganese and rhenium carbonyls at temperatures from 0° to 70°C is accompanied by cleavage of carbon–tin bonds, while the metal–metal bonds are preserved. The replacement of phenyl groups may be successive:

$$(C_6H_5)_2Sn[M'(CO)_5]_2 \xrightarrow{+2Hal_2} C_6H_5Hal_2Sn-M'(CO)_5 \rightarrow Hal_3Sn-M'(CO)_5$$

where M′ = Mn, Re and Hal = Cl, Br.

In cobalt-containing complexes a metal–metal bond always undergoes cleavage on treatment with halogens under any conditions.

Germyl derivatives of Group VII metal carbonyls do not react with halogen hydrides, whereas the stannyl derivatives do interact with them, the carbon–tin bonds being cleaved while the metal–metal bonds are maintained. The replacement of phenyl groups may be partial or complete depending on the reaction conditions. The above reactions of the dimetallic derivatives are analogous to those of classical organotin compounds.

Reactions between trimetallic complexes and hydrogen halides also involve replacement of phenyl groups and preservation of metal–metal bonds, e.g.

$$(C_6H_5)_2Sn[Mn(CO)_5]_2 \xrightarrow{+2HCl} Cl_2Sn[Mn(CO)_5]_2 .$$

A metal–metal bond is considerably stabilised by the presence of electronegative substituents attached to the non-transition metal. Thus the interaction of $(C_6H_5)_3SnFe(CO)_2C_5H_5$ with mercuric chloride is accompanied by cleavage of the tin–iron bond, whereas the corresponding chloro-derivative does not react:

$$(C_6H_5)_3SnFe(CO)_2C_5H_5 + HgCl_2 \rightarrow (C_6H_5)_3SnCl + ClHgFe(CO)_2C_5H_5 .$$

On interaction with nucleophilic agents, halogen-containing germyl and stannyl derivatives of metal carbonyls, like

ordinary organometallic halides of Group IV elements, exchange halogens for the corresponding anions to form derivatives having different functional substituents attached to the non-transition metal atom, the metal–metal bonds being preserved [88–90]:

$$[L(CO)_mM']_2MCl_2 + 2R^- \rightarrow [L(CO)_mM']_2MR_2$$

where R = NO_2, NO_3, C_2H_3S, C_5H_5, NCS, etc.

From these reactions it has been possible to ascertain the behaviour of metal–metal bonds in these complexes towards various nucleophilic reagents and different reaction media, and to prepare several derivatives containing donor or acceptor substituents attached to the non-transition metal atom. Under these conditions the stannyl derivatives of carbonyls of Groups VII and VIII metals have proved to be the most stable. Derivatives of Group VI metals readily break down in alkaline media. On the other hand, derivatives of iron carbonyl show exceptional stability towards both acidic and alkaline reagents. Derivatives of manganese and rhenium carbonyls occupy an intermediate position, the former being the less stable. Derivatives of cobalt carbonyl are the most sensitive to conditions in the exchange reactions.

The germyl and stannyl derivatives of manganese, rhenium, and iron react with Grignard reagents in the normal fashion:

$$Br_3GeMn(CO)_5 + 3C_6H_5MgBr \rightarrow (C_6H_5)_3GeMn(CO)_5$$

$$[C_5H_5(CO)_2Fe]_2MCl_2 + 2RMgX \rightarrow [C_5H_5(CO)_2Fe]_2MR_2$$

where R = CH_3, C_2H_5, C_3H_7, C_4H_9, C_6H_5 and M = Ge, Sn.

The carbonylmetal portions of dinuclear and polynuclear derivatives exhibit all the properties characteristic of ordinary metal carbonyls: they are able to exchange the carbonyl groups for other ligands, e.g. triphenyl-phosphine, -arsine, and -stibine, without cleavage of metal–metal bonds:

$$R_3SnM'(CO)_5 + P(C_6H_5)_3 \rightarrow R_3Sn{-}M'(CO)_4P(C_6H_5)_3 .$$

Investigation of these reactions has shown that the ease of exchange is largely governed by the electronegativity of the substituents attached to the non-transition metal atom. The presence of electron-acceptor substituents facilitates exchange; electron-donor substituents, on the other hand, make exchange more difficult.

Derivatives containing two metal atoms undergo extremely interesting photochemical reactions with π-donor ligands. Thus the ultraviolet irradiation of $(C_6H_5)_3Sn{-}Fe(CO)_2C_5H_5$ in the presence of ethylene at atmospheric pressure results in the detachment of one carbonyl group with the formation of a π-ethylene complex:

$$(C_6H_5)_3Sn{-}Fe(CO)_2C_5H_5 + CH_2{=}CH_2 \xrightarrow[\text{benzene}]{h\nu} (C_6H_5)_3Sn{-}Fe(CO)(CH_2{=}CH_2)C_5H_5 + CO .$$

An X-ray study of the crystalline structure of compounds [91] containing tin–iron, tin–manganese, and tin–cobalt bonds has shown that the metal–metal bonds are always shorter than the sums of the singly bound covalent radii of the metals and are very sensitive to the nature of substituents attached to the Group IVb atom. Thus in compounds of the type $X_2Sn[Fe(CO)_2C_5H_5]_2$ increase in the electronegativity of X is accompanied by an appreciable shortening of the tin–iron bonds together with an increase in the iron–tin–iron angles (see Table).

In the same series of compounds there is observed a parallel increase in the frequency νCO, which indicates an increase in the carbon–oxygen bond order:

$$X{-}Sn{-}M{=}C{=}O \leftrightarrow \bar{X}{-}Sn{-}M{-}C{\equiv}\overset{+}{O} .$$

Compound	Bond lengths, Å			Fe–Sn–Fe angle, °	ν_{CO}, cm^{-1}	$\sigma_{C_5H_5}$,* p.p.m.
	Sn–Fe	Fe–CO	C–O			
$(CH_3)_2Sn[Fe(CO)_2C_5H_5]_2$	2.60	1.72	1.20	124	1981	4.91
$(ONO)_2Sn[Fe(CO)_2C_5H_5]_2$	2.56	1.72	1.19	126	2027	4.93
$Cl_2Sn[Fe(CO)_2C_5H_5]_2$	2.49	1.76	1.08	128.6	2022	5.19

*These are apparently τ-values (Ed. of Translation).

All these changes have been explained by the hypothesis of d_π–d_π interaction between completed *d*-orbitals of the transition metal and vacant *d*-orbitals of the tin atom, with a consequent increase in order of the tin–iron bond. Further support for the occurrence of such interaction has been obtained from an analysis of the infrared spectra [79], the most convenient for investigation being those of manganese carbonyl derivatives of the type $X_3MMn(CO)_5$. These compounds have an approximately octahedral structure, with a substituent other than carbonyl at one of the vertices of the octahedron. The presence of two types of carbonyl groups (equatorial and axial) in these molecules enables us to delimit the transmission of electronic effects of MX_3 substituents through the metal atom to the carbonyl groups.

Analysis of the infrared spectra reveals that the frequency of the vibrational band due to equatorial carbonyl groups varies linearly with the Taft inductive σ^*-parameter for the MX_3 groups, whereas the vibrational frequency of the axial group is influenced by both inductive and mesomeric effects of the substituent.

All compounds containing a bond between a manganese atom and a non-transition element of Group IVb exhibit a considerable contribution of d_π–d_π interaction to the metal–metal bond.

The infrared spectra of π-cyclopentadienyl derivatives of the carbonyls of molybdenum, tungsten [92], and iron [93] containing M–Ge or M–Sn bonds, of the types $[C_5H_5(CO)_3M']_2MX_2$ and $[C_5H_5(CO)_2Fe]_2MX_2$, exhibit satisfactory correlation between the frequencies νCO and the σ^*-values for the substituents X, which indicates a predominantly inductive transfer of electronic effects from substituents of the non-transition metal to carbonyl groups located at an angle to the metal–metal bond.

In a study of the infrared spectra of compounds of the type $X_2M[Fe(CO)_2C_5H_5]_2$, where M = Ge or Sn, it has been suggested that rotational isomers of these compounds are present in solutions, as a consequence of rotation about the germanium–iron or tin–iron bonds [94]. Analogous isomers are possible also with molecules containing one metal–metal bond, in which several different substituents are attached to the non-transition metal atom. This hypothesis has been confirmed for the compound $CH_3Cl_2GeFe(CO)_2C_5H_5$ by determining the relative intensities of the νCO bands in the infrared spectra in various solvents and at various temperatures.

4. Organometallic Compounds of Titanium, Zirconium, and Hafnium

Nesmeyanov, Nogina, and their coworkers have investigated cyclopentadienyl derivatives of titanium, which exhibit several fundamental differences from ferrocene and its derivatives. They have established that cyclopentadienyl compounds of titanium readily decompose under the action of nucleophilic reagents [95-97]. In several cases, for example $C_5H_5Ti(OC_2H_5)_3$ and $(C_5H_5)_2Ti(OCOCH_3)_2$, the Ti–C_5H_5 bond is cleaved even by treatment with ethanol at 20°C. Furthermore, mono- and di-cyclopentadienyl derivatives of quadrivalent titanium, unlike ferrocene, undergo no substitution reactions (acylation, alkylation, mercuration, cyanation, and probably radical substitution reactions). In this connection Nesmeyanov concerned himself mainly, in the chemistry of the cyclopentadienyl derivatives of titanium, with the exchange of ligands on the titanium and the accompanying change in the properties of the Ti–C_5H_5 bond. Several convenient and accessible methods were developed for preparing various types of mono- and di-cyclopentadienyl derivatives of titanium [98-101]. Examples are methods for synthesising trialkoxides, trihalides, and also cyclopentadienyl derivatives of titanium which are at the same time inner-complex compounds, as well as compounds containing different atomic groupings (alkoxy-, aryloxy-, and acyloxy-groups, halogen atoms, and several others) attached simultaneously to the titanium atom.

Chemical and physical methods have been used to investigate the way in which the effect of various ligands is transmitted through the titanium atom to the cyclopentadienyl ring [102-104]. It was found that, as the number of electron-acceptor halogen atoms in the molecule decreases, the yield of cyclopentadiene produced by the alcoholysis and hydrolysis of the above substances increases, as also the yield of ferrocene on reaction with the iron(II) ion [102-104]. This chemical behaviour, combined with the results of comprehensive physical investigations of these compounds by infrared, mass, and nuclear magnetic resonance spectroscopy and conductivity measurements on several substances, has led to the conclusion that the bond between titanium and the cyclopentadienyl ring becomes more polar as the electron-acceptor properties of the ligands diminish [102-104].

The nature of the ligands combined with the titanium affects also the type of rotation of the cyclopentadienyl rings in its dicyclopentadienyl derivatives, as has been shown by nuclear magnetic resonance. The presence of bulky ligands on the titanium impedes rotation of the rings, probably owing to the "catching" of hydrogen atoms in rings located at an angle to one another [105].

Investigation of a large number of monocyclopentadienyl derivatives of titanium by infrared spectroscopy over the range 200–500 cm^{-1} has enabled an assignment to be made of the titanium–cyclopentadienyl ring and titanium–halogen stretching vibrations [106].

Nesmeyanov, Brainina, and their coworkers [107-109] developed several new methods for synthesising cyclopentadienyl compounds of zirconium and hafnium. They prepared and made a detailed investigation of novel types of compounds, such as cyclopentadienyl-oxans containing two metal atoms, mixed compounds containing zirconium (or hafnium), cyclopentadienyl rings, and chelate groups.

Nesmeyanov and Kritskaya studied π-allyl complexes of iron of the type tricarbonyl-π-allyliron halides and di-π-allyliron and carbonyl. In particular, they showed that the π-allyl groups underwent rotation about an axis passing through the centre of the plane of the allyl ligand and the iron atom. The magnitude of the rotational barrier depends on the nature of other groups present in the molecule [110-113].

The same workers have shown that complexes of π-benzyl type are formed comparatively easily with iron by fused aromatic systems starting with naphthalene. Several compounds have been prepared in which naphthylmethyl groups are simultaneously attached to iron by both π- and σ-bonds. π-Benzyls represent a novel type of ligands—the benzologues of π-allyl. [114]

III. ORGANOMETALLIC COMPOUNDS OF NON-TRANSITION METALS AND PROBLEMS OF CONJUGATION, DUAL REACTIVITY, AND TAUTOMERISM

During recent years Nesmeyanov's researches have been concentrated mainly on expanding the chemistry of organometallic compounds of the transition metals. Investigations on compounds of non-transition metals, which are still going on, represent mainly an extension of previously established lines of research, described in detail in a previous review [1]. Therefore they will be only briefly discussed below. During recent years these lines of research have already been independently continued by Nesmeyanov's students. They include the work by O. A. Reutov and his coworkers on the stereochemistry of the electrophilic substitution of a metal at saturated and ethylenic carbon atoms, a series of papers by I. F. Lutsenko et al. on organometallic derivatives of oxo-compounds, and several others.

In studying the properties, structural peculiarities, and effect of atoms and groups on the reactivity of organometallic compounds Nesmeyanov made a big contribution to the solution of important theoretical questions of general significance for chemical science. For example, the investigation by Nesmeyanov, Freidlina, and Borisov of β- and α-alkylated organometallic compounds ("quasi-complex" compounds) led not only to several general methods for the preparation of various compounds of this class and the solution of the hitherto controversial question of their structure but also to new ideas on the dual reactivity of substances, on the "transfer of the reactive centre" along a chain of $\sigma\pi$-, $\sigma\delta$-, $p\pi$-, and $p\sigma$-conjugation in a molecule, and to distinguishing these phenomena from those of tautomerism as equilibrium isomerisation. Many of these ideas have entered widely into the general practice of chemical research.

Nesmeyanov and Lutsenko expanded the investigation of this field by developing a method for the preparation of α-mercurated aldehydes and ketones as well as carboxylic esters, and studying their properties. Compounds having this structure were also found to exhibit dual reactivity.

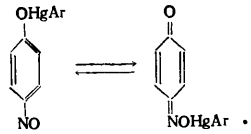
These investigations by Nesmeyanov and Borisov also laid the foundations of the stereochemistry of unsaturated organometallic and organoelementary compounds. They developed methods for the synthesis, separation, and identification of various β-substituted *cis*- and *trans*-unsaturated organometallic compounds, and established the main stereochemical laws in exchange reactions and the reduction of such compounds. These workers formulated the general rule that the geometrical configuration is maintained during electrophilic and radical substitutions at an ethylenic carbon atom [2]. The value of this rule is fully comparable with the well known rules of inversion and non-inversion of stereochemical configuration in the chemistry of optical isomers.

A series of papers by Nesmeyanov and Sazonova on the dual reactivity of metal (magnesium, lithium, sodium, etc.) derivatives of diphenylpropiomesitylene are closely related in concept to the investigation of quasi-complex compounds and α-mercurated oxo-compounds. These enolates were obtained in two stereoisomeric forms—*cis* and *trans*—which under certain conditions were incapable of mutual conversion, i.e. of tautomeric transitions [2]. The investigation under these conditions of the dual reactivity of these enolates served as the experimental basis for extending concepts of dual reactivity and migration of the reactive centre, developed in the study mainly of covalent mercury compounds, to the reactions of ordinary metallic derivatives of keto-enolic and other tautomeric systems and for generalising them throughout the field of tautomerism. Over this period Nesmeyanov has published a series of summary papers [115-117], devoted to problems of tautomerism and dual reactivity.

During recent years the further development of work on vinyl compounds of metals has led Nesmeyanov and Borisov to the synthesis of those of antimony, arsenic, tin, and germanium, and the preparation of ethylene derivatives containing two organometallic groups attached to the ethylenic bond, in which the metal atoms are either like or unlike [118-121]. The structure of β-chlorovinyl compounds of mercury has been confirmed by nuclear magnetic resonance, and the rate of acidolysis of the *cis*-isomer shown to be lower than that of the *trans*-isomer, in confirmation of Nesmeyanov's earlier concept of σπ-conjugation in these compounds and of a link between the geometric configuration of their molecules and their reactivity [122-124].

Nesmeyanov and his coworkers have developed a method for the synthesis of trichloromethyl- and polyhalogenomethyl-mercury salts and trichloromethylarylmercury, which are of interest as a source of halogenated carbenes which cannot be obtained in alkaline medium [125].

Nesmeyanov and Kravtsov have used spectroscopic methods in a broad investigation of the structure of organometallic derivatives of tautomeric and potentially tautomeric systems in which the bonds between metal and cation-acceptor centre are of low polarity. They have established that in most cases the organometallic derivatives have the structure of one of the two possible tautomeric forms, the nature of which depends on the character of the metal atom and the atom of the tautomeric substance [126-129]. Nevertheless, in the cases of the organomercury, organolead, and organotin derivatives of nitrosophenols this work resulted in the discovery of the phenomenon of metallotropy, i.e. the reversible migration of the organometallic grouping in the tautomeric system, and the position of tautomeric equilibrium was shown to depend on the nature of the solvent, of the organometallic grouping, and of substituents in the system, e.g. nitrosophenol [130]. Similar results were obtained for the *N*-organomercury derivatives of arylsulphonylaminopyridines [131]. It was then established for *N*-organomercury derivatives of halogenoimidazoles that intermolecular coordination in the crystalline state can lead to intermolecular mesomerism, in which the metal is simultaneously bound to both possible cation-acceptor centres in the tautomeric system [132]:



An analogous structure, intermediate between two possible states, is possible in intramolecular mesomerism, which is characteristic of the mercury and organomercury derivatives of cyclopentadiene [133]. Thus it has been shown that, depending on the character of the tautomeric system, the nature of the metal, and the physical state, every possible type of structure—(1) one of the extreme forms, (2) tautomeric equilibrium of the two forms, and (3) inter- and intra-molecular mesomerism—can be found in the metal derivatives of tautomeric systems. Thus to the only known form of cationotropy—prototropy—is added a new type—metallotropy.

Nesmeyanov's investigations on the structure of organometallic derivatives of tautomeric systems made it necessary to clear up several related questions of theoretical organometallic chemistry. In the course of this work it was established that the electronic effect of mercury-containing substituents is inductive in character, being markedly dependent on the nature of the solvent, and it was also demonstrated that organomercury, organolead, and organotin groups are capable of intramolecular coordination with halogen atoms [134-136].

IV. INVESTIGATIONS ON ORGANIC COMPOUNDS

Studies of dual reactivity and tautomerism belong equally to organometallic and to organic chemistry. Passing now to a brief account of certain new results of Nesmeyanov's researches in the field of organic chemistry, we may mention a series of papers (with R. Kh. Freidlina, E. I. Vasil'eva, F. K. Velichko, L. I. Zakharkin, Sh. A. Karapet'yan, V. N. Kost, R. G. Petrova, E. Ts. Chukovskaya, and others) on radical telomerisation and rearrangements of radicals, which have been partly described above [1]. At the present time investigations in this field are being conducted over a broad front by Nesmeyanov's students.

1. Investigations on β-Substituted Vinyl Ketones

A characteristic feature of Nesmeyanov's research activity is the close interlinking of three branches of chemistry—theoretical, organic, and organoelementary—which can be especially clearly traced in his work on β-substituted vinyl ketones [137,138].

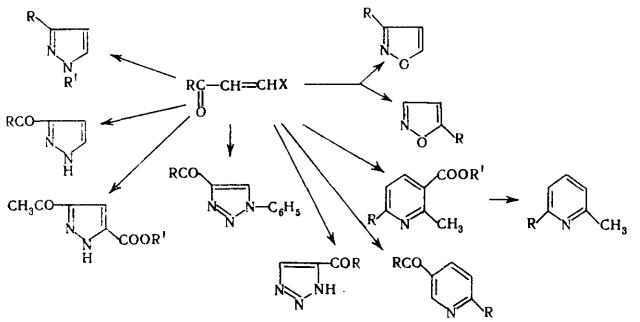
The high activity of the carbonyl group together with the mobility of the β-substituent in compounds of the type RCOCH : CHX was successfully exploited by Nesmeyanov Kochetkov, and Rybinskaya to develop methods for the synthesis of various five-membered nitrogen-containing heterocycles. Nesmeyanov, Kochetkov, and their coworkers used the same compounds to develop methods for the synthesis of pyridine derivatives (see Scheme 7).

Especially interesting examples of these heterocycles were cations isoelectronic with naphthalene and phenanthrene and containing an onium heteroatom $\dot{O}=$ or $>\dot{N}=$. Thus the reaction of β-chlorovinyl ketones with phenols and 2-naphthol was used to develop a method for the synthesis of benzopyrylium, flavylium, and naphthopyrylium salts. Subsequently the synthesis has been accomplished of heterocyclic cations containing an ammonium nitrogen atom in a bridge, so called dehydroquinolizinium salts and their 1-aza- and 1,9-diaza-analogues [138] (see Scheme 8).

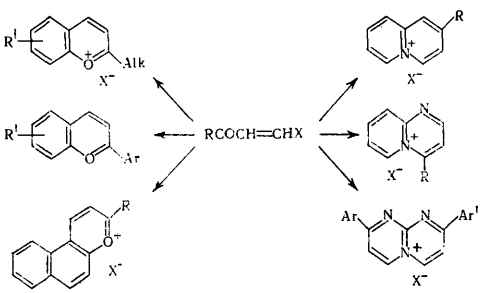
After the rule that geometrical configuration is maintained during electrophilic and homolytic substitution at an ethylenic carbon atom had been formulated, Nesmeyanov, Kochetkov, and Rybinskaya undertook a study of the

stereochemistry of nucleophilic substitution, choosing β-substituted vinyl ketones as model compounds. This investigation required a great amount of preliminary work, which involved developing a broad synthetic method, termed β-ketovinylation [138]. The reaction of β-ketovinylation, which is now taken to imply the introduction of a ready made RCOCH : CH group into a molecule, has permitted the preparation of the most diverse *cis*- and *trans*-β-substituted vinyl ketones. The ketovinyl fragment in these compounds was combined with atoms of various elements, such as carbon, nitrogen, oxygen, sulphur, hydrogen, iron, cobalt, and tungsten. Development of the method of ketovinylation resulted in the synthesis of organic compounds of various classes. In the course of this investigation the choice of ketovinylating agent was shown to be very important, and basic principles for such choice were formulated. For example, β-chlorovinyl ketones can be used for the ketovinylation of weakly basic and strongly polarised anions such as SCN^-, $SC_6H_5^-$, $SO_2C_6H_5^-$, N_3^-, etc., whereas in the case of strongly basic and relatively unpolarised nucleophiles (Alk, Ar^-, H^-, NH_2NH_2) the reaction leads to an addition product involving the carbonyl group [138]. This example thus provides evidence that, in the choice of ketovinylating agent, the selectivity of nucleophilic reagents towards a definite reaction centre has to be taken into account. For the ketovinylation of strongly basic and weakly polarised nucleophiles, therefore, the use of β-dimethylaminovinyl ketones was recommended. Furthermore, very active quaternary β-acylvinyltrimethylammonium salts were proposed [138] for very weakly nucleophilic anions ($OCOCH_3$, NO_2, etc.).

Scheme 7

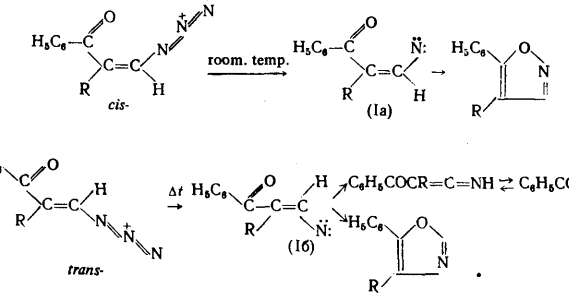


Scheme 8



As a result of this large amount of synthetic work it was found that the most convenient model reaction for studying the stereochemistry of nucleophilic substitution at an ethylenic reaction centre is the reaction of compounds C_6H_5COCR : CHX with the azide ion in various media.

Nesmeyanov and Rybinskaya showed by means of this reaction that the stereochemical course of nucleophilic substitution at an ethylenic carbon atom depends on the nature of the group X which is eliminated. For substrates having X groups (such as the chloride anion) which are "readily removable" as anions it was found that the geometrical configuration was preserved. In the case of "slowly removable" groups X (such as $C_6H_5SO_2$) the reaction resulted mainly in formation of the thermodynamically more stable isomer; and with "very difficultly removable" groups (X = CN, SO_3^-), reaction with the azide ion yields, instead of β-azidovinyl ketones, the isomeric 4-acyl-1,2,3-triazoles. The stereochemical results obtained in this way enabled a mechanism of direct substitution with intermediate formation of carbanions to be suggested for nucleophilic substitution at an activated double bond, and this is supported also by kinetic investigations [138]. A very interesting rearrangement was studied on β-azidovinyl ketones as example, which showed that stabilisation of the intermediate nitren species (Ia and Ib) depends mainly on its configuration:



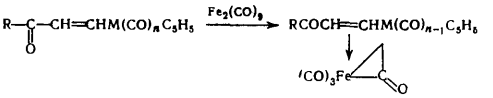
Very interesting compounds, β-aminovinyl ketones, were prepared by β-ketovinylation, and these exhibited a new type of tautomerism, ketiminol ⇌ enamineketone [138].

Another line of research deriving from the study of ketovinylation reactions was concerned with determining the orientation of nucleophilic attack in XCH : CHY systems, where X and Y are strong electron-acceptor groups. The kinetic investigation by Nesmeyanov, Rybinskaya, and Rybin led to a hypothesis which enabled the orientation of nucleophilic attack for systems of this type to be predicted by comparing data on the kinetic or thermodynamic acidities of the corresponding methyl derivatives CH_3X and CH_3Y. These workers started from the view that the orientation of nucleophilic attack should depend on the relative stability of the intermediate carbanions XCH–CHYZ and XZHCH–CHY (where Z is the nucleophilic reagent) [137].

The chemistry of β-substituted vinyl ketones has recently been considerably added to by the investigations of Nesmeyanov and his coworkers on σ- and π-complexes of transition metals, in which β-substituted vinyl ketones were used as ligands. The employment of complex anions $[Fe(CO)_2C_5H_5\text{-}\pi]^-$, $[W(CO)_3C_5H_5\text{-}\pi]^-$ (pyridinatocobaloxime)$^-$ in ketovinylation led to synthesis of the complexes σ-RCOCH : CH.ML_n (where M is a transition metal and L a unidentate ligand). [138]

However, β-substituted vinyl ketones have been most widely used for the preparation of σ-complexes with iron carbonyls [139–142], in which it was possible to trace qualitatively the variation in the complexing power of RCOCH : CHX with the nature of the substituent X. This investigation showed that π-complexes are not formed from ligands containing strongly electron-donor groups (e.g. X = $NAlk_2$) or from RCOCH : CHX in which X = CN, NO_2. In the

latter two cases polymers were isolated having a non-stoichiometric iron content. Stable complexes were obtained only from ligands having X = Cl, SO_2R, COOR, COC_6H_5. Comparison of these results with the calculated energies of antibonding orbitals for the corresponding ligands showed that this energy is too high for a stable π-complex to be formed in the case of RCOCH : CHNAlk$_2$ and too low for the ligands RCOCH : CHX (X = CN, NO_2). The formation of polymers having a non-stoichiometric iron content was explained by the possibility of complete transfer of an electron from the metal to the ligand. The radical-anion obtained $(RCOCH : CHX)^{\cdot -}$ could in turn give rise to a polymeric chain. It is interesting that on π-coordination with metals the ligands maintained their original configuration. Investigation of σ-ketovinyl complexes in reactions with $Fe_2(CO)_9$ enabled Nesmeyanov and his coworkers to obtain a series of novel mixed dinuclear $\sigma\pi$-complexes of type (II), characterised by a metal–metal bond and a bridging carbonyl group:



(II)

where M = Fe, n = 2 and M = W, n = 3.

2. Onium Compounds

The first investigation of this series was made in 1929, when Nesmeyanov examined the decomposition of the double salts formed by diazonium compounds with mercury(II) iodide, and established the formation of iodonium salts [143]:

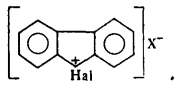
$$C_6H_5N_2HgI_3 \text{ and } (C_6H_5N_2)_2HgI_4 \rightarrow [(C_6H_5)_2HgI_4] + N_2 \ .$$

Some of the most recent (1967) work on these lines is described in a paper on the reactions of arenediazonium fluoroborates with substituted iodobenzenes, which showed the effect of the nature of nuclear substituents both in the diazonium salt and in the iodobenzene on the yield of diaryliodonium salts [144].

A set of methods was developed constituting the onium synthesis [2], based on transfer of the aryl radical or aryl cation of the onium compounds to a metal atom, salts, unsaturated compounds, and substances containing atoms having a lone pair of electrons—O, S, Se, N, P, As, Sb, Cl, Br, I.

The most general results of these investigations include firstly the establishment of two types of decomposition of diazonium, iodonium, and certain other onium salts with transfer of aryl cations or aryl radicals [145]. Conditions which determine the type of decomposition have been worked out (effect of structure of aromatic nucleus of onium compound, nature of salt anion, nature of substrate (aryl acceptor), nature of solvent, presence of catalyst, etc.). The rules established by Nesmeyanov together with Makarova, Tolstaya, et al. for the directed synthesis of various compounds from diazonium or other onium salts are now widely used in synthetic practice (e.g. the synthesis of arylisothiuronium salts by the reaction of arenediazonium fluoroborates with thiourea [146,147]).

Another most important result of this work was the contribution of the onium method to the synthesis of previously unknown types of compounds of multivalent chlorine, bromine, oxygen, nitrogen, and sulphur. Thus, in contrast to compounds of multivalent iodine, which have been known for a long time, the simplest compounds of multivalent chlorine and bromine—diarylchloronium and diarylbromonium salts—were unknown before the work of Nesmeyanov, Tolskaya, and their coworkers [148,149]. Only heterocyclic compounds of this type were known previously [150]:



It appeared that a heterocyclic position of the halogenonium grouping was a necessary condition for the existence of sufficiently stable halogenonium compounds. However, Nesmeyanov, Tolstaya, and their coworkers obtained numerous symmetrical and unsymmetrical diaryliodonium and diarylbromonium salts, as well as heterocyclic compounds of this type. The synthesis of diarylchloronium and diarylbromonium salts was accomplished by the reaction of arenediazonium fluoroborates with aryl halides:

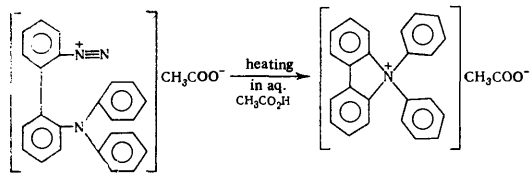
$$ArN_2BF_4 + Ar'Hal \rightarrow [ArAr'Hal]^+BF_4^- \xrightarrow{+X^-} [ArAr'Hal]^+X^- \ .$$

It proved possible to prepare the hitherto unknown triaryloxonium salts by the same method [151]:

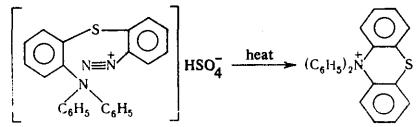
$$ArN_2BF_4 + Ar_2O \rightarrow [Ar_3O^+]\,BF_4^- \xrightarrow{X^-} [Ar_3O^+]\,X^- .$$

In contrast to Meerwein's trialkyloxonium salts [152,153], triphenyloxonium salts are extremely stable compounds, decomposing only when heated above 150°C.

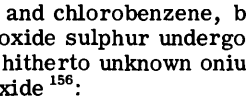
Completely aromatic onium compounds had been known for all elements other than nitrogen in the main subgroup of Group V of the Periodic System. Tetra-arylammonium salts could not be obtained by the arylation of triphenylamine with diphenyliodonium fluoroborate. Compounds of this type, namely *NN*-diphenylcarbazolium salts, could be prepared [154] by the reaction



The same workers have recently described the preparation and properties of another fully aromatic ammonium cation, *NN*-diphenylphenothiazinium [155]:



When benzenediazonium fluoroborate decomposes in a mixture of dimethyl sulphoxide and chlorobenzene, bromobenzene, or acetone, the sulphoxide sulphur undergoes arylation with the formation of hitherto unknown onium salts of dimethyl phenyl sulphoxide [156]:



Nesmeyanov and his coworkers have made a broad investigation of the reactions of the newly prepared onium compounds. They have shown, for example, that diphenylchloronium and diphenylbromonium salts are nitrated in the *meta*-position, thus conforming to the general rule of orientation in the nitration of aromatic onium compounds. On the other hand, the nitration of triphenyloxonium fluoroborate, which could be accomplished only under severe

conditions (with a mixture of anhydrous nitric and concentrated sulphuric acids at 100°C), yields tri-*p*-nitrophenyloxonium fluoroborate. The nitration of triphenyloxonium fluoroborate by means of nitryl tetrafluoroborate takes place even at room temperature and also leads to the same tri-*p*-nitrophenyloxonium fluoroborate.

The explanation given for the unusual behaviour of the triphenyloxonium cation was that the strong negative inductive effect of the oxonium oxygen, which inactivated the phenyl rings, was nevertheless associated, as in the halogenobenzenes, with conjugation of the lone pair of electrons on the oxygen atom with the π-electrons of the phenyl (+ *T*-effect).[157]

Tri-*p*-nitrophenyloxonium fluoroborate was reduced to the corresponding amino-derivative. The basic properties of the amino-groups in tri-*p*-aminophenyloxonium salts are appreciably weakened under the influence of the oxonium oxygen. These amino-groups are diazotised only under conditions for the diazotisation of weakly basic amines, e.g. by the action of nitrosylsulphuric acid. The tri-*p*-aminophenyloxonium cation is formally analogous in structure to the parafuchsine cation, but, unlike the latter, is colourless[158]. Explanations are given for this difference. For the infrared spectra of diphenylhalogenonium and triphenyloxonium compounds see Ref. 159.

Quite recently Nesmeyanov has shown, together with Makarova, Chapovskii, and Ustynyuk, that a rylation by diazonium and other onium compounds can be used for the synthesis of σ-aryl derivatives of transition metals. The action of benzenediazonium, diaryliodonium, and triphenylsulphonium salts on the anions of cyclopentadienylcarbonyl-iron[160,161], -tungsten[162], and -molybdenum[163] has yielded their σ-aryl derivatives. Thus the σ-phenyl derivative has been obtained by the interaction of triphenylsulphonium fluoroborate with the sodium salt of π-cyclopentadienyldicarbonyliron:

$$\pi\text{-}C_5H_5Fe(CO)_2Na + [(C_6H_5)_3S^+]\,BF_4^- \rightarrow \pi\text{-}C_5H_5Fe(CO)_2C_6H_5 \ .$$

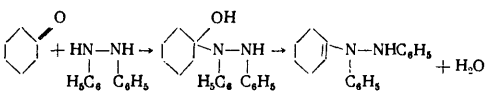
Let us make a brief mention of Nesmeyanov's work on hydride migration. In 1960 Nesmeyanov and Golovnya showed for the first time that the nitrogen atom in the azo- and diazo-groups of organic compounds can act as an acceptor for hydridic hydrogen, being more vigorous than the carbonium cation[164]. Salts of azobenzene with electrophilic reagents such as boron trifluoride, sulphuric acid, hydrobromic acid, hydrochloric acid, orthophosphoric acid, zinc chloride, etc. were able to remove hydride hydrogen from most organic solvents.

The surprising ability of azobenzene to abstract hydrogen from compounds which are so stable to oxidation as benzene, nitrobenzene, cyclohexane, and n-hexane, the ease of occurrence of the reaction with cycloheptatriene, and also the absence of reaction with chloroform and nitromethane led these workers to suggest the following reaction mechanism

$$[C_6H_5{-}NH{=}N{-}C_6H_5]^+HSO_4^- + H{:}\,C\!\!<\!\!\rightarrow C_6H_5NH{-}NH{-}C_6H_5 + \overset{+}{C}\!\!<\!\!\rightarrow + HSO_4^-$$

$$C_6H_5NH{-}NH{-}C_6H_5 + H_2SO_4 - (NH_3^+C_6H_4)_2SO_4^{2-} \ .$$

In the course of their investigation[164] Nesmeyanov and Golovnya discovered a new variant of the classical Fischer–Arbuzov synthesis of indoles. They showed that in the presence of boron trifluoride azobenzene reacts with cyclohexanone to form tetrahydrocarbazole. The reaction takes place also with homologues of cyclohexanone. The first stage is reduction of the azobenzene by hydride hydrogen abstracted from the cyclohexanone, the resulting hydrazobenzene reacts with the ketone to give the corresponding one–hydrazine:



and this cyclises to tetrahydrocarbazole with the elimination of aniline (not ammonia, as in the usual indole ring-closure):

2. Proteins and nutrition 699
3. Amino-acids 702
4. Chemistry of odour and taste 705
5. Structural-physical problems of artifical foods 709

I. INTRODUCTION

The idea that it was opportune for the start of practical studies on the production of food by industrial methods, avoiding agriculture, was suggested by A. N. Nesmeyanov at the beginning of 1961. This idea was based on the one hand on the work of the great chemists of the past—D. I. Mendeleev and M. Berthelot—and on the other, on an understanding of the contemporary state of the science of the physiology of nutrition and the achievements of the chemical industry[1]. Actually, at this time it appeared that man could satisfy all his physiological requirements by living exclusively on rations consisting of substances made synthetically. This gave a confidence in the knowledge of the main ingredients of food.

The great output of organic synthesis, which reaches millions of tonnes per annum in the production of polymeric products, made the question of the creation of a food products industry a real subject. Thus were all the proteins needed for feeding a country with a population of 250 million to be produced industrially it would be necessary to make about 6 million tonnes per annum.

Moreover, at this time the problem of the shortage of foodstuffs, especially proteins, became very acute. According to United Nations Organization data, about two-thirds of the population of the world are now in a state of chronic malnutrition, and often complete starvation[2].

No less alarm is aroused by the progressive destruction of the Earth's exposphere and the associated depletion of natural resources[3].

Hence in contrast to the XIXth century there were the need and real reasons for a practical solution of the problem of the production of synthetic food. There still remained one difficulty without overcoming which it would be impossible to think of the propaganda of new ways of obtaining food. This difficulty consists in the high cost of synthetic foodstuffs used for making synthetic rations. These substances—amino-acids, fatty acids, some vitamins—sold as reagents would be excessively dear. But economics should in the final analysis decide the choice between various methods for obtaining food. Furthermore it would be necessary to give the synthetic mixtures taste in the widest meaning of this word, including odour, taste itself, form, texture, etc.

To solve all these problems laboratory investigations were made under the guidance of A. N. Nesmeyanov in the Order of Lenin Institute of Organoelemental Compounds of the Academy of Sciences of the USSR into the production of edible amino-acids, proteins, and other foodstuffs, the study and reproduction of pleasant natural odours of prepared food, and the physical and chemical processes of structure formation. The need arose for the development of a series of theoretical and practical problems of biochemistry, organic, physical, and analytical chemistry and the foundations of a new branch of science—that of synthetic food—were really laid.

On comparing the various paths for the industrial production of foodstuffs that now most promising is microbiological synthesis. Nesmeyanov first understood the great potential possibilities of this method and under his initiative complex studies on the growing of yeasts on petroleum hydrocarbons were undertaken in the Soviet Union in 1963. As a result, by 1967 several experimental industrial plants for yeast bio-mass had been commissioned.

This bio-mass contains ~40% protein rich in amino-acids, as well as fats and vitamins. It is now being used as an animal food product but it is much more profitable to use these yeasts directly in human nutrition[3]. Naturally for this the beneficial constituents should be separated, freed from ingredients having doubtful nutritive value, and converted into an edible form with the necessary odour and taste.

The present review deals with the studies, mainly under the leadership of A. N. Nesmeyanov, directed to the solution of this problem.

2. PROTEINS AND NUTRITION

Most of the amino-acids needed for active life are obtained by man in the form of various proteins present in the products of plant and animal origin. The great protein deficiency makes the problem of increasing the effectiveness of the use of food proteins very acute and also that of acquiring new unusual sources of proteins which can be used for solving the problem of nutrition directly or through animal husbandry.

The first path—the use of proteins of unusual origin directly in human food—is the more promising, since shortening the nutritive chain increases the effectiveness of use of the proteins by a factor greater than five, that is, to bring about the same results much less protein must be made than in the production of protein food products by traditional methods via animal husbandry[1].

In addition, the separation from various sources of proteins with their simultaneous purification from extraneous substances, sometimes also harmful impurities, enables not only the biological value of the proteins when

used in nutrition to be increased but also food products to be obtained with the required amino-acid composition and with many other nutritive components of the necessary composition, taken in optimal amounts, that is, to convert the foodstuffs into a sufficiently powerful means of regulating the biochemical processes of the human organism.

Table 1. Principal oil-bearing crops.

Name	Mean protein content, %	Lipid content, %	World production, tonnes	Chief producing countries	Factors preventing use for food
Soya bean	42	20	35 000	U.S.A., China	inhibitors of trypsin, chemotrypsin, haemoglutinin, saponins
Groundnut	27	48	14 800	India, Senegal, Nigeria	aflotoxins, saponins
Cotton seed	30	30	20 600	U.S.A., India, U.S.S.R., Mexico, U.A.R., Brazil, Pakistan	gossypol, aflotoxins
Eastern sesame	25	50	1500	China, India, Sudan Mexico	oxalates, fibres
Sunflower seed	30	40	6840	U.S.S.R., Argentina, Uruguay, South Africa, Turkey	fibres

Apart from the usual animal and plant sources of proteins already recommended in nutrition, there is a large number of sources of sufficiently rich proteins, especially plant proteins, which are not widely used in nutrition owing to accompanying impurities. Table 1 gives information about the world production of oil-bearing crops containing large amounts of proteins, sufficiently rich in nutritive respects [4]. However, cotton seeds, which are rich in protein, contain the toxic substance gossypol, soya beans contain a series of growth inhibitors and inhibitors of digestive enzymes, castor plant seeds contain ricin and several allergins, and certain fruits contain glucosides which liberate cyanides and various inhibitors of biological processes [5]. Naturally, such protein products can be widely used in nutrition only after isolating the proteins and freeing them from the harmful impurities.

Table 2.

Components	*Torula*	*Candida tropicalis*	Components	*Torula*	*Candida tropicalis*
Dry substances, %	93.0	92.7	Vitamins, mg per kg		
Protein (total), %	34.0	43.6	thiamin (B_1)	80	3.16
Carbohydrates, %	34.0	21.0	riboflavin (B_2)	120	75
Fats, %	7.8	18.5	nicotinic acid (P-P)	800	180—200
Inorganic substances (ash), %	7.5	4.43	panthothenic acid (B_3)	47	150—192
			pyridoxin (B_6)	26	23

There are still richer sources of valuable proteins in the micro-world among the various algae, yeasts, and non-pathogenic micro-organisms [6-9]. Thus the widely distributed yeasts of the *Candida tropicalis* and *Torula* cultures, the basis for the growth of which are wastes from the alcohol industry and hydrocarbons, are rich sources of valuable proteins [10] (Table 2).

The exceptionally high rate of synthesis of proteins by micro-organisms and also the possibility of the organization of their production on a large scale by industrial methods offers great possibilities for rapidly increasing protein resources by microbiological means. The results given in Table 3 on the rate of accumulation of bio-masses by various organisms show that the rate of synthesis of proteins by micro-organisms is more than 1000 times the rate of synthesis of proteins by higher organisms.

Table 3. Time for a twofold increase in the biomass of growing organisms in the phase of maximal growth [11].

Organism	Time, h
Bacteria and yeasts	0.3—2
Fungi and chlorella	2—6
Grass and plants	144—288
Chicks	288—576
Piglets	576—864
Beef cattle	720—1500

It is noteworthy that unlike most plant proteins, which are often deficient in lysine, tryptophan, and methionine, the proteins which are synthesised by micro-organisms are considerably closer in composition to animal proteins and can be readily assimilated in an isolated state.

Despite repeated attempts to use various yeasts in human nutrition without separating the proteins from them, especially under unusual conditions (war, drought, etc.), microbiological products have not yet found wide application in nutrition without additional chemical treatment owing to several of their properties (flavour, odour, appearance).

One of the possible ways of using valuable foodstuffs which are present in microbiological raw material, and above all in various yeasts consists in the isolation from the hydrolysis products of the microbiological raw material of all the amino-acids suitable for use in human nutrition.

No less promising is the isolation from the micro-biological raw material of all the proteins it contains, their purification, and use directly in foods. In this instance all the factors (colour, odours, and extraneous flavour) which hinder the wide use of new sources of proteins in nutrition can be removed, which simultaneously increases the biological value of such proteins. For example, Mitsuda and coworkers [12] showed that the proteins isolated from *Micrococcus glutamicus* does not differ in amino-acid content from the protein of hen's eggs.

The amino-acid composition of the microbiological proteins isolated (Table 4) shows that they are much more balanced than plant proteins.

In determining the food value of the total proteins isolated by extraction with urea from a *Torula* strain it was found that the product isolated is assimilated and converted much better than entire yeast cells [13]. When chlorella with unbroken cells was used as a source of proteins similar results were obtained. Here it was found that > 40% of the nitrogen was not absorbed in the gastrointestinal tract [14].

The zooplankton of the Pacific Ocean can be a vast source of proteins [15], and their role for increasing the protein resources becomes real after the development of

accessible and economically favourable methods of separation and purification of proteins present in marine microorganisms.

The need for the thorough purification of microbiological proteins destined for food purposes is also confirmed by the investigation of the biological value and harmlessness of the protein–vitamin concentrate obtainable from yeasts cultivated on hydrocarbons and at present usable only as animal food [16,17].

Table 4. Amino-acid composition of proteins in % of the sum of the ten most important amino-acids.

Amino-acid	Products								
	meat (pork)	dried milk (fat-free)	whole egg	protein of *Micrococcus glutamicus*	protein of the yeast *Torula*	white bread	oatmeal	ground-nuts	corn-flakes
Arginine	11.8	6.0	10.3	14.4	—	9.5	12.3	30.1	4.4
Valine	10.7	13.3	12.1	14.1	8.8	15.9	13.1	9.7	12.2
Isoleucine	9.9	10.5	9.9	11.1	13.4	12.0	9.7	8.3	9.3
Leucine	18.4	19.5	15.9	17.3	18.2	20.4	19.0	14.7	39.2
Lysine	16.8	16.3	13.1	12.3	21.0	7.3	8.1	8.7	1.8
Methionine	5.5	4.9	6.1	3.8	1.2	3.8	4.6	2.1	4.9
Thionine	8.9	8.8	8.6	9.2	12.8	8.9	8.7	5.7	8.5
Tryptophan	2.8	3.1	2.9	2.8	2.4	3.7	2.8	2.6	1.5
Tyrosine	6.9	8.3	7.2	5.4	10.0	5.7	7.7	6.5	4.6
Phenylalanine	8.3	9.4	9.4	9.3	11.9	14.1	14.2	11.4	13.5

The extraction and purification of proteins from microbiological raw materials are also necessary for the subsequent creation from them of edible forms suitable for human beings. Most of the products for feeding human beings have a complex structure consisting of three main elements—fibres, films, and gels, which can be obtained and even now are being made for technical purposes in industry [18] from proteins which are polymers of α-amino-acids.

Proteins, like mixtures of amino-acids, are white powders, almost devoid of odour and taste, of little use in this form for food. However, the complex of physicochemical properties of proteins allows any structural elements of the usual nutritive forms to be obtained from them and new nutritive forms based on them to be created, as shown below.

As is well known, after fermentation and separation from the culture medium the bio-mass contains many substances of nutritive value: up to 40% (on the dry weight) of proteins, a certain amount of free amino-acids, fats, polysaccharides, vitamins, nucleic acids, and various other compounds. From the chemist's viewpoint a single-cell organism is a complex system consisting of polymers of three types and a large number of low-molecular-weight compounds entering both into the composition of cell walls, membranes, and other structural elements of cells and also found in protoplasm.

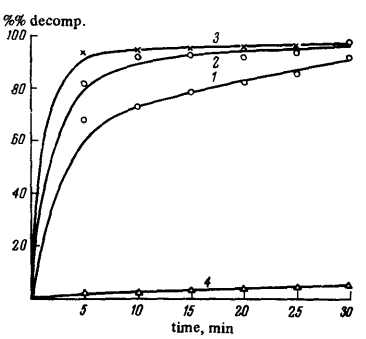
Owing to the semipermeable nature of the cell membranes and other structural formations of the cells, part of the low-molecular-weight compounds—inorganic salts, vitamins, free amino-acids, and part of the lipids—can be separated from the cell material without destroying the cell and its structural elements.

In accordance with their chemical nature, proteins usually dissolve comparatively readily in water or aqueous salt solutions at various pH values, depending on the nature of the protein, and the resulting solutions can be isolated pure. However, owing to the insolubility of the outer sheath of unicellular organisms and the polymeric nature of the proteins their isolation in a pure form without destruction of the cell membranes is almost impossible.

In the literature there are several descriptions of methods of extracting native proteins from microbiological material in which the foremost aim pursued was to retain the enzymic activity of the proteins, their supermolecular structure, and also to obtain narrow protein fractions and, if possible, individual proteins [19-21]. These methods are usually distinguished by low reproducibility, complexity of the technical procedure, and low suitability for obtaining proteins in large amounts.

By using experience on the production of finely disperse aluminium for the synthesis of Ziegler catalysts for the polymerisation of ethylene, success was achieved in creating a method of breaking down the cell material in sufficiently large amounts (1 kg of dry material per operation). As a result of a large number of experiments it was found that at 10–15°C there is almost complete destruction of the cell walls in 15–20 min.

It was found that the effectiveness of the destruction of the cell walls depends on the nature of the medium in which the destruction is carried out; thus the Figure shows the change in the degree of destruction of the cell walls, calculated from the results of electron microscopy in different media depending on the time and temperature.



1) Hexane +7°C; *2*) hexanes −70°C; *3*) methylene chloride −70°C; *4*) water, +2°C.

As the Figure shows, water is quite unusable for these purposes. The most suitable medium for the destruction of the cell walls was methylene dichloride, widely employed in the production of acetate silk. The destruction is just as effective in other low-boiling dehydrated organic solvents: diethyl ether, acetone, alcohol, etc. The great merit of the method is its universality which allows proteins to be obtained from various microbiological and plant sources.

The destruction of cell membranes in methylene dichloride, in which alkanes and lipids dissolve readily, is accompanied by effective extraction of fats and hydrocarbons from the microbiological material and also of fat-soluble vitamins, which can then be isolated from the extractant and used. Complete extraction of the lipids greatly facilitates the further separation of the proteins and ensures a higher degree of purity of the final product.

After thorough removal of the organic solvent the broken-down cell material can be used for the isolation of nucleic acids and proteins.

Nucleic acids, which as a result of enzymolysis are converted into nucleotides [22] from which sodium inosinate and guanylate—the best taste-developing additives—are removed in the form of nucleoprotides by extraction with 10% NaCl. The proteins are transferred into the solution after extraction of the nucleic acids by treatment of the disrupted cell material with dilute alkali solutions (0.2M NaOH) and are purified by reprecipitation with hydrochloric or acetic acid or by electrolysis. The residues of the cell walls and other structural fragments of the cells in the isolation of the nucleic acids and proteins are separated from the solutions by centrifuging or filtration.

Table 5. Amino-acid composition of microbiological proteins and proteins of animal origin.

Amino-acid	Mouse actin	Casein	Protein of the yeast *Candida tropicalis*	Protein from *Saccharomyces cerevisiae*	Protein from *Micobacterium rubrum*	Protein from chlorella
Alanine	5.7	3.4	5.7	6.2	8.2	7.0
Arginine	5.9	3.9	3.9	4.2	8.1	4.1
Aspartic acid	9.8	7.6	10.6	10.0	7.4	7.8
Valine	4.4	5.7	5.4	5.5	7.0	3.4
Histidine	2.3	2.6	2.2	2.1	1.6	1.2
Glutamic acid	13.3	20.3	11.5	12.6	12.2	9.6
Glycine	4.7	2.1	4.2	4.4	4.0	4.7
Isoleucine	6.8	5.8	5.7	5.4	3.9	2.3
Leucine	7.4	7.1	8.8	6.9	7.3	5.3
Lysine	6.8	8.1	7.2	9.2	3.2	5.7
Methionine	4.0	2.3	2.2	1.2	1.6	1.8
Proline	4.6	6.9	3.6	4.0	2.2	3.6
Serine	5.3	5.7	3.8	5.2	2.5	3.5
Tyrosine	5.2	7.3	4.4	3.6	1.9	2.9
Threonine	6.3	4.4	4.1	5.4	4.1	4.1
Tryptophan	1.8	1.5	1.5	1.3	1.2	1.3
Phenylalanine	4.3	4.1	5.4	4.7	3.5	3.0

Note: The data for mouse action and casein are given in the Ajinomoto catalogue, Part 4, 1965. The amino-acid analysis of the microbiological proteins was obtained on an automatic analyser of Czechoslovak manufacture. The results for the last two products are rather low, owing to their containing carbohydrate impurities.

The yield of proteins in laboratory experiments is 65–75% (25–29% of the dry weight) at a purity of 80–95%. The protein products obtained do not contain mineral impurities (ash < 0.5%) or nucleic acids (traces of phosphorus) or organic impurities of a lipid or hydrocarbon nature. The only impurity in the product is 10–15% oligosaccharides entering into the composition of the cell walls, which can be removed by additional purification if necessary.

The amino-acid composition of the total proteins obtained (see Table 5), especially from yeast cultures, shows the exceptionally high value as a future source of rich nutritive proteins, since they are very similar in composition to the best proteins of animal origin (proteins of milk, meat, etc.).

The determination of the concentration in the initial material and in the liberated proteins of the three limiting amino-acids—tryptophan, methionine, and lysine—and also the determination in them of the available lysine convincingly confirms that in the separation and purification the biological value of the microbiological proteins is greatly increased (Table 6).

Table 6. Amino-acid contents of microbiological raw material and of the proteins isolated, obtained on its basis.

Name of initial material	Tryptophan, % calculated on proteins		Methionine, % calculated on proteins		Total lysine, %, calculated on proteins		Available lysine %, calculated on proteins		Ratio of available to total lysine	
	initial material	total proteins	initial material	total proteins	initial material	total proteins	initial material	total proteins	initial material	total proteins
Candida tropicalis	0.88	1.52	1.33	2.10	6.60	7.40	5.47	6.82	0.82	0.92
Saccharomyces cerevisiae	0.93	1.27	1.37	1.75	8.78	9.20	6.25	7.92	0.71	0.86
Micobacterium rubrum	0.83	1.20	1.42	1.82	4.51	5.18	3.16	3.59	0.70	0.69
Chlorella	1.51	1.53	1.98	2.10	7.53	5.30	4.52	4.55	0.60	0.85

It is quite natural that the possibility of using such isolated proteins directly for human nutrition will be determined after detailed biomedical investigations both of proteins themselves and of new food products based on their use. In their physicochemical properties the isolated proteins from yeast cultures are very similar to casein and completely suitable for obtaining granulated food products of the artificial-albumen caviar type, the method for making which was developed in the Institute of Organoelemental Compounds. The specimens of black granular roe obtained by using yeast proteins did not differ in either physico-mechanical or organoleptic properties from the roe obtained from milk casein.

3. AMINO-ACIDS

In recent years important results have been obtained in studying human nutrition with mixtures of amino-acids, although much still remains to be done. It seems definite that in maintaining the nitrogen balance of the human organism it is immaterial whether the person is fed with proteins or the mixtures of the constituent amino-acids.

Table 7. Amino-acid composition of a diet.

Amino-acid	Quantity, g day^{-1}	Amino-acid	Quantity, g day^{-1}
Isoleucine	1.78	Phenylalanine	2.42
Leucine	2.60	Tyrosine	0.66
Lysine	3.60	Threonine	1.21
Methionine	1.88	Tryptophan	0.62
Cysteine	0.31	Valine	1.78

Many investigations on the prolonged feeding of people with synthetic diets have been published recently [23–28]. As an example there is the amino-acid composition of the diet [23], used for feeding 22–25 year old men (Table 7). The remaining (replaceable) nitrogen was given in the form of a 1 : 1 (by weight) mixture of glycine and diammonium citrate. Evidently this mixture is the best source of exchangeable nitrogen [29–31].

The use of such diets no longer in medicine but for food purposes can be limited on the one hand, by the need for their texturing and culinary treatment, and on the other by the possible high cost of individual natural amino-acids. As regards the texturing, the studies which will

be described below have shown that this obstacle can be overcome. As regards cost, progress in the synthesis of amino-acids achieved in recent years gives a basis for hoping that there will be no significant difficulties here.

A very promising method for obtaining mixtures of edible amino-acids is by growing unicellular micro-organisms (usually yeasts on carbohydrate or hydrocarbon raw material), hydrolysis of the proteins thus obtained to amino-acids, and their isolation in pure form.

The growing of yeasts has now been developed very well and is carried out on an industrial scale. The bio-mass thus obtained contains ~40% proteins. The action of proteolytic enzymes on this bio-mass leads to the hydrolysis of the protein molecules [32].

The sum of chromatographically pure amino-acids can be isolated from the product thus obtained. To do this displacement ion-exchange chromatography is used [33]. The solution is passed successively through cation-exchange and anion-exchange resins and the amino-acids, as amphoteric compounds, are separated from all the other impurities which are not amphoteric. The product is a white powder completely soluble in water. The amino-acid composition corresponds to the amino-acid composition of the initial enzyme hydrolysate. The change of the amino-acid composition in the desired direction can be brought about by addition of a little of the pure amino-acids. In this form the product can be used as a basis for synthetic meat and other edible products, for constituents of synthetic diets, and also in various branches of medicine.

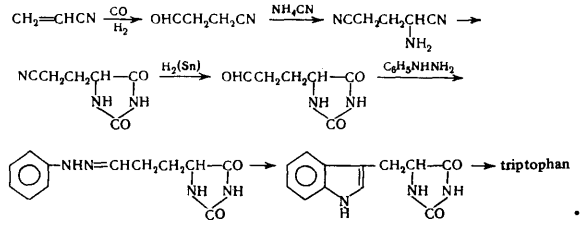
Many amino-acids are obtained on an industrial scale by microbiological means, by growing microbes which produce certain amino-acids on culture medium. The best results are obtained for *L*-glutamic acid and *L*-lysine [34]. The raw material usually employed is glucose or the cheaper molasses with the addition of ammonium salts as a source of nitrogen and of other salts required by the micro-organisms. However, there are results showing that alkanes can also serve as a source of carbon for the micro-organisms which produce amino-acids [35]. The most important precursor of glutamic acid—α-ketoglutaric acid—is isolated in the medium on growing certain strains of yeasts on a mixture of normal hydrocarbons of composition C_{14}–C_{26}. More than 800 g ketoglutaric acid are obtained from 1 kg alkanes [36].

In several instances a purely chemical synthesis is also economically suitable. An example is the production of *L*-lysine from caprolactam, effected by the Dutch firm of Stamicarbon on an industrial scale [37].

The industrial production of methionine in the USSR is based on the following scheme [38]:

$$CH_2{=}CHCHO + CH_3SH \rightarrow CH_3SCH_2CH_2CHO \xrightarrow{NH_3,KCN} CH_3SCH_2CH_2CHCN \rightarrow$$
$$\rightarrow CH_3SCH_2CH_2CHCOOH$$

In Japan there is a combined method for obtaining glutamic acid and tryptophan from acrylonitrile [39]. The part relating to tryptophan includes the following stage:



As regards threonine, the best method for making it can be considered to be the Akabori synthesis carried out on an industrial scale in Japan. The reaction consists in the interaction of copper glycinate with acetaldehyde in alkaline medium [40]. As our last investigations showed [41], a necessary condition for the occurrence of this reaction is the formation of a Schiff base, since if *L*-alanine is introduced into the reaction instead of glycine the rate of racemisation of its copper complex is very greatly increased in the presence of acetaldehyde and the methyl-threonine obtained is always racemised.

On the other hand, *NN*-dimethyl-*L*-alanine not only does not racemise in the presence of acetaldehyde but does not even give a hydroxyamino-acid.

In 1957 Nesmeyanov and Freidlin developed a new method of synthesis of ω- and α-halogeno-acids on the base of telomerisation. The amination of these compounds gives the most varied aliphatic, aromatic, and heterocyclic amino-acids [42].

Several new syntheses of the most important unsubstituted amino-acids have been described recently [43]. The most promising for industry of the synthesis is based on aliphatic nitro-compounds. The key substance in all these syntheses is nitromethane—a cheap and accessible substance. Nitromethane can be readily converted [44] into methyl nitroacetate, $O_2NCH_2CO_2CH_3$, a very reactive compound having a carboxyl group and a potential amino-group.

In the Institute of Organoelemental Compounds of the Academy of Sciences of the USSR and the Leningrad Pedagogic Institute syntheses of amino-acids from the nitroacetate have been developed, based on condensation with aldehydes, addition to an activated double bond, and alkylation of alkyl halides. Thus in the condensation of nitroacetic ester with acetaldehyde in the presence of catalytic amounts of sodium acetate α-nitro-β-hydroxybutyric ester is formed. Quantitative yield of the reaction product is observed when it is carried out in the absence of a solvent and at 10–12°C.

$$CH_3CHO + O_2N{-}CH_2COOCH_3 \xrightarrow{CH_3COONa} CH_3{-}\underset{\underset{OH}{|}}{CH}{-}\underset{\underset{NO_2}{|}}{CH}{-}COOCH_3 \xrightarrow[CH_3COOH]{H_2(Pd/C)}$$
$$\rightarrow CH_3{-}\underset{\underset{OH}{|}}{CH}{-}\underset{\underset{NH_2}{|}}{CH}{-}COOCH_3 \xrightarrow{H^+} DL\text{-threonine.}$$

The reduction of α-nitro- β-hydroxybutyric ester is effected over Pd catalyst in an autoclave [45].

Other α-amino-acids (leucine [46], phenylalanine [47], etc.) are also obtained when almost the same sequence of reactions is used:

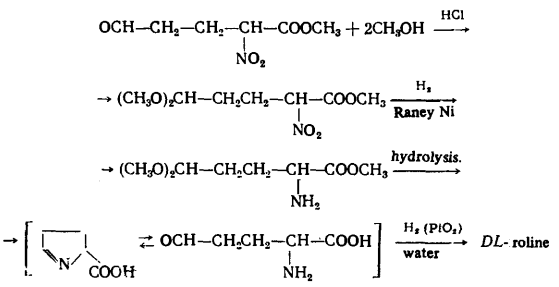
$$R{-}CHO + O_2N{-}CH_2{-}COOCH_3 \rightarrow R{-}\underset{\underset{OH}{|}}{CH}{-}\underset{\underset{NO_2}{|}}{CH}{-}COOCH_3 \xrightarrow{-H_2O}$$
$$\rightarrow R{-}\underset{\underset{NO_2}{|}}{CH}{=}C{-}COOCH_3 \xrightarrow[2)\ \text{hydrolysis}]{1)\ H_2\ (\text{Raney Ni})} R{-}\underset{\underset{NH_2}{|}}{CH_2}{-}CH{-}COOH\,.$$

The addition of methyl nitroacetate to an activated double bond in the presence of bases was proposed as the basis of the synthesis of *DL*-proline [48]:

$$O_2N{-}CH_2COOCH_3 + CH_2{=}CH{-}CHO \rightarrow OCH{-}CH_2CH_2{-}\underset{\underset{NO_2}{|}}{CH}{-}COOCH_3\,.$$

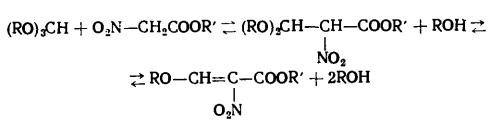
It appeared that when the addition product is hydrogenated over Raney nickel catalyst *DL*-proline is formed, but in low yield and badly contaminated with impurities. This made necessary the preliminary protection of the aldehyde group, which under conditions of reducing alkylation can take part in side-reactions.

The final scheme for making *DL*-proline free from impurities is:

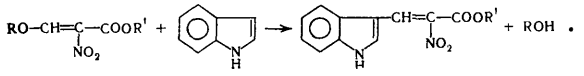


An intermediate in the synthesis of *DL*-proline is Δ^1-pyrrolidonecarboxylic acid which is known to participate in the biosynthesis of proline.

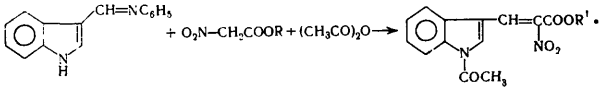
An original method for the synthesis of *DL*-tryptophan was also recently developed[49]. It is based on the condensation of indole with esters of β-alkoxy-substituted α-nitroacrylic acids. The latter is now available and readily obtained by the reaction of a nitroacetic ester with esters of orthoformic acid:



The reaction of indole with α-nitro-β-alkoxyacrylic esters takes place very smoothly and in the absence of catalysts and solvents it leads to an ester of α-nitro-β-(3-indolyl)acrylic acid:

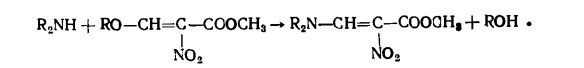


N-Acyl derivative of the same ester was obtained in the reaction of the anil of indolaldehyde with a nitroacetic ester in acetic anhydride[50]:



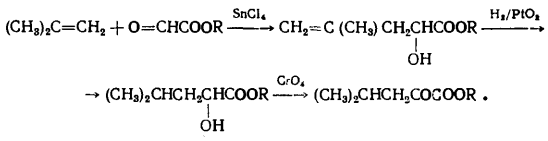
The reduction of both esters and the hydrolysis led to *DL*-tryptophan.

The reaction of α-nitro-β-alkoxyacrylic esters with amines takes place similarly to the reaction with indol[51]. Various substituted esters of β-amino-α-nitroacrylic acid—precursors of αβ-diamino-acids—are formed thereby:



One of the most important diamino-acids—lysine—was obtained by the addition of nitroacetic ester to nitrobutadiene followed by hydrolysis and saponification[52]. The synthesis of *DL*-leucine[53] and *DL*-glutamic acid[54-56] from nitroacetic ester was also described. The path to leucine goes through the alkylation with an alkyl halide, and glutamic acid is obtained after addition to an acrylic ester.

The problem of how much α-amino-acids can be replaced in the diet by the correspondingly constructed α-hydroxy- and α-keto-acids is very interesting. In the last example there is additional interest in that α-keto-acids do not have an asymmetric α-carbon atom. In this connection mention must be made of the interesting synthesis of a keto-analogue of leucine[58,59], by the scheme:



Naturally racemic amino-acids are obtained in the chemical synthesis. The examples of asymmetric synthesis described so far have gone no further than laboratory investigations[57].

The food value of the racemates of amino-acids is naturally lower than that of the natural optically active forms.

The most promising way of resolving the racemates of α-amino-acids is the use of optically active ion-exchange resins, which have become available as the result of investigations conducted in the Institute of Organoelemental Compounds of the Academy of Sciences of the USSR[60]. On the basis of copolymers of styrene with divinylbenzene having a three-dimensional lattice structure of varying density according to the divinylbenzene content, dissymmetric resins containing various optically active compounds (*L*- and *D*- forms of α-amino-acids, their esters and amides, optically active amines, etc.) as ionogenic groupings with an exchange capacity of 3–3.5 mg-equiv. litre^{-1} were synthesised.

On using such exchangers for the resolution of α-amino-acid racemates there is strong enrichment of the eluates by one of the atipodes and in some instances their complete separation[61]. Continuation of the investigations in this direction undoubtedly provides a suitable method of isolating both the *L*- and *D*-isomers of α-amino-acids which gives this method great advantages over others. The *D*-isomers of the *L*-amino-acids thus obtained should find application for carrying out biomedical investigations; after racemisation they can be returned to the separation which allows the total quantity of synthetic α-amino-acids to be used for food purposes.

As regards the analysis of the optical purity of mixtures of amino-acids polarimetric methods are suitable for solving the problems posed by the specific features of the method itself (additivity of total rotation, low sensitivity, and accuracy). It has been shown[62-64] that several compounds which contain asymmetric carbon atoms (amino-acids, hydroxy-acids, alcohols) can be converted into diastereoisomeric esters as a result of the treatment by a corresponding optically active reagent.

The diastereoisomers obtained are chromatographed in the gas phase. This gives a satisfactory separation, both between the stereoisomers and from other substances, including optically active ones. The possibility of a quantitative analysis is determined by the optical purity of the second component used for obtaining the diastereoisomers. Hence it is easy to reach an accuracy exceeding 0.5 rel.% at a sensitivity (in the sense of the possibility of discovering an opposite enantiomer) of 0.2 rel.%[65].

These principles were used in the analysis of protein enzymolysates and hydrolysates. It was shown that the main mass of amino-acids which are present in the enzyme hydrolysate of yeasts are the natural *L*-isomers. The gas chromatographic determination of the ratio of the optical isomers was first used in studying the Akabori reaction. It was found that the copper complex of *L*-alanine reacts with an excess of acetaldehyde and racemic *threo*- and *erythro*-methylthreonines are formed.

The rate of racemisation of the initial substance was less than the rate of formation of the final racemic products. The total experimental results suggested that the reaction proceeds through the copper complex of the imine (Schiff base) which is rapidly racemised by the formation of a carbanion, which reacts with acetaldehyde [41].

4. CHEMISTRY OF ODOUR AND TASTE

The successful progress of the work on the synthesis of food products made it necessary to start investigations of the chemistry of odour and taste in 1963.

Like every purified polymer, the protein constituting the basis of the artificial food has hardly any odour or taste. To make it appetising, it must be given the texture, appearance, flavour, and odour of some particular food product.

The taste of most natural products can be imitated by combinations of four dominating taste sensations, acid, salt, hot, and sweet.† The necessary taste sensations can be matched by combinations of chemicals. The use of natural flavour intensifiers such as sodium *L*-glutamate [69], disodium inosine-5'-monophosphate and disodium guanosine-5'-monophosphate [70] and various others greatly improves the flavour of the product.

The imitation of odour is one of the most complex tasks in the problem of creating synthetic food. Unfortunately it is still impossible to synthesise aromatic compositions with given properties. Attempts to create a theory of odour [71-85] have been made repeatedly [71-85]. That which is best known is the stereochemical theory of Amoore, in which a geometric correspondence of the form and dimensions of the molecules with definite vacancies on the surface of the receptor was postulated. A classification of odours into seven types was proposed: flowery, ethereal, camphor, musky, minty, acrid, and putrid [76,77]. This theory was subjected to thorough criticism [86,87] which was admitted to be correct by Amoore himself, and is now abandoned.

Dyson and Wright's theory [78-82] had many supporters. Wright thought that the sensation of odour arises as a result of vibrational movements proper to the molecules of the odorant and sought to find a correlation between the infrared spectrum of a molecule in the 500–50 cm^{-1} range and its odour. However, under the pressure of the experimental facts Wright admitted that the specificity of the odour could not be connected with the characteristic frequencies of the molecule in the far infrared range [88].

The most promising theory at present is the "membrane puncture" theory developed by Davies and Taylor [83-85] by analogy with the theory of flavour proposed earlier by Beidler [66,89]. According to this theory the corresponding impulse of an olfactory receptor can be the result only of an energetically rich process therefore it is improbable that the primary source of the impulse would be the energy of adsorption or dissolution. The mechanism of the penetration of the odorant to the receptor surface includes the adsorption of the odorant molecule from the mucus surface layer which covers the olfactory surface, then diffusion through the water-mucus layer and adsorption on the surface of the membrane of the olfactory cells, its phosphate-lipid protein layer. The adsorption on the surface of the cell membranes leads to the breakdown of the ordering of its surface layer. This brings about a change in potential existing between the wall of the neurone and the external medium. An ionic current arises because of the transfer of K^+ and Na^+ ions and consequently an electrical impulse, that is, a response to the odorant.

However, this theory is still insufficiently developed for the prediction of odour on the basis of the physicochemical properties of molecules. In connection with this, the starting point in the creation of aromatic compositions is the interpretation of the odour of natural food products [90].

The concentration of odour in a food product is negligible; it usually amounts to a few parts per million, and the number of components often exceeds 200. Therefore an investigation of the nature of odour is unthinkable without specially fine methods of analysis.

In the Institute of Organoelemental Compounds of the Academy of Sciences of the USSR the task was attempted of developing standard free gas chromatographic methods of identifying various classes of organic substances. For this purpose it was necessary to find a relation between the gas-chromatographic behaviour and the structure of the compound. Such a task could be solved only if well reproducible gas-chromatographic parameters existed. The Kovats retention index [91] was first used for the identification of the components of odour; it has good reproducibility [92] and can be used successfully in work on polar stationary phases, even such as ββ'-hydroxypropionitrile [93].

The investigations made showed that there is a marked relation between the index and the structure of the compound investigated, namely the number of carbon atoms, the number of functional groups, and the boiling point. The existence of such regularities gives the possibility of predicting gas chromatographic parameters and consequently of identifying a substance in the absence of a standard.

As an example there is the standard-free method of identifying n-aliphatic amines [94-96], which is now unique in studying the amines in an odour. An analysis of a mixture of primary, secondary, and tertiary aliphatic amines is among the most difficult of gas chromatographic tasks owing to their adsorption on solid carriers and frequent instances of the superposition of chromatographic zones.

This problem was solved by using the known ability of primary and secondary amines to form a hydrogen bond with solid alkali carried on a sorbent [97,98]. The heat of formation of a hydrogen bond found from the chromatographic results and equal for primary amines to $\Delta H = -6.3$ kcal $mole^{-1}$ and the secondary to $\Delta H = -3.6$ kcal $mole^{-1}$ includes a considerable contribution to the value of the index. The retention indices of the tertiary amines on various columns changes slightly.

Further study of the gas chromatographic behaviour of amines allowed a series of equations to be found (Tables 8 and 9) connecting the index with the physicochemical properties of the amines.

Table 9 gives equations for the variation of the index with the boiling point for the primary aliphatic amines. For secondary and tertiary n-aliphatic amines such a relation is observed only on a column with liquid paraffin +2% KOH. The equation has the form $I_{100}^{lp} = 4.0\ (t_k + 85)$ for secondary and $I_{100}^{lp} = 4.0\ (t_k + 79)$ for tertiary amines.

† Apart from the taste sensations listed there are various others, for example, cold, pungent, caustic, metallic, soapy, etc. The existing idea of the presence of only four taste sensations and of four corresponding receptors is inaccurate. In reality each taste receptor has a specific spectrum of responses to tasty substances [66-68].

Optimal conditions were found similarly for the gas chromatographic analysis of mixtures of n-aldehydes, methyl ketones, and α-unsaturated aldehydes[99]. The data needed for the identification are given in Tables 10 and 11.

Table 8. Equations connecting the retention indices with the number of carbon atoms in the molecule of aliphatic amines of normal structure*.

Primary amines, $n \geqslant 2$	Secondary amines, $n \geqslant 4$	Tertiary amines, $n \geqslant 9$
$I^{ts}_{100}=100n+283$	$I^{ts}_{100}=100n+176$	$I^{ts}_{100}=85n+162$
$I^{lp}_{100}=100n+386$	$I^{lp}_{100}=100n+176$	$I^{lp}_{100}=86n+146$
$I^{tw}_{100}=100n+461$	$I^{tw}_{100}=100n+266$	$I^{tw}_{100}=85n+183$
$I^{peg}_{100}=100n+568$	$I^{peg}_{100}=100n+330$	$I^{peg}_{100}=85n+200$

*n is the number of carbon atoms in the amine; I^{ts}_{100}, I^{tw}_{100}, I^{peg}_{100} and I^{lp}_{100} are the indices of the amines at a temperature of 100° in columns with tristearin (ts), Tween 80 (tw), polyethylene glycol-1000 (peg), and 5% liquid paraffin +2%KOH (lp) on "Novator" detergent.

In the general form the scheme of analysis leads to the following: after the concentration of the volatile substances from the food product a definite class of organic compounds is extracted with the aid of chemical reactions. For the gas chromatographic analysis of the mixture of substances of each class a system of three or four columns of different polarity was selected to rule out errors due to the superposition of peaks on the chromatograms. The subsequent identification was made on the basis of the values of the indices and their relation with the number of carbon atoms and boiling point of the test substances.

Table 9. Variation of the retention indices with the boiling point of the amine (t_b).

Equation	Amine	t_b, °C, calculated from I^{ts}_{100}	I^{tw}_{100}	I^{peg}_{100}	t_b, °C (published data)
$I^{ts}_{100}=4.0\ (t_b+91)$	propylamine	54	55	55	45—50
	butylamine	80	80	80	78—79
	pentylamine	104	105	105	104
$I^{peg}_{100}=4.0\ (t_b+116)$	hexylamine	131	130	130	130
	heptylamine	155	155	155	155
$I^{tw}_{100}=4.0\ (t_b+135)$	isopropylamine	35			33—34
	isobutylamine	69			68—69
$I^{peg}_{100}=4.0\ (t+164)$	isopentylamine	96			95
	vinylamine	56			56
	allylamine	54			53

The extract of the odour usually contains many organic substances belonging to different homologous series. In this instance the study of the relation between the index and the structure of the compound assists the identification. The additivity of the contributions reflecting the specific interaction of each functional group with the substrate of the column was established. It appeared that if a substance has several functional groups the total contribution to the value of the index will be equal to the sum of the contributions of all the functional groups. Table 12 gives the equations found for the calculation of the indices of the substances with several functional groups.

Table 10. Equations connecting the retention indices with the number of hydrocarbon atoms in the molecule of monocarboxylic acids*.

Alkanals	2-Alkenals	Methyl ketones
$I^{apm}_{125}=100n+188$	$I^{apm}_{125}=100n+251$	$I^{apm}_{125}=100n+171$
$I^{pega}_{125}=100n+555$	$I^{pega}_{125}=97n+732$	$I^{pega}_{125}=100n+558$
$I^{apm}_{50}=100n+179$	$I^{apm}_{50}=100n+243$	$I^{apm}_{50}=100n+167$
$I^{\beta\beta}_{50}=82n+820$	$I^{\beta\beta'}_{50}=81n+993$	$I^{\beta\beta'}_{50}=81n+856$

*n = number of carbon atoms in the compound; I^{y}_{x}, where x is the temperature of the analysis and y the liquid phase: Apiezon-M (apm), polyethylene glycol adipate (pega), and hydroxydipropionitrile ($\beta\beta'$) on celite.

In an analysis on a polar column the contribution to the index which characterises a functional group rises sharply whereas the contribution introduced by the peculiarities of the structure of the carbon skeleton does not change appreciably. In this connection a very useful quantity for the identification is ΔI, the difference between the indices of a single substance on polar and non-polar columns. ΔI estimates the contribution of a functional group to the value of the index.

Table 11. Variation of the retention indices with the boiling point of monocarboxylic compounds.

*dnp = dinonyl phthalate.

From Table 13, clearly despite the difference in the value of the indices of the substances of normal and isostructure the value of ΔI for a single functional group is almost the same.

A comparison of the results of an analysis on two phases—polar and non-polar immediately gives the possibility of finding a substance with the same functional group.

A knowledge of the functional group in turn allows the number of carbon atoms (n) and boiling point of the compound being determined to be found, by using the appropriate equation.

Table 12. Relation between the retention index and the structure of the substance being analysed.

Equation for variation of the index with the number of carbon atoms $n \geqslant 2$ and the nature of the functional group	Functional group	dI*
For tertiary amines $I_{100}^{peg} = 100\,n + 586$	$-NH_2$	586
For diamines $I_{100}^{peg} = 100\,n + 586.2$		
For secondary amines $I_{100}^{peg} = 100\,n + 330$	>NH	330
For tertiary amines $I_{100}^{peg} = 85\,n + 200$	>N—	200
For alkenes-1 $I_{125}^{apm} = 100\,n - 17$	$>C=CH_2$	−17
For n-alkanals $I_{125}^{apm} = 100\,n + 188$	$-C(=O)H$	188
For ω-alkenals $I_{125}^{apm} = 100\,n - 17 + 188$	$H_2C=C<$ …$-C(=O)H$	
For α-alkenals $I_{125}^{apm} = 100\,n + 251$	$>C=C-C(=O)H$	251
For methyl ketones $I_{125}^{apm} = 100\,n + 171$	>C=O	171
For n-mercaptans $I_{60}^{se**} = 101\,n + 297$	—SH	297
For n-sulphides $I_{60}^{se} = 91\,n + 330$	—S—	330
For n-disulphides $I_{130}^{se} = 93\,n + 546$	—S—S—	546

*∂I is a quantity characterising the interaction of the functional group with the substrate of the column.
** = silicone elastomer SE-30.

*$\Delta I^{peg\text{-}tw}$ is the difference in the indices of the amine on columns with 10% polyethylene glycol-1000 and Tween-80.

The methods of identification considered above relate to isothermal conditions of analysis. Evidently, the analysis of the components of an odour may sometimes be more convenient by use of gas chromatography with programmed temperature. Therefore attempts were repeatedly made to use isothermal data for identification under conditions of programmed gas chromatographic analysis. A series of empirical formulae was found [100,101].

Recently success was achieved in relating theoretically the isothermal index with parameters which can be determined experimentally [102,103]. A formula was obtained:

$$I_{t_0/\beta} = I_{t_0} + \frac{\beta\tau_x}{2}\frac{\partial I}{\partial t} \qquad (1)$$

in which $I_{t_0/\beta}$ is the index of the test substance with linear programming of the column temperature as a rate β, deg min^{-1}, from an initial temperature of t_0; I_{t_0} the isothermal index at temperature t_0, τ_x the time for the loss of the test substance under the programming conditions, and dI/dt the temperature increment of the index per 1 deg.

Di-isobutylamine	0.3	0.1			
Unidentified secondary amines	2.3	6.4			

Formula (1) was verified on a large volume of experimental material and allows a substance to be identified in a programmed analysis from the values of isothermal indices.

The methods of identification developed allowed for the first time extremely valuable information to be obtained about the composition of amines and carbonyl compounds in the odours of various natural food products [104-108]. Tables 14–17 give the results.

It is interesting to note that the composition of the volatile components of cheeses have been intensively studied abroad but so far in every instance no more than 11 monocarboxylic compounds were found by gas chromatography [109-111], whereas 30 were identified with the aid of the standard-free method [112].

The use of analytical methods developed in the Institute of Organoelemental Compounds made it possible to establish for the first time that in the volatile components of food products which contain proteins there is a large number of organic bases. Table 15‡ gives the composition of the amines identified in the aroma of 4- and 10-month Russian cheese. During the storage of cheese there is an accumulation of heterocyclic bases. The proportions of some of them were determined by the absolute calibration method (Table 16).

Table 16. Accumulation of amines during storage of Russian cheese.

Substance	Concn. mg per kg cheese	
	4-months	10-months
Piperidine	1.5	50.0
2-Picoline	13.0	80.0
Pyridine	36.0	3.3
Triethylamine	6.0	3.0

The composition of the amines in the volatile components of soft caviar and salmon roes were determined similarly with the aid of standard-free gas chromatography [104,105].

The amines identified are shown in Table 17, which indicates that the relative proportions of the amines is rather specific for each foodstuff. Thus in the volatile components of soft caviar the pyridine content is 21 times that in salmon roe, in which trimethylamine predominates. This shows its organoleptic properties. On the basis of these results an imitation odour was created for synthetic soft caviar. On comparing the composition of the amines in the odour of such varied foodstuffs as caviar and cheese (Tables 15 and 17) the great similarity in the qualitative composition of the amines is seen [106]. This may be because both products contain proteins of animal origin which serve as the precursors of the amines.

The composition of the nitrogenous bases in the volatile components of the foodstuffs is extremely diverse. In addition to the primary amines, secondary and tertiary aliphatic amines are present. The presence of secondary and tertiary amines is somewhat unexpected. It is generally accepted that aliphatic amines are formed in the decarboxylation of amino-acids. However, only primary amines can arise in this manner; secondary and tertiary amines can be formed only as a result of alkylations, which, with the exception of methylation, are unknown. It was interesting to find whether these amines are products of the activity, or arise as a result of decomposition of the organism after the death. For this purpose the composition and kinetics of accumulation of the amines in the volatile components of rapidly growing organisms was studied. The lactic acid bacterium *Streptococcus lactis* was selected as the subject of the investigation.

Table 18 gives the composition of the amines identified in the volatile components of *Streptococcus lactis* at the stage of the logarithmic phase of growth. The organic bases were identified with the aid of the gas chromatographic method of analysis described above.

‡ Under the conditions of the analysis amines appearing on the chromatogram up to n-dodecane were identified.

As Table 18 shows, the total concentration of amines in the growth of lactic acid bacteria increases, their ratio in the mixture changes sharply, and the concentration of butylisopropylamine and tertiary amines with ten carbon atoms and b.p. 166°C increases [113]. This shows that in the exchange process the bacterial cell secondary and tertiary amines are synthesised, which suggests the existence of specific enzyme systems carrying out the process of synthesis of the amines. Hence a phenomenon

new in principle in biochemistry has been discovered—the synthesis of secondary and tertiary amines by living organisms.

The results of the analysis of the components of the vapour made at the Institute of Organoelemental Compounds of the Academy of Sciences of the USSR shows that under exceptionally thorough work with the aid of gas chromatography it was possible not just to obtain interesting results about the composition of complex aromas of foodstuffs but also to arrive at an understanding of the processes of formation of the food odours. The results obtained show that the problem of odour and taste can be solved successfully. Its solution will enable synthetic foodstuffs to be successful and accepted by people.

5. STRUCTURAL-PHYSICAL PROBLEMS OF ARTIFICIAL FOODS

The production of artificial food requires the solution of yet another great problem—the giving of the usable foodstuffs (of natural, artificial, or synthetic origin) of taste, odour and an attractive appearance. It must be emphasised that each of these factors plays an extremely important part and an underestimate of any of these can lead to the impossibility of admitting and assimilating the food even when its composition is ideal. It is quite evident that an unpleasant or even simply unfamiliar taste of a food provokes in any person an apprehension or even a refusal to use it. The same can naturally be said also about the odour of food.

However, the colour of food and its form are no less serious factors; their being unusual can bring about extremely unpleasant physiological sensations. For example, it was found that artificial soft caviar, the preparation of which was developed in the Institute of Organoelemental Compounds of the Academy of Sciences of the USSR [114-118], having the same composition, structure, and physical properties, exhibiting the same odour and flavour, but differing in colour, aroused greatly differing reactions in a meal. Whereas caviar with the natural colour (greenish grey, dark grey) was regarded as excellent, that coloured bright green was impossible to eat.

Therefore the giving to artificial food of taste and odour and also an attractive appearance was an important problem. It will be examined in greater detail.

It is usually thought that taste is determined by a combination of four sensations, namely, acid, sweet, salt, and hot. However, this is true only in relation to the chemical aspect of taste, since the taste receptors found in the cavity of the mouth actually perceive just these principal taste sensations. Hence this part of the problem of the creation of flavour is readily solved. It is sufficient just to select correctly the ratio of four carriers of these sensations, for example, salt, sugar, any food acid, and coffee.

It is much more difficult to solve another part of the problem of taste having a physical or physicochemical character, which includes above all the creation of a physical structure and definite complex of physical properties for the artificial food.

Actually, the taste sensations in eating are determined not only by the chemical action of the food on the taste receptors but also by the distribution of the sensations of acid, sweet, salt, and hot in relation to individual receptors and also by the mechanical action of the food on the tongue, palate, and teeth, the degree of wetting of the food by the saliva, and by the change in the physical properties of the food–saliva system during its interaction, by bringing about swelling and other physicochemical processes. All this requires a thorough physicochemical investigation of the substances used for preparing artificial foods. Here an investigation of structural and mechanical characteristics is of most value.

Since two of the main ingredients of food—proteins and polysaccharides—are high-molecular-weight substances, the structure-physical task of creating specific forms of artificial food seems [119] part of the general physicochemical problem of creating a desired structure and complex of physical properties for polymeric articles, that is, part of the problem which has occupied investigators working in the field of the physical chemistry of polymers for many years [120].

It must be particularly emphasised that processes of dissolution or dispersion of proteins or polysaccharides, their mixing with one another and with other foodstuffs, odour carriers, dyestuffs, etc. and also the formation of gels from such systems is hindered by a series of problems relating to the physicochemical theory of true and colloidal solutions of polymers. Among such problems there are, for example, the swelling and solubility of food polymers in water, fats and other solvents, the mutual solubility of proteins and polysaccharides, the surface properties of solutions and gels of these polymers, the formation of a structure in solutions of the polymers, the relation between various mechanical properties of the solutions and gels, and their composition and supermolecular structure.

Therefore the whole approach to the modern physicochemistry of polymers can be used for the development of procedures for the production of various forms of artificial food.

The preparation of a specific form of artificial food, for example, caviar, groats, meat, fish, etc. requires, on the one hand, the determination of the complex of structural and physical properties characteristic for the natural product, and on the other hand the development of procedures for the formation of artificial food exhibiting these characteristics. Whereas the first aspect of the problem requires the use of methods of polymer physical chemistry the second aspect seems closely connected with many technological procedures developed in the production of plastics, resins, polymer films, and polymer fibres, adhesives, and lacquers. Actually among foodstuffs there are a series of corresponding forms, namely, homogeneous and heterogeneous, liquid and solid systems (broths, milk, jelly, cheese), layer forms (confectionary), fibrous forms (meat, fish), granular forms (roe, berries, groats), etc. Here the structure can be fine or coarse (porous and frothy foods, emulsions, suspensions, stuffed foods, etc.) and mechanical or other physical properties are extremely varied.

Hence there is a very far-reaching analogy between food and commercial polymer goods allowing the enormous existing experience from the development of various polymers in a variety of articles to be widely used in the creation of one or another form of artificial food. In the development of procedures for the structuring and forming of artificial foodstuffs specific sanitary and hygiene requirements must be borne in mind.

The solution of the problems of artificial food required the development of a large complex of physicochemical investigations of proteins, polysaccharides, and compositions based on them. This is also of general interest for the physical chemistry of polymers. These include, for

example, the investigation of the properties of aqueous and oily solutions and the dispersion of individual food polymers and their mixtures, the study of the effect on these of liquid and gel-forming systems of substances which differ in nature (fats, vitamins, enzymes, sodium chloride, etc.) and also in conditions (temperature and pressure).

To create artificial macaroni and grain articles [121] it is necessary to give them a definite stability of form and volume since on boiling groats or macaroni swelling should occur, but not breakdown of the particles.

Corresponding investigations [122-126] led to the creation of articles of artificial food containing all the necessary nutritive substances (proteins, starch, etc.) with a special space lattice structure. This lattice, completely harmless for the organism, constitutes a negligible part of the mass of the food product but nevertheless gives it elasticity and strength, ensuring the retention of the entity on swelling in boiling water. This naturally gives to the product a certain quality of taste depending on the mechanical properties of the food.

From the physicochemical aspect these investigations led to interesting new results on the physicochemical properties of three-dimensional polymer structures, in particular the properties of the double lattice structures, for example, systems which contain two lattices simultaneously—gelatin and calcium alginate [127].

At present the most far-reaching physicochemical investigations relate to the production of artificial soft caviar. Taking this into account and also the special value of such a delicatessen product this subject will be discussed in greater detail.

In general the preparation of granular forms of artificial food products, for example, artificial groats, berries, roe, etc. leads to the preparation of granules of edible jelly of definite dimensions, chemical composition, and structure, and with the necessary physicochemical properties [128], the creation on these granules of a covering and their colouring the desired shade [123].

In accordance with the process developed for the preparation of artificial caviar various foodstuffs of animal, plant, and microbiological origin and also the products of chemical synthesis can be used. However, at present casein is used as the food raw material; it is a high-quality protein and the problem of its use for feeding is extremely urgent. The essence of the process is as follows. To prepare edible granulated gels, a hot solution of gelatin containing casein or other food substances is supplied dropwise into previously chilled vegetable oil or liquid paraffin.

The resulting granules are kept in the oil at 5–10°C until a gel with a modulus of elasticity of 10^4 dyn cm^{-2} is formed, after which they are separated from the oil and washed with cold water to free the surface from traces of the latter. The formation of gelatin gels is complicated here by the presence of a considerable proportion of casein and other foodstuffs, and also by sorption of oils by the protein components of the gel. Thus, sorption of hydrocarbons by the liquid paraffin leads to a significant change in the melting point, rate of swelling and mechanical properties of the granulated gels. The phase state of the initial mixture of foodstuffs, the conditions of formation, structure, and the corresponding complex of physicochemical properties of granulated gels is determined by the possibility of preparation of a high grade product. To study the effect of these factors on the properties of granulated gels simple and precise methods of determining the temperature range for their fusion, the rates of swelling, and pliability were developed [128] and also a method of investigating the mechanical properties of gels under conditions of uniaxial compression [129,130] and a method of determining the degree of swelling [131] were developed. The possibility of removing oil from the surface of granulated gels when these are washed with water depends significantly on the surface properties of the gel. Gelatin gels are very poorly wetted by water [132]. The introduction of globular proteins into them leads to a distinct change in surface properties, depending on the nature of the protein introduced [133]. The addition of egg albumen is accompanied by some increase in the hydrophobic nature of the gelatin gel, whereas the introduction of even small proportions of casein makes them hydrophilic.

Therefore unlike granules of pure gelatin gel, those of gelatin containing casein are readily washed by water from oil on remixing. The latter treatment of granular gels with aqueous extractants of vegetable tanning agents allows sufficiently definite dense and elastic walls of tanning products to be obtained. The homogeneity of the covering here is determined by the degree of removal of oil from the surface of the granules and by the surface properties of the gel. Aqueous extracts of green tea or the wastes from tea production are used for tanning the granules. [114,123] The colouring of their walls grey-black for the imitating of sturgeon roe is done by treating the granules with solutions of iron(III) salts of bile acids [114,115], that is, by using the well-known reaction of phenolic compounds with iron(III) ions. The properties of the granules are greatly influenced by reagents and media with different osmotic properties applicable for the development of granulated gels (washing, tanning, colouring), and also the conditions of cooking and subsequent storage of the product. The volume properties of the granulated gels do not change appreciably during their tanning. The intensity of the swelling of the gel is depressed in this as a result of the resistance of the granule sheath to extension. The diffusion into the gel of iron(III) ions being used for colouring the sheath is accompanied by the tanning of the proteins through the entire volume of the gel, as a result of which the pliability and intensity of swelling of the gel decrease and its melting point rises.

To make caviar and granules of a gel coated with coloured elastic sheaths, sodium chloride, vegetable oil, fish oil and various other tasty and aromatic substances are added. The combination of casein, vegetable oils, fish oil, and also the additional mineral salt and vitamins introduced weakens the high food values of the product, for the preparation of which high-grade but nevertheless expensive edible raw material was used. In connection with the fact that tea extracts are used for tanning granulated gels their effect has been investigated on the enzyme activity of pepsin, trypsin, and chromotrypsin in vitro [134]. It was shown that the complex of tanning agents of green tea not only does not have an inhibiting action on enzymes under these conditions, but even raises the activity of pepsin and chemotrypsin. Whereas the comparative investigation of the vulnerability of proteins to enzymes of the gastrodigestive tract in vitro and of the same proteins in the composition of various sorts of roe investigated showed that the biological value of these proteins increases on their inclusion in the composition of the product [135]. The investigations of the physicochemical and mechanical properties and also the biological value of the granulated gels allowed the conditions for the preparation of granulated gels to be determined and the influence of various factors on the composition and properties of the prepared product to be characterised, which was a

necessary stage in the development of a method of making artificial soft caviar.

As a result of the studies made in the Institute of Organoelemental Compounds of the Academy of Sciences of the USSR, under the direction of A. N. Nesmeyanov, the first results on the creation of a high quality artificial caviar have been obtained. These studies created the necessary chemical, physicochemical, and technological basis for subsequent development of the investigations in this new and interesting field of science and industry.

Study of the Mechanisms of Heterogeneous-catalytic Reactions by the Method of Labelled Molecules (labelled with ^{14}C)

Yu.I.Derbentsev and G.V.Isagulyants

The present review differentiates between the method of labelled atoms (the LA method) and the method of labelled molecules (the LM method). Unlike the LA method, in which an experimental study is made of the distribution of the isotopic tracer over various positions in the molecules of the starting materials and reaction products, the LM method involves the study of the distribution of the isotopic tracer between the molecules of different substances. The basic equations of the LM method for integral and differential reactors are given, and literature on the application of the LM method with the ^{14}C isotope to study the mechanisms of heterogeneous-catalytic reactions is reviewed. The bibliography contains 163 references.

1. INTRODUCTION

At the present time there are two main ways in which isotopes are used to study the mechanisms of catalytic reactions. In the first, it is possible to follow experimentally the distribution of the isotopic tracer in various positions in the molecules of the starting materials and reaction products, and this in turn makes it possible to obtain information on the relative reactivity of the atoms in the positions selected, on the course of the reaction, etc. This method could be called the labelled atom method in the narrow sense (the LA method).

In the second, we follow the distribution of the isotope not inside the molecules, but between the molecules of different substances or, as for example in the isotopic differential method for studying the surface of catalysts, between different parts of molecules of the same substance. This makes it possible to determine the role of the labelled substance in a multi-stage catalytic process, and to study the properties of the catalyst and the nature of the products of its interaction with the reacting molecules. This method might be called the labelled molecule method (the LM method).

The LM method can be used to study a wider range of specific problems in heterogeneous catalysis than is possible by the LA method. It need only be pointed out that this method has been used to study inhomogeneity (see for example Refs. 1–3), acid–base properties[4], surface area[5,6], the poisoning of catalysts[7], the interaction of adsorbed substances on a surface[8–10], the kinetics of heterogeneous-catalytic reactions[11–15], etc. Many theoretical aspects of the use of isotopes in catalysis were examined in detail in a monograph by Roginskii[16] and to a lesser extent in other monographs (see for example Refs. 17–19). A brief review by Trimm[20] was devoted to the use of carbon isotopes to study neterogeneous catalysis.

At the present time, nowever, there is no sufficiently complete review of work carried out by the LM method in various fields of heterogeneous catalysis, and in the study of the mechanisms of the reactions in particular. The aim of the present work is to fill this gap.

2. POSSIBILITIES OF THE LM METHOD IN THE STUDY OF THE MECHANISMS OF CATALYTIC REACTIONS

A particular example of the method of "labelled molecules" is provided by the analytical method of isotopic dilution[21,22], which makes it possible to determine extremely small quantities of substance when radioactive tracers are used; it is better to have the tracer in the substance being determined then to have it in the diluent. An example of the use of this method for the analysis of the products of a heterogeneous-catalytic reaction was described by Blau and Willard[23], who studied the reaction of benzene-^{14}C and ethyl chloride vapours over solid aluminium chloride (sublimed on the walls of the flask) at room temperature. The reaction products, obtained in small quantities, were diluted with a measured amount of unlabelled benzene, ethylbenzene, and diethylbenzene, after which the mixture was fractionated and the yields of the corresponding products were determined from the specific radioactivity of the components. In this work it was possible to show that the rate of formation of ethylbenzene depends on the pressures of both starting materials.

The method of isotopic dilution as such apparently will not be very important for the study of organic reactions, since the development of chromatography has given research workers more convenient and sufficiently sensitive methods of analysis. The determination of specific radioactivity is widely used, however, in other isotopic methods for studying reaction mechanisms, in particular in the kinetic isotopic method, which makes it possible to determine quantitatively the rates of formation and consumption in given directions for a given substance in a reacting system, and this helps to establish a scheme of genetic relationships for the products.

As early as 1937, Wilson and Dickinson[24] showed that for the reversible redox reaction

$$H_3A^{V}O_3 + I_3^{-} + H_2O \rightleftarrows H_3AsO_4 + 3I^{-} + 2H^{+} \quad (1)$$

it is possible, by using radioactive tervalent arsenic, to study the rates of the forward and back reactions at equilibrium by making use of the equation

$$\frac{d\alpha}{dt} = \frac{R}{[As^{V}]}(\beta - \alpha) \quad (2)$$

where α is the specific radioactivity of H_3AsO_4; β the specific radioactivity of H_3AsO_3; R the reaction rate; and $[As^{V}]$ the concentration of H_3AsO_4 (assumed constant). To calculate R, Wilson and Dickinson[24] used the integral form of this equation.

The kinetic features of biochemical processes have been studied with labelled substances by Zilversmit[25], Barnum and Huseby[26], and others. A review of work by non-Soviet authors in this field is given in Aronoff's monograph[27].

Neiman[28-30] gave the derivation of the equation

$$\frac{d\alpha}{dt} = \frac{w(\beta - \alpha)}{[X]} \quad (3)$$

where w is the rate of formation of the product from a single radioactive precursor; [X] the concentration of the product X; β the specific radioactivity of the precursor; and α the specific radioactivity of the product, and used it to find the rates of the formation and decomposition of the intermediate products; he called this method the kinetic isotopic method (KIM) for studying reaction mechanisms.

Eqn. (3) can be written for the general case of the formation of a substance X from any number of radioactive precursors[31]:

$$\frac{d\alpha_X}{dt} = \frac{1}{n[X]}\sum_{i=0}^{i} w_i(\alpha_i - \alpha_X) \quad (4)$$

where w_i is the rate of the process i leading to the formation of the substance X; α_i the specific radioactivity of the corresponding precursor; α_X the specific radioactivity of the substance X; [X] the concentration of the substance X, %; and n the total number of moles of the substance in the system. The overall equation of the material balance for X can evidently be written in the form

$$\frac{dn[X]}{dt} = \sum_{i=0}^{i} w_i - \sum_{j=0}^{j} w_j \quad (5)$$

where w_j is the rate of consumption of the substance X.

In integral form and applied to the conditions of heterogeneous catalysis, Eqns. (4) and (5) are written in the form

$$\frac{\alpha_X - \alpha_{X_0}}{st} = \frac{1}{n_0[X]_0}\sum_{i=0}^{i} w_i(\alpha_i - \alpha_X) \quad \text{or}$$
$$\frac{\alpha_X - \alpha_{X_0}}{s} = \frac{1}{u[X]_0}\sum_{i=0}^{i} w_i(\alpha_i - \alpha_X) \quad (6)$$

and

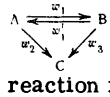
$$\frac{n_0\{[X] - [X]_0\}}{st} = \sum_{i=0}^{i} w_i - \sum_{j=0}^{j} w_j \quad \text{or} \quad \frac{u\{[X] - [X]_0\}}{s} = \sum_{i=0}^{i} w_i - \sum_{j=0}^{j} w_j \quad (7)$$

where α_{X_0} is the specific radioactivity of the substance X in the original mixture; n_0 the number of moles of the starting material; $[X]_0$ the percentage concentration of the substance X in the original mixture; [X] the same in the reaction products; s the catalyst surface area; and u the rate of supply of the starting material ($u = n_0/t$).

Eqns. (4) and (5) [or (6) and (7) respectively] are the most general equations of the kinetic isotopic method, and they make it possible to find the rates of formation and consumption of a substance in complicated reactions.

In the study of genetic relationships and in the verification of stepwise schemes, the first problem which arises concerns the extent to which a product B, formed from the starting material A, takes part in the formation of the final product C.

To solve these problems, Balandin and coworkers[32,33], beginning in 1958, used the triangular scheme



(8)

The equations for the reaction rates in this system can readily be obtained from a system of equations of types (4) and (5) or (6) and (7) respectively.

Differential reactor

$$w_1 = \frac{u[B_0](\alpha_{B_0} - \alpha_B)}{s(\alpha_B - \alpha_A)} \quad (9)$$

$$w_1' = \frac{u[A_0](\alpha_{A_0} - \alpha_A)}{s(\alpha_A - \alpha_B)} \quad (10)$$

$$w_2 = \frac{u\{[C] - [C_0]\}}{s} - w_3 \quad (11)$$

$$w_3 = \frac{u\{[C](\alpha_C - \alpha_A) + [C_0](\alpha_A - \alpha_{C_0})\}}{s(\alpha_B - \alpha_A)} \quad (12)$$

Integral reactor

$$w_1 = \frac{d\beta}{d\tau}\frac{[B]n}{(\alpha_A - \alpha_B)} \quad (13)$$

$$w_1' = \frac{d\alpha}{d\tau}\frac{[A]n}{(\alpha_B - \alpha_A)} \quad (14)$$

$$w_2 = \frac{dn[C]}{d\tau} - w_3 \quad (15)$$

$$w_3 = \frac{\frac{d\alpha_C}{d\tau}n[C] + \frac{dn[C]}{d\tau}(\alpha_C - \alpha_A)}{\alpha_B - \alpha_A} \quad (16)$$

The significance of the symbols in Eqns. (9)–(16) is clear from the foregoing.

It is obvious that when $w_3 = 0$, B and C are formed by parallel independent paths. When $w_2 = 0$, the formation of the product C is a purely consecutive process. In this case the rate w_3 can be found from Eqn. (3)

$$w_3 = \frac{d\gamma}{d\tau}\cdot\frac{[C_3]}{\beta - \gamma} \quad (17)$$

or

$$w_3(\beta - \gamma) = [C_3]\cdot\frac{d\gamma}{d\tau} \quad (18)$$

Eqn. (18) has important consequences:

$$\text{for } \frac{d\gamma}{d\tau} > 0, \quad \beta > \gamma \quad (19)$$

and

$$\text{for } \frac{d\gamma}{d\tau} < 0, \quad \beta < \gamma \quad (20)$$

The inequalities (19) and (20) are necessary but not sufficient conditions for formation of the product C from a single precursor B. Although these conditions follow from the equations of the kinetic isotopic method, they are of independent importance, and, as shown below, they are used more widely than the other equations of the method.

Hightower and Emmett[34], in a study of the cracking of cetane, expressed the fraction of the consecutive path for the formation of the product i through the product a in the form of the ratio

$$\alpha_a^i(\text{obs})/\alpha_a^i(\text{max})n \qquad (21)$$

where α_a^i (obs) is the experimental value of the ratio of the specific radioactivities of the product i and the product a in the catalysate, α_a^i (max) the calculated maximal value of this ratio, and n the number of moles of substance a required for the formation of one mole of substance i. Assuming that the consecutive reactions in this instance are of first order, the authors cited find that the value of α_a^i (max) lies in the range 1–3.

A number of authors (see for example Refs. 35 and 36), in experiments with mixtures containing a labelled substance, calculate the so-called intensities of the reaction, by which is meant the yields of the products separately from each component of the original mixture. The ratio of the intensities indicates the relative reactivity of the substances when present together in the reaction zone, and can be used to obtain information on the reaction mechanism; the ratio of the intensities, however, unlike the ratio of the rates of the processes, does not contain information on the reaction paths, and in most instances it does not make it possible to obtain unambiguous information on the adequacy of the proposed and real sequence of processes.

In concluding this section we may point out that the LM method is fundamentally related to the analytical method of radiochromatography, which makes it possible to carry out the simultaneous chemical and radiometric analysis of complex mixtures of substances.

The high efficiency of this method makes it possible in turn to use micro-catalytic apparatus to carry out experiments, and this is extremely convenient from the safety viewpoint and in connection with the use of expensive radioactive materials. The foundations of the application of radiochromatography combined with micro-catalytic apparatus were laid by Emmett and coworkers[37], and in the Soviet Union the use of radiochromatography in catalysis was pioneered by Roginskii and Yanovskii and coworkers[38–40].

3. DETERMINATION OF THE STOICHIOMETRIC NUMBER

The stoichiometric number of a reaction characterises the reaction mechanism[41]. The stoichiometric number γ can be determined experimentally if the rates of the forward and back reactions are measured under the same conditions

$$\gamma = \frac{-\Delta G/RT}{\ln \frac{v_+}{v_-}} \qquad (22)$$

where ΔG is the Gibbs free energy under the conditions of the reaction; R the gas constant; T the absolute temperature; v_+ the rate of the forward reaction; and v_- the rate of the back reaction.

When isotopes are used to determine the forward and back reaction rates, a reasonable integral value of the stoichiometric number can be expected only if the isotope takes part in the limiting stage of the reaction. Thus to determine precisely the limiting stage it is best to determine the stoichiometric number by means of various isotopes. Using ^{14}C, Kaneko and Oki[42] determined the forward and back reaction rates for the conversion of water gas:

$$CO + H_2O \rightleftarrows CO_2 + H_2 \qquad (23)$$

in the presence of iron(III) oxide, and this enabled them to determine γ, which was found to be equal to 1. After examining three possible mechanisms:

$$\left.\begin{array}{l} H_2O \rightarrow 2H\,(a) + O\,(a) \\ CO + O\,(a) \rightarrow CO_2 \\ 2H\,(a) \rightarrow H_2 \end{array}\right\} \qquad (24)$$

$$\left.\begin{array}{l} H_2O \rightarrow H_2O\,(a) \\ CO \rightarrow CO\,(a) \\ H_2O\,(a) + CO\,(a) \rightarrow H_2 + CO_2 \end{array}\right\} \qquad (25)$$

$$\left.\begin{array}{l} H_2O \rightarrow H_2O\,(a) \\ H_2O\,(a) + CO \rightarrow H_2 + CO_2 \end{array}\right\} \qquad (26)$$

where (a) denotes the adsorbed state, and pointing out that according to published data[43] the value of γ determined by means of deuterium is also equal to 1, the authors cited rejected mechanism (24), since it does not contain a stage in which carbon and hydrogen atoms take place simultaneously, and concluded that the mechanism operating is either (25) or (26).

In analogous studies, Atkins and Happel[44] used ^{14}C to determine the stoichiometric number for the dehydrogenation of butane

$$C_4H_{10} \rightleftarrows C_4H_8 + H_2 \ . \qquad (27)$$

In this instance also, γ was found to be equal to 1. From this it follows that the adsorption or desorption of hydrogen cannot be the limiting stage of the reaction; a limiting stage, if one exists, can only be a stage in which transformation of the carbon framework of the molecule takes place. Atkins and Happel[44] assume that the reaction has not one but several limiting stages, the stoichiometric number of each being equal to unity.

4. PROBLEM OF THE ISOTOPIC EXCHANGE OF CARBON

For the interpretation of the results obtained by the labelled molecule method, it is important that intermolecular isotopic exchange of carbon in the organic compounds is unlikely under the usual conditions in which catalytic reactions are carried out. In a number of studies the possibility of exchange has been verified experimentally.

For example, Emmett and coworkers[45] showed that methane, n-butane, and acetylene under the conditions of the Fischer–Tropsch synthesis remain almost non-radioactive after contact with labelled carbon deposited on the catalysts: appreciable transfer of radioactivity (2%) was observed only for but-1-ene. Under the severe conditions of cracking over an aluminosilicate catalyst (500°) the transfer of radioactivity between ethane and propane, and between methane and ethylene, amounted to fractions of 1%[46]; there was almost no transfer of radioactivity between methane and carbon. In the interpretation of the results obtained, it must of course be borne in mind that the transfer of radioactivity from one product to another (in the works cited) does not in itself prove that exchange

takes place, if the back reaction has not been studied experimentally. It is quite probable that labelled compounds took part in the synthesis of those substances in which the radioactivity was determined.

In this connection, mention must be made of the so-called isotopic-radical exchange of carbon. Vasserberg and coworkers [47-49] found that when substances containing radiocarbon, for example $^{14}CH_3OH$ (called the "tracer donor") are passed over alumina together with an unlabelled oxygen-containing compound, for example ethanol (called the "tracer acceptor"), the products of the transformation of the latter (in this instance ethylene) were found to contain a small amount of radioactivity. This led to the development of the idea that exchange of carbon takes place between methanol and ethanol and also between other compounds as a result of the reaction of intermediate radical-like formations on the surface of the alumina.

These observations attracted some attention [50], but it was later shown [51,52] that under the conditions of dehydration on alumina, methanol gave small quantities of ethylene and propene, and ethanol gave propene. The addition of non-radioactive ethanol to radioactive methanol does not increase the formation of radioactive ethylene. It is evident that in the interpretation of the results of this work [47-49] we may be dealing not with the exchange of carbon but with side reactions involving the transformation of the tracer donor. The use of the acceptor merely facilitated the detection of small quantities of these side products.

It may thus be concluded that at present there is no evidence of the possibility of heterogeneous-catalytic exchange of carbon in organic compounds.

5. CATALYTIC CRACKING OF HYDROCARBONS

First in Roginskii's laboratory, and subsequently in work by Emmett and coworkers, it was shown that in the cracking of hydrocarbons, alkenes with lower molecular weight are the primary reaction products; the addition of ethylene-^{14}C to n-hexane [53], propene-^{14}C to 2,2,4-trimethylpentane [53], and propene-^{14}C, pent-1-ene-^{14}C, and hept-1-ene-^{14}C to n-hexadecane [34,54,55] over aluminosilicate catalysts under the conditions of cracking led to the formation of products whose specific radioactivity was close to or greater than that of the added labelled substance in the catalysate.

The addition of labelled alkanes to the starting materials in the cracking usually did not lead to the formation of hydrocarbons with appreciable radioactivity [34,53-55]. An exception is provided by work [56] in which labelled ethane mixed with n-octane at 500° over an aluminosilicate was dehydrogenated with the formation of ethylene.

These results show good agreement with the idea that cracking takes place by an ionic mechanism. In agreement with the fact that primary carbonium ions require more energy for their formation than secondary carbonium ions, ethylene takes a smaller part in the formation of the final products compared with other alkenes used as labelled additives to alkanes [34,53,55]. It should be noted, however, that the labelled compounds added to alkanes during cracking influence the reactivities of the original hydrocarbons.

It has been found [53] that labelled ethylene added to 2,2,4-trimethylpentane and propene under the conditions of cracking over an aluminosilicate takes part in the formation of products with the C_3 and C_4 compositions; in the experiments in which labelled ethane was added to 2,2,4-trimethylpentane, an even greater interaction was observed. In the opinion of the authors cited, these changes are due to degradative alkylation, taking place with the formation of intermediate bimolecular complexes, for example:

$$^{14}C_2H_6 + C_3H_8 \rightarrow (^{14}C_2H_6 \cdot C_3H_8) \begin{matrix} \nearrow {}^{14}C_4H_8 + CH_4 \\ \searrow C_4H_8 + {}^{14}CH_4 \end{matrix} . \qquad (28)$$

It is possible that in these processes a definite part is played by the recently discovered reaction of alkene disproportionation. It has been suggested [57,58] that this reaction involves the intermediate formation of a bimolecular complex with a four-membered ring structure:

$$\begin{matrix} R_1{-}CH{=}CH_2 \\ +CH_2{=}CH{-}R_2 \end{matrix} \rightarrow \begin{matrix} R{-}CH \cdots \vdots \cdot CH_2 \\ H_2C \cdots \vdots \cdot CH{-}R_2 \end{matrix} \rightarrow \begin{matrix} R_1{-}CH & CH_2 \\ \| & + \| \\ CH_2 & CH + R_2 \end{matrix} . \qquad (29)$$

Andrianova and Roginskii [56,59] showed that the addition of small quantities of alkenes (up to 2.5%) increases the extent of the cracking of n-octane, whereas an increase in the quantity of additive decreases the rate of cracking. The addition of alcohols has a similar influence, and this, in the opinion of the authors cited, is due to the formation of alkenes from the alcohols under the conditions of the reaction. They suggested that the cracking reactions take place by a chain mechanism, and that small quantities of alkenes initiate the process, whereas large quantities suppress it.

It might be expected that aromatic hydrocarbons would also take part in alkylation in the same way as alkenes, but the experiments of Hightower and Emmett [34,55] with the addition of labelled benzene and toluene to n-hexadecane under the conditions of cracking over an aluminosilicate catalyst showed that when these hydrocarbons are used, only a small proportion of alkylaromatic compounds are obtained. These are obtained chiefly from the products of the cracking of n-hexadecane as a result of the polymerisation and copolymerisation of alkenes with three or more carbon atoms in the molecule.

The use of labelled mixtures of alkanes and alkenes established that under the conditions of cracking, the carbonaceous deposits on the catalyst are also obtained chiefly from the alkenes [53,54,56,59,70]; with increase in the molecular weight of the alkane, the extent to which it takes part in the formation of carbon increases [59,61].

To study the problem of whether carbon is obtained by the gradual loss of hydrogen atoms or by the removal of terminal carbon atoms from the hydrocarbon molecules, McMahon [62] determined the specific radioactivity of the carbon after passing n-heptane-4-^{14}C, n-octane-1-^{14}C, and oct-1-ene-1-^{14}C over a catalyst. In all instances the specific radioactivities of the starting material and the carbon were equal, providing evidence in support of the first hypothesis. In Wynnemer's experiments [63], however, the specific radioactivities of carbon deposits obtained at 454° and 510° from the same substance (n-decane-2-^{14}C) were different, indicating that the mechanism of carbon formation may depend on the temperature.

6. OXIDATION OF HYDROCARBONS

The mechanism of the extensive oxidation of alkenes has been studied by Neiman's method, chiefly by Margolis and coworkers in Roginskii's laboratory; this work has been reviewed in sufficient detail [64,65] and we shall give only a brief description here. A series of experiments were undertaken to observe the reaction sequence: alkene → product of incomplete oxidation → carbon dioxide,

which might indicate the primary product of the oxidation of the alkene. Oxides of hydrocarbons, aldehydes, and other compounds were considered as possible primary products. It was shown that over a silver catalyst, ethylene is oxidised to carbon dioxide by a parallel-consecutive mechanism—through the intermediate formation of ethylene oxide and also directly[66-68]. Formaldehyde and acetaldehyde decreased the rate of oxidation, so that they could not be intermediate products[67,68]. Ethylene oxide and acetaldehyde added to ethylene over vanadium oxide took an active part in the formation of carbon monoxide and dioxide, but since almost no ethylene oxide and acetaldehyde are detected in the oxidation of ethylene, the authors cited[69,70] concluded that ethylene is for the most part oxidised directly to carbon dioxide.

In studies of the oxidation of propene on copper catalysts, it was established that carbon dioxide is formed by a parallel-consecutive mechanism with the participation of acrolein formed as an intermediate[71,72].

It has also been shown[69,70] that aldehydes take an active part in the formation of the carbonaceous film on the catalyst, and that this has some influence on the selectivity of the oxidation processes.

Radiocarbon ^{14}C has also been used to study the mechanism of the extensive oxidation of toluene over a copper catalyst[73]. In experiments in which labelled benzyl alcohol and benzaldehyde were added to toluene, the authors cited concluded that toluene is oxidised to carbon dioxide partly through the intermediate formation of benzyl alcohol. Unfortunately, the results of this work are not reported in sufficient detail.

7. SYNTHESIS OF HYDROCARBONS AND ALCOHOLS FROM CARBON DIOXIDE AND HYDROGEN

Radiocarbon ^{14}C has been used in a large number of studies to investigate the problems of the mechanism of the synthesis of hydrocarbons and alcohols from CO and hydrogen. Most of this work was recently reviewed by Eidus[74], and we shall here list only the main features and the results obtained in this work.

Emmett and coworkers[45] used catalysts carbonised in the presence of radioactive carbon monoxide, and found that the radioactivity is transferred to the products of the synthesis to only a slight extent; this proved that surface metal carbides are not intermediate products of the synthesis. Subsequently, similar results were obtained in other studies over cobalt[75] and iron[76,77] catalysts. It is now generally accepted that some surface complexes involving CO and H_2 must be formed during the reaction to act as intermediate link. Ganguli[78], in a study of the simultaneous adsorption of CO and H_2 on a cobalt catalyst, showed that whereas exchange of the adsorption complex with gaseous CO takes place to a slight extent, the reaction products contain appreciable radioactivity; this proves that the CO–H_2 complex take part in the synthesis. In a large number of studies, various labelled substances have been added to the gas taken for the synthesis, in order to detect intermediate compounds. Examination of the published material shows that all the radioactive additives used can be divided into three groups according to the nature of their participation in the synthesis. The first group contains substances capable of generating radioactive carbon monoxide—methanol[79-81], formaldehyde[80], methyl formate[82], and keten[83] labelled in the carbonyl group. A characteristic feature of this group of substances is that in their presence, the molar radioactivity of the products increases with increase in molecular weight, and this can be regarded as confirming their role as the source of radioactive carbon monoxide, which is the chief "building material" in the synthesis.

The second group contains labelled substances whose addition leads to the formation of hydrocarbons with constant molar radioactivity—ethylene[77,84-86], ethanol[82,87-91], n-propanol[79-81], acetaldehyde[82], propionaldehyde[85], and keten labelled in the methylene group[92]. These substances are apparently capable of generating methylene radicals, which can initiate the synthesis[93].

In a study of the addition of ethanol to the gas taken for the synthesis[87,90,91], it was shown by the LA method that C_3 hydrocarbons are obtained by the attachment of a new carbon atom to the carbonyl carbon atom of the alcohol. Added aldehydes under the conditions of the synthesis are apparently readily hydrogenated with the formation of alcohols[82], and this explains the similarity in the behaviour of aldehydes and alcohols. It should be noted, however, that over a fused iron catalyst, added acetaldehyde was converted into higher alcohols more rapidly than added ethanol, by a factor of several orders of magnitude[94].

The third group contains substances which take little part in the synthesis (propene[75], butenes[95], isopropyl alcohol, and n-butanol[79-81]), and also methane[96,97] and carbon dioxide[80] which take almost no part in the synthesis.

Among the substances added to the gas taken for the synthesis, a unique position is occupied by ethylene. Fletcher and Gibson[98] showed that a mixture of hydrogen and ethylene in the presence of a small quantity (5%) of ^{14}CO gave hydrocarbons whose specific radioactivity was several times smaller than that of the original carbon monoxide; the low radioactivity of methane and the absence of any periodicity in the radioactive higher hydrocarbons with even and odd numbers of carbon atoms suggested that during the synthesis, ethylene is first dissociated to methylene radicals. When large quantities were added, it was found that ethylene takes part not only in the initiation of the synthesis but also in the growth of the hydrocarbon chains[75]. In recent years, the hydropolymerisation of ethylene in the presence of small quantities of CO over a cobalt catalyst has acquired independent interest. It has been shown[99] that the quantity of CO in the mixture remains almost unchanged during the experiment, whereas the process does not take place without CO. It might be suggested, however, that the maintenance of the CO concentration is due to the attainment of equilibrium in reactions involving its consumption and formation. This possibility was examined[100] by means of labelled CO and it was found that under certain conditions its specific radioactivity remains unchanged, so that CO is not formed during the synthesis, whereas ethylene is used up intensively in the reaction; it was thus proved that CO under these conditions acts as reaction initiator.

Radiochromatographic analysis has indicated that the highest radioactivity is shown by α-alkenes and the corresponding alkanes; β-alkenes, among which the cis-isomers predominated, showed a lower radioactivity, so that they were obtained by a different mechanism, and were not produced from the α-alkenes by isomerisation. An interesting feature is that in this work, although ^{14}CO was only the reaction initiator, an increase in the molar radioactivity of the hydrocarbons with increase in molecular weight was observed. A possible explanation is that with increase in the length of the chain there is an increase in the probability of a type of hydrocarbon desorption in which the primary complex on the surface decomposes and

the radioactive carbon is introduced into the molecule; it is suggested that most of the hydrocarbon molecules are desorbed in a different way, without decomposition of the primary complex.

It is also interesting to note that under the conditions of the synthesis of alcohols with the addition of labelled ethylene to the gas taken for the synthesis, propanol with a high specific radioactivity was obtained [86,101], and this has made it possible to come closer to the development of conditions for the preparation of propanol from ethylene, carbon monoxide, and hydrogen [86].

8. SYNTHESIS OF BIVINYL FROM ALCOHOL

^{14}C has been used to study the mechanism of the formation of bivinyl from alcohol on Lebedev's catalyst. It has been shown that ethylene and ether are not intermediate products [102,103], and that methanol takes part only in the formation of side products of the synthesis of bivinyl [104,105]. On the other hand, the addition of labelled crotonaldehyde to the original alcohol led to the formation of highly radioactive bivinyl [102,103]. Although crotonaldehyde was not detected in the condensates under the conditions of the experiments, so that the specific radioactivities of these products could not be compared, the results can be taken as confirming Gorin's familiar scheme [106], in which crotonaldehyde takes part as an intermediate product.

When labelled acetaldehyde was added to the alcohol, it was established that these substances in the mixture are readily interconverted [102,103]:

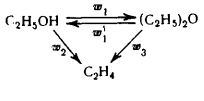
$$^{*}C_2H_5OH + CH_3CHO \rightleftarrows C_2H_5OH + {}^{*}CH_3CHO. \qquad (30)$$

Because of this, the part played by acetaldehyde in the synthesis of bivinyl could not be determined by this method. A radiochromatographic study [38] established that the formation of butenes takes place not as a result of the hydrogenation of bivinyl but by the dehydration of butanol produced in the reaction. The use of ^{14}C also showed that under the conditions of the synthesis of bivinyl by Lebedev's method the formation of carbonaceous deposits on the catalyst takes place chiefly from the original alcohol, and not from the bivinyl [107]. It may also be noted that in the dehydration of alcohol over titanium dioxide the carbonaceous film is again formed chiefly from the alcohol, and not from the alkene [108]; in the decomposition of alcohol over a dehydrogenating catalyst (copper on silica gel), the carbonaceous film was obtained chiefly from the acetaldehyde [109].

9. DEHYDRATION OF ALCOHOLS AND ACCOMPANYING REACTIONS

^{14}C has been used to make detailed studies of various problems of the mechanism of the dehydration of alcohols. Thus a discussion has been going on for a long time in the literature on the mechanism of formation of ethylene in the dehydration of ethanol over alumina.

Some authors consider that the formation of the alkene takes place by consecutive reactions, and that ether is first formed as an intermediate product. Others consider that ethylene and ether are formed by two independent parallel reactions. In 1958, a parallel-consecutive scheme was proposed for the dehydration of ethanol:



(31)

and the rates of the separate processes were determined experimentally [32,110]. For this purpose the dehydration of ethanol was studied with the addition of ^{14}C-labelled diethyl ether, at 275, 300, 350, and 400° in a flow reactor over industrial alumina.

It was found that at 275°, ethylene is formed directly from the alcohol and with the intermediate formation of ether at approximately equal rates; with increase in temperature the direct formation of ethylene from alcohol predominates. Thus on alumina, direct decomposition of alcohol to ethylene and water is possible; the bimolecular dehydration with the formation of ether and water takes place independently, but the ether formed is unstable under the conditions of the reaction and is itself able to undergo dehydration with the formation of ethylene and water. The mechanism of the dehydration of alcohol on an aluminosilicate catalyst is analogous [111].

In connection with the suggestion that the formation of ether and ethylene takes place through a common surface intermediate compound, which is present in equilibrium with the alcohol and ether [112,113], the method of isotopic dilution was used to study the chemosorption of mixtures of alcohol and ether on alumina at 120°; transfer of the radioactive tracer between the alcohol and the ether was not observed, so that, at low temperatures at least, there is a difference between the surface compounds formed from alcohol and ether [10].

Unlike alumina, a number of other oxides bring about not only dehydration but also dehydrogenation of alcohols with the formation of aldehydes or ketones. Saturated hydrocarbons are often detected in the catalysate gas together with unsaturated hydrocarbons and hydrogen. It is often assumed that the saturated hydrocarbons are formed by hydrogenation of an alkene. A number of authors, however, have pointed out the possibility of hydrogenolysis of alcohols at the C–C bond under the conditions of the reaction, since the catalysates were found to contain alkanes with one carbon atom less than the original alcohol [114,115]; in this connection it was suggested that alkanes may also be formed by the hydrogenolysis of alcohol at the C–O bond [116].

Experiments in which ethanol containing labelled ethylene was passed over titanium dioxide [108] and in which isopropyl alcohol with added propene was passed over vanadium(III) oxide [116] showed that the radioactive tracer was not converted into ethane and propane respectively, and was not detected in the liquid catalysates. These experiments confirmed that under the conditions of dehydration the alkanes are probably produced by the hydrogenolysis of alcohols, and not by hydrogenation of alkenes liberated into the gaseous phase.

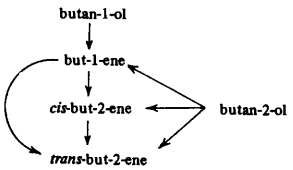
The isotopic-kinetic method has also been used to study the genetic relationships between the products in the more complex system formed in the dehydration of butanols.

The aim of the study was to follow the change in the ratio of the rates of the dehydration of alcohols and the isomerisation of the resulting butenes, and also to determine the reasons for the frequently observed preferential formation of but-1-ene and *cis*-but-2-ene from secondary butyl alcohol, which cannot be explained on the basis of a mechanism of dehydration involving a classical carbonium ion and for which the concept of a π-complex has been introduced [117] or for which it has been suggested that but-1-ene is an intermediate product of the formation of but-2-ene from butan-2-ol [118].

The studies were carried out over two specimens of alumina: grade A-1 [119] and industrial fluorinated grade [120]. These catalysts differ in their isomerising properties.

^{14}C-labelled butan-1-ol was added to the butan-2-ol to act as a source of labelled but-1-ene (it should be noted that in this instance the labelled hypothetical intermediate compound was not introduced in prepared form into the reaction zone but was synthesised during the reaction on the surface of the catalyst).

The reaction products were studied by the radiochromatographic method. Interconversion of the primary and secondary alcohols was not observed. The genetic relationships between the products according to scheme (32) was studied:



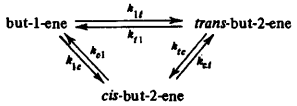
(32)

Determination of the rates in this scheme showed that most of the but-2-enes are obtained directly by the decomposition of butan-2-ol, and not by the isomerisation of but-1-ene, although the rate of isomerisation of but-1-ene into but-2-enes is also appreciable. The ratio of the rates of dehydration of butan-1-ol and the isomerisation of but-1-ene did not change on going from A-1 alumina to fluorinated alumina, indicating that the rates of dehydration and isomerisation change in the same sense on going from one alumina specimen to the other.

Butan-2-ol gave a relatively larger quantity of but-1-ene on the fluorinated alumina. The acidity of the surface apparently influences the selectivity of the dehydration of the secondary alcohols. The specific radioactivity of *trans*-but-2-ene was always greater than that of *cis*-but-2-ene, so that the *cis*- and *trans*-but-2-enes are formed by independent paths and through different intermediate surface compounds, whose interconversion is possibly difficult.

10. ISOMERISATION OF BUTENES

Hightower and coworkers [121,122], using original mixtures of two butenes, one of which was labelled with ^{14}C, showed that on catalysts based on alumina, all possible transformations of the three butenes take place according to the scheme



(33)

Thus when a mixture of *cis*-but-2-ene and but-1-ene-1-^{14}C was used, the specific radioactivity of the *trans*-but-2-ene was not greater than or equal to that of the but-1-ene in the catalysate, indicating direct formation of *trans*-but-2-ene from *cis*-but-2-ene.

It was shown that the isomerisation is a first-order reaction. By selecting rate constants to satisfy the experimental dependence of the specific radioactivities on the degree of transformation, the authors cited obtained, for example for an aluminosilicate catalyst at 23°: $k_{c_1}/k_{1c} = 0.15$, $k_{t_1}/k_{1t} = 0.04$, and $k_{tc}/k_{ct} = 0.26$.

Examination of the selectivity of the processes of butene isomerisation led the authors cited to the conclusion that the reaction takes place by different mechanisms on different catalysts based on alumina. Thus in the case of the aluminosilicate catalyst the selectivity of the isomerisation was independent of the butenes used as starting material, the origin of the catalyst and its degree of poisoning, and temperature, in agreement with the idea that a common intermediate compound is formed; this was assumed to be the classical s-butyl carbonium ion:

$$CH_3\overset{+}{C}HCH_2CH_3. \qquad (34)$$

With alumina, however, the selectivity depended to a marked extent on the butenes used as starting material, and this does not agree with the suggestion that the reaction takes place through a common intermediate compound. In this respect, fluorinated alumina is intermediate between the aluminosilicate and alumina. These results show good agreement with other observations and conclusions [119,120] regarding the isomerisation of butenes under the conditions of the dehydration of butanols on Al_2O_3.

11. DEHYDROGENATION OF HYDROCARBONS

The dehydrogenation of hydrocarbons, leading to the formation of alkenes or aromatic hydrocarbons, is an important industrial reaction. In the study of this process, Balandin and coworkers were the first to use the kinetic isotopic method under the conditions of heterogeneous catalysis. The studies were carried out in a flow assembly on a chromium catalyst (KI) with dilution by water vapour [123-127] and on an aluminium–chromium catalyst (K-544) at reduced pressure [127,128].

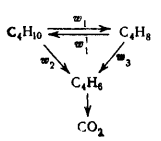
Mixtures of butane and butene in which one of the components contained ^{14}C were studied. The dependence of the experimentally determined specific radioactivities and the concentrations of butane, butene, butadiene, and carbon dioxide (or the carbonaceous deposits on the catalyst) on the duration of contact were examined. Experiments were also carried out on the dehydrogenation of mixtures of butane and butene with added labelled butadiene [125].

The chief source of loss in the dehydrogenation of butane and butene is by deposition of carbon, or, when the process is carried out with dilution by water vapour, by the formation of carbon dioxide.

The specific radioactivity of the carbon dioxide in all instances was found to be very close that of the butadiene obtained, and calculation of the rates of decomposition of butane, butene, and butadiene to carbon dioxide showed that these rates are in the ratio 1 : 4 : 60. Thus more than 90% of the carbon dioxide is obtained from the butadiene formed [125]. These results show qualitative agreement with the results of an earlier study [128], in which it was found that in the dehydrogenation of butane with the addition of labelled butene over a chromium catalyst the extent to which butane takes part in the formation of the carbonaceous deposits amounted to only 25%.

The results obtained show that the formation of carbon dioxide in the experiments with water vapour and the formation of carbonaceous deposits in the experiments in a vacuum are related processes, and led to the suggestion that water vapour in the dehydrogenation prevents the formation of carbonaceous deposits on the catalyst by oxidising the corresponding intermediate products [125].

With the assumption that the overall process can be represented by the scheme:



(35)

the value of the specific radioactivity of the butadiene was used to estimate the rate ratio $w_2 : w_3$; the values found were 1 : 1000 for the KI chromium catalyst and 1 : 25 for the aluminium–chromium catalyst. The calculations showed that for both catalysts the proportion of butadiene obtained by the consecutive path through butene is greater than 90%.

Comparison of the results shows that the ratio of the rates of the dehydrogenation of butane to butene and to butadiene is approximately the same for the two catalysts ($w_1 : w_2 \simeq 20 : 1$). The ratio of the rates w_2 and w_3 is different for these catalysts, however. Thus the formation of butadiene is a consecutive process with the intermediate formation of butene and its desorption from the catalyst surface. This result is important for the kinetics of dehydrogenation and shows that in accordance with the theory of reaction on quasi-donor surfaces, the constants of the kinetic equation in this instance have the significance of adsorption coefficients [127].

In the experiments with the chromium catalyst it was found that the rates of the transfer of the radioactive tracer from butane to butene and from butene to butane at 635° are similar [123,124,129].

Since the thermodynamic equilibrium

$$C_4H_{10} \rightleftarrows C_4H_8 + H_2 \qquad (36)$$

under the conditions of the experiments was displaced considerably to the right, it must be assumed that redistribution of the hydrogen takes place between butane and butene:

$$\begin{array}{l} CH_3{-}CH_2{-}CH_2{-}CH_3 \\ {}^{14}CH_3{-}CH_2{-}CH{=}CH_2 \end{array} \rightarrow \begin{array}{l} CH_3{-}CH_2{-}CH{=}CH_2 \\ {}^{14}CH_3{-}CH_2{-}CH_2{-}CH_3 \end{array} \qquad (37)$$

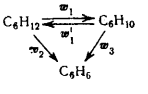
Since the products of this reaction do not differ from the starting materials (if we do not consider the isotopic composition), the equilibrium constant at any temperature should be close to unity, so that the rate constants in the forward and back directions should be approximately equal.

A number of interesting observations are reported in papers by Roginskii and Yanovskii and coworkers, who used radiochromatography to study the transformations of mixtures of butenes containing a radioactive tracer over dehydrogenating [130,131] and bismuth–molybdenum [132] catalysts. In particular, it was shown that the dehydrogenation is accompanied by cis–trans isomerisation of the butenes.

Radiochromatography and Neiman's method have been used in Balandin's laboratory to study the mechanism of the dehydrogenation of cyclohexane and methylcyclohexane over a number of catalysts.

In the multiplet theory, doublet and sextet models of the dehydrogenation of cyclohexane on oxide and metallic catalysts respectively have been developed [133]. In later papers, the sextet mechanism has been introduced for the interpretation of data obtained on oxide catalysts [134,135]; on the other hand, a number of authors [136–139] relate the hydrogenation–dehydrogenation of cyclohexane on metallic catalysts to the intermediate formation of cyclo-alkenes. Conclusions regarding the relationship between cyclo-alkenes and the process of benzene formation are based on indirect results.

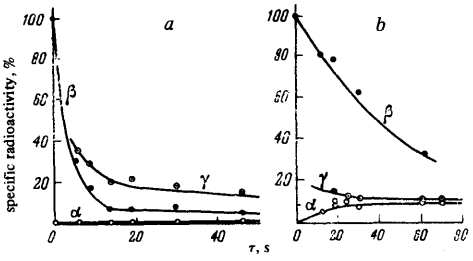
For the dehydrogenation of cyclohexane with the addition of labelled cyclohexene, studies have been made [140,141] of genetic relationships according to the scheme:



(38)

over metallic rhenium [140] and chromium oxide [140] and holmium oxide [141] catalysts; the rates of the analogous transformations of methylcyclohexane with the addition of labelled methylcyclohexene over a chromium catalyst have been determined [142].

The Figure illustrates two examples of the determination of the specific radioactivities of the products in catalysates for chromium and rhenium catalysts. It can be used to obtain information on the reaction mechanism in qualitative form by means of relationships (19) and (20).



Dependence of the specific radioactivities on the duration of contact: a: chromium catalyst; α-methylcyclohexane, β)-methylcyclohexene, γ-toluene; b: rhenium catalyst; α-cyclohexane, β-cyclohexene, γ-benzene.

For the chromium catalyst, the curve for the specific radioactivity of toluene lies above the curve for methylcyclohexene. This indicates a consecutive path with the intermediate formation of the cyclo-alkene. On the other hand, for the rhenium catalyst the specific radioactivity of cyclohexene is much greater than that of benzene ($\beta > \gamma$), indicating the direct formation of the aromatic hydrocarbon without the intermediate formation of the cyclo-alkene. Calculation of the rates of scheme (38) from Eqns. (13)–(16) confirms these conclusions, but shows that the direct formation of benzene or toluene also takes place on chromium oxide in addition to the consecutive reactions. The calculation of the rates also shows that the chief path by which cyclohexene is transformed is by dehydrogenation to benzene on the chromium catalyst and by hydrogenation to cyclohexane on the rhenium catalyst. On holmium oxide at 560° the ratio of the rates of scheme (38) is the same as that for chromium oxide.

In the doublet mechanism there should be a consecutive path for the dehydrogenation. Thus the experimental confirmation of the consecutive path for the formation of benzene (and also toluene) on chromium oxide and on holmium oxide, in contrast to the results for the rhenium catalyst, indicate than on these catalysts the dehydrogenation may take place by a doublet mechanism.

The results indicate a similarity in the mechanisms of dehydrogenation on oxide catalysts, which differ significantly from the mechanism of formation of benzene on metallic rhenium catalyst.

Tétényi and coworkers [143] suggest that over a metallic nickel catalyst the dehydrogenation of cyclohexane takes place by a consecutive path, since in experiments with

mixtures of labelled cyclohexane and non-labelled cyclohexene they detected transfer of the tracer to the cyclohexene. In this work, however, the specific radioactivities of the products were not determined, so that there is insufficient justification for this conclusion. It is possible that the cyclohexene was obtained under the conditions of the experiments by a parallel-consecutive scheme.

12. DEHYDROCYCLISATION OF PARAFFINIC HYDROCARBONS

A recently published review[144] on the dehydrocyclisation of paraffinic hydrocarbons examined the most important work in this field, including work carried out by the labelled atom method with ^{14}C. Work carried out by the labelled molecule method appeared only recently and was not included in the review[144].

The problems of the mechanism of dehydrocyclisation which can be solved by this method relate chiefly to the possibility of establishing stepwise mechanisms involving the participation of unsaturated compounds with an open chain or cyclic six-membered compounds as intermediate products.

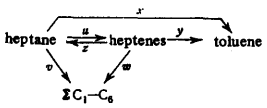
Table 1. Dehydrocyclisation of hydrocarbons on a potassium–aluminium–chromium catalyst[145].

Original mixture	Volume rate, h^{-1}	Specific radioactivity, counts min^{-1} (mg $BaCO_3$)$^{-1}$		
		heptane	heptene	toluene
n-Heptane + hept-1-ene-4-^{14}C	2.1	34	258	254
	7.4	32	280	226
n-Heptane-4-^{14}C + hept-1-ene	2.1	253	75	82
	7.5	288	58	66
n-Heptane + hept-2,3-enes-4-^{14}C	2.2	28	250	258
	7.2	34	291	274

Results obtained by Lipovich and coworkers[145] on the dehydrocyclisation of paraffinic hydrocarbons on an aluminium–chromium–potassium catalyst indicate that this reaction takes place with the intermediate formation of the alkene. Table 1 gives the characteristic values of the specific radioactivities of the chief products, obtained in experiments with mixtures of alkanes and alkenes.

Despite the slight scatter in the results, it can be seen from Table 1 that the specific radioactivities of toluene are extremely close to those of the alkenes, indicating a consecutive path for the reaction. The slight decrease in the value of the specific radioactivity of toluene compared with the values for alkenes at high volume rates is apparently due to the fact that under these conditions, adsorption equilibrium is not established between the alkene in the gaseous phase and on the catalyst surface.

From the results obtained, Lipovich and coworkers[36] calculated the "intensities" of the processes in the scheme:



(39)

The authors cited found the value of y by multiplying the mole fraction of the heptane taken by the fraction of the radioactivity converted into toluene; the value of x was found as the difference between the quantity of toluene formed and y, etc. As expected, the alkene is converted into toluene more rapidly than the alkane (that is $y \gg x$)†.

The authors cited also found that in mixtures with heptane, labelled hept-2,3-ene was converted into toluene much more slowly than hept-1-ene; this was attributed to the more intensive deposition of carbon on the catalyst by hept-2,3-ene, leading to a decrease in its activity. It may be suggested, however, that in this instance an important part is played by the specific orientation of the molecule on the catalyst surface as a result of the interaction of the π electrons of the double bond with the surface.

A study of the same reaction on metallic Ni, Pt, and mixed (Ni/Al_2O_3, Pt/Al_2O_3) catalysts was described by Tétényi and Paal[146,147]. Using a pulse procedure and radiochromatography, the authors cited reached analogous conclusions regarding the consecutive nature of the reaction, and showed that in the dehydrocyclisation of hexane, alkenes and dialkenes with the normal structure are intermediate products, whereas cyclanes and cyclenes are not formed. Characteristic values of the specific radioactivities of the products in arbitrary units from various series of experiments are given in Table 2.

Table 2. Dehydrocyclisation of hydrocarbons on metallic catalysts.

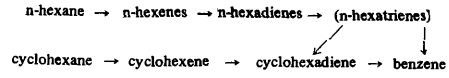
Catalyst	Original mixture	Specific radioactivities of products (arbitrary units)					Refs.
		n-hexene	n-hexane	cyclohexane	cyclohexene	benzene	
Pt	n-Hexane-1-^{14}C	0.5	33.5	—	—	34	146
Ni/Al_2O_3	n-Hex-1-ene, n-Hexane-1-^{14}C	36.5	4.8	—	—	4.6	146
Pt	n-Hex-1-ene, n-Hexane-1-^{14}C, cyclohexane	64	80	1.6	—	27	147
Pt	n-Hexane, cyclohexane-^{14}C	background level	—	38	—	15	147
Ni/Al_2O_3	n-Hexane-1-^{14}C, cyclohexane	52*	—	0.9	—	10	147
Pt	n-Hex-1-ene-1-^{14}C, cyclohexane	94	94	0.5	22**	63	147
Pt	n-Hex-1-ene-1-^{14}C, cyclohexene	74*	—	—	6	52	147
Pt	Hex-1-ene-1-^{14}C, cyclohexa-1,3-diene	355*			6.3***	2.6	147

*Hexane + hexenes.
**Cyclohexane + hexadienes.
***Cyclohexa-1,3-diene.

By comparing their own and published results on the mechanism of the dehydrocyclisation of alkanes, the authors cited concluded that the main features of the mechanism of this reaction are the same for metallic and for oxide catalysts, and that for hydrocarbons with an open chain and for

† In the interpretation of the results obtained it is important to remember the inadequacy of the concepts of intensity and reaction path. For example, the observed magnitude of the intensity x by itself does not make it possible to conclude that heptane under the conditions of the experiments is converted directly into toluene: the intensity x merely shows that part of the heptane is converted into toluene by some means or other (possibly through the alkene).

cyclic hydrocarbons the mechanism can be described by the scheme:



(40)

Experiments with mixtures of labelled hex-1-ene and hexatriene showed[148] that the latter is in fact an intermediate product in the formation of cyclohexadiene and benzene on a platinum catalyst. The relatively low value of the specific radioactivity of hexatriene compared with that of cyclohexadiene and benzene in the catalysates, however, may indicate that there is another reaction path by which the dialkene undergoes cyclisation.

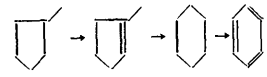
13. HYDRO-DEHYDROISOMERISATION OF CYCLANES

A number of papers describe the use of radiocarbon to study the mechanism of the interconversion of methylcyclopentane, cyclohexane, and benzene in an atmosphere of hydrogen over bifunctional (oxide–metallic) catalysts, and also over tungsten sulphide. Kalechits and coworkers[149,150] showed that when cyclohexane is heated with labelled benzene in an autoclave over tungsten sulphide, the product is methylcyclopentane, whose specific radioactivity is greater than that of the cyclohexane in the catalysate.

When a mixture of benzene and labelled cyclohexane was used, the specific radioactivity of the latter in the catalysate was greater than that of the methylcyclopentane; radioactivity was not detected in the benzene. When mixtures of cyclohexane and methylcyclopentane were passed over a platforming catalyst[151], the radioactivity of the cyclohexane in the catalysate was considerably greater than that of the benzene when the cyclohexane was labelled; when the methylcyclopentane was labelled, however, the specific radioactivities of the cyclohexane and benzene in the catalysate were approximately equal. According to conditions (19) and (20), these results show that on both catalysts studied, the interconversion of methylcyclopentane and benzene takes place partly without desorption of any intermediate substances, including cyclohexane; the other reaction path lies through cyclohexane. It has been shown[152] that the concentration of non-stoichiometric sulphur has no influence on the overall rate of hydrogenation of benzene, but influences the ratio of the rates of the two paths for the formation of methylcyclopentane. The authors cited believe that on the surface of the catalyst the cyclic hydrocarbons undergo a number of transformations, including the intermediate formation and isomerisation of cycloalkenes, which may not be related to the gaseous phase by an adsorption equilibrium. These ideas formed the basis of the familiar stepwise scheme for the reforming of cyclanes, proposed by Mills and coworkers[153].

The experimental justification for this scheme was provided by the characteristic properties of bifunctional catalysts combining the dehydrogenating properties of metals of the platinum group with the isomerising properties of an acidic oxide. The theoretical justification was the possibility of applying the ideas of the mechanism of homogeneous isomerisation in accordance with Whitmore's concept, with the formation of a carbonium ion as a result of the reaction of a proton of the catalyst with the π electrons of the double bond of the alkene. An analysis of published results shows that although this scheme has been in existence and has been used for 15 years, there are no results which confirm it directly or indicate the part played by cyclenes as intermediate products, in particular in the isomerisation and dehydrogenation of cyclohexane and the dehydroisomerisation of methylcylopentane.

To obtain these results, experiments were carried out[154–159] with cyclohexane and methylcyclopentene. Studies were made of the transformation of methylcyclopentane into benzene according to the scheme[157]:



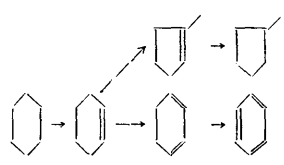
(41)

The experiments were carried out in a flow assembly at a pressure of 20 atm and 480°, at a molar ratio of hydrogen to carbon equal to 5 : 1, on a number of specimens of bifunctional catalysts (platinum on alumina and palladium on alumina). The reaction products were analysed by radiochromatography. Labelled methylcyclopentene was added to the original methylcyclopentane. In accordance with Eqns. (19) and (20), if the methylcyclopentene were a necessary intermediate product [according to scheme (41)], its specific radioactivity into the catalysate should be less than that of benzene or cyclohexane.

A detailed study of the reaction products indicated that dehydroisomerisation of the five-membered rings, splitting of the rings, and hydro-cracking with the formation of lower molecular-weight products take place. It was found that the specific radioactivity of benzene and cyclohexane were close to that of methylcyclopentane and much less than that of methylcyclopentene, and this contradicts the above scheme. A remarkable feature was that the specific radioactivities of the lighter hydrocarbons, particularly the pentanes, was very high and in a number of instances exceeded the specific radioactivity of the methylcyclopentene. This means that methylcyclopentene is an intermediate product in the hydro-cracking. The marked difference in the specific radioactivities of the products of the cracking and the products of the isomerisation of the cyclo-alkanes indicates that these processes take place through different intermediate surface compounds. The similarity in the specific radioactivities of the methylcyclopentane, cyclohexane, and benzene apparently indicates not only that methylcyclopentene is not a necessary intermediate product, but also that methylcyclopentane undergoes isomerisation more rapidly than methycyclopentene.

Similar results were obtained[160] when methylcyclopentane and labelled methylcyclopentene were passed over AP-56 catalyst under the conditions of platforming. The authors cited point out that if methylcyclopentane forms a complex "corresponding to the cyclo-alkene structure", it differs from the complex obtained directly from the unsaturated hydrocarbon.

The transformation of cyclohexane and cyclohexene according to scheme (42) was studied on catalysts consisting of palladium on alumina, rhenium on alumina, and molybdenum oxide on alumina[155].



(42)

A mixture of labelled cyclohexane and cyclohexene was used. In this instance, if the cyclohexene were an intermediate product, its specific radioactivity in the catalysate should have been greater than that of the benzene

and methylcyclopentane. Radiochromatographic analyses showed the opposite, however. Radioactivity was detected in methylcyclopentane and benzene, but not in cyclohexene. This indicates the possibility of isomerisation of cyclohexane independently of cyclohexene; the latter is not an intermediate product. Later, a similar result was obtained[160] when a mixture of cyclohexane and labelled cyclohexene was passed over an AP-56 platinum catalyst under the conditions of platforming.

It is now assumed by a number of authors[161-163] that in reforming reactions the intermediate alkenes are not only formed, but are necessarily desorbed. In early papers, however, it was suggested that the alkene may undergo further transformation without desorption. In some studies[154], cyclohexene remained in the catalysates, so that it was either desorbed or did not reach the catalyst surface during the reaction.

Special experiments with deuterium[155] showed that at atmospheric pressure the cyclohexene of the original mixture takes part in deuterium exchange almost quantitatively, so that it passed through a stage involving adsorption on the catalyst.‡ In experiments under pressure, the degree of exchange was also fairly high, and some of the molecules of the cyclohexene remaining had undergone multiple exchange. Almost no exchange took place in the absence of a catalyst.

These results showed that the transformations of the cyclo-alkanes and -alkenes under the conditions studied apparently take place by independent paths. In this connection, the problem of the mechanism of the action of bifunctional reforming catalysts is becoming more urgent.

The solution of this problem will make it possible to improve the technology of one of the most important petrochemical processes.

---o0o---

The material examined shows that the LM method is most effectively used in the study of the mechanism of multi-stage catalytic reactions, when the usual chemical methods lead to ambiguous results and it is necessary to make a choice between several possible reaction paths. This situation usually arises at a definite stage in the experimental study of a given process. Thus the reactions studied are often familiar reactions for which definite views, widely encountered in scientific circles, already exist regarding the mechanism. The use of the LM method makes it possible in many instances to develop significantly more penetrating views regarding the mechanisms of these processes; in some instances the results are extremely unexpected and make necessary a new approach to the interpretation of familiar results and stimulate their further study at a new and higher level.

Mechanism of the Catalytic Hydrogenation of Oxides of Carbon to Methane

V.M.Vlasenko and G.E.Yuzefovich

The present review examines the mechanisms of the formation of methane from carbon monoxide and dioxide and hydrogen in the presence of contact catalysts based on metals of the iron group (chiefly nickel). The experimental results obtained by various methods are examined, the reactive forms of the adsorbed molecules and the signs of their charges are considered, and particular attention is paid to the determination of the reactive complexes under the conditions preceding the start of the catalytic reaction, and the results of kinetic studies. It is shown that there is a significant difference in the mechanisms of the hydrogenation of carbon monoxide and dioxide to methane. This difference is attributed to the poisoning effect of carbon monoxide on the processes involved in the hydrogenation of CO_2. Attention is drawn to a number of results which are of considerable importance for the solution of the problems of the catalytic purification of hydrogen from oxides of carbon. The bibliography contains 129 references.

I. INTRODUCTION

Syntheses based on carbon monoxide and hydrogen (and to a much smaller extent on carbon dioxide and hydrogen), from their discovery[1-3] up to the present, have attracted considerable attention from many research workers. This is due to the variety of possibilities for the practical utilisation of reactions involving the catalytic hydrogenation of oxides of carbon. A large number of versions of the synthesis of hydrocarbons, the synthesis of methanol, and the direct synthesis of higher alcohols[4,5] are among the reactions of carbon monoxide with hydrogen which have been carried out on the industrial scale.

The possibilities of synthesis from oxides of carbon and hydrogen apparently have not been fully realised. Moreover, with other components in the reaction mixture it is possible to carry out the most rational production of complex end products. Examples of such processes are the preparation of higher alcohols by the oxo-process[5] and the synthesis of amines from carbon monoxide, hydrogen, and ammonia[6,7].

The mechanisms of all these reactions and of other reactions which have not yet been realised but which are thermodynamically possible may be the same in the initial stages, so that the study of these stages is of considerable interest. Usually, however, the compositions of the reaction products are complex, and this makes it very difficult to obtain a true picture of the process. If, however, we exclude from consideration some stages of the reaction, it is possible to simplify the problem and to concentrate attention on the study of the first stages of the synthesis. This can be done by studying the formation of methane, since in this way it is possible to investigate in purest form the primary stages of the reaction of oxides of carbon with hydrogen. This possibility has been underestimated, apparently because there are no reviews devoted specially to the mechanism of the synthesis of methane, whereas studies of the mechanism of formation of the higher hydrocarbons are published periodically[8-16].

As the simplest aliphatic hydrocarbon, methane exhibits the basic features of its homologous series, so that the study of the mechanism of its formation is of primary importance in the investigation of the synthesis of alkanes.

In this study, it is naturally necessary to choose reaction conditions under which the formation of methane is the only process or at least the predominant process. A decisive feature is the selection of a highly selective and active catalyst, in the presence of which the most definite results are obtained; it is also desirable that the results be of practical use.

Nickel is one of the most active catalysts for the synthesis of methane from carbon monoxide and hydrogen[17]. The other metals of the iron group have lower activities. Nickel, cobalt, and iron can be arranged in the same sequence with reference to the conversion of carbon dioxide into methane[1,2,18-22]. The present review deals chiefly with results obtained with nickel catalysts, which in our view are of greatest interest.

II. MECHANISM OF THE FORMATION OF METHANE FROM CARBON MONOXIDE AND HYDROGEN

The hydrogenation of carbon monoxide to methane can be regarded as the simplest example of the synthesis of hydrocarbons. This makes it possible on the one hand to introduce existing theories of the synthesis of hydrocarbons to explain the mechanism of formation of methane, and on the other hand, as shown above, it makes it possible to some extent to use the results obtained to understand the mechanism of formation of higher hydrocarbons.

The earliest theory of hydrocarbon synthesis was the carbide theory[23-27], which was subsequently found to be inadequate to explain these processes in the presence of catalysts based on metals of the iron group[9]. In fact, carbide formation cannot be an intermediate stage in the synthesis of methane from carbon monoxide and hydrogen, since the temperature of hydrogenation of the surface nickel carbide is higher than the temperature of appreciable methane formation[28] and the rate of the synthesis is much greater than the rate of carbide formation[29-33].

Other widely held ideas, in addition to the carbide theory, have included various schemes according to which oxygen-containing substances—methanol[34] or formaldehyde[5]—are intermediate products. Attempts to detect formaldehyde or methanol in the synthesis of methane on a nickel catalyst were unsuccessful, however[35]. Moreover, it was shown[36] that on a cobalt catalyst the yield of hydrocarbons when methanol is used as starting material is less than that obtained when a mixture of carbon monoxide and hydrogen is used. The formation of hydrocarbons from methanol is evidently a secondary process involving carbon monoxide and hydrogen obtained by the decomposition of methanol.

A suggestion related to these hypotheses was put forward by Fischer and coworkers[17], according to whom the reaction with carbon monoxide leads to the intermediate formation of the metal carbonyl, which is then reduced with the formation of methane. A similar explanation for the synthesis of hydrocarbons was put forward by Pichler[5,16].

In contrast to early hypotheses based on Sabatier's theory of phase intermediate compounds[37], the idea of primary compound formation represents a definite change towards modern theories of catalytic action, which make use of the concept of intermediate *surface* compounds[38,39]. In connection with these theories, the search for reactive surface complexes and radicals is acquiring primary importance.

Orlov's suggestion[40] that methylene radicals are formed in the primary stages of the hydrogenation of carbon monoxide

$$CO + 2H_2 \rightarrow CH_2 + H_2O$$

was later verified experimentally by Eidus and Zelinskii[41], who proved the existence of CH_2 radicals in the methylation of benzene to toluene. It was established that the CH_2 species are formed from carbon monoxide and hydrogen[29]. On the basis of the results obtained, Eidus[36] concluded that on cobalt and nickel contact catalysts the primary stages of the process involve the successive hydrogenation of carbon monoxide first to an unstable oxygen-containing group, and then to the methylene radical:

A similar mechanism was proposed by Hamai[42].

The idea that an adsorbed complex of HCOH is formed provided the basis of the mechanism of hydrocarbon synthesis proposed by Anderson[5,43]. This mechanism differs from Eidus' scheme[9] in the subsequent stages of hydrocarbon chain formation. In a study of syntheses based on carbon monoxide and hydrogen in the presence of iron catalysts, Bashkirov and coworkers[44-46] also concluded that these processes should involve the production of an unstable intermediate adsorption complex which contains carbon, hydrogen, and oxygen atoms and is the precursor of both hydrocarbons and alcohols.

The conclusion that an intermediate compound of this kind exists was also reached[47] on the basis of a study of the Fischer–Tropsch synthesis in the presence of a nickel catalyst. Similar ideas were put forward by Eidus[48] and by Gibson and Clarke[49] on the basis of a study of the synthesis of hydrocarbons from carbon monoxide, hydrogen, and ethylene.

Thus irrespective of the composition of the products, the formation of a primary complex is assumed in all schemes of catalytic synthesis from carbon monoxide and hydrogen. The existence of this compound has not yet been confirmed experimentally, however, although this problem is a central problem in the study of the mechanisms of various reactions of carbon monoxide with hydrogen.

The possibility of existence of *adsorption complexes* in itself does not prove that they play a leading part in the reactions. In order to reach this conclusion it is necessary to rely on the results of direct kinetic studies, which make it possible to determine the limiting stage of the reaction.

The available data[50,51] indicate that the adsorption of the components of the reaction cannot be taken as the limiting stage. Similarly, the desorption of the reaction products does not determine rates of hydrogenation on nickel contact catalysts[50]. Study of the infrared spectra of water[52] showed that it is not adsorbed on a nickel contact catalyst, and it has also been shown[53] that methane and water are not adsorbed on a nickel–chromium catalyst.

On the other hand, the results of kinetic studies of the process indicate that the rate of formation of methane is determined by the reaction of carbon monoxide and hydrogen adsorbed on the surface of the contact catalyst.

It has been found by the static method[54] that at 271° and H_2/CO ratios from 2 to 20 in the presence of a nickel wire catalyst the rate of formation of methane is approximately proportional to the pressure of hydrogen and is retarded by carbon monoxide. A similar conclusion was reached by Luyten and Jungers[55], who studied the formation of methane in a static system at 300° and H_2/CO ratios from 1 to 6 in the presence of nickel deposited on kieselguhr. The reaction rate was given by the equation

$$W = k \cdot p_{H_2}^{0.9} \cdot p_{CO}^{-0.2}.$$

The heat of activation was 27 kcal mole^{-1}. This value differs considerably from the value 35 ± 1 kcal mole^{-1} found by Nicolai and coworkers[56], although the studies were carried out under identical conditions, on similar contact catalysts. The discrepancy is apparently due to the non-steady state of the catalyst surface.

The flow method has been used[50] to make a detailed study of the kinetics of the synthesis of methane at atmospheric pressure on an industrial nickel–kieselguhr contact catalyst in the range 300–350° at H_2/CO ratios from 1.2 to 4. The limiting stage of the process is the reaction between a molecule of carbon monoxide adsorbed on the contact surface and three molecules of hydrogen, according to the equation

$$W = \frac{p_{CO} \cdot p_{H_2}^3}{(A + Bp_{CO})}$$

where A and B are constants.

The retarding influence of carbon monoxide at high concentrations, observed in the works cited, is apparently due to the fact that the CO covers the contact surface to a considerable extent, leading to a corresponding decrease in the degree of covering of the surface by hydrogen. Moreover, in this instance there is a possibility of a change in the phase composition of the contact catalyst as a result of the formation of nickel carbides. Changes in the phase composition can be avoided if the studies are carried out at low concentrations of carbon monoxide in a large excess of hydrogen. The kinetic relationship obtained in this way by a flow-circulation method with a nickel–chromium catalyst at 135–175° and a concentration of carbon monoxide in hydrogen equal to 0.3 vol. % has the form[57,58]

$$W = k \cdot p_{CO}^0 \cdot p_{H_2}^0$$

which indicates directly that the process takes place by a Langmuir–Hinshelwood mechanism. The zero order of

the reaction with respect to both components can be attributed to the non-uniformity of the nickel surface with respect to the adsorption of carbon monoxide and hydrogen under the given conditions. Non-uniformity of the surface with respect to the adsorption of hydrogen at room temperature was established[59-61] by the differential isotopic method, and the non-uniformity of the surface of iron catalysts in the synthesis of hydrocarbons has also been observed[62]. Studies by a method enabling the change in the weight of the catalyst during the contact process[57] to be observed established that under the conditions of the experiment at 160° the degree of covering of the nickel surface by carbon monoxide amounts to about 1/3, and 2/3 of the surface is covered with hydrogen. This apparently explains the fact that the heat of activation (16.2 kcal mole^{-1}) is less than that in the works cited above[55,56], in which the degree of covering of the surface by carbon monoxide might have been much greater, because of the high concentration of CO in the gaseous phase. From these results it follows that in all examples of the synthesis of methane and higher hydrocarbons from carbon monoxide and hydrogen, on nickel catalysts at least, the reaction components interact in the adsorbed layer. This indicates that the adsorption complexes produced may play a leading role in syntheses from carbon monoxide and hydrogen. The detection of these complexes is therefore of considerable interest in the investigation of the mechanism of the catalytic formation of hydrocarbons.

The formation of adsorption complexes can be established if their steady-state concentration is sufficiently high. To determine the temperature range corresponding to the existence of adsorption complexes, it is necessary not only to establish that the limiting stage is the reaction in the adsorption layer, but also to establish whether the rate of the catalytic reaction is controlled by the rate of formation or the rate of transformation of the complexes. These stages can be studied experimentally by measuring the temperature dependence of the contact potential difference (c.p.d.) in the reaction mixture. The formation of adsorption complexes generally leads to a marked change in the contact potential difference relative to the values for each of the reagents.

For example, in the reaction of carbon monoxide and hydrogen on zinc oxide a decrease in the value of the c.p.d., which remained constant at the temperatures of catalysis, was observed[63]. In this instance the rate of the hydrogenation of carbon monoxide is limited by the rate of transformation of the adsorption complexes formed[64]. A different picture is observed in the hydrogenation of carbon monoxide in the presence of a nickel–chromium contact catalyst[65]. The temperature dependence of the c.p.d. is given by a characteristic curve with a minimum corresponding to the highest concentration of the adsorption complexes. With increase in temperature the value of the c.p.d. under the conditions of catalysis becomes close to its value for the adsorption of carbon monoxide. This indicates that the catalyst surface carries adsorbed carbon monoxide, and the rate of the contact process is determined by the rate of its conversion into chemisorption complexes. Thus in the reduction of carbon monoxide to methane on nickel, the rate of formation of the reaction complexes is the rate-determining stage of the reaction. It may be assumed that this is also true of the synthesis of methane from carbon monoxide and hydrogen in the presence of catalysts based on iron and cobalt.

It is clear from the foregoing that studies carried out under the conditions directly preceding catalysis are of greatest value in the investigation of the mechanism of the process. The study of the adsorption of the reaction components under these conditions, both separately and in mixtures, is acquiring primary importance, and may give important information on the formation and composition of the adsorption complexes.

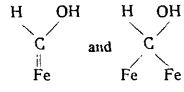
In spite of an extensive literature devoted to the adsorption of hydrogen and carbon monoxide on metallic contact catalysts, however, comparatively few studies have been made of the adsorption of these reagents and their mixtures under conditions close to those of catalysis or at the temperatures of catalysis.

Among studies of this kind carried out for cobalt Fischer–Tropsch contact catalysts, mention may be made of studies[66-71] of the adsorption of carbon monoxide and hydrogen, and their mixtures, in the range 25–97°. It was shown that at 97° over a period of 12 h, the formation of hydrocarbons, water, or carbon dioxide from CO and H_2 is not observed, whereas at 110°, methane was detected in the gas[67]. Special experiments established that cobalt carbonyls are not formed at 53, 76, or 97°,[70] that is the adsorption relationships were studied on an almost unaltered contact surface. In the study of the adsorption of mixtures of CO and H_2 it was established that the adsorption of each gas from the mixture is greater than the adsorption of the individual gas at the same partial pressures. With increase in the total pressure, the adsorption of carbon monoxide is greater from the mixture with $CO:H_2 = 1:2$ than from the mixture with $CO:H_2 = 1:1$. The adsorption of hydrogen is characterised by the opposite relationship[66,69]. With increase in temperature the quantity of adsorbed hydrogen increases, the dependence of the quantity of adsorbed carbon monoxide on the quantity of adsorbed hydrogen tending towards a linear relationship, and this, in the opinion of the authors cited[66], may indicate the formation, on the catalyst surface, of chemisorbed complexes which are possibly intermediate products in the Fischer–Tropsch synthesis. The same conclusion was reached by the other authors cited[69], who showed that the ratio of carbon monoxide and hydrogen adsorbed on the contact surface reaches 1 : 1 at 97°. This may indicate the formation of a complex with the composition HCOH. In other work[67], however, the value of this ratio for the same temperature was 2 : 1, and it was concluded that the complex ≡C–H is formed. The mutual intensification of adsorption, observed with consecutive adsorption of the components[68,70,71], also indicates strong chemical interaction between carbon monoxide and hydrogen in the adsorption layer.

These results of adsorption measurements on cobalt contact catalysts, however, cannot establish sufficiently clearly the compositions of the stoichiometric chemisorption complexes[72]. This is due, in particular, to the lack of information on the chemisorbed forms of the molecules of carbon monoxide and hydrogen and their reactivities; this makes it impossible to reach definite conclusions regarding the participation of various forms of chemisorbed molecules in the formation of the surface complexes.

To some extent these difficulties were overcome in a study[72] of the adsorption and desorption of carbon monoxide and hydrogen on a deposited iron catalyst at 50°. As with the cobalt contact catalysts, the adsorption measurements could not prove the formation of chemisorption complexes, since it was shown that, in addition to the formation of reactive forms of the molecules, irreversible adsorption of part of the gas took place, and this fraction did not take part in the formation of complexes. To eliminate the contribution from the irreversible adsorption, the authors cited used a method involving desorption with decrease in

pressure. It was established that, irrespective of the CO : H_2 ratio in the original mixture, a gas mixture with the almost constant ratio 1 : 1 is desorbed from the contact surface after 38 h. This indicates the existence of a weakly-bound chemisorbed complex, which decomposes on desorption. After determination of the composition of the chemisorption complex, we are faced with the problem of its structure and the type of bonds present. Linear and bridged bonds are formed when carbon monoxide is adsorbed on iron [73,74]. In this connection, two structures are possible for the complex HCOH:



A choice between these structures can be made on the basis of work by Blyholder and Neff [75], who used infrared spectroscopy to study the reaction of carbon monoxide and hydrogen on the surface of a deposited iron catalyst. The authors cited established that at 180°, complexes of the type

are formed, where R may be either a hydrogen atom or a hydrocarbon radical with unsaturated bonds. Although this structure differs slightly from that proposed by Eidus, it may be concluded that it is formed by the reaction of hydrogen with carbon monoxide adsorbed in linear form. An interesting feature is that at temperatures at or close to room temperature the authors cited, in agreement with Eischens [76], did not observe reaction between carbon monoxide and hydrogen. This work [75] is almost the only proof of the existence of surface complexes obtained by infrared spectroscopy; this is apparently due to the fairly high concentration of the complexes at 180°.

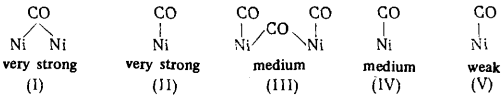
A number of studies [28,57,63,65] have been made of the reactive forms of adsorbed molecules, their interactions, and the part played by the primary complexes in the synthesis of methane from carbon monoxide and hydrogen in the presence of a nickel–chromium catalyst.

The study of the adsorption of carbon monoxide and hydrogen, separately and in a mixture, was carried out at 75°, since at low temperatures carbon monoxide may form volatile nickel carbonyls, which decompose above 60°, [77] and formation of methane begins at temperatures slightly greater than 80°. [78] Thus the conditions established corresponded to those directly preceding the start of the catalytic reaction. Under these conditions the adsorption of the gases takes place only on the nickel surface, and neither hydrogen nor carbon monoxide are adsorbed on the chromium oxide used as carrier.

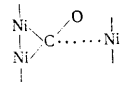
In a number of papers it has been suggested that in hydrogenation on nickel contact catalysts, hydrogen may penetrate into the interior of the catalyst, with a significant influence on the catalytic activity [79–84]. The adsorption of hydrogen and carbon monoxide was therefore studied [28,63,65] both on a clean nickel catalyst surface (treated specimens) and on specimens containing dissolved hydrogen (untreated specimens).

It was established that on the treated catalyst specimen, hydrogen is adsorbed at 75° by a dissociative mechanism, and the surface acquires a positive charge [65]. When dissolved hydrogen is present in the nickel, however, the adsorption is accompanied by the transfer of electrons from the catalyst, and the adsorbed hydrogen acquires a negative charge [65]. This result shows that dissolved hydrogen has a significant influence on the adsorption properties of nickel.

Carbon monoxide is adsorbed on nickel in molecular form. Study of the infrared spectra of the adsorbed molecules [85–87] showed the existence of at least five forms of bonding between carbon monoxide and the nickel surface, with different structures and bond strengths:



The production of a given form depends on the crystal structure of the nickel [87]. With crystalline specimens, the production of bridged (I) and linear (II) forms is observed primarily, but at higher degress of covering, linear groups are produced on nickel atoms which already have chemisorbed carbon monoxide by a bridging type of bond (III). On disordered crystallites, carbon monoxide is much less strongly chemisorbed, and only in linear structures (IV) and (V). Recently, another form of bridging bond has been found [88]:



The formation of this bond is facilitated by comparatively low pressures of carbon monoxide, when the neighbouring Ni atoms are not bonded to CO molecules by other types of bond.

Some authors doubt the existence of bridging bonds. Thus calculation by the MO method [89] showed that all available data on the infrared spectra of chemisorbed CO can be explained by assuming only a linear form of bonding for carbon monoxide adsorbed on various surface centres. The strengths of the bonding and the frequencies of the CO stretching vibration also differ. This view is held by other authors [90], who however do not exclude completely the possibility that a small proportion of the carbon monoxide molecules are adsorbed in bridged form. These views, however, are not fully justified.

The production of the various forms of adsorbed carbon monoxide apparently depends on the conditions of the experiment. For the adsorption of carbon monoxide on a treated specimen of nickel–chromium catalyst at 75°, it was established that at low pressures the chemisorption is accompanied by the production of a bridged form of bond [type (I)], and that with increase in pressure the nature of the bonding changes, and a surface layer of the single-centre type is formed [28], in agreement with the results of other studies [85,89,91]. The layer of chemisorbed gas is positively charged, and when the bridged structure changes to the linear structure there is no change in the electronic properties of the catalyst surface [65].

Each type of adsorption should evidently be characterised by bonds of different strength between the adsorbate and the contact surface, so that the form of bonding should determine, in particular, the thermal stability of the adsorbed carbon monoxide and its stability towards hydrogenation. For the bridged structure, decomposition of carbon monoxide is not observed up to 300°, and its hydrogenation begins only above 140°. Carbon monoxide joined to nickel by a linear bond is hydrogenated at a temperature slightly greater than 80°. Thus the linear form of bonding for the adsorbed carbon monoxide is weaker than the bridging form, and hence more reactive. This form is apparently of types (IV) or (V).

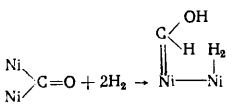
The presence of adsorbed and dissolved hydrogen in the contact catalyst influences the properties of the nickel towards the adsorption of carbon monoxide. The dissolved hydrogen alters the electronic properties of the metal. Thus changes have been observed[92] in the infrared spectra of carbon monoxide adsorbed on nickel, corresponding to the change from linear structures to bridging structures, depending on the thoroughness with which hydrogen was removed from the metal after reduction. In agreement with these observations, according to published data[28], in the adsorption of carbon monoxide on an untreated nickel–chromium catalyst, sorbed hydrogen is displaced from the contact catalyst into the gaseous phase, and a linear form of bond is produced between the adsorbed carbon monoxide and the contact surface. As with the adsorption of CO on a clean nickel surface, the layer of carbon monoxide is positively charged[65].

The influence of dissolved hydrogen on the adsorption properties of the contact catalyst is due to the two-layer adsorption of carbon monoxide[28]

As a result of the formation of the chemisorption bond between the carbon monoxide molecule and the contact surface, the bonds in the CO molecule are weakened to such an extent that two CO molecules interact with the rupture of one carbon–oxygen bond and the formation of a carbon–carbon bond.

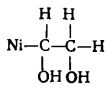
The determination of the forms of the adsorbed molecules makes it possible to examine the mechanism of the adsorption of carbon monoxide and hydrogen from their mixtures. Carbon monoxide is adsorbed in linear form. At the same time the adsorption of hydrogen increases. The absorption of hydrogen in the presence of carbon monoxide takes place slowly, evidently due to chemical reaction with the formation of complexes of a type corresponding to the enol form of formaldehyde:

The formation of complexes of this kind also takes place if hydrogen is adsorbed on a contact catalyst on which carbon monoxide has previously been adsorbed by the two-centre mechanism. The bridged type of bond is converted into the linear type with the formation of a complex, and the molecular hydrogen is adsorbed on the liberated centres of the nickel



The mean rate of formation of the complex at 75° corresponds to the transformation of 5.6×10^{-7} cm³ CO cm^{-2} Ni h^{-1}; the concentration of adsorption complexes formed amounts to ~ 10^{15} per 1 cm² nickel surface.

The reaction between hydrogen and carbon monoxide adsorbed in two layers leads to the formation of complexes of the type



at a mean rate corresponding to the transformation of 12.8×10^{-7} cm³ CO cm^{-2} Ni h^{-1} and the concentration of the complexes amounts to ~ 3.8×10^{16} per 1 cm² nickel. The possibility of formation of carbon–carbon bonds during the adsorption of carbon monoxide and hydrogen from their mixtures was proposed[75] on the basis of a study of the infrared spectra.

The concentrations of the complexes formed are sufficient for their detection by infrared spectroscopy. This in turn would have been significant evidence for the existence of surface compounds of this type. The failure of Blyholder and Neff[52] to detect adsorption complexes on a nickel contact catalyst at 180° and above by this method can apparently be attributed to the excessively high temperature of the experiment, at which the complexes formed are readily transformed into the final products. The suggestion, made by the authors cited[52], that the reacting substances are much less firmly bound to the nickel than to the iron catalyst, on which it was possible to detect surface compounds at 180°, [75] can be disputed: at this temperature, the reaction on iron does not take place very intensively, whereas in the presence of the more active nickel the reaction rate is quite high, and this leads to a sharp decrease in the concentration of chemisorption complexes.

Unlike Koelbel and coworkers[72], Vlasenko and coworkers[28] detected stoichiometric chemisorption complexes, indicating that all the adsorbed carbon monoxide has the same reactivity.

Thus surface compounds of at least two types—a type corresponding to the enol form of formadehyde and a type containing two carbon atoms—may be formed on the surface of the nickel contact catalyst, depending on the conditions of adsorption. The existence of complexes with two carbon atoms indicates that under certain conditions of the synthesis of hydrocarbons, at least on nickel contact catalysts, carbon–carbon bonds may be produced even in the stage of carbon monoxide adsorption. The possibility of existence of primary complexes not only with one carbon atom but also with a larger number of carbon atoms was pointed out by Eidus[10]. The possible role of complexes of this type in the synthesis of hydrocarbons requires further detailed study, but they are not formed in the hydrogenation of carbon monoxide in a large excess of hydrogen, since only methane and water are detected in the reaction products.

The information obtained in the study of the adsorption of mixtures of carbon monoxide and hydrogen on a nickel–chromium catalyst under the conditions preceding the start of catalysis[28] shows that hydrogen is adsorbed on nickel chiefly in the form of molecules. The almost complete absence of atomic hydrogen in the synthesis of hydrocarbons was demonstrated by Craxford and Rideal[25]; the absence of dissociative adsorption of hydrogen was also noted for nickel with ethylene present in the gas[93]. Thus hydrogen is adsorbed in the form of molecules both under the conditions of formation of methane and also apparently in the synthesis of hydrocarbons on nickel, cobalt, and possibly iron catalysts. The fact that dissociation of the hydrogen molecules does not take place during adsorption on these metals is due to the influence of the adsorbed carbon monoxide. The electronic state of the catalyst surface, and hence its adsorption properties, change in such a way that there is a decrease in the energy of the bonding between the hydrogen molecules and the surface, so that decomposition of the molecules to form atoms does not take place. The adsorption of hydrogen on the nickel–chromium catalyst is accompanied by the formation of a negatively charged layer of chemisorbed gas [H_2^-] on the surface[65], due to the presence of dissolved hydrogen in the contact catalyst. These regular features of the adsorption of hydrogen are apparently preserved under the conditions

of the synthesis of higher hydrocarbons, since the catalysts for the synthesis always contain dissolved hydrogen.

In the synthesis of methane, and also apparently in the synthesis of higher hydrocarbons, carbon monoxide is adsorbed in the form of molecules with the production of a linear form of bond between the chemisorbed species and the surface atoms of the nickel; the chemisorbed layer of $[CO^+]$ is positively charged[65].

The oppositely charged adsorbed molecules of hydrogen and carbon monoxide interact in the adsorption layer. The primary products of this interaction may be adsorption complexes of the type corresponding to the enol form of formaldehyde; the existence of these complexes on metallic contact catalysts of the iron group can be taken as established. The formation of these complexes $[HCOH^+]$ takes place at a high rate[28] and is accompanied by a decrease in the work function[65]. The rate of their formation limits the rate of the catalytic conversion of carbon monoxide into methane. This is confirmed not only by the results of the measurement of the contact potential difference[65] but also, in particular, by the results of a kinetic study of the reaction in the presence of a nickel–chromium contact catalyst[57], since the rate of formation of the complexes at 75°[28] almost coincides with the hypothetical rate of the catalytic process at this temperature. In the subsequent stage, the oxygen-containing complexes apparently react in the adsorption layer with hydrogen molecules, to produce methylene radicals and water. In subsequent changes, the methylene radicals may undergo either polymerisation with the formation of hydrocarbon chains or hydrogenation to form methane.

These regular features of the mechanism of the conversion of carbon monoxide into methane on a nickel–chromium catalyst are apparently general in character and are observed in the synthesis of hydrocarbons on nickel, cobalt, and possibly iron catalysts.

Thus the following is the most probable scheme for the mechanism of the reduction of carbon monoxide to methane on these catalysts[28,65]:

1. $[\ ] + e + H_2 \rightarrow [H_2]^-$
2. $[\ ] + CO \rightarrow [CO]^+ + e$
3. $[CO]^+ + [H_2]^- \rightarrow [HCOH]^+ + e$ (slow stage)
4. $[HCOH]^+ + [H_2]^- \rightarrow [CH_2] + H_2O + [\ ]$
5. $[CH_2] + [H_2]^- \rightarrow CH_4 + e + [\ ]$†

For the synthesis of higher hydrocarbons, the fifth stage of this scheme should reflect not the reaction of methylene radicals with hydrogen, but their polymerisation.

III. MECHANISM OF THE FORMATION OF METHANE FROM CARBON DIOXIDE AND HYDROGEN

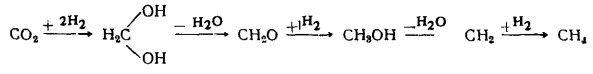
The mechanism of the hydrogenation of carbon dioxide, unlike that of the reduction of carbon monoxide, has been very little studied, although the study of the behaviour of carbon dioxide in its reaction with hydrogen is necessary for carrying out the catalytic purification of technological gases—a problem whose importance has been increasing recently. Moreover, the study of the mechanism of the synthesis of methane from carbon dioxide, in view of the high selectivity of the process, is of undoubted theoretical interest and makes it possible to develop more penetrating ideas regarding the nature of the hydrogenation of carbon monoxide.

Two proposed schemes for the mechanism of the synthesis of methane from carbon dioxide and hydrogen have been discussed in the literature. One of these was proposed by Bahr[94], who considers, on the basis of experimental data, that in the presence of Fe–Cu, Cu–Cr_2O_3, and Co–Cu–ZnO contact catalysts the reduction of carbon dioxide to methane is accompanied by the intermediate formation of carbon monoxide. This view is supported by research workers who have studied the hydrogenation of carbon dioxide on ruthenium contact catalysts[95] and in the presence of catalysts based on metals of the iron group and on various binary systems[96–100].

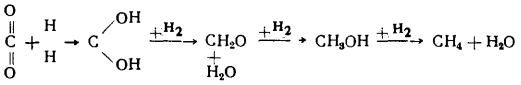
A number of facts, however, cast doubt on the correctness of Bahr's ideas. If the hydrogenation of carbon dioxide were accompanied by the intermediate formation of carbon monoxide, it might be possible under certain conditions to obtain higher hydrocarbons from CO_2, yet the hydrogenation of carbon dioxide on metallic contact catalysts of the iron group, unlike the reactions of carbon monoxide, are characterised by a high selectivity. Thus it has been shown[98,101–105] that in the presence of nickel and cobalt catalysts carbon dioxide is converted only into methane, and the formation of a small quantity of higher hydrocarbons was detected only in some instances, when mixed iron–cobalt[97] and copper–cobalt[98] contact catalysts were used. This must be due to a difference in the mechanisms of the hydrogenation of these oxides. Carbon dioxide is apparently hydrogenated to methane without the intermediate formation of carbon monoxide. Evidence in support of this is also provided by the behaviour of carbon monoxide and dioxide when these are present together in the gas. In a study of the hydrogenation of the oxides of carbon on nickel contact catalysts, Fischer and Pichler[102] showed that carbon dioxide is not hydrogenated in the presence of carbon monoxide and does not influence the transformation of the latter. These results were subsequently confirmed[56,106].

The independent mechanism of the conversion of carbon dioxide into methane is confirmed by studies of the process in the presence of a nickel–chromium catalyst. As already noted, in the presence of this catalyst carbon monoxide begins to undergo hydrogenation only above 80°.[78] Thus if the formation of methane from carbon dioxide were accompanied by the intermediate formation of carbon monoxide, it would not be observed below the temperature of the start of the hydrogenation of CO. It has been established[107], however, that carbon dioxide is hydrogenated at an appreciable rate even at 70° and below.

The idea that carbon dioxide reacts by an independent mechanism (without the intermediate formation of carbon monoxide) was reflected in a hypothesis put forward by Medsforth[108], who proposed the following scheme for the formation of methane from carbon dioxide:



Later, Medsforth's scheme was developed in detail by Pichler[109], who suggested that the hydrogenation of carbon dioxide takes place with atomic hydrogen present on the surface of the contact catalyst. According to Pichler, the reaction of carbon dioxide is described as follows:



† The symbol [ ] denotes a vacant active centre on the catalyst surface. The symbols in square brackets represent adsorbed species.

Bahr's theory[94], and the theories of Medsforth[108] and Pichler[109], start from the assumption that carbon dioxide is adsorbed on the surface of the contact catalyst in the initial stage of the process. This opinion is also held by other workers[56,103,110,111], who studied the kinetics of the hydrogenation of carbon dioxide to methane by static and flow methods. Thus it has been shown[56] that at various partial pressures of the reagents and with change in the total pressure from 0.1 atom to 1 atm in the temperature range 180–300° in the presence of a catalyst consisting of nickel on kieselguhr, the dependence of the reaction rate on the total pressure P is described by an equation of the Langmuir type

$$W = \frac{aBP}{1+BP},$$

where B and a are constants. In the opinion of the authors cited, hydrogen and carbon monoxide are comparatively weakly adsorbed on the surface of the contact catalyst. The heat of activation was 13.1 kcal mole^{-1}.

Binder and White[103], who studied the kinetics of the reaction in a flow system at atmospheric pressure in the temperature range 260–400° on a nickel–kieselguhr catalyst at stoichiometric H_2/CO_2 ratio and also in an excess of carbon dioxide, concluded that the rate-limiting stage of the process is the reaction between one adsorbed molecule of CO_2 and two (or four) dissociated hydrogen molecules. Although the kinetic equations effectively describe the experimental facts, this mechanism, in the opinion of the authors cited themselves, may be fictitious.

In a study of the kinetics of the hydrogenation of carbon dioxide above atmospheric pressure (up to 30 atm) in the presence of a nickel contact catalyst on kieselguhr[110], it was also suggested that four adsorbed hydrogen molecules react with one CO_2 molecule on the contact surface. The experimental results indicate that the activation energy has values in the range 13.1–13.9 kcal mole^{-1}. The authors cited[110] consider that the adsorption of CO_2 is weaker than the adsorption of hydrogen by a factor of 10–20.

In contrast to these studies, in which mixtures with a high concentration of carbon dioxide were used, other studies[111] were carried out at a very low concentration of CO_2 in the original gas (0.1%). The studies were carried out in a flow system at atmospheric pressure in the comparatively narrow temperature range 160–180°. A nickel–chromium contact catalyst obtained by reducing nickel chromate was used. The reaction rate is described by the empirical equation

$$W = k \cdot C_{CO_2}^{0.5},$$

indicating that carbon dioxide is adsorbed on the contact surface. The heat of activation was found to be 20.5 kcal mole^{-1}, which is much greater than the heat of activation given in the works cited earlier[56,110]. The discrepancy is due to the fact that one of the studies[111] was carried out on a contact catalyst which contained nickel oxides in addition to reduced nickel[112].

The theory of hydrogenation of carbon dioxide in an adsorption layer, developed on the basis of these studies, is disputed, however, and is not confirmed by work carried out by other experimental methods.

Although a number of workers[113-120] have shown that carbon dioxide is firmly bound to a clean nickel surface, the behaviour of CO_2 in the presence of hydrogen was not studied until recently. The only work in this direction was an attempt[121] to interpret the kinetic results of Binder and White[103] on the basis of a study of the separate adsorption of carbon dioxide and hydrogen at the temperatures of the synthesis. The mutual influence of the components during the adsorption of a mixture of gases, however, as shown for the example of carbon monoxide and hydrogen, may be considerable and may play a significant role in the reaction mechanism.

Despite the fact that in the absence of hydrogen the bond formed by carbon dioxide with the nickel surface is fairly strong, the CO_2 molecule is weakly bound to the surface under the conditions of the contact process. This follows from the results of kinetic studies[56,103] which indicated that carbon dioxide is bound to the contact surface. Thon and Taylor[122], however, in an interpretation of the mechanism of the hydrogenation of carbon dioxide, considered it unnecessary to assume that the CO_2 is adsorbed on the contact surface. On the basis of the idea that the active centre is a hydrogen atom chemisorbed on the catalyst, they suggested that this atom reacts with a molecule of carbon dioxide from the gaseous phase. Thus the same experimental results[56] have led research workers to different conclusions regarding the hydrogenation of carbon dioxide. It is obvious that kinetic data alone cannot confirm a particular reaction mechanism directly. For this, other independent methods are required.

A flow-circulation gradient-free method has been used[53] to study the kinetics of the synthesis of methane in the presence of a nickel–chromium contact catalyst by a procedure which makes it possible to follow directly the change in the weight of the catalyst during the reaction[123]. The kinetic results[53,58] are described by equations of first order with respect to carbon dioxide and of zero order with respect to hydrogen:

$$W = k \cdot p_{CO_2}^{1} \cdot p_{H_2}^{0}.$$

A change in the weight of the contact catalyst was not observed during hydrogenation, even at low temperatures (as far as 125°). It may therefore be assumed that under the conditions of the contact process there is no significant adsorption of carbon dioxide and the products of its transformation. This is confirmed by results[121] which showed that neither methane nor water are adsorbed on the surface of a nickel contact catalyst at the temperature of the synthesis. The results of the kinetic study were confirmed by a study[124] of the change in the contact potential difference during the hydrogenation of CO_2 on a nickel–chromium catalyst. When a mixture of hydrogen and carbon dioxide was introduced on to the untreated contact catalyst, the work function remained unchanged relative to that in an atmosphere of hydrogen. Moreover, sharp changes in the work function with change in temperature were not observed. This indicates that adsorption of carbon dioxide and the formation of complexes influencing the electronic structure of the catalyst does not take place on the surface of a contact catalyst containing dissolved hydrogen. The fact that carbon dioxide is not adsorbed on the surface of a contact catalyst containing adsorbed and dissolved hydrogen is also confirmed by direct data on the adsorption of CO_2 at 20°, [125] when the reaction rate is small[107].

Thus recent experimental results refute the suggestion that the start of the formation of methane from carbon dioxide on nickel catalysts is preceded by the adsorption of both components of the reaction, and indicate that hydrogen adsorbed on the contact surface reacts with molecules of carbon dioxide in the gaseous phase.

Since neither carbon dioxide nor the products of its transformation under the conditions of the synthesis of methane are adsorbed on the catalyst surface, the regular features of the adsorption of hydrogen under these conditions should apparently be the same as those under the

conditions of its separate adsorption on an untreated catalyst specimen. Thus under the conditions of the conversion of carbon dioxide into methane, the adsorbed hydrogen is present in the atomic state, and this surface layer has a negative charge [65].

The results of these studies show that the first stage in the reaction is not the reaction between molecules of carbon dioxide and hydrogen adsorbed on the contact surface. This introduces a significant correction into Pichler's scheme, given above. The experimental results also make it possible to introduce various other changes and refinements into this scheme.

The facts that the weight of the contact catalyst remains unchanged [53,123] and that the work function remains constant under different temperature conditions of the contact process [124] indicate that the transformation of carbon dioxide takes place either in the bulk or on the catalyst surface with a very low concentration of intermediate compounds, that is with a very low lifetime for these compounds in the adsorbed state. If, however, the complexes of the formaldehyde type (CH_2O) given in the scheme were formed on the catalyst surface, the formation of methane from CO_2 on the nickel–chromium contact catalyst could not be observed below 80°, [78] so that at these temperatures the complexes do not react, as was shown in an examination of the mechanism of the hydrogenation of carbon monoxide. Moreover, carbon dioxide is converted into methane at a lower temperature.

Although the formation of complexes of the type corresponding to the enol form of formaldehyde in the gas volume is quite possible, the hydrogenation of these complexes to methanol appears unlikely. In fact, if methanol were formed as an intermediate product in the hydrogenation of carbon dioxide, its conversion into methane should not have taken place at a lower rate than the formation of methane. The synthesis of hydrocarbons from methanol, however, takes place as a result of the reaction of CO and H_2 produced by the decomposition of the alcohol, and not by the direct transformation of methanol [36]. It therefore appears more probable that the enol complexes are converted into methylene radicals CH_2, as in the hydrogenation of carbon monoxide.

From the foregoing, the most probable scheme for the formation of methane from carbon dioxide and hydrogen appears to be one in which the formation of complexes of a type corresponding to the enol form of formaldehyde takes place initially, and in which the subsequent transformations are analogous to the stages in the hydrogenation of carbon monoxide, but with the significant difference that in the reduction of CO_2 these changes take place not on the catalyst surface, but in the volume of the gas. This probably explains the high selectivity of the process with respect to the formation of methane, since in this instance neither condensation of the enol complexes nor polymerisation of methylene groups can apparently take place.

For an understanding of the mechanism of a catalytic process, it is of considerable importance to determine the composition and structure of the intermediate compound, whose rate of formation determines the observed reaction rate. In accordance with the scheme being considered, it is assumed that the limiting stage of the process involving the conversion of carbon dioxide into methane is the stage involving the formation of the dioxymethylene radical, which can be regarded as an isomer of formic acid.

Golodets and Roiter [126] showed that evidence in support of the proposed composition and structure of an active complex is provided by agreement between the thermodynamic characteristics of the activated complex, such as the heat and entropy of activation calculated from kinetic data, and the values of these quantities calculated approximately for the assumed activated complex.

Analysis of the experimental entropy of activation of the hydrogenation of carbon dioxide on a nickel–chromium catalyst [56] showed that the first stage of the reaction apparently does involve the formation of dioxymethylene radicals, and that the rate of this stage determines the overall rate of the process.

On the basis of the foregoing, the mechanism of the hydrogenation of carbon dioxide is most probably represented by the following scheme [56,124]:

1. $2[\ ] + 2e + H_2 \rightarrow 2[H]^-$
2. $2[H]^- + CO_2 \rightarrow [HCOOH] \rightarrow 2[\ ] + C(OH)(OH) + 2e$ (slow stage)
3. $C(OH)(OH) + H_2 \rightarrow H{-}C{-}OH + H_2O$
4. $H{-}C{-}OH + H_2 \rightarrow CH_2 + H_2O$
5. $CH_2 + H_2 \rightarrow CH_4$ ‡

According to this scheme, the process is initiated by the activation of only the hydrogen on the catalyst surface, after which the reaction takes place in the gas volume.

The proposed scheme agrees with the experimental results of the study of the process on a nickel–chromium catalyst, within the limits of the sensitivity of the methods of study. It may be of general significance for the synthesis of methane in the presence of catalysts based on nickel. Evidence in support of this is indicated by the fact that the same value is obtained for the heat of activation (13.1–13.9 kcal mole^{-1}) in studies of the kinetics of the process at extremely low (as far as 0.4%) concentrations of carbon dioxide [53] and at concentrations close to the stoichiometric ratio at atmospheric pressure [56] and at pressures up to 30 atm [110]. From this it follows that over a wide range of partial pressures, carbon dioxide does not react with the contact surface and the same mechanism is observed for the synthesis of methane.

IV. HYDROGENATION OF CARBON MONOXIDE AND DIOXIDE PRESENT TOGETHER IN THE GAS PHASE

A knowledge of the mechanism of contact reactions makes it possible not only to explain the observed kinetic features but also to predict the possibility of carrying out these reactions in other more complex examples. In this connection it is appropriate to examine data on the synthesis of methane from carbon monoxide and dioxide on the basis of theories of the mechanisms of the transformation of these oxides.

The transformation of carbon monoxide and dioxide on nickel catalysts has been studied [56,102,106]. It was established that CO_2 is not hydrogenated in the presence of carbon monoxide and does not influence the transformation of CO. Nicolai and coworkers [56], in particular, considered that the oxides of carbon are hydrogenated according to their adsorbability. Since in the presence of hydrogen, carbon monoxide is adsorbed more strongly than CO_2, the authors cited assumed that in the presence of adsorbed CO, adsorption of carbon dioxide is impossible, so that the surface reaction of CO_2 with hydrogen is impossible. This view is incorrect, however, since under the conditions of the hydrogenation of CO_2, carbon dioxide is not adsorbed, even in the absence of carbon monoxide.

‡ See footnote to page No. 733.

The results obtained by Nicolai and coworkers[56] were also discussed by Thon and Taylor[122], who suggested that the active centre is a hydrogen atom adsorbed on the catalyst surface. When carbon monoxide and dioxide are present in the gas under the conditions of the hydrogenation, the CO and CO_2 compete for these active centres. Since the carbon monoxide molecules react more rapidly with the active centres under these conditions, the CO is hydrogenated, and not the carbon dioxide. This suggestion cannot be correct, however, since the mechanism of the transformation of carbon monoxide is different from that of the hydrogenation of carbon dioxide.

A difference in the behaviour of carbon monoxide and dioxide was observed in a study of the hydrogenation of their mixtures on a nickel–chromium catalyst in a large excess of hydrogen at various concentrations of the oxides of carbon in the gas[127]. Under these conditions, as in the process at high concentrations of the oxides of carbon[56,102,106], the rate of hydrogenation of carbon monoxide is independent of the presence of carbon dioxide in the gas. Observation of the change in the weight of the catalyst in addition to kinetic studies showed that the increase in weight corresponds to the values observed for the hydrogenation of carbon monoxide in the absence of CO_2. From this it follows that when the oxides of carbon are present together in the mixture with hydrogen, only the processes involving the transformation of the carbon monoxide take place on the contact surface. Hydrogenation of carbon dioxide does not take place at all over a wide range of CO concentration. These results indicate that carbon monoxide is a powerful poison for the hydrogenation of CO_2 on nickel catalysts.

These ideas regarding the mechanisms of the formation of methane from carbon monoxide and dioxide enable the kinetic features of the hydrogenation of mixtures of these oxides to be explained in terms of the influence of adsorbed carbon monoxide on the position of the equilibrium for the dissociation of molecular hydrogen adsorbed on the catalyst surface:

$$[H_2] \rightleftarrows 2[H] .$$

The presence of carbon dioxide in hydrogen has no influence on the electronic state of the catalyst surface, and hence on its adsorption properties. In this instance the equilibrium is displaced to the right, that is the hydrogen is adsorbed chiefly in atomic form, which is active with respect to the carbon dioxide present in the gaseous phase.

In the presence of hydrogen, carbon dioxide is not adsorbed on nickel. Carbon monoxide is readily chemisorbed on the contact surface and alters its properties: when carbon monoxide is present, the equilibrium for the dissociation of H_2 is displaced to the left, and hydrogen is adsorbed on the nickel surface chiefly in the form of molecules, that is in a form which is active with respect to adsorbed CO molecules but is not capable of reacting with CO_2 molecules from the gaseous phase.

Thus the poisoning of the catalyst, by carbon monoxide, with respect to the hydrogenation of CO_2 is not due to simple blocking of the active centres by carbon monoxide. Similarly, it cannot be regarded as a result of competition between the molecules of carbon monoxide and dioxide for the active regions of the surface. This phenomenon results from differences in the mechanisms of the hydrogenation of the oxides of carbon, and the poisoning influence of adsorbed carbon monoxide is not a direct influence, but results from a change in the electronic state of the catalyst, leading to the production of forms of adsorbed hydrogen which are unable to reduce CO_2.

It is only at a very low concentration of carbon monoxide, when its hydrogenation takes place under external transition conditions, that the concentration of atomic hydrogen on the nickel surface becomes sufficient for the rate of transformation of carbon dioxide to become appreciable, and this is in fact observed[127]. The equilibrium for the dissociation of molecular hydrogen is apparently displaced considerably to the right in those instances when the formation of methane from carbon monoxide takes place in the range of external diffusion and the concentration of CO on the contact surface is close to zero, so that the carbon monoxide cannot alter the properties of the surface significantly.

Thus the possibility of carrying out the reduction of carbon dioxide in the presence of carbon monoxide is determined by the macro-kinetic features of the transformation of the latter.

This conclusion has a number of consequences, which may be of practical importance for the fine catalytic purification of gases from oxides of carbon by transformation into methane.

The purification of gases from oxides of carbon obviously must be carried out in the range of external diffusion with respect to CO. It is only under these conditions that the degree of transformation of carbon dioxide achieved is the same as that in the absence of carbon monoxide and that most complete removal of traces of both substances from the gas can be effected. This agrees with the results of a study[128] of the purification of a nitrogen–hydrogen mixture from oxides of carbon on a nickel–chromium catalyst.

Carbon monoxide is a powerful poison with respect to the hydrogenation of many substances, particularly unsaturated compounds, on nickel. In a number of contact processes, for example the hydrogenation of ethylene, benzene, and phenol, carbon dioxide is not a catalyst poison. In these instances the removal of carbon dioxide from the hydrogen used for the hydrogenation is not necessary, whereas purification from carbon monoxide is required. This selective removal of carbon monoxide can be carried out under the conditions of hydrogenation in the external transition range, when almost no hydrogenation of carbon dioxide takes place. The possibility of carrying out the purification in this way has been demonstrated[129]. It should, however, be noted that these conditions can be used only when very thorough purification of the gas from carbon monoxide is not required.

---o0o---

Examination of the mechanism of the synthesis of methane from carbon monoxide and hydrogen indicates that the most probable reaction scheme is that proposed by Eidus. The accumulated data obtained by various methods make it possible to establish the reactive forms of the adsorbed molecules and the signs of their charges, and also to demonstrate fairly reliably the existence of chemisorbed complexes of a type corresponding to the enol form of formaldehyde. Strong evidence in support of their existence is provided by information obtained from the infrared spectra of the surface compounds. Success in these studies, however, requires the accumulation of these complexes in sufficient concentration. This may be achieved by carrying out the reaction of the adsorbed molecules of carbon monoxide and hydrogen under the conditions immediately preceding the catalytic action and, in view of the low rate of formation of the complexes, when the process has proceeded for a sufficient length of time.

The mechanism of the synthesis of methane from carbon dioxide and hydrogen differs significantly from the mechanism of the reduction of carbon monoxide.

The mechanism of the poisoning action of carbon monoxide, demonstrated for the example of CO_2, may be of general importance for finding the most rational solution to the problem of carrying out the important industrial processes involved in the hydrogenation of organic substances (benzene, phenol, ethylene, etc.), where it is known that the presence of carbon monoxide in the synthesis gas poisons the catalyst. In these instances, hydrogen is subjected to thorough purification to remove carbon monoxide. If the concentration of carbon monoxide in the original gas is such that under the conditions of the hydrogenation of the organic substances the reduction of CO takes place under external diffusion conditions, however, preliminary purification of the hydrogen from CO apparently is not required.

Experimental Determination of the Dipole Moments of Organic Molecules in Excited Electronic States†

N.G.Bakhshiev, M.I.Knyazhanskii, V.I.Minkin. O.A.Osipov, and G.V.Saidov

Modern experimental methods for the determination of dipole moments of organic molecules in excited electronic states are reviewed in detail and their relative merits are discussed.
The principal results obtained with the aid of these methods are presented (compiled in a Table). The bibliography includes 88 references.

I. INTRODUCTION

The properties of excited‡ molecular states as well as those of the ground state are ultimately determined by the distribution of electron density in the molecule. From this point of view, it is of interest to determine the dipole moments of the molecule in excited states, since the magnitude and orientation of the dipole moment relative to the molecular framework are directly related to the distribution of electron density in the corresponding eigen state. Comparison of the dipole moments in the ground ($\vec{\mu}_g$) and excited ($\vec{\mu}_e$) states makes it possible to infer the nature of the changes in electron density at individual groups of atoms in the molecule following excitation, which is of particular interest for the determination of the reaction centre in the excited state of the molecule undergoing a photochemical reaction and also for the understanding of the relation between the migration of the charge and the redistribution of electron excitation energy. The latter in turn is closely related to various non-radiative deactivation processes and hence to the capacity of the compound for luminescence. Furthermore, the use of the experimental dipole moments of excited states may facilitate a more soundly based choice of parameters in quantum-mechanical calculations of various physicochemical properties of molecules.

Unfortunately $\vec{\mu}_e$ cannot be determined experimentally by the usual methods for the measurement of electrical polarisation, since the lifetime of the excited states is extremely short so that even under intense irradiation this factor makes it difficult to establish an equilibrium concentration of excited molecules sufficiently high for the measurement of electrical polarisation. At the same time, since one is dealing with the optical excitation of the molecule, the method for the determination of the dipole moments of excited states must clearly be spectroscopic. Consequently it is necessary to establish a relation between the principal spectroscopic parameters of the molecule [the energy (frequency) and probability (intensity) of the electronic transition], on the one hand, and the electric dipole moments characteristic of the molecule in the ground and excited states, on the other.

In the last 10–12 years a number of methods for the experimental determination of the moment $\vec{\mu}_e$ have been proposed. It is significant that these methods differ sharply from one another in the nature of the physical phenomena on which they are based and consequently in the spectroscopic parameters which are measured. However, despite the urgency of the problem, so far there has been no adequate review of these methods. The reviews known to the authors[1,2] are extremely short, do not give a complete idea of the available methods and their modifications, and many important results are omitted. The present review probably includes most of the studies (up to 1967) in which the dipole moments of molecules in excited states were measured or estimated experimentally. The principal formulae used to determine the dipole moments are presented in a form convenient for direct practical use—achieved as a result of a number of assumptions which have been justified in practice. At the end of the review there is a Table which presents the principal data on the dipole moments $\vec{\mu}_e$ of a number of molecules and complexes obtained to date.

The methods for the determination of dipole moments which have been fairly widely adopted recently can be usefully combined into the following four groups.

1. The method of spetral shifts, based on the study of the displacements of the frequencies of electronic transitions in the electric field of intermolecular forces and consisting in the analysis of the shifts of the absorption and luminescence bands under the influence of a solvent.

2. The method of electrical polarisation of fluorescence. Here the degree of polarisation of the emission by solutions of the test substances in a powerful electric field is measured, i.e. ultimately the anisotropy of the emission in the direction of the field orienting the molecules is investigated.

3. The method of electrical dichroism. Here the dichroism of the absorption by molecules in a solution placed in a powerful electric field is studied, i.e. the anisotropy of absorption in the direction of the orienting field is considered.

4. The method based on the investigation of the splitting of the fine rotational structure of the absorption bands of

†This paper is an expanded version of the report delivered at the First All-Union Conference on Dipole Moments and Molecular Structure at Rostov-on-Don in 1967.

‡Only excited electronic states are considered here.

certain molecules in the gas phase in a powerful electric field (the Stark effect, which includes not only the excited electronic states but also the ground state).

It must be emphasised yet again that all the methods enumerated above are spectroscopic and require that the test molecule be acted upon by electric fields (external or intermolecular). It should also be noted that all the methods are based on definite model hypotheses concerning the interaction of the molecule with the medium (the Onsager theory, Debye's theory of orientation polarisation, etc.). Each group of methods will be discussed in greater detail.

II. METHOD OF SPECTRAL SHIFTS

The determination of the dipole moments of excited states by the methods of spectral shifts is based on the study of solvatochromism—the displacement of the bands in electronic absorption and emission spectra of the test molecules under the influence of a solvent. The phenomenon of solvatochromism arises from the difference between the energies of the interaction of the molecule with the medium in different electronic states, which is in turn determined by the change in the physicochemical properties (in particular the dipole moment) of the molecule on optical excitation. The fundamental postulates concerning the relation between the parameters characterising the system "test molecule–solvent" and the displacement of the spectra in solution relative to those in the gas phase were described for the first time by Bayliss, McRae, and Ooshika [3-6]. Taking into consideration the equilibrium (eq) and Franck–Condon (F–C) levels in the ground (g) and excited (e) states (Fig. 1), the authors calculated, using second-order perturbation theory, the stabilisation energy of the dissolved molecule (i.e. the energy of its interaction with solvent molecules) in various states. Account was taken of different types of van der Waals interaction (orientation, inductive, and dispersion), while specific interactions of donor–acceptor type were disregarded.

To derive the final expression relating the experimental band shifts to the characteristics of the molecule and the medium, use is made of the Onsager model [7], according to which the molecule is treated as a point dipole in a spherical cavity with radius a (the Onsager radius) within the solvent which is treated as a homogeneous continuous medium with a dielectric constant ϵ and refractive index n. The point dipole interacts with the "reactive" field arising as a result of the orientation-inductive polarisation of the solvent molecules under the influence of the dissolved molecule. The general treatment of the problem [4-6] leads to very complex expressions containing terms each of which describes a particular type of interaction between the molecule and the solvent. These formulae cannot be used directly to determine dipole moments, since they contain a large number of parameters which have not been determined and cannot be determined experimentally. However, with certain assumptions made by McRae (in particular it is assumed that the molecular polarisibility α does not change on excitation, i.e. $\alpha_e = \alpha_g$), it is possible to obtain a fairly simple formula for the frequency shift of a purely electronic absorption transition in polar solvents:

$$\Delta\nu_a = (AL_0 + B)\frac{n_D^2-1}{2n_D^2+1} + C\left[\frac{\varepsilon-1}{\varepsilon+2} - \frac{n_D^2-1}{n_D^2+2}\right], \qquad (1)$$

where A, L_0, B, and C are constants characterising both the solvent and the solute molecule and $C = (2/hca^3)$: $:(\vec{\mu}_g - \vec{\mu}_e)\vec{\mu}_g$. Here h is the Planck constant, c the velocity of light in a vacuum, n_D the refractive index of the solvent corresponding to the sodium D-line, ϵ the static dielectric constant, a the Onsager radius, and $\vec{\mu}_g$ and $\vec{\mu}_e$ are the dipole moments of the solute molecule in the ground and excited states respectively. It should be noted that, if the shape of the band depends only slightly on the solvent, i.e. the band is displaced virtually as a whole, the shift $\Delta\nu_a$ may be determined from the position of the absorption band maximum.

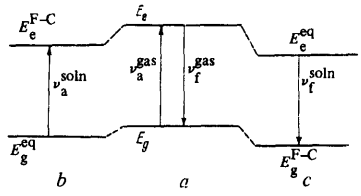

Figure 1. Schematic representation of the electronic levels of a molecule in the gas phase and in solution (ground and first excited states): *a*) absorption and emission (gas); *b*) absorption (solution); *c*) emission (solution).

McRae used Eqn. (1) to estimate $\vec{\mu}_e$ of Phenol Blue having investigated the shifts in the absorption spectra in 21 solvents. The constants A, L_0, and B were determined very approximately from additional experimental data and on the basis of different postulates. Using the known value $\vec{\mu}_g \simeq 5.8$ D and assuming that $\alpha \simeq 4$–5 Å and $\vec{\mu}_g \| \vec{\mu}_e$, McRae estimated $|\mu_e|$ for Phenol Blue to be 7.5–9.1 D and noted that, although this value is of the expected order of magnitude, it does not constitute a significant confirmation of a considerable contribution of the dipolar structure to the excited state of the molecule investigated.

The work of Lippert [8-11], who proposed a method for the determination of μ_e of the first singlet excited state of fluorescing polar molecules, which is significantly higher than μ_g, played an important role in the development of a method for the measurement of the dipole moments of excited molecules. This method is based on the application of the Ooshika formula to determine the difference between the shifts of the absorption ($\Delta\nu_a$) and fluorescence ($\Delta\nu_f$) bands under conditions such that the orientation relaxation time of the solvent molecules (τ_{or}) is much less than the lifetime of the excited fluorescent state (τ_f). The following simple expression is then obtained (neglecting the small terms and the constant):

$$\Delta\nu_{a-f} = \nu_a - \nu_f = \frac{2}{hc}\left(\frac{\varepsilon-1}{2\varepsilon+1} - \frac{n_D^2-1}{2n_D^2+1}\right)\frac{(\vec{\mu}_e - \vec{\mu}_g)^2}{a^3}, \qquad (2)$$

which relates the Stokes shift of the fluorescence spectrum relative to the absorption spectrum ($\Delta\nu_{a-f}$), to the characteristics of the molecule and the medium. Here ν_a and ν_f are the frequencies of the absorption and fluorescence band maxima respectively and the significance of the remaining quantities is clear from the preceding description. The measurement of ν_a and ν_f in a set of polar and non-polar ($\epsilon = n_D^2$) solvents makes it possible to calculate

μ_e, using specified values of μ_g and a, under the condition $\vec{\mu}_e \| \vec{\mu}_g$ by means of the simple formula

$$\mu_e = \mu_g \pm 0.001\sqrt{ma^3},$$

m being found from a plot of the relation $\Delta\nu_{a-f} = m\Delta f$, where

$$\Delta f = \left[\frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{n_D^2 - 1}{2n_D^2 + 1}\right].$$

The method described was used by Lippert [8-11] to determine the dipole moments μ_e of a number of molecules, in particular stilbene derivatives assuming that $a \sim 0.8\rho$, where ρ is the radius of the smallest sphere enclosing the molecule.

The disadvantages of Lippert's method consist mainly in the failure to take into account the capacity of the molecule to be polarised in an electric (and in particular in a reactive) field and also there is the following important defect: namely, having restricted the treatment to the analysis of the Stokes shift $\Delta\nu_{a-f}$, Lippert [8-11] in fact fails to realise the additional possibilities [compared with formula (1) for example] associated with the independent measurement of both absorption and fluorescence bands. As a result, the experimenter has at his disposal, as in the case of Eqn. (1), only one experimentally measured spectroscopic parameter ($\Delta\nu_{a-f}$) instead of two ($\Delta\nu_a$ and $\Delta\nu_f$), which considerably reduces the effectiveness of the method.

Independently of Lippert, Mataga and coworkers [12-16] also obtained Eqn. (2) on the basis of the Ooshika formula and, having analysed it in detail and compared it with experimental data, concluded, in agreement with Lippert [8-11], that it is possible to determine the difference between the dipole moments of molecules in the ground and excited states from the changes in the Stokes shift $\Delta\nu_{a-f}$ due to orientation interactions. No hypotheses concerning the relative orientation of the moments $\vec{\mu}_g$ and $\vec{\mu}_e$ or the values of μ_g have been put forward by Mataga and coworkers [12-16] and only the values of $|\Delta\vec{\mu}|$ are considered.

Comparison of the experimental and theoretical values makes it possible in some cases to estimate the applicability of a particular method for the calculation of charge distribution in the excited molecule (for example for naphthols, naphthylamines, and carbazole [13,14] and also aniline [17]) and to arrive at certain conclusions concerning the structure of the molecule in the excited state. Molecular excitation is accompanied, according to Mataga's data, by a considerable increase of the dipole moment, which is associated with charge transfer from electron-donor substituents along the conjugated bond chain. It has been established that in α-naphthylamines the increase of the dipole moment on excitation is greater (4.4 D) than in the corresponding β-derivatives (3.5 D), while the values of $|\Delta\vec{\mu}|$ for naphthols are considerably lower (0.5–1 D) than for naphthylamines and the sequence of the changes $|\Delta\vec{\mu}|$ for α- and β-derivatives is reversed.

A rough estimate shows [12-16] that $|\Delta\vec{\mu}|$ for isomeric aminobenzoic acids increases on going from *ortho*- to *meta*-isomers. The quantity $\delta = |\Delta\mu|^2/a^3$, determined from Eqn. (2), is $\delta = 7500$ cm^{-1} for *NN*-dimethyl-α-naphthylamine. This suggests that the $N(CH_3)_2$ group rotates about the C–N bond during the lifetime of the excited state [16]. The authors believe [16] that such rotation becomes possible as a result of charge transfer from the nitrogen to the π-electron system of naphthalene on electronic excitation.

The work of Ito et al. [18], where an attempt was made to measure the change in dipole moments on $n-\pi^*$ excitation of ketone molecules, is of interest. The authors used the McRae formula [5], in which a small term, characterising the so called quadratic Stark effect, was omitted:

$$\Delta\nu_a = \text{dispersion term} + B\frac{n_D^2 - 1}{2n_D^2 + 1} + C\left[\frac{\varepsilon - 1}{\varepsilon + 2} - \frac{n_D^2 - 1}{n_D^2 + 2}\right], \quad (3)$$

$$B = \frac{1}{hc}\cdot\frac{\mu_g^2 - \mu_e^2}{a^3}, \quad (4)$$

$$C = \frac{2}{hc}\frac{\vec{\mu}_g(\vec{\mu}_g - \vec{\mu}_e)}{a^3} \quad (5)$$

(the notation is the same as above). Since according to Eqns. (4) and (5) it is necessary to determine experimentally either the parameter B or C in order to find μ_e, Ito et al. [18] proposed two versions of the method.

The first version is based on the measurement of the shifts $\Delta\nu_a$ in non-polar solvents with different refractive indices (n_D) (for example hexane, carbon tetrachloride, dioxan§, benzene). For such solvents ($n_D^2 \simeq \epsilon$), the following equation should hold:

$$\Delta\nu_a = \text{dispersion term} + B\frac{n_D^2 - 1}{2n_D^2 + 1} + \text{const.} \quad (6)$$

It has been established experimentally [18] that, for all the compounds investigated, except acetone, the dispersion interaction may be neglected and the following linear relation may be employed:

$$\Delta\nu_a \simeq B\frac{n_D^2 - 1}{2n_D^2 + 1} + \text{const.} \quad (7)$$

The authors confine themselves to the determination of the sign of B only. Since $B > 0$ ("blue" shift of the absorption band), it follows that $\mu_e < \mu_g$, i.e. on $n-\pi^*$ excitation the dipole moment falls.

In the second version of the method the difference between the positions of the absorption band maxima in two polar solvents with approximately the same values of n_D but different ϵ is measured. In such solvents the dispersion terms and the term involving $(n_D^2 - 1)/(2n_D^2 + 1)$ do not change, so that the difference between the frequencies at the band maxima is described by the simple formula

$$\nu_1 - \nu_2 = C\left(\frac{\varepsilon_1 - 1}{\varepsilon_1 + 2} - \frac{\varepsilon_2 - 1}{\varepsilon_2 + 2}\right). \quad (8)$$

Ethyl ether and acetonitrile ($n_D = 1.356$ and 1.344 respectively), for example, may be used as solvents. The absorption spectra of these solvents are similar and do not contain intense bands above 2000 Å, which ensures approximate equality of the dispersion terms in Eqn. (3). [5] The dielectric constants ϵ of these solvents differ sharply (4.34 for ether and 37.50 for acetonitrile), which permits the variation of ϵ¶ of their mixtures over a wide range. By measuring ν_a for solutions in each mixture of this kind, it is possible to test the validity of Eqn. (8) and, if it holds, to determine the parameter C and hence μ_e for known values of μ_g and a. The measurements carried out in this way enabled Ito et al. to estimate the dipole moments μ_e of acetophenone on $n-\pi^*$ excitation as 0.5 D ($a \simeq 4.0$ Å). For the remaining ketones investigated by the authors the corresponding values of μ_e do not exceed 0.5 D. Then in all cases μ_e is less than μ_g approximately by 3 D. Using

§However, dioxan behaves in the majority of cases as a polar solvent and does not obey Eqn. (6).

¶The dielectric constant ϵ of the mixture of solvents may be calculated from the formula $\epsilon = \epsilon_0 + bw$, where ϵ_0 is the dielectric constant of ether, b the difference between the dielectric constants of acetonitrile and ether, and w the weight fraction of acetonitrile in solution.

the same method, Semba [19] observed an increase in the dipole moment of nitrobenzene derivatives on excitation in the long-wavelength region and determined the dipole moment of the first singlet state of the *p*-nitroanisole molecule (for $a \simeq 4$ Å and $\mu_g \simeq 5$ D, the dipole moment is $\mu_e \simeq 7$ D).

The version of the McRae method described is very convenient for the estimation of μ_e of sparingly soluble non-fluorescent compounds, but it requires a very cautious approach and tests in each individual case, since the McRae theory, developed for two-component solutions cannot be formally extended to mixtures of two solvents, i.e. to three-component solutions [20].

Gosavi and Rao [21] used Eqn. (8) to determine the dipole moments of the $n-\pi^*$ excited states of thiourea derivatives from the shifts of the $n-\pi^*$ absorption band maximum in ether and acetonitrile without using a mixture of solvents.

Baba et al. [22] applied the McRae formula [Eqn. (3)] and analysed the shifts of the fluorescence spectra. The authors calculated the relative shifts of the absorption ($\delta\nu_{abs}$) and fluorescence ($\delta\nu_{fl}$) bands for various solvents with the same values of n and dispersion terms but different ϵ. Then one obtains for absorption

$$\delta\nu_{abs} = \Delta\nu_{2abs} - \Delta\nu_{1abs} = \frac{2}{hc}\frac{\vec{\mu}_g(\vec{\mu}_e - \vec{\mu}_g)}{a^3}\left(\frac{\varepsilon_2 - 1}{\varepsilon_2 + 2} - \frac{\varepsilon_1 - 1}{\varepsilon_1 + 2}\right)$$

and for fluorescence

$$\delta\nu_{fl} = \Delta\nu_{2fl} - \Delta\nu_{1fl} = \frac{2}{hc}\frac{\vec{\mu}_e(\vec{\mu}_e - \vec{\mu}_g)}{a^3}\left(\frac{\varepsilon_2 - 1}{\varepsilon_2 + 2} - \frac{\varepsilon_1 - 1}{\varepsilon_1 + 2}\right),$$

where $\Delta\nu$ are the shifts of the absorption and fluorescence bands in the corresponding solvents (1 and 2) relative to the spectra of the vapour. Hence, under the condition $\vec{\mu}_e \parallel \vec{\mu}_e$, we have

$$\frac{\mu_e}{\mu_g} = \frac{\delta\nu_{fl}}{\delta\nu_{abs}}. \qquad (9)$$

Using acetonitrile and ether and also other solvents [23] with similar n_D, Baba et al. [22] calculated the dipole moment μ_e for $n-\pi^*$-fluorescent states of pyridazine, pyrimidine, and pyrazine [22] and also 9,10-diazaphenanthrene [23]. They found that the dipole moments of pyridazine, 9,10-diazaphenanthrene, and pyrimidine decrease significantly on $n\pi^*$ excitation (by factors of 3.6, 3.4, and 4.2 respectively) and the sign of the dipole moment of pyrimidine is reversed. The authors suggest that these changes are associated with the transition of the sp^2-hybridised n electrons of nitrogen to the π orbital. At the same time for pyrazine $\mu_e \simeq \mu_g \simeq 0$ due to the symmetrical positions of the hetero-atoms.

The method employed by Baba is attractive because in the calculations it is unnecessary to specify the Onsager radius, the value of which usually involves a considerable error. At the same time the exclusive use of solvents with refractive indices n_D which differ only slightly and the assumption that the moments $\vec{\mu}_g$ and $\vec{\mu}_e$ are parallel greatly restricts the scope of the method.

The McRae formula enabled Robertson et al. [24] to estimate the dipole moments of certain excited states (^1L_b, ^1L_a, and ^1B_b) of azulene. The authors demonstrated experimentally the validity of the assumptions underlying the McRae formula [Eqn. (1)] and showed that $AL_0 + B = K$ is constant for the entire series of solvents which they employed. The constant K for the series of solvents (hexane, heptane, pentane, etc.) was determined from the formula $\Delta\nu_a = K(n^2 - 1)/(2n^2 + 1)$ by least squares. In turn, the constant $C = (2/hc)\mu_g(\mu_g - \mu_e)/a^3$ was calculated from the absorption bands shifts in polar solvents so as to obtain best agreement between the calculated and observed shifts $\Delta\nu_a$. The data for alcohols are excluded, since in this case hydrogen bonds may have a significant effect, which is not taken into account by the McRae formula [Eqn. (1)]. The values of $\vec{\mu}_e$ for molecules in the above three excited states were determined for two Onsager radii, $a \simeq 3$ and $a \simeq 4$ Å, and the results obtained were compared with those of the theoretical calculations of Pariser. The authors state that best agreement between the calculated and experimental moment $\vec{\mu}_e$ in the state ^1L_b is achieved with $a > 4$ Å. For the remaining states, the agreement is less satisfactory.

In a study based on the McRae theory and the formula for the shift of the electronic spectra under the influence of the solvent derived by Liptay [26], Beens and Knibbe [25] determined from fluorescence spectroscopic data alone the dipole moments of certain molecular charge-transfer complexes in the excited state. They assumed that $\vec{\mu}_e \parallel \vec{\mu}_g$ and that the Onsager radius $a \simeq 5$ Å. According to these measurement, the dipole moment in the excited state proved to be 10 D, which is consistent with the hypothesis of charge transfer on excitation. Liptay [27] determined the dipole moment of aniline as $\mu_e = 6$ D.

In contrast to these investigations, Kosower [28] attempted to estimate the dipole moment of the excited state without using any previously derived relations. He determined the stabilisation energy ΔE_e of the excited $\pi-\pi^*$ state of the mesityl oxide molecule in water from the shift of the absorption spectra of the aqueous solution relative to the spectrum in iso-octane (it was assumed that in this non-polar solvent the position of the absorption band of the test molecule is the same as in the spectrum of the gaseous compound). The molecular complex of iodine with 1-ethyl-4-methoxycarbonylpyridine ($\mu_g = 13.90$ D; $\Delta E_g = 17.3$ kcal mole^{-1}) was chosen as standard and it was assumed that the stabilisation energy is proportional to the dipole moment; then, according to the authors estimate, $\mu_e \simeq 7.6$ D for mesityl oxide. The lower limit of the dipole moment of Phenyl Blue in the excited state was estimated similarly as 10.2 D, which exceeds the value obtained by McRae [5]. However, this approach to the determination of μ_e cannot be regarded as adequately justified.

The additional possibilities mentioned above, associated with the independent investigation of the shift of the absorption ($\Delta\nu_a$) and fluorescence ($\Delta\nu_f$) spectra of the solutions relative to those in the gas phase, were employed by one of the authors of the present review [29-37]. The method is based on the hypothesis that the effect of solvents on the position of the electronic spectra of molecules is in general determined by intermolecular interactions of the universal van der Waals type. Using these hypotheses, the Onsager model, and general physical considerations without resorting to quantum-mechanical methods of calculation, the author obtained relatively simples expressions for the shifts of the electronic spectra as a function of n and ϵ for the solvent [29]. In the derivation of the formulae, account was taken of the polarisibility of the molecule in the ground and excited states. It is particularly important that the author dealt with the general case where the angle φ between the moments $\vec{\mu}_g$ and $\vec{\mu}_e$ is not 0° or 180°. Such treatment makes it possible to determine this angle together with the moment $\vec{\mu}_e$ from the experimental data and thereby investigate the anisotropy of the distribution of electron density in molecules on optical excitation. Subsequently the author developed a more general theory of the interaction between the solvent and the solute molecule which is valid for any relations between the orientation relaxation time τ_{or} and the lifetime

of the molecule in the excited electronic state τ_{fl}.[38] Furthermore, account was taken of the additional shift of the observed spectrum relative to the true spectrum as a result of the spectral variation of the field strength associated with a light wave acting upon the molecule in the condensed medium. The following expressions were obtained[38] for the case $\tau_{or} \ll \tau_{fl}$, which is most frequently encountered in practise:

$$hc\Delta\nu^s = C_2\left[\frac{2n^2+1}{n^2+2}\frac{\varepsilon-1}{\varepsilon+2} + p^s\frac{n^2-1}{n^2+2}\right] = C_2 f(\varepsilon, n), \quad (10)$$

$$hc\,\Delta\nu^{a-f} = \Delta C^{a-f}\left[\frac{2n^2+1}{n^2+2}\left(\frac{\varepsilon-1}{\varepsilon+2}-\frac{n^2-1}{n^2+2}\right) + p^{a-f}\frac{n^2-1}{n^2+2}\right] = \Delta C^{a-f}\varphi(\varepsilon, n) \quad (11)$$

where $\Delta\nu^S = (\Delta\nu_a + \Delta\nu_f)/2$, $\Delta\nu^{a-f} = \Delta\nu_a - \Delta\nu_f$ (the change in the Stokes shift), and $f(\epsilon, n)$ and $\varphi(\epsilon, n)$ are the so called universal interaction functions.

The dipole moment μ_e and the angle φ between $\vec{\mu}_e$ and $\vec{\mu}_g$ are defined by the following formulae, provided that μ_g and a (the Onsager radius) are known:

$$\mu_e = \sqrt{\mu_g^2 - C_2 hca^3}\ ,$$
$$\cos\varphi = \frac{1}{2\mu_g\mu_e}\left[(\mu_g^2+\mu_e^2) - \frac{\Delta C^{a-f}}{2C_2}(\mu_g^2-\mu_e^2)\right]. \quad (12)$$

The parameters C_2 and ΔC^{a-f} are found from plots based on Eqns. (10) and (11). The auxiliary parameters p^S and p^{a-f} are determined either from the condition that the straight line must pass through the point corresponding to the vapour phase (no shift) or (if no data for the spectra in the gas phase are available) from the condition of optimum linearity of the relation investigated. In the calculation of the parameters C and p good results are obtained by the method of least squares. We may also note that, in the absence of data for the spectra in the vapour phase, one can use the results of measurements of the relative shifts of the band maxima in polar media and the formulae

$$\frac{hc}{\Delta F(n)} = C_2\frac{\Delta f(\varepsilon, n)}{\Delta F(n)} + \text{const.}, \quad (13)$$

$$\frac{hc\delta(\Delta\nu^{a-f})}{\Delta F(n)} = \Delta C^{a-f}\frac{\Delta\varphi(\varepsilon, n)}{\Delta F(n)} + \text{const.}, \quad (14)$$

where

$$\delta\nu^s = \nu_2^s - \nu_1^s; \quad \delta(\Delta\nu^{a-f}) = \Delta\nu_2^{a-f} - \Delta\nu_1^{a-f},$$
$$\Delta F(n) = \frac{n_2^2-1}{n_2^2+2} - \frac{n_1^2-1}{n_1^2+2},$$

in which subscripts 1 and 2 refer to different polar solvents. The values of μ_g and a required for the calculations by Eqn. (12) are determined from electrical measurements (or from tabulated data) and from structural models of the molecules respectively.

Apart from the case discussed above, a widely occurring important special case, corresponding to the condition $\varphi \simeq 0$ or 180°, is also of interest. Then, according to Bakhshiev's investigations[29-32], we have

$$\mu_g = \sqrt{\frac{C_2 hca^3}{1-K^2}}; \quad \mu_e = K\mu_g, \quad (15)$$

where

$$K = \pm\frac{1-\frac{\Delta C^{a-f}}{2C_2}}{1+\frac{\Delta C^{a-f}}{2C_2}}$$

(+ for $\varphi = 0$ and − for $\varphi = 180°$).

It is readily seen that, by specifying the value of a, it is possible to determine independently both μ_e and μ_g from spectroscopic data using Eqns. (15). Furthermore, it is significant that μ_e can be found in this case from the known value of μ_g without using the Onsager radius a, because the coefficient K in Eqn. (15) is determined solely by spectroscopic data. Finally, Eqns. (15) may be used for the direct experimental determination of the Onsager radius itself, which is important in studies on new classes of compounds.

The methods described above were employed to investigate the changes in the distribution of electron density on excitation and to determine μ_e and μ_g of a large number of compounds—in particular derivatives of naphthalene, stilbene, diphenyl, aniline, and pyridine[30-32,35,37], for the symmetrical molecules of which $\varphi = 0°$ or 180°. In this case, on excitation to the first singlet state, electron density shifts significantly along the conjugated bond chain from electron-donor to electron-acceptor substituents, this being accompanied by a marked increase of the dipole moment. A similar shift of electron density along the conjugated bond chain occurs also in symmetrically substituted phthalimides[30,37]. However, the greatest interest attaches to the application of these methods to molecules without a symmetry axis, for which $\varphi \neq 0°$ or 180°. Then, as already mentioned, it is possible to determine both the dipole moment μ_e and the angle φ and hence the direction in which electron density is displaced on excitation. The study of asymmetric derivatives of phthalimide[32,34,37] showed that, on excitation of these compounds, electron density is also markedly displaced from donor to acceptor functional groups, approximately along the line joining these groups (Fig. 2). In this connection, it is remarkable that the properties of the long-wavelength electronic transition responsible for the ability of phthalimides to fluoresce depend primarily on the properties of the substituents and the benzene ring appears to play a subsidiary role, behaving, as it were, as a conductor in charge transfer.

A study of $n-\pi^*$ and $n-\sigma$ transitions in molecules with a symmetry axis (acetone, nitromethane, methyl iodide, and bromoform) was undertaken by Bakhshiev[39] using a formula[31] suitable for molecules of this type:

$$\mu_e = \mu_g - \frac{C_1^a hca^3}{2\mu_g}\ , \quad (16)$$

where C_1^a is a constant determined from the shifts of absorption bands only in a series of solvents. The applicability of the method of universal interaction functions and in particular Eqns. (12) and (16) in the study of the physicochemical characteristics of certain molecular charge-transfer complex has been demonstrated[40]. The difference between the dipole moments of the first excited singlet and ground states of a number of benzene derivatives, calculated by the LCAO-MO method in the π-electron approximation and the same quantity determined experimentally by the method of universal interaction functions have been compared[41]. It has been shown that the theoretical and experimental results agree satisfactorily.

In the analysis of the electronic spectra of many organic compounds (in particular derivatives of phthalimide and stilbene), the long-wavelength bands of which correspond to intramolecular charge transfer, it has been found[37,42] that the difference between the dipole moments of the molecule in the ground and first excited electronic state $|\Delta\vec{\mu}|$, determined from the shifts in the spectra, is close in order of magnitude to the dipole moment of the transition $|\vec{D}|$, which is calculated from the intensity of the corresponding band. Since the comparison of $\Delta\vec{\mu}$ and $\vec{D}$ has a definite physical significance, the condition $|\Delta\vec{\mu}| \simeq |\vec{D}|$ can probably serve as one of the quantitative

criteria for the interpretation of the corresponding transition as an "intramolecular charge transfer" band (for further details, see also Saidov et al.[43]). This criterion was successfully employed by Kutsyna and coworkers for the assignment of bands in the spectra of 1,3,4-oxadiazole[44,45] and 1,3,5-triphenyl-2-pyrazoline[45] derivatives. In these and other investigations[45,47,48] Kutsyna and coworkers determined using Bakhshiev's method[29-35] the values of μ_e for the above compounds, the angle φ for 1,3,5-triphenylpyrazoline and its derivatives, and μ_e and μ_g for certain 1,3,4-oxadiazole derivatives, for which $\varphi = 0°$ or 180°. For the latter compounds, values of μ_g and μ_e in fairly good agreement with experimental data were calculated by the LCAO-MO method in the Hückel approximation.

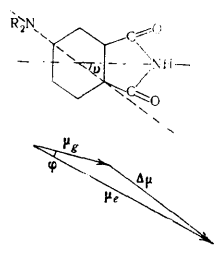

Figure 2. Orientation of the vector $\Delta\vec{\mu}$ relative to the molecular skeleton of 4-aminophthalimide (long-wavelength electronic transition).

The results of the determination of the dipole moments μ_g and μ_e by Bakhshiev's method[29-36] agree well in most cases with the results of other investigators, who employed both similar and completely different methods[31]. At the same time Bakhshiev's method[29-36] makes it possible to obtain relatively simply additional information about the excited state (the orientation of $\vec{\mu}_e$ and the anisotropy of the redistribution of electron density), which cannot be secured by the majority of similar procedures.

The method of determination of μ_e and φ from the shifts of the absorption and fluorescence bands was also proposed independently by Bilot and Kawski[49-56]. Like McRae and Ooshika, they solve[49] the quantum-mechanical problem of the interaction of the molecule with the solvent in second-order perturbation theory and then use the Onsager model. However, in contrast to the earlier investigators[4,5], Bilot and Kawski do not neglect the polarisibility of the molecule but take into account, as in Bakhshiev's work[29,57], the average polarisibility α, which is the same for the ground and excited states. In the special case where it is possible to neglect the polarisibility of the molecules ($\alpha = 0$), Eqn. (2), derived by Lippert and Mataga, follows from the formula of Bilot and Kawski. In the general case Bilot and Kawski[49], following Bakhshiev, assume that $\beta = 2\alpha/a^3 \simeq 1$ (a is the Onsager radius), which simplifies significantly the final relation. Then the formulae of Bilot and Kawski, relating the shifts of the absorption and fluorescence spectra to the parameters of the solvent and the test molecule, assume the following form[53]:

for absorption spectra:

$$\Delta\nu_a = -m_3\left(\frac{2n^2+1}{n^2+2}\right)\left(\frac{\varepsilon-1}{\varepsilon+2}-\frac{n^2-1}{n^2+2}\right)-m_2\frac{3}{2}\frac{n^4-1}{(n^2+2)^2}, \quad (17)$$

for fluorescence spectra:

$$\Delta\nu_f = -m_4\left(\frac{2n^2+1}{n^2+2}\right)\left(\frac{\varepsilon-1}{\varepsilon+2}-\frac{n^2-1}{n^2+2}\right)-m_2\frac{3}{2}\frac{n^4-1}{(n^2+2)^2}, \quad (18)$$

and for the Stokes shift:

$$\nu_a - \nu_f = m_1\frac{2n^2+1}{n^2+2}\left(\frac{\varepsilon-1}{\varepsilon+2}-\frac{n^2-1}{n^2+2}\right)+\text{const.}, \quad (19)$$

where

$$m_1 = \frac{2(\vec{\mu}_e-\vec{\mu}_g)^2}{hca^3}, \quad m_2 = \frac{2(\mu_e^2-\mu_g^2)}{hca^3},$$
$$m_3 = \frac{2\vec{\mu}_g(\vec{\mu}_e-\vec{\mu}_g)}{hca^3}, \quad m_4 = \frac{2\vec{\mu}_e(\vec{\mu}_e-\vec{\mu}_g)}{hca^3}. \quad (20)$$

The following obvious relations obtain between the parameters m:

$$m_3 = \frac{m_2-m_1}{1}, \quad m_4 = \frac{m_1+m_2}{2}. \quad (21)$$

Using Eqns. (17)-(21), Bilot and Kawski[49-56] determined the dipole moments in the excited state μ_e and the angle φ between $\vec{\mu}_g$ and $\vec{\mu}_e$, with a and μ_g known. In order to calculate μ_e and φ, it is sufficient to find two independent parameters (out of four), for example m_1 and m_2, and then use the following working formulae:

$$\mu_e = \sqrt{\mu_g^2+\frac{1}{2}m_2hca^3}, \quad (22)$$

$$\cos\varphi = \frac{1}{2\mu_g\mu_e}\left[(\mu_e^2+\mu_g^2)-\frac{m_1}{m_2}(\mu_e^2-\mu_g^2)\right], \quad (23)$$

which are virtually the same as Eqns. (12) quoted above. The parameter m_1 is determined as in Bakhshiev's method[29-36] from the slope of the linear plot based on Eqn. (19). The remaining parameters, in particular m_2, can be found most simply from a graphical comparison of the theoretical and experimental shifts of the spectra of the solutions relative to the spectrum of the vapour or a solution in a non-polar solvent [for example on the basis of Eqn. (18)]. When $\varphi = 0°$ or 180°, we obtain from Eqns. (20) and (21)

$$\mu_g = \frac{m_2-m_1}{2}\sqrt{\frac{0.5\,hca^3}{m_1}},$$
$$\mu_e = \frac{m_2+m_1}{2}\sqrt{\frac{0.5\,hca^3}{m_1}}, \quad (24)$$

i.e., by analogy with Eqn. (15), an independent determination of the dipole moments in the ground and excited states is possible. The authors applied this method in the measurement of the dipole moments μ_e of derivatives of stilbene, fluorene, several phthalimides (for the majority of which $\varphi \neq 0$), naphthols, naphthylamines, and a number of other compounds. In particular, Bilot and Kawski[51,53] determined in addition to μ_e the angle φ for phthalimide derivatives, they subsequently measured μ_e for a number of other compounds[54] (including stilbene derivatives) with known values of μ_g and $\varphi \simeq 0$, and finally Kawski[56] determined from Eqns. (24) the values of μ_g and μ_e for naphthols.

On excitation of the molecules of all the compounds investigated to the first singlet state, the dipole moment increases. The experimental values of $|\Delta\vec{\mu}|$ for naphthols and naphthylamines[55] agree satisfactorily with the values calculated theoretically by Mataga and coworkers. The values of μ_e which they obtained agree also with the data of Bakhshiev, Czekalla, Meyer, and Wick (see below) but differ considerably (are lower than) from the analogous data of Lippert. According to these authors, this is

because Lippert fails to take into account the role of the polarisibility of the molecule in the ground and excited states.

In Abe's studies [58-61] a formula whereby it is possible to determine from the shift of the spectra both the dipole moment μ_e and the polarisibility of the molecule α_e in the excited state (using the results of the theoretical study of Margenau [62]) was derived from a direct consideration of the van der Waals interaction between the solvent and solute molecules with a large number of various simplifying assumptions (in particular the assumption that the molecules are spherical and that their polarisibility in combined electronic states is isotropic). To facilitate the calculations, the formula is written in the following simple form [59]:

$$(\mu_e^2 - \mu_g^2) + A\alpha_e = B \ , \qquad (25)$$

where A and B are quantities which depend in a complex manner on a number of the parameters of the test molecule and the medium and have different forms depending on the degree of interaction of the solvent molecules (the significance of the remaining quantities is clear from the foregoing). The method of determination of μ_e and α_e consists in plotting a linear relation between B and A for 7-10 solvents. It is then possible to find α_e from the slope, while the intercept on the ordinate axis yields $B = \mu_e^2 - \mu_g^2$, whence μ_e can be found provided that μ_g is known.

Abe and coworkers used this method to determine the values of μ_e and α_e in $^1B_{1u}$ and $^1B_{2u}$ excited states of the non-polar naphthalene molecule [59] and also in the $n-\pi^*$ excited state of the acetone molecule [60]. In the last case μ_e is much lower than the corresponding values for the ground state. It is also remarkable that the dipole moment μ_e which Abe obtained for acetone proved to be much less than the value which he calculated from the McRae formula (Robertson's method [24]). This last finding the author explains by the fact that McRae did not take into account the polarisibility of the molecule in the excited state, whereas according to Abe's data it increases markedly on excitation of the molecule. Somewhat earlier, while testing the relation which he derived Abe [58] determined, using a less rational method, the polarisibilities and dipole moments of nitrobenzene and acetophenone molecules in the excited state and then, using a simplified formula for the spectral shift, he found the values of μ_e and μ_g also from the spectral shift in non-polar solvents. He established thereby that electronic excitation increases the dipole moments of the molecules. Finally, using his method, Abe determined the dipole moments and polarisibilities in the excited states of four benzene derivatives (nitrobenzene, anisole, acetophenone, and *p*-chloroacetophenone). The high dipole moments of nitrobenzene and acetophenone (μ_e = 6.780 and 4.230 D respectively) were attributed to charge transfer on excitation.

An important feature of Abe's method [58-61] is that he does not employ the model concepts of the physics of dielectrics (in particular the Onsager model), i.e. there is no need to specify or determine independently the Onsager radius of the molecule. Unfortunately, however, the method [58-61] as a whole is based on not altogether correct postulates (the author does not take into account the Franck-Condon principle in the system "test molecule-medium" in the electronic transition and neglects the possibility that the moments $\vec{\mu}_g$ and $\vec{\mu}_e$ are not parallel, etc.), which probably makes this method suitable only for qualitative or semi-quantitative estimates. Furthermore, the applicability of the method is significantly complicated by the fact that it is necessary to know a number of physicochemical parameters of the test substance and the solvent which are difficult to determine.

In a number of studies an attempt was made to use certain of the above relations to determine the dipole moments of the excited state from the measured spectral shifts of the solutions as a function of temperature. The principal advantage of such methods consists in the fact that a smaller number of solvents is required to obtain the necessary data. The physical properties of the solvents and hence also the energy of the interaction of the test molecule with the medium, both in the ground and excited states vary with temperature, which leads to a shift of the electronic spectra. Piterskaya [63] determined μ_e and φ for a number of phthalimide derivatives with the aid of Bakhshiev's formulae (10)-(12). For this purpose, only five solvents (isopentyl alcohol, ethyl acetate, dioxan, anisole, and benzene) were required, instead of the usual 10-15. The dielectric constant ϵ and the refractive indices n of these solvents varied with temperature in the range 20-300°C ($\tau_{or} \ll \tau_{fl}$). The data obtained by this method agree well in most cases with the results obtained in the study of the spectral shifts as a function of the solvent at room temperature [32,34,37].

Pikulik and coworkers [64,65] attempted to extend the limits which restrict the applicability of the McRae formula to liquid solutions and derived a formula suitable for viscous and solid solutions:

$$\nu_{00}^a - \nu_{00}^f = \frac{2(\vec{\mu}_e - \vec{\mu}_g)}{hca^3}\left(\frac{\varepsilon-1}{\varepsilon+2} - \frac{n^2-1}{n^2+2}\right)\frac{\tau_{fl}}{\tau_{fl}+\tau_{or}} \ . \qquad (26)$$

On the basis of this formula the authors proposed a method for the determination of the dipole moment $\vec{\mu}_e$ by analysing the mirror-image absorption and fluorescence spectra in one solvent (in particular in isobutyl alcohol) at low ($\tau_{or} \gg \tau_{fl}$) and room ($\tau_{or} \ll \tau_{fl}$) temperatures. In Eqn. (26) ν_{00}^a and ν_{00}^f are the frequencies of the purely electronic transitions for absorption and emission respectively. These frequencies may be determined by the method proposed by Pikulik for mirror-image spectra [66]. Eqn. (26) was used to determine $\vec{\mu}_e$ for several phthalimide derivatives with known $\vec{\mu}_g$ and φ (taken from Bakhshiev) and an Onsager radius $a \simeq 4$ Å. The data obtained in this study differ somewhat from Bakhshiev's results but, as pointed out by the authors, when certain additional factors are taken into account, the agreement becomes fairly satisfactory.

For fluorescent but sparingly soluble compounds, it is convenient to employ a method involving the approximate determination of the change in the dipole moments on excitation ($|\Delta\vec{\mu}| = |\vec{\mu}_e - \vec{\mu}_g|$) proposed by Löber [67]. This method involves the measurement of the positions of the fluorescence band maxima only at low ($\tau_{or} \gg \tau_{fl}$) and room ($\tau_{or} \ll \tau_{fl}$) temperatures in one solvent. The method is based on the Lippert-Mataga theory [see Eqn. (2)], and the final relation is of the form

$$(\nu_f)_T - (\nu_f)_t = \frac{2}{hca^3}\left(\frac{\varepsilon-1}{2\varepsilon+1} - \frac{n^2-1}{2n^2+1}\right)|\Delta\vec{\mu}|^2, \qquad (27)$$

where $(\nu_f)_T$ and $(\nu_f)_t$ are the frequencies at the fluorescence band maxima at low and room temperatures respectively. Löber suggests that the measurements may be performed in any solvent because the additional shift of the fluorescence bands due to possible specific interactions over short distances (in particular due to hydrogen bonding) is eliminated in Eqn. (27). Löber determined $|\Delta\vec{\mu}|$ for a series of aminoquinols with a merocyanine group on transition to the first excited singlet state. The solvent

was ethanol because its viscosity (and hence τ_{or}) varies gradually with temperature. In all cases the dipole moment of the molecules was found to increase on excitation and the properties of the substituents proved to be correlated with $|\Delta\bar{\mu}|$ (the Onsager radius a was assumed to be 3 Å). It was also established that, for compounds of the type investigated, non-radiative transitions from excited states with a large dipole moment have a high probability. Unfortunately the data obtained by Löber cannot be compared with the results of other workers.

Summarising, it must be noted that the methods for the experimental determination of μ_e and φ based on the measurements of spectral shifts, are fairly reliable and experimentally simple. It has been shown that these methods do not require the use of any special equipment and reduce solely to the measurement of the contours of the absorption and emission bands for solutions of the test substance in various solvents using standard spectroscopic apparatus. The accuracy of the spectral shift method is almost entirely determined by the accuracy with which μ_g and a are specified. In those cases where the values of a are specified on the basis of chemical structure, the error of the determination may reach 15–20%. However, it should be noted that at present studies are being carried out with the aim of developing methods for the direct experimental determination of a for substances which are not liquid at room temperature. Such methods can evidently significantly increase the precision of the determination of μ_e and φ.

III. METHOD OF ELECTRICAL POLARISATION OF FLUORESCENCE

In 1959 Czekalla [68-70] suggested that the phenomenon of the polarisation of the fluorescence of molecules in liquid solutions placed in an electric field (electrical polarisation of fluorescence) be used to determine the dipole moments of the excited states of the fluorescing molecules. The central feature of this phenomenon consists in the fact that, under the action of a strong electric field of about 150 kV cm^{-1}, the excited polar molecules of the solute are oriented and, on excitation with ultraviolet light, emit partially polarised fluorescence, the degree of polarisation P being low: $P = \dfrac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}}$, where $I_{\parallel}$ and $I_{\perp}$ are the intensities of the fluorescence polarised parallel and perpendicular to the direction of the electric field respectively. According to the classical phenomenological theory developed by Czekalla, the degree of polarisation of the fluorescence P varies linearly with the square of the field strength:

$$P_E - P_0 = 0.1\,\frac{3\cos^2\alpha - 1}{2}\left(\frac{\mu_e}{kT}\right)^2\left(\frac{\varepsilon+2}{3}\right)^2 E^2, \qquad (28)$$

where P_E is the degree of polarisation of the fluorescence of the solution in a field E for a solvent with a dielectric constant ϵ, P_0 the degree of polarisation for the same solution without the field, the α the angle between the vector of the electronic transition moment and the dipole moment of the excited state $\vec{\mu}_e$. This angle can be determined either by measuring the electrical dichroism (see below) or on the basis of additional considerations concerning the molecular structure [70]. In the derivation of Eqn. (28) it is assumed, firstly, that the same excited state is responsible for both absorption and fluorescence and, secondly, that the ratio of the average lifetime of the excited state (τ_F) to the dielectric relaxation (principally orientation) time of the molecules in solution (τ_ϵ) is sufficiently large for the attainment of orientation equilibrium in the excited state ($\tau_F/\tau_\epsilon > 3$). The ratio τ_E/τ_ϵ can be determined, for example, from measurements of the degree of polarisation of the fluorescence of the solution P_0 without an electric field using the formula

$$\frac{\tau_F}{\tau_\varepsilon} = \frac{P_\infty - P_0}{P_0(3 - P_\infty)}, \qquad (29)$$

where P_∞ represents the degree of polarisation of the fluorescence for a solvent with infinite viscosity (usually $P_\infty \simeq 0.45$).

In Czealla's phenomenonological theory only factors associated with the anisotropy of the distribution of the polar molecules oriented by the external electric field are considered but no account is taken of the shift of the fluorescence band occurring because the different dipole moments in the ground and excited states interact in different ways with the external field. Nevertheless, analysis shows that this last factor can have decisive importance in many cases. Therefore Liptay [71] developed a quantum-mechanical theory of the effect of electric fields on the fluorescence of solutions and derived formulae for different experimental conditions giving the relation between the degree of polarisation of fluorescence, on the one hand, and the strength of the external electric field and the form of the fluorescence band, on the other. In these formulae, which were obtained for particular values of the ratio τ_F/τ_ϵ, account is taken of the shift of the fluorescence band on application of the electric field. In its general form this relation is very complex, so that the experimental determination of the dipole moments of excited states using such formulae is possible only in special cases.

In the study of the polarisation of fluorescence by an external field, both linearly polarised and non-polarised ultraviolet radiation can be used for excitation, fluorescence perpendicular to the direction of the distribution of the exciting radiation being observed in both cases. Although the working formula is simpler than in the first case, nevertheless it is desirable to employ non-polarised radiation, because the intensity of the fluorescence and hence the precision of the experiments is thereby considerably increased. With this method of excitation, the following relation, derived with certain simplifying assumptions (in particular assuming the conditions $\vec{\mu}_g \parallel \vec{\mu}_e$), is used to determine μ_e:

$$\frac{P_{E\nu} - P_{0\nu}}{E^2\left(\frac{\varepsilon+2}{3}\right)^2}\left(1 + \frac{0.9}{\tau_F/\tau_\varepsilon}\right) = 0.1\,\frac{\mu_e^2}{k^2T^2} + 0.2\,\frac{\mu_e(\mu_e - \mu_g)}{hckT}\,\frac{d\ln I_\nu}{d\nu}, \qquad (30)$$

where I_ν is the intensity of fluorescence with frequency ν and the significance of the remaining quantities is the same as in Eqn. (28). The first term of Eqn. (30) describes orientation effects and the second is due to the displacement of the band under the influence of the field E. The ratio τ_F/τ_ϵ is related by means of Eqn. (31) to the degree of polarisation of fluorescence in the absence of the field when excited by non-polarised radiation:

$$P_0 = \frac{0.3}{0.9 + \tau_F/\tau_\varepsilon}. \qquad (31)$$

For liquid solutions, $\tau_F/\tau_\epsilon \gg 1$ and Eqn. (30) becomes simpler:

$$\frac{P_{E\nu} - P_{0\nu}}{E^2\left(\frac{\varepsilon+2}{3}\right)^2} = 0.1\,\frac{\mu_e^2}{k^2T^2} + 0.2\,\frac{\mu_e(\mu_e - \mu_g)}{hckT}\,\frac{d\ln I_\nu}{d\nu}. \qquad (32)$$

This expression can be used for both excitation methods mentioned above[71].

If the conditions $\tau_F/\tau_\epsilon \gg 1$ does not hold, Eqn. (30) is used to estimate μ_e to a first approximation and the estimate is then employed to calculate μ_e to a second approximation by the above general formula containing terms which depend on the form not only of the emission but also of the absorption bands. This procedure greatly complicates the calculation of μ_e but it is necessary in all cases where $\tau_F/\tau_\epsilon \leqslant 1$.

In the determination of the moments μ_e by the method of electrical polarisation of fluorescence, the left-hand side of Eqn. (30) is plotted against $d\ln I/d\nu$. It is significant that the values of μ_e can then be found by two independent methods†: from the intercept which the straight line makes on the ordinate axis and from the slope of the straight line (for known μ_g). Czekalla et al.[72] state that the first method is more accurate and gives rise to an error not exceeding 5%. It is striking that the two methods yield closely similar results in most cases.

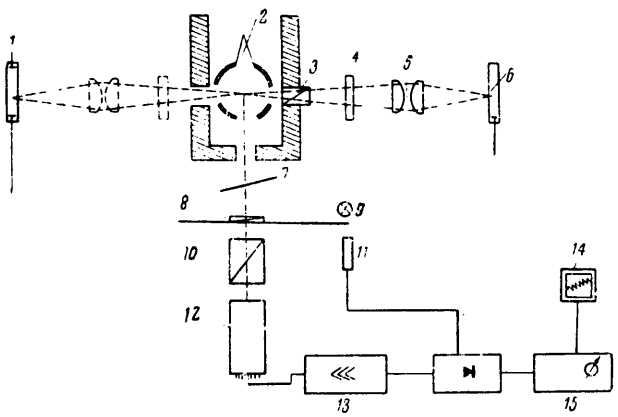

Figure 3. Outline of the apparatus for the determination of $\Delta\bar{\mu}_e$ by electrical polarisation of fluorescence: 1) NVO-200 mercury lamp; 2) cuvette; 3) polariser; 4) filter; 5) condenser; 6) NVO-200 mercury lamp; 7) compensator; 8) $\lambda/2$ plate; 9) reference signal lamp; 10) analyser; 11) photo-cell; 12) photomultiplier; 13) amplifier; 14) pen recorder; 15) valve voltmeter.

The apparatus employed by Czekalla and coworkers for the measurement of the degree of polarisation of fluorescence in an electric field is shown schematically in Fig. 3. The excitation of fluorescence is achieved by radiation from one or two high-pressure mercury lamps. The exciting radiation passes through a light filter which isolates intense lines from the mercury arc spectrum and the light is focussed by means of condensers on the specimen placed between the electrodes of the measuring high-voltage chamber. The radiation from the right-hand side lamp can be linearly polarised by means of a polariser built into a calibrated rotating ring. The measuring high-voltage cuvette is fitted with electrodes of special form (Rogovskii's profile) to exclude edge effects. A constant high potential chosen to give $E \simeq 150$ kV cm^{-1} is applied to the electrodes, the distance between which is 0.465 cm.

The system is thermostatted by passing a special liquid with a high resistivity and a high breakdown voltage through the hollow electrodes. The chamber is fitted with a special device in the form of a bent matt-black tube designed to eliminate the effect of scattered light.

Partially polarised fluorescence is observed in the direction perpendicular to the exciting beam. The beam analysed passes through a half-wave plate rotating at a definite frequency, and then through a rigidly fixed analyser. By means of this device, the polarised part of fluorescence is modulated at a definite frequency and a variable signal is transmitted to a photoelectric multiplier (PEM), is amplified, rectified, and fed to an electronic voltmeter coupled to a pen recorder. The non-polarised part of luminescence remains non-modulated and is therefore not recorded. The signal from the polarised component of the fluorescence can be concentrated by rotating the plane of the compensator through a definite angle. From this angle, read off a dial, it is possible to calculate the degree of polarisation of the fluorescence, using Fresnel's formulae[68]. The auxiliary signal from the incandescent lamp is modulated at the same frequency as the polarised light and controls the operation of the rectifier, locking it to the rotation of the plate.

To determine the degree of polarisation as a function of frequency within the limits of the fluorescence band, it is necessary to place a monochromator or an interference filter between the analyser and the photoelectric multiplier[71,72]. Particular attention is paid to the preparation of the specimen. Apart from the usual methods of purification, it is necessary to degas the solution carefully in order to avoid the electrical breakdown of the specimen in the powerful electric field.

The method of electrical polarisation of fluorescence was used to determine the dipole moments of the excited states of a number of derivatives of a biphenyl, fluorene, and stilbene in benzene and dioxan and also the complex of tetrachlorophthalic anhydride with hexamethylbenzene[70]. Comparison of the results obtained by the method of electrical polarisation of fluorescence with those determined from spectral shifts and by the method of electrical dichroism (see below) shows that the agreement is satisfactory in all the cases investigated.

IV. METHOD OF ELECTRICAL DICHROISM

The phenomenon of electrical dichroism was observed and explained for the first time by Kuhn et al.[73] It consists in the fact that a solution placed in a powerful electric field exhibits anisotropy of absorption in the region of the electronic bands of solute molecules. Hence it follows that, after passage through the solution, natural light becomes partially polarised (degree of polarisation P_E) and the intensity of initially linearly polarised light depends on the angle between the directions of light polarisation and the electric field.

Electrical dichroism is explained by partial orientation of solute molecules in the powerful electric field in consequence of their permanent dipole moment or the anisotropy of their polarisability. It is significant that, under the action of the electric field, the absorption band is also displaced in proportion to the difference $\mu_g - \mu_e$ because of the difference between the dipole moments and polarisibilities of the molecule in the ground and excited states.

†The same also applies to Eqn. (32).

A theory of the phenomenon, taking into account the band shift and therefore making it possible to relate P_E to μ_e, was developed by Liptay and Czekalla [74,75] and also by Labhart [76] (for polarisable molecules). Several versions of this method for the determination of the dipole moments of excited states, differing in the method of measurement of electrical dichroism, were proposed by Liptay, Czekalla, and Wick [69,75,77] and by Labhart [78,79].

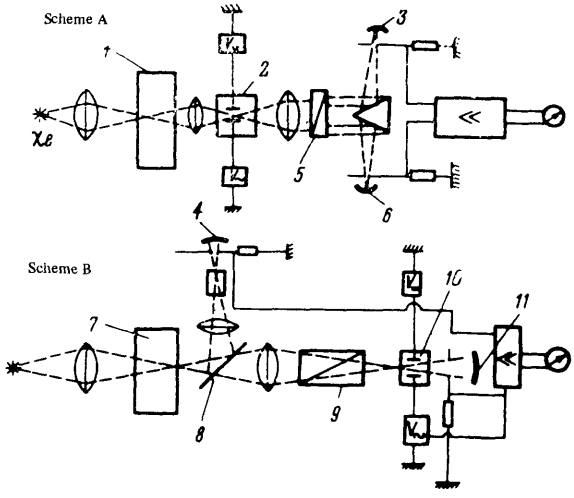

Figure 4. Outline of the apparatus for the determination of $\vec{\mu}_e$ by the method of electrical dichroism: 1) monochromator; 2) cuvette; 3) photomultiplier; 4) photomultiplier; 5) analyser; 6) photomultiplier; 7) monochromator; 8) half-silvered plate; 9) Nicol prism; 10) measuring cell; 11) photomultiplier.

In Czekalla's method‡ (Fig. 4, scheme *A*) the degree of polarisation of natural light at frequency ν is investigated in an electric field of 20–90 kV cm^{-1} (ν is in the region of the absorption band of the solution). Light from a xenon lamp is directed through a monochromator into a measuring cuvette, placed in a steady electric field interrupted at a frequency of 75 Hz. After passing through the analyser, the partially polarised light falls upon the photocathode of the photoelectric multiplier, the signal from which is amplified and recorded.

For the simplest case, in which the dipole moments $\vec{\mu}_g$ and $\vec{\mu}_e$ and also the dipole moment of the electronic transition $\vec{M}$ are parallel, the following relation is valid:

$$P_{E_\nu} = -2.3 D_\nu \left(0.1 \frac{\mu_g^2}{k^2T^2} + 0.46 \frac{(\mu_e - \mu_g)\mu_g}{hckT} \frac{d \lg \varepsilon_\nu}{d\nu}\right)\left(\frac{\varepsilon+2}{3}\right)^2 E^2, \quad (33)$$

where P_{E_ν} is the degree of polarisation of light at a frequency ν which has passed, in a direction perpendicular to that of the field E, through a solution with an optical density $D\nu$, molar extinction coefficient ϵ_ν, and dielectric constant ϵ. It is readily seen that the number μ_e can be found from the slope of the linear plot of P_E against E^2 knowing the value of μ_g and having determined experimentally D_ν and $d \lg \epsilon_\nu / d\nu$. In the more complex case the method permits the determination also of the angle between the vectors $\vec{\mu}_g$ and $\vec{\mu}_e$ and the dipole moment of the transition $\vec{M}$.

In the method for the investigation of electrical dichroism proposed by Labhart, measurements were made of the intensity of light at frequency ν polarised at a definite angle relative to the direction of the field and transmitted through the absorbing solution at right angles to the direction of the field (Fig. 4 scheme *B*). In this case the light leaving the monochromator falls on a half-silvered mirror which divides the beam into two components: one passes through the comparison cuvette (without an electric field) and the other is polarised and passes through the measuring cuvette to which a constant high potential interrupted at a frequency of 75 Hz has been applied. Both beams are received by the photomultiplier cells and the signals are amplified and transmitted to the apparatus in which the difference between them is recorded.

In Labhart's method the relative change in the intensity of the polarised light I which has passed through the solution without a field (through the comparison cuvette) and in the presence of the field E is also linearly related to E^2 and in the simplest case ($\vec{\mu}_e \parallel \vec{\mu}_g$) the corresponding formula is

$$\frac{\Delta I}{I} \equiv q_E = -\frac{5.29}{3} D_\nu \frac{(\mu_e - \mu_g)\mu_g}{hckT} \frac{d \lg \varepsilon_\nu}{d\nu} \left(\frac{\varepsilon+2}{3}\right)^2 E^2. \quad (34)$$

It is readily seen that the dipole moment μ_e can also be obtained from Eqn. (34) given μ_g and having calculated $d \lg \epsilon_\nu / d\nu$ from the absorption spectrum.

Using a method of measurement analogous to that described above [79] and the theory of optical absorption by molecules in solution in an electric field which they developed previously [80,81], Liptay and coworkers determined the dipole moments in the ground and excited states and also the dipole moments of the electronic transitions of a number of symmetrical molecules (nitrobenzene, 4-nitroaniline, 3,5-diamino-1-nitrobenzene, 3,5-dinitroaniline, carbazole, and 3,6-dinitrocarbazole) in dioxan [82]. The results agree well with the determinations of μ_g by the usual electrical methods and also with simple theoretical calculations of μ_g and μ_e. Comparison of the experimental and theoretical data makes it possible to assign to charge transfer two absorption bands of 3,6-dinitrocarbazole. The combination of the methods of measurement proposed by Czekalla and Labhart provides a convenient method for the determination not only of dipole moments but also (in more complex cases) of the mutual orientations of the vectors of the dipole moments and the transition moments. The available methods for the observation of electrical dichroism and also the electrical polarisation of fluorescence have been reviewed in detail [78,79]. The dipole moments μ_e of a number of derivatives of stilbene, fluorene, and biphenyl have also been determined by the method of electrical dichroism. In most cases the results were compared with data obtained by other methods and satisfactory agreement was found.

V. METHOD BASED ON THE STARK EFFECT

The method of determination of the dipole moments of molecules in the ground state from the splitting of the rotational lines in an electric field (Stark effect) measured by microwave spectroscopy is well known [83]. In order to

‡The method of measurement by Czekalla's method described here is due to Labhart [78,79]. For Czekalla's scheme, see, for example, Ref. 69.

use the Stark effect for the determination of the dipole moments of the excited states of molecules, it is necessary to observe the splitting of the fine rotational structure of the vibronic bands in the absorption spectra in an electric field, i.e. optical spectroscopic methods must be used. Such splitting becomes observable in the fairly strong electric fields employed to investigate the electronic spectra of gaseous diatomic or simple monotomic molecules whose rotational structure is well resolved. This of course greatly restricts the choice of the possible objects for investigation.

The dipole moments of $n-\pi^*$-excited states of simple organic molecules (formaldehyde and propynal) were determined for the first time by Freeman and Klemperer [84-86] and the corresponding dipole moment of formyl fluoride was determined by Lombardi et al. [87] Even for these comparatively simple organic molecules, it is not possible to observe complete splitting of the rotational structure. However, when the mutually perpendicular polarised Stark components in the formaldehyde spectrum are observed separately, well resolved doublets are revealed. This makes it possible to determine the dipole moment of the excited state after identifying the bands, provided that the dipole moment of the ground state, the splitting between the components of the doublet, and the electric field strength are known. A different procedure is used for the propynal molecule: after calculating the Stark spectra for postulated dipole moments and comparing them with those observed experimentally, the authors choose the most suitable value of the dipole moment.

It should be noted that only for molecules of the symmetric top type (the formaldehyde molecule may be regarded as such) is it possible to determine by this method the overall dipole moment μ_{ea} of the molecule along the axis of rotation directed along the bond C=O. In other cases it is necessary to determine also the component of the dipole moment μ_{eb} in the plane perpendicular to the direction of μ_{ea}. Despite its restricted applicability, the method based on the Stark effect is important, since it makes it possible, using a simple model, to observe the change in the dipole moment on excitation of the molecule in the gaseous phase, by the most direct method.

---o0o---

It is useful to compare briefly the characteristics of modern methods used to determine the dipole moments of excited states. As can be seen from the foregoing, the methods most widely used at present are based on the measurement of spectral shifts under the influence of the solvent. These methods are distinguished by simplicity of experimental technique and of the formulae used for the calculations. The preferred methods [29-38,49-56] are those which permit the determination not only of the magnitude but also of the orientation of the moment $\vec{\mu}_e$ relative to $\vec{\mu}_g$, allowing at the same time the role of the polarisability (particularly for molecules with not very large permanent dipole moments). It has been shown [8-16] that failure to take into account the polarisability leads to significantly high values of $\vec{\mu}_e$. However, methods based on the measurements of spectral shifts constitute at the same time also the most approximate procedures for the determination of the permanent dipole moments of free molecules. This is due to the approximations made in the derivation and in the practical application of the formulae required for the calculation. This includes the obligatory use of the simple Onsager model of the interaction between the solute molecule and the solvent and also the necessity to specify or determine independently the Onsager radius which enters into the formulae of the majority of methods based on spectral shifts§. Moreover, another disadvantage of these methods is the need to employ a large number (10-15) of solvents with specially selected values of ϵ and n in order to obtain a sufficiently reliable result; this limits their applicability to sparingly soluble compounds. From this point of view, methods based on the measurements of the temperature variation of the spectral shift, in which the number of solvents required for the investigation is greatly reduced, are very promising.

Unfortunately the most convenient versions of the method of spectral shifts are applicable only to fluorescent molecules and permit the determination of $\vec{\mu}_e$ for the first singlet excited state only. Therefore, despite their approximate nature, the methods based on the analysis of the displacement of absorption spectra alone also merit attention, since they permit the determination of the dipole moments of the higher excited and non-fluorescent (for example $n-\pi^*$) states [18,19,27,39].

The formulae for the determination of $\vec{\mu}_e$ by electrical polarisation of fluorescence were derived on a more rigorous basis. At the same time, for the practical application of these formulae it becomes necessary to make additional simplifying assumptions (for example no account is taken of terms containing polarisibility) which introduce significant systematic errors into the results. Furthermore, there are experimental difficulties associated with the fact that, due to the very weak polarisation of luminescence under the action of an external electric field, a very powerful electric field must be employed, which may lead to the breakdown of the experimental cuvette. This risk leads in turn to the necessity for preliminary careful treatment (degassing) of the solution (usually in benzene). However, even in very powerful fields the effect remains small, which necessitates the employment of very sensitive methods for the recording of the polarised luminescence. This greatly complicates the apparatus and excludes the possibility of the determination of $\vec{\mu}_e$ of weakly luminescent compounds. Because of these considerations, the method of polarised fluorescence is less attractive, although it remains nevertheless the only fairly accurate method for the determination of $\vec{\mu}_e$ in the fluorescent (equilibrium) excited state of the molecule in non-polar solvents.

The method of electrical dichroism permits the determination of the dipole moment of an excited non-equilibrium (Franck-Condon) state with a relatively high precision, although in this case the final formulae are appreciably simplified by various (sometimes very approximate) assumptions. The experimental technique, which remains very complex, is nevertheless simpler than in the previous method because in this case a weaker field is required and the intensity of the partially polarised emission recorded is relatively high. Furthermore, the method is more general, since it permits the determination of μ_e of both fluorescent and non-fluorescent molecules and also of higher excited non-fluorescent singlet and triplet states. Finally, the procedure used to calculate $\vec{\mu}_e$ is much simpler than in the method of polarised fluorescence. All these factors undoubtedly constitute

§Here attention should be drawn to Eqns. (15) and (25) and also the method employed by Baba [22] in which the Onsager radius need not be known for the determination of μ_e.

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

definite advantages of the method of electrical dichroism and it is desirable that it be widely employed by the determination of $\vec{\mu}_e$.

The Stark effect has a restricted applicability, as already mentioned. However, this is the most accurate and

Experimental dipole moments of organic compounds in excited electronic states.

NOTES TO TABLE

1. In a few cases the limiting values employed by various authors to determine μ_e are indicated in the μ_g column and the figures in brackets represent values obtained by the spectral shift method.

2. In the μ_e column the figures in brackets represent the angles between $\vec{\mu}_g$ and $\vec{\mu}_e$ proposed on the basis of structural considerations when these are 0° or 180°, or obtained by the spectral shift method if they are not 0° or 180°; the values of $|\Delta\vec{\mu}|$ (and not $|\vec{\mu}_e|$) obtained from spectral shifts and also μ_e for the $n-\pi^*$ and $n-\sigma^*$ states and states the symmetry of which is known are indicated on the left-hand side by the appropriate symbols. All the remaining values refer to the lowest singlet excited electronic states.

3. The significance of the symbols in the "method" column is as follows: S—spectral shift method; F_1 and F_2—method of electrical polarisation of fluorescence in which the values of μ_e are determined from the slope or from the intercept on the ordinate axis respectively; D—method of electrical dichroism; St—method based on the Stark effect.

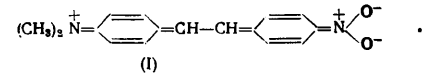
4. All the values of μ_e obtained by the F_1, F_2, and D methods are given for solutions in benzene with the exception of compounds 9 and 29 in Class I whose values are quoted for solutions in dioxan.

direct method for the determination of the dipole moments of excited states of free (i.e. unperturbed by the solvent) molecule. Furthermore, it appears that there is hope that the application of more refined analytical methods and better apparatus will extend somewhat the range of objects susceptible to investigation by this procedure.

It follows from the foregoing that various methods, despite their disadvantages, supplement one another to a considerable degree, which makes it desirable to determine $\vec{\mu}_e$ simultaneously by several of the above methods in important cases.

In conclusion a Table is presented in which the results of the determination of the dipole moments of the excited states of many molecules and complexes by different investigators using the methods described above are compiled. These data lead, in the first place, to the important conclusion that the values of $\vec{\mu}_e$ obtained by different procedures are similar. This finding shows that both the postulates on which the methods employed are based and the results themselves are correct. Furthermore, the data permit certain interesting conclusions to be drawn concerning the electronic structure of the excited states of organic molecules.

Thus comparison of $\vec{\mu}_e$ and $\vec{\mu}_g$ indicates a considerable increase of the polarity of many molecules in the excited state compared with the ground state. For example, in 4-dimethylamino-4′-nitrostilbene this indicates a considerable contribution of the dipolar structure (I) to the electronic state attained when the molecule is excited in the region of the long-wavelength electronic system:

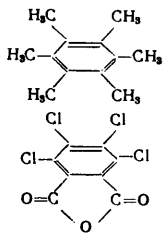


(I)

As already mentioned, the increase of polarity on electronic excitation of the molecule is in general characteristic of many singlet excited states of substances with active functional groups. This behaviour is shown particularly clearly for stilbene, fluorene, and biphenyl derivatives investigated by all the available methods and also oxadiazole and triphenylpyrazoline derivatives. On excitation, not only the magnitude but also the direction of the dipole moment usually changes appreciably. The direction of the vector for the difference between the dipole moment in the excited and ground states indicates the migration of charge from a donor to an acceptor group (transitions with charge transfer). These results, obtained mainly in the study of phthalimides [30,32,34,37,51,53], were described in detail above. Here we shall mention only that they agree well with the conclusions of many theoretical investigations [1,44,45,88].

Interesting data were obtained in the study of the dipole moments of the excited $\pi-\pi^*$ state of alternant and non-alternant hydrocarbons. It was found [59], in particular, that the naphthalene molecule is non-polar in the $^1B_{1u}$ and $^1\Gamma_{2u}$ excited states, as in the ground state, in agreement with the postulates of the molecular orbital theory. The azulene molecule remains polar also in $\pi-\pi^*$ excited states [24], but the direction of $\vec{\mu}_e$ in the first two singlet excited states is the opposite of that of $\vec{\mu}_g$. This indicates electron transfer from the five-membered to the seven-membered ring on excitation. The measurements of $\vec{\mu}_e$ of the first singlet excited state of certain molecular charge-transfer complexes yielded decisive proof of a sharp increase in the polarity of the complex in the excited state. Furthermore, it has been shown, for example [40,57], that in the formation of the iodine complex of 4-methoxycarbonylpyridine there is complete electron transfer from the aromatic molecule to the iodine atom with formation of an ion pair.

The dipole moment $\vec{\mu}_e$ of the sandwich type complex (II), determined by Lippert's spectral shift method and by the method of electrically polarised fluorescence, amounts to 14 ± 3.0 D and 10 ± 1.5 D respectively [70], which indicates an appreciable charge transfer from hexamethylbenzene to tetrachlorophthalic anhydride on excitation (the calculated moment of the structure D^+A^- is about 16 D, while $\vec{\mu}_g$ is only 3.6 D).



(II)

If however, one does not begin with the assumption that the vectors of the difference between the dipole moments of the steady states and the dipole moment of the electronic transition are parallel, as was done by Czekalla and Meyer [70], and the angle between the moments $\vec{\mu}_e$ and $\vec{\mu}_g$ is determined by the spectral shift method, then, as shown by Bilot and Kawski [52], the angle is about 50° and, although the polarisation in the excited state does increase, the increase is much less than found in the preceding investigation ($|\vec{\mu}_e| = 7.6$ D). These results are confirmed by those of Bakhshiev [40].

On transition of molecules to the $n-\pi^*$ excited state, the polarity of the molecule diminishes appreciably compared with the ground state in the majority of cases. Thus the values of $\vec{\mu}_e$ determined by the Stark method for the $n-\pi^*$ states of formaldehyde and propynal are much lower than the corresponding values of $\vec{\mu}_g$. Analogous relations between $\vec{\mu}_e$ and $\vec{\mu}_g$ on $n-\pi^*$ excitation are characteristic also of other carbonyl compounds (various ketones [18] and acetones [39,60]). This is evidence that the transition to the $n-\pi^*$ excited state is localised at the carbonyl group and is associated with its polarisation in the direction opposite to that which obtains in the ground state. The results of recent measurements of $\vec{\mu}_e$ of nitromethane [9,10,39] diazaphenanthrene [23], and derivatives of thiourea [21], pyridazine, and pyrimidine [22] lead to similar conclusions, that is, the decrease of the dipole moment on $n-\pi^*$ excitation, and, for pyrimidine, the reverse direction of the vector $\vec{\mu}_e$ with respect to that of the vector $\vec{\mu}_g$. Similar changes in the direction of the dipole moment on excitation are particularly characteristic of the $n-\sigma^*$ transition [39] (methyl iodide, bromoform), which is evidence of a more important displacement of electron density on $n-\sigma^*$ excitation compared with the $n-\pi^*$ transition. The results of Lombardi et al. [87] do not agree, however, with the concept of the localisation of excitation at a C=O group in the $n-\pi^*$ excitation of the formyl fluoride molecule, since the dipole moment would not then decrease and its sign would remain the same.

The above data for the difference between the changes of dipole moments in charge-transfer $\pi-\pi^*$ and $n-\pi^*$ transitions lead to the conclusion that the difference is one of the principal factors which determine the direction of the shift of the corresponding absorption band when non-polar solvents are replaced by polar solvents (the so called red and blue spectral shifts). The latter, in turn, throws light on the nature of solvatochromism, linking it

mainly to the difference between the electrostatic interactions of the molecules with the solvent in the ground and excited states in consequence of the change in the dipole moment of the molecule in the quantum jump.

Despite the large number of published studies, the investigation of the dipole moments of excited states has essentially only just begun. The main importance of the results obtained consists in the fact that the dipole moment of the excited state is at the present time virtually the only experimental quantity characterising its electronic configuration.

Semirigid Chain Molecules

V.N.Tsvetkov

The problem of the extent to which the hydrodynamic and optical behaviour of chain molecules in solutions can be used for the observation and the quantitative assessment of their rigidity and of the internal ordering of their structures is examined. The general theoretical positions are illustrated by experimental results for a series of polymers, the molecules of which have a rigid chain structure. There is a bibliography of 106 references.

I. INTRODUCTION

A characteristic property of chain molecules of polymers is their flexibility, that is, their ability to change conformation under the influence of thermal motion or under the action of deforming forces. This property explains the rubberlike behaviour of high-molecular-weight elastomers in the temperature range above their glass points. In solutions such flexible chain molecules have the conformation of a statistical coil which in Θ conditions (an "ideal" solvent) can be regarded as a "gaussian" coil.

The properties of solutions of flexible chain molecules have been the subject of detailed and thorough study by many investigators and have been described in several reviews and monographs [1-10].

In connection with the development of the synthesis of polymers suitable for the creation of high-strength and thermally stable fibres, films, and other materials for special purposes, the need for a study of the morphological and conformational properties of the macromolecules of such polymers has become increasingly evident in recent years.

The chemical structure of these macromolecules shows that many of them, despite their chain structure, should have limited flexibility, occupying a position intermediate between the absolutely rigid submicroscopic species (such as viruses or globular proteins) and the ideally flexible chain molecules of many synthetic polymers.

The classical examples of such "semirigid" chain molecules are the molecules of natural celluloses, and also of polypeptides and nucleic acids in helical conformation. Until comparatively recently our practical information about rigid chain molecules was limited to these examples. However, in recent years various investigators synthesised new polymers, the macromolecules of which show the properties characteristic of semirigid chain molecules.

II. THEORETICAL PRINCIPLES

1. Conformation and Rigidity of the Molecular Chain

The estimation of the rigidity or flexibility of a macromolecule can be approached in various ways, leading to two concepts: thermodynamic (equilibrium) and kinetic (non-equilibrium) flexibility. The opinion about the equilibrium flexibility of the chain is divided on the basis of a study of the equilibrium conformation (dimensions and geometric form) which the macromolecule adopts in various media.

Information about kinetic flexibility has been obtained by investigating the rate of occurrence of the processes which convert the macromolecule from one conformation into another.

Although there are grounds for assuming that for a definite molecular structure both types of flexibility are interconnected, the extent and nature of this relation in each individual instance requires special study.

The first of the two above-mentioned types of flexibility—equilibrium flexibility (and the corresponding rigidity) of chain molecules will be examined below. A quantitative measure of the equilibrium rigidity of a molecular chain could be the length of a statistical segment A (Kuhn and coworkers [10]) or the persistent length of the chain $a = A/2$ (Porod [11]).

The length A is determined from two conditions [10]. The first is the equality $L = NA$, where N is the number of segments in the chain and L its contour length, that is, the length of the chain at its greatest extension without destroying the valence angles and bonds; when an ordered secondary structure is present in the molecules (for example, the α-helix type) the retention of this structure during the extension must be borne in mind. The second condition is formulated as follows: at long chain lengths ($L \gg A$) and in the absence of higher order interactions [12] it is modelled by a gaussian chain, that is, the mean square distance between its ends $\overline{h^2}$ is proportional to its contour length $\overline{h^2} = NA^2$. The combination of these two conditions leads to the equation

$$A = \overline{h^2}/L \qquad (1)$$

valid for a gaussian chain.

When the contour length L is insufficient for satisfying the conditions $L \gg A$, $N \gg 1$ (which for rigid chain molecules, where A is large, can occur at rather high values of L, that is, in the range of rather large molecular weights), then the molecular chain is not gaussian and relation (1) is not satisfied.

In this instance an effective method of describing the conformational properties of a molecule is the model of a "persistent" or "wormlike" chain [11]—a three-dimensional line of constant curvature. This curvature is characterised by the parameter a—the persistent length (correlation length) [11-15]; a is determined by the relation

$$a = -\Delta L / \ln \overline{\cos \Delta\theta},$$

where $\Delta\theta$ is the angle between the tangents to the segment of the wormlike chain at its initial and final points. The bar denotes an average over all the conformations of the

chain corresponding to the given values of L and h. Hence a is a measure of the equilibrium rigidity of the chain, increasing with decrease in the convolution of the latter.

For persistent chains instead of formula (1) the theory[11,16] leads to the relations:

$$\overline{h^2}/L = A[1-(1/x)(1-e^{-x})], \quad (2)$$

$$6\overline{R^2}/L = A\{1-(3/x)[1-(2/x)\{1-(1/x)(1-e^{-x})\}]\}, \quad (3)$$

where $\overline{R^2}$ is the radius of gyration of the molecules, $x = L/a = 2L/A$. Equations (2) and (3) are applicable in any range of values of parameter x, that is, to chain molecules of any length under the condition of no effects of long-range order interactions (action at a distance).

In the limit, when $x \to 0$, from Eqns. (2) and (3) it follows that $h = L$ and $\overline{R^2} = L^2/12$, that is, the conformation of the molecule is similar to a linear bar. On the other hand, when x is large Eqns. (2) and (3) correspond to the properties of gaussian chains—Eqn. (2) is equivalent to Eqn. (1), and (3) gives $\overline{R^2} = \overline{h^2}/6$.

The variation of $\overline{h^2}/LA$ and $6\overline{R^2}/LA$ with x according to Eqns. (2) and (3) is shown by curves *1* and *2* in Fig. 1.

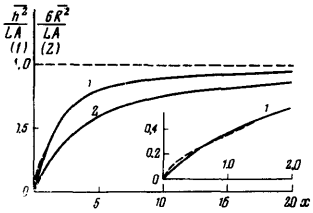

Figure 1. Variation of the statistical dimensions of a persistent (wormlike) chain with its contour length L. *1*) $\overline{h^2}/AL$ as a function of the parameter $x = L/A$. Continuous curve: according to theory[11]; broken curve: according to theory[17]. *2*) $6\overline{R^2}/AL$ as a function of $x = L/A$ according to theory[16].

For comparison with experimental results it is convenient to make the substitution $L = P\lambda$ in Eqns. (2) and (3) where P is the degree of polymerisation and λ the projection of the monomeric unit on the direction of the molecular chain. Instead of Eqn. (2) we obtain:

$$\overline{h^2}/P = S\lambda^2[1-(S/2P)(1-e^{-2P/S})] \quad (2')$$

where S is the number of monomeric units in the segment.

On plotting the experimental values of $\overline{h^2}/P$ as a function of P, a curve like curve *1* in Fig. 1 is obtained. Its initial slope gives λ^2, whereas the asymptotic level $S\lambda^2$ allows S to be determined and correspondingly $A = S\lambda$. The value of S can also be determined from the form of the curve, by its departure from the asymptotic limit at a given value of P (this departure is determined by the value of the parameter S/P). Similar results can be obtained from the experimental dependence of $6\overline{R^2}/P$ on P.

The advantage of the above wormlike model is its universality, since in it the flexibility of the molecular chain is determined without any a priori hypotheses about the mechanism of this flexibility (restricted or free rotation around the valence bonds, rotational isomerism defects of the secondary structure, etc.). On the other hand, starting from the experimental data on the dimensions of the molecules ($\overline{h^2}$ or $\overline{R^2}$) and the degree of their polymerisation P this theory not only allows the rigidity of the molecular chain to be estimated but also makes possible judgements about its conformation since the projection of the monomer λ is also determined in this.

On the other hand it can be shown that, for example, for a molecular chain with restricted rotation the persistent model leads to the same results as the calculation of $\overline{h^2}$ by the method of statistical mechanics in the rotational isomer approximation. Flory[18] recently developed such a method for application to chains of any length and used it for calculating the molecular dimensions of certain polymers[17,19]. The results are given as a plot of $\overline{h^2}/nl^2$ against n ($1 < n < \infty$), where n is the number of valence bonds in the chain with a valence angle of $\pi - \theta$ between neighbouring bonds, and l the length of the chain. This can be easily converted into the relation $\overline{h^2}/AL = f(x)$ on taking into account that in this instance

$$x = 2n\cos^2\frac{\vartheta}{2}/\lim_{n\to\infty}(\overline{h^2}/nl^2), \qquad A = l\lim_{n\to\infty}(\overline{h^2}/nl^2)/\cos\vartheta/2$$

and

$$L = nl\cos\vartheta/2.$$

The curve $\overline{h^2}/Al = f(x)$ for the polyethylene chain (from Flory and Jernigan's results[17]) is shown in Fig. 1 (broken curve). In the range $0.5 < x < \infty$ it coincides with curve *1* determined by Eqn. (2). The difference in the models is noticeable only for extremely short chains for which $x < 0.5$ and $n < 3$, that is, in the range of molecular weights without practical significance.

It should be borne in mind that all the relations examined, (1)–(3), characterising the skeleton rigidity of the chain (short-range action), assume the absence of effects of long-range action in the molecule and therefore strictly speaking are applicable only to chain molecules, which are found in a Θ-solvent.

In thermodynamically good solvents owing to the effects of the excluded volume (action at a distance) the dimensions of the molecular coils are increased and the molecular chains are no longer gaussian[12]. In the range of molecular weights where under Θ conditions relation (1) is obeyed, in good solvents it is not satisfied and can be replaced[1] by Eqn. (4):

$$\overline{h^2} = N^{1+\varepsilon}\cdot A^2 = A^{1-\varepsilon}L^{1+\varepsilon} \quad (4)$$

where $0 < \epsilon < 0.2$ and ϵ does not depend on L.[12]

Kurata and coworkers[20] concluded that in very good solvents the parameter ϵ can reach the value 1/3. From Eqn. (4), the effect of the excluded volume leads to an increase in $\overline{h^2}/L$ with increase in L, that is, it brings about a departure from gaussian properties of the same nature as the short-range action (rigidity of the chain) describable by Eqns. (1)–(3). However, the departure from gaussian properties due to the rigidity of the chain appears in the range of low molecular weights and disappears at higher molecular weights. On the other hand these departures due to action at a distance increase steadily with the molecular weight and therefore will appear in the range of high molecular weights. This circumstance allows (at least in principle) the effects of short-range and long-range action to be distinguished from the form of the dependence of $\overline{h^2}/L$ on L.

The effects of long-range action (non-ideality of the solutions) show the decisive influence on the conformation of flexible chain molecules and were considered in detail for such molecules in several monographs[1,4-8,12]. On the other hand, for rigid-chain polymers the excluded volume

effect, even in good solvents, is expressed relatively weakly and in several instances it cannot be taken into consideration.

In accordance with Eqns. (2) and (3) the study of the conformational properties and rigidity of the persistent chains requires the experimental determination of their molecular weights (degrees of polymerisation P) and radius of gyration $\overline{R^2}$. The first characteristic is readily determined by one of the well-known methods [1].

The determination of $\overline{R^2}$ is a much more complex task. A direct method which can be employed for this is the study of the angular asymmetry of light scattering by the polymer in solution [1]. However, it must be remembered that these measurements are usually accompanied by considerable experimental errors, since they must be made in the range of comparatively low molecular weights (where departure from gaussian properties occurs), in which the degree of asymmetry of light scattering is slight and is easily quenched by the presence of a minute amount of dust, the formation of molecular associates, or traces of the non-dissolved polymer, and also by other accidental factors. Therefore although there have been investigations (chiefly with cellulose derivatives) in which the dimensions and rigidity of the molecules were determined by the asummetry of light scattering method using the theoretical relations (2) and (3), their results are not always reliable and sometimes difficult to explain [21-23].

Another method of determining the rigidity of a molecular chain is the direct measurement of its persistent length $a = A/2$ using small-angle scattering of X-rays [24]. This method has as yet had only limited value since as well as the complexity of the experimental technique it is applicable only to polymers the scattering ability of which differs markedly from that for the pure solvent. In this connection it is the rule that in studying the conformation of molecules in solutions hydrodynamic methods are more widely employed.

2. Hydrodynamic Properties of Chain Molecules

The rigidity of a molecular chain is usually judged from its hydrodynamic properties in solutions by examining the variation of the sedimentation coefficient $[S]$, diffusion coefficient D, and characteristic viscosity $[\eta]$ with the molecular weight M.

This relation can be most simply represented in the form of Mark–Kuhn empirical expressions (M–K):

$$[\eta] = K_\eta \cdot M^\alpha, \tag{5}$$

$$D = K_D \cdot M^{-\beta}, \tag{6}$$

$$[S] = K_s \cdot M^{1-\beta}. \tag{7}$$

In measurements under Θ-conditions, that is, in the absence of the excluded volume effect, high values of α and β show the appreciable influence of the flowability effect, that is, the "loose" structure of the molecular coil and therefore can serve as an index of the increased rigidity of the molecular chain.

However, in non-ideal solvents the volume effects lead to osmotic distention of the coil and to a corresponding increase in the indices α and β, that is, they act in the same direction, as increased rigidity of the chain. Therefore to find the true ("skeleton") rigidity of the molecular chain the influence of the volume effects should be excluded.

For flexible chain polymers, the molecules of which are coiled in rather compact tangles even in good solvents, the hydrodynamic interaction inside the tangle is great and the flow effect is almost absent. For such molecules the influence of the volume effects can be excluded by extrapolation of the hydrodynamic properties to the range of low molecular weights using the effects of the excluded volume [12,25]. Eqn. (8) can be applied to the viscosimetric results for this purpose [26]:

$$[\eta]/M^{1/2} = (LA/M)^{1/2} \cdot \Phi + 0.51\,\Phi \cdot B \cdot M^{1/2}. \tag{8}$$

When using sedimentation or diffusion results, Eqn. (9) [27] or (10) [28] can be employed:

$$(DM^{1/2})^{-1} \equiv (1-\bar{v}\rho)\,M^{1/2}/[S]\,RT = (\eta_0 P_0/kT)\,[(LA/M)^{1/2} + 0.2\,BM^{1/2}], \tag{9}$$

$$(DM^{1/2})^{-3} = (\eta_0 P_0/kT)^3\,[(LA/M)^{1/2} + 0.51\,BM^{1/2}]. \tag{10}$$

Here $\Phi = 2.8 \times 10^{23}$, $P_0 = 5.11$, B is the parameter of the thermodynamic polymer–solvent interaction, η_0 the solvent viscosity, and L the contour length of the molecule.

On plotting the left part of Eqns. (8), (9), or (10) as a function of $M^{\frac{1}{2}}$, the intercept on the ordinate axis of the curve yields the undisturbed dimensions of the molecular chain and the corresponding rigidity, determined by the quantity A. However, this method is inapplicable for rigid-chain polymers, since for them the flow effect usually (although not always) plays a significant part.

Fortunately, for rigid chain molecules the excluded volume effect does not play a significant part, even in thermodynamically good solvents and can be neglected in the first approximation. Under such conditions the theory of the hydrodynamic properties of wormlike chains developed by Kuhn [29] and by Hearst and Stockmayer [30] (K-S) can be used for estimating the rigidity of the chain. At sufficiently high molecular weights when the molecule can be modelled by a gaussian chain, the K-S theory leads to the expressions

$$M/[\eta] = \Phi^{-1}\{(M/LA)^{1/2} M^{1/2} + 0.93\,[\ln(A/d) - 1.43]\,(M/L)^2 A^{-1}\}, \tag{11}$$

$$DM/RT = (1.843/3\pi\eta_0 N_A)\,(M/LA)^{1/2} M^{1/2} + (3\pi\eta_0 N_A)^{-1}\,(M/L)\,[\ln(A/d) - 1.43]. \tag{12}$$

Apart from the quantities L and A, which characterise the conformation and rigidity of the chain, Eqns. (11) and (12) contain the diameter d of the wormlike model, which must be allowed for in the correct description of its hydrodynamic properties.

On plotting the left part of Eqns. (11) or (12) as a function of $M^{\frac{1}{2}}$, the value of M/LA can be found from the slope of the straight line obtained, that is, the chain rigidity can be estimated. A/d and consequently the chain diameter d can be found from the intercept on the ordinate axis.

Eqns. (11) and (12) show that in the range of extremely large molecular weights when the first term on the right-hand side (dependent on M) is much greater than the second, the variation of the viscosity and diffusion coefficients with molecular weight is described by Eqns. (5)–(7) with indices $\alpha = \beta = 0.5$. Besides it must be borne in mind that in non-ideal solvents an increase in M is accompanied by an increase in the part played by the excluded volume effects; this leads to values of α and β exceeding 0.5. This effect is evidently observed in solutions of high-molecular-weight desoxyribonucleic acid [31,32].

At moderate values of M and considerable rigidity of the chain the part played by the second term on the right-hand side of Eqns. (11) and (12) becomes appreciable and there is a corresponding increase in the index α in Eqn. (5) to values approaching unity (cellulose derivatives, DNA).

Finally, for extremely rigid chain molecules in the range of low molecular weights, when the chain length $L \leq A$, but

much greater than the diameter d (slightly curved fine rods), theory[30] leads to the expression:

$$[\eta] = 2\pi N_A L^3 [45\,(M/L)\,(\ln\,(L/d) - 1.03)]^{-1} \cdot [1 - f\,(L/A)] \qquad (13)$$

from which it follows that the index in Eqn. (5) lies between 1 and 2. This is actually realised, for example, for polypeptide molecules in helical conformation[33]. Hence high values of the exponent in Eqn. (5) were obtained for these well-known rigid chain polymers.

However, this is by no means a general rule, since for gaussian chains the values of α and β are determined by the intramolecular hydrodynamic interaction, which depends on the diameter d as well as the degree of convolution L/A of the chain.

Thus from Eqns. (11) and (12) if the diameter of the molecular chain is d and is comparable with the length of the segment A—for example, $A \simeq 4d$ and $\ln(A/d) = 1.43$—then the indices α and β in Eqns. (5)–(7) will be close to 0.5, irrespective of the rigidity of the chain. A similar situation occurs, for example, for oligomers with flexible chain molecules[34-37]. As will be shown below, it can also occur with some rigid chain polymers where the segment length A is considerable (graft polymers)[38].

From what has been said above, the viscosity and translational friction for chain molecules and their dependence on the molecular weight can vary considerably. They are determined by the main parameters of the chain—diameter, contour length, and segment length, and also depend on the thermodynamic interaction of the molecules with the solvent. Consequently in several instances use of hydrodynamic properties alone seems insufficient for the quantitative determination of the rigidity, conformation, and internal structure of macromolecules.

The information obtainable becomes much more complete when a study of the hydrodynamic properties of the solutions is supplemented by an investigation of their dynamo-optical and electro-optical properties.

3. Dynamo-optical Properties of Chain Molecules[39]

The segment length A or the persistence length $a = A/2$, being a measure of the equilibrium rigidity of the main chain of the molecules, reflects to a certain extent another important property, the orientation order in the molecule. However, optical anisotropy is a more direct and much more sensitive measure of the orientation ordering of the structure of the molecule.

The optical anisotropy of a chain molecule of a polymer is measured by the difference between two of its principal polarisabilities $\gamma_1 - \gamma_2$ in directions parallel to and perpendicular to the vector h joining the ends of the chain.

For the simplest model—a gaussian chain[29]—the optical anisotropy of the molecule in the equilibrium conformation is independent of its contour length, that is, the molecular weight, and close to the anisotropy of the segment $\alpha_1 - \alpha_2$:

$$\gamma_1 - \gamma_2 = \frac{3}{5}(\alpha_1 - \alpha_2) \qquad (14)$$

The difference in polarisability of the segment $\alpha_1 - \alpha_2$ depends on the anisotropy of a monomeric unit $a_\parallel - a_\perp$ and the number of monomeric units S constituting the segment:

$$\alpha_1 - \alpha_2 = S\,(a_\parallel - a_\perp)\ . \qquad (15)$$

Therefore molecules with high rigidity (that is, having a high value of S) are characterised by high optical anisotropy.

On the other hand it has been shown that the swelling of molecules in good solvents, which greatly alters their dimensions and hydrodynamic properties, has hardly any effect on their optical anisotropy[1,39,40]. Therefore anisotropy can serve as a measure of the true skeletal rigidity of the molecular chain, irrespective of the effects of excluded volume, that is, the thermodynamic interaction of the molecule with the solvent.

It is very important that the anisotropy of the monomeric unit $\alpha_\parallel - \alpha_\perp$, and also the anisotropy of the molecule, can be either positive or negative, depending on the degree and nature of the ordering of the valence bonds of the monomeric unit relative to the direction of the main chain. Therefore optical anisotropy is a measure of the axial orientation order in the arrangement of the structural elements of the molecule—both of the main chain and also its lateral groups.

In a system having a uniaxial orientation order the degree of this order Q is known[41] to be given by:

$$Q = \frac{1}{2}(3\overline{\cos^2\theta} - 1) \qquad (16)$$

where θ is the angle of the departure of the longitudinal axis of the structural element (segment) from the direction of preferential orientation (that is, from the direction of the vector h in the molecule). $\overline{\cos^2\theta}$ is a quantity obtained by averaging over all the orientations of the segments in the molecule, at given values of $\bar{h}^2$ and L.

From Eqns. (15) and (16) there is a simple relation between the degree of orientation order Q and the anisotropy of the molecule:

$$Q = (\gamma_1 - \gamma_2)/P\,(a_\parallel - a_\perp) \qquad (17)$$

where P is the degree of polymerisation.

Experimentally, the anisotropy of the molecule described by a gaussian chain can be determined by measuring the double refraction Δn in flow in solution of the polymer being studied and a calculation by Kuhn's formula[10]:

$$\Delta n/\Delta\tau = \Delta n/g\,(\eta - \eta_0) = [n]/[\eta] = [4\pi\,(n_S^2+2)^2/45kTn_s](\alpha_1 - \alpha_2). \qquad (18)$$

Here $\Delta\tau = g(\eta - \eta_0)$ is the effective shear stress in flow with a velocity gradient of g, $[n]$ is the characteristic birefringence of the solution, with $[n] = (\Delta n/g\eta_0 c)_{c \to 0}$ where c is the concentration.

When the refractive index of a polymer n_k differs from that of a solvent n_S, an additional positive anisotropy of the molecule arises, owing to the optical interaction of parts of the chain with one another—the "form effect"[39,42].

The overall form effect can be divided into two parts—the "macroform" effect and the "microform" effect. The first of these is due to the interaction of parts rather far apart along the chain (optically long-range action) and is determined by the asymmetry of the form of the macromolecular coil as a whole. The double refraction of the macroform for a gaussian chain equals:

$$([n]/[\eta])_f = [0.058\,\Phi\,(n_s^2+2)^2(n_k^2 - n_s^2)^2/\pi\rho^2 N_A RTn_s^3](M/[\eta]) \qquad (19)$$

where Φ is the Flory coefficient, and ρ the density of the polymer. For a given polymer–solvent system the macroform effect is proportional to $M/[\eta]$ and therefore increases with the molecular weight.

The "microform" effect is due to the optical interaction of parts of the molecule which are neighbours along the chain. Unlike the macroform effect, the double refraction of the microform for a gaussian chain is independent of the molecular weight but proportional to the molecular weight

of a segment $M_S = A(M/L)$ and consequently increases with the rigidity of the chain:

$$([n]/[\eta])_{fs} = [(n_s^2+2)^2 (n_k^2 - n_s^2)^2/180\pi RTn_s^2\rho](L_2 - L_1)_s \cdot M_s \quad (20)$$

where $(L_2 - L_1)$ is the coefficient of the asymmetry of the form of the segment.

The principal role in the total, experimentally observable form effect for flexible chain molecules is taken by the macroform anisotropy, Eqn. (19), whereas for molecules with high skeletal rigidity of the chain it is the macroform anisotropy, Eqn. (20). Therefore for rigid-chain molecules the experimental measurement of the microform effect is an independent method of determining the skeletal rigidity of the molecular chain.

A characteristic feature of the macroform effect is its marked decrease with increase in the concentration of the solution[1,43]. On the other hand, the quoted value of the microform birefringence $[\Delta n/g(\eta - \eta_0)]_{fs}$ varies little with concentration[39,42]. Therefore a study of the concentration dependence of the form birefringence can enable the relative parts of its macro- and micro-constituents to be estimated and information obtained about the rigidity of the polymer investigated.

If the contour length L of a chain molecule is not very great in comparison with the segment length A (that is, the condition $h \ll L$ is not satisfied), it can no longer be regarded as a gaussian chain and Kuhn's formula (14) is inapplicable.

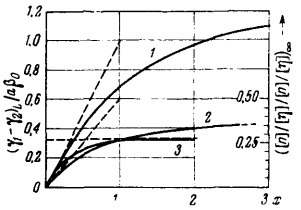

Figure 2. Variation of the optical anisotropy of the persistent length $(\gamma_1 - \gamma_2)_L$ and reduced birefringence of the solution $[n]/[\eta]$ with the parameter $x = L/a$. *1*) $(\gamma_1 - \gamma_2)_L/a\beta_0$ as a function of x; *2*) $\cdot[n]/[\eta]_L/[n]/([\eta])_{x\to\infty}$ as a function of x; *3*) $(\gamma_\parallel - \gamma_\perp)_L/a\beta_0$ as a function of x.

In this instance the difference in the principal polarisabilities $(\gamma_1 - \gamma_2)_L$ of molecules of length L is calculated by the theory of persistent anisotropy[44], which yields the relation

$$(\gamma_1 - \gamma_2)_L = \frac{3}{5}(\alpha_1 - \alpha_2)(1 - e^{-6x/6}) = a\beta_0 x\left[1 - \frac{5}{12}x + \frac{25}{216}x^2 - \frac{125}{5184}x^3 + \ldots\right], \quad (21)$$

where $x = L/a$, $a = A/2$, and $\beta_0 = (\alpha_1 - \alpha_2)/A$ is the anisotropy of unit length of the chain.

In distinction from the gaussian chains the anisotropy of a persistent chain increases with its length L (and consequently, the molecular weight), tending (at $x \to \infty$) to a limiting value of $\frac{3}{5}(\alpha_1 - \alpha_2)$ corresponding to the anisotropy of a gaussian chain. The corresponding dependence is shown in curve *1*, Fig. 2, where the ratio $(\gamma_1 - \gamma_2)_L/a\beta_0$ is represented as a function of the parameter x. The initial slope of the curve is evidently 1, the limiting value equals 6/5.

On plotting the values of $(\gamma_1 - \gamma_2)_L$ as a function of the contour length L of the molecule, then according to Eqn. (21), the initial slope of the curve determines the value of β_0, whereas the asymptotic limit gives a value of $\frac{6}{5}a\beta_0$.

It must be remembered that according to theory—Eqn. (21)—the decrease in molecular anisotropy with chain shortening is determined solely by the parameter $x = L/a$, and not by the absolute length of the segment A. Consequently, this phenomenon should occur not only for rigid but also for flexible chain molecules in the range of rather low molecular weights (oligomers). In reality the decrease in flow anisotropy with decrease in molecular weight was observed experimentally in oligomers with flexible chain molecules[37] although their hydrodynamic behaviour exhibited no special features.

This phenomenon is of special significance for rigid-chain molecules (large A) since then it should be observed in the range of rather high molecular weights and can serve as a direct proof of increased skeletal rigidity of the chain.

In accordance with Eqn. (21) and unlike the gaussian coils, Eqn. (18), the flow birefringence $([n]/[\eta])_L$ in solution of persistent chains should increase with the molecular weight, tending to a limiting value of $([n]/[\eta])_\infty$ as $x \to \infty$, determinable by Eqn. (18).

For rigid wormlike chains ($A \gg d$) in the range of low x ($x < 3$) this increase is determined by the formula:

$$([n]/[\eta])_L = (4\pi/45\,kTn_s)(\gamma_1 - \gamma_2)_L \cdot F(x) \cdot (n_s^2+2)^2, \quad (22)$$

where $F(x)$ is a tabulated[44] function reflecting the change in the geometric asymmetry of the molecules with increase in length, and the value of $(\gamma_1 - \gamma_2)_L$ is determined by Eqn. (21).

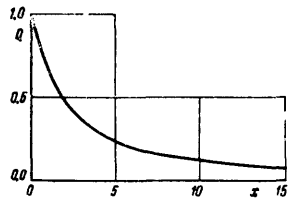

Figure 3. Variation of the degree of intramolecular orientation ordering Q with the parameter $x = L/a$ for a persistent chain.

The variation of $([n]/[\eta])_L/([n]/[\eta])_\infty$ with x, according to Eqn. (22), is represented by curve *2* of Fig. 2. The initial slope of the curve obtained is 0.5, the asymptotic limit is 1.

A comparison of the experimental dependence of the birefringence on the molecular weight with the theoretical (22) enables the anisotropy of unit length β_0 and the persistence length $a = A/2$ of the molecular chain to be determined.

Eqn. (21) also enables the change in the degree of intramolecular orientation order Q with increase in chain length to be presented clearly. On combining Eqns. (21), (17), and (14) and taking into account that $P/S = x/2$, we obtain:

$$Q = (6/5x)(1 - e^{-6x/6}). \quad (23)$$

Fig. 3 shows the dependence of Q on x according to Eqn. (23). With increase in x the degree of ordering falls sharply from values close to unity to values close to zero.

Values of $Q \simeq 1$ are characteristic of systems with an almost perfectly ordered structure, which occurs, for example, in ideal three-dimensional single crystals.

Less perfect, but nevertheless extremely high, orientation order is observed in liquid crystalline (mesomorphic) systems; thus for a nematic mesophase the value of Q lies in the range 0.4–0.7.[41]

As the graph in Fig. 3 shows, the same level of orientation ordering in the structure of chain molecules can be achieved in the range of molecular weights where x does not exceed a few units. Several examples can now be given (see below) of extremely rigid chain molecules for which this range corresponds to molecular weights of tens and even hundreds of thousands.

For such "crystal-like" polymeric molecules the degree of intramolecular orientation order corresponds to the level of the supermolecular organisation of the nematic mesophase.

However, for most flexible-chain polymers even at $P \simeq 10^3$, Q has an order of magnitude of 0.01 and this decreases with a further increase in molecular weight. Such a low degree of orientation order can be observed and measured only by using such sensitive quantities as the optical anisotropy of the molecule determinable from the stream birefringence.

These features of the optical properties of rigid-chain molecules, predicted by theory, are independent of both excluded volume effects and of hydrodynamic interaction in the molecular chains. Therefore the use of these properties as characteristics of rigidity and the degree of ordering of the structure of a molecule is not complicated by a need to allow for the thermodynamic quality of the solvent and a flow effect.

4. Electro-optical Properties

In examining the order of the structure of macromolecules a distinction must be made between orientation axial order and orientation dipole order. Many chain molecules contain polar groups or bonds and in the presence of a coaxial order in the mutual orientations of these groups the macromolecule should have a high total dipole moment. However, for flexible chain molecules this is usually not observed. One of the reasons can be the mutual compensation of the local and group moments in their vector addition. The main reason is the flexibility of the macromolecule, which results in local polar groups of the molecule in an external electric field being orientated practically independently of one another. Here the dipole polarisation of the molecule in an electric field is simply equal to the sum of the polarisation of its polar units and does not differ much from the polarisation of a liquid monomer of equal mass.

For rigid-chain molecules the situation can be significantly different. Owing to the rigidity of the molecular structure the orientations of the polar groups of the molecule in an electric field are independent of one another but are mutually correlated to a greater or less extent with the molecular chain or its parts (segments). Therefore if the vector sum of the local group moments is not equal to zero, that is, if their orientation-polar ordering inside the molecule is realised, the latter can have a significant dipole moment and under the action of an electric field it rotates as a rigid particle.

Note that these properties of the molecule depend not only on its equilibrium rigidity but also to a considerable extent on its kinetic rigidity.

In solutions of such polar rigid-chain molecules a high birefringence is produced in an electric field E (the Kerr effect). The value of Δn and the sign of the birefringence depend on the magnitude and sign of the optical anisotropy of the molecule $\gamma_1 - \gamma_2$ and also on its dipole moment μ and the angle θ formed by the axis of the dipole with the optical axis of the molecule[45]:

$$\lim_{\substack{c\to 0\\ E\to 0}} (\Delta n/cE^2) = \frac{\pi N_a}{15n}\left(\frac{n^2+2}{3}\right)^2\left(\frac{\varepsilon+2}{3}\right)^2 \cdot \frac{\gamma_1-\gamma_2}{M}\left(\frac{\mu}{kT}\right)^2 (3\cos^2\vartheta - 1). \quad (24)$$

Here c is the concentration, n the refractive index, and ϵ the dielectric constant of the solution.

An experimental study of this effect and a comparison of the results with those on flow birefringence enables information to be obtained about the value and direction of the molecular dipole and additional conclusions to be drawn about the conformation, rigidity, and ordering of the structure of the molecule.

On modelling a semirigid molecule by a persistent chain the value of its dipole moment μ can be linked[11,46] with the contour length $L = ax$ by the theoretical relation:

$$\overline{\mu^2} = (\mu_0 S)^2 (x - 1 + e^{-x})/2 \quad (25)$$

or

$$\overline{\mu^2}/L = (\mu_s^2/A)[1 - (1 - e^{-x})/x], \quad (26)$$

where μ_0 is the component of the dipole moment of the monomeric unit along the axis of the molecule, S the number of monomeric units in its segment, and μ_S the dipole moment of the segment.

An experimental study of the variation of the dipole moment μ with the molecular weight M and a comparison of this relation with the theoretical one—Eqns. (25) and (26)—enables the persistent length a to be found and hence the rigidity of the molecule to be estimated from electro-optical results.

In a periodic electric field solutions of rigid-chain polar molecules exhibit a dependence of the Kerr effect on frequency, which shows the existence of relaxation in the dipole orientation process. A study of the frequency dependence enables the rotational mobility of the molecules to be determined and additional information to be obtained about their conformation and rigidity.

III. SOME EXPERIMENTAL RESULTS

1. Cellulose and Its Derivatives

As shown above, cellulose and its derivatives have for long been the best known, "classical" example of chain molecules with high skeletal rigidity. This property follows directly from the geometry of the molecular chain (Fig. 4).

The monomeric unit is a glucoside ring with two adjacent valence bonds OC_1 and OC_4, around which rotation is possible. In calculating the statistical dimensions of the chain its monomeric unit can be denoted[47] by an equivalent "effective" unit consisting of two parallel bonds $b = 2.7$ Å, around which rotation takes place and one bond $d = 1.45$ Å (normal to the first two) around which there is no rotation. On using this scheme it can be shown that for a sufficiently long chain with completely free rotation around bonds OC_1 and OC_4 (that is, "bonds" b) the mean square distance between its ends $\overline{h_f^2}$ is[47]:

$$\overline{h_f^2} = P[d^2 + (2b)^2(1 + \cos\vartheta)/(1 - \cos\vartheta)], \quad (27)$$

where P is the number of monomeric units in the chain, and $\pi - \theta$ is the valence angle between the neighbouring bonds OC_1 and OC_4.

On substituting the values of b and d and assuming $\theta = 70°$ we obtain $\overline{h_f^2} = 62P \times 10^{-16}$ cm^2, and for the length of a segment of the cellulose chain with completely free rotation:

$$A_f = \overline{h_f^2}/P\lambda = \overline{h_f^2}/P\left(2b\cos\frac{\vartheta}{2} + d\sin\frac{\vartheta}{2}\right) = 12 \text{ Å}.$$

This value of A_f corresponds with the number of monomeric units in the segment $S_f = 2.5$.

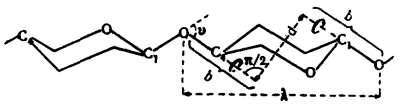

Figure 4. Conformation of the cellulose chain. λ = projection of the monomeric unit on the chain direction; $b = 2.7$ Å is the length of the "effective bond" around which rotation is possible; $d = 1.45$ Å is the length of the "effective bond" around which rotation is impossible.

For a carbochain polymer not containing rings in the chain under the condition of free rotation an analogous calculation gives[1]:

$$A_f = l(1 + \cos\vartheta)/(1 - \cos\vartheta)\sin\vartheta/2,$$

which for $\theta = 70°$ and $l = 1.54$ A leads to the value $A_f = 3.8$ Å.

Hence even when there is completely free rotation the segment length of the cellulose chain should be more than three times as great as the segment length of a flexible carbochain polymer.

An analogous conclusion can be reached by considering the possible conformations of another linear polysaccharide—amylose. However, here the theoretical values are less definite since spiral structures can be formed with amylose[48].

The real polymeric chains in a Θ-solvent have the undisturbed dimensions $(\overline{h_\Theta^2})^{\frac{1}{2}}$, which owing to restricted rotation exceed the chain dimensions in free rotation:

$$\overline{h_\Theta^2}/\overline{h_f^2} = \sigma^2,$$

where σ is the rotation restriction factor. Many flexible carbochain polymers are characterised by values of σ lying in the range $\sigma^2 \simeq 4$–5, which corresponds with segment lengths of $A = A_f\sigma^2 \simeq 15$–$20$ Å.[1,25,49]

The problem of the value of the restriction factor σ for cellulose derivatives has been the subject of discussion recently. The method with the best theoretical basis for determining σ is the direct measurement of the undisturbed radius of gyration of the molecule $\overline{R^2}$ from the asymmetry of its light scattering in solutions. There are considerable experimental difficulties in such measurements for polysaccharides[21-23] and evidently for this reason they are rather few. Some examples are given in Table 1. The values of $A = S\lambda$ were calculated from the experimental values of $\overline{R^2}/P = \frac{1}{6}S\lambda$, obtained in the range of limitingly large values of P, Eqns. (3) and (2′). Here the values of λ were taken as 5.15 and 3 Å for cellulose and anylose chains respectively (the value $\lambda = 3$ Å corresponds to a helical model of the amylose chain[48,50]). Corresponding values of the restriction factor $\sigma = (A/A_f)^{\frac{1}{2}}$ are given here.

The value of A for polysaccharides is an order of magnitude greater than the corresponding values found by the light scattering method for most of the flexible carbochain polymers[1]. The rotation restriction factor σ in polyglucose chains is, according to the light scattering results, at least twice the value of σ for flexible chain polymers[1,25,49].

Table 1. Segment length A, number (S) of monomeric units in the segment, and rotation restriction factor for molecular chains of some derivatives of polysaccharides obtained from measurements of the asymmetry of light scattering.

Polymer	Solvent	10^8A, cm	S	σ	Reference
Cellulose trinitrate	acetone	230	44	4.4	51
	acetone	235	45	4.4	52
	acetone	233	44	4.4	53
	ethyl acetate	234	44	4.4	54
	isopentyl acetate	216	42	4.25	53
	dioxan	220	43	4.3	53
	nitrobenzene	58	11.2	2.2	53
Cellulose tricarbanilate	dioxan–methanol mixture (Θ-solvent)	268	52	4.7	55
Amylose tricarbanilate	dioxan–methanol mixture (Θ-solvent)	414	80	5.8	55
Amylose acetate	nitromethane	100	19	2.9	56

Conclusions about the high rigidity of the molecules of cellulose derivatives[51-56] also agree with hydrodynamic properties of their solutions. Thus the index α in the Mark–Kuhn equation (5) for many of them is close[49] to unity, which is usually connected with the flow effect, whereas the excluded volume effect (ideality of the solvent) is less important[53,55].

At the same time it was noted in several studies[53,57-60] that certain properties of the solvent and the temperature have a pronounced influence on the undisturbed dimensions (that is, the skeletal rigidity) of the molecules of the cellulose derivatives.

In recent years another point of view on the rigidity of molecules of cellulose derivatives has been advanced, based on the use of viscosimetric results for the determination of their unperturbed dimensions[25]. Here it was suggested that the high value of the index α in Eqn. (5) and the large molecular dimensions observable experimentally in polysaccharides are the consequence not of their increased rigidity but of the exceptionally marked influence of the volume effects, since modern theories in principle admit a value of $\epsilon = \frac{1}{3}$ in Eqn. (4) and correspondingly $\alpha = 1$ in Eqn. (5) owing to the non-ideality of the solution[20]. A second a priori assumption, which is made in this is the postulation of almost complete non-flowability of molecules of cellulose derivatives in solutions, like the molecular coils of flexible chain polymers. On starting from this assumption the undisturbed dimensions of the molecules are determined from the viscosimetric results of the extrapolation of the latter into the range of low molecular weights, using Eqn. (8). The unperturbed dimensions and the restriction factor σ, obtainable as a result of such a

procedure are close to the corresponding values for flexible carbochain polymers and on this basis it is concluded that the molecular chains of cellulose and its derivatives do not exhibit a high rigidity[25,61-64].

Recently Flory[65] criticised this viewpoint by observing that in addition to an unproven neglect of the flow effect in molecules of cellulose derivatives it also ignores the departure from gaussian behaviour of their chains in the range of low molecular weights—factors, the presence of which makes the use of formula (8) quite improper. The reality of the pronounced influence of flow on the hydrodynamic properties of molecules has been demonstrated for several polysaccharides[66,67].

The departure from gaussian behaviour in the range of low molecular weights for polysaccharide chains has been shown in several papers[51-55] by the direct determination of their dimensions by the method of asymmetry of light scattering in solutions. This gave the dependence of the dimensions on the molecular weight which corresponded at least qualitatively to Eqns. (2) and (3) and to the theoretical curve (Fig. 1) for rigid wormlike chains.

Unlike flexible chain molecules[34-36], the dependence of the viscosity $[\eta]$ on the molecular weight M in the range of low M for cellulose derivatives also has features which show the absence of gaussian properties[68].

What has been stated above gives grounds for considering that the characteristic parameters of the rigidity of polysaccharide molecules found by direct measurements (Table 1) are much more reliable than the corresponding quantities obtained by use of model theories and making several doubtful assumptions[25,61-63].

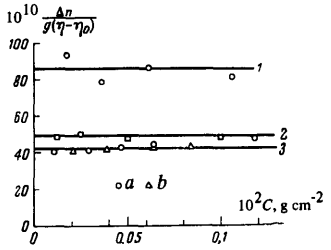

Figure 5. Reduced birefringence of solutions of cellulose monophenylacetate in various solvents depending on the concentration[69]: *1*) in ethyl acetate; *2*) in cyclohexanone; *3*) *a*) in bromoform; *b*) in acetophenone.

Because of the discussion and existence of two opposite viewpoints it is extremely important to obtain data on the rigidity of cellulose molecules by other methods free from model assumptions of hydrodynamic theories and independent of the thermodynamic properties of the solution. As already stated, a study of the dynamo-optical properties of the solutions can be such a method.

Usually the value of the flow birefringence and the corresponding optical anisotropy of a segment are appreciably greater for cellulose derivatives than for flexible-chain polymers[1], which by itself is a qualitative index of the high skeletal rigidity of polysaccharide chains.

In solutions of cellulose derivatives where the refractive index of the polymer n_k differs from the refractive index of the solvent n_s a very high form effect is observed.

It is characteristic that the reduced birefringence $\Delta n/\Delta\tau$ is here independent of concentration (see Fig. 5) unlike the marked concentration dependence of the form birefringence for solutions of flexible-chain polymers[1,43].

Another characteristic feature of the form effect, observable in solutions of cellulose derivatives, is the extremely weak dependence of the reduced birefringence $\Delta n/\Delta\tau = [n]/[\eta]$ on molecular weight (Fig. 6), whereas for flexible-chain polymers the value of $[n]/[\eta]$ increases sharply with the molecular weight (Fig. 7).

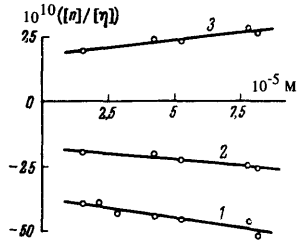

Figure 6. Variation of the reduced anisotropy of solutions of cellulose nitrate with the molecular weight[70]. *1*) $[n]/[\eta]$ for fractions of cellulose nitrate in cyclohexanone ($n_k - n_s = 0$, proper anisotropy); *2*) $[n]/[\eta]$ for the same fractions in butyl acetate ($n_k - n_s$, total birefringence); *3*) $[n]/[\eta]$ corresponding to the microform effect, calculated by subtracting the ordinate of curve *1* from the ordinate of curve *2*.

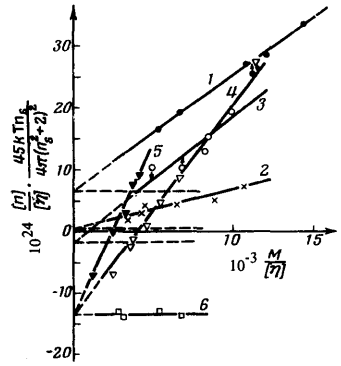

Figure 7. Variation of the quantity

$$x=\frac{[n]}{[\eta]}\cdot\frac{45kTn_s}{4\pi(n_s^2+2)^2},$$

which forms part of Eqns. (18) and (19) with $M/[\eta]$ for solutions of certain flexible-chain polymers[1]. *1*) Polyisobutene in hexane; *2*) polydimethylsiloxane in toluene; *3*) poly(butyl methacrylate) in ethyl acetate; *4*) polystyrene in dioxan ($n_k - n_s = 0.18$); *5*) polystyrene in butanone ($n_k - n_s = 0.22$); *6*) polystyrene in bromoform ($n_k - n_s = 0$).

Both the first and the second feature show that the form birefringence observable in solutions of cellulose derivatives (unlike flexible chain molecules) is an effect of the chain microform and determinable by Eqn. (20).

In accordance with Eqn. (20) the experimentally found variation of $[n]/[\eta]$ with the refractive index of the solvent n_S is a parabolic curve (Fig. 8). The minimum of the parabola gives the proper anisotropy of the segment $\alpha_1 - \alpha_2$. From the remaining points of the curve, using Eqn. (20), the molecular weight of the segment $M_S = A(M/L)$ can be calculated and hence its length A. The values thus obtained for certain cellulose esters are given in Table 2.

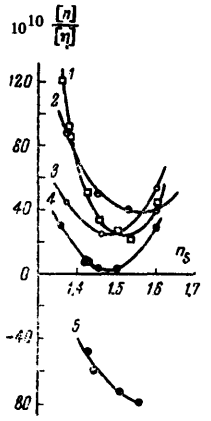

Figure 8. Variation of the reduced birefringence $[n]/[\eta]$ of solutions of cellulose esters with the refractive index of the solvent: *1*) cyanoethyltritylcellulose[73]; *2*) monophenylacetylcellulose[69]; *3*) ethyl cellulose[71]; *4*) cyanoethylacetylcellulose[72]; *5*) cellulose benzoate[69].

For specimens 3, 4, and 5 with large lateral substituents $(L_2 - L_1)_S = 2$ is taken for calculating A, for the other specimens $(L_2 - L_1)_S = 2\pi$.

As Table 2 shows, the segment lengths A and the corresponding values of σ obtained by measuring the flow birefringence have magnitudes close to the values of A and σ found by the light scattering method (Table 1). Similar results are given by an investigation of the photoelasticity of gels of cellulose derivatives in various solvents[72,73].

Hence the dynamo-optical properties of solutions and gels of cellulose derivatives are not only a qualitative but also a quantitative index of the high skeletal rigidity of their molecular chains.

This rigidity is determined not only by the presence of rings in the chain—a high value of $\overline{h_f^2}$ in Eqn. (27) and hence of A_f—but also by the higher (than for carbochain molecules) value of the restriction factor σ. It is very probable that a significant part in the retardation of intramolecular rotation is played by the hydrogen bonds established between the oxygen, hydrogen, and nitrogen atoms forming part of the lateral substituents of the polyglucose chain.

For polysaccharide molecules containing ionogenic groups the skeletal rigidity can be increased even more, owing to the electrostatic interaction of these groups.

A decrease in the ionic strength of the solution and an increase in the dissociation of the ionogenic groups is accompanied by the uncoiling of the chain of the polyion due to the electrostatic repulsion of its charged parts. During this there is an increase in both the characteristic viscosity of the solution (owing to the increase in the size of the molecular coils), and in its characteristic flow birefringence $[n]$. However, $[n]$ increases more rapidly than $[\eta]$ and therefore the ratio $[n]/[\eta]$ increases. This shows that in a polyelectrolytic uncoiling of a molecular chain of a polyion (unlike its osmotic swelling in a strong solvent) there is an increase in the segment anisotropy $\alpha_1 - \alpha_2$, Eqn. (18), and consequently also in the segment length A.

Table 2. Optical anisotropy and parameters of the rigidity of various cellulose esters from the flow birefringence.

Polymer	Degree of substitution	$(\alpha_1 - \alpha_2)\cdot 10^{25}$, cm^3	$10^8 A$, cm	s	$(\alpha_\parallel - \alpha_\perp)\cdot 10^{25}$, cm^3	$\sigma = \left(\frac{\overline{h_0^2}}{\overline{h_f^2}}\right)^{1/2}$	Reference
Cellulose nitrate	2.60	−300	260	50	−12	4.7	70
Ethyl cellulose	2.60	310	180	35	18	3.9	71
Cellulose benzoate	3.0	−900	270	52	−36	4.8	69
Cellulose phenylcarbanilate	1.9	−1100	180	35	−60	3.9	69
Monophenylacetyl cellulose	2.5	440	250	49	18	4.6	69
Cyanoethylacetyl cellulose	1.7 0.9	15	250	49	0.7	4.6	72
Cyanoethyltritylcellulose	2.0 1.0	220	280	54	8	4.9	73

In other words, polyelectrolytic uncoiling of the chain is accompanied by an increase in its skeletal rigidity.

This is shown by Table 3, which gives the results of viscosimetric and dynamo-optical investigations of aqueous solutions of the sodium salt of a specimen of a sulphite ester of cellulose (Na-SC with a lateral substituent $-SO_3Na$, molecular weight $M = 10^5$) at various ionic strengths I.

Table 3. Hydrodynamic, optical, and conformational characteristics of the molecule of the sodium salt of sulpho-ester of cellulose at various ionic strengths of the solution[74].

I, M	$[\eta]$, cm^3 g^{-1}	$10^{10}\frac{[n]}{[\eta]}$	$10^{25}(\alpha_1 - \alpha_2)$, cm^3	$10^{25}\frac{\alpha_1 - \alpha_2}{[\eta]}$, g	$10^8 A$, cm
0.200	290	46.6	634	2.19	195
0.150	290	47.4	645	2.22	195
0.100	310	50.0	680	2.19	216
0.010	500	72.0	980	1.96	330
0.005	610	96.7	1320	2.16	410
0.001	870	127.0	1730	2.00	575

From Table 3, clearly the value of the ratio $(\alpha_1 - \alpha_2)/[\eta]$ is approximately the same for different ionic strengths and is equal to 2.1×10^{-25}. Because of the identity

$$\alpha_1 - \alpha_2 \equiv \beta_0 A$$

and Eqn. (1), we have

$$\overline{h^2}/[\eta] = 2.1 \cdot 10^{-25} \ (L/\beta_0).$$

for all ionic strengths. This signifies that (since for a particular chain molecule L/β_0 is independent of its convolution) in the polyelectrolytic uncoiling of the Na-SC chain the characteristic viscosity $[\eta]$ increases in proportion to $\overline{h^2}$, which is characteristic for hydrodynamically flowing gaussian coils. Therefore the assumption about the non-flowability of molecules of ionogenic derivatives of cellulose made in some studies[20,61,62] is untenable.

Judging by the structure of substituent groups, it can be expected that the proper segment anisotropy Na–SC in the range of high ionic forces ($I = 0.2$), when the polyelectrolytic effects are suppressed is close to the proper anisotropy of an ethylcellulose segment[71] $(\alpha_1 - \alpha_2)_i = 310 \times 10^{-25}$ cm^3. The fact that in aqueous salt solutions at $I = 0.2$ the observed anisotropy $(\alpha_1 - \alpha_2)$ is 634×10^{-25} cm^3, that is, is 634/310 = 2.05 times the value of $(\alpha_1 - \alpha_2)_i$, shows that half the birefringence thus observable is due to the microform effect. Starting from this and using Eqn. (20) the segment length A can be calculated. The values of A obtained at various ionic strengths (Table 3) show the increase in the skeletal rigidity of the chain during its polyelectrolytic uncoiling.

2. Molecules with a Regular Secondary Structure

a. Deoxyribonucleic acid (DNA). DNA, like cellulose derivatives, can be regarded as a classic example of a polymer with semirigid chain molecules. The generally accepted model of the molecule is the rigid double-helix structure proposed by Watson and Crick[75], maintained by hydrogen bonds, which "reinforce" the purine and pyrimidine bases of the DNA chain.

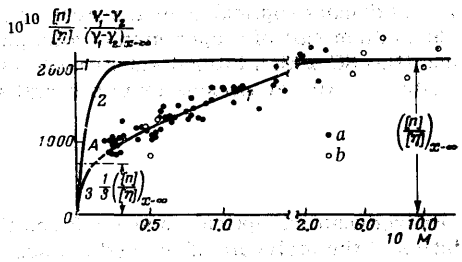

Figure 9. Flow birefringence $[n]/[\eta]$ and optical anisotropy of the DNA molecule as a function of molecular weight M. *1*) The curve of $[n]/[\eta] = f(M)$ drawn according to the experimental points; *a*) DNA fragment obtained by treatment of the DNA solutions; *b*) fragments obtained by ultrasonic destruction; *2*) curve for the variation of the relative anisotropy of the molecule $(\gamma_1 - \gamma_2)_L/(\gamma_1 - \gamma_2)_{x\to\infty}$ with $x = L/a$; *3*) initial part of the theoretical curve *2* of Fig. 2.

The application of the hydrodynamic theory of wormlike chains to the experimental results on sedimentation, Eqn. (12), leads to the values of the segment length A = 700–900 Å,[30–32] which is two to four times the value obtained for cellulose derivatives (Tables 1–3). The optical anisotropy of the DNA molecule found from the flow birefringence is very high and negative in sign. This corresponds to the high degree of orientation order of the base, the plane of which is perpendicular to the axis of the molecule.

The optical anisotropy increases with the molecular weight of DNA[76] in accordance with the theory of persistent chains[44] (Fig. 9). A comparison of the experimental curve with the theoretical one, Eqn. (22), leads to the value A = 600 Å.[76]

b. Polypeptides $-\overset{\overset{O}{\|}}{C}-CHR-\overset{\overset{H}{|}}{N}-$ Polypeptides in a helical conformation are a good example of a rigid-chain molecule with a very high rigidity. The most complete information about the hydrodynamic, optical, and electrical properties of molecules was obtained for poly-γ-benzyl-L-glutamate (PB-L-G).

The high rigidity of spiral molecules is best shown by the high value of the exponents α and β in the Mark-Kuhn equations (5)–(7).[33,46,78]

Experimental results on diffusion and sedimentation have been used for the quantitative determination of rigidity. Fig. 10 shows the variation of the sedimentation coefficient $[s]$ or the quantity DM/RT with the square root of the molecular weight $M^{\frac{1}{2}}$. According to Eqn. (12) the slope of the straight line obtained leads to a value of 2200 Å for the segment length A.[33,46] The flow birefringence in solutions of α-spiral polypeptides is very high and increases with the molecular weight (Fig. 11). Use of this relation and the theory of persistent anisotropy[44], Eqns. (21) and (22), lead to values for the anisotropy and length of the segment of respectively $\alpha_1 - \alpha_2 = 20\,000 \times 10^{-25}$ cm^3 and A = 2400 Å.

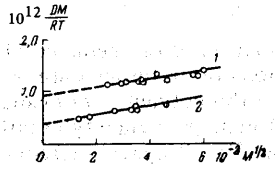

Figure 10. Variation of DM/RT with $M^{\frac{1}{2}}$ for poly-γ-benzyl-L-glutamate (*1*) and poly(butylisocyanate) (*2*).

These values agree with the hydrodynamic values and show the high degree of intramolecular orientation ordering Q, determined from Eqn. (23).

A comparison of the curves in Figs. 3 and 11 shows that in the molecular weight range investigated the value of Q for the PB-L-G molecules varies in the range 0.35–0.8, that is, it corresponds with the level of the orientation order characteristic for the nematic mesophase. Therefore the PB-L-G molecules are typical examples of a "crystal-like" molecule.

In an electric field a high birefringence arises in the PB-L-G solutions, showing the high degree of orientation-dipole order in the molecule. The positive sign of the Kerr effect shows that the total dipole moment of the molecule is directed along its axis, being the sum of the local moments of the C=O...H–N group joined by hydrogen bonds.

A comparison of the dynamo-optical and electro-optical results, Eqns. (22) and (24), enables the segment length A to be determined. The value A = 1400 Å thus obtained[46] is less than that found from the results of measurement of diffusion, sedimentation, and flow birefringence.

This fact shows that the processes in the orientation of polar polypeptide molecules in mechanical and electric fields cannot be identified. There is evidently a significant difference in the degrees of the axial and polar correlations of the units of the polypeptide helix chains.

The high value of the optical anisotropy and dipole moments are characteristic only for polypeptide molecules in

a helical conformation maintained by hydrogen bonds. When the latter are broken in strong solvents, in addition to the breakdown of the spiral structure the crystal-like orientation ordering is also destroyed and furthermore there is almost complete disappearance of the large optical effects observable in mechanical and electrical fields. An illustration is given by Figs. 12 and 13, which show the changes in birefringence in flow and in an electric field and the viscosity of the PB-L-G solution during the spiral–coil intramolecular conformational transformation[104].

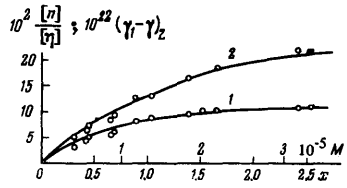

Figure 11. Variation of the reduced anisotropy of the solution $\Delta n/g(\eta - \eta_0) = [n]/[\eta]$ (*1*) and $\gamma_1 - \gamma_2$ (*2*) with the molecular weight for fractions of poly-γ-benzyl-L-glutamate in dichloroethane.

3. Polymeric Molecules with Rings in the Main Chain

The rigidity of the spiral conformation of polynucleotides or polypeptides is maintained by hydrogen bonds formed by intramolecular cyclic parts of the chain and leading to a "lattice" structure of the molecule.

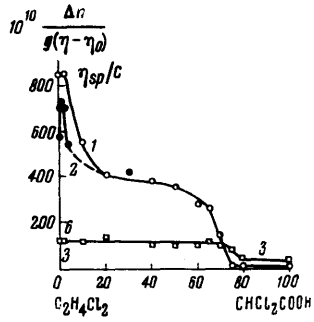

Figure 12. Variation of the optical anisotropy (*1* and *2*) and viscosity (*3*) of a solution of poly-γ-benzyl-L-glutamate during the destruction of the helical structure of the molecule. Solvent: *1*) dichloroethane—2% dimethylformamide with the addition of dichloroacetic acid; *2*) dichloroethane with the addition of dichloroacetic acid.

It could be expected that the same result can be reached for synthetic chain polymers by the introduction of heterocycles, some atoms of which enter the main chain of the polymer.

Although a large number of polymers with heterocycles in the chain have been obtained in recent years[79-82], quantitative data about the conformation and rigidity of such molecules in the solutions are very few. One of the probable reasons for this is the poor solubility of such polymers in ordinary solvents.

Detailed quantitative data about the properties of the solutions were obtained for polymers of N-substituted maleimides[83], which are readily soluble in organic solvents and occupy a sufficiently wide range of molecular weights[84].

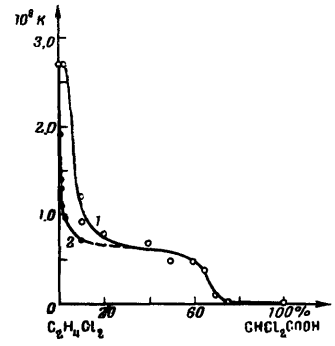

Figure 13. Variation of the Kerr constant (K) of a solution of poly-γ-benzyl-L-glutamate during the destruction of the helical structure of the molecule. Solvent: *1*) dichloroethane–dimethylformamide with the addition of dichloroacetic acid; *2*) dichloroethane with the addition of dichloroacetic acid.

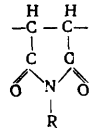
a. Poly-N-isobutylmaleimide[84] (PIBMI)



As follows from the structural formula of this polymer, the presence of imide rings halves the number of single bonds around which rotation in the main chain is possible. In accordance with this, increased rigidity of the molecular chain can be expected. The rigidity of the chain was determined from the experimental results on sedimentation, diffusion, and viscometry. To rule out the influence of volume effects and to determine the undisturbed dimensions of the molecule, the hydrodynamic results were extrapolated to limitingly small molecular weights in accordance with Eqns. (8) and (10). Such a construction is shown in Fig. 14 for fractions of PIBMI in butyl acetate. The intercepts made by the straight lines on the ordinate axis give for the length of the Kuhn segment the value A = 35–40 Å, which is twice the value usually obtained for flexible chain volumes without rings in the chain[1].

However, the doubling of the rigidity due to cyclisation of the chain is not high enough for the molecule concerned to be classified as semirigid from its behaviour in solution. Thus the values of the indices $\alpha = 0.65$ and $\beta = 0.59$ in the M–K formulae (5–7) for PIBMI molecules (which are greater than 0.5) are due to the excluded volume effects and hence are unconnected with the increased rigidity of the chain. In accordance with this the anisotropy of the molecules and the reduced birefringence $[n]/[\eta]$ for PIBMI solutions in the investigated range of molecular weights

corresponds to the Kuhn equations (14) and (18) for gaussian chains and does not depend on the molecular weight[84].

Hence to reduce the flexibility of the chain to a value characteristic for semirigid chain molecules the fraction of the cyclised chains should be appreciably greater than one-half. Complete cyclisation of all the chains gives the limitingly rigid structure of the "staircase" polymer.

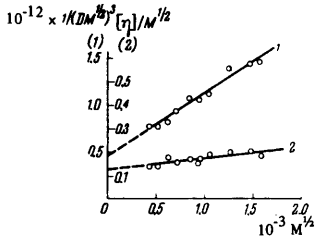


Figure 14. Variation of the quantities $(1/DM^{\frac{1}{2}})^3$ (*1*) and $[\eta]/M^{\frac{1}{2}}$ (*2*) with $M^{\frac{1}{2}}$ for fractions of poly-*N*-isobutylmaleimide in butyl acetate.

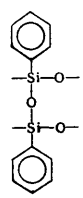
b. Staircase polyphenylsiloxane [85].



This polymer has been obtained by several investigators [86,87]. Fig. 15 shows the probable structure of its molecule. Here the cyclisation is effected by transverse Si–O bonds, which strengthen the two siloxane chains. Study of the hydrodynamic properties of fractions of one of the specimens in solutions leads to M–K dependences (5)–(7), in which the indices greatly exceed 0.5 ($\alpha = 0.88$, $\beta = 0.63$). [85]

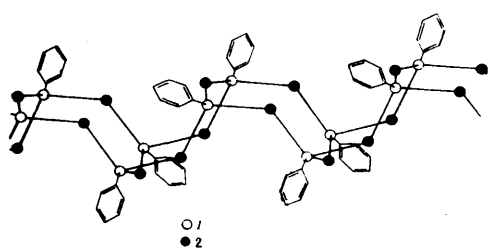


Figure 15. Structure of the molecule of staircase polyphenylsiloxane: *1*) silicon atoms; *2*) oxygen atoms.

This is due to the considerable skeletal rigidity (the flow effect) whereas the role of the excluded volume effects is small and cannot be considered.

In accordance with this the rigidity of the chain can be determined by constructing the variation of $[s]$ with $M^{\frac{1}{2}}$ and of $M/[\eta]$ with $M^{\frac{1}{2}}$ shown in Fig. 16 for one of the specimens of a staircase polymer. The slopes of the straight lines obtained lead, by use of the theory—Eqns. (11) and (12)—to values of A = 200 Å for the segment length. This value is ten times the value of A for the chain molecules of a staircase polyphenylsiloxane without rings in the chain. [1] The considerable rigidity of the molecule of the staircase polymer is quite adequate for the appearance of properties characteristic for semirigid chain molecules in the molecular weight range investigated.

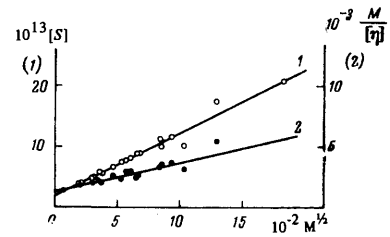

Figure 16. Variation of the quantities $[s]$ (*1*) and $M/[\eta]$ (*2*) with $M^{\frac{1}{2}}$ for fractions of staircase polyphenylsiloxane.

These properties are shown clearly in the optical behaviour of the solutions. In these there is great negative flow birefringence (which corresponds to the sign of the anisotropy introduced by the lateral phenyl radicals), the reduced value of which increases with the molecular weight (see Fig. 17) in complete agreement with the theory of the anisotropy of persistent chains—Eqns. (21) and (22).

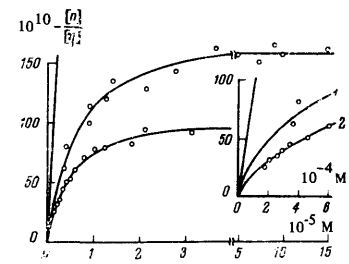

Figure 17. Variation of the reduced birefringence $[n]/[\eta]$ with the molecular weight M for fractions of two specimens of staircase polyphenylsiloxane: *1*) specimen 1; *2*) specimen 2. The experimental points correspond with the following values of the persistent length and anisotropy: for specimen 1) a = 90 Å, $\alpha_1 - \alpha_2 = -1.8 \times 10^{-22}$ cm^3; for specimen 2) a = 50 Å, $\alpha_1 - \alpha_2 = 1 \times 10^{-22}$ cm^3.

The segment length A, estimated from the initial slope and the asymptotic limit of the experimental curves of Fig. 17, is 180 Å, which agrees with the values obtained from hydrodynamic results.

The anisotropy of the segment, determinable from the asymptote of curve *1*, Fig. 17, is $\alpha_1 - \alpha_2 = -1800 \times 10^{-25}$ cm^3, which is 20 times the anisotropy of linear isotactic metaphenylsiloxane without rings in the chain [88].

At the same time the fractions $\Delta\alpha$ introduced into the anisotropy of the molecule by a single phenyl ring are almost the same for staircase and linear single-chain polyphenylsiloxanes ($\Delta\alpha = -20 \times 10^{-25}$ cm^3). This indicates that transverse oxygen bridges, which strengthen the double chain molecule of the staircase polymer and greatly increase its skeletal rigidity, are without any significant effect on the rotational mobility of the lateral phenyl groups.

Although the rigidity of the molecule of a staircase polymer is great, it is completely terminal and close, for example, to the rigidity of the chains of the cellulose esters. At a molecular weight of about 100 000 the molecule is already a gaussian coil in several of its properties, that is, considerable rigidity appears. A comparison of the curves of Figs. 17 and 3 shows that for the fractions investigated the degree of intramolecular ordering Q lies in the range from 0.2 to 0.005, that is, considerably below the level of organisation of a smectic mesophase.

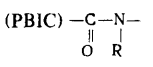
It should be noted that in the example of a staircase polymer we encounter a mechanism for chain rigidity which is greatly different from that for linear chain molecules without a secondary structure. Here the flexibility is due not to restricted rotation around valence bonds (or rotational isomerism) but to microdeformations of the macromolecular "lattice" in its thermal vibrations. However, local defects of the intramolecular lattice probably play some part in this. An illustration of this is provided by curve *2* of Fig. 17, which shows the relation $[n]/[\eta] = f(M)$ for the fractions of a specimen of cyclolinear polyphenylsiloxane obtained under somewhat different conditions than for specimen *1*. Although this polymer undoubtedly has a staircase structure, which appears in its hydrodynamic and optical properties, the presence of local defects in the structure of the molecule diminishes its rigidity and anisotropy to the values $A = 100$ Å and $\alpha_1 - \alpha_2 = -1060 \times 10^{-25}$ cm^3 respectively.

The rigidity of the molecule of a staircase polymer can be markedly decreased by the creation of "chemical" defects in its lattice, for example, by the introduction of single bonds into the molecular chain. Such partial "decyclisation" of the molecule leads to a partly staircase structure[89,90]. The poly-(*N*-isobutylmaleimide) considered above can evidently serve as an example of a "semistaircase" polymer.

The conformational properties of the molecules of other possible partial-staircase polymers have not been studied.

4. Molecules with Resonance Interaction in the Chain

The presence of additional intramolecular bonds (hydrogen or chemical), which "cyclise" the structure and thus ensure its rigidity is characteristic of all the above polymers with rigid chain molecules. Until comparatively recently it could have been thought that these structural properties are a necessary condition for the existence of semirigid chain molecules. However, the synthesis of polyisocyanates[91,92] and the study of the properties of their solutions[93-96] shows this to be incorrect. It was shown that the molecules of certain polyalkylisocyanates in solution have exceptionally high rigidity and ordering of the structure. The polybutyl isocyanate



where R = C_4H_9, was investigated in the most detail.

Solutions of this polymer in non-polar solvents are characterised by high values of the exponents α and β ($\alpha = 1.2$; $\beta = 0.85$) in the Mark–Kuhn equations (5)–(7).

To illustrate the great rigidity of the PBIC molecule, the viscosimetric results obtained for it can be treated[96] using the main formulae of the theory of viscosity of solutions of rigid ellipsoids:

$$[\eta] = \bar{v}\nu(p);\ H^3 = 6p^2\bar{v}M/\pi N_A\ . \qquad (28)$$

where $p = H/d$; H and d are respectively the long and short axes of the ellipsoid modelling the molecule, $\bar{v}$ and M the partial specific volume and molecular weight of the polymer, and $\nu(p)$ the viscosity increment, a function of the asymmetry p of the ellipsoid, tabulated by Simha[1].

The values of $d = H/p$ and H/Z calculated by Eqn. (28) and the experimental values of $[\eta]$, $\bar{v}$, and M are shown in Fig. 18 as functions of the degree of polymerisation Z. The decrease in H/Z and the increase in d with increase in Z show the considerable flexibility of the chain and the departure of its form (with increase in Z) from rod-shaped. However, the limiting values of $H/Z = 2 \times 10^{-8}$ cm and $d = 11 \times 10^{-8}$ cm agree reasonably with the length and diameter of the monomeric unit of the molecular chain of PBIC.

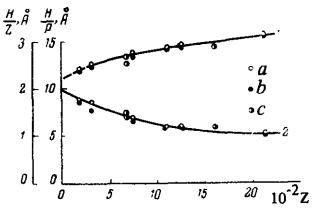


Figure 18. Variation of the quantity $H/p = d$ (*1*) and H/Z (*2*) with the degree of polymerisation Z for poly(butyl isocyanate) fractions in various solvents: *a*) benzene[93]; *b*) tetrahydrofuran[93]; *c*) benzene[96].

It follows from this analysis that in a range of molecular weights of a few tens of thousands (Fig. 18) the form of the PBIC molecule is close to a straight rod.

An analysis of the results on diffusion and sedimentation using the theory of wormlike chains—slope of the straight line *2* in Fig. 10, and Eqn. (12)—leads[96] to the enormous segment length A of 3000 Å, which surpasses even the segment length of the helical polypeptide molecules. The results on flow birefringence, which is very high and positive in solutions of polybutyl isocyanate, lead to similar conclusions.

The use of the microform effect, Eqn. (20), enables the segment length to be determined; the value obtained $A = 2600$ Å is close to the value found from hydrodynamic data. The anisotropy of the segment is great ($\alpha_1 - \alpha_2 = 9000 \times 10^{-25}$ cm^3) and its magnitude is close to the anisotropy of helical polypeptide molecules.

In PBIC solutions there is also an extremely large positive electrical birefringence[96], which shows the existence in the molecule not only of axial but also of polar orientation ordering.

The pronounced frequency dependence of the Kerr effect (Fig. 19) is also proof of high rigidity (both equilibrium and kinetic) and of the ordering of the structure; it can be

used for determining the orientation relaxation time and the geometric parameters of the molecule[96].

The effect of the saturation of the electrical birefringence observed in strong fields (Fig. 20) shows the high value of the molecular dipole and can be used for determining the dipole moment μ of the molecule[96]. The values obtained are close to the values of the dipole moments of the polypeptide molecules in the helical conformation. Similar results are obtained from a comparison of the dynamo-optical and electro-optical results[96].

The values of the dipole moments of the molecules μ obtained from measurements of the dielectric properties of the solutions[95] can also be used for determining the segment length. Having constructed a plot of μ^2/L against L, we obtain the curve of Fig. 21. In accordance with theory—Eqn. (26)—the initial slope gives the square of the dipole moment of unit length of the persistent chain $(\mu_S/A)^2$. The ratio of the asymptotic limit to the initial slope gives the segment length A. The value found by this method, A = 3000 Å, agrees with the value obtained from hydrodynamic results.

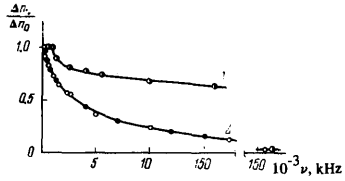

Figure 19. Variation of the relative value of the electric birefringence $\Delta n_\nu/\Delta n_0$ with the frequency ν for solutions of poly(butyl isocyanate) in tetrachloromethane: *1*) $M = 1.6 \times 10^5$; *2*) $M = 0.66 \times 10^5$.

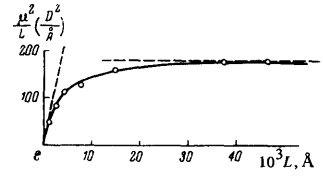

Figure 21. Variation of μ^2/L with L for poly(butyl isocyanate) in benzene.

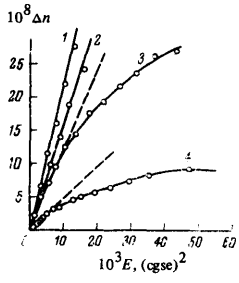

Figure 20. Variation of the electric birefringence with the square of the field strength E^2 for solutions of poly(butyl isocyanate) and poly(tolyl isocyanate) in bromoform (c = 1.77 g dl^{-1}); *3*) and *4*) poly(tolyl isocyanate) in tetrachloromethane (specimen 3; $M = 1.6 \times 10^5$, $c = 0.6 \times 10^{-3}$ g dl^{-1}); (specimen 4: $M = 0.66 \times 10^5$, $c = 0.7 \times 10^{-3}$ g dl^{-1}).

Table 4 summarises the molecular characteristics of PBIC. All these experimental results taken together show that the conformation of the PBIC molecule in weakly polar solvents corresponds to the wormlike chain model. The rigidity and ordering of its structure determined by various methods are very great and close to the rigidity and ordering of the molecules of synthetic polypeptides having an α-helical secondary structure. On taking into account the value found above for A and using Fig. 3 it is clear that for the fractions shown in Fig. 18 the value of Q lies in the range $0.4 \leq Q \leq 0.9$. Hence the PBIC molecules are crystal-like molecules with a very high degree of orientation order. Similar properties were observed in the polymers of other substituted alkyl isocyanates—polyhexyl isocyanate[94] and poly(chlorohexyl isocyanate)[96].

The chemical structure of the molecules of polyisocyanates are similar to the structure of polypeptide molecules, but the hydrogen atom in them is replaced by a side chain and the CHR group is absent from the main chain. The first feature (the absence of an N–H bond) rules out the possibility of the formation of a rigid α-helix conformation, since there are no intramolecular hydrogen bonds.

Table 4. Structural characteristics of molecules of some rigid-chain polymers.

Polymer	Mechanism of rigidity	10^{-5}M	$10^8 A$ cm	$10^{25}(a_1 - a_2)$ cm^3	$10^{23}(a_\parallel - a_\perp)$ cm^3	$10^{18}\mu$ cgse	Q
Polystyrene (for comparison)	restriction of rotation	1—100	20	—140	—18	—	$5 \cdot 10^{-3}$—$3 \cdot 10^{-5}$
Polybutylmaleimide	semistaircase structure	1.9—34	40	160	10	—	$8 \cdot 10^{-3}$—$4.4 \cdot 10^{-4}$
Polyphenylsiloxane	staircase structure						
Specimen 1		0.36—33.5	180	—1800	—25	—	0,42—$4.8 \cdot 10^{-3}$
Specimen 2		0.17—3.11	100	—1060	—25	—	0,34—0.02
Deoxyribonucleic acid	secondary helical structure	0.2—110	800	—40000	—200	—	0,41—$8.5 \cdot 10^{-3}$
Poly-γ-benzyl-*L*-glutamate	secondary helical structure	0.4—3.4	2400	20000	17	150—370	0.88—0.41
Poly(butyl isocyanate)	resonance interaction of the chain	0.2—2.0	3000	9000	7	253—2900	0.89—0.40
Phenylmethacrylic ester of cetyloxybenzoic acid	interaction in side-chains	18	65	—2700	—100	30	$3.1 \cdot 10^{-3}$
Graft copolymer of styrene and methyl methacrylate	interaction in side-chains	2.0—50	100	750		—	0.12—$0.48 \cdot 10^{-3}$

The second feature can have a decisive importance in the stabilisation of the rigidity of the molecular chain. Actually, since the peptide bonds in the polyisocyanate molecule are not separated by CHR groups, the coplanarity of all the bonds inside one peptide group (–CO–NR–) can be extended to each neighbouring pair of peptide groups, ensuring a rigid conformation of the whole chain. Here the resonance interaction of each nitrogen atom is extended to both carbonyl groups adjacent to it, giving the C–N bonds the rigidity of conjugated bonds[94].

Of the two possible planar structures of the chain (Fig. 22) the more probable is the *cis*-form, since it alone ensures the presence of a molecular dipole moment parallel to the axis of the molecule, and, corresponding to this, the agreement of the signs of the electrical and dynamic birefringences[96].

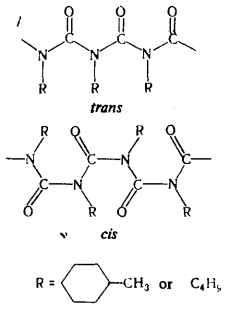

Figure 22. *trans*- and *cis*-conformations of polyisocyanate chains.

Hence poly(alkyl isocyanates) are unique instances when the exceptionally high rigidity of the conformation and the high degree of intramolecular ordering of the chain molecule are due not to the secondary structure but to the true skeletal rigidity of its single-track chain.

In addition to giving rise to these properties the structure of the side-radical at the nitrogen atom plays an important part. Thus replacing an aliphatic by an aromatic radical (tolyl isocyanate)[96] leads to the breakdown of the unique structure of the molecule. The reason for this can be sought both in the weakening of the resonance interaction in the nitrogen–carbonyl system owing to the effect of conjugated bonds of the aromatic ring and in the steric repulsion of neighbouring tolyl side-groups.

5. Molecules with Chain Side-radicals

The effect of the size and structure of the side-groups on the conformation of the polymeric molecules and the rigidity of their main chains has been studied repeatedly. Although in principle such an influence should occur the effects observable experimentally always appear insignificant[1].

Some new information about this problem was obtained recently in connection with the study of the conformational and optical properties of chain molecules having a "comb-shaped" structure. The latter is inherent to molecules with sufficiently long (linear) side-radicals or can be obtained by the grafting of one chain polymer on to another. However, in every instance the side-groups should be much shorter than the main chain.

A new approach to the study of the conformations of such molecules consists in the application of the theory of persistent anisotropy to the optical properties of the side-groups and in the calculation of their optical anisotropy in the axes of their primary element[38,44].

On drawing a tangent to the initial element of the persistent chain of length L and denoting the polarisability of the chain in the directions parallel and perpendicular to it by $\gamma_{\parallel}$ and $\gamma_{\perp}$ respectively, then for the difference $(\gamma_{\parallel} - \gamma_{\perp})_L$ the theory gives

$$(\gamma_{\parallel} - \gamma_{\perp})_L = \frac{1}{3} a\beta_0 (1 - e^{-3x}) = a\beta_0 x \left(1 - \frac{3}{2}x + \frac{3}{2}x^2 - \right.$$
$$\left. - \frac{9}{8}x^3 + \frac{27}{40}x^4 - \frac{27}{80}x^5 + \ldots\right). \quad (29)$$

The symbols in Eqn. (29) agree with those used in Eqn. (21).

The dependence of the ratio $(\gamma_{\parallel} - \gamma_{\perp})_L / \alpha\beta_0$ on the parameter x is shown in curve *3* of Fig. 2. The initial slope and asymptotic limit of the curve are respectively 1 and 1/3.

A comparison of curves *3* and *1* of Fig. 2 shows that the anisotropy of the gaussian chain (at $x \to \infty$), calculated using the axes of its primary element is 5/18 of the anisotropy calculated using the axes of vector h.

The application of Eqn. (29) to the anisotropy of the side-chain of the comb-shaped molecules shows that the contribution Δb_L introduced by the side radical to the anisotropy of the monomeric unit of the molecule is:

$$\Delta b_L = -S^* \cdot \Delta a \,(1 - e^{-6n/S^*})/12 \quad (30)$$

where n and S^* are the numbers of valence bonds in the side-chain and in its segment respectively, Δa the anisotropy of the part of the side-chain containing one valence bond.

Hence from the contribution made by the side-chain groups to the anisotropy of the whole molecule the anisotropy and flexibility of these groups can be studied by the above method.

a. Poly-α-alkenes $-\overset{R}{\underset{|}{C}}H-CH_2-$ $(R = C_nH_{2n+1})$

tematic experimental results on the dependence of the anisotropy of molecules on the number n of methylene groups in its side-radicals have been obtained for a number of poly-alkenes[97]. It was shown that in several poly-α-alkenes the lengthening of the side-group is accompanied by a monotonic rise in the negative anisotropy of the segment of the molecule $\alpha_1 - \alpha_2$. This increase can be caused both by increase in rigidity of the main-chain (an increase in A or S) and also by an increase in the negative contribution introduced into the anisotropy of the monomeric unit of the molecule by its side-group with lengthening of the latter.

If the change in the rigidity of the main-chain in the lengthening of the side-group is neglected (which is true only for the lower homologues of the series), then the experimentally obtained dependence can be represented in the form $\Delta b_L = 2.73 \times 10^{-25} n$ cm^3. On the other hand if it is assumed that the flexibility of the lateral hydrocarbon chain of the molecule of the poly-alkene equals the flexibility of the polyethylene chain, then assuming that $S^* = 16$,[1] from Eqn. (30) we obtain the theoretical relation $\Delta b_L = -7.3 \times 10^{-25}(1 - e^{-3n/8})$. Both relations are shown in Fig. 23.

The theoretical curve shows that owing to the flexibility of the side-chain with increase in its length (that is, n) the anisotropy of Δb_L should reach an asymptotic limit determinable from the degree of flexibility of the side-groups.

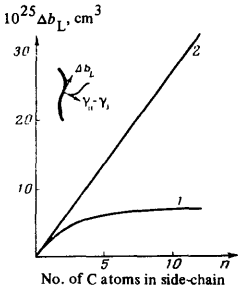

Figure 23. Contribution Δb_L introduced by the side-group to the anisotropy of the monomeric unit of a poly-α-alkene molecule as a function of the number (n) of carbon atoms in the side-chain. *1*) Theory of non-interacting chains with a flexibility equal to the flexibility of a polyethylene chain $\Delta b_L = 7.3 \times 10^{-25}(1 - e^{-3/8n})$ as follows from Eqn. (30); *2*) $\Delta b_L = 2.73 \times 10^{-25} n$ (see experimental results of Ref. 3).

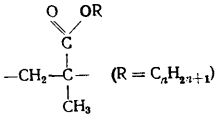
However, in the range of values of n studied the experimental relation shows no tendency to saturation. This shows that the rigidity and orientation ordering of the side-groups of poly-α-alkenes greatly exceed the values which can be obtained from the experimental investigation of the conformational and optical properties of the individual hydrocarbon chains in the solution.

b. Poly(alkyl methacrylates).



A study of the conformation and optical anisotropy of the molecules of several poly(alkyl methacrylates) leads to similar conclusions[28]. Unlike the poly-α-alkenes, in addition to optical data results for this series were also obtained about the statistical dimensions and rigidity of the main-chain[28,98,99]. Consideration of these results can include more quantitative results than in the previous instance.

The experimental results on the rigidity of the main-chain and the anisotropy of the molecules of the poly(alkyl methacrylates) are given in Table 5. Up to $n = 8$ the length of the side-group has little effect on the rigidity of the main chain (the number of monomers S in its segment is close to 7–8). With a further growth of the side-chain the rigidity of the main chain increases considerably and at $n = 16$ is already twice that of molecules of the usual flexible chain polymers. This increase must evidently be regarded as the result of the interaction of long side-radicals of the molecule.

A much steeper expression of the increase in the negative anisotropy of the molecular segment $\alpha_1 - \alpha_2$ occurs with lengthening of the side-groups. Fig. 24 gives corresponding experimental values of the anisotropy of the monomeric unit of the molecule $a_\parallel - a_\perp$ as a function of the number $Z = n + 2$. The points lie satisfactorily along the theoretical curve (30) (where n is replaced by Z) under the condition $S^* = 60$ (continuous line). The broken line shows the theoretical relation corresponding to $S^* = 16$, that is, under the condition that the flexibility of the side-chain equals the flexibility of a polyethylene chain.

Table 5. Number of monomeric units S in the segment, segment anisotropy $\alpha_1 - \alpha_2$, and anisotropy of the monomeric unit $a_\parallel - a_\perp$ of the molecules of some esters of poly(methacrylic acid). n is the number of carbon atoms in the alkyl side-chain of the molecule.

Polymer	n	S	$10^{25}(\alpha_1 - \alpha_2)$ cm^3	$10^{25}(a_\parallel - a_\perp)$ cm^3
Poly(methyl methacrylate)	1	7.0	−2	−0.2
Poly(butyl methacrylate)	4	6.7	−14	−2.1
Poly(hexyl methacrylate)	6	8.6	−40	−4.6
Poly(octyl methacrylate)	8	7.9	−47	−5.9
Poly(cetyl methacrylate)	16	19	−170	−8.9
Poly(phenylmethacrylic ester of cetyloxybenzoic acid)	16	26	−2500	−100

Hence the rigidity of the side-chains of poly(alkyl methacrylates), in the range n investigated (up to $n = 16$) is four times the rigidity of chain vinyl polymers of similar structure. This result shows the presence of significant orientation ordering in the side-chains of the macromolecules, considerably surpassing the conformational ordering of the ordinary gaussian chains. The reason for this ordering is evidently to be sought in the interaction of regularly constructed alkyl radicals, which leads to the formation of an intramolecular structure with a short-range orientation order in the positions of the side-chains. This effect is all the greater the longer the side-chains, just as lengthening assists the crystallisation of the polymer in bulk.

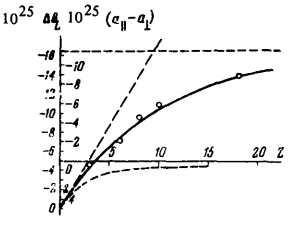


Figure 24. Variation of the anisotropy of the monomeric unit of the alkyl esters of poly(methacrylic acid) with the number of valence bonds $Z = n + 2$ in the side-chain. Continuous curve: theoretical relation according to Eqn. (30) at $\Delta a = 3.3 \times 10^{-25}$ cm^3 and $S^* = 60$. The broken curve is obtained from the equation at $\Delta a = 3.3 \times 10^{-25}$ cm^3 and $S^* = 16$.

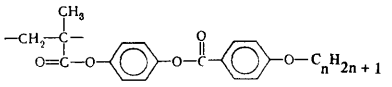
A natural consequence of this effect is also a decrease in the flexibility of the main-chain.

c. Polyphenyl methacrylic esters of alkyloxybenzoic acids. Convincing proof that the observable increase in the orientation order both in the main- (increase in S) and in the side- (increase in $a_\parallel - a_\perp$) chains

is the consequence of the interaction of the side-groups is given by the conformation properties of the polyphenyl methacrylic ester of alkyloxybenzoic acids (PPMEAOBA).[100]

These polymers, which have a structure of the form:



can be regarded also as esters of polymethacrylic acid where the hydrogen in the side-group is replaced by the radical:

Hence the main-chains of these macromolecules do not differ from those examined above and the lateral substituents are distinguished by the presence of groups instrumental in the formation of a liquid-crystal phase, that is, a state with a clearly expressed orientation ordering[101].

The structural characteristics of macromolecules of one of these polymers—polyphenylmethacrylic ester of cetoxybenzoic acid (PPMECOBA) ($n = 16$ in the C_nH_{2n+1} group) are given in Tables 4 and 5.

The presence of strongly interacting side-groups increases the rigidity of the main-chain of the polymer ($S = 25$). However, its optical properties are completely unique. The negative segment anisotropy of the molecule is more than an order of magnitude greater than the anisotropy of poly(cetyl methacrylate) and comparable only with the anisotropy of "crystal-like" molecules—polyisocyanate or poly-γ-benzyl-L-glutamate and the anisotropy of the monomer $a_{\parallel} - a_{\perp}$ is even appreciably greater than the anisotropy of the monomeric unit of these molecules. The last fact shows that the extremely high anisotropy of the molecule is due not so much to the rigidity of its main-chain (which is much less than for crystal-like molecules) as to the extremely perfect orientation order in its side-groups.

It is also remarkable that this order is not only axial but also polar—solutions of PPMECOBA give a high negative birefringence in an electric field. The use of these experimental results and Eqns. (18) and (24) gives a value of $\mu = 30 \times 10^{-18}$ cgse for the component of the dipole moment along the axis of the molecule. Significantly, these unique properties are combined with properties characteristic for flexible chain polymers: unlike the crystal-like molecules the dimensions of the PPMECOBA molecule are sensitive to the thermodynamic nature of the solvent and can change markedly as the latter is changed. All these facts show that in PPMECOBA molecules there is orientation ordering of a mesomorphic type, in which the side-chains of the molecule form a mobile liquid-crystalline structure.

d. Graft copolymers. Similar, although less perfect, structures are evidently formed in other macromolecules of the comblike type—graft polymers. They have quite specific optical properties, demonstrated by the example of graft polymers of styrene and alkyl methacrylates[38,102,103].

The optical anisotropy of the molecules of a graft copolymer can be many times greater than the anisotropy of the graft homopolymers. It is positive, that is, opposite in sign to the negative anisotropy of the chain of graft polystyrene, although the mass of the polystyrene in the graft copolymer exceeds 90%.

An analysis of these experimental results together with the hydrodynamic properties of the molecules [see Eqns. (11), (12), and 30)] enables the rigidity of both the main chain of the copolymer and also the chains of the graft copolymers to be determined[38]. Here the observable properties can be explained not only qualitatively but also quantitatively by the existence in the graft polymer of an intramolecular structure with a high degree of orientation order.

It is characteristic that despite the high rigidity of the main-chain of the graft polymer ($A = 100$–200 Å) the exponent in the M–K equations (5)–(7) for this polymer are close to the values $\alpha = \beta = 0.5$. This fact is explained by the high value of the diameter d of the wormlike chain, modelling the graft polymer molecule, in complete agreement with theory, Eqns. (11) and (12).

---o0o---

The facts considered above show that the structural features of macromolecules leading to the appearance in them of properties characteristic for "semirigid" chains can be extremely varied (see Table 4).

Apart from the true skeletal rigidity of the single-track chain—poly(alkyl isocyanates)—additional interactions of quite different origins are possible in the molecules; however, these can be classified as "short-range actions". These interactions lead to increased rigidity of the molecular conformation. They include both purely chemical and also hydrogen bonds, leading to the formation of regular rings in the chain (staircase and partly staircase polymers, derivatives of polysaccharides, secondary helical structures of polypeptides and polynucleotides).

Furthermore, the rigidity and ordering of the conformation can be considerably increased by van der Waals interaction of the side-radicals and electrostatic repulsion of the ionogenic groups of the chain[74,105,106].

There is no doubt that the list of molecular structures which can be classified as semirigid is not limited to the examples considered above. However, in selecting the subjects for discussion we considered only those examples in which the morphological properties of the molecule have been investigated quantitatively and in sufficient detail for forming a definite opinion.

From these examples clearly the semirigid molecules cannot be regarded as a class of polymer with a definite chemical structure. This terminology should rather be applied to all the group of structures which exhibit a certain combination of physicochemical properties, which has been discussed above.

The most characteristic of these properties are a high degree of intramolecular ordering and a high value for the persistence length of the wormlike chain modelling the macromolecule.

In the range of low and moderate molecular weights these properties appear as a departure from the regularities characteristic for gaussian chains—in a specific dependence on the molecular weight of such parameters as the radius of gyration of the molecule, their optical anisotropy and dipole moments. The hydrodynamic behaviour of the semirigid chains corresponds to the conformation of a slightly bent rod.

In the range of high molecular weights the semirigid chains are already gaussian, but for these large radii of gyration, segment anisotropy (proper and microform) and dipole moments are characteristic. Considerable flow capability of the molecules is a characteristic of the hydrodynamic behaviour (when the chain diameter is not too large).

The combination of all these parameters (or some of them) can be used for the experimental observation and as a quantitative characteristic of equilibrium rigidity and the ordering of the structure of the molecular chain.

Hence we consider that the above information can be useful in two respects. Firstly, it contains various examples of those structural features of a polymer which can be responsible for its molecule having properties characteristic for semirigid chains. Secondly, it shows that the hydrodynamic, dynamo-optical, and electro-optical properties of chain molecules in solutions are reliable criteria for a quantitative appraisal of their rigidity and the internal degree of order of the structure.

Benzoisoquinolines and Azafluorenes

N.S.Prostakov

Methods of preparation, synthetic reactions, and properties are surveyed for the difficultly accessible polyfused nitrogen-containing heterocyclic systems—benzo[*f*] isoquinoline, benzo[*g*] isoquinoline, benzo[*h*] isoquinoline, and azafluorenes in which the position of the nitrogen atom in the pyridine ring varies. A list of 77 references is included.

CONTENTS

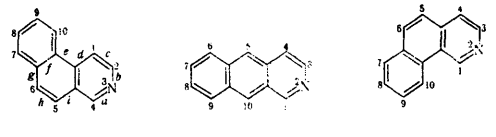
I. Benzoisoquinolines 774
1. Benzo[*f*] isoquinolines 774
2. Benzo[*g*] isoquinolines 774
3. Benzo[*h*] isoquinolines 776
II. Azafluorenes 777

Benzoisoquinolines and azafluorenes, which are tricyclic fused nitrogen-containing systems, still remain a little studied group of compounds. An apt comparison is that the monograph "Heterocyclic Compounds"[1] devotes a long chapter to benzoquinolines, whereas only a few words are said about benzoisoquinolines and azafluorenes. Only one example is given of the synthesis of benzo[*g*]isoquinoline and the isolation of a small quantity of 9-oxo-3-phenyl-4-azafluorene-1-carboxylic acid by the oxidation of 2-phenylbenzo[*h*]quinoline-4-carboxylic acid. The information on this group of compounds to be found in the literature is also limited.

Yet both benzoisoquinolines and azafluorenes are of definite interest. Among compounds of this type have been found quite effective physiologically active substances. Their use for the synthesis of various dyes is also promising. But perhaps the greatest value of these compounds is that they can form portions of systems which closely resemble alkaloids.

I. BENZOISOQUINOLINES

The nomenclature of the benzoisoquinolines is similar to that of the benzoquinolines:



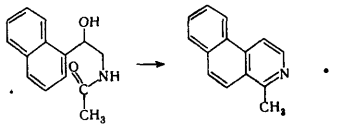
(I) (II) (III)

(I) benzo[*f*]isoquinoline (5,6-benzoisoquinoline, 2-azaphenanthrene)
(II) benzo[*g*]isoquinoline (6,7-benzoisoquinoline, 2-azaanthracene)
(III) benzo[*h*]isoquinoline (7,8-benzoisoquinoline, 3-azaphenanthrene).

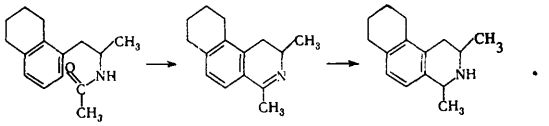
Synthetic routes for building up benzoisoquinoline systems are as yet relatively few, being limited mainly to Bischler–Napiralski[2], Pictet–Gams[3], and Pictet–Spengler[4] condensations and the dehydrocyclisation of *ortho*-substituted benzylpyridinecarboxylic acids, 4-*o*-xylylpyridines, and 4-benzyl-3-methylpyridines. The photochemical cyclisation of stilbazoles has been used in the synthesis of benzoisoquinolines.

1. Benzo[*f*]isoquinolines

4-Methylbenzo[*f*]isoquinoline can be obtained by boiling *N*-(2-hydroxy-2-naphth-1′-ylethyl)acetamide with phosphorus pentoxide in xylene[5]:

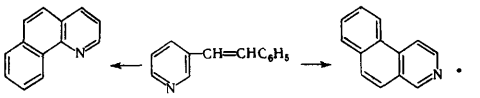


Partly hydrogenated substituted derivatives of benzo[*f*]isoquinolines have been synthesised by the Bischler–Napiralski method from *N*-[1-methyl-2-(5,6,7,8-tetrahydronaphth-1-yl)ethyl]acetamide, cyclisation being accomplished in the presence of phosphoryl chloride[6]:



1,2,7,8,9,10-Hexahydro-2,4-dimethylbenzo[*f*]isoquinoline was converted by catalytic hydrogenation into 1,2,3,4,7,8,9,10-octahydro-2,4-dimethylbenzo[*f*]isoquinoline. Several other partly hydrogenated substituted benzo[*f*]isoquinolines have been obtained by the same scheme of reactions.

The photochemical cyclisation of stilbazoles has been studied. Prolonged ultraviolet irradiation of a solution of 3-styrylpyridine and also of 3-*p*-methylstyrylpyridine in hexane yields a mixture of benzo[*f*]isoquinoline and benzo[*h*]quinoline (or the methyl derivatives of these heterocycles), which has been separated by chromatography on alumina[7,8]:

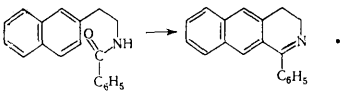


The *trans* and *cis* isomers of 3-styryl- and 3-*p*-methylstyryl-pyridines have been used in these reactions. In the same way 6-cyanobenzo[*f*]isoquinoline has been obtained from *trans*-3-β-cyanostyrylpyridine[9].

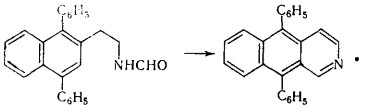
2. Benzo[*g*]isoquinolines

From the point of view of synthesis this benzoisoquinoline system has been studied in greater detail than the benzo[*f*]isoquinoline system. It can be constructed by

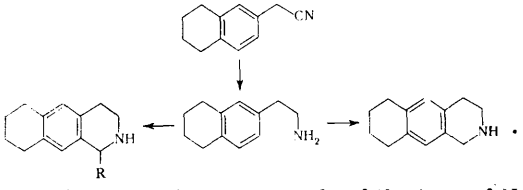
various methods. Several substituted benzo[*g*]isoquinolines have been obtained by the Bischler–Napiralski reaction. 3,4-Dihydro-1-phenylbenzo[*g*]isoquinoline has been isolated[10] by the condensation of *N*-2-naphth-2′-ylethylbenzamide (boiling in toluene with phosphoryl chloride):



3,4-Dihydrobenzoisoquinoline systems are readily converted into benzoisoquinoline systems, even by the action of atmospheric oxygen[11]. Condensation of the *N*-formyl derivative of 2-(1,4-diphenylnaphth-2-yl)ethylamine in the presence of phosphoryl bromide at once yields 5,10-diphenylbenzo[*g*]isoquinoline[12]:



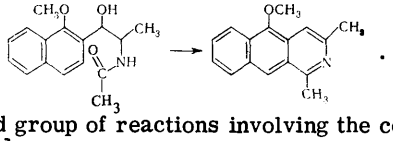
Several hydrogenated benzo[*g*]isoquinolines have been synthesised from 2-cyanomethyl-5,6,7,8-tetrahydronaphthalene[6]. On reduction with lithium tetrahydroaluminate this cyanide was converted into 2-(5,6,7,8-tetrahydronaphth-2-yl)ethylamine, which after acetylation, subsequent Bischler–Napiralski cyclisation, and hydrogenation gave 1,2,3,4,6,7,8,9-octahydro-1-methylbenzo[*g*]isoquinoline. When the same amine was condensed with formaldehyde by the Pictet–Spengler method, 1,2,3,4,6,7,8,9-octahydrobenzo[*g*]isoquinoline was isolated:



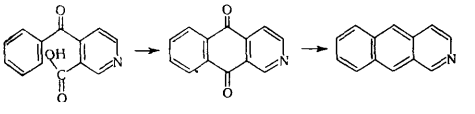
There are indications that compounds of the type of *N*-substituted 1,2,3,4,6,7,8,9-octahydro-3-methylbenzo[*g*]isoquinolines have a strong analgesic effect.

The condensation of *N*-acylated 2-(5,6,7,8-tetrahydronaphth-2-yl)-1-methylethylamines has been accomplished. 1-Benzyl-3,4,6,7,8,9-hexahydrobenzo[*g*]isoquinoline has been obtained by the cyclisation of *N*-β-(6-tetralylethyl)-phenylacetamide[13].

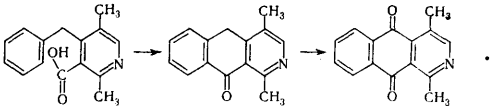
The Pictet–Gams method has been used in syntheses of benzo[*g*]isoquinolines as well as in the preparation of benzo[*f*]isoquinolines. An example is the synthesis of 5-methoxy-1,3-dimethylbenzo[*g*]isoquinoline[14]:



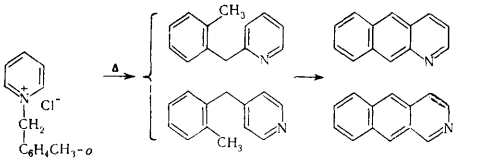
In a second group of reactions involving the construction of the benzo[*g*]isoquinoline system use is made of a preformed pyridine ring. Benzo[*g*]isoquinoline is obtained from 4-benzoylpyridine-3-carboxylic acid, which was converted by intramolecular condensation (with sulphuric acid at 175°C) into 2-aza-anthraquinone, from which benzo[*g*]-isoquinoline was obtained by reduction with zinc dust in aqueous ammonia[15]:



The cyclisation of 4-benzyl-2,5-dimethylpyridine-3-carboxylic acid by means of polyphosphoric acid yields the corresponding 2-aza-anthrone (in 85% yield), which is readily oxidised by atmospheric oxygen to 1,4-dimethyl-2-aza-anthraquinone[16]:



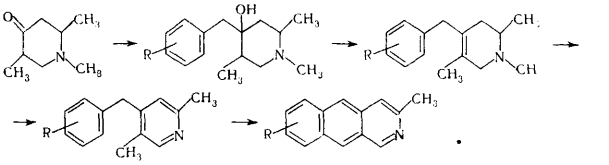
Similarly to the dehydrocyclisation of *o*-benzyltoluene to anthracene, benzo[*g*]isoquinoline has been obtained from 4-*o*-xylylpyridine. The initial substituted benzylpyridines are synthesised by Ladenburg's method, which was first developed in detail for these purposes by Chichibabin[17,18]. When *o*-xylyl chloride is heated (to 250°C) with pyridine in the presence of copper, a mixture of 2- and 4-*o*-xylylpyridine is formed, in which the latter isomer predominates. When the mixture of these substituted pyridines is passed over copper turnings or over pumice impregnated with lead oxide at 580–590°C, dehydrocyclisation takes place, with the formation of benzo[*g*]quinoline and benzo[*g*]-isoquinoline, the latter being comparatively easily isolated from the mixture because of its sparing solubility[19]:



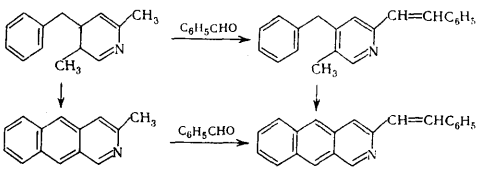
8-Methylbenzo[*g*]isoquinoline has been obtained in the same way from *o*- and *p*-dimethylbenzylpyridinium chloride.

A method has been worked out for obtaining benzo[*g*]-isoquinoline systems by the dehydrocyclisation of 4-benzyl-3-methylpyridines. The latter are synthesised from 4-oxopiperidines. The tertiary alcohols obtained from the oxopiperidines are converted by dehydration followed by catalytic dehydrogenation and *N*-dealkylation into quite high yields of substituted pyridine bases[20–22]. The dehydrocyclisation of 4-benzyl(alkylbenzyl)pyridines containing a 3-methyl group in the pyridine ring is accomplished at 500–510°C on the same dehydrogenation catalysts as are used at the stage of synthesis of 4-benzylpyridines.

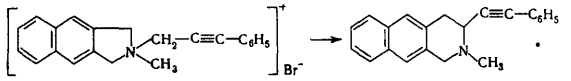
The reaction scheme given below is for the synthesis of 3-methylbenzo[*g*]isoquinoline[23] and its homologues from 1,2,5-trimethyl-4-oxopiperidine[24]:



3-Styrylbenzo[*g*]isoquinoline can be synthesised in two ways—by the direct condensation of 3-methylbenzo[*g*]isoquinoline with benzaldehyde and by the dehydrocyclisation of 4-benzyl-5-methyl-2-styrylpyridine:



The partly hydrogenated substituted derivative 1,2,3,4-tetrahydro-2-methyl-3-2′-phenylethynylbenzo[*g*]isoquinoline is formed on heating 2-(3-phenylprop-2-ynyl)benzo[*f*]-isoindolinium bromide in the presence of anhydrous caustic soda in benzene, the starting material being obtained from 2-methylbenzo[*f*]isoindoline and 3-phenylprop-2-ynyl bromide. These transformations are based on the rearrangement of derivatives of prop-2-ynylammonium halides:



The structure of the heterocyclic compound obtained was proved by means of its ultraviolet and nuclear magnetic resonance spectra[25].

Benzo[*g*]isoquinoline[3] are high-melting, usually sparingly soluble substances, which sublime in a high vacuum. In some solvents they fluoresce. They resemble anthracene in electronic structure. Their ultraviolet spectra are very alike[12,26,27]. Benzo[*g*]isoquinolines, like anthracene, exhibit two systems of absorption bands—a Y-band (2500 Å), due to vibrations of π-electrons in the plane of the rings, and an X-band (3000–3500 Å), due to vibrations of excited π-electrons perpendicular to the plane of the rings.

Comparison of the ultraviolet spectra of unsubstituted benzo[*g*]quinoline and benzo[*g*]isoquinoline with that of anthracene reveals a slight (10 Å or 140 cm^{-1}) bathochromic shift in the Y-band in the former, and a slight (20 Å or 350 cm^{-1}) hypsochromic shift in the same band in the latter. The X-system of bands exhibits a bathochromic displacement of the long-wavelength boundary of the region by 90 and 160 Å (625 and 1000 cm^{-1}) respectively in benzo[*g*]-quinoline and benzo[*g*]isoquinoline, and a decrease in intensity of absorption in the X-region (by a factor of about 1.5).

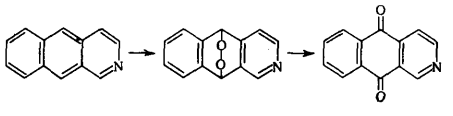
The effect of the nitrogen atom in these systems is analogous to that of such non-chromophoric substituents in the anthracene molecule as chloro and alkyl.

meso-Disubstituted benzo[*g*]isoquinolines show an additional absorption peak in the region of 3000 Å. It is assumed[26] that the pyridine ring, and also phenyl rings in *meso*-positions in substituted benzo[*g*]isoquinolines, do not lie in the plane of the naphthalene ring system.

Several papers present results of quantum-mechanical calculations on benzo[*g*]isoquinoline systems[28–32].

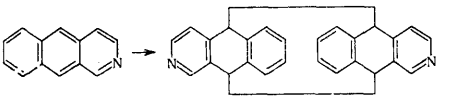
Benzo[*g*]isoquinoline forms an adduct with maleimide[12].

Like aromatic linear fused tricyclic systems, benzo[*g*]-isoquinolines undergo photochemical reactions[33,34]. When a solution of benzo[*g*]isoquinoline in carbon disulphide is exposed to sunlight, an unstable photo-oxide is formed, which is oxidised in the air to 2-aza-anthraquinone (3,4-phthaloylpyridine):



Exposure of a solution of 5,10-diphenylbenzo[*g*]isoquinoline in carbon disulphide gave a 20% yield of its photo-oxide (colourless), and this decomposes at 145–165°C, evolving up to 80% of the combined oxygen[12,35].

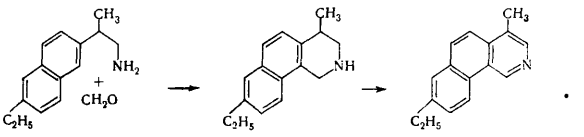
As with anthracene, illumination of solutions of benzo-[*g*]isoquinoline in alcohol, acetone, benzene, or ether in the absence of air yields greenish crystals of a "photo-dimer", which does not melt, but on being heated regenerates the monomer[34]:



The ultraviolet spectrum of the "photodimer" contains maxima characteristic of pyridine and benzene, the reason for this being the "disengagement" of these rings.

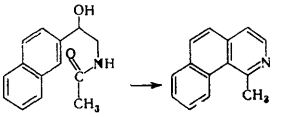
3. Benzo[*h*]isoquinolines

The usual methods for building up isoquinoline systems are employed in the synthesis of benzo[*h*]isoquinolines. Application of the Pictet–Spengler method for the condensation of 2-(6-ethylnaphth-2-yl)propylamine with formaldehyde gives 8-ethyl-1,2,3,4-tetrahydro-4-methylbenzo[*h*]isoquinoline, which on dehydrogenation by means of selenium (at 340°C) is converted into 8-ethyl-4-methylbenzo[*h*]isoquinoline[36]:

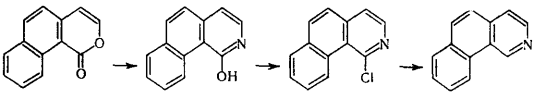


1,2,3,4-Tetrahydrobenzo[*h*]isoquinoline has been synthesised by the same method—by condensing 2-naphth-2′-ylethylamine with formaldehyde[37].

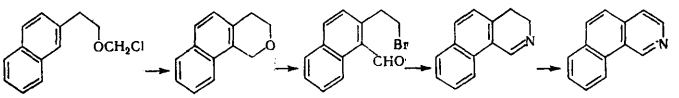
The Pictet–Gams method has been used to obtain 1-methylbenzo[*h*]isoquinoline from *N*-(2-hydroxy-2-naphth-2′-ylethyl)acetamide[38]:



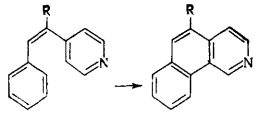
Several preparations of benzo[*h*]isoquinolines start from oxygen-containing fused tricyclic heterocycles. When 7,8-benzoisocoumarin is heated with an alcoholic solution of ammonia, 1-hydroxybenzo[*h*]isoquinoline is formed. Replacement of the hydroxyl by chlorine and subsequent removal of the latter by hydrogenation (palladium on charcoal, alcoholic caustic soda solution) converted it into benzo[*h*]isoquinoline[38]:



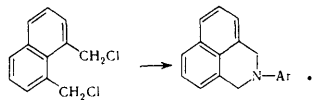
2-2′-Chloromethoxyethylnaphthalene on treatment with aluminium chloride in carbon disulphide is converted into 7,8-benzoisochroman, subsequent bromination of which with cleavage of the oxygen ring leads to 2-2′-bromoethyl-naphthal-1-aldehyde. Heating this δ-halogenated aldehyde with ammonia, by the well known method used in the synthesis of isoquinolines[39], gave 3,4-dihydrobenzo[*h*]isoquinoline, which on dehydrogenation over platinum black was converted into benzo[*h*]isoquinoline[40]:



Benzo[*h*]isoquinolines are formed by the photocyclisation of γ-stilbazoles. *trans*-4-Styrylpyridine and *trans*-4-α-methylstyrylpyridine yield respectively benzo[*h*]isoquinoline and 5-methylbenzo[*h*]isoquinoline[9]:

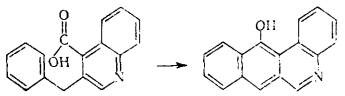


The synthesis of a partly hydrogenated benzo[*de*]isoquinoline system has been described. Several 2-aryl-2,3-dihydro-1*H*-benzo[*de*]isoquinolines have been obtained from 1,8-bischloromethylnaphthalene and primary amines in the presence of triethylamine (boiling in toluene):



Compounds of this type do not form peroxy-compounds when treated in chloroform or benzene solution with oxygen in the light at 60°C.[41]

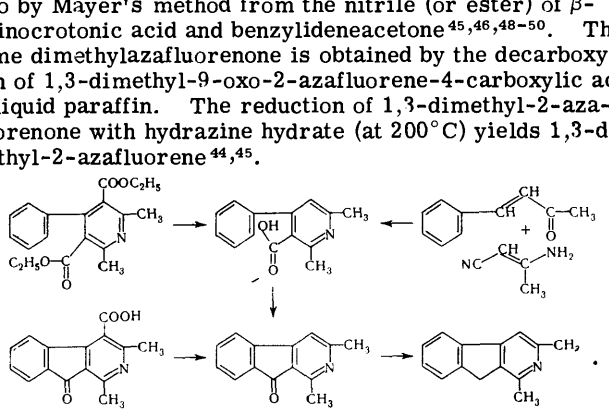
Information on the synthesis of dibenzoisoquinolines is extremely limited. An example is 5-hydroxy-3,4:6,7-dibenzoisoquinoline, which is obtained by the intramolecular condensation of 3-benzylcinchoninic acid in the presence of aluminium chloride:



Similarly 5-hydroxy-1-phenyl-3,4:6,7-dibenzoisoquinoline has been synthesised from 3-benzyl-2-phenylcinchoninic acid (obtained from ω-benzylacetophenone and isatinic acid)[42,43].

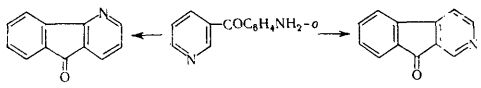
II. AZAFLUORENES

Among this group of compounds the 2-azafluorenes have been the most thoroughly studied. A usual method of synthesising 2-azafluorenes and their derivatives consists in the cyclisation of substituted pyridinecarboxylic acids. 1,3-Dimethyl-2-azafluorenone is obtained in ~90% yield from 2,6-dimethyl-4-phenylpyridine-3-carboxylic acid (by heating with sulphuric acid at 100°C) and in lower yield from the chloride of this acid (by treatment with aluminium chloride)[44-46]. The initial 2,6-dimethyl-4-phenylpyridine-3-carboxylic acid is obtained by the partial hydrolysis of diethyl 2,6-dimethyl-4-phenylpyridine-3,5-dicarboxylate with subsequent decarboxylation of the 5-ethoxycarbonyl-2,6-dimethyl-4-phenylpyridine-3-carboxylic acid[47], and also by Mayer's method from the nitrile (or ester) of β-aminocrotonic acid and benzylideneacetone[45,46,48-50]. The same dimethylazafluorenone is obtained by the decarboxylation of 1,3-dimethyl-9-oxo-2-azafluorene-4-carboxylic acid in liquid paraffin. The reduction of 1,3-dimethyl-2-azafluorenone with hydrazine hydrate (at 200°C) yields 1,3-dimethyl-2-azafluorene[44,45].



Dehydrocyclisation of the appropriate substituted pyridine-3-carboxylic acids yields 9-oxo-2-azafluorene-1-carboxylic acid and 7-methoxy(or hydroxy)-1,3-dimethyl-2-azafluorenone[44,51,52]. 2-Azafluorene itself (pyridofluorene) can be isolated by the decarboxylation of 2-azafluorene-1,3,4-tricarboxylic acid in the presence of soda-lime[51]. Condensation with conversion to the corresponding 2-azafluorenone could not be achieved with 2,6-dimethyl-4-*p*(or *m*)-nitrophenylpyridine-3-carboxylic acid. The condensation of 4-*o*-methoxyphenyl-2,6-dimethylpyridine-3-carboxylic acid yields 9,10-dihydro-1,3-dimethyl-10-oxo-9-oxa-2-azaphenanthrene[44,51,52].

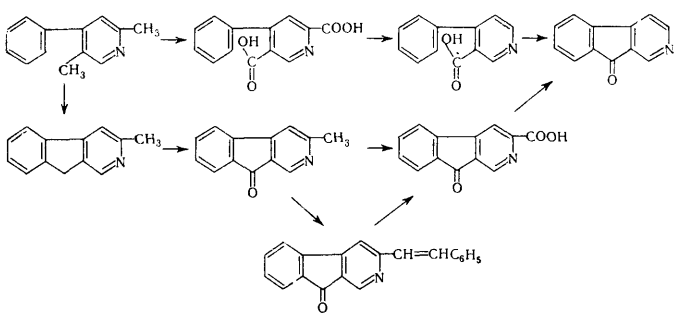
The cyclisation of 3-*o*-aminobenzoylpyridine has been accomplished in investigations of the mechanism of the Pschorr reaction. Ultraviolet irradiation in acid solution was used, the products being 2-azafluorenone (26.2%) and 4-azafluorenone (36.8%)[53]:



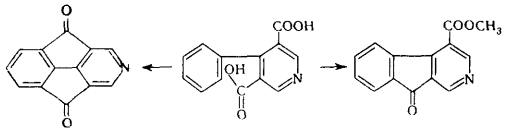
3-Mesitoyl(or duroyl)pyridine reacts with phenylmagnesium bromide to form compounds corresponding to dihydrophenylated 3-mesitoyl(or duroyl)pyridine. On dehydrogenation they yield 3-mesitoyl(or duroyl)-4-phenylpyridine, which when heated (185–200°C at 25 mm) is converted into 2-azafluorenone in 50% yield[54].

4-Aryldimethylpyridines have also been used in the synthesis of substituted 2-azafluorenes. Such systems can be obtained in two ways from 2,5-dimethyl-4-phenylpyridine. Oxidation of the pyridine base and partial decarboxylation of the resulting 4-phenylpyridine-2,5-dicarboxylic acid led to the preparation of 4-phenylpyridine-3-carboxylic acid, cyclisation of which yielded 2-azafluorenone[23].

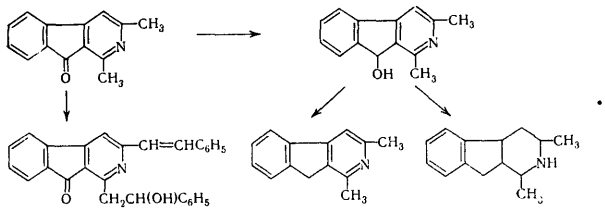
The second route consists in the dehydrocyclisation of 4-aryl-2,5-dimethylpyridines on dehydrogenation catalysts at 500–520°C. The 3-methyl-2-azafluorene obtained from 2,5-dimethyl-4-phenylpyridine in this way was converted into 3-methyl-2-azafluorenone, into 9-oxo-2-azafluorene-3-carboxylic acid, and into 2-azafluorenone[55]:



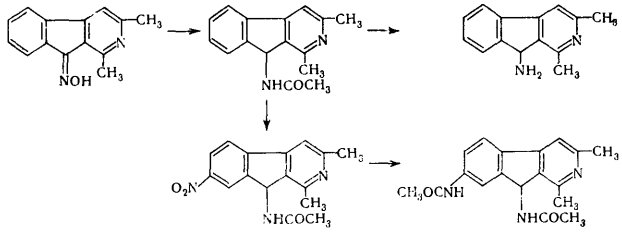
The dehydrocyclisation of 2,5-dimethyl-4-*p*-tolylpyridine yields 3,7-dimethyl-2-azafluorene, which has been converted into 3,7-dimethyl-2-azafluorenone[56]. When 4-phenylpyridine-3,5-dicarboxylic acid undergoes dehydrocyclisation, methyl 9-oxo-2-azafluorene-4-carboxylate is obtained together with a small quantity of 3-azatetracyclo-[9,2,1,$0^{5,13}$,$0^{7,12}$]tetradeca-2,4,7,9,11,13-hexaene-6,14-dione[57]:



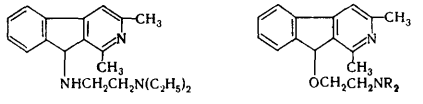
There are indications that derivatives of 1,3-dimethyl-2-azafluorene exert a spasmolytic action. 1,3-Dimethyl-2-azafluorenone has been subjected to several chemical transformations in order to obtain physiologically active substances. Its reduction with zinc dust in an aqueous-alcoholic solution of ammonia gave 1,3-dimethyl-2-azafluorenol (identified as the picrate), which on further reduction with sodium in alcohol was converted into hexahydro-1,3-dimethyl-2-azafluorene and 1,3-dimethyl-2-azafluorene. Condensation of 1,3-dimethyl-2-azafluorenone with benzaldehyde in the presence of zinc chloride gives 1-2′-hydroxyphenethyl-3-styryl-2-azafluorenone:



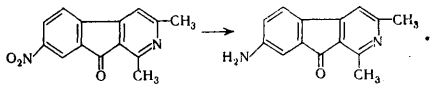
1,3-Dimethyl-2-azafluorenone oxime is reduced by zinc dust in acetic acid or anhydride to 1,3-dimethyl-2-azafluorene and 9-acetamido-1,3-dimethyl-2-azafluorene. The latter could be hydrolysed by treatment with phosphoric acid at 200°C. The resulting 9-amino-1,3-dimethyl-2-azafluorene is a strong base, which actively absorbs carbon dioxide from the air. 9-Acetamido-1,3-dimethyl-2-azafluorene can be nitrated, the nitro-derivative obtained in quantitative yield being assumed to have the structure 9-acetamido-1,3-dimethyl-7-nitro-2-azafluorene. Reduction of this product with zinc dust in acetic anhydride yields (presumably) 7,9-diacetamido-1,3-dimethyl-2-azafluorene[44,51].



9-2′-Diethylaminoethylamino-1,3-dimethyl-2-azafluorene, obtained from 9-amino-1,3-dimethyl-2-azafluorene and 2-diethylaminoethyl chloride, is similar in structure to Antergan[58]. Other derivatives of 2-azafluorene, the 9-2′-dialkylaminoethoxy-1,3-dimethyl-2-azafluorenes, resemble Dimedrol, and have been prepared from 1,3-dimethyl-2-azafluorenol and the corresponding dialkylaminoethyl chlorides (by heating with sodamide in benzene):



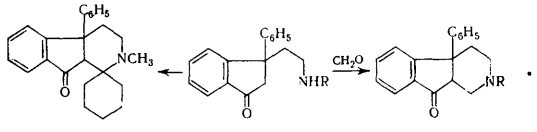
The nitration of 9-acetamidofluorene with fuming nitric acid yields two nitro-derivatives—9-acetamido-2,7(and 2,5)-dinitrofluorenes—which have been oxidised to the corresponding dinitrofluorenones[59]. The nitration of 1,3-dimethyl-2-azafluorenone gives a good yield of a mononitro-derivative, which by analogy with the nitro-derivative formed by the nitration of fluorenone itself under similar conditions, is assumed to be 1,3-dimethyl-7-nitro-2-azafluorenone. This nitro-derivative is reduced to 7-amino-1,3-dimethyl-2-azafluorenone, in which the amino-group exhibits an imino-character[48]:



The isomeric 4-amino-1,3-dimethyl-2-azafluorenone is obtained by Hofmann's reaction from 4-carbamoyl-1,3-dimethyl-2-azafluorenone. It did not prove possible to effect the conversion from ethyl 5-amino-2,6-dimethyl-4-phenylpyridine-3-carboxylate, through the 5-diacetylamino- and 5-benzamido-2,6-dimethyl-4-phenylpyridine-3-carboxylic acid (cyclisation in the presence of sulphuric acid), to a 4-amino-1,3-dimethyl-2-azafluorenone substituted in the amino-group[48].

When 3-benzoyl-1,2,5,6-tetrahydro-1-methyl-4-phenylpyridine is treated with hydrazine hydrate in the presence of sodium methoxide (in triethylene glycol at 190°C), 3-benzyl-1,2,5,6-tetrahydro-1-methyl-4-phenylpyridine is formed, and in the form of its hydrochloride has been subjected to cyclisation (with polyphosphoric acid at 130°C). Chromatographic separation of the reaction products on aluminium oxide led to the isolation of a partly hydrogenated substituted 2-azafluorene—racemic 1,2,3,4,4a,9a-hexahydro-2-methyl-4a-phenyl-4*H*-indeno[2,1-*c*]pyridine.

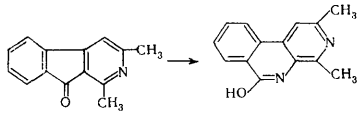
Analogous partly hydrogenated 2-azafluorene systems have been obtained by the Wolff–Kishner reduction of 1,2,3,4,4a,9a-hexahydro-6-methoxy-2-methyl-9-oxo-4a-phenylindeno[2,1-*c*]pyridine and by reducing 1,2,3,4,4a,9a-hexahydro-9-oxo-4a-phenyl-2-propyl(or cyclopropyl)-indeno[2,1-*c*]pyridine with zinc. In one of the procedures the initial oxo-derivatives are obtained by condensing *N*-methyl(propyl, or cyclopropyl)-2-(3-oxo-1-phenylindan-1-yl)ethylamine with formaldehyde in acid medium:



When a mixture of *N*-methyl-2-(3-oxo-1-phenylindan-1-yl)-ethylamine and cyclohexanone is treated with aluminium isopropoxide in toluene, spirocyclohexane-1,1′-1,2,3,4,4a,9a-hexahydro-2-methyl-9-oxo-4a-phenylindeno[2,1-*c*]pyridine is obtained, and the spirocycloheptane analogue is obtained in the same way[60].

Among compounds containing a partly hydrogenated 2-azafluorene system, 2,3,4,9-tetrahydro-2-methyl-9-phenyl-1*H*-indeno[2,1-*c*]pyridine (Phenindamine, Tephorin) has been proposed as an antihistamine preparation[61].

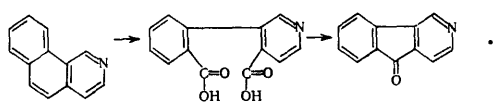
The possibility has been studied of passing from the 2-azafluorene to the diazaphenanthrene system. Beckmann expansion of the ring, with 1,3-dimethyl-2-azafluorenone oxime as starting material, could not be accomplished. Application of the Schmidt reaction to the ketone gave 9-hydroxy-1,3-dimethyl-2,10-diazaphenanthrene, the structure of which was proved by comparison with the analogous substance formed by the oxidation of 1,3,9-trimethyl-2,10-diazaphenanthrene with chromic acid[48]:



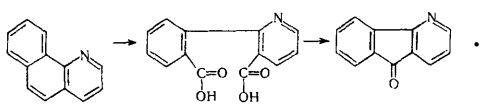
Ethyl 1,3-dimethyl-9-oxo-2-azafluorene-4-carboxylate has been converted by the Schmidt rearrangement into a

35% yield of ethyl 9-hydroxy-1,3-dimethyl-2,10-diazaphenanthrene-4-carboxylate, some of whose reactions and whose structure have been studied.

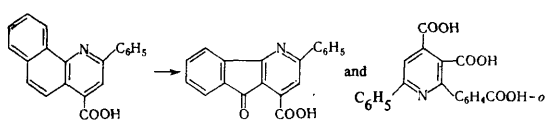
There are indications that compounds of the 3-azafluorene series possess sedative, neuroleptic, and adrenolytic activity[62]. However, very little work has been done on 3- and 4-azafluorenes. Benzo[*h*]isoquinoline has been used to obtain 3-azafluorenone itself. 3-Phenylpyridine-4,*o*-dicarboxylic acid was isolated from its oxidation, and thermal condensation of this compound led to 3-azafluorenone[38]:



4-Azafluorenone has been obtained in a similar way from 2-phenylpyridine-3,*o*-dicarboxylic acid, which was isolated from the oxidation of benzo[*h*]quinoline:

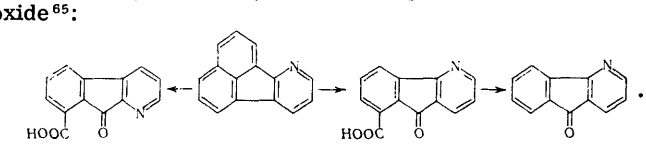


A small quantity of 9-oxo-3-phenyl-4-azafluorene-1-carboxylic acid is formed together with 2,6-diphenylpyridine-3,4,*o*(2)-tricarboxylic acid by the oxidation of 2-phenylbenzo[*h*]quinoline-4-carboxylic acid[63]:

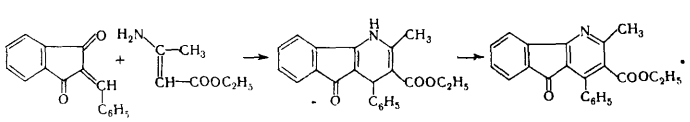


In a similar manner 9-oxo-4-azafluorene-1,3-dicarboxylic acid has been obtained from benzo[*h*]quinoline-2,4-dicarboxylic acid, and 9-oxo-1-azafluorene-2,4-dicarboxylic acid from benzo[*f*]quinoline-1,3-dicarboxylic acid[64].

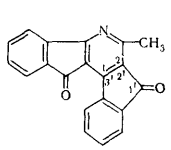
The oxidation with potassium permanganate of 10-azafluoranthene, isolated by the fractional distillation of coal-tar pitch, yields a mixture of 9-oxo-1(and 4)-azafluorene-8-carboxylic acids, from the latter of which 4-azafluorenone is obtained by decarboxylation in the presence of calcium oxide[65]:



Condensation of 2-benzylideneindane-1,3-dione with ethyl β-aminocrotonate produces ethyl 1,4-dihydro-3-methyl-9-oxo-1-phenyl-4-azafluorene-2-carboxylate, which after oxidation with chromic acid in acetic acid is converted into ethyl 3-methyl-9-oxo-1-phenyl-4-azafluorene-2-carboxylate:



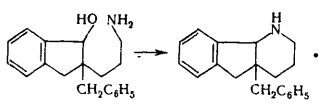
Hydrolysis of this ester (by heating it with concentrated sulphuric acid) leads to further condensation, with the formation of 3-methyl-4-azaindeno(3′,2′ : 1,2)fluorene-1′,9-dione



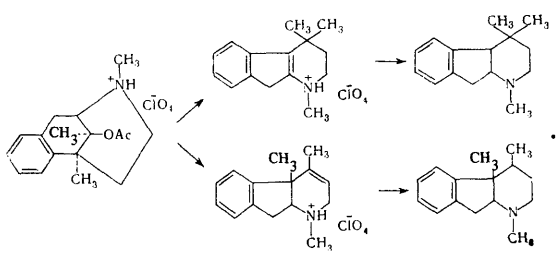
Various substituted 1-aryl-4-azafluorenones have been obtained by the method used to synthesise ethyl 3-methyl-9-oxo-1-phenyl-4-azafluorene-2-carboxylate. The oxime of this ester has been converted into the 9-diacetylamino- and 9-acetamido-derivatives[66]. 2-Aminopropenyl methyl and phenyl ketones and β-aminocinnamonitrile have also been used for condensation with benzylideneindane-1,3-dione, the products being respectively 2-acetyl- and 2-benzoyl-3-methyl-1-phenyl-4-azafluorenones and 2-cyano-1,3-diphenyl-4-azafluorenone. An attempt to prepare 1-alkyl-4-azafluorenones in a similar manner was unsuccessful.

α-(1,3-Dioxoindan-2-yl)benzylmalonamide has been cyclised to 1,2,4-trihydro-3,9-dioxo-1-phenyl-4-azafluorene-2-carboxyamide, from which saponification followed by decarboxylation yielded 1,2,3,4-tetrahydro-1-phenyl-4-azafluorene-3,9-dione[67].

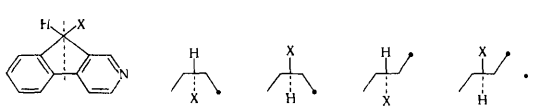
A partly hydrogenated substituted 4-azafluorene system, 4a-benzyl-1,2,3,4-tetrahydro-5*H*-indeno[1,2-*b*]pyridine, has been isolated by the condensation of 2-2′-aminopropyl-2-benzylindan-1-ol, this being obtained by the hydrogenation of 2-benzyl-2-2′-cyanoethylindan-1-one:



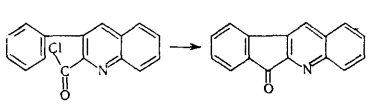
Information on the preparation of 1-azafluorene derivatives is extremely sparse. A partly hydrogenated substituted 1-azafluorene is obtained by the pyrolysis of the perchlorate of 9-acetoxy-2,5,9-trimethyl-6,7-benzomorphan. The perchlorates of 1,2,3,4-tetrahydro-1,4,4-trimethyl-9*H*-indeno[2,1-*b*]pyridine and 1,2,4a,9a-tetrahydro-1,4,4a-trimethyl-9*H*-indeno[2,1-*b*]pyridine were isolated, and were then hydrogenated in the nitrogen-containing ring[68,69]:



Papers on the stereochemistry of substituted azafluorenes are almost completely lacking. It has been suggested[52] that 9-substituted azafluorenes may have four geometrical isomers owing to a non-planar structure:

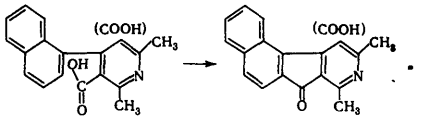


Intramolecular cyclisation is the principal method employed in the synthesis of azabenzofluorene structures. Application of the Friedel–Crafts reaction to 3-phenylquinoline-2-carbonyl chloride (in nitrobenzene) yields 1-aza-2,3-benzofluorenone[70]:

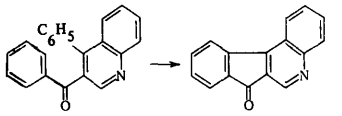


1,3-Dimethyl-2-aza-5,6-benzofluorenone has been obtained from 2,6-dimethyl-4-naphth-1′-ylpyridine-3-carbonyl

chloride and also from 2,6-dimethyl-4-naphth-1′-ylpyridine-3,5-dicarboxylic acid, 1,3-dimethyl-9-oxo-2-aza-5,6-benzofluorene-4-carboxylic acid also being isolated in the latter case[44]:

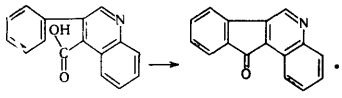


3-Benzoyl-4-phenylquinoline and also 3-mesitoyl-4-phenylquinoline are cyclised under the influence of polyphosphoric acid to 2-aza-3,4-benzofluorenone[54]:

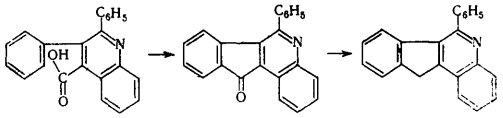


The same azafluorenone is obtained by the cyclisation of 4-phenylquinoline-3-carboxylic acid[71].

3-Aza-1,2-benzofluorenone can be synthesised by the condensation of 3-phenylcinchoninic acid by means of sulphuric acid[70]:

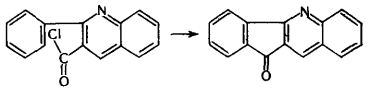


Analogous 4-alkylated (or 4-phenylated) azabenzofluorenones are obtained from 2-substituted 3-phenylcinchoninoyl chlorides by the Friedel–Crafts reaction and also from the acids themselves[43,71]. An example is the synthesis of 4-phenyl-3-aza-1,2-benzofluorenone from 2,3-diphenylcinchoninic acid:

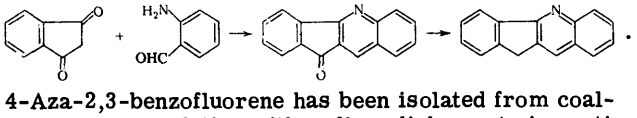


Conversion to azafluorene structures is accomplished by means of hydrazine hydrate or by reduction with tin in a mixture of acetic and hydrochloric acids.

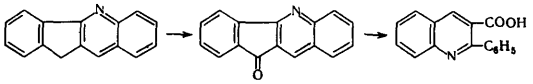
2-Phenylquinoline-3-carboxylic acid and also its chlorides are used in the synthesis of 4-aza-2,3-benzofluorenone[71]:



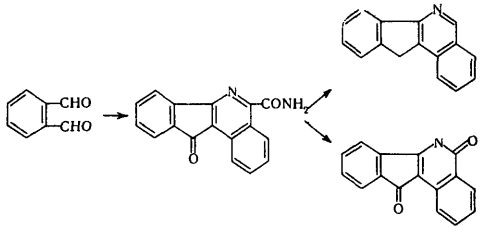
4-Aza-2,3-benzofluorenone is also obtained by condensing *o*-aminobenzaldehyde with indane-1,3-dione, and is then reduced with zinc dust to 4-aza-2,3-benzofluorene[72]:



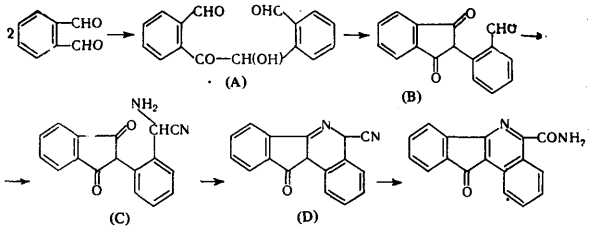
4-Aza-2,3-benzofluorene has been isolated from coal-tar pitch. Its oxidation with sodium dichromate in acetic acid yielded 4-aza-2,3-benzofluorenone. In molten caustic potash the latter is converted into 2-phenylquinoline-3-carboxylic acid[65]:



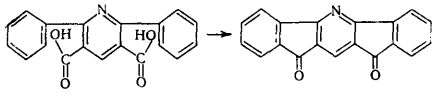
Treatment of phthalaldehyde with sodium cyanide gives a low yield of 9-oxo-4-aza-1,2-benzofluorene-3-carboxyamide. Hydrolysis of the latter with hydrochloric acid, followed by reduction with zinc in acetic acid, led to 4-aza-1,2-benzofluorene, oxidation of which with copper sulphate in pyridine yielded 11-oxoindeno[1,2-*c*]isocarbostyryl[73]:



The mechanism suggested for this reaction is that treatment of phthalaldehyde with sodium cyanide involves initially a normal benzoin condensation (A). Intramolecular condensation then yields an indanedione structure (B), the free aldehyde group of which is attacked by cyanide and ammonia with conversion into an amino-nitrile grouping (C). This latter undergoes cyclisation with formation of the dihydroisoquinoline system (D). On oxidation with atmospheric oxygen hydrolysis takes place, with formation of the final product—9-oxo-4-aza-2,3-benzofluorene-3-carboxyamide (1-carbamoyl-11-oxoindeno[1,2-*c*]isoquinoline).

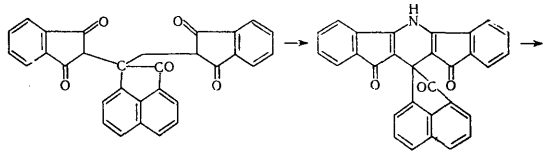


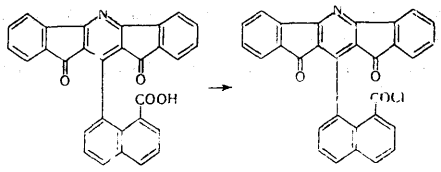
Pentacyclic fused ring systems containing nitrogen, belonging to azafluorene systems, have been obtained by the intramolecular condensation (double cyclisation) of diphenylated 3,5-dicarboxylic acids. Thus 2,6-diphenylpyridine-3,5-dicarboxylic acid yields 2,3 : 5,6-dibenzoylenepyridine[45]:



Similarly, 6-methyl-2,3 : 4,5-dibenzoylenepyridine has been synthesised from 6-methyl-2,4-diphenylpyridine-3,5-dicarboxylic acid[49,66].

An azafluorene compound of this type is a preparation termed Dibepyne, which is 8-(2,3(CO) : 6,5(CO)-dibenzoylenepyrid-4-yl)naphth-1-oyl chloride. Dibepyne is an analytical reagent for primary amines. The starting material in its synthesis is 2,2-di-indanedionylacenaphthen-1-one. When this interacts with ammonium acetate the nitrogen-containing ring closes, with the formation of acenaphthen-1-onespiro(2,4′)-2′,3′(CO) : 6′,5′(CO)-dibenzoylene-1′,4′-dihydropyridine. Subsequent treatment of this compound with hydrogen peroxide, followed by thionyl chloride, leads to the formation of Dibepyne[74–76]:





Several compounds have been synthesised which are analogous in structure to Dibepyne[77].

A Century of Mendeleev's Periodic Law

V.I.Spitsyn

At the beginning of March 1869 D.I. Mendeleev, Professor of Chemistry at the University of St. Petersburg, distributed among many Russian and foreign scientists sheets which depicted the system of the elements which he had worked out on the basis of their atomic weights and chemical similarity (Fig. 1).

Figure 1. First representation of D.I. Mendeleev's Periodic System of the elements (1869).

* Trial system of the elements based on their atomic weight and chemical similarity.

A lecture on this work by Mendeleev was given at a meeting of the Russian Chemical Society held on 18th March 1869, and in May of the same year his paper "Relationship between the Properties of Elements and their Atomic Weights" was published in the next issue of the Journal of the Russian Chemical Society[1]. This contained the first formulation of the Periodic Law: "The elements, when arranged in the order of their atomic weights, exhibit a clear periodicity of properties". A few years later Mendeleev gave a still more precise formulation of the Periodic Law: "The properties of the elements, as well as the structure and the properties of their compounds, vary periodically with the atomic weights of the elements".

The discovery of the Periodic Law and the associated natural system of the chemical elements was a consequence of Mendeleev's work on "The Principles of Chemistry", his famous textbook of inorganic chemistry, which he began to write in 1868. "It contains many original ideas..., the chief of which is the periodicity of the elements, which was actually discovered in working on 'The Principles of Chemistry'", as Mendeleev subsequently pointed out[2].

It is well known that attempts to classify the elements—to arrange them into groups and tables—had been made even before Mendeleev's time. Mention may be made of Döbereiner's triads (1829)—calcium, strontium, barium; sulphur, selenium, tellurium; etc.—which developed into Pettenkofer's groups (1850)—nitrogen, phosphorus, arsenic, antimony; magnesium, calcium, strontium, barium; etc.—Chancourtois's spiral (1862), the tables of Odling (1864) and Meyer (1864), and Newlands' octaves (1866). However, these works were devoted either to particular isolated questions of the similarity of groups of elements

Figure 2. Mendeleev's Periodic System of the elements (1872).

or to the search for relations between their atomic weights. None of these authors sought general relations between the properties of all known chemical elements; no-one before Mendeleev had formulated the Periodic Law.

It must be remarked that Mendeleev, although he stressed his view that "the value of the atomic weight determines the character of the element", considered that other characteristics of the chemical elements were also of fundamental importance. The chemical properties of the compounds formed were no less significant for determining the position of elements in the Periodic System. In some cases—cobalt and nickel, tellurium and iodine—the sequence of increasing atomic weight was disregarded in Mendeleev's table.

The outstanding scientific and philosophical value of Mendeleev's discovery consisted primarily in the establishment of an interrelationship between all the chemical elements, their physical and chemical properties. Groups and series in the Periodic System became a reliable basis for revealing families of related elements.

The first practical application of the Periodic Law was to correct the valencies and the atomic weights of certain elements, for which incorrect values had hitherto been accepted. This applied in particular to indium, cerium and other rare-earth metals, thorium, and uranium. Indium had been regarded as a bivalent element, and on the basis of its atomic weight (75.6)† was located between arsenic and selenium, although clearly not resembling them in properties. Measurement of the heat capacity of metallic indium, together with a detailed examination of the properties of its compounds, led Mendeleev to the conclusion that indium must be regarded as tervalent in its higher state of oxidation. Its atomic weight then became 113, and indium found a place in Group III of the Periodic System between cadmium (112) and tin (118), in full agreement with its chemical properties. However, this position had originally been occupied by uranium, which had been assumed to be a tervalent element having an atomic weight of 116. Mendeleev soon came to the conclusion that uranium was closer to molybdenum and tungsten than to aluminium in chemical properties, doubled the atomic weight of uranium, and placed it in Group VI of the Periodic System.

Mendeleev adduced similar considerations to justify the tervalency of the ceritic elements (lanthanum, etc.), which many chemists regarded as bivalent. He assigned the formula CeO_2 to the higher oxide of cerium, and ThO_2 (instead of ThO) to that of thorium. Hence new values were calculated for the atomic weights of these elements.

This work, of course, was by no means easy. It must be remembered that no methods were then available for measuring directly the atomic weights of elements; only Dulong and Petit's law of atomic heats gave some assistance in this direction. The great expert on the chemistry of the rare-earth metals K. Rammelsberg objected to Mendeleev's proposed changes in the atomic weights of cerium, didymium, and lanthanum, while Lothar Meyer considered that in general "it would be rash to alter the hitherto accepted atomic weights on such an unreliable basis", by which he meant the Periodic Law.

Mendeleev's view that the atomic weights of the platinum metals should be corrected so that they would increase—not diminish—in the sequence osmium–iridium–platinum (as followed from old analytical results) was soon confirmed. However, his suggestion that the atomic weight of tellurium should be lower than that of iodine was not justified, the reason for this depending, as we now know, on the nature of the isotopes of these two elements, not on the chemical properties of their atoms. In spite of the apparent inconsistency with the main rule on which the Periodic System was constructed—the arrangement of the elements in order of increasing atomic weight—Mendeleev left tellurium in Group VI, and iodine in Group VII, on the basis of their valency and chemical properties.

Thus as a result of intense creative work, overcoming immense difficulties, Mendeleev produced within a short time (less than two years) essentially the same Periodic System of the chemical elements as we continue to use nowadays (Fig. 2).

† Here and subsequently atomic weights of that time are indicated.

Nevertheless, there were clearly several unfilled positions in the Periodic System, and in the first publication on the Periodic Law Mendeleev already expressed the view that many then unknown elements existed, examples of which, for instance, should resemble aluminium and silicon, and have atomic weights of 65–75. Mendeleev was profoundly convinced that the best evidence that the main principles of the Periodic Law were correct was the fulfilment of predictions based on it. Two years after the discovery of this periodicity, therefore, he published a paper[3] in which he predicted in detail the physical and chemical properties of some hitherto undiscovered elements. "I have decided to do this so that, at least in time, when one of these bodies which I have predicted has been discovered, it will be possible finally to convince other chemists and myself of the rightness of the hypotheses underlying my proposed system". The most detailed examination was given to the expected properties of unknown analogues of boron, aluminium, and silicon, which were provisionally named by Mendeleev "ekaboron", "eka-aluminium", and "ekasilicon"‡.

The elements predicted by Mendeleev were very soon discovered. In 1875 the French chemist P. Lecoq de Boisbaudran discovered in a Pyrenean zinc blende a new element gallium, the properties of which coincided with those indicated by Mendeleev for eka-aluminium. In 1879 the Swedish chemist L. Nilson, while studying ytterbia earths, isolated from the Scandinavian minerals gadolinite and euxenite a new rare-earth element scandium, which proved to be ekaboron. In 1886 the German chemist C. Winkler, in analysing the mineral argyrodite, discovered in it a new element germanium, whose properties coincided extraordinarily closely with those predicted by Mendeleev for ekasilicon (Table 1). Winkler wrote: "It is hardly possible to find a more striking demonstration of the correctness of the concept of periodicity than the realisation of the hypothetical ekasilicon in the newly discovered element. This is not simply support for a daring theory: here we see an obvious extension of the chemical horizon, a powerful step in the field of knowledge".

Mendeleev described more briefly the expected properties of undiscovered analogues of manganese, tellurium, caesium, barium, lanthanum, and tantalum. Some of these elements—radium, actinium, and polonium—were discovered during his lifetime, and the others—technetium, rhenium, francium, and protactinium—only in the twentieth century.

At the end of the nineteenth century the Periodic System was subjected to a severe test, from which it emerged victorious. After Rayleigh and Ramsay had discovered argon in the air (1894), it appeared that this element could not find a place in the Periodic System. However, Ramsay's subsequent discovery of helium (in the gas expelled from the mineral cleveite) showed that a group of elements similar to argon existed.

In 1897 Ramsay gave a lecture on "A Still Undiscovered Gas". As he himself pointed out subsequently, in this lecture "following the example of our teacher Mendeleev, I described, as far as it was possible, the properties expected for and the presumable relations of the gaseous element which would fill the gap between helium and argon". Ramsay soon isolated this gas, of atomic weight 20, from liquid air, and called it *neon*. Heavy analogues of argon—krypton and xenon—were discovered almost simultaneously. According to the researches of that time all these elements were characterised by inertness—inability to enter into ordinary chemical reactions of oxidation and reduction—and the family of inert gases therefore found a place in the Periodic System as the newly formulated Group 0. In 1900 the radioactive element radon (radium emanation), discovered by A. Debierne, was added to this group.

‡ Here *eka* (Sanskrit) = "one" is used in the sense of the first adjacent analogue.

Table 1. Properties of germanium predicted and found.

Property	Predicted for ekasilicon	Found for germanium
Atomic weight	Es = 72	Ge = 72.60
Valency	quadrivalent, but can exhibit also a lower valency	4 and 2
Free element		
Atomic volume	about 13	13.5
Specific gravity	about 5.5	5.36
Fusibility and volatility	"fusible metal, able to volatilise at a high temperature"	b.p.958.5°C m.p.2700°C
Highest oxide	EsO_2	GeO_2
Molecular volume	about 22	22.2
Specific gravity	4.7	4.703
Chemical properties	acidic and extremely weakly basic	amphoteric with acidic properties predominating
Highest chloride	$EsCl_4$	$GeCl_4$
Boiling point	close to 90°C	83.1°C
Specific gravity	about 1.9	1.874
Chemical properties	decomposed by water	readily hydrolysed by water
Hydrogen compounds	"a hydrogen compound can also be greatly expected" "EsH_4 should decompose readily into hydrogen and the metal"	GeH_4 and other germanium hydrides obtained GeH_4 decomposes at 350°C
Organometallic compounds	"it will, of course, form organometallic compounds"	many organometallic compounds of germanium
$(C_2H_5)_4R$, b.p.	160°C	163.5°C
$(C_2H_5)_4R$, sp. gr.	0.96	0.99

The discovery of elements predicted by Mendeleev, the exact coincidence of their properties with those calculated on the basis of the Periodic Law, and the confirmation of the corrections made by Mendeleev to atomic weights—all this reinforced the materialist view of the chemical elements, and immeasurably extended the possibilities of the understanding of Nature by man. The Periodic System became a powerful weapon for use by research workers in the further development of chemistry and physics.

Various properties of the chemical elements and their compounds began to be correlated on the basis of the Periodic Law. In 1869 Mendeleev demonstrated periodicity in the structure of compounds formed by elements, i.e. in the most important chemical property, the valency. He even established periodicity in the specific gravities and atomic volumes of elements. Other workers showed that the melting points of elements vary periodically, and this was noted also for the melting points of metal chlorides. The quantity of heat involved on formation of chlorine, bromine, and iodine compounds was found to vary periodically with increasing atomic weight of the elements interacting with the halogens.

In 1889 Mendeleev directed attention also to the periodicity of structure of the spectra of elements as a function of their atomic weights. A relation was observed between the position of elements in the Periodic System and their

magnetic properties. Investigations of copper alloys by A. A. Baikov (1902) showed the applicability of periodicity principles to the composition of the intermetallic compounds formed in alloys.

For many years after the discovery of the Periodic Law Mendeleev continued to improve the appearance of his table, using both short and long forms. Fig. 3 shows the last table drawn up by Mendeleev not long before his death in 1907.

Even during Mendeleev's lifetime the Periodic Law and the system of elements based on it achieved immense success. However, several sites in the system still remained obscure. It was unknown whether elements should exist between hydrogen and helium, and the number of rare-earth elements, as also their position in the Periodic System, was indefinite. In view of all these difficulties it was impossible to compute the total number of elements between hydrogen and uranium. The actual

cause of the periodicity was obscure. One must be amazed by the genius of Mendeleev, who was able to set up the Periodic System of the elements in the almost complete absence of information on the structure of matter, and to set it up in such a way that even after a century it has not required any fundamental changes.

Since Mendeleev's death the Periodic Law has exerted an immense influence on the development of the work of physicists and chemists on the structure of matter.

---o0o---

We must first note the part played by the Periodic System in unravelling the phenomenon of radioactivity and elucidating the nature of isotopes. The discovery by Becquerel in 1896 of "uranium rays" with their remarkable properties led to many investigations in this new branch of science. Another heavy element, thorium, also proved to be radioactive. In 1898 Marie and Pierre Curie discovered in uranium ores two new elements—radium and polonium—exhibiting still stronger radioactivity than uranium. They isolated a pure preparation of radium from residues from the processing of uranium ore. This element proved to be an analogue of barium, and corresponded in properties to Mendeleev's ekabarium. The properties of polonium were very close to those of ekatellurium.

In 1899 Debierne discovered yet another radioactive element, actinium, an analogue of lanthanum. The existence of this element had been predicted by Mendeleev as early as 1871.

It was established in 1900 that radium preparations evolve continuously a radioactive gas—radium emanation—which proved to be analogous to xenon in Group 0 of the Periodic System, and is now called *radon*. A remarkable property of radon is its rapid disintegration, which is half complete in 3.85 days. Ramsay and Soddy discovered in 1902 that, after radium emanation has been sealed in a discharge tube for some time, it begins to show the spectrum of helium. This was the first experimentally proved case of the transmutation of elements.

Mendeleev referred very doubtfully to the possibility of the interconversion of elements, pointing out that all reports of this kind require especially careful checking and usually are not confirmed. Nevertheless, he regarded himself as "not an opponent, but rather inclined to accept the concept of the complexity of elements". He wrote (1898) that "it would be extremely interesting to be present when data are established to prove the interconversion of elements, because I could then hope that the cause of the periodic regularity would be discovered and understood". As we shall see, the development of science made this task urgent within a few years.

In 1902, on the basis of a detailed study of the radioactivity of thorium, Rutherford and Soddy put forward the hypothesis that radioactive phenomena are due to transformations of atoms and hence of elements. Subsequent investigations completely confirmed this suggestion.

The study of radium emanation showed that the so called "active residue" remaining after its disintegration contained several elements differing from one another in radioactive properties, i.e. in the character and energy of the emission. Many radioactive elements were detected in studying the changes undergone by uranium, actinium, and thorium.

Only a proportion of the newly discovered radioactive elements could be placed in empty positions in the Periodic System. Examination of a large number of the radioactive elements which were members of the various radioactive series established that many of them, while differing in radioactive properties, could not be separated from one another or from certain ordinary elements by chemical methods. For example, one of the products of the disintegration of uranium—the radioactive element ionium—while differing in its radioactivity from thorium could not be distinguished from it chemically. One of the initial products in the disintegration of thorium—the so called radiothorium—disintegrated immeasurably more rapidly than thorium, but chemically was completely identical with it. It thus appeared that many newly discovered radioactive elements did not differ in chemical properties from uranium, thorium, radium, lead, bismuth, and other elements in the last two rows of the Periodic System. Hence one chemical element corresponded to more than one type of atoms, differing in mass and in rate of radioactive disintegration.

In 1913 Soddy suggested the name *isotopes* ("isos" = same, "topos" = place) for such varieties of elements, to indicate that they occupy the same place in the Periodic System.

The numerous radioactive elements formed in the disintegration of uranium, thorium, or actinium were now combined into series strictly related to Mendeleev's Periodic System. Each α-emission gave a product which was an isotope of an element located two places nearer to the beginning of the Periodic System. As a result of β-disintegration an element was obtained one place closer to the end of the system. This so called Fajans displacement law enabled many new radioactive elements to be discovered, and introduced order into obscure positions in radioactive series.

Electromagnetic analysis of a beam of canal rays by Thomson in 1913 yielded, with neon as example, the first information on the existence of isotopes of non-radioactive elements. Aston's development of the design of the mass spectrograph enabled isotopes of several ordinary elements to be detected.

The phenomenon of isotopy gave a additional content to the Periodic System. The ideas of A. M. Butlerov, W. Crookes, and other scientists on the possibility of varieties of atoms of the same element, differing in mass, were brilliantly confirmed. Furthermore, the subsequent observation of an appreciable difference in chemical properties between the isotopes of hydrogen opened a new chapter in science—the chemistry of isotopes, closely connected with the Periodic System.

---o0o---

The discovery of the phenomena of radioactivity and the vigorous development of atomic physics at the beginning of the twentieth century led, as is known, to the nuclear theory of atomic structure (Rutherford 1911), the discovery of the law relating the wavelengths of the characteristic X-ray spectra of elements to the charges on their atomic nuclei (Moseley 1913), and the working out of the principles underlying the quantum theory of atomic structure (Bohr 1913). The Periodic Law had an extraordinary influence on the development of these scientific trends, since it gave investigators a natural system of chemical elements with all the structural regularities of atoms latent in it.

On the other hand, the contemporaneous theory of atomic structure explained the reasons for the phenomenon of periodicity itself, and improved still further the methods for predicting the properties of unknown elements. The

experimental determination of the charges on atomic nuclei, based on Moseley's law, was especially important. It provided an exact method for determining the atomic numbers of the elements in the Periodic System and establishing the total number of elements between hydrogen and uranium. The correctness of the arrangement of all the elements in Mendeleev's table was confirmed. The atomic number of iodine (53) proved to be higher than that of tellurium (52). In 1914 empty spaces remained in the Periodic System at Nos. 43, 61, 72, 75, 85, 87, and 91, of which Nos. 61, 72, 75, and 85 belonged to the third long period.

The theory of atomic structure explained the peculiar position in the Periodic System of the rare-earth metals which follow lanthanum in the third long period. It turned out that, in this part of the system, successive electrons in the atoms of elements beginning with cerium enter a lower electron shell of the fourth energy level at the 4*f*-sublevel, which may contain up to fourteen electrons and is completed at lutetium. The number of valency electrons remains unchanged, being three as in lanthanum. At the present time, therefore, it is usual to group the elements in the cerium–lutetium family under the name *lanthanides*. They fit into the same space as lanthanum, and are listed as a separate series below the table.

Table 2. Structure of electron shells in atoms of rare-earth metals.

Note. *n* is the principal quantum number; *K*, *L*, *M* are energy levels in the atoms; *s*, *p*, *d*, *f* are groups of electrons.

The structure of the electron shells in atoms of the rare-earth metals, based on present-day results, is set out in Table 2. It is seen that two valency electrons of the lanthanides belong to the 6*s*-sublevel, while the third is usually detached from the 4*f*-sublevel and is located in the 5*d*-sublevel only for a few members of this series. At the start of formation of the 4*f*-shell the electrons in it are not very firmly bound. As a consequence cerium, praseodymium, and probably neodymium are capable of forming compounds in which they are quadrivalent. After this the increasing charge on the nucleus strengthens the structure of this shell. It must be added that the shell is apparently completed in two layers, each comprising seven electrons. Ability to form compounds of higher valency is therefore exhibited also by terbium, which is characterised by completion of the second layer. The elements preceding gadolinium (samarium, europium) and lutetium (ytterbium), on the other hand, may approach a more stable configuration by splitting off a smaller number of electrons, and are therefore bivalent under certain conditions.

Subsequent investigations established an important rule for the variation in size of the lanthanide atoms [4]. Electrons entering the inner 4*f*-layer do not completely screen the increasing nuclear charge. The electrons in the outer shells are therefore drawn towards the nucleus, and the overall size of the atom diminishes (lanthanide contraction). The ionic radii for the rare-earth metals in the tervalent state are given below.

Ionic radius, Å

Sc	Y	La	Ce	Pr	Nd	Pm	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	Lu
0.68	0.88	1.04	1.02	1.00	0.99	(0.98)	0.97	0.96	0.94	0.92	0.91	0.89	0.87	0.86	0.85	0.8

The phenomenon of the lanthanide contraction results in a weakening of the basic properties of the hydroxides in the sequence lanthanum–lutetium. Whereas lanthanum hydroxide is similar in properties to strontium hydroxide, lutetium hydroxide is a weak base, approaching in this respect the hydroxide of scandium, which is located far higher in the same group of the Periodic System. Dysprosium and holmium are similar to yttrium in this respect.

Thus the similarity in structure of the outer electron shell of the atoms and the lanthanide contraction converted scandium, yttrium, lanthanum, and the lanthanides into a closely intertwined tangle of elements, greatly resembling one another in properties and in natural occurrence. This in turn was responsible for all the difficulties involved in their separation, purification, and identification.

The theory of atomic structure made it clear that element No. 72, immediately following lutetium, should have two valency electrons in each of the sublevels 6*s* and 5*d*, and would therefore be quadrivalent, an analogue of zirconium, not a rare-earth metal. A search in zirconium preparations undertaken by G. Hevesy and D. Coster on this basis using X-rays proved successful, and in 1923 the element was discovered and named *hafnium* (Hf = 178.5). It is noteworthy that an analogue of zirconium of atomic weight 180 had been envisaged by Mendeleev in the very first form of his table (see above).

Thus the bundle of rare-earth elements in the Periodic System was disentangled. Elements which were missing from the Periodic Table at the time when Moseley's law was discovered were either isolated from natural minerals or synthesised by nuclear reactions within a fairly short period.

In 1918 L. Meitner and O. Hahn isolated the radioactive element No. 91, protactinium, from the processing wastes of a uranium ore. In 1925 W. Noddack, I. Tacke, and O. Berg detected element No. 75 in specimens of native platinum, tantalite, and molybdenite, and termed it *rhenium*. The discovery by these workers of element No. 43 was not subsequently confirmed. This latter element was found in 1937 by C. Perrier and E. Segrè in a sample of molybdenum which had undergone prolonged irradiation with a powerful beam of deuterons in a cyclotron. The nuclear reaction was represented by the scheme ${}_{42}\mathrm{Mo}(d, n)43$. After identification the element was named *technetium* to emphasise its artificial production. Considerable quantities of technetium were subsequently found in fission fragments from uranium, and it can be extracted from waste products of the atomic industry.

In 1939 Mlle Perey was studying the natural radioactive disintegration products from actinium, and found in them a radioactive isotope (half-life 21 min), similar in chemical behaviour to caesium. This proved to be element

No. 87—the ekacaesium predicted by Mendeleev—and was termed *francium*.

A radioactive isotope of ekaiodine—element No. 85 (half-life 7.5 h)—was discovered in 1940 by D. R. Corson, K. R. MacKenzie, and E. Segrè by bombarding bismuth with accelerated helium nuclei of energy 38 MeV. The process was represented by $^{209}_{83}Bi(^{4}_{2}He, 2n)^{211}85$. The name *astatine*, given to this element, is an indication of its instability.

Finally element No. 61, which had been unsuccessfully sought for a long time by many chemists in rare-earth preparations, was discovered in 1947 among the fission products of uranium. It was identified by J. A. Marinsky, L. E. Glendenin, and C. D. Coryell in the form of two radioactive isotopes having half-lives of 55 h and 2.6 years. The element acquired the name *promethium* in commemoration of the practical utilisation of atomic energy, which the authors compared with theft of fire by Prometheus.

Thus by 1947 all the places between hydrogen and uranium in the Periodic System had been filled.

Completely new problems facing the Periodic System arose in connection with the successful development of the synthesis of new heavy elements[5]. It is noteworthy that Mendeleev admitted the possibility of extending the Periodic System beyond uranium, and this suggestion of his has been justified.

The idea of synthesising transuranic elements became topical in the 1930s, when E. Fermi and his coworkers developed a method for the artifical production of radioactive isotopes by means of slow neutrons. In 1935 they detected in neutron-irradiated uranium several short-lived β-radioactive isotopes, one of which (half-life 13 min) was coprecipitated with manganese and rhenium, and was assumed to be an analogue of rhenium $^{239}_{93}$EkaRe. However, further investigations by L. Meitner, O. Hahn, and F. Strassmann showed that in these experiments many radioactive isotopes—fission products of uranium—are formed, which are coprecipitated with various elements. Among them a β-emitter was found (half-life 23 min), identical in chemical properties with uranium and assumed to be an isotope $^{239}_{92}U$. As a result of β-disintegration it should have been converted into element No. 93. However, these workers were unable to detect a new element here, owing to the weakness of the neutron source used.

Element No. 93, given the name *neptunium* (Np), was discovered by E. D. McMillan and P. H. Abelson in 1940 by irradiating thin layers of ammonium uranate with a powerful beam of neutrons obtained by bombarding a beryllium target with deuterons of energy 16 MeV in the large cyclotron at the University of California. Fragments arising from the fission of uranium were removed by the recoil phenomenon. Two types of β-activity, having half-lives of 23 min and 2.9 days, were detected in the uranium preparation. The nature of the first was known, being due to $^{239}_{92}U$. Conversion of the first into the second emitter served as proof of the formation of element No. 93. McMillan and Abelson concluded that neptunium was not an analogue of rhenium. It was found to have at least two states of oxidation, in the lower of which neptunium resembled the rare-earth metals, whereas in the higher state of oxidation it was similar to uranium.

The β-disintegration of neptunium must be expected to yield element No. 94, which was named *plutonium* (Pu). The first isotope of the latter $^{238}_{94}Pu$ (half-life 89.6 years) was synthesised at the end of 1940 by G. T. Seaborg, E. D. McMillan, J. W. Kennedy, and A. C. Wahl by bombarding uranium with deuterons in a cyclotron. The neptunium isotope $^{238}_{93}Np$ (half-life 2.1 days) was obtained as an intermediate product:

$$_{92}U^{238} + {}_{1}H^{2} = {}_{93}Np^{238} + 2n; \quad {}_{93}Np^{238} = {}_{94}Pu^{238} + \bar{\beta} \ .$$

The most important chemical properties of the new element and the principles of its separation from uranium were studied on tracer quantities of the above isotope. In its highest valency plutonium resembles uranium, but is more readily reduced. The properties of the compounds of lower valency recall thorium and the rare-earth metals. For military reasons the first information on plutonium was published only in 1946.

In 1941 a longer-lived isotope of plutonium ^{239}Pu (half-life 24 360 years), capable of fission by slow neutrons, was discovered after the prolonged bombardment of uranium with deuterons in a cyclotron. As a consequence of the above properties it subsequently acquired practical value as a form of atomic fuel.

Painstaking work on the irradiation of a few tens of kilogrammes of uranyl nitrate with neutrons in a cyclotron resulted by the end of 1942 in the isolation of 0.5 mg of plutonium in the form of pure compounds. These investigations were continued in the first laboratory uranium reactor, which became operative on 2nd December 1942 in the University of Chicago. At the same time planning went ahead for a pilot plant to isolate plutonium from uranium irradiated in the reactor, with an enrichment factor of 10^{10}, which was unprecedented in the chemical industry. The first factory-scale reactor was started up after a year. Less than seven weeks later an experimental separation plant began to operate, and plutonium was soon available to the research workers in gramme quantities. In September 1944 the first works began to operate to produce kilogrammes of plutonium. Thus less than three years elapsed between the first artificial separation of the new element and the organisation of its isolation on an industrial scale! Nowadays plutonium is manufactured in several countries, and its production is measured in many tons per annum.

The development of further investigations on the transuranium elements is due to the work of the distinguished American scientist Seaborg and his collaborators. During 1944–1955 seven further transuranium elements were discovered. Americium (Am, No. 95) was obtained by irradiating plutonium with neutrons; and curium (Cm, No. 96), berkelium (Bk, No. 97), and californium (Cf, No. 98) by the bombardment with high-energy helium ions of targets containing plutonium, americium, and curium respectively. Isotopes of einsteinium (Es, No. 99) and fermium (Fm, No. 100) were first detected when uranium was irradiated with a very intense instantaneous flux of neutrons during the thermonuclear explosion produced in 1952. Many repeated neutron captures resulted in the formation of very heavy isotopes of uranium, which then disintegrated with the emission of β-particles and the formation of several transuranium elements, including einsteinium and fermium. These elements were later synthesised by other routes. Element No. 101 was obtained by the action of high-energy (41 MeV) helium ions on einsteinium. In the first experiments seventeen atoms in all of the new element were identified from its conversion into fermium. The discoverers gave the name *mendelevium* (Md) to element No. 101 "in honour of the leading part played by the great Russian chemist Dmitrii Mendeleev, who was the first to use the Periodic System of the elements to predict the chemical properties of hitherto undiscovered elements—a principle which gives the key to the discovery of the last seven transuranic elements (actinides)...".

Table 3 indicates the nuclear reactions first used to obtain the transuranium elements, together with their discoverers.

The first information on the discovery of element No. 102 appeared in 1957. A group of research workers—P.R. Fields, J. Milsted, H. Atterling, et al.—irradiated a preparation from curium with carbon-13 ions:

$$_{96}Cm^{244}(C^{13}, 6n)\,102^{251} \quad \text{or} \quad _{96}Cm^{244}(C^{13}, 4n)\,102^{253}.$$

The products of the nuclear reaction had a half-life of about 10 min. The name *nobelium* (No) was proposed for the new element. However, these results were not confirmed when checked in Seaborg's laboratory.

Table 3. History of the discovery of the transuranium elements.

Element	Atomic No.	Year	Nuclear reactions	Discoverers
Np	93	1940	$_{92}U^{238}(n, \gamma)_{92}U^{239}$; $_{92}U^{239} = {}_{93}Np^{239} + \bar{\beta}$	E.D.McMillan and P.H.Abelson
Pu	94	1940	$_{92}U^{238}(H^2, 2n)_{93}Np^{238}$; $_{93}Np^{238} = {}_{94}Pu^{238} + \bar{\beta}$	G.T.Seaborg, E.D.McMillan, J.W.Kennedy, and A.C.Wahl
Am	95	1944	$_{94}Pu^{239} + 2n = {}_{94}Pu^{241}$; $_{94}Pu^{241} = {}_{95}Am^{241} + \bar{\beta}$	G.T.Seaborg, R.H.James, L.O.Morgan, and A.Ghiorso
Cm	96	1944	$_{94}Pu^{239}(_2He^4, n)_{96}Cm^{242}$	G.T.Seaborg, R.H.James, and A.Ghiorso

Es	99	1955	$_{92}U^{238} + 15n = {}_{92}U^{253}$; $_{92}U^{253} \xrightarrow[6\bar{\beta}]{} {}_{98}Cf^{253} \rightarrow {}_{99}Es^{253}$	A.Ghiorso, S.G.Thompson, G.H.Higgins, and G.T.Seaborg
Fm	100	1955	$_{92}U^{238} + 17n = {}_{92}U^{255}$; $_{92}U^{255} \xrightarrow[7\bar{\beta}]{} {}_{99}Es^{255} \xrightarrow{\bar{\beta}} {}_{100}Fm^{255}$	ditto
Md	101	1955	$_{99}Es^{253}(_2He^4, _1)_{101}Md^{256}$	A.Ghiorso, B.Harvey, G.Choppin, S.G.Thompson, and G.T.Seaborg
No?	102	1957	$_{96}Cm^{244}(C^{13}, 4n)\,102^{253}$; $_{96}Cm^{246}(C^{13}, 4n)\,102^{254}$; $_{94}Pu^{241}(_6O^{16}, 4n)\,102^{253}$	various workers
Lr	103	1961	$_{98}Cf^{252}(B^{11}, 6n)\,103^{257}$; $_{98}Cf^{250}(B^{10}, 3n)\,103^{257}$	A.Ghiorso, T.Sikkeland, A.Larsh, and R.Latimer
Ku	104	1966	$_{94}Pu^{242}(_{10}Ne^{22}, 4n)\,104^{260}$	G.N.Flerov, N.A.Dugin, I.Zvara, *et al.*

In the same year G. N. Flerov, S. M. Polikanov, A. S. Karamyan, et al. in the USSR irradiated plutonium-241 with a flux of quintuply charged oxygen ions and detected α-particles of energy 8–9 MeV, which could be attributed to an isotope $^{253}102$ having a half-life between a few seconds and 1 min. No chemical identification was made.

During 1958–1959 Ghiorso, Seaborg, et al. made repeated attempts to obtain isotopes of element No. 102 by the reactions

$$_{96}Cm^{246}(C^{12}, 4n)\,102^{254} \quad \text{or} \quad _{96}Cm^{244}(C^{13}, 4n)\,102^{253}$$

but detected only products having half-lives of a few seconds. The authors of the original communication on element No. 102 also changed their view, and came to think that the isotope $^{255}102$ had been obtained in their experiments. In 1963 the Soviet scientists G. N. Flerov, E. D. Donets, V. A. Shchegolev, et al. synthesised an isotope of element No. 102 having mass number 256 in a powerful accelerator of multicharged ions. Metallic uranium was bombarded with high-energy neon nuclei. The half-life of the new isotope proved to be close to 8 min. Thus the question of the synthesis of element No. 102 had been considerably clarified, but its name is still under discussion.

At the beginning of 1961 a paper appeared by A. Ghiorso, T. Sikkeland, A. Larsh, and R. Latimer on the discovery of element No. 103, named *lawrencium* (Lr). These workers bombarded a target containing 3 mg of a mixture of californium isotopes with boron (^{10}B and ^{11}B) nuclei of energy 10.3 MeV in the large cyclotron at Berkeley. An α-emitter was formed with a half-life of 8 ± 2 s, the energy of the α-particles being 8.6 MeV. Calculations led to the conclusion that an isotope of element No. 103 having mass number 257 was formed. A longer-lived isotope $^{256}_{103}Lr$ (half-life 35 s) was also obtained later.

In 1966 G. N. Flerov, N. A. Dugin, I. Zvara, et al., working at the Joint Institute for Nuclear Research (at Dubna), synthesised the first atoms of element No. 104. A plutonium-242 preparation was irradiated with neon-22 ions of energy 115 MeV on a cyclotron. The nuclear reaction $^{242}Pu(^{22}_{10}Ne, 4n)^{260}104$ took place. The isotope obtained underwent spontaneous fission with a half-life of 0.3 s. It was detected from the tracks made by the fission fragments in glass or mica. It was identified chemically from the volatility of the chlorine compounds (see below). Element No. 104 received the name *kurchatovium* (Ku).

Table 4. Initially discovered and longest-lived isotopes of transuranium elements.

Atomic No. Z	Element	Initially discovered isotope		Longest-lived isotope	
		A	$T_{1/2}$	A	$T_{1/2}$
93	Np	239	2.3 days	237	$2.2 \cdot 10^6$ years
94	Pu	238	86.4 years	244	$7.6 \cdot 10^7$ years
95	Am	241	458 years	243	$8 \cdot 10^3$ years
96	Cm	242	162.5 days	247	$1.6 \cdot 10^7$ years
97	Bk	243	4.5 h	247	$1.4 \cdot 10^3$ years
98	Cf	244	2.5 min	251	800 years
99	Es	246	7.3 min	254	480 days
100	Fm	254	3.2 h	257	95 days
101	Md	256	30 min	258	54 days
102	No?	256	8 min	—	—
103	Lr	257	8 s	256	35 s
104	Ku	260	0.3 s	—	—

Thus twelve transuranic elements, having atomic numbers 93–104, are now known. It is significant that their first isotopes to be isolated were usually short-lived, after which methods were found for obtaining longer-lived isotopes (Table 4). It may be supposed that this rule will apply also to the most remote transuranic elements.

The principal method for obtaining large quantities of transuranic elements is the irradiation of ordinary uranium, uranium enriched with its isotope of mass 235, or plutonium with a high-power flux of neutrons in a nuclear reactor. The method of subterranean explosions, in which extraordinarily powerful fluxes of neutrons are produced, is of value for certain far transuranic elements, e.g. fermium-257 (half-life 95 days). In this case, however, the resulting isotope must be extracted from a large quantity of rocks which have fused together during the explosion.

Nowadays the annual production of plutonium throughout the world amounts to many tons. Neptunium, a by product of the manufacture of plutonium, is obtained in tens of kilogrammes. Americium is available in kilogramme

quantities, and curium in tens and hundreds of grammes; milligrammes of berkelium and californium have been isolated, and microgrammes of einsteinium and fermium. Mendelevium (atomic number 101), element No. 102, and lawrencium (atomic number 103) are studied in tracer amounts. The question can already be posed now of expanding scientific research and developing practical applications for many transuranic elements.

The position of the transuranic elements in the Periodic System is closely connected with the structure of their atoms and the valency they exhibit. The theory of atomic structure envisages that the inner 5*f*-layer, analogous to the 4*f*-layer formed in the lanthanides, should be filled with electrons at the beginning of the fourth long period in Mendeleev's system.

Table 5. Structure of electron shells in actinide atoms.

In 1945 Seaborg suggested that this filling begins after actinium, resulting in a group of elements, having atomic numbers 90–103, similar to the lanthanides, which have been termed *actinides*. The actinide theory envisages an analogy between corresponding elements in the lanthanide and actinide families. However, the valency properties of the actinides have proved to be more complicated. With thorium, protactinium, and uranium the most characteristic compounds correspond to the higher valency indicated by the numbers of the groups in which Mendeleev placed them (Groups IV–VI respectively). Spectral investigations by W. F. Meggers (1947) showed that the first 5*f*-electrons probably appear only when protactinium is reached. W. H. Zachariasen's crystallographic measurements (1954) even led to the conclusion that metallic thorium, protactinium, and uraniun contain no 5*f*-electrons, and that metallic neptunium contains only one 5*f*-electron. On the other hand, the magnetic properties indicate the presence of 5*f*-electrons beginning with uranium. It is probable that the strength of bonding of 5*f*- and 6*d*-electrons is closely similar in the atoms of actinides. Furthermore, it is obviously weaker than that of 4*f*-electrons in the lanthanides.

Table 5 contains up-to-date information on the atomic structure of the actinides. For many of the elements, however, especially the higher actinides, these values are hypothetical, and have not yet been confirmed experimentally.

The original investigation of neptunium and plutonium had established that these elements exhibit variable valency—from 6 to 3—neptunium being mainly quinquevalent, and plutonium quadrivalent. It was supposed that all subsequent actinides would be tervalent. However, compounds of americium were soon obtained in which this element exhibited valencies of 4, 5, and 6, as well as compounds of quadrivalent curium and berkelium. The valencies of lanthanides and actinides are compared in Table 6.

Table 6. Valency of lanthanides and actinides.

Lanthanides			Actinides

Lu	71	**3**	**3**	103	Lr

N. N. Krot and A. D. Gel'man have recently (1967) made the important discovery that neptunium and plutonium can exist in the septivalent state. If aqueous suspensions of neptunates(VI) and plutonates(VI)—K_2NpO_4 and K_2PuO_4—are oxidised with ozone in strongly alkaline medium, the deposits gradually dissolve to form dark green solutions of neptunates(VII) and plutonates(VII): e.g.

$$2K_2NpO_4 + O_3 + 2KOH = 2K_3NpO_5 + O_2 + H_2O \quad .$$

Several compounds of septivalent neptunium and plutonium have been obtained in the solid state from these solutions—$[Co(NH_3)_6]NpO_5.3H_2O$, $[PtCl(NH_3)_5]NpO_5$, $Sr_3(NpO_5)_2.nH_2O$, $Ba_3(NpO_5)_2.nH_2O$, $Ba_3(PuO_5)_2.nH_2O$—neptunium(VII) compounds being dark green, and plutonium(VII) compounds brownish black. They exhibit strong oxidising properties, this applying especially to septivalent plutonium. The oxidation of neptunium and plutonium to the septivalent state can be effected not only with ozone but also with hypochlorite, hypobromite, xenon compounds, and other active oxidants, necessarily in strongly alkaline medium.

A carrier method has recently been used to study the valency states of the shortest-lived far actinides, which have been used either in tracer quantities or as solitary atoms[6]. A bivalent state was found from entrapment with a barium sulphate precipitate, and tervalent and quadrivalent states were shown by extraction with 4-methylpentan-2-one or other solvent. The experiments showed that in aqueous solution mendelevium ($Z = 101$) occurs in the tervalent form, but can easily be reduced to the bivalent state with zinc dust, bivalent chromium, and other reductants. This distinguishes mendelevium from its formal lanthanide analogue thulium, with which the bivalent state is unknown.

In nitrate solutions element No. 102 was found to exist solely in the bivalent form, strong oxidising agents being required to convert it into the tervalent state. Here, too,

a fundamental difference from the properties of the lanthanide analogue, ytterbium, is observed.

Preliminary experiments on a small number of lawrencium atoms ($Z = 103$) indicated that this element is probably stably tervalent, although the possibility of its reduction or oxidation is not excluded. Lawrencium completes the family of actinides, and it should be similar to lutetium, which is characterised by tervalency.

The difference in properties, notably in valency, between lanthanides and actinides cannot be regarded as unexpected. It is completely explicable in terms of Mendeleev's Periodic Law. In each group of the Periodic System increase in the atomic numbers of analogous elements is accompanied by a definite change in their physical and chemical properties. This applies not only to individual elements but also to groups thereof, an example being the ionisation potentials (Fig. 4).

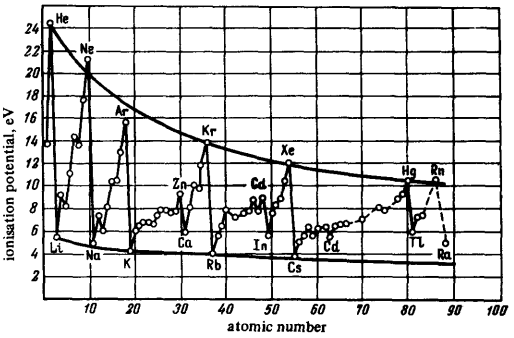

Figure 4. Ionisation potentials of the elements (for the first electron).

In each period of Mendeleev's system the highest ionisation potential corresponds to an inert gas, and the lowest to an alkali metal. With these and with other extreme elements the ionisation potentials diminish with increase in the atomic number, this undoubtedly being due to the increase in atomic radius resulting from the filling of increasingly remote electron shells of the atom. It is also significant that the difference between the ionisation potentials of the inert gas and the alkali metal shrinks considerably on passing to the end of the Periodic System. This explains the enhanced chemical activity of the heavy inert gases—xenon and radon—and also the ability of the near and intermediate actinides to exhibit a high and variable valency. It may be supposed that the far actinides will also give compounds of high valency, although under normal conditions their most characteristic valencies are 3 and 2.

The valency of element No. 104, kurchatovium, is of great interest. This element is not an actinide, but should be analogous to hafnium and quadrivalent. Zvara and coworkers[7] at the Joint Institute for Nuclear Research (in Dubna) used an elegant method to show that the valency of kurchatovium actually differs from that of the lanthanides and the far actinides (Fig. 5). The products of the nuclear reaction leading to the formation of $^{260}_{104}$Ku nuclei were carried away by a stream of nitrogen and chlorine with the addition of hafnium tetrachloride and niobium pentachloride through a special filter, which at 350°C retained the less volatile chlorides of the lanthanides and elements 101–103. After this the spontaneous fission counters detected element No. 104 as before, which indicates that it differs from the lanthanides and the actinides.

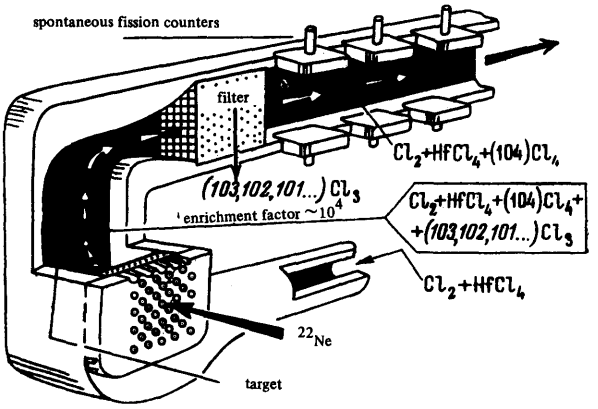

Figure 5. Diagram of apparatus for determining the valency state of element No. 104.

Formally element No. 105 should be an analogue of tantalum, element No. 106 of tungsten, and so on. However, in view of the energetic similarity of 5*f*- and 6*d*-electrons, the nearer transactinides (having $Z = 104$–106) may be expected to exhibit also an anomalous high valency, similarly to elements of the copper subgroup, where the higher valency is due to the closeness of the energy levels of the *d*- and outer *s*-electrons.

---o0o---

A valuable contribution to the Periodic System has been made by a study of the chemical properties of Group 0 elements. During the 1930s B. A. Nikitin showed, using a method of cocrystallisation with sulphur dioxide hydrate $SO_2.6H_2O$, that radon and certain other inert gases form the hexahydrates $Rn.6H_2O$, $Ar.6H_2O$, $Ne.6H_2O$, etc. Later he found that radon interacts also with toluene, *p*-chlorophenol, and other organic compounds to yield the coordination compounds $Rn.2C_6H_5CH_3$, $Rn.3ClC_6H_4OH$.

The first compound of the inert gas xenon formed by means of a valency bond was obtained in 1962 by N. Bartlett, who found that platinum hexafluoride PtF_6, an extremely strong oxidant, was able to oxidise xenon to a compound having the formula $Xe^+(PtF_6)^-$. This is hydrolysed by water:

$$2XePtF_6 + 6H_2O = 2Xe + O_2 + 3PtO_2 + 12HF \ .$$

After this discovery other workers obtained the fluoride XeF_4 by the direct interaction of fluorine and xenon at 400°C followed by rapid cooling to room temperature. Xenon tetrafluoride is stable at ordinary temperatures. It is hydrolysed by water:

$$XeF_4 + 2H_2O = Xe + O_2 + 4HF \ .$$

Ultraviolet irradiation of a mixture of xenon and fluorine yields the difluoride XeF_2. With excess of fluorine at

high pressures (60–70 atm) the hexafluoride XeF_6 is also formed. On hydrolysis by water this compound forms a non-volatile solid product, which has proved to be xenon trioxide XeO_3. This solid is stable in light and air, but deliquesces in the presence of moisture. When heated, xenon trioxide explodes. It can also undergo disproportionation, with the formation of a tetroxide:

$$4XeO_3 = 3XeO_4 + Xe$$

The salts $CsHXeO_4$, $BaXeO_4$, termed *xenonates*, correspond to xenon trioxide, and *perxenonates* ($Na_4XeO_6.8H_2O$, $K_4XeO_6.9H_2O$, etc.) to xenon tetroxide.

The simple compounds of xenon known at the present time are listed below:

Valency			
2	4	6	8
XeF_2 $XeCl_2$ XeO	XeF_4 XeF_2 XeO_2	XeF_6 XeF_4 XeO_3F_2 XeO_3	(XeF_8) XeO_4

Xenon fluorides are white crystalline substances, which decompose when heated. They possess strong oxidising properties: for example, a mixture of the tetrafluoride and the hexafluoride ignites methanol and aqueous ammonia, and converts bivalent manganese into permanganic acid. Perbromates were first prepared by means of xenon fluorides.

Radon has been found to react with fluorine. Chemical compounds of radon will probably be more stable than those of the other inert gases. However, the strong radioactivity of this element makes study of its chemistry difficult. Only one compound of krypton KrF_2 has been obtained, and it is not very stable at ordinary temperatures. On theoretical grounds the formation of chemical compounds by argon, neon, and helium is improbable.

---o0o---

The physical and chemical properties of elements and their compounds already began to be compared with the position of the corresponding elements in the Periodic System during the first few decades after the discovery of the Periodic Law. Increasing attention has recently been paid to the search for quantitative relations in this field. The following papers may be cited as examples.

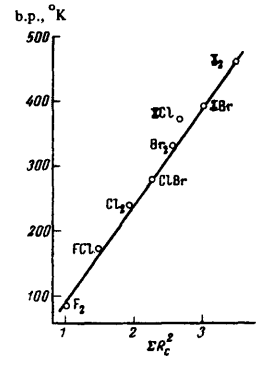

Figure 6. Dependence of boiling points of diatomic interhalogen compounds on covalent radii of halogen atoms.

G.R. Somayajulu and S.R. Palit (1957) studied the relation between the boiling point of various halogen derivatives and the dimensions of the atoms they contained. It was found that the boiling point of members of a given series of halogen derivatives, e.g. interhalogen compounds, was a linear function of the surface area of the halogen atoms calculated for the given molecule. The boiling point can be calculated by means of the formula $T_b = a\Sigma R_c^2 + b$, where T_b (°K) is the boiling point, R_c are the covalent radii of the halogen atoms in the molecule, and a and b are constants.

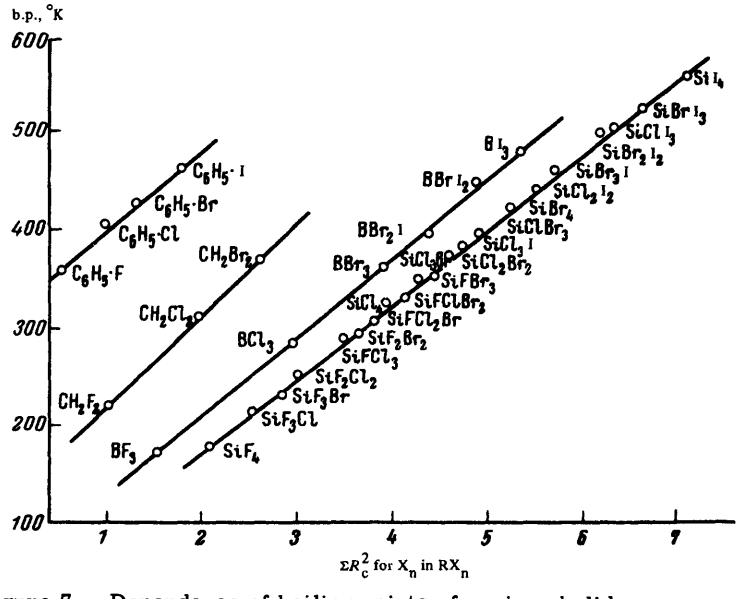

Figure 7. Dependence of boiling points of various halides on covalent radii of halogen atoms.

Fig. 6 shows the applicability of this formula to determining the boiling points of interhalogen compounds of the type X_2, and Fig. 7 those of four series of halogen derivatives of various types.

Z. Szabo and B. Lakatos (1952) put forward the view that the physical properties of uncombined elements (their melting and boiling points, heats of sublimation) depend not only on the atomic numbers but also on the fine distribution of electrons among s-, p-, and d-sublevels.

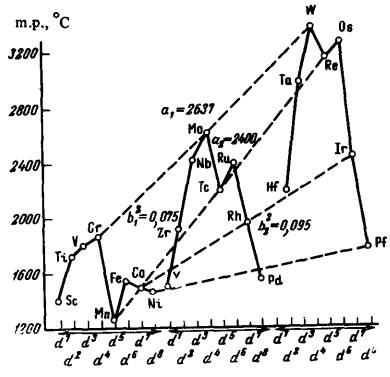

Figure 8. Melting points of the transition elements.

This leads to additional periodicity within each period of Mendeleev's system. Fig. 8 illustrates this phenomenon for the melting points of the transition metals in three long periods. Points representing the melting points of analogous elements usually lie on straight lines. To calculate the melting points of elements these workers proposed the equation

$$T = a_1 e^{-b_1^2(d-4)^2} + a' e^{-b'^2(d-5)^2}(n - n_5), \quad \text{if} \quad d \leqslant 5$$

or

$$T = a_2 e^{-b_2^2(d-6)^2} + a' e^{-b''^2(d-5)^2}(n - n_5), \quad \text{if} \quad d > 5$$

where T is the melting point, a_1, a_2, b_1, and b_2 are constants of the periodic curve, a', b', and b'' are constants in the function representing the slope of the curve, n is the principal quantum number, and d is the number of d-electrons if the whole calculation is derived from the properties of elements in the fifth period (n_5). The average difference between calculated and experimental values was 4%.

An. N. Nesmeyanov and N. E. Khandamirova (1960) found quantitative relations between the heats of sublimation of elements ΔH°_{298} and their positions in the Periodic System. Regarding the lattice energy of a solid as a function of two main variables—the interatomic distance r and the atomic weight A—these workers established that the quantity $\Delta H^\circ_{298} A/r$ is a linear function of the atomic weight within each subgroup of the Periodic System. Heats of sublimation can be calculated from the appropriate graphs. In most cases satisfactory agreement is found between calculated and experimental values. Deviation is observed in the copper and zinc subgroups, which is explained by penetration of s-electrons below the screen of d-electrons and the resultant relative decrease in size of the atoms.

---o0o---

The centenary of the Periodic Law has revealed the whole multiplicity of its applications in chemistry, physics, and several related fields of knowledge. It has not only explained many known facts, but has enabled new, frequently unexpected phenomena to be predicted. However, the successes achieved do not mean that the possibilities of the Periodic Law are exhausted. As a guiding light it will always indicate to researchers the path to new discoveries, while the name of its author, the great Russian scientist Dmitrii Mendeleev, has been introduced forever into the golden tables of modern science.

The Application of the Hammett Equation with the Constants σ^{ph} in the Chemistry of Organophosphorus Compounds

T.A.Mastryukova and M.I.Kabachnik

The review deals with the application of the Hammett equation to organophosphorus reactions and equilibria using the constants σ^{ph}. As far as possible a complete list of the constants σ^{ph} is given. Analysis of the application of the constants σ^{ph} shows that linear correlations between the rate and equilibrium constants for organophosphorus reactions are usually obtained when the phosphorus atom is not a reaction centre.
For reactions involving phosphorus directly, linear correlations are achieved with the aid of the inductive (σ_I^{ph}) and resonance (σ_R^{ph}) constants, namely: $\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph})$. A method of calculation of the constants σ_I^{ph} and σ_R^{ph} is described and as far as possible a complete list of these constants is given for various groups attached to the phosphorus atom.
It has been demonstrated on 124 reaction series as examples the function $\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph})$ makes it possible to construct a universal system for the $\sigma\rho$ analysis of reactions, equilibria, and certain physical constants in the chemistry of organophosphorus compounds on the basis of the equation $\lg K = \lg K^0 + \rho\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph})$ with high correlation coefficients.
The relation between the constants α and ρ on the one hand and the type of reaction and its mechanism on the other is discussed.
The bibliography includes 117 references.

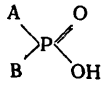
1. INTRODUCTION

A characteristic feature of studies on the reactivity of organophosphorus compounds in recent years consists in the measurement of a large number of rate and equilibrium constants and the application of correlation equations to them. The first Hammett equation[1]:

$$\log \frac{K}{K^0} = \rho\sigma \qquad (1)$$

with the constants σ_p and σ_m^2 was applied to organophosphorus compounds in 1953 by Jaffé et al.[3] for the ionisation of aromatic phosphonic acids. In 1956 Kabachnik[4] showed that the Hammett equation is applicable to a wide variety of phosphorus acids:



and not only to aromatic acids provided that one uses the constants σ^{ph} specific to substituents linked to the phosphorus atom:

$$pK = pK^0 - \rho\Sigma\sigma^{\Phi}. \qquad (2)$$

In order to determine the constants σ^{ph}, about 150 ionisation constants of phosphorus acids in water and in 50% aqueous alcohol were employed in the calculation and the first 57 constants σ^{ph} were obtained. The use of these constants resulted in entirely satisfactory correlations between the ionisation constants (pK_a) of the acids (Table 2, series No. 1, 5, 12, 13).

2. THE CONSTANTS σ^{ph} FOR SUBSTITUENTS AT THE PHOSPHORUS ATOM

In recent years numerous quantitative data have accumulated on equilibrium and rate constants for reactions of organophosphorus compounds. Part of these data were used to determine new constants σ^{ph}. Thus, Kabachnik, Mastryukova, Melent'eva, and Shipov[5-7] determined the constants σ^{ph} for the C_6H_5O, p-$CH_3C_6H_4O$, cyclo-C_5H_9, and $CH_2{=}CH$ groups and Kabachnik, Balueva, and coworkers[8,9] determined the constants for the cyclo-C_6H_{11}, $NC{-}CH_2CH_2$, and $C_6H_{13}O$ groups. Ryss and Tul'chinksii[10] determined the constants σ^{ph} for fluorine directly linked to phosphorus, etc. However, the majority of the quantitative data have not been interpreted from this standpoint although their use would permit the determination of many new values of σ^{ph}.

Column 3 of Table 1 gives a complete compilation of the constants σ^{ph} published previously and calculated by the present authors from the literature data. Many of these constants were obtained as averages from several measurements in different reaction media and were then successfully used in various correlations. These constants are fairly reliable and have been printed in bold type in Table 1. The less reliable constants are printed in the usual type; the least reliable values are quoted with only one figure after the decimal point.

3. CORRELATIONS BETWEEN THE EQUILIBRIUM AND RATE CONSTANTS FOR REACTIONS AND THE CONSTANTS σ^{ph}

The constants σ^{ph} were found to be applicable in all those cases where the reaction does not involve directly the phosphorus atom, i.e. when the phosphorus atom is not subject to direct attack and hence σ-bonds involving phosphorus are not dissociated and new ones are not formed.

Table 1. The constants σ*, σ^{ph}, σ_I^{ph}, and σ_R^{ph} for substituents.

[a] There was a misprint in the original: 0.50 was printed instead of 0.7 for σ^{ph}.
[b] Derived as the mean from numerous correlations for reactions of organophosphorus compounds.
[c] For two and more aryl groups at the phosphorus atom.
*Studies the data from which we employed in the calculation of the corresponding values of σ are denoted by an asterisk.

Table 2 presents the results for the correlations between the ionisation constants (pK_a) of organophosphorus acids in various media. Evidently the ionisation constants of acids of different types—phosphoric and phosphonic (first and second ionisations), phosphinic, phosphonous, and thioic, selenoic, and dithioic phosphorus acids—as well as the ionisation constants for phosphonium salts treated as acids show a satisfactory linear correlation with $\Sigma\sigma^{ph}$ regardless of the nature of the groups attached to phosphorus: alkyl and cycloalkyl groups, alkyl groups with electronegative substituents, aryl groups with different substituents, and also alkoxy-, aryloxy-, and other groups (see Figs. 1–3). It should be noted that such universal correlation is not always observed with other σ constants (σ*, σ^0, σ_p, σ_m, etc.). Whereas a satisfactory correlation is observed with the constants σ* for alkyl substituents[51] and the constants σ^0 [51] and σ [52] for aryl substituents, alkoxy-substituents remain outside the correlations. Here, of course, a unique correlation is not attainable.

Many of the acid ionisation constants listed in Table 2 are due to the authors of the review and others were taken from the literature. They were correlated in most cases by the present authors.

Table 3 presents the correlation of the protolysis constants (pK_p) of phosphorus acids in non-aqueous media using Hexamethoxy-Red as the base indicator.

Table 4 shows the relation between the basicity constants (pK_a) of phosphines, phosphine oxides, iminophosphoranes, and other substances and the constants σ^{ph}.

Table 2. Correlation of the ionisation constants of phosphorus acids in aqueous alcohol with the constants σ^{ph} ($pK = pK^0 - \rho\Sigma\sigma^{ph}$; $\alpha = 1.00$).

*Studies the data from which were used for the correlations.

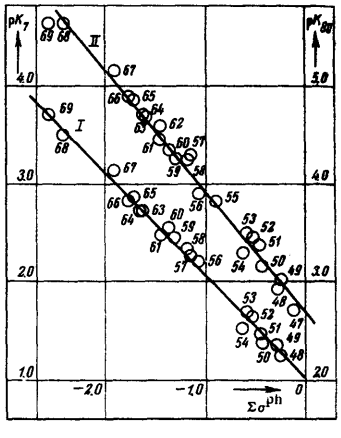

Figure 1. Variation of the ionisation constants (pK_a) of phosphorus acids of the type ABPOOH with $\Sigma\sigma^{ph}$ in 7% (I) and 80% (II) aqueous alcohol (see Table 2, series 4 and 8). The numbers of the points and the substituents A and B for the acids are indicated: 47) C_6H_5O, C_6H_5O; 48) CH_3O, CH_3O; 49) p-$CH_3C_6H_4O$, p-$CH_3C_6H_4O$; 50) C_2H_5O, C_2H_5O; 51) C_6H_5O, OH; 52) p-$CH_3C_6H_4O$, OH; 53) p-ClC_6H_4, p-ClC_6H_4; 54) C_3H_7O, C_3H_7O; 55) CH_2=CH, C_2H_5O; 56) CH_2=CH, OH; 57) CH_2=CH, C_6H_5; 58) C_6H_5, C_6H_5; 59) C_6H_5, p-$CH_3C_6H_4$; 60) CH_2=CH, CH_2=CH; 61) p-$CH_3C_6H_4$, p-$CH_3C_6H_4$; 62) p-$CH_3OC_6H_4$, p-$CH_3OC_6H_4$; 63) cyclo-C_5H_9, OH; 64) C_3H_7, C_6H_5; 65) cyclo-C_5H_9, C_6H_5; 66) iso-C_3H_7, C_6H_5; 67) CH_3, CH_3; 68) C_4H_9, C_4H_9; 69) iso-C_4H_9, iso-C_4H_9.

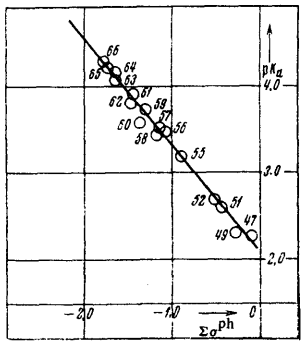

Figure 2. Variation of the ionisation constants (pK_a) of phosphorus acids of the type ABPOOH with $\Sigma\sigma^{ph}$ in 50% aqueous alcohol (see Table 2, series 6; the legend is the same as in Fig. 1).

These data were obtained mainly in nitromethane and are due to different investigators. Here too satisfactory correlation coefficients have been obtained (see also Figs. 4 and 5).

The attempt by Henderson and Streuli[61] to correlate the pK_a for phosphines with the inductive constants σ^* should be noted. They obtained a pronounced scatter of points which they interpreted as three parallel straight lines with relatively satisfactory correlation for primary, secondary,

and tertiary phosphines. When the constants σ^{ph} are employed, a single correlation is achieved for phosphines of all types with a better correlation coefficient.

Table 5 presents the correlations between the rate constants for certain reactions of organophosphorus compounds. These are alkylation of salts of dithioic phosphorus acids with benzyl chloride, bromination of the double bonds in vinyl derivatives of phosphorus, Pishchimuka rearrangement, etc. (Figs. 6 and 7). It should be noted that unfortunately the reaction mechanisms have not always been established[65], which makes $\sigma\rho$ analysis difficult.

Nikolaev et al.[66] showed that the constants σ^{ph} are applicable to the correlation of the quantitative data on the extraction of actinide salts by organophosphorus extracting agents from nitric acid media into organic solvents. It was found that linear correlations hold not only for the effective extraction constants ($\bar{k}$) or the stability constants of the complexes but also for the partition coefficients (K_p); the relevant data are presented in Table 6.

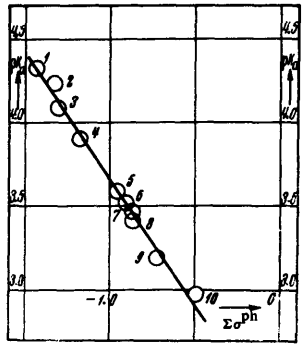

Figure 3. Variation of the ionisation constants (pK_a) of phosphorus acids of the type Ar_2POOH with $\Sigma\sigma^{ph}$ in 60% aqueous tetrahydrofuran (see Table 2, series 11): 1) p-$CH_3C_6H_4$, p-$CH_3C_6H_4$; 2) p-$CH_3OC_6H_4$, C_6H_5; 3) p-$CH_3C_6H_4$, C_6H_5; 4) C_6H_5, C_6H_5; 5) p-ClC_6H_4, C_6H_5; 6) p-BrC_6H_4, C_6H_5; 7) m-BrC_6H_4, C_6H_5; 8) m-ClC_6H_4, C_6H_5; 9) p-ClC_6H_4, p-ClC_6H_4; 10) p-$NO_2C_6H_4$, C_6H_5.

Table 3. Correlation of the protolysis constants for phosphorus acids at 20°C in non-aqueous media using Hexamethoxy-Red as the indicator base ($pK_p = pK_p^0 - \rho\Sigma\sigma^{ph}$; $\alpha = 1.00$).

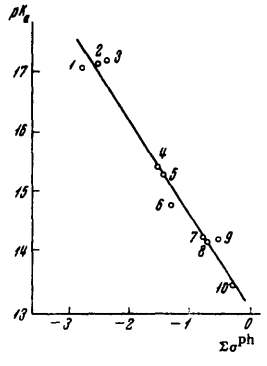

Figure 5. Variation of the basicity constants (pK_a) of phosphamidines of the type ABP(=NR)NHR′ with $\Sigma\sigma^{ph}$ in nitromethane (see Table 4, series 11). The numbers of the points and the substituents A and B are indicated for constant R = p-$CF_3C_6H_4$ and R′ = p-$CH_3OC_6H_4$: 1) iso-C_4H_9, iso-C_4H_9; 2) C_3H_7, C_3H_7; 3) C_2H_5, C_2H_5; 4) C_2H_5, iso-C_3H_7O; 5) C_2H_5, C_2H_5O; 6) C_6H_5, C_6H_5; 7) C_6H_5, C_2H_5O; 8) C_3H_7O, C_3H_7O; 9) C_2H_5O, C_2H_5O; 10) CH_3O, CH_3O.

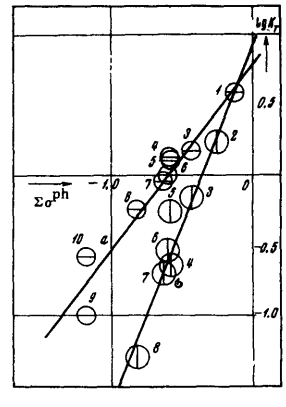

Figure 7. Variation of the tautomeric equilibrium constants ($\lg K_T$) for monothioic phosphorus acids of the type ABPSOH with $\Sigma\sigma^{ph}$ in 7% (*a*) and 80% (*b*) aqueous alcohol (see Table 5, series 13 and 14): 1) C_6H_5O, C_6H_5O; 2) CH_3O, CH_3O; 3) C_2H_5O, C_2H_5O; 4) iso-C_3H_7O, iso-C_3H_7O; 5) ClC_6H_4; ClC_6H_4; 6) iso-C_4H_9O, iso-C_4H_9O; 7) C_3H_7O, C_3H_7O; 8) C_4H_9O, C_4H_9O; 9) CH_3, C_2H_5O; 10) C_6H_5, C_6H_5.

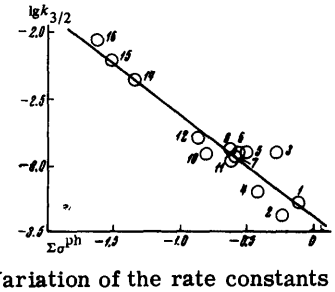

Figure 6. Variation of the rate constants ($\lg k_{3/2}$) for the bromination of derivatives of the type ABP(O)$CH{=}CH_2$ in carbon tetrachloride (see Table 5, series 11): 1) C_6H_5O, C_6H_5O; 2) CH_3O, CH_3O; 3) p-$CH_3C_6H_4O$, p-$CH_3C_6H_4O$; 4) C_2H_5O, C_2H_5O; 5) C_2H_5O, C_3H_7O; 6) iso-C_3H_7O, iso-C_3H_7O; 7) iso-C_4H_9O, iso-C_4H_9O; 8) C_3H_7O, C_3H_7O; 10) C_4H_9O, C_4H_9O; 11) $C_6H_{13}O$, $C_6H_{13}O$; 12) C_6H_5, C_4H_9O; 14) CH_3, C_4H_9O; 15) C_2H_5, C_4H_9O; 16) C_4H_9, C_4H_9O.

4. SEPARATION OF THE CONSTANTS σ^{ph} INTO INDUCTIVE AND RESONANCE COMPONENTS

The application of the constants σ^{ph} to reactions in which the phosphorus atom participates directly and to the physical properties of organophosphorus compounds proved to be more complicated. Numerous examples are known where the correlation with the aid of the constant σ^{ph} does not yield satisfactory results. Thus, in the attempt to correlate the rate constants for the alkaline hydrolysis of compounds of the type ABP(O)X, where X is fluorine or the p-nitrophenyl group (Maklyaev et al.[67]) it was found that the linear relation embraces only groups of similar substances: the data for phosphonates lie on one line and those for phosphates, as it were, lie on another (Fig. 8*a*). Similarly the data of Henderson and Buckler[68] for the rate constants for the alkylation of phosphines with ethyl iodide in acetone

are not correlated with the constants σ^{ph}. The points corresponding to different phosphines in Fig. 9 are distributed in a most peculiar fashion. At the same time the basicities of these phosphines show a satisfactory linear correlation between pK_a (in nitromethane) and $\Sigma\sigma^{ph}$ (Table 4, series 3)[8].

It is noteworthy that in both these and other known cases, where there is no correlation with the σ^{ph}, it is also impossible to achieve a linear correlation with any other known σ constants, for example, σ^* (Fig. 8*b*), σ^0, and others.

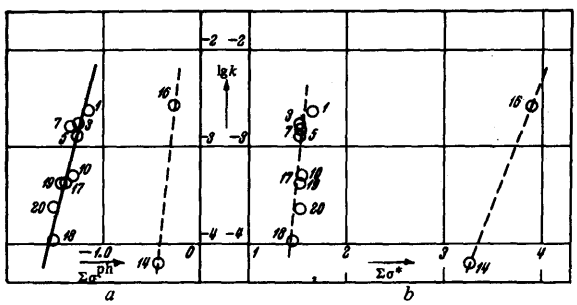

Figure 8. Correlation between the rate constants for alkaline hydrolysis ($\lg k$) of phosphorofluoridates and phosphonofluoridates of the type ABPOF: *a*) with $\Sigma\sigma^{ph}$; *b*) with $\Sigma\sigma^*$: 1) CH_3, C_2H_5O; 3) CH_3, iso-C_3H_7O; 5) CH_3, iso-C_4H_9O; 7) CH_3, iso-$C_5H_{11}O$; 10) C_2H_5, C_2H_5O; 14) C_2H_5O, C_2H_5O; 16) C_2H_5O, C_3H_7O; 17) C_3H_7, C_2H_5O; 18) iso-C_3H_7, C_2H_5O; 19) C_4H_9, C_2H_5O; 20) iso-C_4H_9, C_2H_5O.

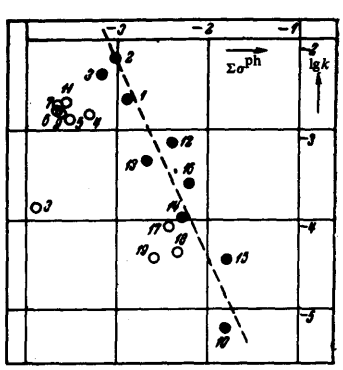

Figure 9. Correlation of the rate constants ($\lg k$) for the alkylation of phosphines of the type R′R″R‴P (according to the data of Henderson and Buckler[68]) with $\Sigma\sigma^{ph}$. The numbers of the points and the substituents R′, R″, and R‴ are indicated: 1) CH_3, CH_3, CH_3; 2) CH_3, CH_3, C_2H_5; 3) CH_3, C_2H_5, C_2H_5; 4) C_2H_5, C_2H_5, C_2H_5; 5) C_3H_7, C_3H_7, C_3H_7; 6) C_4H_9, C_4H_9, C_4H_9; 7) C_4H_9, C_4H_9, C_4H_9 [the second value of $\lg k$ quoted by the authors for $(C_4H_9)_3P$ was employed]; 8) iso-C_4H_9, iso-C_4H_9, iso-C_4H_9; 9) C_5H_{11}, C_5H_{11}, C_5H_{11}; 10) $CNCH_2CH_2$, $CNCH_2CH_2$, $CNCH_2CH_2$; 11) cyclo-C_6H_{11}; cyclo-C_6H_{11}, cyclo-C_6H_{11}; 12) CH_3, CH_3, C_6H_5; 13) C_2H_5, C_2H_5, C_6H_5, 14) C_2H_5, C_6H_5, C_6H_5; 15) C_6H_5, C_6H_5, C_6H_5; 16) *p*-$CH_3OC_6H_4$, *p*-$CH_3OC_6H_4$, *p*-$CH_3OC_6H_4$; 17) C_4H_9, C_4H_9, H; 18) C_8H_{17}, C_8H_{17}, H; 19) iso-C_4H_9, iso-C_4H_9, H.

The complexity of the application of $\sigma\rho$ analysis to organophosphorus reactions of this type and the consequent apparent failure of the universality of the constants σ^{ph} gave rise to a number of papers in which other methods for the correlation analysis of organophosphorus compounds are proposed. These include the correlation of Peppard et al.[24] embracing the carboxylic and phosphonic acid series, the correlation between the NMR chemical shifts of ^{31}P with special constants[69], the constants σ_X^{ph} derived by Knunyants et al.[22] specifically for the hydrolysis of phosphorochloridates, phosphorofluoridates, and *p*-nitrophenyl phosphates, another set of constants for the hydrolysis of the corresponding phosphonates, and a third set for phosphonochlorido-thiolates[26], the correlation of Rozen and coworkers[70] between the extraction constants and the electronegativities of the substituents at the phosphorus atom, the multiparameter correlation of Pal'm et al.[71], etc. All these attempts at correlation in the chemistry of organophosphorus compounds were not developed further, since the constants proposed were not universal and could be applied only to a very limited range of substances and reaction series.

[a] $c_{UO_2(NO_3)_2} = 0.1$ M; [b] $c_{UO_2(NO_3)_2} = 50$ g litre^{-1}; [c] $c_{UO_2(NO_3)_2} = 0.2$ M; [d] $c_{UO_2(NO_3)_2} = 8.4 \times 10^{-4}$ M; [e] $c_{UO_2(NO_3)_2} = 0.01$ M; [f] On further increase of the concentration of nitric acid, the correlation became greatly impaired; [g] $c_{Pu(NO_3)_4} = 1$ g litre^{-1}; [h] $c_{Pu(NO_3)_4} = 0.9$ g litre^{-1}.

At the same time, the extensive experience gained in the application of the constants σ^{ph} gave rise to the hope that it might be possible to develop correlation methods with the aid of σ^{ph} constants which would be universal and would permit $\sigma\rho$ analysis of the rate and equilibrium constants for a wide variety of organophosphorus compounds in which the phosphorus atom does and does not participate directly.

In order to develop such a system, it was necessary to elucidate first the nature of the electronic effects characterised by the constants σ^{ph}. In the paper quoted above[4], Kabachnik does not deal with the problem of the nature of the constants σ^{ph} at all; this was done for the first time by Pal'm[51], who established two linear relations: between the constants σ^0 of the *meta*-, and *para*-substituents in phenyl groups and the corresponding (for the substituted phenyl groups) constants σ^{ph}:

$$\sigma^{pH} = -0.48 + 0.78\sigma^0 \quad (3)$$

and between the constants σ^{ph} for alkyl substituents and Taft's inductive constants σ^*:

$$\sigma^{ph} = -0.965 + 1.97\sigma^*. \quad (4)$$

Hence Pal'm concluded that the constants σ^{ph} refer to inductive effects. At the same time he took into account the fact that numerous σ^{ph} constants for substituted alkyl, alkoxy-, and many other groups cannot be related by any simple procedure to the known constants σ. He suggested that in the case of such groups one is dealing with a "field effect"—the electrostatic interaction between the charge of the phosphonate or phosphate anion and the dipole of the substituent, which contributes to the constant σ^{ph}. However, this explanation, on which, incidentally, Pal'm does not insist, contradicts many experimental data. Firstly, there are reaction series, readily susceptible to correlation with the constant σ^{ph} in which there are no ionic centres either in the ground or in the transition state. For example, the radical bromination of vinyl derivatives of phosphorus[9], the order of which is 3/2, is a reaction of this type. Secondly, it is difficult to postulate powerful ion–dipole interaction for groups such as phenyl or vinyl, which nevertheless deviate from the linear relation between σ^{ph} and σ^*.

Finally, recently Mastryukova and Kabachnik[52] established that the constants σ^{ph} for aromatic groups are well correlated not only with Taft's σ^0 constants, characterising the inductive effect of the substituents in a phenyl group, but also with the usual σ constants, which include both the inductive and resonance components:

$$\sigma^{ph} = -0.415 + 0.634\sigma. \quad (5)$$

The correlation in the latter case is just as satisfactory. The the concept of the purely inductive nature of the constants σ^{ph} is found not to hold even after corrections for the "field effect".

On the other hand, there are convincing data indicating that the electronic effect of substituents at the phosphorus includes a resonance component. Thus in many studies the concept of d_π–p_π conjugation was invoked by the authors in the discussion of the results of chemical investigations or physical measurements. In their study on the kinetics of the hydrolysis of substituted phosphinyl chlorides, Dostrovsky and Halman[72] attribute the effect of substituents in the phosphinyl group on the rate of hydrolysis to inductive and resonance effects. Other investigators of the kinetics of the substitution reactions (solvolysis, hydrolysis) at a saturated phosphorus atom (Heat[73], Larsson[30], Hudson[74], Maklyaev and coworkers[23,67,75], Bel'skii and coworkers[76,77], etc.) also developed this point of view. In 1962 Kabachnik et al.[6] showed that the constants σ^{ph} of aryl groups can vary under the influence of steric hindrance to conjugation. A systematic description of the evidence in favour of the resonance interaction of the phosphorus atom with the groups joined to it may be found in papers by Hudson[65], Kabachnik[78], Loshadkin[79], etc. At present there is no doubt that the generally adopted hypothesis is valid.

In this connection there arose the idea that the constants σ^{ph} be divided into inductive (σ_I^{ph}) and resonance (σ_R^{ph}) components and that their role in the correlation of the reactivities of organophosphorus compounds be elucidated. Mastryukova[80] reported such subdivision of the constants at the Fourth Conference on the Chemistry and Application of Organophosphorus Compounds at Kazan in January 1969.

In the series of organic phosphorus compounds it was of course impossible to apply the procedures for the subdivision of the constants σ^{ph} into σ_I^{ph} and σ_R^{ph} employed in the aromatic series. In the latter case several methods were used to divide the constants into the inductive and resonance components: the inductive constants were calculated from model reaction series such as ionisation of bicyclo[2,2,2] octane-1-carboxylic acid[81], from Taft's σ^* constants[82], from the ionisation constants of substituted acetic acids[83], or from the ionisation constants of substituted *p*-toluic acids[84] or they were evaluated by comparing the constants σ_p and σ_m put forward by Taft and Lewis[85] and modified by Roberts and Jaffé[86]. With organophosphorus compounds, it was of course impossible to employ any of these methods.

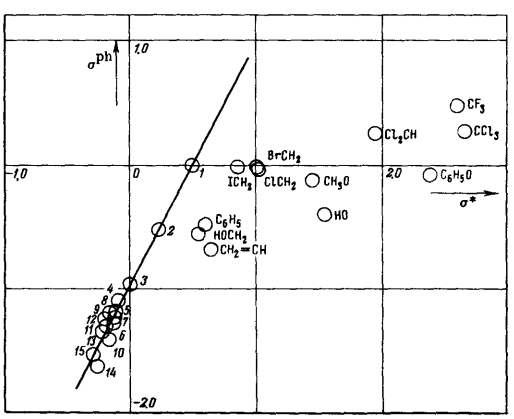

Figure 10. Relation between the constants σ^{ph} and Taft's σ^* constants for the substituents R. The numbers of the points and the substituents R are indicated: 1) H; 2) $C_6H_5CH_2$; 3) CH_3; 4) C_2H_5; 5) C_3H_7; 6) iso-C_4H_9; 7) C_4H_9; 8) cyclo-C_6H_{11}; 9) C_6H_{13}; 10) $(CH_3)_3CCH_2$; 11) iso-C_3H_7; 12) cyclo-C_5H_9; 13) s-C_4H_9; 14) $(CH_3)_3SiCH_2$; 15) $(CH_3)_3C$.

The subdivision of the constants σ^{ph} into σ_I^{ph} and σ_R^{ph} is based on the following considerations. It was noted above that the constants σ^{ph} for alkyl groups are linearly related to Taft's σ^* constants, i.e. they reflect only inductive effects. Fig. 10 shows the correlation between the constants σ^{ph} and σ^* for alkyl groups. Points corresponding to different substituents are also included. They do not lie on the straight line for the alkyl groups but are located to one side, in the direction of higher values of σ^*. It might have been supposed that the inductive effects of all these groups also follow the linear relation shown in Fig. 10 and the

deviations are due to resonance effects. Fig. 11 illustrates this hypothesis: for the points Q we have $OA = \sigma^*$, $AQ = \sigma^{ph}$, $BQ = \sigma_R^{ph}$, and $AB = \sigma_I^{ph}$. It follows from the above that the inductive components of the constants σ^{ph} for these substituents can also be calculated from the constants σ^* using the linear equation†

$$\sigma_I^{ph} = -0.960 + 1.99\,\sigma^* \qquad (6)$$

and the constants σ_R^{ph} can be found by difference

$$\sigma_R^{ph} = \sigma^{ph} - \sigma_I^{ph}.$$

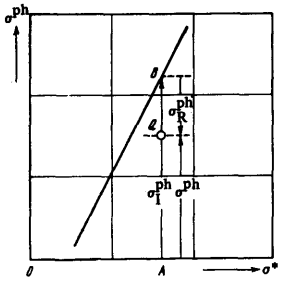

Figure 11. Relation between the constants σ^{ph}, σ_I^{ph}, and σ_R^{ph}.

Thus it has been arbitrarily assumed here that in the ionisation of acids the ratio $\sigma_I^{ph} : \sigma_R^{ph} = 1 : 1$ ($\alpha = 1$, see below).

One must of course bear in mind that the above treatment includes a number of arbitrary assumptions. For example, it is assumed that the inductive effects of alkyl groups follow the same relation as the inductive effects of substituted alkyl, aryl, alkoxy-, and other groups. Analysis of the constants for purely organic reaction series shows that this is not quite true, at least as regards the transmission of inductive effects along a saturated chain[87]. Probably the chemistry of phosphorus provides a better justification for the above hypothesis. This is evident if only from the existence of a unique correlation for all substituted and unsubstituted aromatic and aliphatic phosphorus acids.

The second assumption is that all the deviations from the linear relation (Fig. 10) have been attributed solely to resonance effects, without taking into account steric factors and hyperconjugation. The influence of steric factors on the reactivity of organophosphorus compounds will be discussed below. It is clearly shown only in a few cases. In most of the other cases the large bulk of the phosphorus atom ensures low steric hindrance due to the atoms and groups attached to it. At any rate, steric hindrance is in this case significantly lower than at the carbon atom. The effect of hyperconjugation is also probably slight (see below).

The above assumptions do not of course have a rigorous justification. However, they are no more arbitrary than those made in the separation of the inductive and resonance constants in the aromatic series, which does not preclude their fruitful employment.

† We revised the parameters of the equation, which differ somewhat from those quoted by Pal'm[51].

The constants σ^*, which are necessary in the calculation of inductive constants σ_I^{ph} by Eqn. (6), are presented in column 2 of Table 1. For electronegative substituents such as F, Cl, OH, CF_3, CCl_3, C_6H_5, CH_2=CH, and certain others, the constants σ^* were taken from Pal'm's book[15]; he calculated them from the ionisation constants of substituted acetic acids by the equation

$$\sigma^* = (2.623 - 0.552\,pK_a) \pm 0.034 \qquad (7)$$

using the conversion $\sigma^*_{XCH_2} = 0.388\sigma^*_X$. These constants differ somewhat from those quoted in "The Chemist's Handbook"[88] and are probably more accurate. The constants σ^* for CH_2=$CHCH_2$, $ClCH_2CH_2CH_2$, and other XCH_2 groups were calculated from the corresponding constants for the groups X by multiplying the latter by 0.388.[15]

Table 7. The constants σ^* for RO groups calculated from the ionisation constants of alkoxyacetic acids ($ROCH_2COOH$).[19]

R	pK_a	$\sigma^*_{ROCH_2}$	σ^*_{RO}	σ^*_{RO} calc. from σ_I

C_4H_9	3.81	0.52	1.34	1.43	1.43

*$\sigma^* = 1.44 \pm 0.06$ according to Pal'm[15].

The constants σ^* of alkoxy- (RO) and alkylthio- (RS) groups were calculated by the authors of this review. In the first case Palomaa's data[19] were employed. The constants σ^* for $ROCH_2$ groups (Table 7) were evaluated by Eqn. (7) from the ionisation constants of alkoxyacetic acids $ROCH_2COOH$ determined conductimetrically in water at 25 °C and these yielded the corresponding constants for the RO groups on being divided by 0.388. The constants σ^* for $RSCH_2$ groups were evaluated similarly from the data of Ramberg[25] and Larsson[27] from the ionisation constants of alkylthioacetic acids $RSCH_2COOH$ and from them the values for the RS groups were calculated (Table 8). For comparison, Tables 7 and 8 include the values of σ^* for alkoxy- and alkylthio-groups calculated from the constants σ_I by the familiar relation $\sigma^* = 6.23\sigma_I$.

Among aromatic groups, the constants σ* have been reliably determined only for the phenyl group (0.62).[15] In the calculation of the constants σ* for phenyl groups, one resorts sometimes to the relation between σ* and σ^0:

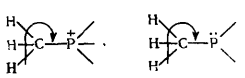
$$\sigma^*_{XC_6H_4} = \sigma^0_X + 0.600. \quad (8)$$

However, the applicability of this relation is very limited[87] and the use of the values of σ* thus obtained in the calculation of σ_I^{ph} gives rise to considerable doubts. Therefore Table 1 lists the constants σ*, σ^{ph}, σ_I^{ph}, and σ_R^{ph} only for the phenyl and pentafluorophenyl groups, the values for the latter having been calculated by an independent method from experimental NMR data[39] for ^{19}F. For the remaining aromatic groups, only the values of σ^{ph} are quoted. The literature sources from which the constants σ* were calculated or taken directly are indicated in column 6 of Table 1.

5. INDUCTIVE (σ_I^{ph}) AND RESONANCE (σ_R^{ph}) COMPONENTS OF THE CONSTANTS σ^{ph}

The constants σ_I^{ph} differ of course from the constants σ* by the choice of the starting point of the scale, i.e. the standard substituent: in the σ* scale the standard substituent is the CH_3 group ($\sigma^*_{CH_3} \equiv 0$), while hydrogen is employed as the standard in the σ^{ph} scale ($\sigma_H^{ph} \equiv 0$). Therefore Eqn. (6) contains a constant term of −0.960 equal to the constant σ^{ph} for the methyl group. The coefficient 1.99 in this equation characterises the relation between the σ^{ph} and σ* scales.

As stated in Table 1, the constants σ_R^{ph} for all alkyl groups are equated to zero. Formally this follows from the system employed in the calculation. The physical significance of this corresponds to the assumption that the hyperconjugation effects of the alkyl groups attached to phosphorus are negligible. An attempt to take into account the hyperconjugation effects in the hydrolysis of chlorophosphinates was made by Pal'm et al.[71], but they obtained the hyperconjugation component with the sign reversed, which is contrary to the known S_N2 mechanism of this reaction. Furthermore, the value of h obtained proved to be unusally high and without reasonable physical significance. Theoretically the greatest hyperconjugation effects might be expected in the reactions of organophosphorus compounds where the valence state of phosphorus changes. These include protonation and alkylation of phosphines[8,61,68]. Hyperconjugation, i.e. in this case σd conjugation, should stabilise to a greater extent the phosphonium compound



than the phosphine as a result of the contraction of the d orbitals when a positive charge appears[89]. A consequence of this should be an increase of the basicity of phosphines containing methyl groups. However, the basicity of trialkylphosphines decreases in the series $(CH_3)_2PC_2H_5 > (C_2H_5)_2PCH_3 > (CH_3)_3P >$ all remaining phosphines $>$ (iso-C_4H_9)P.[61] In alkylation the same series is maintained. Hence Henderson and Buckler[68] concluded that combined hyperconjugation and steric effects operate. In reactions without change of the valence state of phosphorus, the problem of the possible hyperconjugation

is altogether obscure. In the literature there is no rigorous evidence indicating the existence of this phenomenon. It may be supposed that the hyperconjugation effects in these cases are small if they exist at all.

All the resonance constants of the groups attached to phosphorus are negative. This reflects the fact that phosphorus in its organic compounds behaves as an electron acceptor. For pentavelent (tetracoordinate) phosphorus this has been known for a long time[78,90] and is due both to the presence of an effective positive charge and to vacant low-lying higher atomic orbitals (3d and possibly 4s). It is interesting that in the trivalent state phosphorus also exhibits slight but definite acceptor properties (−M-effect, see Tsvetkov et al.[91] and Schiemenz[92]).

The resonance constants σ_R^{ph} of alkoxy-groups have high absolute magnitudes. This corresponds to a powerful effect of the type

in which the unshared electron pairs of the oxygen atoms partially fill the atomic d orbitals of phosphorus forming molecular d_π–p_π orbitals‡.

With increase in the size of the alkoxy-group σ_R^{ph} decreases. The constants σ^{ph} for alkoxy-groups, which have small absolute magnitudes, consist of the sum of a large negative σ_R^{ph} and a somewhat smaller but still large positive σ_I^{ph}. Thus alkoxy-groups attached to phosphorus have large resonance and inductive effects acting in opposition. This is particularly characteristic of the phenoxy-group for which σ^{ph} is close to zero (−0.06), while $\sigma_R^{ph} = -2.89$ and $\sigma_I^{ph} = 2.83$.

The resonance constants of alkylthio-groups differ from those of alkoxy-groups by having smaller absolute magnitudes. In this case the relative influence of the inductive effects is greater and for the C_2H_5S group σ^{ph} is positive. Probably this is due to the smaller p-component of the atomic orbitals of sulphur compared with oxygen[93], as a result of which purely resonance interaction is weaker.

The inductive and resonance components of the constants σ^{ph} of halogens (fluorine and chlorine) attached to phosphorus have the greatest absolute magnitudes: $\sigma_I^{ph} = 5.21$ and $\sigma_R^{ph} = -4.65$ for fluorine and $\sigma_I^{ph} = 4.37$ and $\sigma_R^{ph} = -3.44$ for chlorine. This is evidence of intense electron withdrawal by an inductive effect and a somewhat weaker mesomeric effect. As a result σ^{ph} are large and positive.

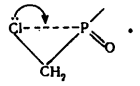
In general, it should be noted that there is a definite parallelism between the absolute values of σ_R^{ph} and σ_I^{ph} for the groups examined above: the greater the degree of withdrawal of electrons by the inductive effect the greater is the injection of electrons by the resonance effect. Possibly this is a consequence of the increase of the effective

‡ In all cases we are considering the participation of the atomic d orbitals of phosphorus following the concept generally adopted in the literature. The participation of atomic 4s or hybrid orbitals is disregarded. This problem is still not quite clear and requires special investigation.

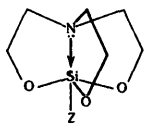
positive charge of the phosphorus by the inductive withdrawal of electrons. The atomic *d* orbitals of phosphorus then contract, which in turn leads to improved conditions for $d-p$ overlapping[89]. The parallel variation of the constants σ_I and σ_R has also been noted in the literature[94], particularly in those cases where the substituents compared have the same first atom, attached to the transmitting system. Then, for rigorously similar substituents, there is a linear relation between σ_R and σ_I.[95]

The resonance constants of the phenyl and vinyl groups have much smaller absolute values than those for alkoxy-groups. The π-electron system of the benzene ring or the double bond gives up its electrons to the *d* orbitals of phosphorus to only a slight degree. This is well known in view of the weak conjugation effects characteristic of aromatic and vinyl phosphorus compounds[78].

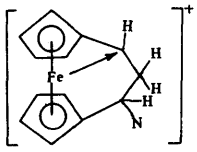
The fairly high values of σ_R^{ph} for groups such as $ClCH_2$, $BrCH_2$, Cl_2CH, and Cl_3C is striking. In the chemistry of aromatic compounds these groups are characterised by almost pure inductive effects. It may be supposed that resonance effects are in this case associated with the direct overlapping of the orbitals of the unshared electron pairs of chlorine with the *d* orbitals of phosphorus, forming a dative bond, which can be conventionally represented thus:



This effect is most characteristic of α-substituted derivatives; it is weaker for β-halogeno-derivatives and is virtually absent for γ-halogeno-derivatives. It is specific to phosphorus and probably to other elements with vacant *d* orbitals. Thus $p-d$ bonds of this type in organosilicon compounds have been discussed in the literature. As an example, one may quote the transannular $p-d$ bond in silatranes (triptychsiloxazolidines), first suggested by Frye et al.[96]:



It is interesting that a direct intramolecular donor-acceptor bond in ferrocene has been discussed by Richards and Hill[97] in connection with the stability of carbonium ions, for example:



This type of bond with phosphorus is probably present also in other groups with atoms having unshared electron pairs or π bonds in the α- or β-positions, formally separated from the phosphorus atoms by CH_2 groups. These include groups such as $CH_2OH(\sigma_R^{ph} = -0.69)$, $C_6H_5OCH_2$ $(\sigma_R^{ph} = -0.9)$, $C_2H_5OCH_2CH_2$ $(\sigma_R^{ph} = -0.35)$, $N{\equiv}CCH_2CH_2$ $(\sigma_R^{ph} = -1.22)$, $CH_2{=}CHCH_2$ $(\sigma_R^{ph} = -0.33)$, and even $C_6H_5CH_2$ $(\sigma_R^{ph} = -0.16)$.

6. CORRELATION BETWEEN THE RATE CONSTANTS FOR NUCLEOPHILIC SUBSTITUTION AT THE PHOSPHORUS ATOM

There is every reason to suppose that in nucleophilic substitution reactions at the phosphorus atom the relative contributions of the inductive and resonance components are different than in the ionisation of phosphorus acids. It has now been established that in the nucleophilic attack on phosphorus acid esters or esterified acid halides and similar compounds the transition state has the configuration of a trigonal bipyramid, and there is reason to believe that the *d* orbitals of phosphorus participate in its formation. If this model is correct, then substituents capable of $p-d$ conjugation (with a $+M$-effect) should sharply reduce the rate of nucleophilic substitution. In the estimation of their influence in $\sigma\rho$ analysis this should affect the contribution of the resonance σ_R^{ph} constant, namely it should increase it. Therefore it was to be expected that in the correlation of solvolysis and other nucleophilic substitution reactions the equation

$$\lg \frac{k}{k^0} = \rho\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph}) \qquad (9)$$

would hold for $\alpha > 1$.

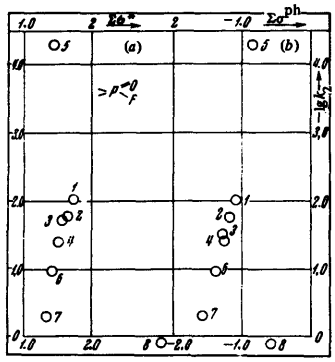


Figure 12. Correlation of the rate constants ($\lg k$) for the alkaline hydrolysis of the fluorides of phosphorus acids of the type ABPOF according to Larsson's data[30]: *a*) with Taft's σ^* constants; *b*) with the constants σ^{ph}. The substituents A and B for the acid fluorides are indicated: 1) CH_3, CH_3O; 2) CH_3, C_2H_5O; 3) CH_3, C_3H_7O; 4) CH_3, iso-C_3H_7O; 5) CH_3, C_2H_5S; 6) C_2H_5, iso-C_3H_7; 7) iso-C_3H_7, iso-C_3H_7O; 8) iso-C_3H_7O, iso-C_3H_7O.

Fig. 12 shows the correlation between the rate constants for the alkaline hydrolysis of phosphorus acid fluorides of the type APBOF on the basis of Larsson's experimental data[30]: two of the graphs (*a* and *b*) show the variation of $\lg k$ with $\Sigma\sigma^*$ and $\Sigma\sigma^{ph}$. Evidently there is no general correlation here, in agreement with previous findings. Fig. 13 shows the correlation between $\lg k$ and $\Sigma(\sigma_I^{ph} + 1.5\sigma_R^{ph})$. Here the points corresponding to di-isopropyl phosphorofluoridate (*8*), bis-(*NN*-dimethyl)phosphorodiamidic fluoride (*9*), (*NN*-dimethyl)methylphosphonamidic fluoride (*10*), and ethyl methylphosphonofluoridothiolate (*5*) together with

all the points for alkyl methylphosphonofluoridates fit very closely the linear relation. This means that in the $\sigma\rho$ analysis of the hydrolysis reactions of acid fluorides the resonance effects make a contribution 1.5 times as great ($\alpha = 1.5$) as in the ionisation of acids. The above corelation ($r = 0.95$, $S = 0.23$, $S_\rho = 0.13$) is remarkable, because here the rate constants vary by 8 powers of 10 ($\lg k$ varies from −4.26 to 4.29).

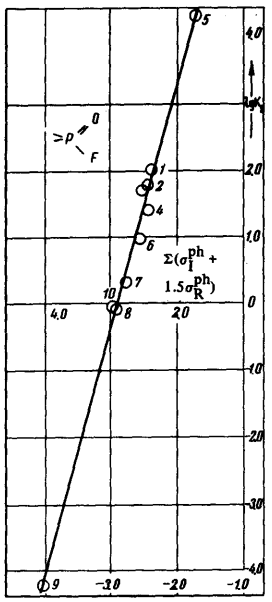

Figure 13. Variation of the rate constants ($\lg k$) for the alkaline hydrolysis of the fluorides of phosphorus acids of the type ABPOF according to Larsson's data [30] with $\Sigma(\sigma_I^{ph} + 1.5\sigma_R^{ph})$. For substances *1–8*, see Fig. 12; 9) $(CH_3)_2N$, $(CH_3)_2N$; 10) CH_3, $(CH_3)_2N$.

The coefficient $\alpha = 1.5$ is an optimum in this case, since poorer correlations are obtained with smaller and greater values of α. For all the reaction series discussed below, optimum values of α are also quoted.

Table 9 presents the results of the correlations between the rate constants for the solvolysis of compounds of the type ABP(O)X, where X = F, p-$NO_2C_6H_4O$, or Cl at different temperatures and in different media. In the hydrolysis of the acid fluorides and p-nitrophenyl esters the coefficient α varies in the range 1.5–1.55 (Table 9, series 1–8). In the solvolysis of acid chlorides in ethanol α = 1.30 (Table 9, series 13 and 14); for the hydrolysis of the chlorides in aqueous acetone, two values are quoted in Table 9—$\alpha = 1.5$ calculated from the experimental data of Hudson and Keay [74] (series 9) and $\alpha = 1.85$ calculated from the data of Neimysheva et al. [100] (series 10). The reason for this discrepancy is obscure. At any rate, it is evident that α depends not only on the type of reaction but probably also on the temperature and the medium.

Resonance effects play a major role in the hydrolysis of the chlorides of thionic acids of phosphorus (series 15 and 16); here $\alpha = 1.8$. The high contribution of the resonance component is in this case probably related to the high effective positive charge of the phosphorus atom [89], which leads to intensified d_π–p_π conjugation.

All the reaction series quoted in Table 9 are characterised by high positive values of the constants ρ, which is probably due to the high polarity of the transition states. Positive values of ρ correspond to an S_N2 mechanism. Substituents which increase the electron density at the phosphorus atom, i.e. with large negative values of $\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph})$ retard the reaction and conversely.

Table 10 presents data for the hydrolysis of the alkyl esters of phosphorus acids. Alkaline hydrolysis of ethylphosphonates at 59.2 °C is characterised by $\alpha = 1.6$ according to the data of Hudson et al. [99] (series 1), while according to the data of Bel'skii and coworkers [76,77] (series 3) the alkaline hydrolysis of ethylphosphinates at 80 °C is characterised by a lower value: $\alpha = 1.25$. Possibly this discrepancy is due to a difference in the experimental conditions. Both series have high values of ρ, which corresponds to nucleophilic attack by the hydroxide ion.

Table 9. Correlation of the rate constants for the solvolysis of compounds of the type ABP(Z)X with the constants σ_I^{ph} and σ_R^{ph}.

[a] The point corresponding to di-isopropyl phosphorofluoridate was excluded.
[b] The coefficient α is unknown since the substituents varied exhibit only an inductive effect.
*Studies the data from which were used for the correlations.

On the other hand, neutral hydrolysis of alkylphosphinates (Table 10, series 4) has a low value of ρ (0.93), which is evidence of low polarity at the transition state. Here the rate of reaction is very low ($\lg k^0 = -5.27$) and $\alpha = 0.90$. Efremov et al.[101] recently established that in this case there is attack on the carbon of the alkyl group with subsequent dissociation of the alkyl–oxygen bond. Here too the S_N2 mechanism is reflected in a positive value of ρ.

Table 10. Correlation of the rate constants for the hydrolysis of phosphorus acid esters in an aqueous medium with the constants σ_I^{ph} and σ_R^{ph} [$\lg k = \lg k^0 + \rho\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph})$].

[a] The coefficient α is unknown since the substituents varied only the inductive effect.
*Studies the data from which were used for the correlations.

An interesting reaction series, investigated by Neimysheva et al.[26], consists in the hydrolysis of alkyl phosphonochloridothiolates R(RS)POCl in 95% aqueous acetone and 0°C. The correlation data ($n = 11$, $\alpha = 1.65$, $\lg k^0 = 3.08$, $\rho = 1.82 \pm 0.27$, $r = 0.914$, and $S = 0.14$) indicate a profound difference between the hydrolysis of these compounds and that of other substances of the type ABPOCl.

Here ρ is unusually low for the hydrolysis of acid chlorides. It would probably be of interest to investigate this reaction in greater detail. There is no doubt that steric effects play a major role in it, as is in fact pointed out by the authors. Therefore the points corresponding to phosphonothiolates with isopropyl and s-butyl groups at the phosphorus atom were excluded in the calculation of the correlation parameters.

7. CORRELATION BETWEEN PHYSICOCHEMICAL DATA

Considerable interest attaches to the correlation between the equilibrium constants for the formation of complexes of various phosphoryl compounds with alcohols and phenols. The complexes are formed as a result of hydrogen bonding:

$$\rangle C{-}OH \ldots O{=}P\langle$$

These reactions were investigated by infrared spectroscopy mainly by Gramstad and coworkers[102-104].

On complete transfer of a proton, i.e. when an acid–base reaction takes place, the coefficient α is unity (Tables 2–4). It is reasonable to suppose that inductive effects play a major role in the formation of a hydrogen bond and therefore one may expect that the coefficient α will be less than unity. Indeed in all cases quoted in Table 11 α varies from 0.80 to 1.00. The lower is the acidity of the proton donor the smaller is α. Thus $\alpha = 0.80$ for the methanol complex, $\alpha = 0.90$ for the phenol and β-naphthol complexes, $\alpha = 0.95$ for the pentachlorophenol complex, and finally $\alpha = 1.00$ in the formation of a hydrogen bond with hydroxyphosphonium ions:

$$R_3P{=}O \ldots HO{-}\overset{+}{P}R_3.$$

All these reaction series are characterised by low negative values of ρ. A negative value of ρ shows that the equilibrium constant increases with increasing electron density at the phosphoryl oxygen atom. Electron-donor substituents of course increase the stability of the hydrogen bond. These effects are naturally small, in agreement with the low values of ρ.

Interesting complexes with iodine have been investigated by a similar method (series 10 and 11). Here the association constants are low ($\lg K^0 = 0.24$ at 20°C), but ρ is negative in this case too and consequently the iodine molecule adds as an electrophilic agent.

Table 11. Correlation of the association constants ($\lg K_{ass}$) in carbon tetrachloride determined from infrared spectra with the constants σ_I^{ph} and σ_R^{ph} [$\lg K_{ass} = \lg K_{ass}^0 + \rho\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph})$].

*Studies the data of which were used for the correlations.

Gramstad and coworkers[102-104] correlated the association constants for the complexes of organophosphorus compounds with alcohols, phenols, and iodine with Taft's σ^* constants. Linear relations were observed, but the correlation coefficients were much lower than those in Table 11 (see the footnote to this Table).

Table 12. Correlation of half-wave potentials $E_{1/2}$ for the polarographic reduction of organophosphorus aldehydes and ketones with the constants σ_I^{ph} and σ_R^{ph} [$E_{1/2} = E^0_{1/2} + \rho\Sigma(\sigma_I^{ph} + \alpha\sigma_R^{ph})$].

[a] The correlation coefficient was calculated after rotating the coordinate axes by 45°.
*Studies the data from which were used for the correlations.

Razumov, Savicheva, and coworkers[105-107] investigated the polarographic reduction of organophosphorus oxo-compounds and observed a slight but nevertheless definite dependence of the half-wave potentials on the substituents at the phosphorus atom. Table 12 shows the correlation between the experimental data and the constants σ_I^{ph} and σ_R^{ph}. The positive values of the constant ρ indicate, as stated by the authors, that the potential-determining stage of the process consists in the addition of an electron to the molecule of the phosphorylated oxo-compound. Unexpectedly α proved to be greater than unity in these reactions, which undoubtedly indicates the participation of the phosphoryl group in the reduction process.

Table 13 lists data on the correlation between the chemical shifts in the ^{19}F NMR spectra of fluorine-containing organophosphorus compounds. In all cases α is close to unity and high correlation coefficients are obtained regardless of the type of compound.

There are literature data[111-113] for the ^{19}F NMR shifts in the spectra of phosphorus acid chlorides of the type ABPOF, i.e. compounds in which fluorine is linked directly to phosphorus. The attempts to correlate the chemical shifts in the ^{19}F NMR spectra of these compounds with the constants σ_I^{ph} and σ_R^{ph} and also with any other known σ constant were not successful.

A correlation between the ^{35}Cl NMR frequencies for compounds of the type $APOCl_2$ with the constants σ^{ph} was published by Tsvetkov et al.[114] Two linear relations were observed: one for the dichlorides of unsubstituted alkylphosphonic acids and another for the dichlorides of alkylphosphoric, vinylphosphonic, and arylphosphonic acids. When the constants σ_I^{ph} and σ_R^{ph} are used and the available data[114-116] for all substances of the type ABPOCl (where A and B can also be chlorine or fluorine atoms) are treated, then, with the exception of POF_2Cl, all the remaining data are satisfactorily correlated with $\Sigma(\sigma_I^{ph} + 1.20\sigma_R^{ph})$ (r = 0.970) (Table 13, series 10).

8. SPECIFICITY OF THE CONSTANTS σ^{ph}. STERIC EFFECTS

There is of course the problem of the relation between the constants σ^{ph}, σ_I^{ph}, and σ_R^{ph} on the one hand and the constants characterising the polar effects of substituents in the chemistry of carbon compounds: σ^*, σ_p, σ_m, σ^0, etc. Above it was noted that the inductive constants of the substituents σ_I^{ph} attached to phosphorus atoms differ from Taft's inductive constants σ^* only by the scale and the starting point adopted for their calculation. Thus the constants σ_I^{ph} can be derived from the constants σ^*. The constants σ^{ph} for aromatic groups can also be derived from the σ or σ^0 for the corresponding constituents in the aromatic ring[51,52]. Probably these two relations are the only ones between the constants σ^{ph} and other σ constants derived for purely organic compounds. The constants σ^{ph}

are compared in Fig. 14 with the constants σ_p for substituents in the aromatic ring. On the basis of this figure, it is difficult to arrive at any conclusion more definite than the statement that the constants agree as regards sign. Since the inductive components of the constants are linearly related, one may conclude that the reason for the differences lies in the resonance components.

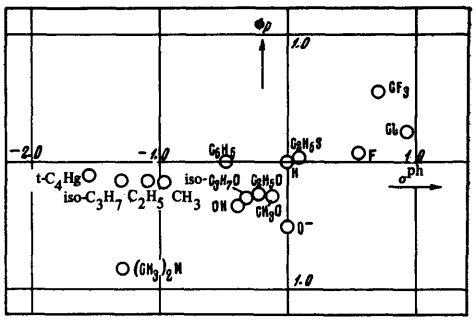

Figure 14. Relation between the constants σ^{ph} and σ_p for different substituents.

The resonance components of the constants σ^{ph} and σ_p, i.e. σ_R^{ph} and σ_R, are compared in Fig. 15. Evidently there is no simple relation between them. This is also found when the constants σ_R^0 are employed. Probably there are fundamental differences between the resonance effects in p_π–p_π conjugated systems and the conjugation effects in systems with a central phosphorus atom (d_π–p_π conjugation), associated with differences between the symmetries and other properties of atomic p and d orbitals. Thus σ^{ph} are specific constants.

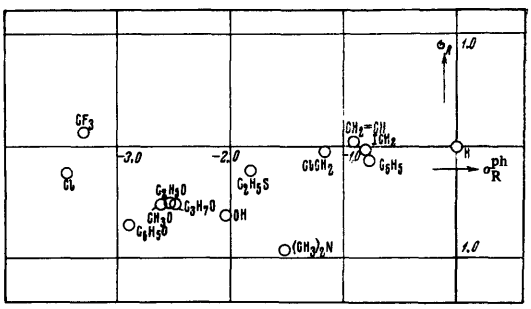

Figure 15. Relation between the constants σ_R^{ph} and σ_R for different substituents.

Rakshys et al.[108] successfully correlated the inductive and resonance constants σ_I and σ_R^0 for groups attached to trivalent phosphorus in phosphorylated fluorobenzene derivatives ($R_2PC_6H_4F$) and chemical shifts in the ^{19}F NMR spectra of these compounds. However, the principles of this correlation could not be extended to compounds of pentavalent (tetracoordinate) phosphorus.

We must now consider the effect of steric factors. This problem has been frequently discussed in the literature. The most pronounced effect of steric factors is observed in the alkylation of tertiary phosphines with alkyl halides. Henderson and Buckler[68] investigated the kinetics of the addition of ethyl iodide to tertiary aliphatic and aromatic phosphines. Although they did see a very limited dependence of the rate constants on the constants σ^*, only a few points in their graph fit a linear relation. The authors ascribe all the deviations to steric and hyperconjugation effects. In the correlation of the rate constants for the hydrolysis of dialkylphosphinic chloride in a neutral medium, Pal'm et al.[71] included Taft's E_S constants characterising steric effects and also the corresponding cross terms. Some workers, who have investigated the correlation of equilibrium or rate constants for reactions of organophosphorus compounds with the constants σ^*, σ^0, and σ_p and who observed deviations from linearity, attributed the latter to the effect of steric factors. Since in many cases these deviations are not observed when the constants σ^{ph} (or $\sigma_I^{ph} + \alpha\sigma_R^{ph}$) are employed, the conclusion that steric factors are responsible for these deviations must be treated with caution.

In general it may be supposed that, in reactions of organophosphorus compounds with participation of the phosphorus atom, steric effects play a smaller role than in the corresponding reactions of purely carbon compounds. This is related to the important fact that the phosphorus atom has a much greater radius than the carbon atom. Therefore for the tetrahedral structures of the initial or final compound and the trigonal bipyramid structure of the transition state, the difference between the hindering groups at the phosphorus atom is greater than at the carbon atom which means that the steric hindrance to the approach of the attacking agent is smaller.

It may be supposed that in all the correlations presented in Tables 2–6 the effect of steric factors is negligibly small. Nevertheless it must be noted that in the alkaline hydrolysis of *p*-nitrophenyl esters of phosphorus acids, investigated by Fukuto et al.[12,98], the point corresponding to compound with a t-butyl group at the phosphorus atom deviates from the linear relation (this point was disregarded in the correlation; Table 9, series 3). There is no doubt that the steric hindrance due to the bulky t-butyl group has an effect here. There is also no doubt that in the hydrolysis of phosphinic chlorides and even phosphonochloridates, investigated by Neimysheva et al.[71], the steric hindrance due to the isopropyl and isobutyl groups reduces the rate constant for S_N2 attack.

In Fig. 9 discussed above the filled circles correspond to tertiary phosphines containing only small alkyl groups or phenyl rings. These points are concentrated near the straight line drawn in the diagram. For these phosphines, the steric hindrance is least and there is a tendency towards a linear relation. All the substances containing higher alkyls (starting with propyl) markedly deviate towards lower rate constants. The deviations are particularly pronounced for tri-isobutylphosphine, the steric hindrance for which should be a maximum. At the same time, in the protonation of the same phosphines (Fig. 4 and Table 4, series 3), steric hindrance may in fact have an effect on the positions of the points near the straight line, but in this case the deviations are small and quite satisfactory correlation is observed ($r = 0.950$). In reactions of nitrogen compounds the greatest steric hindrance is observed in the alkylation of tertiary amines (the Menshutkin reaction) and in the formation of complexes with trimethyl-

boron[117]. In reactions of organophosphorus compounds steric hindrance is much less and yet it does have an effect in the alkylation of tertiary phosphines and in certain solvolysis reactions.

---o0o---

All the correlations quoted above were calculated by least squares using Jaffé's method[2]. Tables 2–6 and 9–13 show that 124 reaction series were employed—for the equilibria and reactions of organophosphorus compounds.

Table 14.

Quality of correlation	r	Percentage of total number	
		This review	Jaffé's review (Ref.2)
Very good	>0.989	25	32.4
Good	0.970—0.989	37	24
Quite Satisfactory	0.950—0.970	20	13.7
Satisfactory	0.900—0.950	14	9.9
Poor	<0.900	4	20

These series include about 1300 individual constants. The statistical distribution of the correlation coefficients is shown in Table 14, according to which the number of very good and satisfactory correlations for organophosphorus compounds is somewhat greater (62%) than in Jaffé's compilation (56.4%), but the number of very good correlations is somewhat less and that of poor correlations is significantly less. It should be borne in mind that in many cases considerable experimental difficulties arise in the measurement of the rate constants for reactions of organophosphorus compounds and reduce the accuracy so that some of the σ^{ph} constants employed require revision. These revisions may alter the parameters of the individual correlations. However, there is no doubt about the wide applicability of correlation analysis to a wide variety of reactions and equilibria of organophosphorus compounds when the constants σ^{ph} or σ_I^{ph} and σ_R^{ph} (of different relative values) are employed.

Ionic Hydrogenation

D.N.Kursanov and Z.N.Parnes

Papers on the ionic hydrogenation of a double bond, consisting in the successive addition of a proton and a hydride ion, are surveyed. The use of trifluoroacetic acid as donor of the proton and of triethylsilane as donor of the hydride ion has permitted the hydrogenation of alkenes, dienes, cyclopropane hydrocarbons, saturated and unsaturated ketones, aldehydes, quinones, and anils. Each class of compounds shows selectivity on ionic hydrogenation with the above pair of hydrogenating agents. The reaction extends to single bonds in the case of disulphides and ethers, which undergo ionic hydrogenolysis. Ideas on the mechanism of ionic hydrogenation are examined.

I. INTRODUCTION

Interest in the hydrogenation of unsaturated organic compounds arose in an early stage of the development of organic chemistry. The outstanding event in this field was the discovery of hydrogenation on heterogeneous catalysts. This discovery led to the founding of new branches of organic and physical chemistry, and also acquired important industrial applications.

Intense study of hydrogenation reactions continues at the present time, the reason being the great practical and theoretical interest of hydrogenation. Each of the proposed methods of hydrogenation has fundamental limitations as well as its own merits. In particular, such methods frequently do not possess the required selectivity.

Reactions involving hydrogenation in the presence of complex organometallic catalysts under homogeneous conditions are being comprehensively investigated at the present time. Complex metal hydrides are being widely used in practical hydrogenation.

A special place among methods of hydrogenation is occupied by reactions involving stages of successive addition of a proton and of a hydride ion to the substance to be hydrogenated:

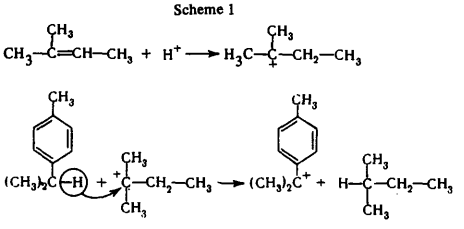
$$A{=}E + H^+ \rightleftarrows AH{-}E^+ \xrightarrow{+H^-} AH{-}EH\ .$$

The above is not the only possible path of ionic hydrogenation. A different sequence of stages can be imagined, the first stage being addition of the hydride ion, and addition of a proton to the resulting carbanion the second stage. Ionic hydrogenation reactions are also possible involving the transfer of two electrons and two protons. However, the present Review will be confined to reactions of ionic hydrogenation taking place solely by the first route, which for brevity we shall term reactions of ionic hydrogenation.

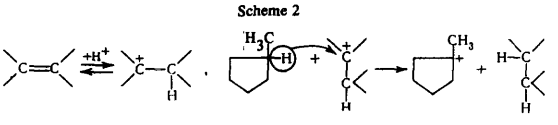
Several investigators have observed ionic hydrogenation as a side reaction in the study of the alkylation and the polymerisation of alkenes [1-3]. Nametkin and Abakumovskaya [4] as early as 1932 probably observed ionic hydrogenation by the action of sulphuric acid on cyclohexene. From the reaction products they isolated a hydrogenated dimer, obviously formed by interaction between the carbonium ion (formed by protonation of cyclohexene) and another cyclohexene molecule acting as a donor of a hydride ion.

Ipatieff and Pines [5-7], in an attempt to alkylate alkylbenzenes with alkenes in sulphuric or hydrofluoric acid, obtained good yields of alkanes (Scheme 1). In the above cases and in the work of Haaf and Koch [8] (Scheme 2) the proton donor was sulphuric or hydrofluoric acid, while the donor of a hydride ion was an alkane or an alkylbenzene.

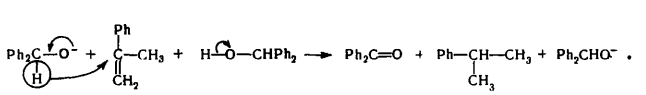
Scheme 1



Scheme 2



Vitt and Martinkova [9] effected a reaction closely similar to ionic hydrogenation on reducing the activated double bond in methylstyrene with diphenylmethanol and its alkoxide:



In contrast to the reactions considered earlier, in which the intermediate formation of carbonium ions is either demonstrable or extremely probable, it is difficult to assume such formation in the present reaction. Hydrogenation apparently takes place by a different mechanism in this case.

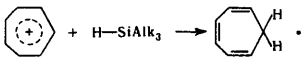
In ionic hydrogenation it is necessary that the proton donor should be sufficiently active to form a carbonium ion, but its activity should be limited, since it must not react with the hydride-ion donor to form molecular hydrogen. Besides, the carbonium ion should possess a certain stability, so that its lifetime is sufficient for

reaction with the hydride-ion donor. Yet increase in stability of the carbonium ion diminishes its rate of interaction also with the hydride donor, so that a more active source of hydride ions may be required in conducting the reaction. Ionic hydrogenation will yield only one product provided that the rate of interaction of the carbonium ion with the hydride-ion donor exceeds the rates of isomerisation and polymerisation of the carbonium ion.

It follows from the above that the choice of pair of hydrogenating agents is of decisive significance. Kursanov, Parnes, and their coworkers proposed trifluoroacetic acid and a trialkylsilane as a hydrogenating pair. These compounds hardly interact at all. Trifluoroacetic acid is a strong acid ($H_0 = -3.2$) having strong ionising and solvating properties [10]. The ability of alkyl- and aryl-silanes to split off a hydride ion has now been proved. The hydride activity of the hydrogen in a silane was already evident from the work of Whitmore, Pietrusza, and Sommer [11], who found that neopentyl chloride reacts with triethylsilane in the presence of aluminium chloride, being converted into isopentane:

$$(CH_3)_3CCH_2Cl + H{-}SiEt_3 \xrightarrow{AlCl_3} (CH_3)_3CHCH_2CH_3 .$$

More recent work has shown that a trialkylsilane transforms the tropylium ion into cycloheptatriene [12]:



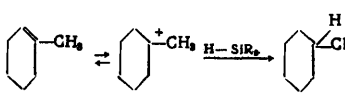
Corey and West [13] studied the exchange of hydrogen for halogen in a silane–triphenylmethyl halide system, and showed that the reaction occurs in those polar solvents in which the carbon–halogen bond undergoes dissociation (nitromethane, nitrobenzene, and dichloroethane), but not in non-polar solvents, in which dissociation is not observed. Diphenylmethyl halides and t-butyl chloride do not react with a silane. On the addition of boron tribromide to the reaction mixture, however, reaction takes place, in conformity with results for the dissociation of t-butyl chloride in the presence of boron tribromide [14].

Kursanov, Setkina, and Novikov [15] have established that phenylsilanes are capable of the ionic exchange of hydrogen with lithium tetradeuterioaluminate. Since lithium tetrahydroaluminate is a strong hydride-ion donor, the occurrence of hydrogen exchange is evidence of the hydride activity of the hydrogen in silanes.

II. IONIC HYDROGENATION OF HYDROCARBONS

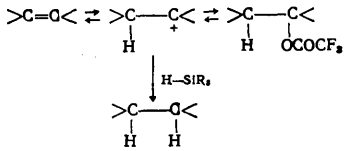
1. Alkenes

(*a*) Monoalkenes. Investigations have shown [16,17] that, with relative proportions of the components—alkene, triethylsilane, and trifluoroacetic acid—of 1 : 1 : 2 at 20–50°C, selective hydrogenation takes place of those alkenes in which branching occurs at the ethylenic carbon (such as methylcyclohexene, methylcyclopentene, 2-methylbut-2-ene, 2-methylpent-1-ene, etc.), saturated hydrocarbons being formed in 80% yield:



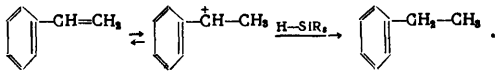
Unbranched alkenes and cycloalkenes, as well as alkenes in which there is no branching at the ethylenic carbon, are not hydrogenated.

This reaction was explained on the basis that ionic hydrogenation is undergone only by alkenes which, as a result of the protonation or dissociation of the corresponding trifluoroacetate, are able to form a sufficiently stable carbonium ion:

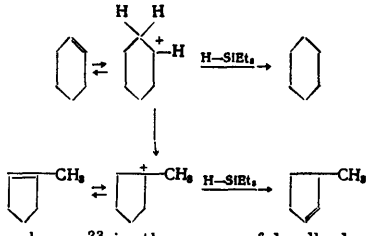


In a study of the isotopic exchange of hydrogen Setkina and Kursanov showed [18–21] that trifluoroacetates of secondary alcohols, unlike those of tertiary alcohols, do not form carbonium ions in trifluoroacetic acid. It was found, in full agreement with this, that, under the conditions of ionic hydrogenation, the trifluoroacetate of a tertiary alcohol reacts with a silane in trifluoroacetic acid (with equimolecular proportions of the components) to form a saturated hydrocarbon [16]. The trifluoroacetate of a secondary alcohol does not react with the silane under these conditions.

The fact that styrene, in which there is no branching at an ethylenic carbon atom, is hydrogenated to ethylbenzene is formally inconsistent with the above scheme. However, such behaviour of styrene is apparently due to the formation by its protonation of a carbonium ion which is stabilised by conjugation with the benzene ring †:



Similar behaviour is shown by indene ‡ and vinylcyclopropane [22], which on protonation also give carbonium ions, stabilised by the benzene ring and by the cyclopropane ring respectively. Further support for the scheme is provided by the slow ionic hydrogenation of unbranched alkenes and cycloalkenes when the acidity (the relative quantity of trifluoroacetic acid) is increased or when the reaction is conducted under more severe conditions (heating in sealed tubes at 140°C). Under these conditions, however, isomerisation products are also formed, and the yield of saturated hydrocarbons is very low.



It has been shown [23] in the case of 1-alkylcyclohexenes that the yield and the rate of ionic hydrogenation are independent of the number of atoms in the alkyl group.

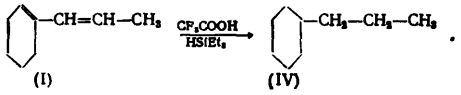
The fact that unbranched alkenes and cycloalkenes undergo ionic hydrogenation with increase in the acidity of the medium agrees well with results obtained by Setkina, Kursanov, and their coworkers [21], who have shown that the formation of a carbonium ion from trifluoroacetates depends on the acidity of the medium.

† It must be noted that the yield of ethylbenzene is small (~ 30%) in the case of styrene, probably because of the competitive effect of polymerisation.

‡ Indene polymerises under the reaction conditions, so that its yield is small.

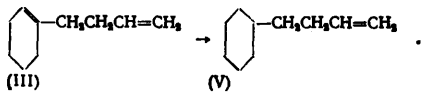
(*b*) Dienes. Various 1-alkenylcyclohexenes—1-propenylcyclohexene (I), 1-allylcyclohexene (II), and 1-but-3′-enylcyclohexene (III)—have been investigated[23] in studying the behaviour of dienes under conditions of ionic hydrogenation, when only one of the ethylenic bonds is able to yield a tertiary carbonium ion on protonation.

Propenylcyclohexene, which contains conjugated double bonds, is completely hydrogenated to propylcyclohexane (IV):



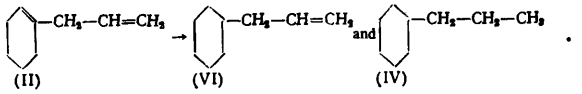
(I) (IV)

In 1-but-3′-enylcyclohexene (III), in which the multiple bonds are separated by two carbon atoms, only the branched ethylenic bond is hydrogenated, with the formation of but-3-enylcyclohexane (V):



(III) (V)

In the case of 1-allylcyclohexene (II), where the multiple bonds are separated by a single carbon atom, two hydrogenation products—allylcyclohexane (VI) and propylcyclohexane (IV)—are formed in the proportions 4 : 1 (see Table 1):



(II) (VI) (IV)

Table 1. Ionic hydrogenation of dienes (at 50°C for 10 h).

Initial alkene	Reaction product	Yield (%) with proportions of alkene : silane : acid	
		1:1:2	1:2:3
1-Propenylcyclohexene	propylcyclohexane	35	70
1-Allylcyclohexene	allylcyclohexane,	28	55
	propylcyclohexane	7	15
1-But-3′-enylcyclohexene	but-3-enylcyclohexane	30	65
Cyclohexadiene	cyclohexene	<2	

The formation of propylcyclohexane from allylcyclohexene may, perhaps, be explained by partial isomerisation of the latter, in the presence of trifluoroacetic acid, into propenylcyclohexene, which has been shown to be completely hydrogenated to propylcyclohexane.

Conjugated dienes containing no branchings undergo hardly any ionic hydrogenation. Under the reaction conditions cyclohexa-1,3-diene gives cyclohexene in less than 2% yield.

2. Aromatic Hydrocarbons

Trifluoroacetic acid and triethylsilane convert anthracene into 9,10-dihydroanthracene[24]. In benzene solution, with the hydrocarbon, silane, and acid in the proportions 1 : 1 : 3.5, the yield of dihydroanthracene at 50°C is 80% after 10 h. Benzene and naphthalene do not react even under considerably more severe conditions.

3. Cyclopropane Hydrocarbons

Cyclopropanes behave similarly to alkenes in many reactions[25]. In particular, they are able to form salts of carbonium ions on treatment with acids. They might therefore be expected to undergo ionic hydrogenation, and obey the same rules as alkenes.

It has in fact been shown[22] that *gem*-dimethylcyclopropanes are hydrogenated with cleavage of the ring to form saturated hydrocarbons (in yields up to 80%). Ethylcyclopropane does not undergo ionic hydrogenation. Phenylcyclopropane is hydrogenated to n-propylbenzene (in 70% yield) (see Table 2).

Table 2. Ionic hydrogenation of cyclopropane hydrocarbons.

Substituents in cyclopropane	Hydrocarbons obtained	Yield, %
1,1,2-Trimethyl	2,3-dimethylbutane,	75
	2-methylpentane	25
Phenyl	propylbenzene	70
Isopropyl	2-methylpentane	40

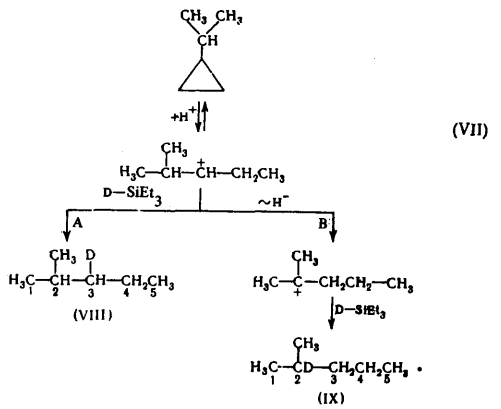
First of all it was necessary to establish the site of ring cleavage during ionic hydrogenation. It was found that the bond between the most and the least hydrogenated carbon atoms ruptures preferentially, as occurs in the action of mercury acetate and inorganic acids[26,27].

It is interesting that, in heterogeneous hydrogenation on palladium, the bond between the two most hydrogenated carbon atoms breaks[28], which leads to the formation of hydrocarbons isomeric with those obtained by ionic hydrogenation.

Isopropylcyclopropane also can be hydrogenated under these conditions, although protonation cannot lead directly to the formation of a tertiary carbonium ion. The capacity of isopropylcyclopropane for ionic hydrogenation may be due to the formation in this case, as an exception to the general rule, of a secondary carbonium ion, which reacts with the silicon hydride to give an alkane. However, the reaction could also occur in a different way, intramolecular hydride transfer producing isomerisation with formation of a tertiary carbonium ion, which reacts with the silane.

To settle this question a study has been made[29] of the reaction of isopropylcyclopropane (VII) with trifluoroacetic acid and deuteriotriethylsilane. If the secondary carbonium ion reacts with the silane, the 2-methylpentane formed by the reaction should contain deuterium in position 3 (VIII) (path A). If, however, a tertiary carbonium

ion reacts with the silane, the deuterium should be located in position 2 (IX) (path B):



(VII)

(VIII)

(IX)

Analysis of the proton magnetic resonance spectra has shown unambiguously that the deuterium is in position 2, which indicates that hydrogenation takes place by path B.

The ionic hydrogenation of isopropylcyclopropane is peculiar in occurring approximately to the extent of 40%, this yield not increasing with the duration of the experiment[30]. The formation of 2-methylpentane is accompanied by that of 1-ethyl-2-methylpropyl trifluoroacetate $CH_3CH(CH_3)CH(C_2H_5)OCOCF_3$. These results can be understood on the assumption that the cyclopropane ring is not opened in the first act of protonation, but a protonated cyclopropane is formed, the possibility of which in the first stage is widely accepted at the present time[31-33]. The protonated cyclopropane then undergoes cleavage, with the irreversible formation of the trifluoroacetate of the secondary alcohol. Partial isomerisation occurs at the same time as ring cleavage, and yields a tertiary carbonium ion, which reacts with the silane to give 2-methylpentane.

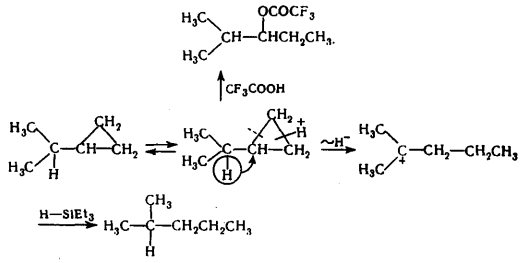


Table 3. Comparative results for the ionic hydrogenation of unsymmetrical trimethylcyclopropane and of 2,3-dimethylbut-2-ene.

Hydrocarbon	Tim, h			
	1	3	6	12
1,1,2-Trimethylcyclopropane	27	32	49	65
2,3-Dimethylbut-2-ene	20	38	45	67

The rates of hydrogenation of 1,1,2-trimethylcyclopropane and of 2-methylpent-1-ene are approximately the same[29].

It is interesting to compare these data with results obtained by Peterson[34], who has found that butylcyclopropane reacts 300 times as rapidly as hex-2-ene with trifluoroacetic acid. From this he concludes that cyclopropane hydrocarbons react more rapidly than the corresponding alkenes with this acid. If this conclusion is regarded as generally applicable, our results indicate that protonation is not the rate-determining stage in the ionic hydrogenation of cyclopropanes.

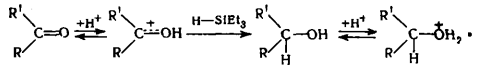
III. IONIC HYDROGENATION OF THE CARBONYL GROUP

In acid media the carbonyl group in ketones and aldehydes is capable of protonation, the following equilibrium being established in the solutions:

Hydride transfer with formation of the alcohol might be expected to occur on addition of a hydride-ion donor to the reaction mixture. Ionic hydrogenation of the carbonyl group in ketones and aldehydes on treatment with trifluoroacetic acid and a silane is in fact observed. However, the composition of the reaction products depends on the structure of the initial ketones and aldehydes.

1. Ketones

Under conditions of ionic hydrogenation aliphatic ketones[35] (acetone, butan-2-one, cyclohexanone, phenylpropan-2-one) give a mixture of the alcohol and its trifluoroacetate. Aromatic and aliphatic–aromatic ketones (acetophenone, benzophenone, pentamethylacetophenone, Michler's ketone), however, undergo further reduction, the reaction product being a hydrocarbon. This difference in behaviour between aliphatic and aromatic ketones is easily explained by means of the general reaction scheme:



If R′ = Ar, further change is possible:

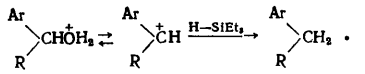


Table 4. Ionic hydrogenation of ketones.

Ketone	Ketone : silane : acid	Time, h	Yield, %	
			alcohol + trifluoroacetate	hydrocarbon
Butan-2-one	1:1.5:3	10	80	—
Cyclohexanone	1:1:2	10	55	—
Cyclohexanone	1:2.5:2	20	75	—
Acetophenone	1:2.5:2	10	—	70
Benzophenone	1:2.5:2	15	—	94

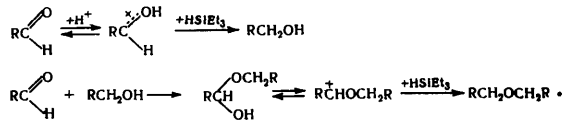
Protonation of the resulting alcohol followed by elimination of water may lead to the formation of secondary carbonium ions. In the case of aromatic and aliphatic–aromatic ketones, however, the carbonium ion is stabilised by the adjacent benzene ring(s). Such a carbonium ion is shown by the ionic hydrogenation of styrene[17] to react with a

silane to form a hydrocarbon. Similarly, the hydrogenation of cyclopropyl methyl ketone results in the formation of ethylcyclopropane and *trans*-pentene, the latter of which has been shown earlier to appear in attempts at the ionic hydrogenation of ethylcyclopropane.

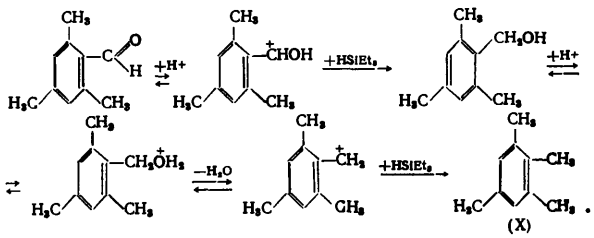
The introduction of electron-acceptor substituents into the benzene ring of an aromatic ketone should diminish the reaction velocity. In fact, Michler's ketone forms bis-*p*-dimethylaminophenylmethane in 75% yield after being heated with a large excess of acid at 80°C for 40 h, whereas benzophenone is converted into diphenylmethane at 55°C almost completely after 15–20 h.

2. Aldehydes

Aldehydes react extraordinarily rapidly with triethylsilane in trifluoroacetic acid to form a mixture of an ether and an alcohol (and the trifluoroacetate of the latter)[36], the amounts of ether and alcohol being approximately the same in the case of aliphatic aldehydes, whereas aromatic aldehydes are almost entirely converted into ethers (e.g. benzaldehyde gives 80% of dibenzyl ether immediately the reactants are mixed). Such a result cannot be explained by condensation of alcohol formed in the first stage, since in trifluoroacetic acid alcohols form little or no ether at all. Moreover, conducting the ionic hydrogenation of an aldehyde in the presence of an alcohol having a different hydrocarbon radical yields an unsymmetrical ether. These facts suggest that production of the ether involves the intermediate formation of a hemiacetal:



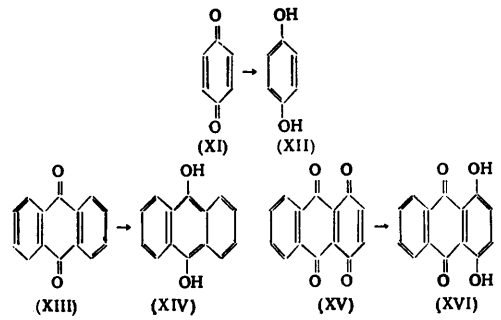
The benzyl cation might be expected to be stable, so that its lifetime would be sufficient for reaction with the silane, and consequently the ionic hydrogenation of benzaldehyde would yield toluene. However, it has been shown[36] that toluene is not formed under these conditions. Hanazaki and Nagakura[37] showed that the stability of the 2,4,6-trimethylbenzyl cation is comparable with that of the α-methylbenzyl cation, which is formed by the protonation of acetophenone. From this it could be expected that 1,2,3,5-tetramethylbenzene would be formed by the ionic hydrogenation of 2,4,6-trimethylbenzaldehyde. In fact, this hydrocarbon (X) is formed under these conditions in 70% yield:



(X)

3. Quinones and αβ-Unsaturated Ketones

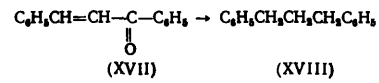
It was of interest to ascertain the mutual influence of carbon–carbon and carbon–oxygen multiple bonds conjugated with one another. The first compounds chosen for investigation were quinones[38]. Study of the ionic hydrogenation of quinones has shown that benzoquinone (XI) is converted into quinol (XII), anthraquinone (XIII) into anthraquinol (XIV), and anthra-1,4:9,10-diquinone (XV) into quinizarin (XVI):



(XI) (XII) (XIII) (XIV) (XV) (XVI)

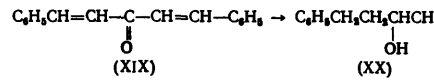
It is interesting that the resulting quinizarin does not undergo further ionic hydrogenation either on prolonged heating of the mixture or on the addition of trifluoroacetic acid.

The ionic hydrogenation of 1,3-diphenylpropenone (XVII) leads to the formation of 1,3-diphenylpropane (XVIII) in 80% yield:



(XVII) (XVIII)

The hydrogenation of 1,5-diphenylpenta-1,4-dien-3-one (XIX) gives 1,5-diphenylpentan-3-ol (XX) as the main product[39]:



(XIX) (XX)

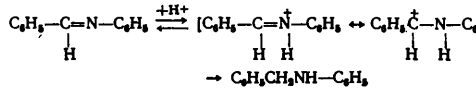
4. Carboxylic Acids

The carbonyl group in carboxylic acids and esters does not undergo ionic hydrogenation.

IV. IONIC HYDROGENATION OF A C=N BOND

The electronic structures of the C=N and C=O bonds have much in common, this being responsible for the similarity in their chemical properties, apparent especially in addition reactions. From this it could be supposed that azomethines would undergo ionic hydrogenation to form amines.

It has in fact been found[40] that benzylideneaniline and *o*- and *p*-benzylidenetoluidines react with triethylsilane and trifluoroacetic acid. With molar proportions of anil, silane, and acid of 1:1:3 at 60–70°C the amines are formed in yields respectively of 78%, 86%, and 95% after 60 min.



In contrast to the above anils, cyclohexylidene-*o*-toluidine does not form an amine under these conditions. The reason for such behaviour requires further study.

V. IONIC HYDROGENOLYSIS

The fact that cyclopropane hydrocarbons containing no multiple bonds undergo ionic hydrogenation enables us to hope that certain single bonds may be hydrogenated under these conditions. Compounds containing an atom having a lone pair of electrons were chosen to test this hypothesis. Addition of a proton produces a cation. If then a bond is ruptured with formation of a new cation, it is in principle possible for this to interact with a hydride-ion donor. The concentration of this cation must be sufficient for such interaction to occur. The first class of such compounds to be studied was the disulphides.

Table 5. Ionic hydrogenolysis of disulphides.

Disulphide	Yield of thiol, %
$(t\text{-}C_4H_9)_2S_2$	67
$(C_6H_5)_2S_2$	45
$(4\text{-}CH_3OC_6H_4)_2S_2$	73.5
$(2\text{-}NO_2C_6H_4)_2S_2$	0
$[2,4\text{-}(NO_2)_2C_6H_3]_2S_2$	0

1. The S–S Bond

Disulphides have been found[41] to interact with trifluoroacetic acid and triethylsilane, the S–S bond being cleaved and hydrogenated to form the corresponding thiols as the sole products of the reaction. Unchanged disulphide was isolated.

Table 6. Interaction of sulphenyl chlorides with triethylsilane.

Sulphenyl chloride	Solvent	Reaction product (yield, %)	Sulphenyl chloride	Solvent	Reaction product (yield, %)
C_6H_5SCl	none	disulphide (95)	$2\text{-}NO_2\text{-}4\text{-}ClC_6H_3SCl$	CF_3COOH	disulphide (65), thiol (30)
C_6H_5SCl	hexane	disulphide (slow reaction)	$4\text{-}NO_2C_6H_4SCl$	hexane	disulphide (slow reaction)
S_2Cl_2	none	no reaction			
S_2Cl_2	CF_3COOH	S, $CF_3COOSiEt_3$			
$2\text{-}NO_2C_6H_4SCl$	CCl_4	no reaction	$4\text{-}NO_2C_6H_4SCl$	CF_3COOH	disulphide (98)
$2\text{-}NO_2C_6H_4SCl$	HCOOH	disulphide (quantitative)	$2,4\text{-}(NO_2)_2C_6H_3SCl$	CF_3COOH	no reaction
$2\text{-}NO_2C_6H_4SCl$	CF_3COOH	disulphide (76), thiol (18)			

Separate experiments had shown that trifluoroacetic acid does not visibly react with a disulphide in the absence of a silane, and in the absence of the acid the silane does not react with the disulphide.

The scheme

$$RSSR + CF_3COOH \rightleftarrows RSH + [RS]^+CF_3COO^-$$
$$[RS]^+CF_3COO^- + H{-}SiEt_3 \rightarrow RSH + (SiEt_3)OCOCF_3$$
$$RSSR + H{-}SiEt_3 + CF_3COOH \rightarrow 2RSH + CF_3COOSiEt_3$$

was proposed for the reaction. It is supported by the fact that sulphenyl chlorides, which are potential sources of the sulphenium ion[42], react with triethylsilane under mild conditions, to give a theoretical yield of reduction products[43] (see Table 6). The general scheme of the reaction is

$$RSCl \overset{+H^+}{\rightleftarrows} [RS]^+ + HCl;\ [RS]^+ + H{-}SiEt_3 + CF_3COOH \rightarrow$$
$$\rightarrow RSH + CF_3COOSiEt_3;\quad RSH + RSCl \rightarrow RSSR + HCl\ .$$

Formation of the thiol precedes that of the disulphide, since nitro-disulphides do not react with the silane in trifluoroacetic acid (Table 5). The fact that a thiol results from the reaction means that its rate of formation exceeds the rate of interaction with the initial sulphenyl chloride.

Table 5 shows that electron-donor substituents increase the yield of thiols, whereas electron-acceptor substituents prevent the reaction. Increase in acidity raises the yield of thiol. This is consistent with the view that the first act in the reaction is protonation, leading to rupture of the S–S bond. It is noteworthy that the interaction of sulphenyl chlorides with trifluoroacetic acid and a silane involves hydrogenation of the S–Cl single bond with the formation of HCl and HSR.

2. The C–O Bond

It has already been noted that aromatic and aliphatic–aromatic alcohols undergo ionic hydrogenation of the C–O bond to form a hydrocarbon and water. Results obtained for the ionic hydrogenation of ketones and aldehydes show that ethers do not undergo this reaction under mild conditions. With a large (tenfold) excess of trifluoroacetic acid, however, certain ethers are able to react with a silane to form a hydrocarbon[44].

Table 7. Ionic hydrogenolysis of ethers.

Ether	Hydrocarbon	Yield, %
$t\text{-}C_4H_9OC_2H_5$	$CH_3{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}{-}CH_3$	60
$(C_6H_5)_2CHOCH(C_6H_5)_2$	$C_6H_5CH_2C_6H_5$	60
$C_6H_5CH_2OC_2H_5$	$C_6H_5CH_3$	7
$C_6H_5CH_2OCH_2C_6H_5$	$C_6H_5CH_3$	3

Table 7 indicates that ionic hydrogenation occurs with those ethers which, on protonation followed by rupture of the C–O bond, are capable of forming a relatively stable carbonium ion. The hydrogenolysis of an ether can be represented by the following scheme

$$ROR' \overset{+H^+}{\rightleftarrows} \underset{\displaystyle H}{\overset{+}{\underset{|}{R}}}OR' \rightarrow ROH + R'^+$$
$$R'^+ + H{-}SiEt_3 \rightarrow R'H\ .$$

VI. MECHANISM OF IONIC HYDROGENATION

The ionic hydrogenation of a multiple bond comprises two acts—addition of a proton to form a cation and transfer to the latter of a hydride ion to form the hydrogenation product—the relative rates of which depend on the structure of the reactants. The sequence of the acts may even be reversed as a consequence of this structure. Such a

reaction was reported by Knunyants, Cheburkov, and Aronov [45], who hydrogenated perfluoro-2,4-dimethylpenta-2,3-diene by the action of hydrogen sulphide and sodium hydrogen sulphide in sulpholan. These workers considered it probable that the first act in the reaction was the removal by the allene of a hydride ion from the hydrosulphide, followed by addition of a proton from the hydrogen sulphide:

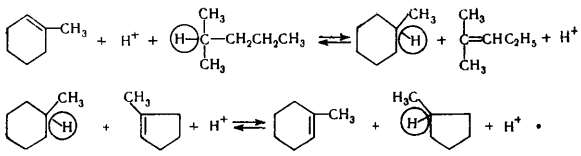
$$(CF_3)_2C{=}C{=}C(CF_3)_2 \xrightarrow[\text{sulpholan}]{H_2S+NaHS} (CF_3)_2CHCH{=}C(CF_3)_2 + S \ .$$

It is quite obvious that triethylsilane is not the only possible hydride-ion donor in ionic hydrogenation, just as trifluoroacetic acid is not the sole possible donor of protons.

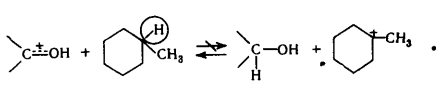
1. Donors of Hydride Ions

In the consideration of possible hydride-donors it must be borne in mind that the less stable a carbonium ion the more active it is as a hydride-ion acceptor but the shorter its lifetime (or the less probable its formation in a kinetically free state). And conversely, the more stable carbonium ions live longer, but are less active. Compounds which can act as hydride-ion donors in other reactions are of interest for use as possible donors of hydride ions in ionic hydrogenation. Examples of such compounds are saturated hydrocarbons containing a tertiary carbon atom. Their ability to act as hydride-ion donors has been demonstrated by Ipatieff and Pines [5-7], Haaf and Koch [8], Kramer [46], and Setkina et al. [47].

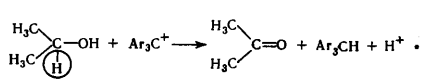
A mixture of four hydrocarbons—methylcyclohexene, methylcyclohexane, 2-methylpentane, and 2-methylpent-2-ene—was isolated from the reaction between methylcyclohexene and 2-methylpentane in trifluoroacetic acid. Similarly, the interaction between methylcyclopentene and methylcyclohexane in trifluoroacetic acid yielded a mixture of methylcyclopentene, methylcyclopentane, methylcyclohexane, and methylcyclohexene:



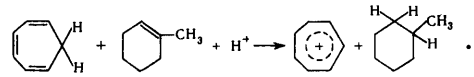
However, it has proved impossible to use a hydrocarbon containing a tertiary carbon atom as a hydride-ion donor to hydrogenate the carbonyl group. The apparent explanation is that the carboxonium ion is too stable to detach a hydride ion from the hydrocarbon, while the tertiary carbonium ion which should result is less stable. Since no reaction takes place between a hydrocarbon containing a tertiary carbon atom and a protonated ketone, it might be expected that the reverse reaction between an alcohol and a tertiary carbonium ion would occur:



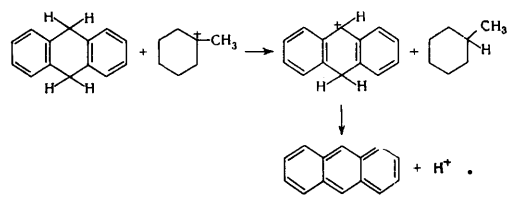
Actually, the reaction discovered by Bartlett [48] between an aliphatic alcohol and a triarylmethanol in sulphuric acid is in effect a reaction between an alcohol and a carbonium ion:



We have studied cycloheptatriene as another hydride-ion donor in ionic hydrogenation. The ability of cycloheptatriene to donate a hydride ion is due to the fact that the stable aromatic ion tropylium is thereby formed. Cycloheptatriene has been used as a hydride-ion donor in various reactions by Kursanov and Vol'pin [49], Dauben [50], Volz [51], and other workers [52]. It has been found [16,17] to react with methylcyclohexene in trifluoroacetic acid to form methylcyclohexane. Owing to competition by the polymerisation of cycloheptatriene in acid medium, however, the yield of the saturated hydrocarbon is low (~5%):



9,10-Dihydroanthracene proved to be a good hydride-ion donor in ionic hydrogenation. Its ability to donate a hydride ion was demonstrated by Braude and Linstead [53], Bonthron and Reid [54], and Nenitzescu and Balaban [55]. Kursanov, Parnes, and Bolestova [24] have found that 9,10-dihydroanthracene is able to give up a hydride ion to methylcyclohexene protonated with trifluoroacetic acid. This results in the formation of anthracene and methylcyclohexane (yield 70%):



The use of dihydroanthracene as a hydride-ion donor has enabled a stronger acid than trifluoroacetic to be used, which is impossible with triethylsilane, since the latter reacts with strong acids with the evolution of hydrogen.

An attempt to use acenaphthene as hydride-ion donor has shown merely the theoretical possibility of such a reaction, since the yield of saturated hydrocarbon is very small.

It follows from the above results that various hydride-ion donors can be employed in the ionic hydrogenation of alkenes, but so far the best results have been achieved with trialkylsilanes and 9,10-dihydroanthracene.

Methyldiethylsilane and mono-, di-, and tri-phenylsilanes have also been used as hydride-ion donors. In the series of phenylated silanes the ability to transfer a hydride ion diminishes in the sequence $(C_6H_5)_2SiH_2 > C_6H_5SiH_3 > (C_6H_5)_3SiH$ [17]. A similar relationship had been established earlier by Kursanov, Setkina, and Novikov [15].

2. Donors of Protons

Trifluoroacetic acid has been used as proton donor in ionic hydrogenation because, while being a strong acid ($H_0 = -3.2$), it possesses great ionising and solvating power [10]. Study of the effect of the quantity of acid on the yield of alkane has shown that the reaction takes place only in the presence of excess of acid, and is strongly accelerated by increase in this excess.

With a hundredfold excess of acid, isomerisation also becomes appreciable, this being absent when smaller quantities of trifluoroacetic acid are used. The work of Kursanov and Setkina [18-21] on the isotopic exchange of hydrogen in trifluoroacetates has shown the influence of acidity on the formation of carbonium ions from trifluoroacetates. These workers have established that the rate of

formation of carbonium ions is equal to the rate of formation of alkenes. It has also been found that, with $H_0 = -3.2$, trifluoroacetates of tertiary alcohols form carbonium ions. Those of secondary alcohols do not undergo heterolysis at this acidity, and carbonium ions are not formed. With increase in acidity, however, secondary carbonium ions are, nevertheless, formed.

Table 8. Effect of quantity of trifluoroacetic acid on yield of methylcyclohexane.

Molar ratio of acid to methylcyclohexene	Yield of methylcyclohexane, %	Duration of expt., h
1	4	120
2	73	120
10	78	1
100	80	0.3

3. Mechanism of the Hydride Migration

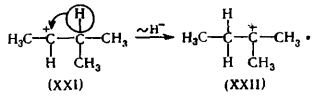
Hypotheses on the intramolecular and intermolecular transfer of a hydride ion were put forward long ago, but their proof encountered considerable difficulties because the hydride-ion acceptor was most often an unstable carbonium ion, the appearance of which during the reaction was very difficult to establish.

The hypothesis of hydride migration would appear to be inconsistent with the absence of molecular hydrogen evolution when the reaction is conducted in acid medium. Actually, in this case it would be necessary to expect that gaseous hydrogen would be produced by the process

$$H^- + H^+ \rightarrow H_2 .$$

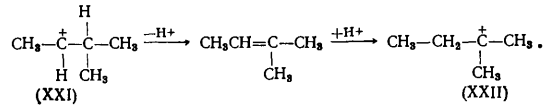
However, this discrepancy can be explained on the assumption that hydride migration takes place without the formation of a kinetically independent hydride ion, the transfer of a hydride ion taking place directly from molecule to molecule (or ion). In fact, a sufficiently active acceptor should be present to detach a hydride ion from a molecule. The solvated proton of an acid may not possess the required activity, so that it will not react with the hydride-ion donor and molecular hydrogen will not be formed. However, it is then impossible to check the act of hydride-ion transfer, which may involve the proton and the two electrons migrating in either one or more steps.

The question of the mechanism of the act of hydride-ion transfer is part of the general problem of establishing the mechanism of nucleophilic substitution. Just as the latter can be regarded as occurring in two steps (an electron, followed by an atom), hydride transfer can be divided into two steps (electron and hydrogen atom). However, whether hydride migration actually takes place in two steps, and if so in what cases, will be shown by future research. It must be stressed that the question of whether hydride transfer takes place in one or two stages is a matter of the relative rates of these steps. If the rate of the second step—transfer of a hydrogen atom to an already formed radical—considerably exceeds the rate of the first step, this is identical for chemical reactions to a one-step hydride transfer:



(XXI) (XXII)

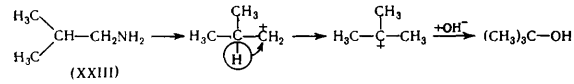
However, the same result will be achieved if the carbonium ion (XXI), having lost a proton, is converted into an alkene, which adds a proton from the medium to form a tertiary carbonium ion (XXII):



(XXI) (XXII)

Cannell and Taft showed[56] that under certain conditions the isomerisation of a carbonium ion cannot be explained by the intermediate formation of an alkene. They studied the deamination of isobutylamine (XXIII) by the action of nitrous acid in a medium containing deuterium oxide. The main reaction product was t-butyl alcohol: i.e. the initially formed isobutyl cation had rearranged to a t-butyl cation. If isomerisation occurred as a result of intramolecular hydride transfer (Scheme 3), the t-butyl alcohol formed should not contain deuterium bound to carbon. If, on the other hand, isomerisation were a consequence of the reversible formation of an alkene (Scheme 4), the t-butyl alcohol should contain deuterium bound to carbon (XXIV).

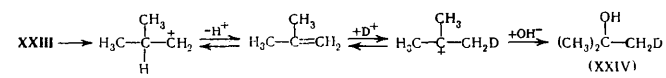
Scheme 3



(XXIII)

It was found that, if the reaction is conducted at pH > 3 and 38°C, the t-butyl alcohol will not contain deuterium bound to carbon. Since alkenes (but-1-ene, but-2-ene, isobutene) are formed as well as the alcohol in the reaction, it is obvious that no protonation of the alkenes takes place under the experimental conditions, isomerisation of the carbonium ion being a consequence of hydride transfer (Scheme 3). In a more acid medium, in which protonation of alkenes takes place, isomerisation of the carbonium ion will occur both as a consequence of intramolecular hydride migration and as a consequence of reversible formation of alkenes (Scheme 4).

Scheme 4



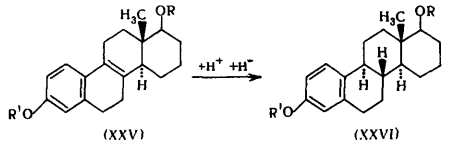
(XXIV)

From the above work it may be concluded that in any case, under certain conditions, isomerisation of the carbonium ion will occur as a result of intramolecular hydride transfer.

---o0o---

The stereochemical study of ionic hydrogenation is of great interest. Carey and Tremper have shown[57] that the ionic reduction of 1-phenyl-4-t-butylcyclohexene yields a mixture of *trans*- and *cis*-1-phenyl-4-t-butylcyclohexanes. If a disubstituted silane is used as hydride-ion donor, the *trans* : *cis* ratio is ~ 4 independently of the nature of the substituents (alkyl, aryl). If three substituents are attached to the silicon atom, this ratio is ~ 2. This fact is explained by these workers on the basis that the transition state in the *trans*-form is sterically more difficult for trisubstituted silanes. The *trans*-form is the predominant product in all cases because it is thermodynamically more favourable.

It has been shown quite recently[58] that the ionic hydrogenation of $\Delta^{8(9)}$-dehydro-D-homo-oestrogens (XXV) occurs stereospecifically to give D-homosteroids of *trans-anti-trans*-configuration (XXVI):



(XXV) (XXVI)

Thus the reaction of ionic hydrogenation is of great interest for theoretical organic chemistry, and is also a convenient method for the selective reduction of various classes of organic compounds.

Derivatives of Metal Carbonyls Containing a Bond between Atoms of Transition Metals and Group IVB Elements

N.E.Kolobova, A.B.Antonova, and K.N.Anisimov

This review considers the methods of preparation, properties, and structure of organopolymetallic compounds containing elements of Group IVB connected with a metal carbonyl residue. Compounds of this type are interesting from the point of view of investigating metal-metal interaction, that is, from the theoretical point of view. Their practical use in various fields of chemistry and technology is possible. 176 references.

I. INTRODUCTION

The intensive development of investigations in the field of the chemistry of carbonyl complexes of transition metals led to the preparation of a large number of compounds containing a direct bond between two metal atoms. Despite the fact that the existence of metal–metal bonds in organic derivatives of non-transition metals and in inorganic crystals is generally known, before 1957 no serious attention was paid to the possibility of the formation of a strong covalent bond between the atoms of transition metals in their organic derivatives—the carbonyls. It has now been found [1,2] that a metal–metal bond can be formed by all the transition metals capable of σ-bonding with carbon.

From 1962 onwards chemists have paid special attention to derivatives of metal carbonyls containing two or more covalently bonded atoms of different metals, both transition and non-transition. The present review examines the methods of preparation and properties of organopolymetallic compounds containing Group IVB elements bonded with a metal carbonyl residue. The investigation of metal–metal interaction in compounds of this type is of considerable interest both from the standpoint of the theory of the chemical bond and in view of their possible practical application.

In published reviews [1-5] dealing with the formation of covalent bonds between metal atoms, derivatives of metal carbonyls containing bonds between various transition and non-transition metals were either not considered or the consideration was limited owing to the absence of sufficient facts at the time these reviews were written.

II. STRUCTURES OF COMPOUNDS CONTAINING A BOND BETWEEN ATOMS OF TRANSITION AND NON-TRANSITION METALS

The possibility of the existence of a covalent bond between transition metal atoms was first shown in 1957 in an investigation of the structures of polynuclear metal carbonyls. Before then the only complexes (including carbonyls) known were those in which in addition to the metal–metal bond there were bridging atoms or groups between the metal atoms. The first complexes studied with metal–metal σ-bond structures were dimeric carbonyls of manganese and rhenium [6,7], or technetium [8] and molybdenum π-cyclopentadienylcarbonyl [9].

The ability of transition metals to form σ-bonds with Group IVB elements was observed [10] in 1956. Many series of compounds with chains of several covalently bound metal atoms, which can be classified as "clusters", have now been studied. According to Cotton's definition [4] "clusters" are compounds in which metal atoms are bound to one another exclusively by metal–metal bonds; this definition also includes those compounds in which not all the metals are identical. Several non-metal atoms can also be bound to the "cluster".

Since one or more $M'(CO)_5$ groups enter into most of the best studied clusters we will deal in greater detail with the molecular and electronic structure of this group.

1. Molecular Structure of the $M'(CO)_5$ Group, where M' = Mn, Tc, or Re

The structure of the $M'(CO)_5$ group was first found [6,7] in determining the structure of the dinuclear manganese carbonyl. Subsequent X-ray diffraction investigations showed that the characteristic peculiarities of this group are also kept in other compounds irrespective of the nature of the atoms or groups with which they are connected.

The metal atom in the $M'(CO)_5$ group has an octahedral configuration; five of the vertices of the octahedron are occupied by carbonyl groups and at the sixth there is a substituent X connected with the metal atom by a σ-bond. The C_{4V} symmetry of the $M'(CO)_5$ group is somewhat distorted owing to the non-linearity of the M'–C–O chains and displacement of the four equatorial CO groups to the side of the X substituent. For $Mn(CO)_5$ this displacement averages 3.8°. A possible reason for the departure from coplanarity of the equatorial CO groups is the mutual repulsion between the electrons of the axial and equatorial carbonyl groups. Another reason for the distortion of the molecule could be the intermolecular interaction due to the requirement for compact packing in the crystal lattice.

However, an electron diffraction study of the $Mn_2(CO)_{10}$ molecule showed [11] that the non-linearity of the Mn–C–O groups is also retained in the gas phase, and the oxygen atoms alternately depart to the right and left of the plane formed by the carbon atoms. Finally, rehybridisation of the d^2sp^3 orbitals of the metal atom, leading to release of energy and the strengthening of the bonds in the molecule, can be responsible for the decrease in symmetry [12].

The bonds between the metal atom and the carbonyl groups are not equivalent. In the manganese carbonyl molecule the $Mn-CO_{ax}$ distance is appreciably shorter than the bonds with the equatorial groups [11]. An analogous shortening of the M′–C bond and lengthening of the C–O bond for an axial group in comparison with the equatorial ones was observed in the molecules of $Tc_2(CO)_{10}$, [8] $HMn(CO)_5$, [13,14] $HCF{=}CFMn(CO)_5$, [15] and $HMnRe_2(CO)_{14}$. [16] Evidently this is connected with the reduction of symmetry of the electron shell along the X–M′–C–O axis, owing to the presence of substituent X (other than CO) in the trans-position to CO.

The structure of the $M'(CO)_5$ group is shown in Fig. 1. Table 1 gives the mean interatomic distances and angles between the bonds for M′ = Mn, Tc, and Re.

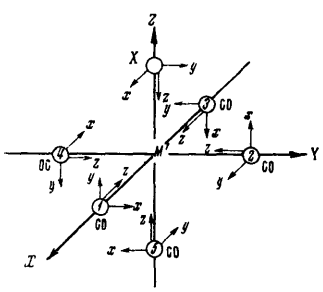

Figure 1. Structure and system of coordinates of the molecules of $XM'(CO)_5$ type.

2. Electronic Structure of Derivatives of the $XM'(CO)_5$ Type

A satisfactory description of the electronic structure of transition metal complexes is at present possible only within the framework of the LCAO-MO method. Unfortunately, there is only one theoretical investigation [17] of the nature of the bonds in the carbonyl complexes of the transition metals of Group VII and this did not include an analysis of the organopolymetallic compounds with direct metal–metal bonds.

The carbonyls of the Group VII metals are stable complexes of metals in the zerovalent state of oxidation with carbon monoxide. All the CO groups are unidentate ligands coordinated with the metal atom through carbon. Coordination by the lone pair of electrons of the carbon is preferable to that due to electrons of the oxygen atom, owing to the high electronegativity of the latter. Derivatives of metal carbonyls of the type $XM'(CO)_5$ obey Sidgwick's rule, which is reflected in the diamagnetism of compounds of this class. The metal atom acquires an inert-gas 18-electron shell by the addition to its 7 valence electrons of 10 electrons from the CO groups and the formation of an M′–X covalent bond.

As already noted above, the metal atom in the $M'(CO)_5$ group which enters into the composition of both the dimeric carbonyl and its derivatives retains the somewhat distorted octahedral configuration. According to the structural data given above and also spectroscopic [18] and kinetic investigations [19–21] the axial carbonyl group $CO_{(5)}$ (see Fig. 1) is bound to the metal atom much more strongly than each of the four equatorial groups $CO_{(1-4)}$. This shows the extensive π-bonding of the metal atom with $CO_{(5)}$. It is therefore necessary to consider three types of bond formed by the central atom with (a) the axial CO group, (b) the equatorial CO groups, (c) the ligand X.

Table 1. Mean bond lengths and valence angles in $M'(CO)_5$ groups.

Parameters of the molecules	Mn [7]	Tc [8]	Re [16]
Bond length Å			
$M'-C_{axial}$	1.792	1.899	1.86
$M'-C_{eq}$	1.840	2.000	2.005
$C-O_{axial}$	1.151	1.205	1.26
$C-O_{eq}$	1.154	1.121	1.125
Valence angles, degrees			
$M'-C-O_{axial}$	177.0±1.6	175.1±1.4	178.5±2.5
$M'-C-O_{eq}$	177.3±1.2	177.7±1.2	170.5±3.0
$C_{axial}-M-C_{eq}$	93.8±0.6	93.8±0.4	92.5±1.8
$cis\text{-}C_{eq}-M'-C_{eq}$	89.8±0.6	89.8±0.4	89.9±1.4
$trans\text{-}C_{eq}-M'-C_{eq}$	172.3±0.6	172.4±0.4	174.8±1.4

The scheme of the energy levels of the molecular orbitals for the $XM'(CO)_5$ compounds is shown in Fig. 2. [17]

(a) The bond between the metal atom and $CO_{(5)}$ has the character of σ- and π-interaction. The stable σ-bond $M'-C_{(5)}$ is the result of the combination of the s-, p_z-, and d_{z^2}-orbitals of the metal and the $2s$- and $2p$-AO's of the carbon. The π-bonding between the M′ atom and $CO_{(5)}$ is mainly effected by the interaction of the d_{xz}- and d_{yz}-orbitals of the metal with the bonding (π) and antibonding (π*) orbitals of the CO. The p_x- and p_y-orbitals of the metal can also participate to some extent in π-bonding, but they are mainly used for σ-bonding with $CO_{(1-4)}$. Hence the $M'-CO_{(5)}$ π-interaction consists of one strong bonding, one mainly non-bonding, and two antibonding MO's.

(b) The four σ-bonds of the metal with the groups $CO_{(1-4)}$ situated in the xy plane are formed as a result of the combination of the s-, d_{z^2}-, $d_{x^2-y^2}$-, p_x-, and p_y-orbitals of the metal and the $2s$- and $2p$-orbitals of carbon. Only the d_{xy}-orbital of the metal is favourable for π-bonding and the other orbitals, which have a symmetry suitable for π-bonding with $CO_{(1-4)}$ participate either, as stated above, in stronger π-bonding with $CO_{(5)}$, or in σ-bonding.

(c) The σ-bond of a metal atom with the X substituent is formed by the s-, p_z-, and partly the d_{z^2}-orbitals of the metal and the corresponding X orbitals. In addition π-bonding can also be effected between the d_{xz}- and d_{yz}-AO's of the metal and the π-orbitals of similar symmetry on substituent X. Two alternatives can be considered here: the π-donation of electrons from X to the metal atom and the dative interaction of the filled d_π-orbitals of the metal with vacant orbitals of X. In the first instance the energy of the non-bonding π-MO in the $M'-CO_{(5)}$ system is

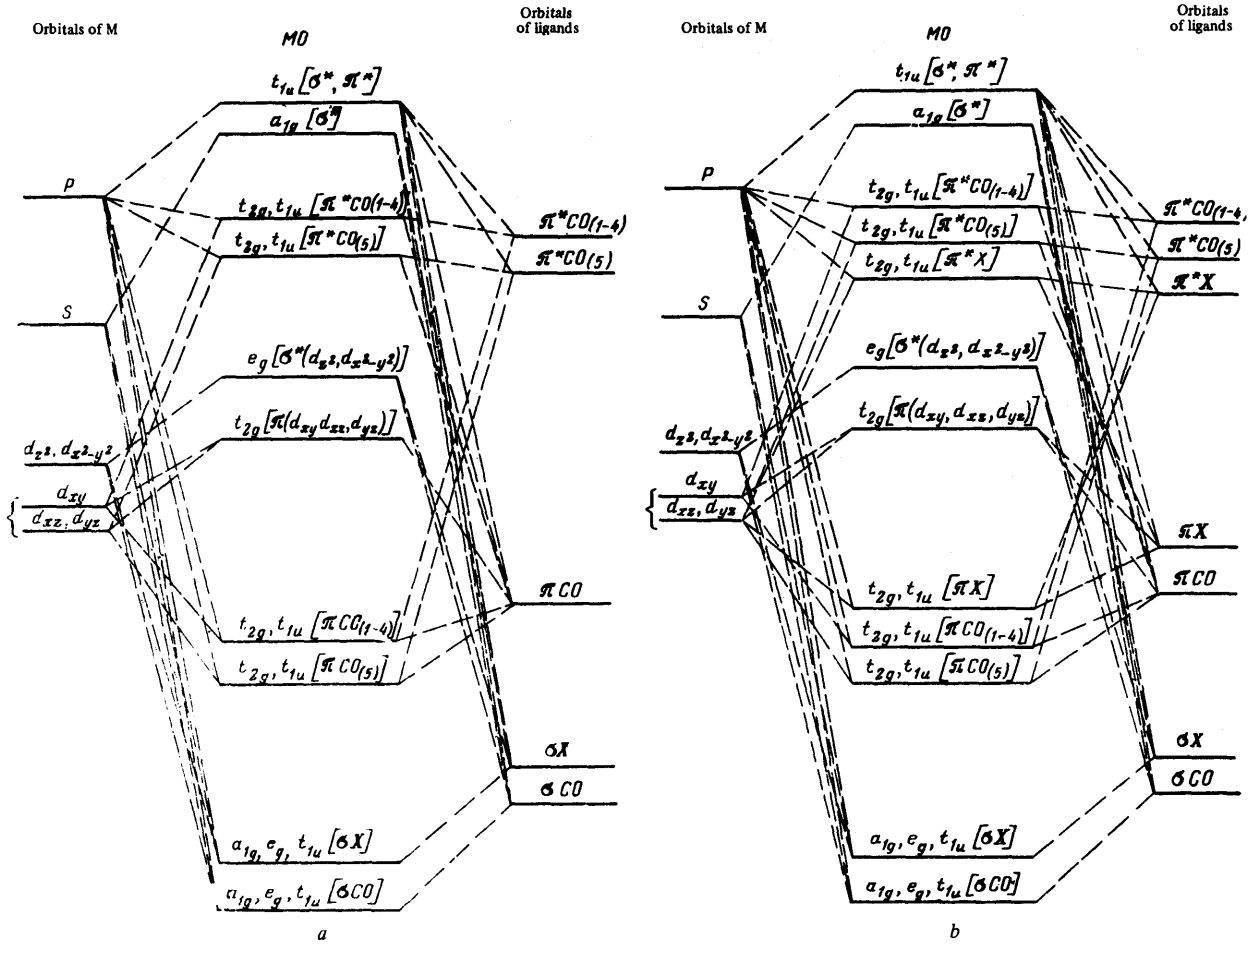

Figure 2. Scheme of energy levels for compounds of the $XM'(CO)_5$ type. *a*) X does not exhibit π-acceptor properties; *b*) X is a π-acceptor.

increased, whereas the energy of the π-orbitals of substituent X is reduced. As a result of this type of interaction additional strengthening of the $M'-CO_{(5)}$ bond should result. On the other hand, in dative π-interaction of M'–X there is competition between the π-orbitals of the ligands X and $CO_{(5)}$ for the electrons with the d_π-orbitals of the metal which should strengthen the M'–X bond and simultaneously weaken the $M'-CO_{(5)}$ bond. The scheme of the energy levels for the latter instance is shown in Fig. 2*b*.

In the diagrams the levels of the coulomb energies of the orbitals are arranged in the following order: $\sigma(CO, X) < \pi(CO) < \pi(X) < (n-1)d < ns < \pi^*(CO_{(5)}) < \pi^*(CO_{(1-4)}) < np$ in accordance with spectroscopic and kinetic results. To simplify the diagrams all the π- and π^*-orbitals of the equatorial CO-groups are shown together.

3. Structures of the Organopolymetallic Derivatives of Metal Carbonyls Containing a Metal–Metal Bond with a Group IVB Element

For the first metal carbonyl derivatives containing a Group IVB element (Si, Ge, Sn, or Pb) to be obtained it was assumed, without proof, that the two metal-containing fragments of the molecule are connected by a covalent metal–metal bond [10,22–24]. Direct proof of the covalent bonding between the atoms of the transition metal and the Group IVB element was obtained in 1964 as a result of X-ray diffraction investigation of organotin derivatives of manganese carbonyl [25,26] and it was found that in these compounds the metal–metal distance is even less than the sum of the so-called "covalent metallic radii" which is taken as the length of a single covalent bond [27].

An analysis of the compound $Ph_3SnMn(CO)_4PPh_3$ [25,28] showed that the covalently bound Sn, Mn, and P atoms are situated in a straight line, which is the principal axis of the distorted octahedron with the Mn atom at the centre; four of the vertices of the octahedron are occupied by CO groups and the other two by the tin and phosphorus atoms with approximately tetrahedral configurations. The phenyl groups at the tin and phosphorus atoms are in an eclipsed configuration relative to one another (Fig. 3). All the CO groups are somewhat displaced towards the tin atom. Table 2 gives the main parameters of the molecule.

The structures of several other derivatives of manganese carbonyl containing an Sn–Mn bond have been studied: $Ph_3SnMn(CO)_5$, [29] $Me_3SnMn(CO)_5$, [30,31] $Ph_2Sn[Mn(CO)_5]_2$, [26] $ClSn[Mn(CO)_5]_3$ [32,33] (Fig. 4*a*), and also the cluster $Ph_2Sn[Mn(CO)_5][Co(CO)_4]$, [34–36] which contains the chain Mn–Sn–CO (Fig. 4*b*). In all these molecules retention of approximately octahedral configuration of the manganese

atom and of the tetrahedral configuration of tin is observed. A comparison of the Sn–Mn internuclear distances (see Table 2) shows how sensitive the length of the metal–metal bond is to the nature of the ligands attached. One of the possible reasons for the appreciable differences in the lengths of the Sn–Mn bond could be the thermal anisotropy of the metal atoms [28]. However, the main reasons for these differences are undoubtedly of an electronic nature.

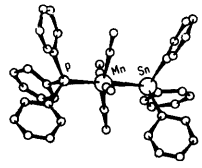

Figure 3. Structure of the $Ph_3SnMn(CO)_4PPh_3$ molecule.

In addition, purely steric factors play a large part. Thus in the series $Ph_3SnMn(CO)_5$, $Ph_2Sn[Mn(CO)_5]_2$, and $ClSn[Mn(CO)_5]_3$ as the number of $Mn(CO)_5$ groups bound to the tin atom is increased a tendency to an increase in the Sn–Mn distance is noted and the valence angles at the tin atom become increasingly distorted in comparison with the tetrahedral angles. As a result of the increase in steric hindrance the configuration of the tin atom gradually changes from tetrahedral to trigonal pyramidal.

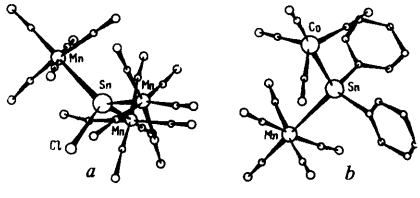

Figure 4. *a*) Structure of the $ClSn[Mn(CO)_5]_3$ molecule; *b*) structure of the $Ph_2Sn[Mn(CO)_5][Co(CO)_4]$ molecule.

The X-ray structural investigation of clusters with Sn–Fe bonds is of considerable interest both for studying the lengths of metal–metal bonds and the coordination of the metal atoms, and also for investigating the nature of the metal–ligand bonds [39–46]. It was found that in these compounds the tin atom also has approximately tetrahedral coordination with different degrees of distortion. In derivatives of iron [39–43,47,48,55] and molybdenum [43] bonded with a π-cyclopentadienyl ring the coordination of the transition metal atoms is of the "piano-stool" type characteristic of the half-sandwich compounds (Fig. 5).

The change in the nature of the metal–metal bond with the nature of the substituent at the non-transition element atom and the transfer of the electronic effects of the substituents along the metal–metal bonds can be readily traced in the series of trinuclear derivatives of the $X_2Sn[Fe(CO)_2.Cp]_2$. [39–41] As the electronegativity of X increase in the series Me < ONO < Cl there is some increase in the multiplicity of the C–O bonds, appreciable strengthening of the Sn–Fe bonds and also successive increase in the Fe–Sn–Fe angles.

*Cp = π-cyclopentadienyl.

This effect agrees with the tendency to an increase in the *s*-character of the hybridised orbitals of the tin atom participating in the Sn–Fe bond (Bent's rule [37,38]). The changes examined can be explained on the basis of hypotheses concerning the existence of d_π–d_π-interaction between the completed $3d_\pi$ orbitals of iron and the vacant $5d_\pi$ orbitals of the tin atom, which is intensified when the π-acceptor ability of the SnX_2 group increases as a result of an increase in the electronegativity of substituent X. As will be shown subsequently, this explanation agrees well with the spectroscopic results and chemical properties of the organopolymetallic derivatives of metal carbonyls.

There is special interest in another class of derivatives of iron carbonyl containing the $Fe(CO)_4$ group. The iron atom in this group is capable of forming two covalent bonds with the atoms of Group IVB elements. On the basis of a measurement of molecular weights [49] and investigations of

infrared spectra[50,51] structures (I)–(IV) (Fig. 6) are proposed for several such clusters. Structures (III) and (IV) were confirmed by X-ray diffraction for the molecules $Me_4Sn_3[Fe(CO)_4]_4$ [44] and $Sn[Fe(CO)_4]_4$ [45,46] respectively.

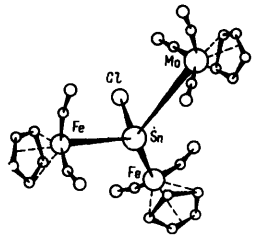

Figure 5. Geometry of the $ClSn[Fe(CO)_2Cp]_2$. $[Mo(CO)_3Cp]$ molecule.

Table 2 gives the principal structural parameters of the compounds which contain a metal–metal bond between a transition metal atom and a Group IVB atom.

III. METHODS OF FORMATION OF COVALENT BONDS BETWEEN ATOMS OF TRANSITION METALS AND ELEMENTS OF GROUP IVB

This chapter considers the methods of preparation of compounds containing from one to four metal carbonyl groups bound to an atom of a Group IVB element. Such reactions of these compounds will be discussed in the following chapter.

Method I. Replacement of Halogen Atoms in Compounds of the $R_{4-n}MHal_n$ Type by Metal Carbonyl Groups

The most general method for the formation of metal–metal bonds is reaction between halogen derivatives of the Group IVB elements and the sodium derivatives of metal carbonyls. This method was first used (in a more general form) by Hein and coworkers[56–59] for the formation of a Pb–Fe bond in the reaction of R_3PbBr or R_3PbOH with $CaFe(CO)_4$.

Exchange reactions have been used to obtain most of the known organopolymetallic derivatives of the carbonyls of chromium, molybdenum, and tungsten[60–62], manganese[22,32,33,62–70], rhenium[62,66,67,71,72], iron[10,22,63,73–75], and cobalt[62,70,76–81]. Depending on the nature and ratio of the reagents and on the reaction conditions there is partial or complete replacement of halogen atoms by metal carbonyl groups:

$$R_{4-n}MX_n + nNaM'(CO)_xL \xrightarrow{THF} R_{4-n}M[M'(CO)_xL]_n + n\,NaX$$

$$R_{4-n}MX_n + m\,NaM'(CO)_xL \xrightarrow{THF} R_{4-n}X_{n-m}M[M'(CO)_xL]_m + m\,NaX$$

where M = Si, Ge, Sn, Pb; $M'(CO)_XL$ = $Cr(CO)_3Cp$, $Mo(CO)_3Cp$, $W(CO)_3Cp$, $Mn(CO)_5$, $Re(CO)_5$, $Fe(CO)_2Cp$, $Co(CO)_4$; R = H, alkyl, aryl; X = Cl, Br, I; n = 1–4; and m = 1–3.

The complexes which contain the $Fe(CO)_4$ group and have structures (I) and (II) (see Fig. 6) are obtained[50,82–84] by the following reactions:

$$2R_3MCl + Na_2Fe(CO)_4 \rightarrow (R_3M)_2Fe(CO)_4 + 2NaCl$$

$$2R_2MCl_2 + 2Na_2Fe(CO)_4 \rightarrow [R_2MFe(CO)_4]_2 + 4NaCl$$

where M = Ge, Sn, Pb; R = Me, Et, n-Bu, similar to the method used earlier by Hein.

Compounds with Sn–Ir bonds were synthesised with the aid of exchange reactions[85]:

$$R_{4-n}SnCl_n + n\,Na[Ir(CO)_3PPh_3] \rightarrow R_{4-n}Sn[Ir(CO)_3PPh_3]_n + n\,NaCl$$

where R = Me or Ph, and n = 1 or 2, as were compounds with Sn–Rh bonds[85]:

$$Me_3SnCl + Na[Rh(CO)_2(PPh_3)_2] \rightarrow Me_3SnRh(CO)_2(PPh_3)_2I + NaCl\ .$$

When the sodium derivatives of metal carbonyls react with polyhalide compounds of Group IVB elements mixtures of products with different degrees of substitution[64,65] are often formed, for example:

$$GeCl_4 + NaMn(CO)_5 \rightarrow Cl_3GeMn(CO)_5 + Cl_2Ge[Mn(CO)_5]_2 + [(OC)_5MnGeCl_2]\ .$$

By starting from halogen-containing organopolymetallic compounds, derivatives with a greater number of M–M' bonds can be obtained, including those with different metal carbonyl groups[86,87]:

$$R_2ClSnMn(CO)_5 + NaM'(CO)_xL \rightarrow R_2Sn[Mn(CO)_5][M'(CO)_xL] + NaCl$$

where $M'(CO)_XL$ = $Mo(CO)_3Cp$, $W(CO)_3Cp$, $Re(CO)_5$, or $Co(CO)_4$; R = Me or Ph.

By the replacement of the chlorine atoms in $Cl_2Sn[Fe(CO)_2Cp]_2$ by metal carbonyl groups clusters containing three different metals were obtained:

$ClSn[Mo(CO)_3Cp][Fe(CO)_2Cp]_2$[43,88], $Sn[Mo(CO)_3Cp]_2[Fe(CO)_2Cp]_2$[88], $ClSn[Mn(CO)_5][Fe(CO)_2Cp]_2$[73] and $ClSn[Re(CO)_5][Fe(CO)_2Cp]_2$[73].

Steric factors have a considerable effect on the nature of the products formed in reactions of this type. For example, compounds with four $M'(CO)_5$ groups (M' = Mn or Re) at germanium or tin atoms could not be obtained since distannanes are formed instead of the expected products[62,71]:

$$X_{4-n}Sn[M'(CO)_5]_n + NaM'(CO)_5 \rightarrow \begin{matrix}(OC)_5M' & & & & M'(CO)_5\\ & \diagdown & & \diagup & \\ (OC)_5M' & - & Sn & - & M'(CO)_5\\ & \diagup & & \diagdown & \\ (OC)_5M' & & & & M'(CO)_5\end{matrix}$$

where n = 1 or 3; M' = Mn or Re; X = Cl or Br. This is evidently explained by the large volume of the metal pentacarbonyl groups. Whereas many tin derivatives of the $XSn[M'(CO)_5]_3$ type have been obtained, where M' = Mn or Re and X = Me, Ph, Cl, Br, I, etc.[32,33,62,66], only one analogous germanium compound is known, $ClGe[Mn(CO)_5]_3$.[65] Instead of the corresponding bromo- and phenyl derivatives digermanes were obtained, for example:

$$2PhBr_2GeMn(CO)_5 + 4NaMn(CO)_5 \rightarrow \begin{matrix}(OC)_5Mn & & & & Mn(CO)_5\\ & \diagdown & & \diagup & \\ & & Ph-Ge-Ge-Ph & & \\ & \diagup & & \diagdown & \\ (OC)_5Mn & & & & Mn(CO)_5\end{matrix}\ .$$

The existence of the compounds $Sn[Fe(CO)_2Cp]_4$ [73] and $Sn[Mo(CO)_3Cp]_2.[Fe(CO)_2Cp]_2$ [88] shows that the steric hindrance produced by the $Mo(CO)_3Cp$ and $Fe(CO)_2Cp$ groups is much less than that due to the steric effects of the $Mn(CO)_5$ and $Re(CO)_5$ groups.

This type of method for the formation of M–M′ bonds includes the reaction of the halogen derivatives of Group IVB elements with the $[Co(CO)_4]^-$ anion [80,81] formed during the dissolution of cobalt carbonyl in nucleophilic solvents [89]:

$$3Co_2(CO)_8 + 12CH_3OH \rightarrow 2[Co(CH_3OH)_6]^{2+}[Co(CO)_4]_2^- + 8CO$$

$$R_{4-n}MCl_n + m[Co(CO)_4]^- \xrightarrow{CH_3OH} R_{4-n}Cl_{n-m}M[Co(CO)_4]_m$$

where M = Ge, Sn, or Pb; R = Me, n-Bu, or Ph; n = 1–3; m = 1–3.

Method 2. The Insertion of Ge^{II} and Sn^{II} Halides at Metal–Metal, Metal–Carbon, and Metal–Halogen Bonds

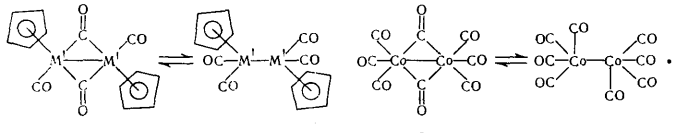
Several compounds which contain a bond between a Group IVB element and iron [24,74,90], cobalt [90–92], nickel [90], or ruthenium [93] atoms have been obtained as a result of the reaction of germanium(II) or tin(II) halides with dimeric carbonyls of the corresponding metals:

$$MX_2 + [M'(CO)_xL]_2 \rightarrow L(OC)_xM'–MX_2–M'(CO)_xL$$

where $M'(CO)_XL$ = $Fe(CO)_2Cp$, $Co(CO)_4$, $Co(CO)_3PR_3$, $Ni(CO)Cp$, $Ru(CO)_2Cp$; M = Ge or Sn; and X = Cl, Br, or I.

Reactions of this type are undergone both by the dihydrates of bivalent metal halides and by the anhydrous MX_2 in solutions in methanol, acetone, benzene or tetrahydrofuran (THF).

The reaction for the insertion of the MX_2 "carbenoids" at metal–metal bonds in dimeric carbonyls is based on the ability of Ge^{II} and Sn^{II} atoms to increase their covalency to four. As the experimental results show, this reaction is quite specific. They proceed comparatively readily with compounds which contain Fe–Fe, Co–Co, Ni–Ni, or Ru–Ru bonds, in the molecules of which in the crystalline state the metal–metal bonds are "maintained" by bridging carbonyl groups [94–96]. However, as the infrared spectra showed, in solutions the bridging forms $[M'(CO)_2Cp]_2$ (where M′ = Fe [97] or Ru [98]) and $Co_2(CO)_8$ [99–102] are in equilibrium with isomeric forms which do not contain bridging CO groups:



A rise in temperature shifts the equilibrium to the right.

The decrease in the coordination number of the metal atoms on going from the bridging form to the non-bridging form facilitates the approach of the MX_2 "carbenoids" to the M′–M′ bonds, which facilitates the insertion. In addition, the dissociation of $[Fe(CO)_2Cp]_2$ into $[Cp(CO)_2Fe]^{\cdot}$ radicals can be assumed to take place in nucleophilic solvents [103], and with $Co_2(CO)_8$ it is found that both $[(CO)_4Co]^{\cdot}$ radicals [104] and $[Co(CO)_4]^-$ anions [89,105] can be formed.

The insertion of $SnCl_2$ into phosphine derivatives of cobalt carbonyl free from bridging carbonyl groups has been effected [90–92]:

$$SnCl_2 + [Co(CO)_3PR_3]_2 \rightarrow Cl_2Sn[Co(CO)_3PR_3]_2$$

where R = n-Bu, Ph, or PhO. These reactions require more severe conditions and a much longer time than for $Co_2(CO)_8$. The insertion is hindered by increase in the π-acceptor capability of the ligands in the order: Bu_3P < < Ph_3P < $(PhO)_3P$.

Until recently insertions at metal–metal bonds in dinuclear carbonyls of molybdenum, tungsten, manganese, and rhenium, the fragments of which are bonded either in the crystalline state [6,7,9] or in solutions (according to the infrared spectra [106,107]) solely by an M′–M′ bond had not been effected. The reaction of $[Mo(CO)_3Cp]_2$ with $SnCl_2$ leads to the formation of $Cl_3SnMo(CO)_3Cp$. [24] The dimeric derivative of manganese carbonyl containing the 1,2-bis-diphenylphosphinoethane ligand reacts with $SnCl_2$ but the insertion product is again not obtained [108]:

$$[Mn(CO)_3L]_2 + SnX_2 \xrightarrow{\text{Acetone}} X_3SnMn(CO)_xL_y$$

where L = $Ph_2PCH_2CH_2PPh_2$; X = Cl, Br; x = 3 for y = 1; x = 1 for y = 2.

Manganese and rhenium carbonyls do not react with MX_2, [24,108] even on boiling in THF for three weeks [90]. It was recently observed [109] that to introduce MX_2 "carbenoids" at Mn–Mn and Re–Re bonds either elevated temperature or ultraviolet radiation, leading to the homolytic fission of these bonds, is necessary.

Hence the possibility of effecting insertion at M′–M′ bonds is determined by the stability of these bonds under the reaction conditions.

The insertion of "carbenoid" systems at transition metal–carbon bonds was first achieved at C–Fe bonds [110]:

$$MeFe(CO)_2Cp + GeCl_2\cdot C_4H_8O_2 \xrightarrow{\text{(dioxan)}} MeCl_2GeFe(CO)_2Cp$$

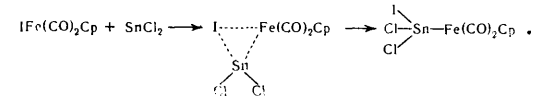
whereas with the C–W bond reaction with $SnCl_2$ led to the replacement of a methyl group by $SnCl_3$: [24]

$$MeW(CO)_3Cp + SnCl_2 \xrightarrow{\text{(acetone)}} Cl_3SnW(CO)_3Cp\ .$$

The reactions of halogen derivatives of metal carbonyls with germanium(II) and tin(II) halides were studied. $SnCl_2$ reacts with $ClFe(CO)_2Cp$ in methanol as follows [24]:

$$ClFe(CO)_2Cp + SnCl_2\cdot 2H_2O \rightarrow Cl_3SnFe(CO)_2Cp\ .$$

The reaction may proceed either by the insertion of $SnCl_2$ at the Fe–Cl bond or by the replacement of a chlorine atom in $ClFe(CO)_2Cp$ by $[SnCl_3]^-$ by an S_N1 or S_N2 mechanism. To find the mechanism $IFe(CO)_2Cp$ was treated with a tenfold excess of $SnCl_2$ as a result of which the complex $CH_3OH.ICl_2SnFe(CO)_2Cp$ was obtained [111]. Evidently the insertion of a "carbenoid" really does occur here, possibly proceeding with preliminary coordination of Cl_2Sn to the iron and iodine atoms and subsequent intramolecular migration of the iodine atom:



The complex of $GeCl_2$ with dioxan reacts smoothly with $ClFe(CO)_2Cp$ with the formation of $Cl_3GeFe(CO)_2Cp$. [112] In the reaction of this same complex with $IFe(CO)_2Cp$ a mixture of products is formed, in which $Cl_3GeFe(CO)_2Cp$ and $I_3GeFe(CO)_2Cp$ are present, as a comparison of the chemical shifts of the protons of the cyclopentadienyl ring shows. This can be due to the ready disproportionation of the compound expected:

$$5\ ICl_2GeFe(CO)_2Cp \rightarrow 3\ Cl_3GeFe(CO)_2Cp + I_2ClGeFe(CO)_2Cp + I_3GeFe(CO)_2Cp\ .$$

By analogy with the reactions of $GeCl_2$ and $MeFe(CO)_2Cp$ [110] it can be assumed that the reaction between the MX_2 halides and compounds with Fe–Hal bonds also proceeds by the insertion mechanism.

Method 3. Reaction of Trichlorogermane with Halogen Derivatives of Metal Carbonyls

The possibility of the formation of metal–metal bonds by reactions of this type was first demonstrated by the condensation of trichlorogermane with pentacarbonylmanganese chloride [113]:

$$Cl_3GeH + ClMn(CO)_5 \xrightarrow{(THF)} Cl_3GeMn(CO)_5 + HCl \ .$$

The compounds $Cl_3GeMo(CO)_3Cp$, $Cl_3GeW(CO)_3Cp$, [114] and $Cl_3GeFe(CO)_2Cp$ [115] were obtained by the same method. Reactions of this type take place in THF solutions or in ether–dioxan mixtures.

It is known [116] that in $HGeCl_3$ there is an equilibrium between the bivalent and quadrivalent forms of germanium, and the presence of ethers facilitates the protonic dissociation of the germyl hydrogen:

$$HGeCl_3 \rightleftarrows H^+ + GeCl_3^- \rightleftarrows H^+ + Cl^- + GeCl_2$$

and the formation of ether addition compounds of the type $[R_2O \rightarrow H \leftarrow OR_2]^+GeCl_3^-$. In dioxan the dissociation goes even further and the complex $Cl_2Ge.C_4H_8O_2$ is formed. As shown above, this complex reacts with $ClFe(CO)_2Cp$, most probably by insertion at the Fe–Cl bond. In the reaction of $HGeCl_3$ with $[Fe(CO)_2Cp]_2$ in THF, $Cl_3Ge[Fe(CO)_2Cp]_3$ formed in additon to $Cl_3GeFe(CO)_2Cp$. [115]

It can be assumed that the reaction of metal halogenocarbonyls with $HGeCl_3$ proceeds either by the insertion of $GeCl_2$ at the M′–Cl bond or by an ionic mechanism with participation of the $GeCl_3^-$ anion by analogy with the reactions of alkyl halides with trichlorogermane leading to compounds of the $RGeCl_3$ type [116]. Possibly both these mechanisms compete but they have not yet been distinguished.

Method 4. Replacement of the Mercury Atom in Mercury Derivatives of Metal Carbonyls by Tin(II) Halides

Sn–M′ bonds are formed in the reaction of SnX_2 with $XHgM'(CO)_xL$ or $Hg[M'(CO)_xL]_2$ in acetone or ethyl acetate [91,117]:

$$RHgR' + SnX_2 \rightarrow X_2SnRR' + Hg \quad (1)$$
$$RHgX + SnX_2 \rightarrow X_2SnR + Hg \quad (2)$$

where R and R′ = $Mo(CO)_3Cp$, $W(CO)_3Cp$, $Fe(CO)_2Cp$, $Co(CO)_4$, $Co(CO)_3PBu_3$; X = Cl or Br. The initial stage of reaction (1) may be the introduction of "carbenoid" groups: $R–Hg–R–SnX_2 \rightarrow [R–Hg–SnX_2–R]$. The intermediate compound is unstable owing to the low strength of the Hg–Sn bond and readily decomposes:

$$[R—Hg—SnX_2—R] \rightarrow Hg + X_2SnR_2.$$

Reaction (2) evidently proceeds by another mechanism. Unlike the electrophilic insertion of SnX_2 mentioned above here nucleophilic attack by SnX_3^- formed in the solution on the RHg^+ or $RHg[(Solv)]^+$ cation is possible:

$$R—Hg—X + SnX_3^- \xrightarrow{(Solv)} [RHgSnX_3] \rightarrow X_2SnR + Hg \ .$$

Method 5. Reaction of Silanes with Dimers of Metal Carbonyls

In the reaction of silanes with cobalt carbonyl a compound with a Si–Co bond is formed readily [118]. The reaction of silanes with dinuclear metal carbonyls serves as a preparative method for the synthesis of various silyl derivatives of molybdenum [119], manganese and rhenium [67, 70, 119], iron [119], cobalt [50, 70, 120, 121], and nickel [119]:

$$2R_3SiH + [M'(CO)_xL]_2 \rightarrow 2R_3SiM'(CO)_xL + H_2$$

where $M'(CO)_xL$ = $Mo(CO)_3Cp$, $Mn(CO)_5$, $Re(CO)_5$, $Fe(CO)_2Cp$, $Co(CO)_4$, $Ni(CO)Cp$; R = H, alkyl, aryl, halogen. It should be noted that the reaction with cobalt carbonyl is very fast even at room temperature, whereas very severe conditions are necessary with manganese and rhenium carbonyls.

Probably the initial stage in these reactions is the formation of $HM'(CO)_xL$, which then reacts with the silane:

$$R_3SiH + HM'(CO)_xL \rightarrow R_3SiM'(CO)_xL + H_2 \ .$$

Confirmation of this mechanism is given by the quantitative formation of compounds of the type $R_3SiCo(CO)_4$ in the reaction of silanes with either cobalt carbonyl or $HCo(CO)_4$. [121]

The reaction of $HSiCl_3$ with $Fe_3(CO)_{12}$ gives a compound with two terminal Cl_3Si groups at the iron atom, $(Cl_3Si)_2Fe(CO)_4$, and in reaction with $Fe(CO)_5$ in addition to this compound the cluster $[Cl_2SiFe(CO)_4]_2$ with two bridging silicon atoms is obtained [119].

Evidently the reaction of alkylgermanes [50,120] and alkylstannanes [51] with metal carbonyls can be classified among this type of reaction:

$$Et_3GeH + Co_2(CO)_8 \rightarrow Et_3GeCo(CO)_4$$
$$2Me_3SnH + Fe(CO)_5 \rightarrow (Me_3Sn)_2Fe(CO)_4 + H_2 + CO$$
$$2Me_2SnH_2 + 2Fe(CO)_5 \rightarrow [Me_2SnFe(CO)_4]_2 + 2H_2 + 2CO \ .$$

Apart from the general methods for the formation of M–M′ bonds considered above, there are specific methods applicable for the synthesis of individual organopolymetallic derivatives of metal carbonyls.

Compounds with Si–Mo or Si–W bonds were obtained by the reaction [122]:

$$HM'(CO)_3Cp + Me_2SiNMe_2 \xrightarrow{(THF)} Me_2SiM'(CO)_3Cp + Me_2NH.$$

Metal–metal bonds are formed by the photolytic reaction [123]:

$$Ph_4AsMCl_3 + M'(CO)_6 \xrightarrow{(CH_2Cl_2)} Cl_3MM'(CO)_5AsPh_4 + CO$$

where M = Ge or Sn; M′ = Cr, Mo, W.

Compounds of the $Cl_3MFe(CO)_4AsPh_4$ type were obtained [123] by a similar method from $Fe(CO)_5$. The formation of products with two metal–metal bonds of the $(Cl_3M)_2M'(CO)_4(AsPh_4)_2$ type, where M = Ge or Sn and M′ = Cr, Mo, or W, is also possible.

Compounds with M–M′ bonds were obtained [124] by reactions with oxidative eliminations, for example:

$$(bipy)Mo(CO)_4 + MeSnCl_3 \rightarrow MeCl_2SnMoCl(CO)_3(bipy) + CO \ .$$

The formation of a Ge–Mn bond was possible as a result of the reaction:

$$GeH_4 + 2HMn(CO)_5 \xrightarrow{(THF)} H_3Ge[Mn(CO)_5]_3 + 2H_2 \ .$$

In this even traces of $H_3GeMn(CO)_5$ or $HGe[Mn(CO)_5]_3$ were not observed although they might have been formed by the simple replacement of hydrogen atoms in the germane by the $Mn(CO)_5$ group. It is assumed that this reaction proceeds by the reduction of GeH_4 by the manganese carbonyl to GeH_2, which then adds two $Mn(CO)_5$ radicals. Traces of $H_2Ge[Mn(CO)_5]_2$ were observed in the reaction of GeH_4 with $Mn_2(CO)_{10}$. However, neither GeH_4 nor H_3GeK react with $ClMn(CO)_5$ or $BrMn(CO)_5$. [125].

Most of the compounds which contain the $Fe(CO)_4$ group were obtained as a result of specific reactions. Thus, compounds of the type $R_nSnR'_{4-n}$, where R = alkyl and R′ = vinyl or phenyl, react with $Fe(CO)_5$ to form clusters

of the $[R_2SnFe(CO)_4]_2$ type [49]. It is characteristic that these reactions are possible only for such compounds in which organic groups bound to the tin atom through sp^3 and sp^2 hybridised carbon atoms are present, for example, Me_2SnPh_2 or $Bu_2Sn(CH=CH_2)_2$; the groups bound to tin by the sp^2 carbon atom are more readily detached. Evidently the initial stage of the reaction is the formation of an unstable π-complex with participation of an iron atom.

The reaction

$$Bu_3SnCl + Fe(CO)_5 \rightarrow [Bu_2SnFe(CO)_4]_2 + Bu_4Sn_2[Fe(CO)_4]_4 + Sn[Fe(CO)_4]_4$$

was studied in detail [46,51]. It was suggested that initially a compound with structure (I) (Fig. 6) is formed:

$$2Bu_3SnCl + Fe(CO)_5 \rightarrow (Bu_3Sn)_2Fe(CO)_4 + CO,$$

which then disproportionates:

$$2(Bu_3Sn)_2Fe(CO)_4 \rightarrow [Bu_3SnFe(CO)_4]_2 + 2Bu_4Sn\ .$$

The composition of the mixture of products depends greatly on the reaction conditions. Thus after intensive boiling for 70 h only $Sn[Fe(CO)_4]_4$ is isolated. This compound can also be obtained by other methods:

$$Bu_6Sn_2 + Fe(CO)_5 \rightarrow Sn[Fe(CO)_4]_4 \leftarrow SnCl_2 + Fe(CO)_5\ .$$

Compounds having structure (II) (Fig. 6) are also formed by the reaction [126,127]:

$$R_2Sn(C{\equiv}CR')_2 + Fe_3(CO)_{12} \rightarrow [R_2SnFe(CO)_4]_2\ .$$

Oxidative elimination leads to compounds with structure (I), for example [124]:

$$SnX_4 + Fe(CO)_5 \rightarrow X_3SnFeX(CO)_4 \rightarrow (X_3Sn)_2Fe(CO)_4.$$

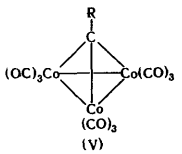
A series of specific methods for the formation of M–Co bonds are known. The direct reaction of MX_4 with cobalt carbonyl [77-81] can give halogen derivatives with from one to three $Co(CO)_4$ groups:

$$GeCl_4 + Co_2(CO)_8 \rightarrow Cl_{4-n}Ge[Co(CO)_4]_n + CoCl_2 + CO$$
$$4SnX_4 + 9Co_2(CO)_8 \rightarrow 4XSn[Co(CO)_4]_3 + 2CoX_2 + 24CO$$

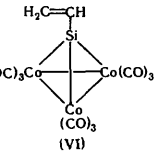
where X = Cl, Br, or I and n = 1 or 2. It is thought that in these reactions after the Co–Co bond is broken unstable carbonylcobalt halides are formed, which then decompose. The rate of these reactions decreases considerably with drop in the nucleophilic nature of the solvent in the series: THF > benzene > heptane [77]. It is not ruled out that reaction in THF is greatly facilitated by the reaction of $Co_2(CO)_8$ with the solvent, leading to the formation of the $[Co(CO)_4]^-$ anion. Clusters with an $RSnCo_3$ skeleton were obtained [79,80,102] by a similar method:

$$RSnCl_3 + Co_2(CO)_8 \rightarrow RSn[Co(CO)_4]_3 \text{ (where R=Me, Bu)}\ .$$

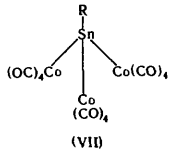
Compounds of the type $RC[Co(CO)_3]_3$ with structure (V) are formed [128,129] in the reaction of organic trihalogenoderivatives with $Co_2(CO)_8$:



(V)



(VI)



(VII)

Kettle and Khan [130] obtained a compound with Si–Co bonds for which the structure (VI) is proposed:

$$(CH_2{=}CH)_4Si + Co_2(CO)_8 \rightarrow CH_2{=}CHSi[Co(CO)_3]_3\ .$$

Tris(tetracarbonylcobalt) derivatives of tin (VII) do not contain Co–Co bonds, unlike the tris(tricarbonylcobalt) derivatives of carbon and silicon (V) and (VI) formed in similar reactions. It is interesting that the products of the reaction of tetravinylstannane with $Co_2(CO)_8$ differ depending upon the solvent: $(CH_2{=}CH)_2Sn[Co(CO)_4]_2$ is formed in pentane whereas in THF $MeC[Co(CO)_3]_3$ is formed. The formation of the latter is evidently explained by the conversion of the vinyl group into an ethylidene group during the reaction. The reasons for the difference in the structure of the complexes with an $RMCo_3$ skeleton, where M = C, Si, or Sn are still unexplained.

When tin(II) acetate reacts with $Co_2(CO)_8$ a mixture of $(CH_3CO_2)_2Sn[Co(CO)_4]_2$ and $CH_3CO_2Sn[Co(CO)_4]_3$ is formed [131].

As a result of the reaction of bis-(2,4-pentadionato)$SnCl_2$ with $[Co(CO)_4]^-$ compounds with a 6-coordinated tin atom are obtained [132]:

$$(C_5H_7O_2)_2SnCo_2(CO)_7,\quad (C_5H_7O_2)_2Sn[Co(CO)_4]_2 \text{ and } (C_5H_7O_2)_2ClSnCo(CO)_4.$$

IV. PROPERTIES OF ORGANOPOLYMETALLIC COMPOUNDS

Derivatives of Group IVB elements and metal carbonyls which contain metal–metal bonds are usually crystalline substances soluble in the usual organic solvents and insoluble in water. These compounds decompose comparatively readily in solution. In the solid state they are rather stable to the action of heat, light, oxygen, and atmospheric moisture. The stability of the compounds which differ in the transition metal atom increases considerably with increase in the atomic number of the metal within each group, for example, in the series Cr < Mo < W. With increase in the number of metal carbonyl groups the stability of the compounds falls slightly. In the series of compounds which differ only in the atoms of the Group IVB elements the stability of the lead derivatives is much less than that of its group analogues. Usually, with increase in the electronegativity of the substituent at the non-transition element the stability of the compounds increases.

The following reaction modes are characteristic for the compounds of the $X_{4-n}M[M'(CO)_xL]_n$ type: (1) substitution of M for X at the Group IVB element; (2) reactions at the M–M' bonds, and (3) replacement of the carbonyl groups at the transition metal atoms by other ligands. Furthermore, some of these compounds are capable of forming addition products with electron-donating reagents.

1. Replacements at the Group IVB Element

It is known [133,134] that halogenogermanes and halogenostannanes with organic groups readily exchange halogen atoms for other substituents. Halogen derivatives of germanium and tin containing metal carbonyl groups are also capable of exchanging halogen atoms for other atoms or groups whilst retaining the metal–metal bonds. Thus the chlorine atoms in $Cl_3GeFe(CO)_2Cp$ are replaced by acetoxy-groups [112]:

$$Cl_3GeFe(CO)_2Cp + 3CH_3COOK \rightarrow (CH_3COO)_3GeFe(CO)_2Cp + 3KCl\ .$$

Compounds are obtained with different functional groups at the germanium or tin atoms bound to two metal carbonyl groups:

$$Cl_2M[M'(CO)_xL]_2 + 2Y^- \rightarrow Y_2M[M'(CO)_xL]_2 + 2Cl^-\ ,$$

where $M'(CO)_xL$ = Mo $(CO)_3Cp$, W $(CO)_3Cp$; M=Sn[135], Mn $(CO)_5$; M=Ge[136]; Fe $(CO)_2Cp$, M = Ge, Sn[79,137]; Y=CH_3COO, MeO, EtS, SCN, OH, S, ONO, NO_3.

In the reaction with organic derivatives of lithium, sodium, or magnesium replacement of halogen atoms by organic groups occurs[73,74,135,137,138], for example:

$$I_2Ge[Fe(CO)_2Cp]_2 + 2MeLi \rightarrow Me_2Ge[Fe(CO)_2Cp]_2 + 2LiI$$

$$Cl_2Sn[Mo(CO)_3Cp]_2 + 2C_5H_5Na \rightarrow (C_5H_5)_2Sn[Mo(CO)_3Cp]_2 + 2NaCl$$

$$Br_3GeMn(CO)_5 + 3PhMgBr \rightarrow Ph_3GeMn(CO)_5 + 3MgBr_2 .$$

On passing gaseous HBr through solutions of $Cl_3GeMn(CO)_5$ or $Cl_2Ge[Mn(CO)_5]_2$ chlorine atoms are quantitatively replaced by bromine[138].

It was noted above that in the reaction of compounds of Group IVB elements containing several halogen atoms with the sodium derivatives of metal carbonyl mixtures of products with different degrees of substitution are obtained. A convenient method for the synthesis of individual halogen-containing compounds is the exchange of acetoxy-groups for halogen atoms:

$$(CH_3COO)_nGe[M'(CO)_xL]_{4-n} + n\,HX \rightarrow X_nGe[M'(CO)_xL]_{4-n} + n\,CH_3COOH$$

where $M'(CO)_xL = Mn(CO)_5$,[136] $Fe(CO)_2Cp$,[112,137] X = F, Cl, Br, I; $n = 2$ or 3.

Compounds with Ge–Fe bonds have been reduced[74]:

$$Cl_2Ge[Fe(CO)_2Cp]_2 + 2NaBH_4 \rightarrow H_2Ge[Fe(CO)_2Cp]_2$$

but attempts to obtain similar compounds with M–Mn or M–Re bonds were unsuccessful since reaction with $LiAlH_4$ or $NaBH_4$ is accompanied by the breaking of M–M′ bonds. Alkylation of compounds with Sn–Mo or Sn–W bonds could not be brought about with Grignard reagents[135]. These facts show the decrease in the stability of the M–M′ bonds under the conditions of these reactions is in the order M–Fe > M–Re ≃ M–Mn > M–W ≃ M–Mo, where M = Ge or Sn.

Carbonyl derivatives of the type $R_{4-n}M[M'(Cl)_xL]_n$, where R is an organic radical, react with halogens or hydrogen halides in two (sometimes competing) directions: either with partial or complete replacement of R or with breaking of the M–M′ bond. The direction of the reaction is determined primarily by the nature of the reactants and also by the quantitative ratio of the reagents and the reaction conditions.

$H_3SiMn(CO)_5$ was rather inert to the action of HCl;[69] gradual replacement of hydrogen atoms takes place only at 75°, and the Si–Mn bond is retained:

$$H_3SiMn(CO)_5 + n\,HCl \rightarrow H_{3-n}Cl_nSiMn(CO)_5 + n\,H_2$$

where $n = 1$–3. The considerable differences in the reactivity of the germanium and tin derivatives of the corresponding metal carbonyls is connected on the one hand with the lesser stability of the C–Sn bond in comparison with C–Ge. On the other hand an analysis of the reactions given below suggests that the stability of the Sn–M′ bonds is much greater than that of the Ge–M′ bonds. The triphenylgermyl derivatives of manganese and rhenium carbonyls do not react with HCl,[64,72] unlike the corresponding tin derivatives, which react with hydrogen halides with partial or complete replacement at the tin atom[22,71]. The Ph_3Sn derivatives of molybdenum, tungsten[60,135], iron[73], and cobalt[77] carbonyls behave similarly:

$$Ph_3SnM'(CO)_xL + n\,HX \rightarrow Ph_{3-n}X_nSnM'(CO)_xL + n\,C_6H_6$$

where X = Cl, Br, I and $n = 1$–3. Diphenylstannanes containing two metal carbonyl groups react with hydrogen halides, usually with retention of the Sn–M′ bonds[72,73,86,135]:

$$Ph_2Sn[M'(CO)_xL]_2 + 2\,HX \rightarrow X_2Sn[M'(CO)_xL]_2 + 2\,C_6H_6 .$$

It is characteristic that $Ph_2Sn[Mn(CO)_5][Co(CO)_4]$ reacts with HCl with replacement of only one phenyl group[86] but $Ph_2Sn[Co(CO)_4]_2$ does not undergo this reaction at all[77]. Evidently, the Sn–C bond is stabilised as a result of the addition of the electronegative $Co(CO)_4$ group to the tin atom. $Ph_2Ge[Re(CO)_5]_2$ reacts with HCl with the loss of one metal carbonyl group and not a phenyl group[72].

In the reaction of halogens with Ph_3Sn derivatives of manganese and rhenium carbonyls, depending on the ratio of the reagents mono-, di-, or tri-halogeno-derivatives are formed with retention of the Sn–M′ bonds[22,71,72]:

$$Ph_3SnM'(CO)_5 + n\,X_2 \rightarrow Ph_{3-n}X_nSnM'(CO)_5 + n\,PhX .$$

The action of halogens on $Ph_2Sn[Re(CO)_5]_2$ leads to the replacement of one of the two phenyl groups (depending on the ratio of the reagents)[71], whereas the analogous manganese compound reacts with the breaking of both C–Sn bonds and one Sn–Mn bond[22].

The reaction of $Ph_3GeMn(CO)_5$ and its rhenium analogue with chlorine or bromine at room temperature leads to breaking of the Ge–M′ bonds without replacement of the phenyl groups at the germanium atom. On the other hand, at temperatures above 70°, irrespective of the ratio of the reactants, all three phenyl groups are replaced by halogen atoms with retention of the Ge–M′ bond[64,72]:

$$Ph_3GeM'(CO)_5 + 3\,X_2 \rightarrow X_3GeM'(CO)_5 + 3\,PhX .$$

The direct action of halogens does not bring about replacement of three phenyl groups in Ph_4Ge or Ph_3GeX, or even one in Ph_2GeX_2, where X = Cl, Br, or I. The capability for ready and simultaneous replacement of three phenyl groups in $Ph_3GeM'(CO)_5$ shows the greater electron-donating ability of the $Mn(CO)_5$ and $Re(CO)_5$ groups in comparison with the phenyl groups.

The introduction of halogen atoms into phenylgermyl derivatives has been shown[65] to greatly strengthen Ge–Mn bond and to some extent the Ge–C bond, in comparison with the corresponding bonds in $Ph_3GeMn(CO)_5$. Thus at room temperature $Ph_2BrGeMn(CO)_5$ does not react with bromine, and at 72° one phenyl group is readily replaced by bromine, but $PhBr_2GeMn(CO)_5$ reacts very slowly with an excess of bromine at 72° to form $Br_3GeMn(CO)_5$.

Hence it can be taken as proved that the Ge–C bond in the germyl derivatives of the Group VII metal carbonyls is broken under the action of halogens much more readily than in ordinary organogermanium compounds.

Unlike the rearrangements[133]:

$$Ph_2GeX_2 + GeX_4 \rightarrow 2\,PhGeX_3$$

where X = Cl, Br, or I, which take place at high temperature in the presence of catalysts, the rearrangement of germanes which contain an $Mn(CO)_5$ group proceeds without a catalyst at a temperature not much above the melting point of the mixture of reagents[64]:

$$Ph_2BrGeMn(CO)_5 + Br_3GeMn(CO)_5 \rightarrow 2\,PhBr_2GeMn(CO)_5 .$$

Reactions with rearrangement at the tin atom are used[22] as a convenient method for making monohalogeno-derivatives:

$$PhBr_2SnMn(CO)_5 + Ph_3SnMn(CO)_5 \rightarrow 2\,Ph_2BrSnMn(CO)_5 .$$

The possibility of the rearrangement of atoms of different halogens in germyl derivatives of iron carbonyl has been demonstrated[112]:

$$Cl_3GeFe(CO)_2Cp + I_3GeFe(CO)_2Cp \rightarrow Cl_2IGeFe(CO)_2Cp + ClI_2GeFe(CO)_2Cp .$$

With derivatives of metal carbonyls which contain lead replacement at the lead atom is not observed although the

Pb–C bond is the weakest in the series of organometallic derivatives of the Group IVB elements [134]; the Pb–M′ bond is broken first.

2. Reaction of Compounds of the $X_{4-n}M[M'(CO)_xL]_n$ type at M–M′ Bonds

A. Breaking of the metal–metal bond. Unlike $H_3SiMn(CO)_5$ its addition product with pyridine reacts rapidly with HCl with quantitative breaking of the Si–Mn bond [69]:

$$H_3SiMn(CO)_5 \cdot 2C_5H_5N + 3HCl \rightarrow H_3SiCl + HMn(CO)_5 + 2C_5H_5N \cdot HCl .$$

$H_3SiCo(CO)_4$ is broken by HCl or water with the formation of cobalt carbonyl hydride [76]:

$$H_3SiCo(CO)_4 + HX \rightarrow H_3SiX + HCo(CO)_4$$

where X = Cl or OH. As noted above, the action of hydrogen halides does not break the M–M′ bond in germanium and tin derivatives of the $Ph_3MM'(CO)_xL$ type or in $Ph_2Sn[M'(CO)_xL]_2$, [22,60,64,72,73,77,135] but one of the Sn–Fe bonds in $PhSn[Fe(CO)_2Cp]_3$ is broken under the action of HCl:[73]

$$PhSn[Fe(CO)_2Cp]_3 + 3HCl \rightarrow Cl_2Sn[Fe(CO)_2Cp]_2 + ClFe(CO)_2Cp .$$

This shows that the M–M′ bond is weakened with increase in the number of metal carbonyl groups at the non-transition element atom. $Ph_2Sn[Mn(CO)_5][Co(CO)_4]$ reacts in a different manner with HCl and HBr: under the action of HCl only one phenyl group is replaced [86] whereas reaction with HBr under these conditions leads to the replacement of both phenyl groups and breaking of the Sn–Co bond [77]:

$$Ph_2Sn[Mn(CO)_5][Co(CO)_4] + HBr \rightarrow Br_2SnMn(CO)_5 .$$

Differences in the reactivity of metal–metal bonds in relation to the action of halogens are more noticeable. For example, in compounds of the $Ph_3MM'(CO)_5$ type (M′ = Mn or Re) the Sn–M′ bond is not broken by halogens at either room or elevated temperature. Whereas Ge–Mn or Ge–Re bonds are stable to the action of halogens at temperatures above 70° they are broken at room temperature [64,72]:

$$Ph_3GeM'(CO)_5 + X_2 \rightarrow Ph_3GeX + XM'(CO)_5 .$$

Probably the reaction of $Ph_3GeM'(CO)_5$ with halogens proceeds by different mechanisms at different temperatures in accordance with a change in the relative strength of the Ge–C and Ge–M′ bonds. Above 70° the rapid homolytic breaking of the Ge–C bond becomes possible [134] and at 20°C the Ge–Mn and Ge–Re bonds become less resistant to the action of halogens and are broken more rapidly than the Ge–C bonds, which are relatively more stable under these conditions. The breaking of Ge–M′ bonds at low temperature can proceed heterolytically, although the possibility of a homolytic process is not excluded.

Under the action of halogens the M–M′ bonds in $Ph_3SnFe(CO)_2Cp$, [22] $Ph_3MM'(CO)_3Cp$ (M = Sn or Pb), and $Ph_2Sn[M'(CO)_3Cp]_2$ (M′ = Cr, Mo, W) [135] are broken. Bromine detaches one metal carbonyl group from $Ph_2Ge[M'(CO)_5]_2$, where M′ = Mn or Re:[64,71,72]

$$Ph_2Ge[M'(CO)_5]_2 + Br_2 \rightarrow Ph_2BrGeM'(CO)_5 + BrM'(CO)_5 .$$

An excess of chlorine splits not only both the Sn–C bonds in $Ph_2Sn[Mn(CO)_5]_2$ but also one of the Sn–Mn bonds, $Cl_3SnMn(CO)_5$ being formed [22]. In the analogous rhenium compound both the Sn–Re bonds are retained under the action of chlorine [71], which shows that the Sn–Re bond is stronger than the Sn–Mn bond.

The bonds of transition metal atoms with lead are less stable. Reaction of $Ph_3PbMn(CO)_5$, $Et_2Pb[Mn(CO)_5]_2$, [22] and $Ph_3PbRe(CO)_5$ [60] with halogens and HCl leads to the complete decomposition of the molecule.

Apart from the breaking of the M–M′ bond under the action of halogens and hydrogen halides, some reactions of this type with other agents are known. The Si–Mn bond is readily broken by ammonia [69]:

$$2H_3SiMn(CO)_5 + NH_3 \rightarrow 2HMn(CO)_5 + (H_3Si)_2NH .$$

A similar reaction was observed for $H_3SiCo(CO)_4$ with the difference that here disilazane was decomposed to SiH_4, $(H_3Si)_3N$, and polymeric products, probably owing to the greater acidity of $HCo(CO)_4$ compared with that of $HMn(CO)_5$.

The reaction of $H_3SiCo(CO)_4$ with mercury(II) iodide is [76]:

$$2H_3SiCo(CO)_4 + HgI_2 \rightleftarrows 2H_3SiI + Hg[Co(CO)_4]_2$$

and the equilibrium is greatly displaced to the right.

Reactions with redistribution at the atoms of the non-transition elements which use the M–M′ bond are also known, for example [24]:

$$Cl_2Sn[Fe(CO)_2Cp]_2 + SnCl_4 \rightarrow 2Cl_3SnFe(CO)_2Cp$$

and also reactions with substitution at the cobalt atom, as a result of which the Si–Co bond is broken and a Ge–Co bond is formed [121]:

$$Me_3SiCo(CO)_4 + GeF_4 \rightarrow F_3GeCo(CO)_4 + Me_3SiF .$$

B. Insertion at Metal–Metal Bonds. In the reaction of perfluoroethylene with $Me_3SnMn(CO)_5$, $Me_3GeMn(CO)_5$, or $Me_3SnCo(CO)_4$ under ultraviolet radiation in pentane compounds containing M–C–C–M′ chains, where M = Ge or Sn and M′ = Mn or Co are obtained [139–142]. Whereas only one $CF_2{=}CF_2$ molecule is inserted per Sn–Mn bond, several perfluoroethylene molecules can be inserted at a Ge–Mn bond with formation of compounds of the $Me_3Ge(C_2F_4)_nMn(CO)_5$ type. As well as insertion products a mixture of fluorinated derivatives is formed in these reactions: Me_3MF, $C_5F_9Mn(CO)_5$, and other organofluorine derivatives of manganese carbonyls.

The reaction mechanism for the introduction of perfluoroethylene at M–M′ bonds has not been explained. Despite the fact that the reaction proceeds only under conditions favourable to free-radical processes, the products characteristic of reactions of Me_3M' radicals with perfluoroalkenes are not observed. The appearance in the reaction mixture of the fluoro-derivatives of germanium, of tin, and of manganese carbonyl can be explained by the decomposition of the insertion products as follows:

$$Me_3M{-}Mn(CO)_5 + CF_2{=}CF_2 \xrightarrow{h\nu} Me_3M{-}CF_2{-}CF_2{-}Mn(CO)_5$$

$$Me_3MCF_2CF_2Mn(CO)_5 \rightarrow CF_2{=}CF{-}Mn(CO)_5 + Me_3MF$$

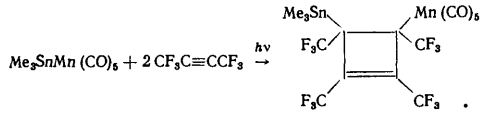
$$CF_2{=}CF{-}Mn(CO)_5 \xrightarrow{-2CO} [CF_2{=}CFMn(CO)_4]_2 \qquad CF_2{=}CF{-}Mn(CO)_5 \xrightarrow{+CO} CF_2{=}CF{-}\overset{\overset{O}{\|}}{C}{-}Mn(CO)_5 .$$

Evidently $Me_3GeC_2F_4Mn(CO)_5$ is more stable than the analogous tin compound.

Unlike perfluoroethylene, $CF_2{=}CFCl$ and $CF_2{=}CFH$ react with $Me_3MMn(CO)_5$ and $Me_3SnCo(CO)_4$ to form not insertion products but mixtures of different fluorinated organometallic compounds. Perfluoropropene also does not form an addition product with $Me_3GeMn(CO)_5$. [139]

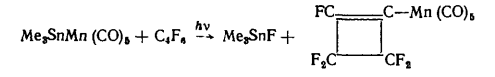
The introduction of acetylene compounds at the M–M′ bond has also been studied [143]. Thus the photochemical reaction of perfluorobut-2-yne with $Me_3SnFe(CO)_2Cp$ in pentane leads to the formation of a 1 : 1 addition product:

A similar reaction with $Me_3SnMn(CO)_5$ gives a cyclic insertion product:



The reaction of $Ph_3SnMn(CO)_5$ with perfluorobutyne proceeds with much greater difficulty and leads to the formation of a compound in very low yield, evidently also a 1 : 2 addition product.

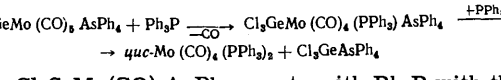
The reaction of $Me_3SnMn(CO)_5$ with perfluorocyclobutene involves breaking of the Sn–Mn bond:



3. Replacement of Carbonyl Groups by Other Ligands

Derivatives of metal carbonyls containing a metal–Group IVB element bond can react with some nucleophilic reagents with the replacement of one or more CO groups.

Triphenylphosphine reacts with a Ge–Mo complex [123]:



whereas $Cl_3SnMo(CO)_5AsPh_4$ reacts with Ph_3P with the simultaneous replacement of CO by phosphine and breaking of the Sn–Mo bond. The analogous derivatives of chromium and tungsten do not react with phosphine.

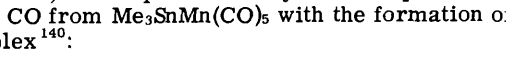
At elevated temperature replacement of CO groups in compounds of the $Ph_3MM'(CO)_5$ type (M = Ge or Sn, M′ = Mn or Re) by triphenyl-phosphine, -arsine, and -stibine takes place with the retention of the metal–metal bonds [22, 64, 71, 72] for example,

The reaction rate decreases slightly in accordance with the nature of the M–M′ bonds: Ge–Mn > Sn–Mn ≳ Ge–Re > Sn–Re. It is characteristic that the replacement of CO groups in compounds with a heteroatomic M–M′ bond proceeds more readily than in the corresponding dimeric carbonyls [144, 145].

Ethylene, unlike perfluoroethylene is capable of displacing CO from $Me_3SnMn(CO)_5$ with the formation of a π-complex [140]:

The germyl analogue does not react with ethylene [141]

The derivatives of iron carbonyl of the $[R_2SnFe(CO)_4]_2$ type react smoothly with PR'_3 under ultraviolet radiation, with formation [126–7] of a compound of the type $[R_2SnFe(CO)_3PR'_3]_2$. Depending on the ratio of the reagents both di- and mono-substituted products can be obtained [50, 84]:



where M = Sn or Pb; R = Et or Bu; and R′ = Et, Ph, or OMe.

The organopolymetallic derivatives of cobalt carbonyl are also capable of replacement of the CO groups. Phosphines react in heptane with the silicon and lead derivatives even at 25–50°C: [50, 69]

where M = Si or Pb; R = H, Et, or Cl; and R′ = Et or Ph.

When $Cl_2Sn[Co(CO)_4]_2$ is boiled with PPh_3 in THF a disubstituted product, $Cl_2Sn[Co(CO)_3PPh_3]_2$, is formed irrespective of the ratio of the initial reagents [90]. An analogous derivative of germanium was obtained [78] in THF at room temperature and also on boiling in hexane. At room temperature in hexane monosubstituted products of the type:

where M = Ge or Sn, are formed.

Hence all the organopolymetallic derivatives of metal carbonyls react with nucleophilic reagents with release of CO, unlike the alkyl derivatives of manganese, rhenium, and cobalt carbonyls $R–M'(CO)_X$ which in analogous reactions [146, 147] form acyl compounds of the $R–\overset{\overset{O}{\|}}{C}–M'(CO)_{X-1}L$ type. It has been found that [69] the introduction of CO at the M–M′ bond does not take place even at high carbon monoxide pressure. Evidently this phenomenon is connected with an increase in the strength of the M–M′ bonds owing to d_π–d_π interaction between the metal atoms [51, 81, 148]. This interaction can be represented schematically as a large contribution from resonance structure (IX):

Evidently the increased strength of the M–M′ bond in comparison with the C–M′ bond hinders the migration of the X_3M radical to the carbonyl group, as occurs with alkyl derivatives [149].

The fact that the replacement of CO groups in $Ph_3SnMn(CO)_5$ and $Ph_3GeMn(CO)_5$ leads to derivatives in which the phosphinic group is in the trans-position to the Ph_3M group [28, 150], whereas the corresponding organic derivatives of manganese and rhenium carbonyls have the *cis*-configuration [151, 152], mentoattention. Evidently apart from the steric factors electronic effects also play a part here. Possibly the presence of d_π–d_π interaction between the manganese and germanium or tin atoms, that is, the high contribution of structure (IX), determines the low strength of the bond of the axial carbonyl group with the metal in comparison with the equatorial ones.

Additional confirmation of the d_π–d_π metal–metal interaction can be seen in the increase in the rate of exchange of the CO groups for PPh_3 in compounds of the $X_2M[Co(CO)_4]_2$ type (where M = Ge or Sn) with increase in the electronegativity of X in the order Me < Ph < Cl. The introduction of substituents of greater electronegativity favours an increase in the electron-accepting power of the tin or germanium atoms leading to an increase in the multiplicity of the M–Co bonds and the weakening of the d_π–π^* Co–CO bonding.

V. PHYSICAL METHODS OF INVESTIGATION OF DERIVATIVES OF METAL CARBONYLS CONTAINING A METAL–METAL BOND

Physical methods of investigating compounds containing bonds between Group IVB elements and transition metals,

are used not only for finding or confirming the hypothetical structure of the molecules, but also give valuable information about the nature of the bonds in these compounds, which often cannot be obtained by purely chemical methods. The results of the X-ray structural investigation of the molecules of organopolymetallic compounds are given in Chapter II. The present chapter deals with the use of optical methods, radio and mass spectroscopy, and also the electrochemical investigation of compounds with M–M′ bonds.

1. Infrared Spectroscopy

The literature now contains information about the infrared spectra of most of the derivatives of metal carbonyls containing a bond between the transition metals and Group IVB elements.

The low-frequency range of the infrared spectra (700 to 100 cm^{-1}) of these compounds has been studied comparatively little and a precise assignment of the bands of the M–M′ and M′–CO stretching vibrations and M′–C–O deformation vibrations, which appear in this range, has not yet been made. In an analysis of the spectra of compounds of type $X_3GeMn(CO)_5$ and $X_2Ge[Mn(CO)_5]_2$ [150] the intense band at 470–450 cm^{-1} is assigned to ν^3_{Mn-C}, and the band in the 660–640 cm^{-1} range to δ_{CO}, by analogy with the assignment of the bands in the infrared spectra of $Mn_2(CO)_{10}$ [106,107] and $XMn(CO)_5$ (X = Cl, Br, I). [153] With increase in the electronegativity of X in the Ge–Mn compounds there is a decrease in the ν_{Mn-C} frequency. In the $Ph_3GeMn(CO)_4PPh_3$ spectrum there is a more significant increase in the ν_{Mn-C} frequency (by 55 cm^{-1}) and a decrease in the frequency of the C–O stretching vibrations, in comparison with the corresponding frequencies in the spectrum of the unsubstituted derivative, which confirms the close relation between the degree of $d_\pi - p^*_\pi$ bonding of M′–CO and of the π-bonding of the C–O groups.

Several papers [154–156] deal with the determination of the frequencies of the M–M′ stretching vibrations. It has been shown that the change in the $\nu_{M-M'}$ frequencies which appears in the 220–160 cm^{-1} range can be correlated with the corresponding changes in the frequencies of the C–O stretching vibrations. Usually, with an increase in the electronegativity of the substituent X in the compounds of type $X_{4-n}M[M'(CO)_xL]_n$, there is an increase in the $\nu_{M-M'}$ frequency which is consistent with increase in the $d_\pi - d_\pi$ interaction between the metal atoms.

The absorption range of the stretching vibrations of the CO groups (2200–1800 cm^{-1}) has been investigated most completely. X-ray diffraction investigations have shown that irrespective of the symmetry of the molecule as a whole in most of the compounds of the $X_{4-n}M[M'(CO)_xL]_n$ type a certain local symmetry of the metal carbonyl groups, found also for the corresponding derivatives of $XM'(CO)_xL$ type, where X is an organic radical or halogen atom, is mainly retained. It must therefore be expected that the infrared spectra of the derivatives or carbonyls which contain an M–M′ bond will be analogous to the spectra of the organohalogen derivatives of the corresponding metal carbonyls. Table 3 gives the theoretical and observable number of bands, ν_{CO}, for the organopolymetallic carbonyl compounds with various symmetries.

As Table 3 shows, the number of ν_{CO} bands in compounds which contain one $M'(CO)_xL$ group corresponds to the theoretical for the local symmetry of this group independently of the general symmetry of the molecule.

However, for compounds which contain several metal carbonyl groups there is always a greater number of bands. The appearance of additional bands in the spectra of these compounds can be connected with the interaction of the individual $M'(CO)_xL$ groups with one another. Furthermore allowance must be made for the decrease in the total symmetry of the molecules $X_{4-n}M[M'(CO)_xL]_n$ where $n > 1$ in comparison with the molecules of the compounds $X_3MM'(CO)_xL$.

Table 3. Number of bands of the stretching vibrations of the CO groups and their assignment in the infrared spectra of organopolymetallic derivatives of metal carbonyls.

Type of compound	Symmetry point group	Assignment of bands	Number of bands: theoretical	Number of bands: observed	Reference
Group VI					
$X_3MM'(CO)_3Cp$	C_{3v}	A_1+E	2	3	61, 135
$X_2M[M'(CO)_3Cp]_2$	C_{2v}		5		
	C_2, C_s, C_1		6	5–6	61, 135
Group VII					
$X_3MM'(CO)_5$	C_{4v}	$2A_1+E(+B_1)$	3–4	2–4	67, 150, 157
$X_2M[M'(CO)_5]_2$	C_{2v}	$3A_1+3B_1+B_2$	7	4–8	66, 150, 157
$XM[M'(CO)_5]_3$	C_{3v}	$3A_1+4E$	7	6–9	65, 66
Group VIII					
a. Iron derivatives					
$X_3MFe(CO)_3Cp$	C_{3v}	A_1+B_1	2	2	158, 159
$X_2M[Fe(CO)_2Cp]_2$	C_2	$2A+2B$	4	4	158, 159
	C_s	$2A'+2A''$	4	4	74, 158
	C_1	$4A$	4	4	
$(X_3M)_2Fe(CO)_4$	C_{2v}	$2A_1+B_1+B_2$	4	3	51
$[X_2MFe(CO)_4]_2$	D_{2h}	$B_{1u}+2B_{2u}+B_{3u}$	4	4	51
$X_4M_3[Fe(CO)_4]_4$	D_{2d}	$3B_2+4E$	7	4	51
$M[Fe(CO)_4]_4$	D_{2d}	$3B_2+4E$	7	4	51
b. Cobalt derivatives					
$X_3MCo(CO)_4$	C_{3v}	$2A_1+E$	3	3–4	81
	C_s	A_1+3A'	4	4	
$X_2M[Co(CO)_4]_2$	C_{2v}	$3A_1+3B_1+B_2$	7	7	81
	C_s	$4A'+4A''$	8	8	
$XM[Co(CO)_4]_3$	C_{3v}		7	6–8	80

It was found [158,159] that in compounds of the type $X_2M[Fe(CO)_2Cp]_2$ (where M = Ge or Sn) the picture of the νCO bands can change significantly with the nature of substituent X. X-Ray structural analysis of compounds of this type [39–41,43,44] showed that in the crystalline state they have C_2 or C_1 molecular symmetry. In solutions where the molecules are in a less sterically hindered state some change in the geometric configuration can be expected. In a study of the infrared spectra it was suggested that owing to rotation around the Ge–Fe bond and Sn–Fe bonds rotational isomers can exist in solutions, having C_2, C_1, or C_S symmetry depending on the electronic features and the volume of substituent X. For the compound $MeCl_2GeFe(CO)_2Cp$ the assumption of the existence of rotational isomers by rotation around the Ge–Fe bond was confirmed [159] in studying the effect of the polarity of the solvent and the temperature on the ratio of the intensities of the absorption bands.

On the basis of the assignment of the bands according to vibrational type, an analysis of the displacement of the corresponding bands as a function of the Group IVB element and the X substituents bound to them becomes possible.

In studying the infrared spectra of derivatives of the type $X_nR_{3-n}GeCo(CO)_4$ it was found[81] that there is a linear relation between the frequencies of the ν_{CO} bands and the total electronegativity of the halogen atoms bonded with the germanium. A similar dependence for the main frequency ν_{CO} was observed[50,120] in compounds of the $X_3SiCo(CO)_4$ type, where X = Et, Ph, OMe, or Cl. The existence of such a relation shows the connection between the charge on the atom of the non-transition Group IV element and the frequency ν_{CO} in all the derivatives of this type.

The nature of the change in the frequencies in the series of cobalt derivatives with the nature of the Group IVB element has been explained[50]. In the spectra of the compounds $Et_3MCo(CO)_4$ there is an almost linear decrease in the mean frequency ν_{CO} in the series of M: C > Si > > Ge > Sn > Pb. Since the electronegativities of Si, Ge, Sn, and Pb are similar[27] it can be suggested that the σ-components of the M–Co bonds should also always be similar. If that is so the decrease in the mean frequency ν_{CO} can be the result of a decrease in the π-transfer from the d_π-orbitals of the cobalt atom to the vacant d_π-orbitals of the non-transition element in the order Si > Ge > Sn > > Pb. Charge transfer in the M–Co π-system is confirmed by a study of the dipole moments of the complexes $X_3MCo(CO)_4$ and agrees with the values of the overlap integrals in these compounds[50].

The most convenient subjects for an analysis of the electronic effects of substituents bound to a transition metal atom are derivatives of Group VII metal carbonyls of the type $X_3MM'(CO)_5$ where M' = Mn or Re. Group theory predicts that in the infrared spectra of these compounds (point group symmetry C_{4V}) there should be three permitted bands ν_{CO}: $2A_1 + E$ and that the B_1 band should be active in Raman spectra[18,160,161]. Fig. 7 shows the vibration types.

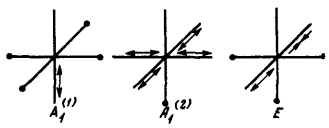


Figure 7. Types of vibrations of CO groups in $XM'(CO)_5$ and $X_3MM'(CO)_5$ (M' = Mn or Re) permitted in the infrared spectra. Only one component of the *E* vibrations is shown.

The band of type $A_1^{(1)}$, which has the lowest frequency, is assigned to the vibrations of the axial CO group. The most intense band of type *E* is assigned to the vibrations of the four equatorial groups. The bands of types $A_1^{(1)}$ and *E* often coincide. The $A_1^{(2)}$ vibrations are active in the infrared spectra only because of the non-coplanarity of the equatorial CO groups; this band of maximal frequency has low intensity and therefore is difficult to use in an analysis of the effects of substituents at the metal carbonyl group.

The study of the infrared spectra of the compounds of $XMn(CO)_5$ showed that there is a linear relation between the position of the type *E* bands and the Taft inductive parameter σ* for substituent X in the order: Me, H, Ph, I, CF_3, Br, Cl.[162] A similar change in frequency with the electronegativity of the substituent $R_nX_{3-n}M$ was also observed in the series of derivatives of type $R_nX_{3-n}MM'(CO)_5$, where M = Ge, Sn; M' = Mn or Re; R = Me or Ph; X = Cl or Br; and $0 \leq n \leq 3$.[67,150]

On the basis of an LCAO-MO examination of the bonds in the $XM'(CO)_5$ molecules (Chapter II) it can be assumed that inductive transfer in the molecules of type $X_3MM'(CO)_5$ should be reflected in the position of all the absorption bands of the CO groups, whereas the mesomeric effect associated with the transfer of electrons from $(n-1)d_{XZ}$ and d_{YZ} orbitals of the transition metal to the vacant d_π orbitals of the Group IVB element will affect only the vibration frequency of the axial carbonyl group.

The analysis of the infrared spectra of several compounds containing an M–M' bond which was made on the basis of this assumption showed[163] that there is a considerable $d_\pi - d_\pi$ interaction between the atoms of the Group VII element and the Group IVB element. The degree of π-bonding increases with increase in the electronegativity of the substituent connected with the transition metal atom. It was found that the degree of π-bonding for germanium compounds is greater than for analogous tin derivatives.

The direction of the inductive effect of the substituents X_3M in compounds with an M–M' bond varies on going from X = alkyl or aryl to X = halogen. The substituents Me_3M and Ph_3M are stronger electron donors than Me (and Ph), whereas the Cl_3M and Br_3M groups are comparable in their electron-acceptor properties with halogen atoms. There is some additivity in the increase in σ-acceptor properties of the $R_nX_{3-n}M$ groups with successive increase in the number of halogen atoms bound to the Group IVB element (Table 4).[150,163]

Table 4. Change in the σ- and π-effects in the series of $Ph_nBr_{3-n}GeMn(CO)_5$ compounds.

Compound	Frequency ν_{CO}, cm^{-1}			σ*	Δσ*	π	Δπ
	$A_1^{(1)}$	*E*	$A_1^{(2)}$				
$Ph_3GeMn(CO)_5$	2004	2004	2094	−0.45	0.97	1.73	0.51
$Ph_2BrGeMn(CO)_5$	2019	2019	2108	0.52	0.90	2.24	0.43
$PhBr_2GeMn(CO)_5$	2033	2033	2117	1.42	0.84	2.67	0.39
$Br_3GeMn(CO)_5$	2046	2046	2136	2.26		3.06	

The effect of the nature of the transition metal on the vibration frequency of the CO groups is much greater than the effect of the Group IVB element. In the series of isostructural derivatives of carbonyls of Group VI metals there is an increase in the mean frequency ν_{CO} with increase in the atomic number of the metal, for example, for $Ph_3SnM'(CO)_3Cp$[61] ν_{CO} is 1987, 1923, 1897 for M' = Cr; 2004, 1934, 1909 for M' = Mo; and 2014, 1927, 1902 cm^{-1} for M' = W. A similar increase in mean frequencies is observed also for derivatives of rhenium carbonyl compared with the corresponding manganese compounds[67,163].

The assignment of the ν_{CO} bands according to the types of vibrations in the spectra of the compounds which contain several metal carbonyl groups is difficult. Nevertheless, it has been shown[61,66,74,80,81,135,136,150,157–159] that with increase in the electron accepting ability of the substituents bound to the Group IVB element there is an increase in all the frequencies of the CO vibrations.

The literature contains information about the ultraviolet spectra of the carbonyl compounds containing an M–M′ bond, limited to the series of compounds $R_3MM'(CO)_3Cp$ (with M = Ge or Sn; M′ = Mo or W; R = Me or Ph),[61] but these results are too few and the observed picture too complex for a successful interpretation.

2. PMR Spectroscopy

As a result of the study of the PMR spectra of compounds of the $X_3SnM'(CO)_3Cp$ and $X_2Sn[M'(CO)_3Cp]_2$ type (M′ = Mo and W) [135] and also of $X_3MFe(CO)_2Cp$ and $X_2M[Fe(CO)_2Cp]_2$ [158,159] (M = Ge and Sn) it was found that the chemical shift of the protons of the cyclopentadienyl ring (in the τ-scale relative to Me_4Si) increases with decrease in the electronegativity of substituent X. In the series of $X_3GeFe(CO)_2Cp$ compounds [112] the value of τ increases with the change in X in the order: F < Cl < Br < I. These facts show the inductive transfer of the electronic effects of the substituents X through the M–M′ bond to the cyclopentadienyl ring.

For methylgermanes and methylstannanes of the $Me_{4-n}MX_n$ type there is a linear dependence of the quantity τ on the total Taft inductive parameter σ^*,[133,164] for example, τ_{CH_3} is 9.93 in Me_4Sn, 9.37 in Me_3SnCl, 8.84 in Me_2SnCl_2, and 8.35 in $MeSnCl_3$, which corresponds with an increase in the inductive withdrawal of electrons from methyl groups of the electron-accepting substituents at tin or germanium atoms. On the other hand, in the trimethylstannyl derivatives of metal carbonyls it is difficult to find any correspondence between the values of τ_{CH_3} and the nature of the metal carbonyl groups. A successive increase in the number of metal carbonyl groups in $Me_{4-n}Sn[M'(CO)_xL]_n$ molecules leads to a displacement of the signal of the methyl protons to the strong field side (see Table 5), which could be due to the electron-acceptor nature of the metal carbonyl groups.

In studying the change in the spin-spin coupling constants J(Sn–H) in compounds of the $Me_{4-n}SnX_n$ type with the electronegativity of X, the following hypothesis was used[165]: the Sn–H spin-spin coupling tends to be proportional to the s-character of the hybrid sp^3 orbitals of the tin used in the Sn–CH_3 bond and the s-character of the tin atom tends to be concentrated in orbitals directed towards electropositive substituents, according to Bent's rule [37,38]. Here it was also assumed that the change in substituent X only affects the electronic state of the tin atom whereas other parameters of the X–Sn–C–H system of bonds remain almost unchanged. In the $Me_{4-n}SnCl_n$ series with successive increase in the number of chlorine atoms the value of $J(^{119}Sn–H)$ gradually increases: Me_4Sn 54.0; Me_3SnCl 59.7; Me_2SnCl_2 71.0, $MeSnCl_3$ 100.0 Hz.[166] The successive replacement of the methyl groups by metal carbonyl groupings leads to a decrease in the value of J [61,66,67,87] (Table 5).

Proceeding from these assumptions the decrease in the value of J in Sn-metal carbonyl compounds in comparison with Me_4Sn can be treated as a decrease in the s-character of the tin orbitals in the Sn–CH_3 bonds and a corresponding increase in it in the bonds with the transition metal atoms. This serves as confirmation of the electron-donating nature of the metal carbonyl groups and of the considerable covalency of the Sn–M′ bonds in these compounds.

Table 5 shows that the value of J is much greater for compounds containing a $Co(CO)_4$ group. This can be explained by the somewhat greater electronegativity of the $Co(CO)_4$ group in comparison with that of the other metal carbonyl groups [66].

The conclusions drawn on the basis of the change in the constant J agree with the X-ray structural data (see Chapter II) which show the increase in the s-character of the Sn–M′ bonds (tendency $sp^3 \rightarrow sp^2$) with increase in the number of metal carbonyl groups in these compounds. Unfortunately there are few compounds for which both structural and PMR data are known.

Hence an analysis of the chemical shifts of the methyl protons and of the value of the spin-spin coupling constants J(Sn–CH_3) (Table 5) leads to directly contradictory results. However, since the interpretation of the change in the constants J agrees with the conclusions from a study of the infrared spectra, and with the X-ray structural data, this characteristic evidently more correctly reflects the properties of the metal carbonyl groups. The contradiction arising in the treatment of the chemical shifts can be connected with the considerable extent of the M′–Sn–C–H chain and also with several other factors which influence the screening of protons.

An example of the use of PMR spectra for determining the composition of compounds and of finding the mechanism of reaction of the metal carbonyl compounds is the work of Nesmeyanov and coworkers [112] where the analysis of the displacement of signals of protons and the change in their intensity in compounds of the type $X_3GeFe(CO)_2Cp$ (X = Br, I) demonstrated exchange between the halogen atoms bound to a germanium atom (see Chapters III and IV).

Table 5. PMR spectra of methylstannyl derivatives of metal carbonyls.

Compounds of the $Me_{3-n}Cl_nSnM'(CO)_xCp$ type	τ	J(Sn–H), Hz	Compounds of the $Me_{2-n}ClSn[M'(CO)_xCp]_2$ type	τ	J(Sn–H), Hz	Compounds of the $MeSn[M'(CO)_xCp]_3$ type	τ	J(Sn–H), Hz
$Me_3SnMo(CO)_3Cp$	9.52	49.0	$Me_2Sn[Mo(CO)_3Cp]_2$	9.15				
$Me_2ClSnMo(CO)_3Cp$	9.02	47.7	$Me_2Sn[Mo(CO)_3Cp][Mn(CO)_5]$		36.9			
$Me_2SnW(CO)_3Cp$		48.7	$Me_2Sn[W(CO)_3Cp][Mn(CO)_5]$		37.3			
$Me_2SnMn(CO)_5$	9.54	48.3	$Me_2Sn[Mn(CO)_5]_2$	9.17	36.7	$MeSn[Mn(CO)_5]_3$	8.62	~24

			$MeClSn[Co(CO)_4]_2$	8.48				

Values given for J ($^{119}Sn–CH_3$).

3. Nuclear Gamma Resonance

Confirmation of the electron donating nature of the metal carbonyl groups in compounds containing a bond between the tin and transition metal atoms was obtained from nuclear gamma resonance spectra (Mössbauer effect)[167-169].

Table 6. Chemical shift* of the resonance of ^{119}Sn in the compounds $Ph_{4-n}Sn[Re(CO)_5]_n$ and $Ph_{4-n}Sn[Fe(CO)_2Cp]_n$.[167,168]

Compound	Chemical shift, δ, mm s^{-1}	Compound	Chemical shift, δ, mm s^{-1}
Ph_4Sn	1.11	Ph_4Sn	1.11
$Ph_3SnRe(CO)_5$	1.45	$Ph_3SnFe(CO)_2Cp$	1.48
$Ph_2Sn[Re(CO)_5]_2$	1.70	$Ph_2Sn[Fe(CO)_2Cp]_2$	1.74
$PhSn[Re(CO)_5]_3$	1.75	$PhSn[Fe(CO)_2Cp]_3$	2.00
		$Sn[Fe(CO)_2Cp]_4$	2.14

*Relative to SnO_2.

In the nuclear gamma resonance spectra of the compounds of the $R_{4-n}Sn[M'(CO)_xL]_n$ type, where $M'(CO)_xL$ = $Mn(CO)_5$, $Re(CO)_5$, or $Fe(CO)_2Cp$, and R = alkyl or phenyl, quadrupole splitting of the ^{119}Sn signal is absent, which shows the high degree of covalency of the metal–metal bond. In compounds which contain the $Co(CO)_4$ group quadrupole splitting occurs but to a lesser extent than the splitting brought about by the introduction of halogen atoms at the tin atom. This is additional confirmation of the high electronegativity of $Co(CO)_4$ in comparison with the other metal carbonyl groups.

Table 7. Nuclear gamma resonance spectra of the compounds $X_2Sn[Fe(CO)_2Cp]_2$.

X	^{119}Sn		^{57}Fe	
	δ, mm s^{-1}	Δ, mm s^{-1}	δ, mm s^{-1}	Δ, mm s^{-1}
Et	1.74	0	0.373	1,88
Me	1.68	0	0.378	1,715
Cl	1.94	2.37	0,361	1,64

In the spectra of the compounds $X_{4-n}Sn[M'(CO)_xL]_n$ (where M' = Mn, Re, Fe, Co; and X = Me, Et, Ph, Cl, or Br) there is a gradual increase in the chemical shift of the δ resonance of ^{119}Sn with increase in the number of metal carbonyl groups (see Table 6), which can be regarded as the consequence of the decrease in the ionicity of the bond due to the electron-donating nature of the metal carbonyl groups.

A comparison of the results[171] from nuclear gamma resonance spectra of the $X_2Sn[Fe(CO)_2Cp]_2$ compounds relative to both ^{119}Sn and ^{57}Fe shows that the substituent X at the tin atom affects the electron density of both metal atoms (Table 7).

4. Mass Spectroscopy

Information about the comparative strength of metal–ligand bonds and about the energies necessary for breaking these bonds can be obtained from the mass spectra of organopolymetallic compounds.

In the fragmentation of metal carbonyl derivatives with M–M' bonds competing processes can take place: removal of CO, loss of ligand containing a Group IVB element as an entity, and also the removal of a part of the ligand from the Group IVB atom and transfer of an atom or group of atoms from the ligand to the transition metal. For example, in the mass spectrum of $Ph_3SnMn(CO)_5$ peaks are observed which correspond with the ions: Ph_3SnMn^+, Ph_3Sn^+, $PhMn^+$, HMn^+, and Mn^+, and in the mass spectra of $PhBr_2SnMn(CO)_5$ there are peaks of $PhBr_2SnMn^+$, $PhSn^+$, $BrMn^+$, $PhMn^+$, HMn^+, and Mn^+.[170]

An investigation of the derivatives of molybdenum[171], manganese and rhenium[66,170,172], iron[172], and cobalt[79,80] carbonyls of the type $X_{4-n}M[M'(CO)_xL]_n$ showed that the fragmentation of these compounds occurs first with the successive removal of ligands (CO and Cp) from the transition metal atom. For compounds which contain several metal carbonyl groups fragmentation proceeds with gradual removal of these groups. The M–M' bond is broken, usually last of all. Thus in the mass spectrum of $ClSn[Mn(CO)_5]_3$ peaks for the presence of $ClSnMn_3(CO)_x^+$ (x = 0, 3–6, 8–11, 15), $ClSnMn_2(CO)_x^+$ (x = 0, 3, 5, 9, 10), $SnMn(CO)_x^+$ (x = 0, 45) have been noted. Hence under the conditions for measuring the mass spectra the M–M' bond exhibits greater stability than the M–X bond and still greater than the M'–CO or M'–Cp bonds. With increase in the number of metal carbonyl groups attached to the atom of the Group IVB element, the strength of the M–M' bonds decreases which agrees with the chemical properties and with the increase in the length of these bonds observed in the structural investigations.

With the aid of mass spectroscopy it was shown that the structure of compounds of the $XSn[Co(CO)_4]_3$ type corresponds with structure (VII) (see Chapter III).[79,80] In the fragmentation of these compounds a considerable proportion of ions formed as a result of the breaking of the Sn–Co bonds was observed, which could mean that the $SnCo_3$ skeleton is weaker than that of $SnMn_3$.[66]

Mass spectroscopy is very valuable for finding the structure of the products formed by the introduction of perfluoroacetylenes at Sn–Mn and Sn–Fe bonds[143] (see Chapter IV).

5. Polarography

Polarographic reduction of a series of metal carbonyl derivatives with M–M' bonds[173-176] allowed the relative polarisation of these bonds to be estimated. The reduction of compounds of this type is always accompanied by breaking of the M–M' bond, which leads to the formation of anions containing a transition metal atom.

$$R_3M{-}M'(CO)_xL \xrightarrow{+1e} R_3M^{\cdot} + [:M'(CO)_xL]^- \quad (A)$$

$$R_3M{-}M'(CO)_xL \xrightarrow{+2e} R_3M^-: + [:M'(CO)_xL]^- \quad (B)$$

When M = Sn and R = Me or Ph the reduction has a single-electron nature (scheme A), whereas phenyl derivatives are reduced at more negative potentials than the methyl derivatives. When M = Pb the reduction proceeds by scheme (B) with the formation of two anions.

The ease of reduction varies in the following sequence:

$$Sn{-}Co > Et_3Pb{-}Mn > Me_3Sn{-}Mn = Me_3Sn{-}Mo > Ph_3Pb{-}Mn = Ph_3Pb{-}Fe > Ph_3Pb{-}Mo > Ph_3Pb{-}Re = Ph_3Sn{-}Mo > Ph_3Sn{-}Mn = Ph_3Sn{-}Re > Ph_3Sn{-}Fe.$$

The reduction of the compounds $Me_2Sn[Mo(CO)_3Cp]_2$ and $Me_2Sn[Fe(CO)_2Cp]_2$ leads to the loss of both metal carbonyl groups as anions:

$$Me_2Sn[M'(CO)_xCp]_2 + 2e \rightarrow Me_2Sn + 2[:M'(CO)_xCp]^- .$$

The reduction potential of the compound with Sn–Fe bonds here is higher than for the Sn–Mo bond.

In the reduction of the compound

$$[Cp(OC)_3Mo]_2Sn[Fe(CO)_2Cp]_2$$

which contains different transition metal atoms, a more complex picture is observed. Evidently loss of the Mo fragment takes place first and then a system with an Fe–Sn–Sn–Fe chain is formed.

Effect of Electron-donor Solvents on the Reactivity of Lithium Alkyls

E.A.Kovrizhnykh and A.I.Shatenshtein

The causes of and the relations governing the acceleration of reactions involving lithium alkyls by electron-donor solvents are discussed. The kinetic effect is due to a change in the polarity of the C-Li bond in consequence of the formation of complexes (of the donor-acceptor type) of the lithium alkyl and the solvent and a change in the state of lithium alkyl in solution.
The bibliography includes 115 references.

CONTENTS

I. Effect of solvents on the degree of association of lithium alkyls in solution 840

III. Effect of electron-donor solvents on the kinetics of reactions of lithium alkyls 843

I. INTRODUCTION

Despite the exceptionally wide applications of lithium alkyls in synthetic organic and polymer chemistry, it is still not quite clear how the state of lithium alkyls changes under the action of different solvents; the problem of the form in which lithium alkyls participate in reactions and of the ultimate mechanism of the change in the reactivity of lithium alkyls under the influence of electron-donor solvents remains controversial. These problems are discussed in the present review†.

I. EFFECT OF SOLVENTS ON THE DEGREE OF ASSOCIATION OF LITHIUM ALKYLS IN SOLUTION

The co-ordination unsaturation of organolithium compounds[1-3] is reflected in their characteristic capacity for association. Thus in hydrocarbon solvents ethyl- and n-butyl-lithium exist in the form of hexamers and t-butyl-lithium in the form of a tetramer (see Refs. 1 and 5). Branching or an increase in the length of the alkyl group R inhibit the association RLi.[4,6]

In connection with the problem of the effect of electron-donor solvents on the reactivity of lithium alkyls, information about their complexes with ethers[7-10], amines[11-13], and dialkyl sulphides[14] is of interest. The structure of such complexes has still not been adequately investigated and there are discrepancies in the data on their composition[10-12,15]. For example, Brown et al.[12] believe that, in benzene solutions containing a large excess of triethylamine relative to ethyl-lithium, a 1 : 1 complex is formed, which is a dimer of ethyl-lithium solvated by two molecules of the base. On the other hand, according to Eastham and coworkers[10,11,15], complexes of lithium alkyls and solvents with one electron-donor atom (triethylamine, ethyl ether, tetrahydrofuran) have a 2 : 1 composition, corresponding to a dimer of the lithium alkyl solvated by one molecule of the amine or ether, even in the presence of a large excess of the solvent. Complex formation with an electron-donor substance D can be represented by the mechanism[15]

$$[(RLi)_2]_n + n\,D \rightarrow n\,(RLi)_2 \cdot D. \qquad (1)$$

In the complex formation process, steric factors play an important role, which is very characteristic of the specific solvation of cations[16]. Thus although triethylamine is a stronger base than tetrahydrofuran (THF),[17,18] the steric hindrance to solvation[11,19,20] makes the complexes of RLi with triethylamine less stable and less polar than those with THF.[11]

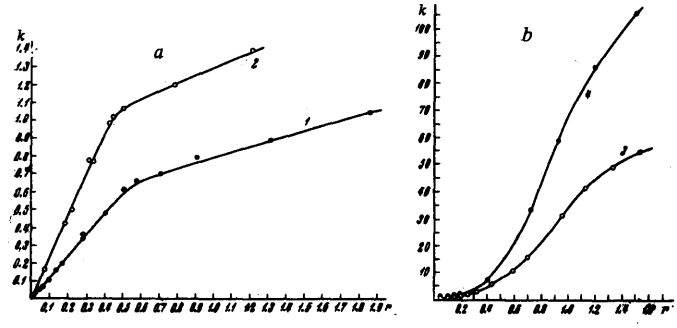

Figure 1. Determination of the composition of n-butyl-lithium solvate from data on the kinetics of the reaction between n-butyl-lithium and n-butyl bromide. Variation of k with r: *a*) for ethyl ether (*1*) and tetrahydrofuran (*2*); *b*) for 1,2-diethoxyethane (*3*) and 1,2-dimethoxyethane (*4*).

Information about the composition of complexes of lithium alkyls with electron-donor solvents can be obtained indirectly in some cases by studying the kinetics of reactions in which the lithium alkyls participate. For example, when the rate of reaction n-butyl-lithium with n-butyl bromide[21] (A) or 1-bromo-octane[22] (B) is studied, the curve relating the rate constant k to the molar ratio r of ether and the lithium alkyl in hexane solution shows an inflection of r = 0.5 (Fig. 1*a*). This indicates the formation of 2 : 1 complexes of n-butyl-lithium with ethyl ether or tetrahydrofuran.

When the reaction of A is carried out with addition of variable amounts of ethylene glycol ethers, each of which contains two oxygen atoms, the concentration dependence of the rate constant has a different form (Fig. 1*b*). The rate constant increases in proportion to the square of the concentration of the ether (c) up to r close to unity This can

† For an exhaustive list of the literature references on the properties and reactions of lithium alkyls, see Talalaeva and Kocheshkov[1].

be satisfactorily explained if it is supposed that in this case 1 : 1 complexes of n-butyl-lithium with the ethylene glycol ether are active in the reaction of n-butyl-bromide with n-butyl-lithium (see also Ref. 23). The different orders of reaction with respect to the ether (first in the case of ethers with one oxygen atom and second when the ether molecule contains two oxygen atoms, Fig. 2) correspond to different compositions of the complexes.

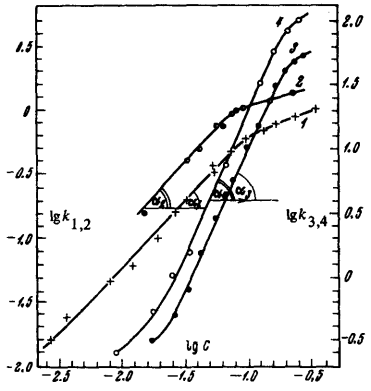

Figure 2. Determination of the order of the reaction between n-butyl-lithium and n-butyl bromide with respect to ethyl ether (*1*), tetrahydrofuran (*2*), 1,2-diethoxyethane (*3*), and 1,2 dimethoxyethane (*4*). (tan $\alpha_1 \simeq$ tan $\alpha_2 \simeq 1$; tan $\alpha_3 \simeq$ tan $\alpha_4 \simeq 2$).

Infrared spectra[4,6,24,25] and NMR (^{1}H and ^{7}Li) spectra[4,15,26] show that the degree of association of lithium alkyls in electron-donor solvents is lower than in hydrocarbon solvents. A reliable determination of the degree of association of lithium alkyls in ether solutions is complicated by the fact that lithium alkyls can react irreversibly with ethers[27-30]‡. Nevertheless, knowledge of the state of lithium alkyls in electron-donor solvents is important not only in understanding the characteristics of the kinetics and mechanisms of their reactions in these media but also because it throws light on the mechanism of the decomposition of association complexes under the action of electron donors.

The decomposition of association complexes is frequently represented by the equation

$$\frac{1}{n}(RLi)_n \rightleftarrows RLi, \qquad (2)$$

which reflects the process occurring, albeit of course in a simplified form. In more realistic hypotheses[34,35] it is postulated that the dissociation of the organolithium complexes is stepwise and is represented by equations of the type

$$(RLi)_n \rightleftarrows (RLi)_{n-1} + RLi. \qquad (3)$$

‡ The rate of decomposition depends on the structure of both reactants[24,27]. This reaction affects significantly the polymerisation processes initiated by lithium alkyls[31-33] and in principle can distort the kinetics of other reactions of lithium alkyls in the presence of ethers.

Thus it is suggested that association complexes of different composition are present in solution in equilibrium with one another and with the monomeric form of the lithium alkyl. This widely held view was objected to by Brown[36], who believes that not all the association complexes are stable in solution. On the basis of NMR (^{7}Li and ^{1}H) spectra, Brown concluded[26] that ethyl- and methyl-lithium have a tetrameric structure in ethyl ether at low temperatures. According to his experimental data for the kinetics of the intermolecular exchange of the alkyl groups of ethyl- and methyl-lithium association complexes in ethyl ether[26] and the association complexes of ethyl-lithium in toluene[37], the rate of this reaction in the hydrocarbon solvent is determined by the breakdown of lithium-alkyl hexamers:

$$(RLi)_6 \rightarrow (RLi)_4 + (RLi)_2, \qquad (4)$$

and in ethyl ether by the breakdown of the tetramer with formation of the dimer:

$$(RLi)_4 \rightarrow 2\,(RLi)_2\,. \qquad (5)$$

In another study[12] Brown investigated cryoscopically the mechanism of the successive breakdown of ethyl-lithium hexamers into tetramers and dimers following the addition of triethylamine to the benzene solution. According to Brown, in the region of low molar ratios of the electron-donor solvent (D) and lithium alkyl the solvation of the hexamer $[(RLi)_6 + 2D \rightarrow (RLi)_6.2D]$ does not result in its breakdown, but in the presence of an excess of the base the hexamer is completely dissociated into the solvated dimer.

Eastham and Gibson inferred the changes in the state of a number of lithium alkyls in different mixtures of an ether or amine with n-hexane from a study of the dielectric constant[10,11], the NMR spectra[10,15], or the vapour pressure of ethyl ether over the solution[10] as a function of its content of the electron-donor solvent. The curves for the above relations have an inflection or break on attainment of a 1 : 2 molar ratio of the electron-donor additive to the lithium alkyl. The subsequent form of the curves showed that, after further increase of the concentration of the ether or amine in solution, the state of the lithium alkyl did not alter significantly. Eastham and Gibson's conclusion[10,15] concerning the dimeric structure of n-butyl- and isobutyl-lithium in ethyl ether and in tetrahydrofuran cannot be regarded as unambiguous. Their results provide evidence only concerning the ratio of the number of moles of the ether (amine) and the lithium alkyl in the solvate complexes.

More reliable information about the degree of association of lithium alkyls in ethereal solutions (at room temperature) was obtained recently by West and Waack[38] by an isopiestic method. The degree of association of methyl- and phenyl-lithium in tetrahydrofuran at 75°C proved to be respectively 4 and 2, benzyl-lithium was not associated under these conditions, and in ethyl ether methyl- and n-butyl-lithium are tetrameric. Furthermore, Brown's[12] and Eastham's[10,15] conclusions are inconsistent with the data of Waack and coworkers[38,39] on the kinetics of the reactions of lithium alkyls with 1 : 1-diphenylethylene and triphenylmethane in ethyl ether and tetrahydrofuran at room temperature. The order of these reactions with respect to methyl- and n-butyl-lithium is close to 3.

Thus not only in hydrocarbon but also in ethereal solutions lithium alkyls are associated, which is evidence of considerable stability of their association complexes. The information about the true state of lithium alkyls under different conditions requires further revision.

II. KINETICS OF REACTIONS OF LITHIUM ALKYLS IN HYDROCARBON SOLUTIONS

The interpretation of data on the kinetics of reactions of lithium alkyls in solutions is far from simple. Any kinetic mechanism must take into account the association of the lithium alkyl. Until recently it was believed that in all cases only the monomer of the lithium alkyl, in equilibrium with association complexes, is reactive. This equilibrium is represented in Scheme 1, where the equation for the rate of reaction of RLi with a substrate S under the conditions of such equilibrium[4] is also included.

Scheme 1

$$(RLi)_n \overset{K_e}{\rightleftarrows} n\,RLi\,,$$

$$K_e = \frac{[RLi]^n}{\left(\frac{[RLi]_0}{n}\right)},$$

$$RLi + S \rightarrow \text{reaction product},$$

$$V = k_1[S][RLi] = k_1 K_e^{1/n}\left(\frac{[RLi]_0}{n}\right)^{1/n}[S] = k_{overall}[S][RLi]_0^{1/n}.$$

Here and henceforth V represents the rate of reaction and the subscript 0 denotes the initial concentration.

Apart from the widely adopted mechanism in Scheme 1, Brown[4] postulates three further possible reaction mechanisms in which the lithium alkyl reacts as the association complex.

Scheme 2

$$(RLi)_6 \overset{K_e}{\rightleftarrows} (RLi)_4 + (RLi)_2\,,$$

$$K_e = \frac{[(RLi)_4][(RLi)_2]}{[(RLi)_6]},$$

$$(RLi)_2 + S \rightarrow \text{reaction product} + RLi\,,$$

$$V = k[(RLi)_2][S] = kK_e^{1/3}[(RLi)_6]^{1/3}[S] = k_{overall}[RLi]_0^{1/3}\,.$$

Scheme 3

$$(RLi)_6 + S \overset{K_e}{\rightleftarrows} (RLi)_6S\,,$$

$$K_e = \frac{[(RLi)_6\cdot S]}{[(RLi)_6][S]} = \frac{[c]}{([S]_0 - [c])([H]_0 - [c])},$$

where $[c] = [(RLi)_6.S]$ and $[H]_0$ is the initial concentration of the hexamers:

$$[c] \approx \frac{K_e\cdot[S]_0\cdot[H]_0}{1 + K_e\cdot([H]_0 + [S]_0)}$$

If K_e is small, then $[c] \simeq K_e[S]_0[H]_0$ and $V = k[c] = kK_e[S]_0[H]_0$.

If $[S]_0 \gg [H]_0$ and $K_e[S]_0 \gg 1$, then $[c] \simeq [H]_0$ and $V = k[H]_0$.

If $[H]_0 \gg [S]_0$ and $K_e[H]_0 \gg 1$, then $[c] \simeq [S]_0$ and $V = k[S]_0$.

Scheme 4

$$(RLi)_6 \rightarrow (R_5Li_6)^+ + R^-\,.$$
$$R^- + S \rightarrow \text{reaction product}\,.$$

In Schemes 1–4 the possible reaction pathways by a heterolytic mechanism are postulated. It should be noted that in a hydrocarbon medium lithium alkyls may react also by a homolytic mechanism, for example, with alkyl halides[40].

According to Brown[4], Scheme 4 should be excluded from consideration as in this case the interaction of the substrate with RLi requires an unduly high activation energy.

Scheme 1 shows that the order of the reaction with respect to lithium alkyl is equal to the reciprocal of its degree of association. In many studies on the kinetics and the initiation of polymerisation by n-butyl-lithium[41] and also on its reactions with 1,1-diphenylethylene[42] and fluorene[43] the order with respect to lithium alkyl proves to be 1/6, which is satisfactorily consistent with data on the degree of association of n-butyl-lithium in hydrocarbons[35]. The principal association complex of t-butyl-lithium in hydrocarbon solutions in the tetramer[44] and, in agreement with this, the reaction order with respect to this lithium alkyl in reactions with fluorene and 1,1-diphenylethylene is close to 1/4.[45]

However, in many cases the agreement of the results with the above mechanism is poor. For example, Ziegler and coworkers[46] already established that the reactions of ethyl-, n-propyl-, and n-butyl-lithium with 1,1-diphenylethylene in a hydrocarbon is of first order with respect to each reactant. West and Glaze[47] arrived at a similar conclusion for the reaction of ethyl-lithium with benzyl chloride in benzene. The data on the kinetics of the reaction of ethyl-lithium with 1,1-diphenylethylene obtained by Brown[4] are inconsistent either with the results of Ziegler[46] or those of Evans and George[42], since the reaction order with respect to ethyl-lithium proved to be variable in the range 0.7–0.95. In reactions involving the metallation of fluorene with ethyl-lithium and the addition of the latter to 1,1-diphenylethylene in benzene solutions, a low order (1/9) with respect to ethyl-lithium was observed[48], although it is known that its degree of association in benzene is 6.[12,49]

Data inconsistent with Scheme 1 are also found in the literature on anionic polymerisation. Thus Hsieh[50] showed that the rate of initiation of the polymerisation of styrene, butadiene, and isoprene is directly proportional to the concentration of the lithium alkyl in hydrocarbon solutions. Worsfold and coworkers[51,52] observed a variable reaction order (0.5–1) with respect to n-butyl-lithium in the polymerisation of the same monomers in cyclohexane. Finally, we may point out the discrepancy between the results of O'Driscoll et al.[53] and Worsfold and Bywater[41] for the degree of association of n-butyl-lithium and benzene if the latter is estimated from the order of the initiation reaction in the polymerisation of styrene. At styrene concentrations in excess of 0.5 M the order is 1/3,[53] while at concentrations less than 0.03 M it is 1/6.[41] Brown[4,36] expressed doubts concerning the universality of the kinetic mechanism in Scheme 1, mainly in its principal postulate that only the monomeric form of the lithium alkyl participates in the reaction. The concentration of the monomer RLi in a hydrocarbon solution must be extremely low. At best, only the dimer of the lithium alkyl, formed by reaction (4), can be present in appreciable amounts. If, on the other hand, the monomer RLi is nevertheless the active species, the reaction rate is limited by the stage involving the dissociation of the dimer into the monomer:

$$(RLi)_2 \rightarrow 2\,RLi\cdot \qquad (6)$$

According to Brown's estimate[36], a reaction with participation of the monomer RLi is possible when the heat of dissociation of the dimer does not exceed 20 kcal mole^{-1}. He suggests that the enthalpy of association of $(RLi)_2$ is not less than the value established by Morton[54] for the dimer of polyisoprenyl-lithium (37 kcal mole^{-1}). In addition, Brown refers to data[55] on the heat of dissociation of the dimer of trialkylaluminium, which is 20.2 kcal mole^{-1}, and notes that the heat of dissociation of $(RLi)_2$ must be appreciably higher, since, in contrast to trialkylaluminium, lithium alkyls are associated in ethereal solutions[2].

Without rejecting the possibility of reactions with participation of lithium alkyl by Scheme 2, Brown believes Scheme 3 to be more likely. He showed previously[12] that

the hexamer of a lithium alkyl is capable of forming complexes with Lewis bases. Brown assumed that such complexes are naturally formed also with less basic nucleophiles: alkyl halides, olefine, and other compounds. The apparent order of the reaction with respect to RLi and the substance reacting with it depends on their relative contents in the solution and on the equilibrium constant K_e for the formation of the complex of the lithium alkyl and the substrate. Studies on polymerisation initiated by lithium alkyls have been carried out over a wide range of relative concentrations of RLi and olefins. Therefore Brown believes that the above examples of discrepancies between different data on the order of the polymerisation initiation reaction are not surprising.

Brown's critical comments concerning Scheme 1 were objected to by certain workers[56,57], who pointed out the errors in Brown's calculation based on Morton's incorrect data for the heat of association of polyisoprenyl-lithium and its degree of association, which is actually four[34,51] and not two[54]. Furthermore, it was pointed out[56,57] that Scheme 1 is as a rule inapplicable in those cases where the solvent is not an aromatic but an aliphatic hydrocarbon.

In contrast to aliphatic hydrocarbons, aromatic hydrocarbons are apparently capable of solvating lithium alkyls, albeit only to a slight extent, by virtue of the formation of π-complexes[34,53]. This is shown by the comparison of both polymerisation rates in these and other solvents[34,50,57] and the ultraviolet spectra of solutions of s-butyl-lithium in benzene and in cyclohexane[57]. The variable reaction order with respect to the lithium alkyl and the S-shape of the kinetic curve for the initiation stage observed in aliphatic hydrocarbons[51,52,57] have been explained by the autocatalysis of the reaction as a result of the formation of cross-association complexes of the lithium alkyl and the product of its addition to the monomer[56,57].

These considerations[56,57] refer to the initiation stage and the polymerisation under the influence of lithium alkyls. The problem of the applicability of Scheme 1 to various reactions of associated organolithium compounds in hydrocarbon media still remains open.

III. EFFECT OF ELECTRON-DONOR SOLVENTS ON THE KINETICS OF REACTIONS OF LITHIUM ALKYLS

1. General Postulates

The powerful effects of electron-donor solvents on the reactivity of lithium alkyls was noted a long time ago. Ziegler[46] already pointed out the much higher rate of addition of n-butyl-lithium and other lithium alkyls to the double bond of 1,1-diphenylethylene in ethyl ether compared with the benzene solution. In tetrahydrofuran the reaction is almost instantaneous[58].

When even small amounts of ether or an amine are added to the hydrocarbon solvent, the initiation stage of the polymerisation of styrene or diene hydrocarbons by the lithium alkyl is also greatly accelerated[51,59-62] and to a much greater extent than the chain propagation stage[51,54,62,63]. The effect of ethers and amines on the kinetics of the initiation stage of the polymerisation by lithium alkyls has not as yet been investigated adequately in a quantitative sense because of the high rates of this stage in the presence of electron-donor additives[58,60-62].

There are literature data concerning the activating effect of electron-donor solvents also on other reactions of lithium alkyls, for example the metallation of hydrocarbons by them or their interaction with alkyl and aryl halides. According to Gilman's data[64,65], metallation by lithium alkyls is facilitated on passing from solutions in hydrocarbons to solutions in ethyl ether and in particular to solutions in tetrahydrofuran, which has been confirmed by Waack[66]. The nucleophilic activity of lithium alkyls increases even more under the influence of bistertiary amines[67]. The complex of n-butyl-lithium with *NNN'N'*-tetramethylethylenediamine readily metallates toluene and benzene even at a moderate temperature.

The reactions of organolithium compounds with alkyl and aryl halides are usually considered from the standpoint of organic synthesis. The number of kinetic studies which provide information about the effect of electron-donor solvents on reactions of this type is small. Ziegler[68] noted that the half-life of the reaction between n-butyl-lithium and n-butyl bromide decreased by a factor of 20 when it was carried out in ethyl ether instead of benzene. The rates of this reaction differ by more than 4 powers of 10 between n-hexane and its mixture with 1,2-dimethoxyethane for an equimolar content of the ether and the lithium alkyl[21]. In ethyl ether n-butyl-lithium reacts with 1-bromo-octane almost 800 times faster than in n-hexane[22].

The solvent can change not only the rate of reaction or its order with respect to the lithium alkyl[39,42,43,58] but the actual reaction path. The change in reaction order under the influence of the solvent is readily understood, since the state of the lithium alkyl in solution depends on the solvent. It is also known that, depending on the type of reactants and the reaction conditions, in particular the solvent, the organolithium compound reacts with alkyl and aryl halides[15,40,69] either by a heterolytic mechanism—the Wurtz reaction [reaction (7)] and the exchange of alkyl radicals [reaction (8)] are of this type—or by a homolytic mechanism [reaction (9)]:

$$R'Li + R''X \rightarrow R'R'' + LiX, \quad (7)$$

$$R'Li + R''X \rightarrow R'X + R''Li, \quad (8)$$

$$R'Li + R''X \rightarrow R'^{\cdot} + Li^{+} + R''^{\cdot} + X^{-} \quad (9)$$

The postulate that the reaction path can change is well illustrated, for example, by the data of Hoeg and Lusk[70], who investigated the reaction of n-butyl-lithium with n-benzyl chloride in several solvents. In ethyl ether and in n-hexane these reactants interact with formation of dibenzyl (I) and *p*-pentylbenzene (II):

$$C_6H_5CH_2Cl \xrightarrow[Et_2O(hexane)]{n\text{-}C_4H_9Li} [C_6H_5CH_2Li] \begin{cases} \xrightarrow{+C_6H_5CH_2Cl} C_6H_5CH_2CH_2C_6H_5 \ (I) \\ \xrightarrow[+n\text{-}C_4H_9Li]{} C_6H_5C_5H_{11} \ (II) \end{cases} \quad (10)$$

When the same reaction was carried out in tetrahydrofuran at room temperature, *trans*-stilbene was obtained in a yield of about 20% in addition to compounds (I) and (II). If the reaction follows the second pathway, then α-chlorodibenzyl (IV) and the carbanion of benzyl chloride (III) are formed as intermediates:

$$C_6H_5CH_2Cl \xrightarrow[THF]{+n\text{-}C_4H_9Li} \underset{(III)}{[C_6H_5\bar{C}HCl\overset{+}{Li}]} \xrightarrow{+C_6H_5CH_2Cl} \rightarrow \underset{(IV)}{C_6H_5CHClCH_2C_6H_5} \xrightarrow{+n\text{-}C_4H_9Li} C_6H_5CH{=}CHC_6H_5 + C_6H_5\underset{|}{\overset{C_4H_9}{C}}HCH_2C_6H_5 \quad (11)$$

An additional example is provided by data[71] on the change in the mechanism of the initiation by n-butyl-lithium of the polymerisation of methyl acrylate and methyl methacrylate when n-hexane is replaced by tetrahydrofuran.

The above findings by no means exhaust the literature data on the effect of solvents on the reactivity of lithium alkyls (see, for example, Bilevich and Okhlobystin[72]).

2. The Causes and the Principal Relations Governing the Effect of Electron-donor Solvents on the Kinetics of Reactions of Lithium Alkyls

The acceleration of the reactions of lithium alkyls in electron-donor solvents compared with hydrocarbon solvents must be attributed to the effect of two main factors: the increase of the polarity of the C–Li bond as a result of the specific solvation of lithium and the decrease of the degree of association of the organolithium compound. One should then bear in mind the change of the polarity of the C–Li bond not only in the ground but also in the transition state[4,22,69].

Thus West[47] established the occurrence of a kinetic isotope effect for the reaction between ethyl-lithium and benzyl chloride ($k^6_{LiEt}/k^7_{LiEt} = 1.029$). This finding is evidence of a significant weakening of the C–Li bond in the transition state. Therefore one may expect the acceleration of reactions of this type following the additional polarisation of the C–Li bond, for example, as a result of the solvation of lithium by the molecules of an electron-donor agent.

The increased polarity of the C–Li bond in electron-donor solvents (or when these are added to hydrocarbons) is confirmed by measurements of the infrared spectra[4,6,24,25] electrical conductivity[73], and dielectric constants[10,11] of RLi solutions and also by measurements of their NMR spectra[4,15,26]. On the other hand, as we have seen, in the presence of an electron-donor solvent the degree of association of the lithium alkyl falls and consequently the number of its kinetically active species should increase[22].

The problem of the interrelation of these factors is not entirely clear, although in some studies[22,58,63] the lowering of the degree of association of the organolithium compound is regarded as the most important factor accelerating the reaction. Probably, in each specific case, this problem must be solved separately considering the specific features of the mechanism of the given reaction. In this connection it is appropriate to consider data[21,74] on the effect of tetrahydrofuran (THF) and other electron-donor substances on the kinetics of the reactions of n-butyl-lithium with n-butyl bromide and with triphenylmethane.

The dependence of the rate constant for the first reaction on the content in n-hexane of ethers with 1 and 2 oxygen atoms is shown in Figs. 1*a* and 1*b* and has been explained[21,22] by the active participation in the reaction of the solvates of the association complexes of n-butyl-lithium, the composition and the reactivity of which are determined by the solvation properties of the electron-donor compounds.

The rate of this reaction changes most markedly with increasing ether content when small amounts of it are added to n-hexane: in the region of small molar ratios of the ether and the lithium alkyl (r), ranging from zero to 0.5 for ethyl ether or THF and in the region $r < 1$ for 1,2-diethoxy- and 1,2-dimethoxy-ethane.

Fig. 1 shows that the rate of reaction between n-butyl-lithium and n-butyl bromide continues to increase when ether with one oxygen atom is added also in the region with $r > 0.5$, although more slowly than for $r < 0.5$. The reasons for this increase are discussed in a recent brief communication by Screttas and Eastham[75]. They believe that the effects of the electron-donor solvent on the rate of reaction with participation of the lithium alkyl in the region of r less and greater than 0.5 are fundamentally different. In the region where $r < 0.5$ the ether (or amine) takes part in the solvation of the lithium alkyl and causes the breakdown of its association complexes into dimers [Eqn. (1)].

On the other hand, the increase in the rate of reaction with the concentration of the ether or amine in solution for $r > 0.5$ is attributed[75] to a kinetic, and not thermodynamic, effect of the electron-donor solvent, which facilitates charge transfer from the lithium alkyl to the substrate S, for example:

$$(BuLi)_2.THF + solvent + S \rightarrow [(BuLi)_2.THF]^+_{solvent} + S^- \qquad (12)$$

To describe the kinetic effect of the excess THF or another ether (D) relative to its amount required for the formation of the solvate $(BuLi)_2.D$, the following equation was proposed[75]:

$$V = k([D] - 0.5[RLi])^{\alpha}[RLi]^{\beta}[S]^{\gamma}, \qquad (13)$$

where α, β, and γ are reaction orders with respect to the electron-donor additive, lithium alkyl, and the substrate. Screttas and Eastham[75] applied this equation to their own[22] and certain literature data in order to determine α. In particular they employed the data of Shatenshtein et al,[21] on the kinetics of the reaction of n-butyl-lithium with n-butyl bromide in the presence of added 1,2-dimethoxyethane for $r > 0.5$, although the type of dependence of the rate constants on the content of THF and 1,2-dimethoxyethane is different (cf. Figs. 1*a* and 1*b*). The value of α proved to be close to unity in all cases.

Screttas and Eastham[75] themselves emphasised that their concepts concerning the kinetic role of the electron-donor solvents are extremely hypothetical. Furthermore, Screttas and Eastham evidently continued to hold the view that lithium alkyls are dimerised in ethereal solution. Nevertheless, one should not disregard the possibility of the acceleration of reaction on addition of ether in the region with $r > 0.5$ due to the additional solvation of the association complexes of the lithium alkyl accompanied by the formation, albeit in a small amount, of new reactive complexes of the lithium alkyl with the Lewis base[20,58,74].

We shall now consider how the addition of THF to n-hexane affects the rate of metallation of triphenylmethane by n-butyl-lithium. Fig. 3 shows that, when the concentration of tetrahydrofuran (c_{THF}) is varied from zero to 90 vol.%, the rate constant k increases continuously and the order of the reaction determined from the plot $\lg k$ against $\lg c_{THF}$ (Fig. 4) is approximately 3/2. A detailed study of the region of low THF concentrations (< 2 vol.%) showed that the k–c_{THF} curve makes an intercept on the abscissa axis corresponding to $c_{THF} = 0.36$ vol.% or 0.04–0.05 M. According to the experimental conditions, it corresponds to a molar ratio of the ether and the lithium alkyl of 0.5. This finding can serve as additional confirmation of the hypothesis[21] of the formation of solvate complexes of tetrahydrofuran with n-butyl-lithium, with composition corresponding to the ratio 1 : 2. However, the formation of such primary solvates is probably still insufficient for any significant acceleration of the metallation reaction. Its rate begins to increase only in the presence of an excess of tetrahydrofuran relative to the amount required for the formation of the above solvates.

Waack et al.[58] observed similar behaviour in the study of the effect of small amounts of tetrahydrofuran added to benzene or hexane on the rate of addition of n-butyl-lithium to 1,1-diphenylethylene. Its dependence on the concentration of tetrahydrofuran is very complex. For given proportions of the ether and lithium alkyl, the rate of reaction is greater at higher concentrations of the lithium alkyl. On the other hand, an increase of the concentration of n-butyl-lithium at a constant concentration of the ether entails a decrease of the rate. Waack[58] explained this by

the fact that the lower solvates of n-butyl-lithium are inactive in the reaction.

There arises now the problem of the causes of this marked difference between the effect of tetrahydrofuran on the kinetics of the normal Wurtz reaction and the metallation reaction. The effect of this ether on the kinetics of the metallation of triphenylmethane can be understood, for example, by assuming that the monomeric form of butyl-lithium is active in the reaction, an increase in its content being favoured by the additional solvation of the dimer of the lithium alkyl:

$$(BuLi)_2 \cdot THF \overset{+3THF}{\rightleftharpoons} 2\,[(BuLi) \cdot 2THF]. \qquad (14)$$

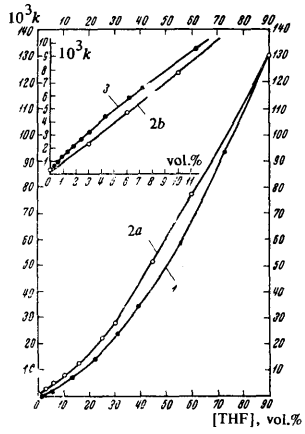

Figure 3. Dependence of the rate constant for the metallation of triphenylmethane with n-butyl-lithium on the content of tetrahydrofuran in n-hexane (*1*) or in ethyl ether (*2a* and *2b*) and on the content in the latter of 1,2-diethoxyethane (*3*).

One cannot exclude the possibility that phenomena involving the solvation of the transition state play a decisive role. Metallation and isotope exchange of hydrogen with bases belong to the same type of protophilic substitution of hydrogen and have similar mechanisms[76]. The transition state in processes of this type has the properties of a carbanion, as shown, in particular, by the determinations of the kinetic isotope effect (KIE) for these and other reactions[77-85].

The determination[74] of KIE (k_H/k_D) for the metallation of triphenylmethane by n-butyl-lithium in tetrahydrofuran, triethylamine, and ethyl ether and also in mixtures of the latter with 1,2-diethoxyethane yielded the same result: $k_H/k_D = 10$ at 25°C, although the rates of reaction in these solvates differed by factors up to 2500.

The relative rate constants (k_{rel}) for the reactions of n-butyl-lithium with n-butyl bromide (I) and triphenylmethane (II) are compared in Table 1. The rate constant for the reaction in the presence of added tetrahydrofuran was assumed to be unity in each case.

There is no correlation between k_{rel} and the polar properties of the solvent, i.e. the dielectric constants (DC) and dipole moments (μ). This is quite reasonable, since the effect of the above solvents on the kinetics of the reactions is due primarily to the specific solvation of the cation, which is of the donor–acceptor type. Furthermore, this hypothesis is not contradicted by the lack of correspondence between k_{rel} and the changes $\Delta\nu_{OD}$ (cm^{-1}) characterising the electron-donor properties of the additives based on the shift of the frequency of the OD bond in deuteriomethanol when the latter forms a hydrogen bond with the heteroatom of the electron donor[17]. The reason for the absence of a parallelism between k and $\Delta\nu_{OD}$ is that the specific solvation processes of alkali metal cations are very sensitive to steric factors[16,20,90,91].

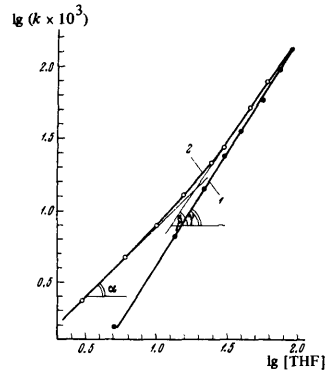

Figure 4. Determination of the reaction order of the metallation of triphenylmethane with n-butyl-lithium from the concentration of tetrahydrofuran in n-hexane (*1*) and in ethyl ether (*2*) (tan $\alpha = 1.0$; tan $\beta = 1.45$; tan $\gamma = 1.6$).

The sequence of the activating effects of the solvents on the reactions of n-butyl-lithium (Table 1) is in the main similar to that observed for other organic reactions of the anionic type[16,92,93]. The higher activity of added tetrahydrofuran and in particular 1,2-dimethoxyethane compared with ethyl ether and triethylamine has also been observed in measurements of the rates of the initiation[61] and chain propagation stages in anionic polymerisation[61,94-96] and also in the analysis of the structure of polydienes and the composition of copolymers[19,61,97-99].

The relative solvating capacity of solvents can also be assessed from the change in the electronic transition energy associated with the principal absorption band in the spectrum of a highly polar organic derivative of an alkali metal[100-102]. In this connection, we may note that the same sequence of solvent effects on the rate of the metallation reaction (Table 1) and on the bathochromic shift in the absorption spectrum of triphenylmethyl-lithium has been observed[74]. The absorption maxima in n-hexane, triethylamine, and ethyl ether are respectively in the region of 420, 430–435, and 435–440 nm. The addition of 11 vol.% of tetrahydrofuran to ethyl ether results in a bathochromic shift of 25 nm and the addition of 11 vol.% of 1,2-diethoxyethane leads to a shift of 55 nm (cf. also Ref. 103).

Attention must be drawn to the following features of the series of relative activities of solvents established for the reactions of lithium alkyls. According to Fig. 3 (curves *2b* and *3*), at low concentrations 1,2-diethoxyethane is more active than tetrahydrofuran but with increase in their content in ethyl ether the order of activity is reversed

(cf. curves *2a* and *3*), i.e. becomes of the type usually observed[16,93,94]. Probably the above concentration dependence is a consequence of different mechanisms of the solvation of the alkali metal by tetrahydrofuran and 1,2-diethoxyethane[16,90,91]. The differences in the solvation of the metal cation by these ethers, which determine their relative activities when the amounts added are small, are obliterated when the ether is used as the solvent. Then other factors, for example, steric considerations become of primary importance. The reversal of the sequence of these ethers is observed also when their effects on the equilibrium formation of diphenylsodium are compared[91] and the reaction itself is carried out in mixtures of either tetrahydrofuran or 1,2-diethoxyethane with n-heptane or when each ether is the solvent.

Relative rate constants for the reaction of n-butyl-lithium with n-butyl bromide (I) for [D]/[n-BuLi] = 1 and with triphenylmethane (II) at 25 °C

Electron-donor additive D	k_{rel} for reaction I[21]	k_{rel} for reaction II[74]	DC(25°) (Ref.86 & 87)	$\Delta\nu$(OD), cm^{-1} (Refs.17 & 18)	μ, D (25°) (Refs.86,88,89)
Diethyl sulphide	0.018	—	5.72	—	—
Triethylamine	—	0.012*	2.42	289	0.77
Ethyl ether	0.6	0.067*	4.33	106	1.15
Tetrahydrofuran	1	1**	7.31	115	1.87
1,2-Diethoxyethane	26	1.25**	4.89	98	1.65
1,2-Dimethoxyethane	52	—	6.96	93	1.72

*90 vol.% of triethylamine or ethyl ether; 10 vol.% of n-hexane.
**5 vol.% of THF or 1,2-diethoxyethane; 85 vol.% of ethyl ether; 10 vol.% of n-hexane.

The study of reactions in mixtures of electron-donor solvents is of interest for the detection of the differences in their solvation properties, since it reveals competitive phenomena between the two solvents in specific solvation processes. Unusual data were obtained in measurements of the rate of anionic polymerisation in mixtures of tetrahydrofuran with 1,4-dioxan[104] and with 1,2-dimethoxyethane[99] and also in the study of the electronic absorption spectra of triphenylmethyl-lithium[74] and 1,1-diphenylhexyl-lithium[102] in mixtures of tetrahydrofuran with aliphatic ethers.

There are still few data on the kinetics of the reactions of lithium alkyls in mixtures of electron-donor solvents. Relations have been established[74] between the rates of metallation of triphenylmethane with n-butyl-lithium and the proportion of 1,2-diethoxyethane or tetrahydrofuran in ethyl ether (Fig. 3, curves *3* and *2a*). The fact that the order of the metallation reaction with respect to tetrahydrofuran changes from unity to 3/2 with increasing concentration of tetrahydrofuran in ethyl ether (Fig. 4), i.e. approaches the order in mixtures of tetrahydrofuran with n-hexane, which is approximately 3/2, may be attributed to competition between the two esters in the lithium solvation processes.

3. The Reactive Forms of Lithium Alkyls in Electron-donor Solvents

In considering the nature of the reactive forms of lithium alkyls in electron-donor solvents one must take into account not only the degree of association and the level and nature of the solvation of the organolithium compound but also the possibility of different states and different degrees of dissociation of the ion pair[16,90,91,105-107]. Bearing this in mind, Ebel[108] suggests the following mechanism for the change in the form of RM in solution and the nature of the bond C–M as a function of the solvent, the nature of the alkali metal M, and the alkyl group R:

$$\overbrace{(RM)_6 \rightleftarrows (RM)_4 \rightleftarrows (RM)_2}^{A} \rightleftarrows \overset{B}{RM} \rightleftarrows \overset{C}{R^-, M^+} \rightleftarrows \overset{D}{R^- \parallel M^+} \rightleftarrows \overset{E}{R^- + M^+}$$

where *A* are association complexes of RM, *B* is a molecule with a covalent bond C–M, *C* and *D* are ion pairs in contact and separated by the solvent, and *E* are free ions. The solvation of the association complexes and ions is not shown in the above mechanism.

As already mentioned, when discussing the kinetics of the reactions of lithium alkyls in the presence of an ether or amine, Scheme 1, (p. 842) is usually employed, i.e. only the monomeric form of the lithium alkyl (*B*) is regarded as reactive[39,58,66,109]. Brown[36] suggests that this is incorrect not only in hydrocarbon but also in electron-donor solvents. Until recently, Brown's hypothesis[4,36] of the possible active participation in the reaction of the association complexes of organolithium compounds was not supported by experimental data if one excludes the results of Eastham and Gibson[15,22] mentioned above (p. 842) (see also Refs. 93, 110, and 111). Brown's conclusions found more definite confirmation in the work of Waack[112], who investigated the kinetics of the metallation of triphenylmethane with phenyl-lithium and the rate of its addition to 1,10-diphenylethylene in tetrahydrofuran. The order of these reactions with respect to phenyl-lithium is 0.65 ± 0.03, i.e. the precision of the determination of the order shows with certainty that it is not unity or 0.5. Analysis of the possible reaction mechanisms and the corresponding reaction orders taking into account the dimeric state of phenyl-lithium in tetrahydrofuran led Waack et al.[112] to the conclusion that both the dimer and monomer of phenyl-lithium participate in the above reactions, the two species being in equilibrium:

$$\frac{1}{2}(PhLi)_2 \overset{K_e}{\rightleftarrows} PhLi\,. \qquad (15)$$

The rate of reaction is given by the equation

$$\frac{V}{[S]} = k_1 K_e \left(\frac{[PhLi]}{2}\right)^{1/2} + k_2 \left(\frac{[PhLi]}{2}\right), \qquad (16)$$

where k_1 and k_2 are respectively the rate constants for the reaction with participation of the monomer and dimer, K_e is the dissociation constant of the dimer, and [S] and [PhLi] are the concentrations of the reactants.

On the basis of these results, Waack[112] arrived at the general conclusion that, depending on the concentration of RLi and the rate constants for the reactions involving the monomer and the association complexes, the reaction order with respect to RLi may vary from 1 to $1/n$, where n is the degree of association of RLi in the given solvent.

The states *D* and *E* (in Ebel's scheme) of the C–M bond, including C–Li, have recently been considered in relation to the active centres of the growing polymeric chains in the study of the kinetics and mechanism of anionic polymerisation in electron-donor solvents. This has been demonstrated particularly clearly in the work of Szwarc and Schulz (see the appropriate reviews[113-115]).

We shall now consider the state of our knowledge concerning the participation of free carbanions in the reactions of lithium alkyls. The electrical conductivity of the hydrocarbon solutions of lithium alkyls is extremely low[63] and remains low even in the presence of electron-donor

additives[73]. Brown[4] admits the possibility that the reaction of RLi takes place partially by a mechanism involving free carbanions in a medium with a high solvating capacity (see Scheme 4, p. 842). However, several attempts[39,63,112] to explain the observed kinetics by the participation of free carbanions of lithium alkyls and even phenyl-lithium have been unsuccessful.

In considering the problem of the reactive forms of lithium alkyls in electron-donor solvents, one must bear in mind that the kinetic effect due to the solvents depends not only on the state of the organolithium compounds in the solutions but also on the mechanisms and other specific features of the reactions.

Summarising, we must emphasise that, although the principal causes of and the relations governing the effect of electron-donor solvents or the corresponding additives on the reactivity of lithium alkyls have been elucidated, some questions, connected with the current problem, still remain controversial.

Alkylsteroids

A.A.Akhrem, T.V.Ilyukhina, and Yu.A.Titov

Alkylsteroids constitute an important class of steroid compounds containing additional alkyl groups compared with natural hormones. The introduction of alkyl groups enhances the physiological activity and narrows the spectrum of the biological activity of steroids. Furthermore alkylsteroids are of interest for the stereochemistry of the reactions which take place with participation of condensed alicyclic systems. The methods for the direct introduction of alkyl groups based on the reactions of steroids ketones and epoxides are described.
The bibliography includes 255 references.

CONTENTS

6. Opening of steroid epoxide rings by Grignard reagents 855
7. Simultaneous introduction of two alkyl substitutents 857

1. INTRODUCTION

One of the principal ways in which the structure of steroids is modified consists in the introduction into the latter of additional alkyl groups (mainly methyl). The alkyl steroids thus produced have in many cases an enhanced physiological activity compared with the initial compound. Even more interesting is the fact that the introduction of alkyl groups alters the relation between different types of physiological activity making it possible to prepare compounds with specific activities. Many alkylsteroids have found application in medical practice—an anabolic preparation dianabol (17α-methyl group), an anti-inflammation agent dexamethasone (16α-methyl group), antiovulatory agents dimethisterone and medroxyprogesterone (6α-methyl group), etc. The effect of methyl groups on certain types of the physiological activity of steroids is described in Table 1.

Table 1. Effect of methyl groups on the physiological activity of steroids (+ increase of activity, − decrease of activity, ± activity unchanged)[2].

Type of activity	Position of methyl group										
	1α	2α	4	6α	7α	9α	11α	16α	16β	17α	21
Androgenic	+	−	−	−	+		−		−	±	
Anabolic	+	−	+	±	+		−			±	
Gestagenic		±	−	+				±	−	+	−
Glucocorticoid	−	+	−	+	−	−	−	+	+	−	±
Mineralocorticoid**	−	+	−	±		−	−	−	−	−	−
Anti-inflammation		+	−	+	−	−	−	+	+	±	+

*Deposition of glycogen in the liver.
**Retention of Na^+ ions.

The study of alkylsteroids has made a considerable contribution both to the stereochemistry of reactions with participation of condensed alicyclic systems and to synthetic organic chemistry. Furthermore, the last available review on alkylsteroids[1] refers to work published up to 1960 and is to a considerable degree obsolete. In view of the large number of studies in which alkylsteroids were synthesised (more than 1500) and the space available, it was necessary to restrict the scope of this review, which includes only the methods for the direct introduction of alkyl groups in reactions with steroid ketones and epoxides. Numerous methods for the indirect synthesis of alkylsteroids in which oxygen- or nitrogen-containing and also unsaturated hydrocarbon substituents are initially introduced into the molecule and then transformed into alkyl groups (formylation and cyanation reactions, reactions with carbenes, Wittig, Mannich, etc. reactions) are not considered in the review. The limits of applicability of various methods for the synthesis of alkylsteroids are shown in Table 2.

Table 2. Different synthetic methods for the preparation of alkylsteroids (according to the data in Sections 2–7).

Method of synthesis	Position of alkyl group introduced															
	1	2	3	4	5	6	7	8	9	10	11	12	15	16	17	20	21
Alkylation of ketones		+		+	+	+	+	+	+			+		+	+		+
Reaction of ketones with organometallic compounds	+	+	+	+		+	+				+	+	+		+	+	
Conjugated addition of Grignard reagents	+			+	+		+		+					+		+	
Reaction of diazomethane with ketones	+			+									+	+	+	+	+
Opening of epoxy-rings by Grignard reagents				+	+	+			+			+	+	+			

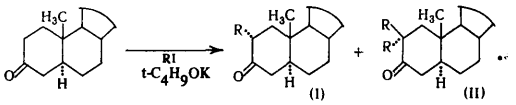
2. ALKYLATION OF STEROID KETONES

In this section two types of alkylation are dealt with—direct alkylation of unsaturated and saturated ketones usually by the action of alkyl iodides in an alkaline medium and reductive alkylation of unsaturated ketones. In the latter case treatment of a conjugated unsaturated ketone with lithium in liquid ammonia yields the enolate which is then treated with alkyl iodide to form the unsaturated alkyl

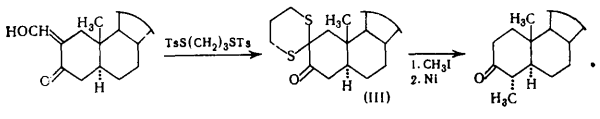
ketone. Methods for the introduction of an alkyl group into α-bromoketones by the simultaneous action of Grignard reagents and alkyl halides and also for the introduction of alkyl groups into unsaturated ketones by treating with alkyl halides the intermediates produced in the conjugated addition of Grignard reagents (see Section 4) resemble this type of alkylation.

The enolic form of the steroid ketone takes part in direct alkylation and therefore the mode of alkylation of the ketone is determined by the mode of its enolisation. Alkaline reaction conditions favour the formation of the most stable isomers. Accordingly 3-oxo-5α,10β- and 3-oxo-5β,10α-steroids are alkylated predominantly at C_2 and 3-oxo-5β,10β- and 3-oxo-5α,10α-steroids[3,4] are alkylated at C_4. 1,3-Diketones are also alkylated at C_2.[5]

The alkylation of 3-oxo-5α-steroids always yields a mixture of 2α-monoalkylsteroids (I) and 2,2-dialkylsteroids (II) the relative amounts of which depend on the reaction conditions. Further alkylation at C_4 either does not occur at all or takes place with a very low yield[6-9]:



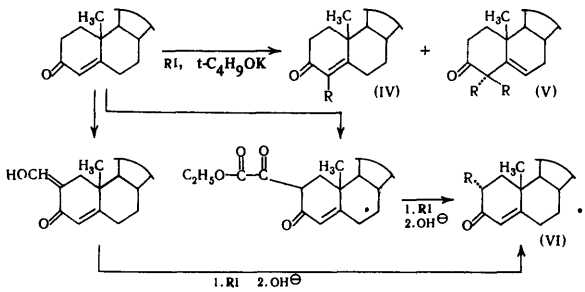
When it is necessary to prepare selectively the 2α-alkylsteroid (I), the formyl or oxalyl derivatives of the initial ketone, which protect it from the introduction of a second group, are alkylated[6,10]. If the desired product is the 4-alkylsteroid, it is necessary to block position 2 completely. One of the possible methods for this consists in the formation of the cyclic thioketal (III) by the reaction of di-*p*-toluenesulphonate of propane-1,3-dithiol with 2-hydroxymethylene derivatives. Subsequent alkylation yields a mixture of 4-methyl derivatives from which the protecting group is readily removed by desulphuration with Raney nickel, the corresponding 4α-methylsteroids being formed[11,13]:



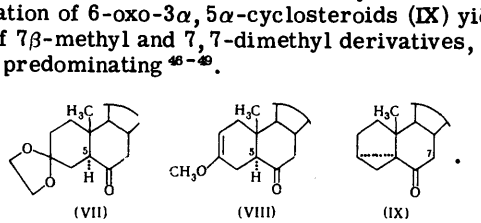
The introduction of a Δ^7-bond into 3-oxo-5α-steroids alters sharply the mode of alkylation towards the formation of 4-methyl derivatives[14-16]. A change of this kind does not take place on introduction of a Δ^6-bond[17] and also in B-norsteroids[18] and Δ^7-5β,10α-steroids[19]; all these compounds are alkylated similarly to the normal series.

The alkylation of 3-oxo-Δ^4-steroids, the products of which usually consist of a mixture of 4-alkyl (IV) and 4,4-dialkyl (V) derivatives, with the latter greatly predominating, has been investigated in greatest detail[6,8,20-25]. Special reaction conditions have been developed for the preferential formation of 4-monoalkylsteroids of type (IV)[26-32]; even under these conditions the presence in the molecule of the initial 3-oxo-Δ^4-steroid of a 6α-methyl group leads to the predominance of dialkyl derivatives in the reaction products[33,34]. It is noteworthy that 3-oxo-$\Delta^{4,7}$-steroids are alkylated similarly to Δ^4-3-ketones, while 3-oxo-$\Delta^{4,6}$-steroids are not alkylated under the usual conditions[35]. This course of reaction was explained by the comparative stability of the conjugated anions corresponding to the successive stages in the alkylation process[36]. The alkylation of 3-oxo-Δ^4-steroids with polymethylene dibromides $Br(CH_2)_nBr$ yields 4,4-spirocycloalkyl derivatives[37].

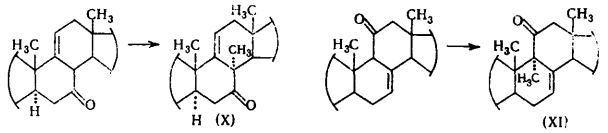
The need to prepare 2-alkyl derivatives of 3-oxo-Δ^4-steroids led to the development of their synthesis via formyl[38,39] and oxalyl[40-43] derivatives. When the primary alkylation product is acted upon by alkalis, the activating groups are hydrolysed with formation of 2α-alkylsteroids (VI).



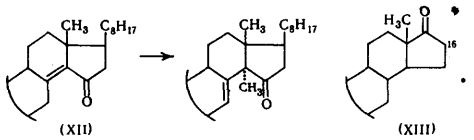
In the alkylation of 6-oxosteroids unsubstituted at C_5 the products are 5-alkyl derivatives the configuration of which depends on the nature of the substituents in the ring A. Thus the ketone (VII) with a dioxolane group forms the corresponding 5β-methyl derivative[44], while the enolic ether (VIII) forms the 5α-methyl derivative[45]. The alkylation of 6-oxo-3α,5α-cyclosteroids (IX) yields a mixture of 7β-methyl and 7,7-dimethyl derivatives, with the latter predominating[46-49].



7-Oxo-Δ^5-steroids are alkylated as a rule at C_6 with formation of dialkyl derivatives[50,51]. However, the introduction of a $\Delta^{9(11)}$-bond into the molecule of a 7-oxosteroid activates the 8-position as a result of which the methylation of these ketones leads to the formation of 8α-methyl derivatives (X)[52,53]. Similarly, 9α-methyl derivatives (XI) were obtained by the methylation of 11-oxo-Δ^7-steroids[54]:

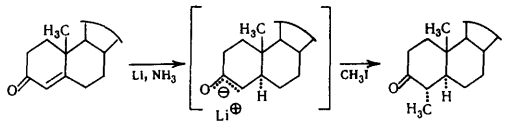


Direct methylation of the 15-oxo-$\Delta^{8(14)}$-steroid (XII) under severe conditions led to the corresponding 14α-methylsteroid with migration of the double bond to the Δ^7-position[24,55,56]. The structural analogues of compound (XII)—A-nor-3-oxosteroids—form on alkylation 5β-methyl derivatives[57]. Both 16α-methyl and 16β-methyl derivatives were obtained from 17-oxosteroids (XIII) under different conditions[29,58,59]:



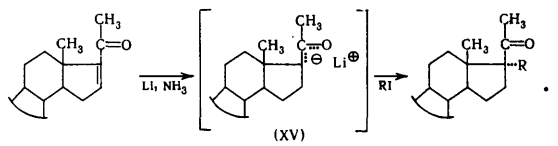
Angular methylation of 18-nor-17-oxo- and 18-nor-17a-oxo-steroids with formation of 13-methyl derivatives is one of the stages in many total syntheses of steroid compounds and has been discussed in detail in a recently published monograph[60].

The so called "reductive alkylation" has found wide application recently in the synthesis of alkylsteroids. For example, when 3-oxo-Δ^4-steroids are acted upon by alkali or alkaline earth metals (lithium, sodium, calcium, or barium) in liquid ammonia, the product is the anion (XIV), the treatment of which *in situ* with methyl iodide gives the 5α-dihydro-4α-methyl derivative[61,62]. When the proportions of the reactants are altered, the 4,4-dimethyl derivative is produced[63]. Similarly, 2α-methyl derivatives were obtained from 3-oxo-$\Delta^{1,4}$-steroids[64] and 4,4-dimethyl-Δ^5-derivatives from 3-oxo-$\Delta^{4,6}$-steroids[61]:



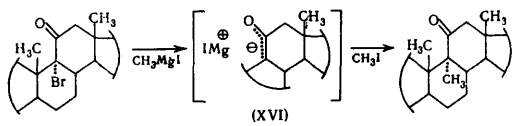
(XIV)

This method of synthesis is employed particularly frequently for the introduction of 17α-alkyl groups into 20-oxo-Δ^{16}-steroids of the pregnane series. 17α-Bromo-, 17α-hydroxy-, and 17α- and 17β-acetoxy-derivatives of 20-oxosteroids, which under the action of lithium and liquid ammonia form the intermediate anion (XV), also enter into this reaction. 17β-Alkyl- and 21-alkyl-steroids are formed in a small amount as side products[56,65-68]:



(XV)

The method for the introduction of alkyl groups into α-bromosteroids by the action of a mixture of a Grignard reagent and a large excess of an alkyl halide has a mechanism similar to that of reductive alkylation. Here the intermediate stage also involves the formation of the enolate anion of type (XV) with loss of a bromine atom; subsequent methylation of compound (XVI) leads to the corresponding 9α-methyl derivative[12,69-71]:



(XVI)

12α-Methylsteroids have been prepared[12] from 12α-bromo-11-ketones by the method described above for the synthesis of 9α-methyl derivatives from 9α-bromo-11-oxosteroids. It proved possible to carry out the same reaction with the enolic acetates of 11-oxo- and 20-oxosteroids, 9α,12β-dimethyl and 17α-methyl derivatives being obtained respectively[70].

3. REACTIONS OF STEROID KETONES WITH ORGANOMETALLIC COMPOUNDS

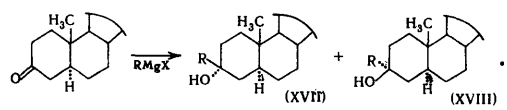
This group of reactions is most widely used for the introduction of alkyl groups into steroid compounds. In recent years it has been shown[72] that ethylene-ketals of 3-, 17-, and 20- oxosteroids also react with Grignard reagents under severe conditions.

A characteristic feature of the reactions of organometallic compounds with oxosteroids is attack from the least sterically hindered side. The stereochemistry of the reaction is influenced by polar groups in the steroid and also by the size and polarity of the attacking agent. The simultaneous effects of all these factors usually lead to the formation of a mixture of reaction products with different steric orientations of the substituted alkyl group[73,74], the isomer with the equatorial alkyl group predominating[74]. Recent studies have shown for 12-, 17-, and 17a-oxosteroids numerous deviations from the so called "rule of attack from the α-side"[75] (opposite to the side of the angular methyl group). Therefore this rule cannot be regarded as having general applicability.

Grignard reactions have been used for the introduction of alkyl substituents into the 1-position[76,77] and the 2-position[78]; in the first case the stereochemistry was not elucidated and in the second only the 2α-alkyl isomer, with an equatorial position of the substituted alkyl group, was obtained.

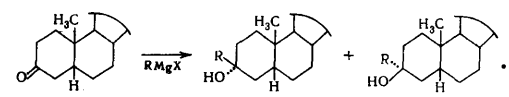
Reactions with participation of 3-oxosteroids have been investigated in incomparably greater detail. Thus in the reaction of 3-oxo-5α-steroids with Grignard reagents a mixture of epimers (XVII) and (XVIII) is usually formed, compound (XVII) with the equatorial 3β-configuration of the substituted alkyl[79-82] or phenyl[83] group [(XVII) : (XVIII) $\simeq$ 1.5–2 : 1)] predominating; in one case the opposite ratio of reaction products was obtained. When the molecule possesses 1α-hydroxy-[84], 1α-methyl-[77], 2α-bromo-[85], and 5α-hydroxy-substituents[86], the reaction of 3-oxo-5-steroids with CH_3MgI and CH_3Li leads exclusively to isomer (XVII) with an equatorial 3β-methyl group. The introduction of a Δ^4-bond into the steroid does not alter significantly the mode of the Grignard reaction: 3-oxo-Δ^4-steroids form approximately equal amounts of 3α- and 3β-alkyl isomers[87], while 3-oxo-Δ^5-steroids yield predominately the 3α-alkyl isomer of type (XVIII)[88].

The Norman reaction with 3-oxo-5α-steroids[81] and ethynylation[74,81,89] involve a stereochemical orientation opposite to that in the Grignard reaction and lead to a mixture of isomers (XVII) and (XVIII), the latter (with an axial alkyl substituent) greatly predominating (1 : 6.5–7.0):



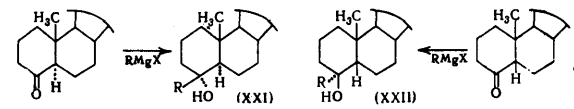
(XVII) (XVIII)

3-Oxo-5β-steroids form in a Grignard reaction mainly the isomer with the axial 3β-configuration of the alkyl group [(XIX) : (XX) = 2 : 1 when R = C_6H_5][90]:



(XIX) (XX)

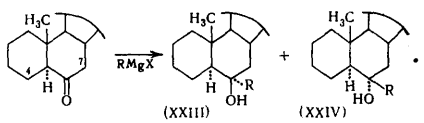
In the Grignard and Iotsich reactions, 4-oxosteroids of the 5α-series yield the axial 4β-alkyl isomer (XXI), while the Iotsich reaction with 4-oxosteroids of the 5β-series results in the formation of the axial 4α-alkyl isomer (XXII)[91-93]:



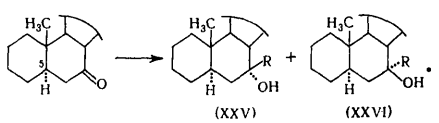
(XXI) (XXII)

6-Oxosteroids form with CH_3MgI only isomer (XXIII) with an equatorial alkyl group[94-98] and introduction of 5α-hydroxy-[99-103] or 7-alkyl[46] substituents does not alter

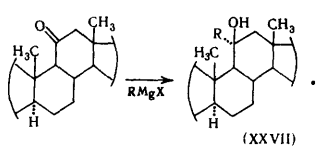
the stereochemistry of the reaction. At the same time in the presence of a 4α-methyl group in the steroid, a 6β-methyl derivative of type (XXIV) was found to predominate [104]. According to some data [105], arylmagnesium bromides form the isomer (XXIII), while according to others [106] the product is the isomer (XXIV). In the Grignard reaction 6-oxo-3α,5α-cyclosteroids form the isomer (XXIV) [107]:



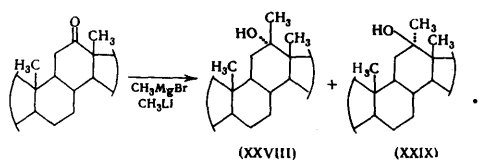
The Grignard reaction with participation of 7-oxo-5α-steroids yields predominately equatorial 7β-alkyl isomers of type (XXV) [108,109]. As with 3-oxosteroids, the introduction of a Δ⁵-bond alters sharply the stereochemistry of the process and isomers of type (XXVI) with an axial methyl group [109,110] at C_7 greatly predominate in the mixture of products of the reaction of 7-oxo-Δ⁵-steroids with CH_3MgI and CH_3Li:



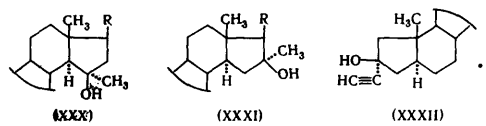
The sterically hindered 11-oxo-group is nevertheless susceptible to attack by organometallic compounds. Only the equatorial 11-alkyl derivatives of type (XXVII) were observed in all cases; methyl-lithium and the Iotsich agent form this product in higher yields than methylmagnesium bromide [111-117]. The reaction is more difficult with 11-ketones of the 5β-series and also in the presence in the steroid molecule of a free 17α-hydroxy-group; in both cases the approach of the reactant from the α-side of the steroid molecule is sterically hindered [112,118,119]:



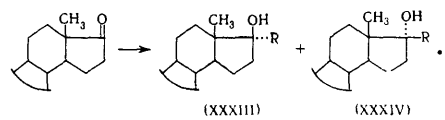
Despite earlier data [120,121], 12-oxosteroids form with organometallic compounds a mixture of isomers (XXVIII) and (XXIX) in which the equatorial 12β-methyl derivative (XXVIII), formed as a result of attack from the β-side of the steroid molecule [122-125], predominates:



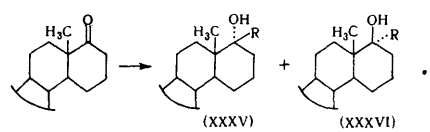
The reaction of 15-oxosteroids of the pregnane series with methylmagnesium bromide yields the 15α-methyl derivative (XXX) [126]. Both in the presence and absence of a 17β-hydroxy-group, 16-oxosteroids form with methylmagnesium bromide [127,128] and ethynyl-lithium [129,130] only 16α-alkyl derivatives of type (XXXI). The C_{16} position is stereochemically equivalent to the C_2 position in A-norsteroids. Therefore 2-oxo-A-norandrostanes react with ethynyl-lithium, forming a mixture of isomers in which the 2α-ethynyl derivative (XXXII) greatly predominates [131,132]:



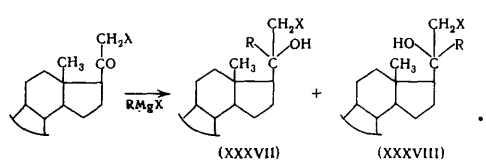
In the reaction of organometallic compounds with 17-oxosteroids, the products are mainly 17α-alkyl derivatives of type (XXXIII) [133]. The stereochemistry of the reaction does not alter when the molecule contains 16α-methyl and 16-spirocyclopropyl groups [29,134,135]. The reaction with methyl-lithium gives higher yields and is more stereospecific than the reactions with Grignard reagents [136,137]. In a number of studies small amounts of the 17β-alkyl isomer (XXXIV) were detected in the mixture of products of reactions of 17-oxosteroids with methyl [138], phenyl [139], and allyl [139,140] Grignard reagents. The isomer (XXXIV) predominates when the 17-oxosteroid molecule contains 12β-hydroxy- [141], 16α-acetoxy- [127], and 16α-fluoro-substituents [142] and also in the reaction of the methyl ether of oestrone with $KC{\equiv}CCH(OC_2H_5)_2$ (the potassium derivative of the diethylacetal of propiolic aldehyde) [143]:



The reaction of 17α-oxo-derivatives of D-homosteroids with organometallic compounds yields a mixture of isomers, the composition of which depends on the reagent employed. Grignard reagents form mainly the isomer (XXXV), corresponding to the equatorial substitution of an alkyl group, while methyl- and ethynyl-lithium give rise to a mixture of products in which the isomer (XXXVI) with an axial methyl (ethynyl) group predominates [144-149]:



A product with the 19-S-configuration is formed in the reaction of steroid 19-aldehydes with methyl-lithium [150]. 20-Oxosteroids unsubstituted at C_{21} react with methylmagnesium iodide, forming almost exclusively the 20β-methyl derivative (XXXVII) [151]. The 21-acetoxy-derivative (X = OAc) forms a mixture of isomers containing up to one-third of the 20α-alkyl derivative (XXXVIII) [152]:

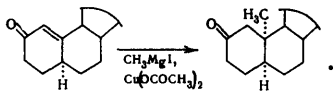


4. CONJUGATED ADDITION OF GRIGNARD REAGENTS TO UNSATURATED STEROID KETONES

In 1941 it was shown [153] that in the presence of copper(I) salts Grignard reagents add to αβ-unsaturated ketones in the 1,4-position forming β-alkyl ketones. The mechanism of this addition is probably similar to that of the Michael reaction but, in contrast to the latter, conjugated addition

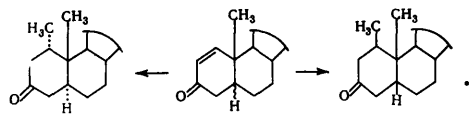
is an irreversible reaction[154]. A special review has been devoted[155] to the stereochemistry of conjugated addition involving cyclic $\alpha\beta$-unsaturated ketones.

Several types of steroid structures allowing the conjugated addition of Grignard reagents have been described. Thus 2-oxo-$\Delta^{1(10)}$-steroids combine with methylmagnesium iodide to form 10α-methylsteroids (XXXIV)[156,157]:



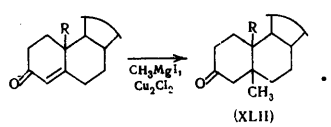
(XXXIX)

The reaction of a Grignard reagent with 3-oxo-Δ^1-steroids of the 5α-series yields the 1α-methyl derivatives (XL)[158-161], while the 1β-methyl derivatives (XLI) are formed from the 5β-analogues[162-164]:



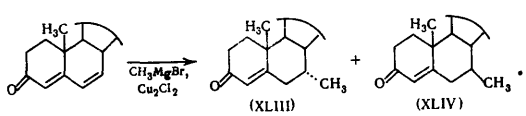
(XL) (XLI)

3-Oxo-Δ^4-steroids usually react with Grignard reagents by a mechanism involving 1,2-addition even in the presence of copper salts[165]. Only with testosterone was it possible to obtain a low yield of the 5β-methyl derivative (XLII; R = CH_3)[166]. Much higher yields (60–80%) were obtained with 19-norsteroids (R = H) where the absence of a methyl group at C_{10} considerably reduces the steric hindrance to the approach of the bulky Grignard reagent[165,166]:



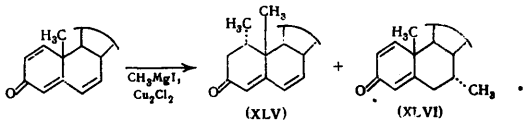
(XLII)

Conjugated 3-oxo-$\Delta^{4,6}$-steroids combine with methylmagnesium bromide in the 1,6-position with formation of 7α-methyl derivatives (XLIII)[29,167]; however, when the steroid contains an 11β-hydroxy-group, a mixture of 7α- and 7β-methyl derivatives is formed, with the 7β-isomer (XLIV) predominating[168]:



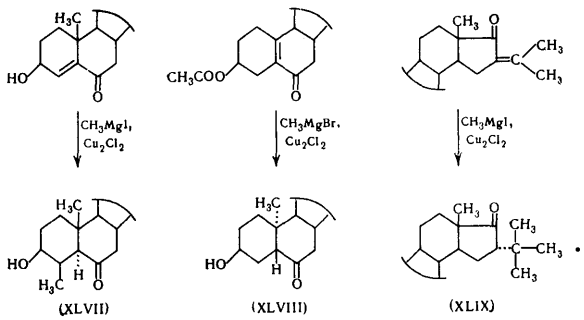
(XLIII) (XLIV)

The addition of Grignard reagents to 3-oxo-$\Delta^{1,4,6}$-steroids takes place in one or other conjugated system depending on the structure of the steroid and either the 1α-methyl derivative (XLV) or the 7α-methyl derivative (XLVI) predominates in the reaction products, with a small admixture of 1α,7α-dimethyl derivatives[169,170]:



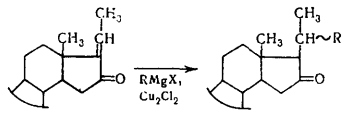
(XLV) (XLVI)

6-Oxo-Δ^4-steroids[171] and 6-oxo-$\Delta^{5(10)}$-steroids[172] form with Grignard reagents 4β-methyl (XLVII) and 10α-methyl (XLVIII) derivatives respectively. The reaction of 16-isopropylidene-17-oxosteroids yields the 16α-t-butyl derivative (XLIX)[78]:



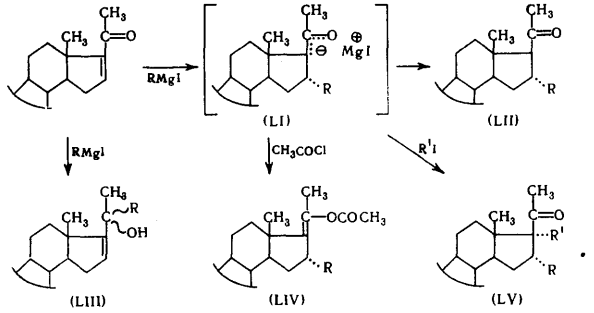
(XLVII) (XLVIII) (XLIX)

16-Oxo-$\Delta^{17(20)}$-steroids react with Grignard reagents to form a mixture of approximately equal amounts of 20α-alkyl- and 20β-alkyl-steroids (L)[173]:



(L)

The conjugated addition of Grignard reagents to 20-oxo-Δ^{16}-steroids has been investigated in greatest detail. Without added copper salts, products of both 1,2-addition [compound (LIII)] and 1,4-addition [compound (LIV)] are formed, the fraction of the latter increasing with the size of the alkyl radical R.[174] The addition of copper salts displaces the reaction almost entirely towards 1,4-addition with formation of 16α-alkylsteroids (LII)[175-182]. Structural changes in rings A and B have hardly any effect on the yield of compound (LII) but the presence of a 21-hydroxy-group lowers it significantly[183]. The presence of a 16-methyl group in the initial 20-oxo-Δ^{16}-steroids does not preclude high yields of 16,16-dimethyl derivatives[184,185]. Treatment of the intermediate enolate (LI) with acetyl chloride yields the enol acetate (LIV) which constitutes the starting material for the synthesis of 17α-hydroxysteroids[183,186] and treatment of compound (LI) with alkyl halides gives 16α,17α-dialkylsteroids (LV)[187]. All these findings greatly extend the scope of the synthetic applications of the conjugated addition reactions of Grignard reagents.



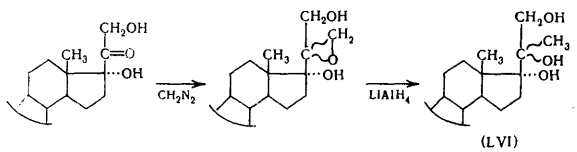
(LI) (LII) (LIII) (LIV) (LV)

5. ADDITION OF DIAZOMETHANE TO STEROID KETONES

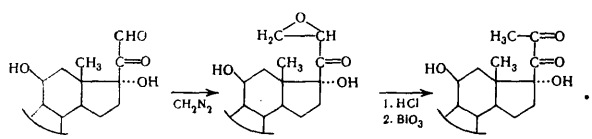
Diazomethane can react with carbonyl-containing steroids in two ways. Either by addition to the carbonyl group with formation of an epoxide or by addition to the

C=C double bond adjacent to the oxo-group with formation of pyrazoline †. The cleavage of the primary addition products leads to the formation of alkylated homologues of steroids.

The first addition mechanism obtains in reactions of diazomethane with 20-ketones [188] and 21-aldehydes [189,190] of the steroid series. The epoxides formed, containing one carbon atom more than the initial compounds, serve as the starting material for the synthesis of 20-methylsteroids (LVI) and 21-methylsteroids (LVII):

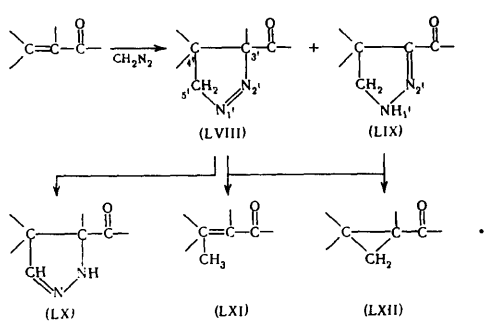


(LVI)



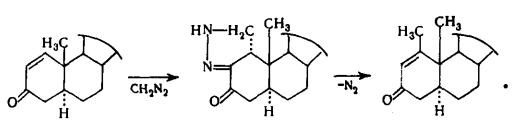
(LVII)

Diazomethane adds to the double bond of $\alpha\beta$-unsaturated ketones with formation of $\Delta^{1'}$-pyrazolines (LVIII) or the isomeric $\Delta^{2'}$-pyrazolines (LIX). Pyrolysis, photolysis, or acidolysis of these pyrazolines can lead to two main products—the methyl ketone (LXI) or the cyclopropyl ketone (LXII)—depending on the reaction conditions and the position of the pyrazoline group in relation to the steroid skeleton. For $\Delta^{1'}$-pyrazoline (LVIII), the possibility of isomerisation to the more stable $\Delta^{5'}$-pyrazoline (LX) has also been noted [39,191,192].



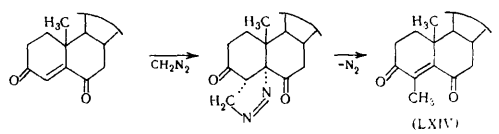
(LVIII) (LIX) (LX) (LXI) (LXII)

In the reaction of 3-oxo-Δ^1-steroids with diazomethane the product is a pyrazoline derivative which on heating or on contact with an acid adsorbent splits off nitrogen forming the 1-methylsteroid (LXIII) as the main reaction product [77,160,193,194]. 3-Oxo-$\Delta^{1,4,6}$-steroids react with diazomethane similarly, forming products of the addition to the Δ^1-bond adjacent to the oxo-group [160,194]:

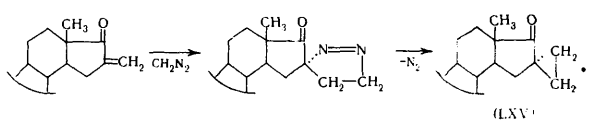


(LXIII)

The products of the addition of diazomethane to 3,6-dioxo-Δ^4-steroids form the 4-methyl derivative (LXIV) on pyrolysis and a mixture of equal amounts of compound (LXIV) and the corresponding $4\alpha,5\alpha$-cyclopropyl derivatives on photolysis [195,196]. At the same time the pyrazoline derivatives obtained from the 16-methylene-17-oxosteroids form 16-spirocyclopropylsteroids (LXV) as the sole product both in pyrolysis and in the reaction with BF_3 in acetone [135]:

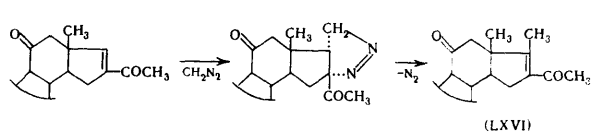


(LXIV)

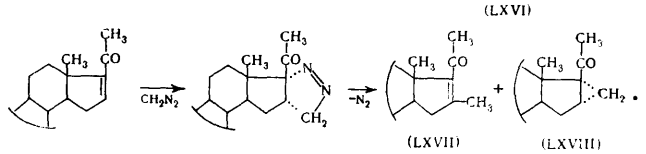


(LXV)

The reaction of 16-acetyl-Δ^{16}-steroids with diazomethane and subsequent pyrolysis yield the 17-methyl derivative (LXVI) [197], while the isomeric 20-oxo-Δ^{16}-steroid can serve as the starting material for the synthesis of 16-methyl derivatives of type (LXVII). Pyrolysis of the intermediate pyrazoline derivative gives predominantly compound (LXVII) and photolysis and acidolysis yield the $16\alpha,17\alpha$-methylenesteroid (LXVIII) [194,196,198-203]. Compounds of type (LXVIII) were also obtained in the reaction of 20-oxo-Δ^{16}-steroids with diazoethane [39] and the diazoacetic ester [204]; at the same time Δ^{16}-etianic acids form 16-methyl derivatives of type (LXVII) [205]:



(LXVI)



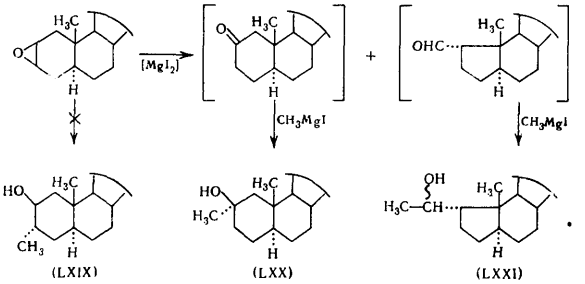
(LXVII) (LXVIII)

6. OPENING OF STEROID EPOXIDE RINGS BY GRIGNARD REAGENTS

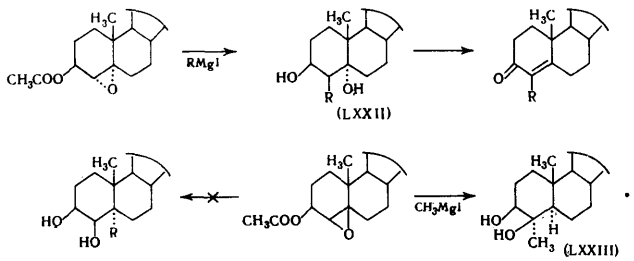
The opening of steroid epoxide rings by Grignard reagents was achieved for the first time in 1939 by Ushakov and Madaeva [206,207]. This reaction is carried out under severe conditions—refluxing in tetrahydrofuran (THF) or a mixture of ether and benzene using a large excess of the Grignard reagent. Therefore, apart from the main ring-opening reaction, various types of rearrangement also take place, due to the effect of magnesium halide in the Grignard reagent [208,209]. Thus in the reaction of the $2\beta,3\beta$-epoxide of the cholestane series with methylmagnesium iodide, a mixture of compounds (LXX) and (LXXI) was obtained instead of the expected ring-opening product (LXIX) [210]. These compounds are formed as a result of the attack of the Grignard reagent on the corresponding ketone and A-noraldehyde, which are the isomerisation products of the initial $2\beta,3\beta$-epoxide. Similar rearrangements also occur in Grignard reactions with participation of steroid 3α-acetoxy-$4\alpha,5\alpha$-epoxides [86,211], 3β-acetoxy-$4\beta,5\beta$-epoxides [212], 3β-acetoxy-$5\beta,6\beta$-epoxides [213], and $11\beta,12\beta$-epoxides. [214]; in the last case rearrangement can be avoided by using

† The ring expansion in reactions of diazomethane with steroid ketones is not discussed in this review.

dimethylmagnesium instead of methylmagnesium 10-dide[214,215].

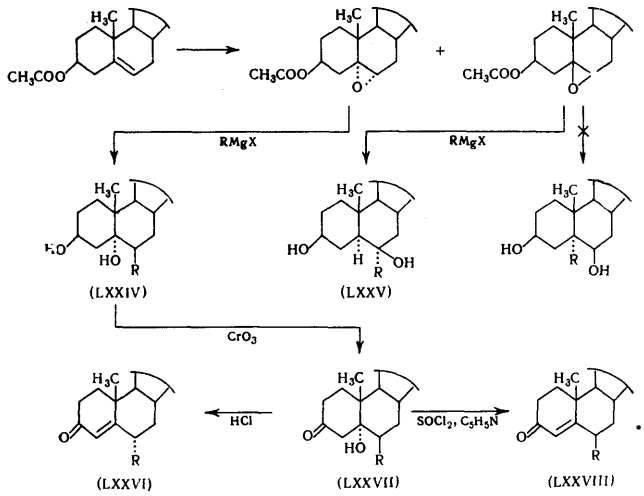


Normal ring opening of the epoxides of the steroid series by Grignard reagents results in the formation of *trans*-diaxial products. For example, the reaction of 3β-acetoxy-4α,5α-epoxide with Grignard, Norman, and Iotsich reagents yields 4β-alkyl(vinyl, ethynyl)-5α-hydroxy-derivatives (LXXII)[216-221]. The presence of a methyl group in the 6α-position does not alter the stereochemistry of the ring-opening reaction[33,222]. By oxidising compounds of type (LXXII) and subsequent dehydration, the corresponding 4-alkyl-3-oxo-Δ⁴-steroids were obtained. Despite earlier data[223], 3β-acetoxy-4β,5β-epoxides do not give rise to normal ring-opening products under the action of Grignard reagents; under these conditions, compound (LXXIII), formed as a result of the rearrangement of the epoxide ring to the 4-ketone and the attack of methylmagnesium iodide on this compound, was isolated[212]:

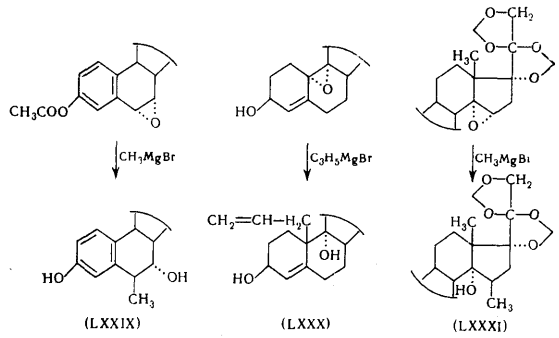


The introduction of epoxy-groups into Δ⁵-steroids leads as a rule to a mixture of both epimeric 5,6-epoxides, in which the 5α,6α-isomer greatly predominates. The opening of the epoxy-ring in the latter under the influence of Grignard reagents yields the 6β-alkyl-5α-hydroxy-derivative (LXXIV)[180,224-232]. Despite earlier data[233], the Grignard reaction involving 5β,6β-epoxides is anomalous. In the first stage the epoxy-ring isomerises with formation of a 6-oxosteroid, which, on being attacked by Grignard reagents, gives rise ultimately to the 6β-hydroxy-6α-methyl derivative (LXXV)[234].

Compounds of type (LXXIV) are converted into the corresponding physiologically active 6-alkyl-3-oxo-Δ⁴-steroids by various methods, depending on the structure of the initial compounds. Oppenauer oxidation or oxidation with CrO_3 of the 3-hydroxy-group yields the 3-oxosteroid (LXXVII), the dehydration of which under acid conditions is accompanied by the inversion of the 6β-alkyl group and the formation of the 6α-alkyl steroid (LXXVI). When the 6β-alkylsteroid (LXXVIII) is required, the dehydration is carried out under neutral or weakly alkaline conditions[29,177,178,235-242].

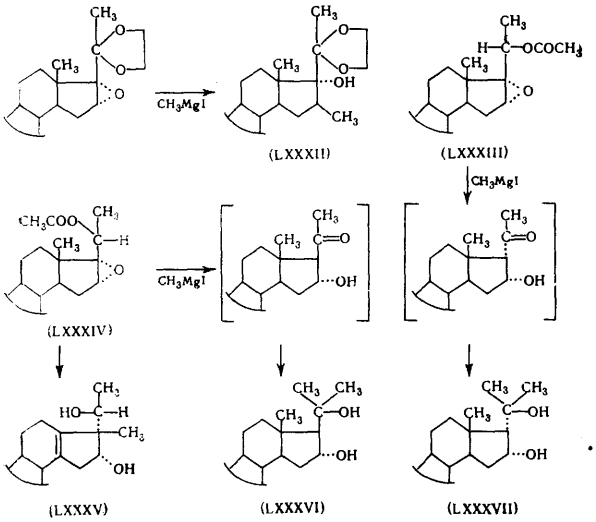


By opening the epoxy-ring of the 6α,7α-epoxide of the oestrane series, the 7α-hydroxy-6β-methyl derivative (LXXIX) was obtained[243]. The 9α,10α-epoxide produced by total synthesis forms the normal epoxy-ring opening product (LXXX) with allylmagnesium bromide; it is interesting to note that this reaction does not take place with Grignard reagents containing saturated alkyl radicals[244]. The reaction of the 14α,15α-epoxide with methylmagnesium bromide yielded the 14-hydroxy-15β-methylsteroid (LXXXI)[245]:



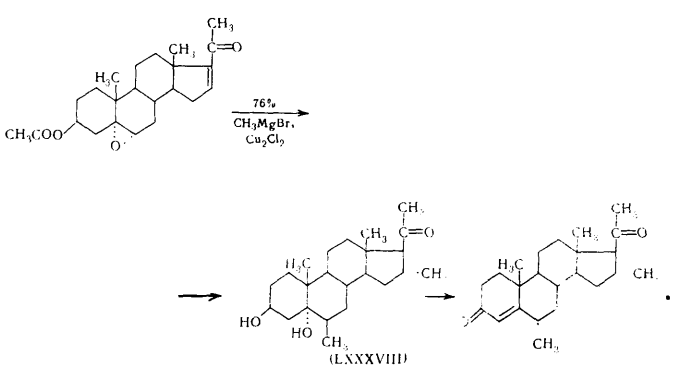
The Grignard reaction of the 20-ethyleneketal of the 16α,17α-epoxy-20-oxosteroid involves the opening of the epoxy-ring and the formation of the 17α-hydroxy-16β-methyl derivative (LXXXII)[246-248]. The Grignard reactions of epimeric 20-acetoxy-16α,17α-epoxysteroids are unusual. Apart from undergoing the Wagner–Meerwein rearrangement to compound (LXXXV), the acetoxy-derivative (LXXXIV) also isomerises to the corresponding 16α-hydroxy-20-ketone which reacts further with the Grignard reagent to form the 20-methylsteroid (LXXXVI). Under the action of the Grignard reagent, the epimeric 20α-acetate (LXXXIII) forms the 20-methyl steroid (LXXXVII) with the 17α-configuration of the side chain, which suggests the

intermediate formation of the 16α-hydroxy-17α,20-oxo-compound[249-254].



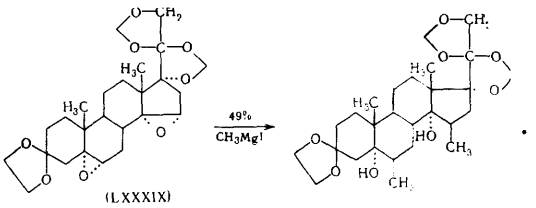
7. SIMULTANEOUS INTRODUCTION OF TWO ALKYL SUBSTITUENTS

The application of the methods discussed in Sections 2–6 to bifunctional steroid derivatives permits the introduction of two alkyl groups in a single stage. An example of this is provided by the reaction of methylmagnesium bromide with the epoxide of hydroxydehydropregnenone in which the epoxy-ring is opened with the introduction of a 6-methyl group and there is conjugated addition to the αβ-unsaturated ketone with the introduction of a 16-methyl group. The product (LXXXVIII) serves as the starting material for the synthesis of 6α, 16α- and 6β, 16α-dimethylsteroids[177,178,182,186]:



The synthesis of compound (LXXXVIII) is an example of reactions with two different functional groups. Other examples of this kind are provided by Grignard reactions with 3,17-dioxo-Δ[1]-steroids[160] and 6,20-dioxo-Δ[16]-steroids[177,182] where dialkyl steroids are formed as a result of 1,2-addition to one of the oxo-groups and conjugated 1,4-addition to the unsaturated group incorporating the second oxo-group.

Dialkylsteroids can also be obtained by the action of organometallic compounds on steroids with two similar reactive groups. Thus, following ring opening under the action of methylmagnesium bromide, the 5α,6α; 14α,15α-diepoxide (LXXXIX) forms the 6,15-dialkyl derivatives[245]:



Two alkyl groups are introduced in the corresponding positions of the steroid skeleton under the action of Grignard reagents on 3,17-dioxo-[82] and 11,17-dioxo-steroids[111]; dialkyl derivatives are also formed as side products form 7,11-dioxosteroids[255]. When an attempt was made to introduce simultaneously two methyl groups by a Grignard reaction with 6,17-diketones, individual products could not be isolated[94].

Condensed Phosphates in the Molten State

N.K.Voskresenskaya and I.D.Sokolova

Problems of the determination of the anionic composition of melts of condensed phosphates and the application of the "theory of the disordered reorganisation of condensed polymers" (Flory, Van Wazer) to them are considered. The part played by water in the formation and breakdown of polymeric chains and rings is noted. The liquidus diagrams of systems based on condensed phosphates of various anionic compositions are reviewed and compounds formed in the system are noted. The physical properties of phosphate melts (mainly surface tension, density, and their temperature coefficients) and their dependence on the type of equilibrium diagram, melt composition, and generalised moments of the cations and anions are examined. It is concluded that the interparticle interaction of polyphosphates in the liquid phase is reflected in their volume and surface properties. 157 references.

I. INTRODUCTION

Melts of condensed phosphates are attracting attention not only for themselves but also as a comparatively easily investigated model of an inorganic polymer, especially of silicate melts. They are of interest to various branches of learning and technology: nuclear physics, fertiliser technology, metals, electrometallurgy, etc. Crystalline and vitreous substances with valuable physical properties are obtained from the melts. There has recently been an increasing number of papers on condensed phosphate melts. However, Van Wazer's monograph[1] and Thilo's review papers[2,3] did not devote much space to the properties of melts, what was said being distributed in various sections. It is interesting to systematise the available information in terms of physicochemical analysis.

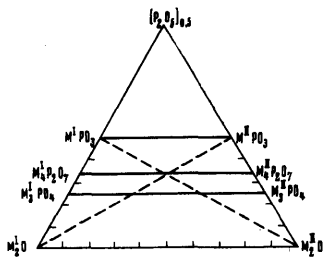

Figure 1. Composition triangle of the $M_2^{I}O-P_2O_5-M_2^{II}O$ system, where M is an equivalent of a metal.

Condensed phosphates are compounds in systems formed by phosphorus pentoxide with oxides of one or two metals; instead of one of the oxides they may contain water. The compositions are characterised by the ratio $R = M/P$, where M is the number of equivalents of the metal and P the number of phosphorus atoms. In the condensed phosphates PO_4 tetrahedra are connected through oxygen atoms with the formation of rings, chains, or networks. Although representatives of this class of compound were known at the start of the last century the study of the condensed phosphates became systematic only after the main feature of their structure as polymers was established. We will be interested in the part of the system (Fig. 1) corresponding to compositions with $R \geqslant 1$, not containing hydrogen. In Fig. 1 this part of the system is represented by the trapezium $M^{I}PO_3-M^{II}PO_3-M^{II}O-M_2^{I}O$. The compounds corresponding to this region are obtained by the thermal dehydration of acid phosphates or their mixtures with oxides or carbonates.

Compositions with $R = 1$ are termed "proper" metaphosphates, or simply metaphosphates. Their general formula is $(MPO_3)_n$, where $n = 3-8$.[2,4,5] They all have a ring structure. Condensed phosphates with $R > 1$ correspond to the general formula $(MPO_3)_n \cdot M_2O$ or $M_{n+2}P_nO_{3n+1}$ and have a chain structure. They are termed polyphosphates. Polyphosphates are the main constituent of melts. The initial member of the series of polyphosphates with very large values of n, that is, with a ratio R which is very little in excess of unity, is usually called metaphosphate, as are the ring phosphates. To distinguish the chain phosphates (with large n) from the ring phosphates with the same number of phosphorus atoms in the formula the word "meta" is inserted in the name when we are dealing with a ring phosphate, or the word "poly" when we are dealing with a chain; however, the word "poly" is sometimes omitted. Hence names such as "tetrametaphosphate" and "tetraphosphate" are obtained; the latter would be more accurately named a tetrapolyphosphate. The final term of the polyphosphate series ($R = 3$) is a compound with one PO_4 group, a monophosphate, better known under the name of orthophosphate; the penultimate term of the series ($R = 2$) is a di- or pyro-phosphate. In the polyphosphates where n is large two equivalents of metal are evidently replaced by hydrogen atoms which enter into the terminal groups with formation of hydroxyl groups. Hence the formula of the long-chain polyphosphates is more accurately written as $M_nH_2P_nO_{3n+1}$. †

† As lattice polyphosphates are almost absent from melts[6] we will not discuss their structure.

Some investigators do not take into account the hydrogen in the terminal groups and the polyphosphates are represented by formulae $M_{n+2}P_nO_{3n+1}$. These formulae are unconditionally applied to polyphosphates with n not exceeding 8–10, which are called oligophosphates[7].

II. ANIONIC COMPOSITION OF THE MELTS

The anionic composition of phosphate melts is determined predominantly by investigating the glasses into which melts of many phosphates with $R < 2$ (that is, in the metaphosphate–diphosphate region) are readily converted. There is a possibility of bringing phosphate glasses into solution without change in anionic composition by the choice of appropriate solvents or by double decomposition with salts and complexones and also with the aid of ion-exchange resins. The anionic composition of the solutions obtained can be determined by chemical analysis[8], by the method of titration of terminal groups[9,10], and by the methods which are general for polymer physics: ultracentrifugation, dialysis, electrophoresis, light scattering studies, viscosity of dilute solutions in the presence of an indifferent electrolyte, etc. However, the greatest possibility was revealed by paper chromatography, applied to polyphosphates by Ebel[11], subsequently perfected and now widely used.

The identity of the structural units of melts and of glasses has been shown by several investigators[12-18] using Raman and infrared absorption spectra, unfortunately for not many compositions. These results showed that in glasses there are chain and a few ring phosphates, and that branching is almost absent. The anions were identified on the basis of a comparison of the spectra of glasses and melts with the spectra of crystals of individual phosphates the structure of which had been found by X-ray diffraction or other methods.

Chromatographic investigation of phosphate glasses was undertaken from the 1950's onwards over the widest front by the schools of Thilo[19-21], Van Wazer and Westmann[22-31], and Meadowcroft and coworkers[32]. In the fusion of even definite crystalline phosphates—tri- and tetra- (but not di-) phosphates—a mixture of anions is formed, in which an anion with a chain length one unit less than the mean chain length ($\bar{n}$) predominates; the mean chain length is easily related to the relative concentration of the oxides $R = M/P$ by the ratio $\bar{n} = 2/(R-1)$. The isolated PO_4^{3-} ion was observed only in melts with $n < 2$, that is, in melts of mixtures of diphosphate and orthophosphate (see Ref. 1, p. 477).

The investigation of the anionic composition of the glasses does not give any idea of the state of the melts, since in the latter, their viscosity being low in comparison with that of glasses, processes connected with the formation of radicals and reactions with participation of the latter are possible. According to some investigators[21,33], many conversions in polyphosphate melts are connected with the formation of intermediate products—the radicals $NaPO_3$, PO_3, etc.

A guideline in ideas about the anionic composition in melts of chain polymers was given by the application to phosphates of the "theory of the disordered reorganisation of condensed polymers", Flory[34] having investigated the polymerisation of organic liquids. He considered the statistical polymerisation of hydroxy-acids, by assuming exchange between the molecular constituents of their "segments". These concepts and methods were transferred by Van Wazer[1,35,36] to polyphosphates. A phosphate melt with a definite value of n is characterised by the retention of some unchanged number of terminal phosphate groups PO_4^{2-}

and of intermediate PO_4^- groups:

analogous to the "segments" of Flory. Van Wazer finally obtained the distribution function—an equation for the determination of the anionic composition with a specified mean chain length $\bar{n}$. If the electrolytic dissociation in the melt were high then the anionic chains would behave as "rigid rods", owing to the high concentration of negative charges; if the dissociation were small then the negative charges would be partly neutralised and the anions would behave as "flexible chains". In the absence of PO_4^{3-} ions and of unreacted oxides the distribution function, which characterises the weight distribution of phosphorus along chains of different length, at a mean chain length of $\bar{n}$ for "flexible chains" will have the form:

$$\omega_{(n)} = \frac{n}{n(n-1)} \left(\frac{n-2}{n-1}\right)^{n-2} \qquad (1)$$

where $\omega_{(n)}$ is the weight fraction of the phosphorus in chains containing n phosphorus atoms; $n \geqslant 2$. For "rigid rods" the distribution function becomes more complex. In some papers[26,28,32] the experimental and theoretical conclusions about the distribution of phosphorus along chains of different length have been compared for glasses of various compositions. The results of chromatographic experiment were treated theoretically on the basis of equations following the Flory theory. The experimental results lie between the calculated ones obtained assuming "flexible chains" and "rigid rods". In recent years the theory has been developed further[37,38]. However, the most significant conclusions yet were derived from Flory's original theory.

Meadowcroft and Richardson[32] attempted to arrive at the thermodynamic properties of polyphosphate melts by using Flory's theory, the equations of which acquired a form convenient for thermodynamic evaluation. The Flory distribution formula is represented in the form:

$$N_n = \left(\frac{\bar{n}-1}{\bar{n}}\right)^{n-1} \cdot \frac{1}{\bar{n}} \qquad (2)$$

where N_n is the mole fraction of the n-mer in the mixture, and $\bar{n}$ is the mean chain length. Each n-mer is in equilibrium with decomposition products:

$$2P_n = P_{n-1} + P_{n+1} \,. \qquad (3)$$

The equilibrium constant (K) of the reaction is given by

$$\frac{[P_{n-1}] \cdot [P_{n+1}]}{[P_n]^2} = K_n \,. \qquad (4)$$

The expressions in square brackets denote the mole fractions of each polymer. The $(n-1)$-mer and $(n+1)$-mer obtained also disproportionate:

$$2P_{n-1} = P_{n-2} + P_n \qquad (4a)$$

$$2P_{n+1} = P_n + P_{n+2} \text{ etc.} \qquad (4b)$$

Each of the equations is characterised by a definite equilibrium constant. When all the other mole fractions of the polymers remaining for the equilibrium constants from

Eqn. (2) are substituted in Eqn. (4) we find that all the constants are equal to unity. It was found[32] that the experimental values of the constants obtained by chromatography of a series of partitions ($n = 4$, 6; cations Na^+, Li^+, Ca^{2+}, Zn^{2+}) are not unity; this shows that the distribution of phosphate along chains of different length is not completely disordered. With increase in n the constants approach 1 and (in some instances) even exceed 1. The departure from 1 at the same mean chain length $\bar{n}$ decreases in the order Na–Li–Ca–Zn.

In the expression:

$$RT \ln K_n = \Delta G_n = \Delta H_n - T\Delta S_n \qquad (5)$$

Meadowcroft and Richardson[32] neglected the entropy term, for doing which there is some justification, since the disproportionating anion is extremely similar to those which are formed. From K_n they found ΔH_n, the heat of disproportionation, which was positive, that is, the process is accompanied by absorption of heat. For a given cation ΔH_n increases as $\bar{n}$ is reduced, that is, as the chain is shortened. This is understandable, since the less $\bar{n}$, the greater the difference between the neighbour n-mers. At a given value of $\bar{n}$ the heats of disproportionation decrease in the order K(Na)–Li–Ca–Zn. Since in the expression

$$d \ln K_n / dT = \Delta H_n / RT^2 \qquad (6)$$

ΔH_n is small, it follows that the temperature change of the anionic composition is insignificant. As experiment shows, it is almost undetectable with the present accuracy of partition chromatographic analysis of glasses.

III. WATER IN PHOSPHATE MELTS

In the formation and changes of condensed phosphates water plays a large part, since as noted above there are hydroxide ions in the terminal groups of long-chain phosphates. The participation of water has been best studied for sodium phosphates. During the dehydration of the dihydrogen phosphate at ~ 240°C in addition to trimetaphosphate chain polyphosphates are formed (crystalline Madrell's salt) and above 400°C these are completely converted into crystals of a cyclic trimetaphosphate[39], the chain closing into a ring with the release of water from the terminal groups. It partly volatilises and partly remains, possibly even forming clathrates. During fusion a large part of the trimetaphosphate is again converted into polyphosphates: water retained in the crystals allows the ends to unwind into long chains with hydroxyl groups at the ends. In the crystallisation of the melt trimetaphosphate is again obtained, with vaporisation of part of the water from the salt mass. On this is based the procedure for the dehydration of melts by alternate crystallisation and fusion.

According to some investigators[40,41] the vapour pressure of water over the melts determines the type of polymers formed and the lengths of the anions present in the melt. Fig. 2 gives the change in the mean chain lengths as a function of the time of holding the melts in air[41]. A melt of dehydrated trimetaphosphate absorbs water from the air and the chains are shortened. The points characterise the change in the melt obtained by dehydration of monosubstituted orthophosphate. The melt loses water in the air and the chains lengthen. After 24 h both melts arrive at the same mean chain length, corresponding to the partial pressure of water in the air. The isotherms shown in Fig. 3 give the decrease in mean length with increase in the partial pressure of water vapour in the atmosphere, At constant pressure a rise in temperature brings about lengthening of the $(NaPO_3)_n.H_2O$ chain, evidently owing to removal of part of the water from the melt.

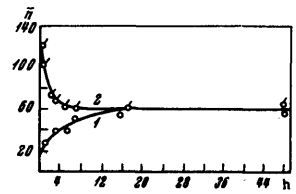

Figure 2. Dependence of the mean chain length ($\bar{n}$) of Graham's salt on the time kept at 650°C at a water vapour pressure of 55.3 torr[4]: *1*) salt obtained from NaH_2PO_4; *2*) salt obtained from anhydrous phosphate.

Prolonged crushing of condensed phosphate crystals or glasses has also been observed[42] to lead to a decrease in chain length. The water from the surrounding atmosphere evidently participates in this process.

The partial pressure of water also affects the relative composition of the dehydration products of crystalline modifications of a single phosphate, as is shown by the example of sodium tripolyphosphate[43]; this is connected with the formation of polyphosphate phases as intermediate compounds; their length is determined by the water vapour pressure. The ability to absorb and liberate water in the formation of different phases is also shown by condensed phosphates of other metals[44–49].

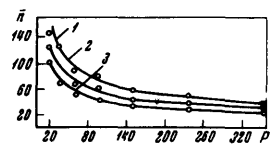

Figure 3. Dependence of the mean chain lengths of sodium polyphosphate melts on temperature and water vapour pressure[41]: Temperatures: *1*) 850°C; *2*) 750°C; *3*) 650°C. $\bar{n}$ = mean chain length; P = water vapour pressure, torr.

The quantitative determination of water present in polyphosphate melts and glasses is difficult and only a few papers‡ give the quantity of water in the melts.

Van Wazer (see Ref. 1, p.593) noted that fusion of NaH_2PO_4 at 700°C gives a preparation of $NaPO_3$ with n = 20–50; on holding the melt at 700–800°C for a month n is increased to 250–500, which corresponds to a water content of 0.07–0.03 wt. %.

‡ For example, according to Owens and Mayer[49] an analysis of a preparation of $NaPO_3$ by the zinc oxide method indicated < 0.2 wt. % H_2O.

The water present in molten metaphosphates is reactive. When molten $NaPO_3$ is held for 2 h at 800°C and then mixed with NaCl, predominantly HCl is liberated. In a melt of KPO_3 + NaCl mixture the liberation of HCl ends after almost 2 h. Judging by the quantity of HCl liberated the formula of the initial preparation was $(KPO_3)_{114}.H_2O$. The preparation of $NaPO_3$ contained more water and the reaction had not ceased after 2 h.[48]

IV. LIQUIDUS DIAGRAMS

1. Metaphosphate–Oxide of the Same Metal Systems

Metaphosphate–oxide systems with a single cation correspond to the sides of the triangle (Fig.1) from the figurative points of the metaphosphates downwards. The diagrams of these systems have been studied mainly by the methods of quenching and thermography; systems with the following oxides have been studied: Li_2O;[50] Na_2O;[51,52] K_2O;[53] MgO;[54] CaO;[55,56] SrO;[57] ZnO;[58] CdO;[59] PbO;[60-62] NiO and CoO;[63] Fe_2O_3.[64] The liquidus curves of all these systems have a chain or ring metaphosphate branch and also diphosphate and orthophosphate branches§.

In systems with Na_2O [51,52] and K_2O,[53] in addition to the diphosphate and orthophosphate branches there is a branch for the tripolyphosphate $M_5P_3O_{10}$; in the system with CaO there is a short branch for a phase of variable composition (tremelite), which was shown to be[65] a hexapolyphosphate with the anion $(P_6O_{19})^{8-}$. In systems with SrO [57] and PbO [66] there are branches for the tetrapolyphosphates $M_3P_4O_{13}$; the analogous Ba compound was obtained from melts and investigated chromatographically[67]. In systems with PbO a compound intermediate between the diphosphate and orthophosphate was also found: $Pb_5P_4O_{15} = 2Pb_2P_2O_7.PbO$.[62] In the systems with CaO, CdO, PbO, Fe_2O_3, and SrO there is yet another compound, different from those mentioned above, and richer in basic oxides than orthophosphates.

In systems with oxides of tervalent elements: B_2O_3,[68] Al_2O_3,[69] and Ga_2O_3 [79] orthophosphates are observed; however, in the diphosphate region only the system with Al_2O_3 has been studied, in which there is a eutectic between $Al(PO_3)_3$ and Al_2O_3. The orthophosphates of Fe^{3+},[71] Al,[72] and B, according to Schulze[73] and to Dachill and Dentglasser[74], are similar in structure to the modifications of SiO_2. According to Van Wazer[1], $AlPO_4$ and BPO_4 are most correctly considered as mixed anhydrides and not orthophosphates. The compound $Bi_3P_4O_{13}$ was isolated and the structure of its anion found chromatographically[68]. In the $Bi_2O_3-P_2O_5$ system, which was investigated by other authors[75] up to 12 mole % P_2O_5, solid solutions based on the high-temperature modification of Bi_2O_3 were found. In the interval between the branches of this phase and of the tetraphosphate there should be a branch of the orthophosphate $BiPO_4$; bismuth diphosphate is stable only in the solid phase.

In systems with the oxides of quadrivalent elements: SiO_2,[76,77] TiO_2,[78] UO_2 [79] there are branches for compounds with the composition of diphosphates: SiP_2O_7, TiP_2O_7, and UP_2O_9. In the first of these compounds various methods have shown the existence of the diphosphate ion[78,80,81,82]. An orthophosphate is not formed in the system with SiO_2; other investigators have not confirmed the report[76] of its formation. The separation of crystalline compounds with composition intermediate between the diphosphate and orthophosphate is characteristic: $Si_2P_2O_9 = SiP_2O_7.SiO_2$; $U_2P_2O_9 = UP_2O_7.UO_2$, close in composition to the $2Pb_2P_2O_7.PbO$ mentioned above[62]. These compounds and others which contain more basic oxide that the orthophosphate do not correspond to the formula of the chain polyphosphates $M_{n+2}P_nO_{3n+1}$.

In the $MoO_3-P_2O_5$ system compounds corresponding to the formulae $MoO_2(PO_3)_2$ (part of the Mo has a lower valency) and $(MoO_2)_2P_2O_7$ have been isolated[83]. As chromatography showed, the first is a polyphosphate with long chains, the second, according to the chemical analysis, is a diphosphate. Compounds of analogous composition but not isomorphous with the Mo compounds are also obtained with WO_3;[83] the composition of their anions could not be found. Schulz's results[83] suggest that the branch of the compounds with the diphosphate formula should extent to the trioxide branch, that is, orthophosphates are not formed in this or in the other system. But since the equilibrium diagrams have not been studied this conclusion needs to be checked.

2. "Metaphosphate–Oxide of Another Metal" Systems

Systems formed from the metaphosphate of one metal and the oxide of another metal constitute the diagonals of the trapezium in the lower part of Fig. 1 and can be represented as sections of the M^I, $M^{II} \parallel O$, PO_3 reciprocal systems. The correctness of this conclusion is confirmed by the experimental results[84-86] on the systems in which M^I = Na or K and M^{II} = Zn: the melts corresponding to the point of intersection of the diagonals appear to be saturated with the same phase (the mixed diphosphate $Na_2ZnP_2O_7$ or $K_2ZnP_2O_7$) irrespective of the initial components: $Zn(PO_3)_2$ and alkali metal oxides, or ZnO and alkali metal metaphosphates. But unlike many well-known salt systems in the present systems both the diagonal sections are stable, that is, they correspond to binary systems having one common branch of mixed diphosphate; its figurative point corresponds to the intersection of the diagonals of the square which represents the reciprocal system. The remaining branches of both sections, apart from the branches of the components, belong to the products of the initial substances—mixed phosphates, which are distinguished in the present systems by the ratio of the cations and even by the anions. In the Na, $Zn \parallel O$, PO_3 system the $NaPO_3-ZnO$ diagonal section[84] has $Na_3ZnP_3O_{10}$ and $NaZnPO_4$ branches (in addition to the branch of the mixed diphosphate); the $Na_2O-Zn(PO_3)_2$ diagonal section[85,86] probably the branches of $Na_2Zn_4P_8O_{25}$ (the structure of the anion was not established) and tentatively, the branch of the mixed orthophosphate. In the K, $Zn \parallel O$, PO_3 system[85,86] on the KPO_3-ZnO and $K_2O-Zn(PO_3)_2$ diagonal sections the compounds $K_3ZnP_3O_{10}$, $KZnPO_4$ and respectively $K_4Zn_3(P_3O_{10})_2$ and (probably) $K_4Zn(PO_4)_2$ are formed.

In the rest of the "$NaPO_3$–basic oxide of another metal" systems studied (M^{II} = Mg;[84] Cd, Pb, Mn;[87] Fe^{3+};[88] Al;[89] Ce, Nd, Sm[90]) mixed salts are also formed: diphosphates (in all the systems with a doubly-charged cation) of the $Na_2M^{2+}P_2O_7$ type; diphosphates with a triply charged cation $Na_6Al_2(P_2O_7)_3$ and $Na_6Ce_2(P_2O_7)_3$; triphosphates $Na_3MgP_3O_{10}$, $Na_3PbP_3O_{10}$, $Na_9Al_2(P_3O_{10})_3$, and $Na_9Fe_2(P_3O_{10})_3$; the orthophosphates of all bivalent metals

§ The system with Fe_2O_3 has not been studied in the range close to $R = 1$. The diagrams of some systems (for example $LiPO_3-Li_2O$) have not been studied in detail: the compounds were obtained by fusing appropriate amounts of the components.

$NaM^{III}PO_4$; the orthophosphates of tervalent metals $Na_3Fe_2(PO_4)_3$ and $Na_3Al_2(PO_4)_3$. It is characteristic that in the Ce and Nd systems mixed orthophosphates are obtained with an excess of the base $(M^{3+}PO_4)_2.Na_2O$. The structure of the compounds with triply-charged cations is probably not reflected in the formula given since tervalent metals can enter into the anion to some extent judging from their role in the Al and B orthophosphates (see above).

In the dissolution of WO_3 and MoO_3 in $NaPO_3$ only one compound (1 : 1) is isolated, as the equilibrium diagram shows [87,91]. A chromatographic investigation of these compounds obtained preparatively somewhat earlier [92] showed them to be mixed orthophosphates of dioxotungsten $(WO_2)^{2+}$ or dioxomolybdenum $(MoO_2)^{2+}$ and sodium.

In the systems mentioned the phases obtained are mixed salts containing both cations. Not one of the diagrams of diagonal sections obtained has branches for compounds formed in the binary systems (that is, represented by points on the sides of the square of the diagram of the reciprocal system). The formation of mixed Na triphosphates by the Mg, Zn, Pb, Al, and Fe^{3+} cations, which do not give triphosphates in the absence of Na, is characteristic. The absence of a mixed diphosphate in the $NaPO_3 - Fe_2O_3$ diagonal section is noteworthy.

The reactions of the compounds which form the equilibrium diagrams of the metaphosphate–oxide systems reflects a characteristic property of the polyphosphate chains to add an oxygen ion. In doing this one initial anion gives two shorter anions and two intermediate groups are converted into two terminal ones. The scanty thermodynamic results suggest that this reaction is exothermic.

However, the formation of a new anion does not always lead to the stabilisation of the diagonal sections. Li and Na [93] and Li and K [94] diphosphates form simple eutectic systems. The diagonal sections of the Li, Na(K) ‖ O, PO_3 reciprocal systems cannot be binary systems, since at oxide concentrations permitting the formation of the P_2O_7 anion instead of the mixed diphosphates characteristic for stable sections the simple ones will be isolated.

As already shown [95] the breakdown of the $P_3O_{10}^{5-}$ anion into $P_2O_7^{4-}$ and PO_4^{3-} leads to the formation of mixed phosphates only when the oxides of doubly-charged cations of small radius—Mg^{2+}, Cd^{2+}, Zn^{2+} (and, according to de Carli [87], also Pb^{2+}) dissolve in sodium triphosphate. When SrO and BaO dissolve, Sr(Ba) diphosphate and sodium diphosphate are obtained separately [95]. Therefore unstable diagonal sections are possible in the Na, Zr(Ba) ‖ O, PO_3 systems. Other phenomena are associated with the instability of the diagonal sections in the K, Na ‖ PO_3, P_2O_7 system [96]; the system passes through the field of the mixed tripolyphosphate $Na_5P_3O_{10}.K_5P_3O_{10}$, the figurative point of which lies off the diagonal sections.

The interaction of $NaPO_3$ with basic oxides does not exhaust the reactions of the compound observed in recording heating curves of annealed melts. When TiO_2, Fe_2O_3, CdO, CuO, PbO, or Sb_2O_3 are held for a long time in $NaPO_3$ melt substances were isolated which could be regarded as products of the replacement of part of the Na in the hypothetical compound $Na_{15}P_7O_{25}$ by another metal; these substances are double decomposition products [97]. During this the melt is enriched in basic oxides, which in one or another form should be separated in further crystallisation of the melt [88].

In the high-temperature treatment of metals by pressure using $NaPO_3$ as lubricant substances were also found [98] which could not be represented as products of the reaction of the metaphosphate with iron(III) oxide but have another polymeric structure.

It has been observed [99,100] that silicon, on being dissolved in $NaPO_3$ melt separates in the form of cristobalite. According to Schwarz [101], notwithstanding earlier statements, silicon does not form a compound with $Na_4P_2O_7$, which separated from the melt as cristobalite. However, $NaPO_3 - SiO_2$ glasses were found by X-ray diffraction [102] to have the P–O–Si bond, that is, are silicophosphates. Thermodynamic calculations also showed experimentally [103] that SiO_2 displaces P_2O_5 from $Ca_3(PO_4)_2$. An even more acid oxide—liquid SO_3—is reported [104,105] to displace P_2O_5 from meta-, tri-, di-, and ortho-phosphates even below 100°C, with the formation of $Na_2S_2O_7$ and $K_2S_3O_{10}$.

3. Systems of Two Polyphosphates with a Common Anion

Systems of two phosphates with a common anion correspond to horizontal sections in the composition triangle (Fig. 1). The common anion in metaphosphates is conventional, therefore at a single figurative point it corresponds to ring phosphates with various n, and chain phosphates. As all the experiments show, these systems are binary. The following metaphosphate systems have now been studied¶: Li–Na, Li–K, Li–Cs, Na–K, [106,107] Na–Ca, [108,109] K–Ca, [110,111] K–Mg, [111] K–Cu, [112] Na–Zn, K–Zn, [113] Mg–Zn, [114] Cd–Zn. [115] In these systems except for the first and the last two, there is a single congruently melting compound $2NaPO_3.KPO_3$, $4NaPO_3.Ca(PO_3)_2$, $2KPO_3.CU(PO_3)_2$ and the 1 : 1 type. In the $LiPO_3 - NaPO_3$, $Mg(PO_3)_2 - Zn(PO_3)_2$, and $Cd(PO_3)_2 - Zn(PO_3)_2$ systems there are extensive ranges of solid solutions up to a continuous series.

These facts show that the formation of mixed polyphosphates is favoured by a difference in the generalised moments of the cations† ($\mu = Z/r$ where Z is the charge, and r the radius of the ion) as in the halide systems in which, during the formation of the compounds, complex anions with covalent bonds are formed to a certain extent. The formation of the compounds $4NaPO_3.Ca(PO_3)_2$, [109,118] $KPO_3.MgPO_3$, and $KPO_3.Ca(PO_3)_2$, [111] which was studied chromatographically, is accompanied by the reorganisation of the anions: all three double salts are trimetaphosphates, whereas $Mg(PO_3)_2$ isolated from melts or glasses is a tetrametaphosphate [19] and $Ca(PO_3)_2$ and KPO_3 have chain anions. Many compounds obtained by fusing oxides with monosubstituted phosphates (for example, by Mehrotra and Gupta [119]) only partly reflected by the equilibrium diagrams in earlier papers, do not contradict the above observations about the connection of the formation of the compounds with the ratios of the crystal-chemical characteristics of the cations.

Polyphosphates do not differ from other salts as regards the conditions of formation of solid solutions. The difference in the anions (chains in $LiPO_3$ and rings in $NaPO_3$), is evidently of no significance, despite the view of Tamman and Ruppelt [120] who associate the absence of solid solutions in the $KPO_3 - NaPO_3$ system with the difference in the anions: $NaPO_3$ is isolated from the melts as trimetaphosphate, that is, with a cyclic anion, KPO_3 as Kurrol's salt, which has a chain anion. The compound which is formed in the $KPO_3 - NaPO_3$ system is similar to that from the system of the sulphates of these metals.

¶ We mention only the most complete investigations.

† Semenchenko [116,117] first showed the value of μ, which characterises the interaction of the species in ionic liquids; we have used this term.

In the Cd, Mg, Zn ‖ PO_3 ternary system, which has been partly investigated[115], solid solutions with $Mg(PO_3)_2$ structure predominate.

In the system of the incongruently melting sodium and potassium tripolyphosphates, which has been studied as a section of the K, Na ‖ PO_3, P_2O_7 reciprocal system[96] the compound $Na_5P_3O_{10}.K_5P_3O_{10}$ is formed it melts incongruently with the formation of solid solutions of diphosphates.

New anions do not arise in the diphosphate systems that have been studied. These systems do not differ from the usual systems with a common anion (see, for example, Refs. 93 and 94).

V. PHYSICAL PROPERTIES OF MOLTEN PHOSPHATES

1. Individual Phosphates

Of the physical properties of molten phosphates, the surface tension σ and the density ρ have been studied most. In 1917 Jaeger[121] first applied a method he had developed for measuring σ and ρ at high temperatures to $NaPO_3$ and KPO_3 melts. Callis and coworkers[122] measured σ and ρ for $NaPO_3$ and calculated the degree of polymerisation by the Eötvös equation in the Foreland form, and using the Sugden parachor, to be 9 and 1 respectively. With allowance for the assumptions made, they considered their results as "weak confirmation of the theory of disordered reorganisation". The values of σ and ρ for $NaPO_3$, KPO_3, and $Ca(PO_3)_2$ explained[123] the decrease in σ along the Ca, Na, K series by the decrease in the "coefficient of extension of the oxygen anion" analogous to that of the generalised moments μ (see p. 866).

Results obtained[124-126] on σ for Li, Na, K, Cs, Ca, Sr, Ba, Zn, and Mg metaphosphates were used for constructing a plot of the surface tension of the metaphosphates against μ for the cations (Fig. 4); the same smooth curve was obtained as for halides, nitrates, etc., but with the difference that unlike these salts there was not a sharp maximum in the region of Sr and Ba. From the curve for the variation of σ for salts with a common cation with the generalised moments of the anions it is found[127] that the value of μ for alkali metal metaphosphates approximately corresponds to the generalised moment of the terminal PO_4^{2-} groups, irrespective of the thermodynamically estimated radius of the orthophosphate ion.

The negative values of the temperature coefficients $d\sigma/dT$ of metaphosphates on an absolute scale are several times less than for other salts. From the values of the temperature coefficients $d\sigma/dT$ the cations of the metaphosphates can be arranged in the following order for the decrease in absolute values of this quantity: K > Na > Ca, and when μ is plotted as a function of the cations a straight line is obtained[123]. This relation was extended[125] to metaphosphates with other cations. $Zn(PO_3)_2$ has[125] a positive $d\sigma/dT$, like B_2O_3 in certain silicates but differing from most of the salts studied. According to Krivovyazov[86] positive values of $d\sigma/dT$ for $Zn(PO_3)_2$ are due to the chains in its melts being mainly connected ("cross-linked") through the Zn atoms, which have fourfold coordinations in this respect.

These ideas follow from the investigations of Zn phosphate glasses[128-130]. With rise in temperature the concentration of the "cross-linked" chains, which are surface active in relation to the other constituents of the melt decreases, which is contrary to the decrease in σ brought about by the decrease in the interparticle interaction as the temperature is raised. The release of Zn from fourfold coordination on heating is also reflected in the volume properties of $Zn(PO_3)_2$. As has been shown[86], the absolute value of $d\rho/dT$ of $Zn(PO_3)_2$ is only a fifth of $d\rho/dT$ of $NaPO_3$ and a tenth the value for the unpolymerised salts. The explanation is that the non-cross-linked chains, the concentration of which increases on heating, permit more compact packing than the "cross-linked" chains, which counteracts the thermal expansion. The more compact packing of the chains is accompanied by greater disorder, which can be explained by a decrease in entropy as the surface increases, which follows from the positive temperature coefficients $d\sigma/dT = -\Delta S$. This explanation is, for $Zn(PO_3)_2$, better founded than the ideas about elongation[131,132], the smoothing out of buckling during the increase of the surface and crumpling of the chains of the surface layer. The formation of the $Zn(PO_3)_2$ surface should take place with liberation of heat, because $\Delta S < 0$. The results[133] on σ and ρ for Li, Na, Ca, and Zn metaphosphates confirms the relation between $d\sigma/dT$ and μ; as Krivovyazov and coworkers[125] found, $d\sigma/dT$ for $Zn(PO_3)_2$ is positive, whereas $Ca(PO_3)_2$ has a small negative temperature coefficient.

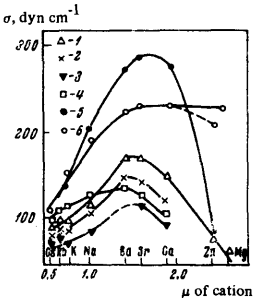

Figure 4. Dependence of the surface tension of metaphosphates on the generalised moments of the cations[122]: *1*) chlorides; *2*) bromides: *3*) iodides; *4*) nitrates; *5*) borates; *6*) metaphosphates.

The internal friction η was studied only for $NaPO_3$; according to Arndt[134] it is 200 times η for NaCl at the same temperature, but only one thirty-fifth that for B_2O_3 heated to 1000°C. The results[135] on η for $NaPO_3$, also calculated by the Bachinskii equation, showed that the viscous flow cell contains not more than eight PO_2 groups—a number close to that found[122] for the degree of polymerisation by the Eötvös equation. Whether the chain segments move separately or the number of PO_4 units in the cell corresponds to a mean length of the reconstructed chains, is thought to be uncertain[122]. On this basis[49,136] it has been found with the aid of the Bachinskii equation that the viscous flow cell contains 30 groups. The values obtained are several orders of magnitude less than found by the investigation of solutions and crystals[137-139].

The vapour pressure of molten phosphates has been studied very little. According to Storonkin and Bobrov's results[140] the vapour pressure of $Al(PO_3)_3$ at 1450°C reaches 115 mmHg. As regards the vapour pressure or dissociation pressure of other metaphosphates there are only notes made in passing that the pressure of some metaphosphate

melts is "insignificant"[49], that dissociation is not noted on heating a melt for 8 h at 1000°C;[141] on the other hand there is a report that above 1000°C "after some time" there is an appreciable loss of P_2O_5;[123] loss of P_2O_5 by calcium metaphosphate has also been noted[55]. Information on the electrical conductivity of molten metaphosphates has been given[142].

2. "Metaphosphate–Oxide" Systems

Of the properties of "metaphosphate–oxide of the same metal" melts the attention of investigators has been mostly directed towards surface and volume properties. The $NaPO_3$–Na_2O system has been studied[122]; the increase in σ and ρ (at constant temperature) with increase in R is explained by the shortening of the chains, this conclusion being drawn from the titration of terminal groups of aqueous solutions of the quenched glasses. Similar conclusions were drawn[123] for the $NaPO_3$–Na_2O, and KPO_3–K_2O systems, studied up to $R = 2$, and the $Ca(PO_3)_2$–CaO system studied up to $R = 1.66$. The slope of the straight lines showing the variation of σ with R increases with increase in μ for the cation. The increase in σ with R is explained by the increase in the "bond density" near the surface. With increase in R there is a decrease in $d\sigma/dT$ for every system‡, that is, the absolute values of $d\sigma/dT$ increase.

A rise in σ with increase in the concentration of the oxide was found in the $Ca(PO_3)_2$–CaO system[143]. An increase in σ with increase in R was also observed for the $Zn(PO_3)_2$–ZnO system[86]; at $R = 2$ a break is found, due[86,143] to the appearance at this concentration of surface inactive PO_3^- anions. The increase in $d\sigma/dT$ on adding ZnO is explained by the favourable action of the oxide on the breaking at elevated temperature of the surface-active "cross-linked" polyphosphate anions. Only on reaching a certain oxide concentration $R = 1.43$, when few "cross-linked" chains are left does $d\sigma/dT$ decrease with increase in R, remaining positive within the range of ZnO concentrations investigated.

σ and the molar volumes v of binary systems of Li, Na, Ca, and Zn metaphosphates and oxides with the same components for compositions with $R = 1$, 1.5, and 1.66 have been studied[133]. The value of σ increases with R for lithium, sodium, and calcium systems; for the zinc system σ was almost independent of R; $d\sigma/dT$, which is negative for the systems with Li and Na and positive for the systems with Ca and Zn, decreases with rise in R. The positive values of $d\sigma/dT$ were thought to be connected with the tendency of Ca and Zn to give covalent bonds with an oxygen atom and also with the fact that at the same values of R in these systems the chain length is greater than in systems which contain Li and Na, as was shown chromatographically[31]. Objections were raised[133] against the application to phosphates of the explanation[144] connecting the $d\sigma/dT$ of silicates with the subdivision of the anions of polymers on heating, since according to the polarographic determination, the anionic composition of polyphosphates varies little with temperature.

In all the studies made the isotherms of the properties investigated do not reflect the formation of alkali metal triphosphates and calcium hexapolyphosphate shown by the equilibrium diagrams. The formation of diphosphates has been noted only in the system with ZnO. The break found[143] in the $Ca(PO_3)_2$–CaO isotherm corresponds to the $(P_4O_{13})^{6-}$ anion.

The shortening of the chains on the introduction into Li, Na, K, and Ca polyphosphates of oxides with a common cation was shown[17] by investigating the infrared spectra of the glasses. The addition of oxides shifts the peak to higher frequencies. These results confirm the above explanation of the dependence of σ on R and μ.

σ and θ of melts of diagonal sections of the Na, Zn ‖ O, PO_3 and K, Zn ‖ O, PO_3 systems have been studied[85,86]. The isotherms of σ for $Zn(PO_3)_2$–K_2O (or Na_2O) sections have minima which differ from the isotherms described above for the binary systems with a single cation. The formation of mixed oligophosphates, shown by the equilibrium diagrams, does, as in the metaphosphate–(oxide of the same metal) systems, not determine the form of the σ isotherm. On adding Na or K oxide to $Zn(PO_3)_2$ σ does not increase—as in the $Zn(PO_2)_2$–ZnO system—but decreases. In the opinion of these investigators[85,86] the decrease is due to the formation of anionic complexes, the nature of which is uncertain, but which are determined by the tendency of Zn to form covalent bonds. In parallel with this there is the shortening of the polymer chains usual on the introduction of an oxide into the melt[144,145]. Starting from a certain concentration the effect of the latter process on σ predominates—σ starts to increase. The course of the temperature coefficients $d\sigma/dT$ can also be explained by its decreasing on adding Na_2O and K_2O but in some concentration ranges it changes very little since as the temperature is raised the surface-active anionic complexes decompose with the formation of inactive ones. The presence of new anionic complexes in the melts is demonstrated by the positive $\Delta\theta$ of mixing, similar to that which is observed in salt systems[146] in which the formation in the melts of anionic complexes with covalent bonds leads to positive values of $\Delta\theta$. The extensive chemical interactions during the dissolution in $NaPO_3$ melt of the oxides of bivalent and tervalent metals also show the excessive changes in free energies noted[147-149] in studying the chemical and concentration cells containing solutions of Pb, Bi, Ni, and Sb oxides in molten $NaPO_3$.

3. Systems with a Common Anion

The Table gives data on the fusion characteristics, the σ isotherm, $d\sigma/dT$, and $\Delta\theta$ for metaphosphate systems. Systems 1, 2, and 3 were classified as ideal by their investigators[152]; the Zhukhovitskii equation[153] in the form given by Guggenheim[154] was taken as a criterion of the ideality for σ; it has shown[141,155] that in most parts of the salt systems with formation of a compound the singular points on the σ isotherms alter. The behaviour (see Table) of system 3 in melts can be placed in accordance with the fact that from the infrared spectra[150] only the components are present in quenched melts, that is, the compounds dissociate during fusion. The same can also be suggested for system 2. Chromatograms of quenched melts of systems 1, 2, and 3 show the additivity of the anionic composition[133]. System 4 represents a change to the systems containing undissociated compounds in the melts; there are no singular points, but there is a negative departure of σ from that calculated by the Guggenheim formula[133,141]. Systems 5 and 7, the diagrams of which show the formation of compounds[86], and also system 6, for which there are grounds for expecting the formation of compounds by analogy with other systems which contain the same cations, have σ isotherms with minima or breaks

‡ Subsequently the increase in the absolute values of negative quantities will also be termed the loss function.

Isotherms of the properties of binary systems of metaphosphates.

No.	System	Type of diagram, compound	σ isotherm	$d\sigma/dT$	θ or $\Delta\theta$ isotherm
1	$LiPO_3$—$NaPO_3$	eutectic [106, 107]	weakly convex to the composition axis	—	straight line [133, 141, 152]
2	$LiPO_3$—KPO_3	$LiPO_3 \cdot KPO_3$ [106, 107]	ditto [152]	—	—
3	$NaPO_3$—KPO_3	$2NaPO_3 \cdot KPO_3$ [106, 107]	ditto [152]	—	convex away from the composition axis [150, 151]
4	$NaPO_3$—$Ca(PO_3)_2$	$4NaPO_3 \cdot Ca(PO_3)_2$ [108, 109]	ditto [133, 141]	—	ditto [133, 141]
5	$NaPO_3$—$Zn(PO_3)_2$	$NaPO_3 \cdot Zn(PO_3)_2$ [86]	minimum at 50 mole % $NaPO_3$	sign change [86]	with inflection [86, 133, 151]
6	KPO_3—$Ba(PO_3)_2$	—	minimum at ~70 mole % KPO_3 [141]	—	—
7	KPO_3—$Zn(PO_3)_2$	$KPO_3 \cdot Zn(PO_3)_2$ [86]	minimum at ~70 mole % KPO_3 [86, 151]	sign change [86]	with inflection [86, 151]
8	$Ca(PO_3)$—$Zn(PO_3)_2$	—	convex away from the composition axis [133]	—	—

(Fig. 5). The chromatograms of systems 4 and 5 show [133] an increase in the chain length on adding the metaphosphate of a bivalent metal to $NaPO_3$ melt. On this basis it is thought [133] that the change in anionic composition during the formation of compounds in polyphosphate melts leads to lengthening of the chain; the constancy of σ in the region of the minima is attributed to constancy of the concentrations of short and long chains.

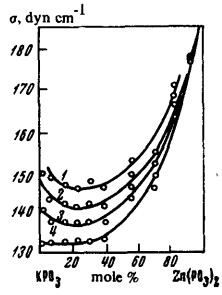

Figure 5. Surface tension of the KPO_3—$Zn(PO_3)_2$ system [86]. Temperature, °C: 1) 800: 2) 900; 3) 1000; 4) 1110.

Melts of systems 4, 5, and 7 are formed from the components with an increase in volume [133]. This is attributed to an increase in the concentration of the long chains under the influence of the doubly-charged cation. According to Krivovyazov [86] the change in $\Delta\theta$ in the last two systems is more complex: at low alkali metal concentrations the $\Delta\theta$ curve is concave ($\Delta\theta < 0$, mixing of the liquid components is accompanied by contraction), at high concentration it is convex away from the abscissa axis ($\Delta\theta > 0$). The shape of the $\Delta\theta$ and $d\Delta\theta/dT$ curves and also the minima on the σ isotherms are explained [86,141,151] by the superposition of effects: the first portions of alkali metal metaphosphate added to $Zn(PO_3)_2$ decrease σ owing to the surface activity of Na (or K) and the formation of surface-active anionic complexes which markedly affect σ. However, during this the volume is not increased§, but reduced, since the destruction of the "cross-linked" $Zn(PO_3)_2$ chains which takes place on the addition of $NaPO_3$ (or KPO_3) has a greater effect than the appearance of a few anionic complexes. Only when there is a high concentration of alkali metal metaphosphates is the concentration of anionic complexes sufficient for the appearance of a $\Delta\theta$ maximum; σ is not sensitive to the appearance of surface-active species, less sensitive to the increase in the concentration of surface-inactive products of the destruction. Only at high alkali metal concentrations does σ increase owing to the accumulation in the melt of surface-inactive cross-linked $Zn(PO_3)_2$ chains and the approach of the composition to pure $NaPO_3$ (or KPO_3).

§ For salts systems in which anionic complexes with predominance of covalent bonds are formed, an increase in volume on mixing is typical [146].

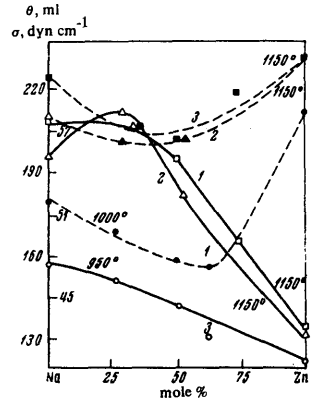

Figure 6. Molar volume (continuous lines) and surface tension (broken lines) of systems of sodium and zinc polyphosphates [133]. R: 1) 1; 2) 1.5; 3) 1.66.

Hence in systems consisting of Zn or Ca metaphosphates and Na or K metaphosphates the change in chain length goes in parallel with complex formation. These connect the phosphate melts with melts of $ZnCl_2$—M^ICl systems [156,157].

σ and θ for binary systems corresponding in composition to the Na and Zn tri- and tetra-polyphosphates have been studied [133]. The nature of the σ isotherms is the same as for systems of the metaphosphates of the same metals (Fig. 6); they have minima. The θ isotherm of the system of tripolyphosphates has a sharply expressed maximum, the system of tetraphosphates a positive departure of θ from a straight line.

The action of Zn and Ca on the change in properties of the alkali metal metaphosphates is thought [133] to be explained solely by the change in the length of the polymeric chains. This point of view is based on chromatographic

results, whereas the conclusion about complex formation[86,151] rests on results of physicochemical analysis. We note that ionic complexes can be decomposed in the dissolution of glasses for the chromatography. Furthermore, the chromatographic behaviour of the polyphosphate ionic complexes is unknown and to deny their existence on the basis of chromatographic results alone is premature.

Radiochemical Methods for the Preparation of Organic Derivatives of the Elements

V.D.Nefedov, M.A.Toropova, and E.N.Sinotova

The review deals with the radiochemical procedures for the preparation of organic derivatives of the elements based on the carrier method and also processes occurring in the β-decay of the constituent atoms of the molecular systems.
These methods are particularly important for the synthesis and investigation of the properties of the organic derivatives of elements without stable and long-lived isotopes and also compounds of the inert gases.
The bibliography includes 147 references.

CONTENTS

I. Introduction	873
II. Method of specific carriers	873
III. Method of stabilisation and fragmentation of primary molecular ions	875

I. INTRODUCTION

The chemistry of organic derivatives of the elements, the "third chemistry"[1], is a branch of science on the borderline between inorganic and organic chemistry. At one time such compounds played an important role in the development of the concept of valence[2] and also in the development of the theory of the structure of organic compounds[3,4]. Nowadays compounds of this class have found wide application in science and engineering and are manufactured on an industrial scale.

The intense development of the chemistry of organic derivatives of various elements began in the USSR at the end of the 1920's. The development of theoretical and practical problems in this field is especially due to Nesmeyanov and his school[5-9]. The establishment of a relation between the ability of elements to form organic compounds and their position in the Periodic System[5,9] led to the discovery of the possible syntheses of organic derivatives of elements which had not been investigated in this respect. These include all the elements with atomic numbers greater than 83 (radioactive elements) and also the inert gases. The relation established by Nesmeyanov can be undoubtedly extended also to radioactive elements such as francium, radium, astatine, and polonium.

II. METHOD OF SPECIFIC CARRIERS

1. Characteristics of the Preparation and Investigation of Compounds of Radioactive Elements

For a long time organic derivatives of the above elements were not prepared because of a number of features encountered in syntheses of radioactive elements[10]. These include, on the one hand, the impossibility of obtaining weighable amounts of individual radioactive elements, even by the most modern methods of nuclear physics, because of their short lifetime (astatine, francium, radon). On the other hand, studies with large amounts of many radioactive elements inevitably involve intense radiation-chemical changes both in the substances themselves and in the surrounding medium. The latter make it impossible to secure

accurate information about the properties and the state of the elements and the nature of the compounds obtained[11,12].

These factors make it necessary to work with extremely small amounts of radioactive elements, which greatly complicates the syntheses in practice and also makes it impossible to establish the composition of the compounds prepared by direct analytical methods. For this reason, the so called method of specific carriers has played a special role in the usual chemical syntheses of compounds of radioactive elements[13-16].

The carrier method is based on the similarity of the properties and behaviour of similar elements and their compounds. Examination of the Periodic Table shows that all the radioactive elements up to element No. 115 inclusive have such close analogues. Therefore the basis of this method is extremely general.

Radiochemical experiments have shown that the data on the behaviour of radioactive elements obtained using submicroscopic amounts and similar elements as carriers adequately reflect the properties of the given radioactive element. Thus the numerous facts established by studies on the chemical behaviour of sometimes even individual atoms of radioactive elements were subsequently confirmed by experiments with macro-amounts of the substance[17,18]. The most striking example in this respect is provided by the design of nuclear manufacturing plant in which the technological isolation of plutonium was developed on the basis of radiochemical investigations of submicroscopic amounts of this element. The scaling-up coefficient on transition to the industrial process was 10^{10}.

The similarity of the properties and behaviour of similar organic derivatives of analogous elements should be even greater. This is because in complex derivatives of this kind the differences between the individual properties of the central atoms are largely obliterated.

Since it is impossible to establish by direct chemical analytical methods the composition of the compounds of the radioactive elements obtained, indirect methods, based on a comparison of the behaviour of the test substances with that of compounds of analogous elements, play a considerable role. In preliminary experiments, the behaviour of compounds of the analogous element is investigated and the data thus obtained constitute the basis for the identification and the determination of the yield of the analogous compound of the radioactive element. Chromatographic methods have proved particularly convenient for this purpose[19-26]. The study of the properties of compounds of radioactive elements based on a comparison with data on the chromatographic behaviour of compounds of analogous elements is widely employed at the present time. In this connection, one can show, for example, that the similar chromatographic behaviour of the trivalent cation of lanthanide and transuranic elements has played a very important role in the identification of americium, californium, and other "far" transuranic elements[27-36].

Numerous compounds of polonium and astatine have been synthesised by the method of carriers[25,37-46].

2. Preparation of Organopolonium Compounds by the Method of Carriers

In view of the position of polonium in the Periodic System and the electronic configuration of its atoms ($6s^26p^4$), it was expected that polonium would form both alkyl and aryl organic derivatives of the following types: R_2Po, R_2PoX_2, R_3PoX, and $RPoX_3$, where R is an organic group and X a halogen atom.

The first studies on the synthesis of organopolonium compounds of the type R_2Po were carried out by Khlopin and coworkers as early as the 1930's for methyl and benzyl derivatives[37-39]. The existence of polonium in the form of an organic compound was proved by the observation that in the recrystallisation of the dibenzyl derivative and in the distillation of dimethyl telluride, polonium behaves analogously to the corresponding tellurium compounds.

Further studies showed that not all the classical methods suitable for organotellurium compounds can be used to prepare organopolonium derivatives[40-42]. The lower thermal stability of fully organic derivatives of divalent polonium of the type R_2Po excluded synthetic methods involving elevated temperatures. For example, the reaction of metallic tellurium with diphenylmercury or the reaction of tellurium chloride with anisole, which give rise to the formation of high yields of tellurium compounds[47,48], gave only 1-5% of the analogous organic derivative in the case of polonium[49]. The tendency towards decreased thermal stability of similar fully organic derivatives with increasing atomic weight of the central atom is well known and has been observed for elements of other Groups[50].

Table 1. Organic compounds of polonium obtained by the carrier method.

R	Type of compound					
	R_2Po		R_2PoX_2		R_2PoX	
C_6H_5	R_2Po	[40]	R_2PoCl_2	[40]	R_2PoCl	[40]
					R_2PoI	[40]
	R_2Po	[41]	R_2PoF_2	[41]		
p-$CH_3C_6H_4$			R_2PoCl_2	[41]	R_2PoCl	[41]
			R_2PoBr_2	[41]		
			R_2PoI_2	[41]	R_2PoI	[41]
p-$CH_3OC_6H_4$	R_2Po	[25]	R_2PoF_2	[41]		
			R_2PoCl_2	[25]	R_2PoCl	[25]
					R_2PoBr	[25]
					R_2PoI	[25]
α-$C_{10}H_7$	R_2Po	[42, 42]	R_2PoF_2	[49]		
			R_2PoCl_2	[49]	R_2PoCl	[49]
			R_2PoBr_2	[49]	R_2PoBr	[49]
			R_2PoI_2	[49]	R_2PoI	[49]

Note. The numerals in the table denote references (Ed. of Translation).

An extremely convenient method for the preparation of aromatic derivatives of divalent polonium consists in the synthesis via a Grignard reagent in the presence of a 2-8-fold excess of the latter. The experiments were performed with amounts of polonium-210 of the order of 10^{-10} g using as carriers tellurium compounds labelled with radioactive tellurium-127.[25,40-42,49]. The use of labelled tellurium compounds as carriers is very convenient, since under these conditions radiometric analysis makes it possible to follow simultaneously the behaviour of both polonium and tellurium compounds. The yields of organic derivatives of divalent polonium were 65-80%. In many cases, by reducing the amount of the Grignard reagent, the relative yield of the organopolonium compounds was increased. Thus the yield of ditolylpolonium in the presence of a 2-3-fold excess of the Grignard reagent exceeded the yield of ditolyltellurium by a factor of 3-5.[41]

Triallylpolonium halides were obtained by the reaction of stoichiometric amounts of tellurium and polonium tetrachlorides with a Grignard reagent. A higher yield of the polonium compound was not observed in this case.

Diarylpolonium dichlorides were synthesised by chlorinating diarylpolonium. Gradual chlorination of a mixture of diarylpolonium and diaryltellurium showed that the latter is chlorinated much more slowly than the analogous polonium compound[49].

Despite the great similarity in the behaviour of the compounds of analogous elements, under certain conditions it is possible to find methods for their separation. In particular, the separation of organic derivatives of polonium and tellurium may be based on the difference between the oxidising properties of the compounds of divalent tellurium and polonium and also on the difference in the chromatographic behaviour of diaryl polonium and diaryltellurium dihalides in certain polar solvents. It has been shown[25,40-42,49] that in general the chromatographic behaviour of tellurium and polonium compounds is almost identical. However, in certain systems (for example, in a 3 : 2 methanol–water mixture) they are completely separated. Organic compounds of polonium obtained by the carrier method are listed in Table 1.

3. Preparation of Organoastatine Compounds

Astatine is immediately adjacent to polonium on the right-hand side in the Periodic System. Since the stability of organic derivatives of polyvalent halogens in Group VII of the Periodic System increases on going from fluorine to iodine, it was reasonable to suppose that astatine, the heaviest halogen, would form organic derivatives in which it would exhibit valence states analogous to those of iodine (III and V).

The most long-lived astatine isotope is astatine-210 with a half-life of 8.3 h. Such a short half-life intensifies the already considerable difficulties of synthesising organic derivatives of this element. The overall duration of synthetic operations must not exceed 3–4 h in this case. Organoastatine compounds were prepared on the basis of the following scheme[44,45,51]:

$$R_2ICl + KI(At) \rightarrow R_2I(At) \xrightarrow{170^\circ} RI(At) \xrightarrow{Cl_2} RI(At)Cl_2 \begin{cases} \xrightarrow{R_2Hg} R_2I(At)Cl \\ \xrightarrow[NaOCl]{} RI(At)O_2 \end{cases}$$

The astatine compounds were separated from the parent substances and analysed by paper and thin-layer chromatography.

III. METHOD OF STABILISATION AND FRAGMENTATION OF PRIMARY MOLECULAR IONS

1. Behaviour of Primary Molecular Species Formed in β^--Decay

A fundamentally new method for the preparation of organic derivatives of radioactive elements is based on the stabilisation and partial fragmentation of the so called primary molecular ions. These ions arise as a result of the β^--decay of the constituent atom in different kinds of molecule.

We shall consider briefly the processes which develop in the β^--conversion of the constituent atoms of molecular systems. The β^--decay of atoms yields isobars of the adjacent elements to the right in the Periodic System according to the following general scheme:

$$^{A}M_z \xrightarrow{\beta^-} {}^{A}N_{z+1} + e^- + \tilde{\nu} \ .$$

If the atom forms part of a neutral molecule or ion, then the initial instantaneous process is the generation of a primary molecular species containing the atom of the new element, for example:

$$C_6H_5{}^{133}I \xrightarrow{\beta^-} [C_6H_5{}^{133m}Xe]^+; \quad {}^{133}IO_3^- \xrightarrow{\beta^-} {}^{133m}XeO_3^* \rightarrow {}^{133m}XeO_3 \ .$$

The new molecular species containing the adjacent element which are produced in this stage have the same structures and electronic configurations as the initial molecule. Subsequent processes undergone by the primary molecular species are associated with the characteristic response of the electron cloud of the initial atom to the sudden change in nuclear charge as a result of the β^--decay (the electron cloud of the parent system is suddenly placed in the field of a nucleus with a new value of z). This inconsistency results in excitation, ionisation, and partial breakdown of some of the primary molecular species[52-66]. The fraction of primary molecular species which break down as a result of excitation and ionisation does not exceed 20%. Investigations have shown that in the case of organic derivatives of the elements this breakdown (fragmentation) involves the splitting off of the organic radical[19,22-24,26,67].

On the basis of a number of characteristic features of the β^--decay process (instantaneous change in nuclear charge and low probability of the interaction of the β^--particle with orbital electrons), an expression was obtained for the probability of the generation of new states of the daughter atom. This expression permits the calculation of the fraction of daughter atoms in excited and ionised states:

$$P_{mn} = \left| \int \psi_m^* \psi_n d\upsilon \right|^2 ,$$

where Ψ_m^* is the wave function of the parent atom in the state m and Ψ_n the wave function of the daughter atom in the state n.

According to the selection rules established by Migdal[53], transitions are possible only between levels differing solely in principal quantum numbers. The formula for the transition probability in the hydrogen-like approximation was obtained by Schwartz[54,63]. Carlson[57-59] and Skorobogatov[68] made the most detailed and thorough calculations of the excitation and ionisation probabilities. The results led to conclusions concerning the relation between the excitation and ionisation probabilities as a function of the valency and the charge state of the atom and also the position of the elements within the limits of the same Group or Period of Mendeleev's System.

According to theoretical considerations and experimental data, the results of calculations for isolated atoms can be extended to processes involving the constituent atoms of molecular systems. Thus, using an expression for the internal wave function of the molecule obtained as a product of the electronic and nuclear functions on the basis of the Born–Oppenheimer approximation (and neglecting, in accordance with the Franck–Condon principle, the dependence of the electronic wave function on the internuclear distance), Wolfsberg[64] obtained an expression for the probability of the transition of the molecular system from one state to another:

$$P_{A \rightarrow B} = P_{a \rightarrow \beta} P_{a \rightarrow b} \ ,$$

where $P_{\alpha \rightarrow \beta}$ is the overlap integral of the electronic wave

function of the initial and final states of the molecular system for the equilibrium internuclear distance in the initial molecule and $P_{a\to b}$ the probability of vibrational and rotational excitations under the action of the momentum of the radioactive recoil in the β-transition. The individual factors in this expression can be calculated independently. The factor $P_{\alpha\to\beta}$ for the molecular system differs little from the analogous factor for the isolated atom [68]. The numerical value of $P_{a\to b}$ can be calculated from the energy spectrum of the recoil atoms, the bond energy, and the rotational-vibrational factor.

If it is assumed that all the electronically excited and multiply ionised states are unstable, the fraction of the residual primary molecular species is determined by the probability of transitions to the ground electronic state and bound rotational-vibrational levels. Since the fraction of the latter corresponds to the transitions in which the recoil energy available for the dissociation of the bond is less than the energy of this bond, the calculations require a knowledge of the energy of the chemical bond involving the daughter atom in the primary molecular species†.

When β-decay leads to isotopes of stable elements, the bond energies can be found experimentally. The estimation of the bond energy in primary molecular species containing atoms of typically radioactive elements or elements of Group 0 may be based on the isoelectronic principle [69,70].

The processes discussed do in fact largely determine the behaviour of the primary molecular species produced in the β-decay of the constituent atoms of isolated molecules‡.

Theoretical and experimental studies on processes in the β-decay of the constituent atoms of molecules in the gas phase do not resolve the question of the fate of the primary molecular species if the molecules of the parent substances are present partly in the condensed phases. Then there is a possibility of a definite change in the electronic states of the parent molecules, of processes involving excitation energy transfer to the surrounding medium, etc., and finally of changes in the nature of the processes in which the primary molecular species take part. At the same time, in condensed phases many changes can be due to processes in which the primary molecular species and their fragments are neutralised by free electrons and the electrons of the surrounding species, by ion–molecule interactions, and by radiation-chemical processes.

It follows from the above that at the present time it is impossible to give a rigorous quantitative explanation of the changes observed in the β-breakdown of the constituent atoms of molecular systems in condensed phases. At the same time the processes occurring in β-conversions of the constituent atoms of molecular systems are of interest for a wide variety of branches of science, including molecular biology, genetics, the science of the origin of pre-biological formations, etc. [71-73] β-Decay processes are particularly important for the development of new research methods and new synthetic pathways.

† In the calculation of the contribution of the transitions leading to bound rotational-vibrational states, it is necessary to consider only breakdown processes of the primary molecular species requiring a minimum expenditure of energy.

‡ Since the lifetimes of the excited states in radiation-induced transitions exceed by 4–5 powers of ten the vibration periods of the atomic bonds, other processes (for example the transfer of excitation energy under conditions excluding intermolecular interaction) cannot play a significant role.

2. The Use of β-Decay Processes for the Development of New Research Techniques

From the standpoint of the development of new research methods, β-decay processes of halogen and tritium atoms, leading to the formation of the inert gas atoms [74-85], are of considerable interest. If these processes occur in molecular systems such as halogen derivatives (except iodine derivatives) and hydrocarbons, then the resulting molecular ions are unstable and their breakdown leads to the formation of free carbonium ions [82-85]. For example:

$$CH_3F \xrightarrow{\beta^-} CH_3Ne^+ \to Ne + CH_3^+ ,$$

$$CT_4 \xrightarrow{\beta^-} CT_3He^+ \to He + CT_3^+ .$$

In principle, these processes make it possible to obtain free carbonium ions of any composition and structure and with any initial localisation of the charge and also to investigate their reactions with substances of different kinds in the gaseous, liquid, and solid phases. The possibility of using β-decay processes to obtain carbonium ions in a free (non-solvated) state has a wide scope for the development of new research methods in organic chemistry. From this point of view, the most interesting is the breakdown of tritium in highly tritiated hydrocarbons, since it is then possible to investigate the reaction of free carbonium ions by radiochemical methods. These studies are at present being vigorously developed in the Department of Radiochemistry of Leningrad University.

3. The Use of β-Decay Processes for the Synthesis of Organic Derivatives of Elements

The β-decay method can be used to obtain and investigate the compounds of any elements the precursors of which are radioactive isotopes undergoing a short chain of β-transformations. For example: $^{125}Sb-{}^{125m}Te$, $^{210}Bi-{}^{210}Po$, $^{133}I-{}^{133m}Xe$, etc. [86-103]

A distinctive feature of the synthetic methods based on the stabilisation and fragmentation of primary molecular ions arising in the β-decay processes of the constituent atoms of molecular systems is the possibility of obtaining neutral and charged molecular species of the daughter element in the matrices of the crystal lattices of the parent substances. This may be of interest from the standpoint of the investigation of the phenomena which occur in molecular systems during β-transformations of atoms, and also from the standpoint of the investigation and preparation of unstable compounds such as di- and tetra-chlorides of zenon and the halides of krypton [104-107], etc. It is also significant that β-decay processes make it possible to obtain radioactive compounds of daughter elements without a carrier, which is important for the investigation of the behaviour of infinitesimal amounts of substances in processes of different kinds, including deep-purification processes.

The study of the processes in the β-transformation of bismuth isotopes in various aryl derivatives resulted in the preparation of all possible types of organic compounds of polonium, containing a wide variety of groups and an essentially new branch of chemistry was created—the chemistry of organic polonium compounds [19,20,22-24,26] (Table 2).

The use of synthetic methods based on β-decay processes is not restricted to typical organic derivatives of the elements. For example, it has been established that, in the β-decay of molybdenum-99 in the hexacarbonyl of this

element, a considerable proportion of the resulting technetium is in the form of a volatile compound. These observations led to the hypothesis that this element forms carbonyls [112,113], which was soon confirmed by direct synthesis of technetium carbonyl [114,115]. The dibenzyltechnetium cation [116] and the pentadienyl derivatives of this element [117] were obtained similarly with the aid of the β-decay process.

4. The Use of β-Decay Processes for the Preparation of Inorganic and Organic Compounds of the Inert Gases

At the present time the β-decay processes of the constituent atoms in molecular systems attract attention in connection with their possible employment for the investigation of many problems in the chemistry of the inert gases. In particular it was suggested in 1963 that synthetic methods based on β-transformations can be extended to prepare inorganic and organic derivatives of the heavy inert gases [118,119]. The first experimental confirmation of the validity of these ideas came from a study [104] based on the following chain transformation:

$$^{129}I \xrightarrow[1.7\cdot10^7\ \text{years}]{\beta^-} {}^{129m}Xe \xrightarrow[7.15\cdot10^{-9}\ s]{} {}^{129}Xe$$

where iodine-129 was introduced into iodates, periodates, and $KICl_4$ and the Mössbauer emission spectra were investigated. Although the method employed by the authors made it possible to follow chemical changes occurring only in the lifetime of the excited level (about 10^{-9} s), the importance of this investigation is evident.

Several months later a more extensive series of studies on the chemical consequences of the β-decay of the isotopes of iodine in its various compounds was published. The studies were carried out by radioactive methods which permitted not only the identification but also the isolation of the corresponding compounds of radioactive xenon [99-102,119-129].

The use of the β-decay method for the preparation of organic compounds of the inert gases is of special interest [99-102].

Despite the exceptionally rapid progress in the chemistry of the inert gases, the problem of the organic compounds of these elements remained uninvestigated for a long time [130-136]. Nevertheless, long before Bartlett's investigations [137], Nesmeyanov put forward ideas concerning the possible existence of these compounds, their nature, and methods of synthesis [4]. On the basis of the general laws governing the formation of 'onium compounds, Nesmeyanov concluded that organic derivatives of the inert gases should in fact belong to this class of compounds.

Inorganic and organic 'onium derivatives are ionic compounds in which the cations are the molecular groups $H_{9-N}M^+$ and $R_{9-N}M^+$, where R is the organic substituent, N the Group number, and M the atom of a transition element in Groups V–VIII (0). Examples of such molecular groups ('onium cations) for the Second and Fifth Periods are R_4N^+, R_3O^+, R_2F^+, RHe^+, R_4Sb^+, R_3Te^+, R_2I^+, and RXe^+. These groups are isoelectronic analogues of fully hydrogenated and fully organic derivatives of the elements of Groups V–VII and VIII (0).

A fundamentally new method for the preparation of 'onium cations is one based on the β-decay of the central atom in the compound. The formation of 'onium cations in β-decay processes can be represented as follows. If the central atom of an element in Groups IV–VII is present in fully organic derivatives with electronic structures similar to those of the inert gases, the primary molecular ion formed directly in the β-transformation is the 'onium cation of the next element to the right (Table 3).

Table 3. The formation of 'onium cations in the β-decay of fully organic derivatives of elements in Groups IV–VII.

IV	V	VI	VII	VIII
$R_4Pb \rightarrow R_4Bi^+$				
	$R_3Bi \rightarrow R_3Po^+$			
		$R_2Po \rightarrow R_2I^+$		
			$RI \rightarrow RXe^+$	

The subsequent stabilisation by suitable anions of the 'onium cations thus produced leads to the formation of the corresponding 'onium derivatives.

The results of numerous studies have shown that 'onium compounds can form in β-decay processes also by a different pathway. If the central atom forms part of 'onium derivatives of elements in Groups V–VII, then the β-transformation of the central atom, accompanied by partial fragmentation of the primary molecular ion, leads directly to the formation of such derivatives (Table 4).

It follows from the above that 'onium cations of the inert gases can be obtained both from fully organic halogen compounds and their 'onium derivatives containing radioactive halogen atoms.

The first data concerning the existence of 'onium cations in the gas phase were obtained from mass-spectrometric studies on ion–molecule reactions [138-145] and also from studies on the products of the β-decay of iodine and bromine isotopes in certain halogen derivatives [77,80,81,138]. Thus, it has been established that the interaction of the atomic radical-ions of the inert gases and hydrocarbon molecules

results in the formation of molecular ions of the type HE^+ and RE^+ (E = Ne, Ar, Kr, or Xe). Similar ions were detected in the study of processes accompanying the β-decay of radioactive bromine and iodine isotopes in halogen derivatives. These molecular species (HXe^+, HKr^+, RXe^+, etc.) are none other than the 'onium cations of the inert gases and have all the characteristics of this group of molecular ions. These include the donor–acceptor type of bond between the ligand and the central atom, the corresponding inert gas electronic structure of the central atom, the fact that these species are isoelectronic with the fully hydrogenated and organic derivatives of elements located to their left in the Periodic System, and finally the presence of a single positive charge.

Table 4. The formation of 'onium derivatives as a result of the partial fragmentation of primary molecular ions.

V	VI	VII	VIII
$R_4BiX \rightarrow R_4PoX^+ \rightarrow R_3PoX + R^+$			
	$R_3TeX \rightarrow R_2IX \rightarrow RIX + R^+$		
		$R_2IX \rightarrow R_2XeX^+ \rightarrow RXeX + R^+$	

These considerations, which follow from the fact that the ions are isoelectronic with the corresponding neutral species, theoretical calculations, and results of experimental studies, suggest that isolated 'onium cations of the inert gases are quite stable. The bond energy in these ions (we are considering the breakdown of 'onium cations requiring the minimum energy expenditure, in which the charge is localised in the fragment with the smallest ionisation potential) is 2–4 eV according to the data of different workers[139,145]. Similar or even somewhat higher values (due, in particular, to the additional $d_\pi - p_\pi$ bonds in the case of aromatic derivatives) characterise the bond in organic 'onium cations of the inert gases. Thus in those cases where derivatives of the 'onium cations of the inert gases have not been obtained, the reason is other than the instability of the cations themselves.

'Onium cations are a constituent of 'onium derivatives. The other constituent is the anion. In crystals and solutions of these substances the 'onium cations must coexist with the corresponding anions. This implies that in such systems the vacant electronic level of the 'onium cations must lie above the occupied electronic levels in the anions and in the molecules of the medium containing the ions. Therefore, to ensure the stability of the 'onium derivatives, it is necessary to select anions with the lowest possible occupied electronic level (maximum electron affinity) and 'onium cations with the highest vacant level (minimum ionisation potential of the group of atoms comprising the given 'onium cation)[146]. Of the anions satisfying this requirement, one may mention ClO_4^-, BF_4^-, etc. For the 'onium cations, the relation between the position of the vacant electronic level and certain other characteristics is given by

$$J = I + D_0 - D ,$$

where J is the energy of the vacant electronic level of the isolated 'onium cation, determined in this case by the ionisation potentials of the corresponding neutral groups (HXe, RXe, HAr, etc.), I the ionisation potential of the atoms or groups of atoms in which the positive charge is localised during the fragmentation process of the 'onium cation, requiring the minimum energy expenditure, D_0 the bond energy in the neutral species (HXe, RXe, HAr, etc.), and D the bond energy in the 'onium cations HXe^+, etc.

It follows from this relation that, for all these 'onium cations of the inert gases, except HXe^+ and HRn^+, the position of the vacant level is determined by the difference between the ionisation potential of hydrogen and the bond energy D in the corresponding cation, i.e. amounts to 10–11 eV. For the 'onium cations HXe^+ and HRn^+, the position of the vacant level, determined by the difference between the ionisation potentials of xenon and radon atoms and the bond energy, is higher by 1.5–3 eV.[139] These values exceed by a factor of more than two the ionisation potentials of the alkali metal atoms (the radii of whose ions are close to the radii of the corresponding 'onium cations of the inert gases, for example Cs^+ and HXe^+). This in fact probably explains the impossibility of obtaining unsubstituted 'onium derivatives of the inert gases.

The situation is different for certain organic (for example phenyl-substituted) 'onium derivatives of the inert gases such as xenon and radon. For the corresponding 'onium cations, the position of the vacant level is determined by the difference between the ionisation potential of the organic ligand and the bond energy. If one remembers that the ionisation potential of the phenyl group is 9.5 eV and the bond energy of the middle and heavy inert gases in substituted organic 'onium cations of these elements appreciably exceeds the bond energy in the unsubstituted 'onium cations, the position of the vacant electronic level in the substituted cation is found to be 6–7 eV, i.e. approaches the position of the corresponding levels in ammonium and alkali metal ions. Therefore one may hope that ions of the phenyl-xenonium type will coexist with the above anions. These anions (ClO_4^-, BF_4^-, etc.), characterised by high electron affinity, low bonding energy with organic radicals, low polarising capacity, and a large radius, are of interest also from the standpoint of the stability of the 'onium derivatives of the inert gases themselves.

The stability of compounds, including the 'onium derivatives of the inert gases in which we are interested, may be characterised by the difference between the standard free energies of the compounds and their decomposition products. Since in normal reactions the free energy changes due to entropy changes are small, the stability may be characterised by the difference between the enthalpies of formation of the products and the starting materials. Remembering that substituted organic derivatives of the 'onium cations decompose by the general mechanism

$$R_{9-N}MX \rightarrow R_{8-N}M + RX\S$$

and using Hess's law, it is possible to establish a relation between the heats of decomposition and the energetics of individual stages of the thermochemical cycle

$$\Delta H^0 = U + D^+ + E - D - I ,$$

where ΔH^0 is the enthalpy of decomposition of the 'onium derivative, U the breakdown energy of its crystal lattice, D^+ the energy of the dissociation of R^+ from RXe^+ in the substituted 'onium cation, E the affinity of the electron for the atom or group of atoms substituting the anion X^-, D

§ The decomposition of organic 'onium derivatives of xenon should take place by the mechanism $RXeX \rightarrow Xe + RX$.

the energy of the homolytic dissociation of the C–X bond in RX, and I the ionisation potential of the organic group.

Since all the terms on the right-hand side of the above relation are greater than zero, the enthalpy of decomposition of the given substituted organic xenon derivative increases with the electron affinity of X and decreases with the energy for homolytic dissociation of the C–X bond in RX. Since for the above groups of atoms (ClO_4^-, BF_4^-, etc.) the electron affinity is a maximum and the energy of the homolytic dissociation of the C–X bond a minimum, the 'onium derivatives containing the above anions must have an enhanced stability.

On the other hand, the relation makes it possible to estimate the relative stabilities of the 'onium derivatives of particular cations containing different anions. Thus it can be shown that the enthalpies of decomposition of phenylxenonium perchlorate and chloride differ by not less than 100 kcal mole^{-1}. The difference between the heats of decomposition should be even greater for phenylxenonium perchlorate and hydroxide.

Summarising the above findings, one may say that, in choosing a system for stability of the 'onium cation, preference must be given to substituted aromatic 'onium cations of the heaviest inert gases (xenon, radon). For the stability of 'onium derivatives as individual species, it is desirable to choose compounds which contain both stable 'onium cations and anions with a high stabilising capacity.

Since the studies on the synthesis of organic 'onium derivatives of xenon are in the development stage, we shall consider them in greater detail.

From the standpoint of nuclear-physical characteristics, the most suitable isotope for the preparation of organic 'onium derivatives of xenon is iodine-133 obtained by the fission of uranium-235. Iodobenzene and diphenyliodonium salts are promising as the initial molecular systems [147].

Iodobenzene containing the above iodine isotope was obtained according to the following scheme:

$$(C_6H_5)_2ICl + K^{133}I \rightarrow (C_6H_5)_2I^{133}I \xrightarrow{180^\circ} C_6H_5{}^{133}I .$$

Various diphenyl diphenyliodonium derivatives containing iodine-133 were synthesised using the following reactions:

$$C_6H_5{}^{133}I + Cl_2 \rightarrow C_6H_5{}^{133}ICl_2 \xrightarrow{(C_6H_5)_2Hg} (C_6H_5)_2{}^{133}ICl ,$$

$$\xrightarrow{AgOH} (C_6H_5)_2{}^{133}IOH \xrightarrow{HX} (C_6H_5)_2{}^{133}IX ,$$

where X = NO_3^-, HSO_4^-, BF_4^-, or ClO_4^-. The purity of the diphenyliodonium salts was checked by thin-layer chromatography.

The products of the radioactive breakdown of iodine-133 in the test compounds were accumulated in iodobenzene and its solutions, in iodobenze deposited on crystals of potassium perchlorate, potassium tetrafluoroborate, etc., and also in crystals and solutions of various diphenyliodonium salts [99-102,147]. For this purpose, the systems were put in bubblers which were sealed and kept in the dark at 0°C for 2–3 days.

The formation of xenon compounds was demonstrated by comparing the radioactivities of the chemically free xenon formed in the β-decay of iodine-133 in the test systems with the radioactivity of the xenon isolated from solutions of $K^{133}I$¶. A $K^{133}I$ solution is used as a standard because here the entire xenon is present in a free state. In both cases the radioactive xenon was transferred to a radioactivity detector by a carrier gas (argon). The lower activity of the xenon accumulated in iodobenzene and diphenyliodonium salts is evidence that part of the xenon is chemically bound. The fraction of chemically bound xenon was determined by measuring the radioactivity of the free xenon after the decomposition of its compounds by substances containing anions capable of coexisting with the 'onium cations of the heavy inert gases (HCl, HI, KOH).

It has been shown that the breakdown of iodine-133 in iodobenzene leads to the formation of xenon compounds only when the substance is deposited on crystals of the corresponding salts. This is evident from the data in Table 5.

Table 5. The formation of xenon compounds in the β-decay of iodine-133 in iodobenzene*.

System in which products accumulate	Activity ^{133m}Xe			Yield of xenon compound
	free	bound	overall activity	
$C_6H_5{}^{133}I$	11500±300	not detected	11020±300	0

*The figures in the second, third, and fourth columns are average values from 5–7 determinations of the yields of the xenon compounds.

The results of experiments on the accumulation of xenon in crystals and solutions of various diphenyliodonium salts are presented in Table 6, which shows that the xenon compounds are not observed when the products are accumulated in crystals and aqueous and hydrochloric acid solutions of diphenyliodonium chloride. In all other cases a considerable proportion of the xenon was present in a chemically bound state.

Further studies were undertaken to elucidate the nature of the xenon compounds (the identity of the chemical state of the xenon formed in the β-decay of iodine isotopes in iodobenzene and in diphenyliodonium salts, proof that xenon forms part of the cation, demonstration of the similarity between the behaviour of the xenon compound obtained and that of the 'onium derivatives of other elements).

To demonstrate that the xenon compounds investigated are of the 'onium type, i.e. that they contain a cationic group incorporating xenon, ion-exchange chromatography and ionophoresis were employed. The chromatographic behaviour of the xenon compounds was investigated in a 2 × 105 mm column filled with Dowex-50X-12 resin (in the H^+-form, 200–400 mesh). The eluent consisted of perchloric acid solutions of different concentrations (Table 7). The elution curves for the xenon compounds formed in the β-decay of iodine isotopes in iodobenzene and diphenyliodonium perchlorate are presented in Figs. 1 and 2.

The ionophoretic behaviour of the xenon compounds was studied in a multicell apparatus of type OE-100, the electrophoretic chamber of which consisted of five cells separated by semipermeable "kutizin" membranes. The outer pairs of cells were filled with 0.001 N perchloric acid and

¶ If the products were accumulated in crystals of the parent substances or in liquid substances deposited on salt crystals, the solid phase was dissolved immediately before the measurement of the radioactivity of free xenon.

the central cells with the solution of the test compound in perchloric acid of the same concentration. The phenylxenonium cations decompose at the cathode with liberation of free xenon. The carrier gas flowing through the cathodic cell passes through a collector and then to a counting chamber. The electrophoretic behaviour of diphenyliodonium cations was investigated at the same time. The results of these experiments are presented in Fig. 3.

Table 6. The formation of xenon compounds in the β-decay of iodine-133 in diphenyliodonium salts.

Accumulation conditions	Yield of Xe compound, %
0.05% soln. of $(C_6H_5)_2ICIO_4$ in 0.1 *N* $HClO_4$	35 ± 3
0.05% soln. of $(C_6H_5)_2IBF_4$ in 0.1 *N* HBF_4	22 ± 2
0.05% soln. of $(C_6H_5)_2IHSO_4$ in 0.1 *N* H_2SO_4	10 ± 2
0.5% soln. of $(C_6H_5)_2INO_3$ in 0.1 *N* HNO_3	6 ± 1
0.05% soln. of $(C_6H_5)_2ICl$ in 0.1 *N* HCl	0
Crystals of $(C_6H_5)_2ICIO_4$	22 ± 2
Crystals of $(C_6H_5)_2ICl$	0

The sum total of the data obtained in the study of the chromatographic and ionophoretic behaviour of the test xenon compounds permits the following conclusions:

(1) The sorption of the test xenon compounds on a cation exchanger and its migration towards the cathode are evidence that xenon forms part of a cationic group;

Table 7. Chromatographic behaviour of organic 'onium cations of xenon and iodine (percentage elution of the cations).

Eluent	Onium cation	Volume of eluent (in free volumes), %																	
		1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19
H_2O	$C_6H_5Xe^+$					is not desorbed														
	$(C_6H_5)_2I^+$					ditto														
0.1*N* $HClO_4$	$C_6H_5Xe^+$					»														
	$(C_6H_5)_2I^+$					»														
1*N* $HClO_4$	$C_6H_5Xe^+$	0	39	48	9	3	1	0												
	$(C_6H_5)_2I^+$					is not desorbed														
3*N* $HClO_4$	$C_6H_5Xe^+$	0	41	44	12	2	2	0												
	$(C_6H_5)_2I^+$															5	12	11	11	
5*N* $HClO_4$	$C_6H_5Xe^+$	0	40	43	11	4	2	0												
	$(C_6H_5)_2I^+$										7	14	14	11	11	11	8	7	7	
7*N* $HClO_4$	$C_6H_5Xe^+$	0	45	48	6	1	0													
	$(C_6H_5)_2I^+$	0	0	8	10	15	14	14	12	9	7	5	4	2	0					

(2) the identity of the chromatographic behaviour of the xenon compounds produced in the β-decay of iodine in iodobenzene and diphenyliodonium salts indicates that in both cases the same xenon compound is formed.

On the basis of the general relations governing the chemical changes following β-transformations of atoms in fully organic and 'onium organic derivatives and also mass-spectrometric data, one may conclude that in this case the cation is $(C_6H_5Xe)^+$.

The possibility of the formation of a xenon cation as such is excluded by the position of its vacant electronic levels. This is consistent with the failure of experiments designed to obtain the corresponding xenon compounds by the radioactive breakdown of iodine in the compound $C_6H_5^{133}I(ClO_4)_2$.

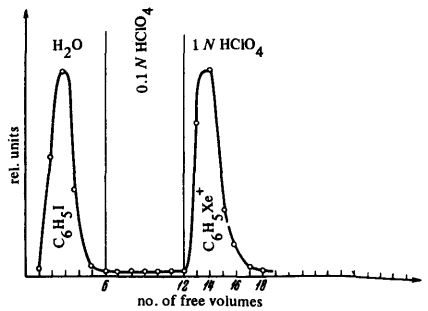

Figure 1. Elution curves of the xenon compound formed in the β-decay of iodine-133 in iodobenzene.

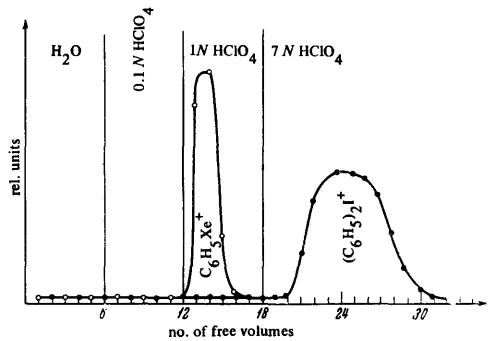

Figure 2. Elution curve of the xenon compound formed in the β-decay of iodine-133 in diphenyliodonium perchlorate.

It is important to note that the processes involving molecular ions formed in β-decay in molecular systems may be determined to a large extent. Thus, by selecting the isotopes of the parent elements with a definite mode of radioactive decay, the type of the initial compounds, and the nature of the substituents, and also by varying the conditions in which the breakdown takes place, it is possible to obtain definite compounds of the daughter elements. In particular mention should be made of the possibility of influencing the processes involving primary molecular ions by introducing substituents of various types into aromatic groups[23,24,26]. This is because electron-donor substituents increase the stability of the primary molecular ions (the yield of the stabilisation product increases at the same

time), while electron-acceptor substituents decrease the stability (the yield of the stabilisation products falls). Since the Hammett equation is applicable to processes involving primary molecular ions formed in the β-decay, it is possible to predict, without resorting to experiments, the fraction of the primary molecular ions which persist and hence also the yield of the products of their stabilisation and partial fragmentation.

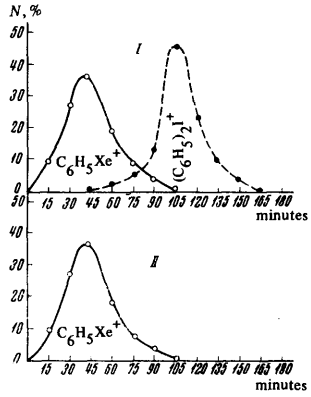

Figure 3. Electrophoretic curves for the xenon compounds formed in the β-decay of iodine-133 in diphenyliodonium perchlorate (I) and iodobenzene (II); N – the fraction of ions which have migrated to the cathodic compartment.

In conclusion we may note that further studies on organic compounds of the inert gases should be designed both to extend the range of investigations in the field of the chemical changes occurring in β-decay processes of halogen isotopes and also to obtain organic derivatives of the inert gases by the usual methods of chemical synthesis.

Nucleophilic Addition of Amino-groups to an Activated Carbon-Carbon Double Bond

S.I.Suminov and A.N.Kost

The review presents data on the effect of structural and steric factors, catalysts, and solvents on the mode and rate of condensation of activated olefins with amines, which indicate that the mechanisms of such condensations are to some extent general. The considerable importance of the steric inhibition of the reactions is evidence in favour of the hypothesis of a polar transition state characterised by a rigid structure. Proton transfer involving a proton donor and (or) acceptor or, more rarely, the ejection of a negative ion (see the reactions of β-halogeno-olefins) plays a significant role in the stabilisation of the transition state. The sequence of relative activities of the olefins $CH_2 = CHX$ is affected both by the polarising effect of the group X and the possibility of the delocalisation of the charges in the activated complex. Nevertheless the problems of the catalytic effect of proton-donating, alkaline, and particularly peroxidic additives are still not completely clear and require further study.
The bibliography includes 266 references.

1. INTRODUCTION

Reactions involving the addition of amines to an activated carbon–carbon double bond are widely known and are used in numerous syntheses (amino-nitriles, amino-acids, are various heterocyclic structures). The available reviews (the addition reactions of acrylic acid and its esters [1,2], acrylamide [3], vinylpyridines [4], and nitro-olefins [5]) are confined largely to the statement of the facts and the noting of a typical reaction conditions.

Usually the Michael reaction takes place in the presence of alkaline agents, i.e. via the formation of carbanions from the CH component with subsequent nucleophilic attack on the olefin [6]; on the other hand, for the condensation of compounds containing an amino- or imino-group, examples of non-catalytic reactions and of processes catalysed by both acids and bases or accelerated by the addition of proton-donor solvents have been described. Recently studies of the kinetics of these reactions have begun to be published. So far they have dealt with a narrow range of objects (particularly solvents) and the results cannot be correlated. Nevertheless the accumulation of experimental data, both preparative and kinetic, permits certain generalisations.

In this review attention is drawn to the effect of the medium, the catalytic additive, and steric factors in the structure of the amine (or imine). Heterocyclic imines such as pyrrole, indole, and phenothiazine and also acid amides are not considered as the amino-components since their alkylation by olefins usually takes place in the presence of alkaline additives (i.e. under typical conditions for the Michael reaction) via the formation of an anion at a nitrogen atom.

The capacity of unsaturated compounds of the type $CH_2=CHX$ for electrophilic addition is determined by the polarisation of the double bond under the influence of the electron-acceptor substituent X. Furthermore the reactivity is influenced by the type of the nucleophilic component and the polar and steric interactions in the transition stage. Thus, judging from the values of L_β (the localisation energy of the nucleophilic group), calculated for the anionic polymerisation of a number of monomers [7], we have the following sequence: nitroethylene > 2-nitropropene > acrylonitrile > methacrylonitrile > methyl vinyl ketone > methyl acrylate. However, a different sequence is usually found in the Michael condensation [6]: acrolein > vinyl ketones > αβ-unsaturated ethers ≥ acrylonitrile > > vinyl sulphones. A recent study of the kinetics of the reaction of alcohols with vinyl compounds [8] established that acrylonitrile is much more reactive than acrylates. Therefore, wherever this is allowed by the available data, we attempted to compare the nucleophilic properties of amines of different classes in relation to a given olefin †.

† See, for example, Ibne-Rasa [9], concerning the differences between the terms "nucleophilicity" and "basicity" (as applied to amines and imines) and also the conditions under which they have the same significance.

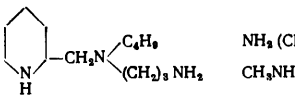
2. ACRYLONITRILE

Lower primary and secondary amines and also diamines are cyanoethylated with formation of mono-derivatives without catalyst at room temperature. With increasing length of the aliphatic group, the rate of reaction of the amines with acrylonitrile falls somewhat (probably due to a decrease in nucleophilic character) and brief heating is required to accelerate the process [10,11]. This method can be used to cyanoethylate a wide variety of amines containing up to 10–18 carbon atoms, benzylamines with ring substituents [12], arylalkylaminomethanes [13-15], etc. No difficulties are encountered in the reaction involving the simplest cyclic (polymethylene) imines: ethyleneimine, pyrrolidine, piperidine, morpholine, and their derivatives in which the NH group is sterically accessible [16,17].

Branching of the aliphatic chain of the amine hinders its cyanoethylation and to a greater extent when the branching point is closer to the amino-group [18-21]. This is shown most clearly for 2,2-disubstituted compounds of the type of t-octylamine [22,23]. Nevertheless the same amines behave normally in alkylation by alkyl halides. Another typical example is provided by 2,6-dimethylpiperidine with two substituents in the α-position relative to the imino-group [24]. In order to cyanoethylate amines with a sterically hindered amino-group, it has been suggested that water, lower alcohols, organic acids [21-26] and catalytic amounts of hydrochloric acid [22] be added to the reaction mixture or that the syntheses be simply carried out in a homogeneous aqueous solution. To increase the solubility of the amine in water, a second solvent may be added (dialkylamides, t-alkylaminopropionitriles, etc.), which in many cases increases significantly the yield [21,26]. It has been stated [27,28] that the cyanoethylation of various higher polymethyleneimines (starting with hexamethyleneimine) is also accelerated by Triton B (40% solution of trimethylbenzylammonium hydroxide). However, so far it is not clear whether the true catalyst is not in fact water, the mole fraction of which in the whole solution is 14/15.

Further studies elucidated the active role of the solvent also in the cyanoethylation of sterically unhindered amines [29-35]. It was established that the addition of the amino-group to the double bond of acrylonitrile is greatly accelerated by proton-donor substances of various classes (water, alcohol, glycols, formamide, organic acids, ammonium salts, ion-exchange resins). The most powerful promoting agent is water, which remains active also in mixtures with inert additives or in mixed solvents. Alcohols catalyse the reaction somewhat less, the promoting effect decreasing on going from methanol to higher members of the series. Branched-chain alcohols (isopropyl and s- and t-butyl alcohols) activate these reaction to only a slight extent [21,31]. Regardless of their polarity and chemical nature, all aprotic solvents (benzene, toluene, cyclohexane, ethyl methyl ketone, dioxan, tetrahydrofuran, ethyl and butyl acetates, acetonitrile, triethylamine, pyridine, etc.) under comparable conditions inhibit the addition of amines and hydrazines to an activated carbon–carbon double bond [29,31]. These findings are confirmed by data on the preparative cyanoethylation of methyl-, hexyl-, nonyl-, and decyl-amines in various media [33-35].

Comparison of the temperature conditions or yields for amines of different classes (primary and secondary aliphatic amines and cyclic imines) (for example, on the basis of the tables in the review of Terent'ev and Kost [10]) leads to the conclusion that a primary amino-group is the most active in the cyanoethylation reaction although the difference is usually small. This is consistent with the lower basicity of primary amines compared with secondary amines (see, for example, Girault-Vexlearchi [36] and Albert and Serjent [37]). When the molecule of the substance cyanoethylated contains various amino-groups, this difference may become distinct. Thus in the cyanoethylation of the triamine (I) [15] the product of addition to the cyclic amino-group was obtained almost quantitatively:



(I)

$NH_2(CH_2)_2N(CH_3)CH_2CH_2CN$ (II)

$CH_3NH(CH_2)_2NHCH_2CH_2CN$ (III)

The cyanoethylation of *N*-methylethylenediamine [38] leads to a mixture of nitriles (II) and (III) in proportions of 73 : 27.

In many cases steric factors can cause a sharp "reversal" of the relative reactivity. On being refluxed with acrylonitrile, 2-amino-1-isopropyl-amino-2-methylpropane forms a 2-cyanoethyl derivative (IV), with the cyanoethyl substituent attached to the NH_2 group and not the imino-group, the steric accessibility of which is much lower [39]:

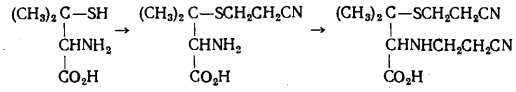
$(CH_3)_2CHNHCH_2C(CH_3)_2NHCH_2CH_2CN$ (IV)

The introduction into the structure of an aliphatic amine of a substituent with a terminal nitrile or ester group lowers appreciably its basicity [40-42]. This effect is particularly marked for CH_2CN and $(CH_2)_2CN$ groups. Thus while the esters of α- and β-amino-acids are cyanoethylated, albeit with difficulty, on being refluxed without catalyst in an inert solvent [43], there is virtually no cyanoethylation in the case of $RNH(CH_2)_2CN$, when R is an alkyl group with more than four carbon atoms [44]. However, the addition to the reaction mixture of methanol or ethanol (or their mixtures with water) greatly facilitates the dicyanoethylation of higher amines [33-35]. Acetic, propionic, and other organic acids have been recommended for the same purpose [45,46]. It is reasonable to suppose that the type of catalysis in these cases is similar to that obtaining for aliphatic amines [30,31].

Successful cyanoethylation of amino-acids requires the formation of an uncharged amino-group from the dipolar ion by the addition of, for example, at least an equivalent of an alkaline agent or a tertiary amine. When the content of alkali is low, the rate of reaction is proportional to its concentration. When an alkali metal salt of the amino-acid in aqueous solution is employed, the corresponding *N*-cyanoethyl derivatives are formed in almost quantitative yields even at room temperature. When the amount of acrylonitrile is raised to 2–3 moles, dicyanoethylation products can also be obtained after refluxing for a short time [43,47].

The study of the cyanoethylation of mercapto-acids and amino-acids of similar basicities showed [48] that in general mercaptide ions are much more nucleophilic than the amino-group. However, the relative rates of reaction involving mercapto- or amino-groups depend on the structure of the compound and may vary from 1300 to 6–8. Thus in the case of dimethylcysteine (penicillamine) the mercapto-group reacts first, but, when the amine : acrylonitrile ratio is 1 : 1, the NH_2 group is also involved to some extent [48,49]; in the presence of acrylonitrile (at a slightly

elevated temperature) satisfactory yields of *NS*-dicyanoethyldimethylcysteine were obtained[50]:



Similar relations involving the ease of cyanoethylation of mercapto- and amino-groups are typical also for other classes of organic compounds‡. For example, the cyanoethylation of 2-aminoethanethiol in an alkaline solution yields a mixture of *NS*-dicyanoethyl and *NNS*-tricyanoethyl derivatives; in a strongly acid medium the reaction does not take place. On the other hand, in the pH range 3.6–6.8 there is a possibility of the selective formation of 3-(2-aminoethylthio)propionitrile[51].

The cyanoethylation of aromatic amines with acrylonitrile encounters considerable difficulties owing to the low basicity of the amino-group (pK_b = 8.5–11.5). However, it is stated in patents that acrylonitrile can add non-catalytically to the most basic representatives of the series, namely to *p*-phenylenediamine[52] and *N*-hydroxyethyl-*m*-toluidine[53], but these findings have not been checked. Aniline is recovered unchanged after prolonged refluxing with acrylonitrile at 180°C[54,55].

The available methods for the cyanoethylation of aniline, its *N*-substituted derivatives, and homologues can be divided into three groups: (a) reactions in the presence of acid reagents; (b) reactions catalysed by copper salts; (c) reactions in proton-donor solvents§. Organic acids and their anhydrides, dialkylammonium and aluminium salts, and, with poorer results, inorganic acids, have been used as the acid catalyst[44,58–61].

The reaction can be conveniently carried out in the presence of added acetic acid and an excess of acrylonitrile with refluxing for 6–24 h, the product being the monocyanoethyl derivative and in rare cases also an admixture of the bisadduct. The yields increase if a large amount of acetic acid is added, since the latter can be used also as a high-boiling solvent[61]. It is possible to establish (albeit only approximately, since the basicity does not always correspond to nucleophilicity) a relation between the basicity of the aromatic amine and the ease of its cyanoethylation[59,61]. For compounds with very low basicity (for example diphenylamine and α- and β-aminoanthraquinones), the yields of the corresponding *N*-cyanoethyl derivatives do not exceed 10–15%; nitroanilines do not combine with acrylonitrile in acetic acid at all[61]. As a rule, for the same basicity, amines containing substituents at the nitrogen atom or in the *ortho*-position relative to the amino-group are cyanoethylated much less satisfactorily (because the reaction centre is sterically hindered).

Contradictory views have been expressed in the literature concerning the catalytic effects of the salts of copper, zinc, cobalt, nickel, iron, and chromium in different valence states and even of metallic mercury on the addition of acrylonitrile to aniline and its substituted derivatives[61–63]. The main practical use has been of copper acetate (or its hydrate), which can catalyse vigorously the monocyanoethylation of various anilines without acid additives[61].

‡ On the other hand, ethanolamine, its *N*-substituted derivatives, and other amino-alcohols are cyanoethylated exclusively at the amino-group without alkaline additives[10].

§ We exclude from consideration the rare examples of the cyanoethylation or aromatic amines in the presence of alkaline reagents (choline hydrate, Triton B, carbazolylpotassium)[44,56,57] for reasons stated above.

The reaction takes place when a mixture of the reagents is refluxed (2–12 h), but sometimes, after a thermal initiation stage, the temperature of the reaction mixture rises spontaneously by 10–15 deg¶.

A characteristic feature of the method is its low sensitivity to the position of the substituent in the ring and to the size of the *N*-alkyl substituent. Even *m*-nitroaniline is readily cyanoethylated in the presence of copper acetate but the *para*-isomer, the basicity of which is low, reacts much less well[61].

Specific co-catalysts of the dicyanoethylation of aromatic amines in acetic acid are copper(I) cyanide and chloride and cobalt (II) chloride[44,62]. The use of the most active of these (Cu_2Cl_2) permits the synthesis, in the presence of only a small excess of acrylonitrile, of dicyanoethyl derivatives of various anilines (including anilines containing electron-acceptor substituents). However, the limitations associated with the steric screening of the reaction centre remain effective. Thus, among *ortho*-substituted amines, only *o*-toluidine gives a dicyanoethyl derivative in a yield up to 35%, while α-naphthylamine and *o*-aminobiphenyl form only monoadducts.

During the last ten years a preparative method has been developed for the cyanoethylation of aniline and its *para*-substituted derivatives in the presence of water as the catalyst[55,65–67]. The yields and the rates of the reaction are determined both by the basicity of the amine and its solubility in water. An almost quantitative yield of 3-phenylaminopropionitriles can be achieved by carrying out the reaction in an aqueous solution, provided that the aniline and the acrylonitrile are fully soluble[66]. The yield of adducts is in most cases unaffected by the variation of the pH of the medium in the range 6.8–10.8.[67,68] Refluxing for 1–5 h with a slight excess of acrylonitrile in aqueous solution also results in the formation of the *NN'*-dicyanoethyl derivative of *p*-phenylenediamine and the monoadducts of *NN*-dimethylphenylenediamine and *o*-toluidine, although in the latter case the yield does not exceed 30%. However, the attempts to cyanoethylate nitroanilines even under more severe conditions (heating in a sealed tube at 150°C) were unsuccessful[69]. On the other hand, heterocyclic imines (pyrazolines, tetrahydroquinolines, aminopiperidines, etc.), whose basicity approaches that of aromatic amines, can be successfully cyanoethylated in the presence of water[30,70–72].

Butskus[73] showed that aliphatic diols and many phenols can be used as solvents for the cyanoethylation of aromatic amines. Thus phenols, hydroquinone, and naphthols (8–9 g per 0.1 mole of aniline) give rise to 98–100% yields after refluxing for 20 h with an excess of acrylonitrile, while ethylene glycol may be recommended as a solvent in preparative syntheses. However, the catalytic activity of lower aliphatic alcohols proved to be slight.

3. MECHANISM OF THE CYANOETHYLATION OF THE AMINO-GROUP

Numerous examples of appreciable steric control of the reaction, of the role of the polarity and the proton-donor

¶ There exists no definitely formulated view concerning the mechanism of the catalysis by metal salts of reactions involving the addition of an amine to the double bond of acrylonitrile and acrylic esters. The hypothesis that a Π-complex of the unsaturated compound with the metal cation takes part in the reaction appears to be the most likely[64].

properties of the solvent, and the possible acid catalysis can all be interpreted only on the assumption that the cyanoethylation of the amino-group (and related reactions) takes place with intermediate participation of ionic species. Earlier it was assumed that these are 1, 4-addition reactions[74,75]. Terent'ev and Kost[10] believed that the cyanoethylation involves the formation of an amine—acrylonitrile complex which rearranges to the corresponding adduct by intramolecular migration of a proton. Later Heininger[61], Luskin et al.[22], and also Bekhli[55,56] explained the sharp acceleration of the cyanoethylation of aromatic amines and t-alkylamines in the presence of various catalysts and water by postulating the protonation of the nitrile group of acrylonitrile by proton-donor elements of the medium:

$$\overset{+\delta}{CH_2}{=}CH{-}\overset{+}{C}{\equiv}N + H^+ \longrightarrow \overset{+\delta_1}{CH_2}{=}CH{-}\overset{+}{C}{\equiv}\overset{+}{N}H \qquad +\delta_1 > +\delta$$

The additional shift of electron density then occurring increases the electron deficiency at the terminal carbon atom in the double bond and consequently the alkylating activity of acrylonitrile. Similar views were put forward by workers who investigated the addition of acrylic acid esters to amines (see, for example, Baltrusis and Macinlis[76]).

Nevertheless, analysis of the experimental data currently available shows that these hypotheses are inadequate[29]. The point is that the cyanoethylation of aniline in the aqueous phase takes place most satisfactorily[67,68] at pH 6.8–8.8 and therefore does not require either alkaline or acid catalysis. Furthermore, an increase or decrease of the pH from the optimum value results in a decrease of the yield. In a study of the kinetics of the addition of acrylic acid esters to cyclic imines in protic solvents the catalytic effect of acid additives was also not observed[68,77,78]. The addition of acids in the cyanoethylation of sterically unhindered aliphatic amines usually does not facilitate but actually hinders the reaction. In reactions with aromatic amines the replacement of acetic acid by phosphoric or hydrochloric acid somewhat inhibits the process[59,65]. Furthermore, it is known that the catalytic effect of water and alcohols in cyanoethylation reactions is not fully correlated with their acidity. Thus methanol is a stronger acid than water (by a factor of 1.5–3 according to different estimates[79]) but it promotes the addition of amines to an activated double bond to a lesser extent[31]. The sharp fall of the yield of cyanoethylation products in alcoholic media on going from methanol to higher homologues and in particular to branched-chain alcohols shows the considerable role which steric factors play, together with acidity, in the catalytic capacity of alcohols[21,29,31].

In addition, nitriles, esters, ketones, and even amides are weak bases which are hardly protonated by weak acids[80]. On the other hand, when the molecule contains a conjugated carbon–carbon double bond, the basicity of a functional group of this type is even lower, and, for example, acrylonitrile in 85% sulphuric acid is only 50% protonated[81].

Thus, under cyanoethylation conditions, acid additives should affect primarily the amino-group of the amines alkylated (which is present in a considerable excess relative to the acid). On the other hand, in the presence of water or alcohol the reversible protonation of the nitrile group when an amine is also present becomes altogether unlikely. One is virtually driven to the conclusion that only hydrogen bonds with participation of ammonium or oxonium salts are formed[82].

Finally, there is no unambiguous proof whether the activity of the carbon–carbon double bond is at all significantly increased (the electrophilic properties are increased) when the functional group of acrylic monomers is protonated[83,84]. Furthermore, hydrogen bonds formed between the solvent and the amine reduce the nucleophilicity of the amino-component and therefore must compensate the effect of monomer activation[85].

Without disproving completely the role of the protonation of the functional group in the activation of $\alpha\beta$-unsaturated compounds, the above findings show that this phenomenon cannot be responsible for the exceptionally high catalytic effect of the solvent.

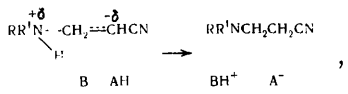
The available data are best explained on the assumption that the process takes place via an activated complex characterised by an appreciable or complete charge separation[21,29-31,50]. The probability of the formation of such an activated complex depends on the polarity of the medium. If the intermediate state is more polar than the initial components, then the reaction does not occur (or occurs with difficulty) in polar solvents[85]. This is probably so in our case. The polarity of amines is relatively low ($\epsilon = 3-7$) and, as their concentration in the mixture increases, the polarity of the medium falls[86,87]. The introduction of a protic solvent (water, alcohols) maintains the dielectric constant of the solution in the range 20–60 D. On formation of the transition state and its further stabilisation, the amino-group should be gradually converted into the ammonium form and the double bond of the monomer should be gradually converted into a single bond. We are thus dealing with the formation of an intermediate ylide structure †. There is at present no doubt that such structures occur as intermediates (and final) products in the reactions of acrylic esters with tertiary amines and in the condensation of nitrogen-containing heterocycles with acetylenecarboxylic acids[89]. A dipolar mechanism has been established for the reactions of acetylenecarboxylic esters with alkyl- and dialkyl-amines[86,90]. If in our case the reaction takes place via the ylide stage, this is of course because of the steric strain of the bonds and valence angles (the change of the sp^2 hybridisation of the carbon atom to sp^3 hybridisation and the conversion of the trigonal C–N–C angle into a tetrahedral angle)[91,92]. During the reaction, alkyl groups are somewhat displaced to the side opposite to that where the bulky alkylating group is introduced and there is steric interaction with the hydrogen atom of other substituents and hence repulsion. This repulsion (G. Brown's B-strain) will of course be a maximum if the reaction centre in the initial molecule is sterically hindered.

By solvating the intermediate ions, polar solvents should lower the activation energy for the reaction. In this respect, the most effective protic solvents (water, alcohols, and to some extent the excess of the amine introduced into the reaction) are capable of forming hydrogen bonds both with anions and with the ammonium ions formed ("specific solvation")[85]. Intermolecular proton migration has been demonstrated for almost all types of organic reactions catalysed by acids and (or) bases[93]. Even simple processes involving exchange between an amine and its conjugate acid and between an acid and its anion probably involve steps in which there is exchange with the medium[94]. In particular, this is why in acid-catalysed (prototropic) reactions proton transport is the rate-determining step over a definite pH range[93].

In our case the conversion of the transition complex (or the intermediate species close to it in structure) into

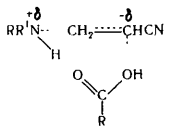
† The hypothesis of the intermediate formation of ionic species in the cyanoethylation of amines was first put forward by Timbekov and Sadykov[88].

the stable cyanoethylation product requires a double proton transfer and consequently the presence in the medium of a potential acid and base:



where B is a base and AH an acid—B and H may be part of the same molecule.

In a synchronous step of this kind[93] the bases may be the amines undergoing alkylation, other amino-components of the reaction mixture (for example reaction products, dimethylformamide, and other dialkylamides), solvent molecules when these are sufficiently basic or sterically accessible (water, alcohols), and hydroxide ions; the acids may be phenols, alcohols, water, and oxonium ions. When dipolar solvents and catalysts (ethylene glycol, organic acids) are employed, different centres of the same molecule function as acids and bases[95-97], so that the reaction complex is more compact. This can explain the higher rate of the reactions in such solvents:



In reactions with participation of metal ions (Cu^+, Cu^{2+}, Hg^{2+}) a metal ion with a vacant electron shell can serve as an acceptor for the electron pair of the CH group in the transition complex. According to some data[75], such solvation by transition metal ions may be more effective than solvation by many solvent molecules.

One can of course regard transfer processes, leading to the stabilisation of the transition state in reactions of amines with activated olefins, as reactions whose mechanism is not only of the synchronous (termolecular) type. Alcohols, water, dialkylamides, and, better still, the free amine can abstract a proton from the ammonium group and transfer it to the solution, whence it adds to the CH group[21], although energetically such a process is less favourable (retention of the charge on one side of the reaction complex). However, in both cases the solvents which show the greatest promoting effect are those which, while showing a considerable tendency towards the addition and dissociation of a proton, have molecules of small geometrical dimensions so that their incorporation in the complex or their approach to different centres of the binary ion is facilitated.

Under certain conditions, the protonation (or deprotonation) stage may compete with the primary alkylation stage as regards its importance for the overall rate of the process and to a greater extent the lower the concentration of the potential acid and the lower its donor capacity. Then the role of the base must of course be fulfilled largely by the amine undergoing alkylation. If the latter is sterically hindered or its basicity is low, both functions are carried out by the solvent (or catalyst) added. This is probably the reason for the anomalously high acceleration of the cyanoethylation of anabasine[86], 2,6-dimethylpiperidine[24], t-butylamine and related amines[21,22] following the introduction of several drops of water and acid, or dilute solutions of acid reagents. Here it is still too early to speak of changes in polarity, solvating capacity, and other macrocharacteristics of the medium. However, according to the literature, the presence of traces of proton-donor substances can strongly promote intermolecular proton transfer processes (see, for example, Giessner-Prettre and Oger[98]). On further dilution with a solvent or on further increase in the amount of catalyst, the rate of reaction increases but less appreciably and the effect is now determined by the sum of all factors. In reactions in highly dilute solutions the addition stage is of course rate-determining.

The kinetic literature data agree with the above mechanism. Cyanoethylation in aqueous or buffer solutions of ammonia[99,100], ethylamine, benzylamine, diethylamine[100], ethanolamine[78,100], amino-acids[48,50,101], and aromatic amines[69] follows second-order kinetics (or pseudo-first-order kinetics in the presence of an excess of one of the components), the non-protonated amine or the anion of the amino-acid with a free NH_2 group participating in the reaction. Therefore the pH probably affects only the concentration of the free amino-component. Thus, for amino-acids and mercapto-amino-acids, a satisfactory correlation has been found between pK_1 and pK_2 on the one hand and the kinetic characteristics of the system on the other; it is possible to estimate quantitatively the steric and polar factors with the air of a modified Hammett–Taft relation.

If one adopts as standard the rate constant for the cyanoethylation of glycine, then the following relation holds for other amino-acids: $\lg k_{A^-} = \rho\sigma^A + E_S$, where σ^A is a parameter representing the polar effect of the substituents and numerically equal to pK_2 (amino-acid) $- pK_2$ (glycine) and E_S is a steric constant, which depends on the size and the steric requirements of the substituent. Plots corresponding to substances with the amino-group at a primary, secondary, and tertiary carbon atom form separate branches with approximately the same slope ($\rho = 0.427 \pm 0.010$); their intercepts on the ordinate axis give E_S. A very sharp fall in the rate of cyanoethylation with increase of E_S (i.e. with increase in the number and bulk of substituents near the reaction centre) is typical, and has been attributed to an increase of the steric strain and steric interaction in the dipolar transition state (the telescopic effect)[50].

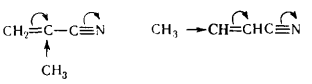
Unfortunately the kinetics of cyanoethylation in non-aqueous media have not been investigated at all[68]. To elucidate the role of proton-transfer processes, experiments in aprotic solvents with the addition of a certain amount of proton donors or acceptors would be particularly desirable.

4. SOME ANALOGUES OF ACRYLONITRILE

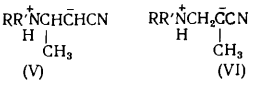
The substitution of a hydrogen atom in the acrylonitrile molecule by an alkyl group and (to a lesser extent) by an aryl group leads to decreased reactivity of the double bond in the addition reactions. Thus the nitrile of crotonic acid (or allyl cyanide, which is converted into the nitrile of crotonic acid in the presence of basic reagents) has been condensed with ammonia[102,103], methyl- and ethyl-amines[103], dimethyl- and diethyl-amines[104,105], pyrrolidine[106], ethylenimine[107], β-alanine[108], and other amino-acids[109]. As a rule these reactions take place at 70–100°C. Most of the syntheses have been carried out in dilute aqueous solutions, although the authors did not establish whether water promotes the reaction. Methods for the 2-cyanopropylation of aromatic amines (aniline, *o*- and *p*-toluidines, *o*-anisidine) are analogous to cyanoethylation methods: catalytic reaction of allyl cyanide at high temperatures in the presence of copper(I) chloride[104] and alkylation with the nitrile of crotonic acid by refluxing in

aqueous solution[105]. In both cases the yield does not rise above 10–40%. The study of the kinetics of the reaction of both isomers of crotononitrile with a number of amino-acids showed that the *cis*-compound is somewhat more reactive[101,110].

It has been established that α-substituted compounds passivate the double bond to a greater extent than substituents introduced at the β-carbon atom. Under the conditions indicated above, methacrylonitrile combines only with ethyleneimine[107], piperidine, and pyrrolidine[106] and does not alkylate diethylamine[106], benzylamine[13], aniline[105], and *p*-phenylenediamine (in the presence of acetic acid[60]). These facts are very interesting, since the +*I*-effect of the methyl group should be approximately the same in both positions[101,110].



In this connection, it has been suggested that in the transition state (VI) additional steric interactions between the CH_3 group and the substituent at the nitrogen atom are more likely than in the transition state (V)[101,107]:



(V) (VI)

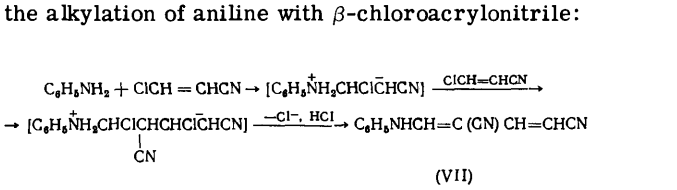
On the other hand the carbanion (V) with a negative charge at a tertiary carbon atom is apparently less stable than a similar carbanion with a negative charge at a secondary carbon atom[101].

Terent'ev and coworkers compared the relative reactivities of certain simplest αβ-unsaturated nitriles in reactions with an aqueous solution of potassium glycinate[111]. The yields of the adducts were as follows (acrylonitrile was adopted as 100): crotononitrile 23; allyl cyanide 5.3; methacrylonitrile 5; nitrile of *trans*-cinnamic acid 5; cyclohexylideneacetonitrile 8; cyclohexene-1-carbonitrile 8. Amines do not add to αβ- and ββ-dimethylacrylonitrile after prolonged refluxing both in the absence of additives and in the presence of an alkaline reagent[105,106]. 1,4-Dicyanobut-2-ene and β-cyanomethylacrylonitrile react with ammonia, various amines, and highly basic diamines at 60–70°C with formation of adducts of the type $NCCH_2CH_2CH(NRR')CH_2CN$. The addition is promoted by water as the solvent[112,113] or by 1–2% of a copper salt[114]. Dialkylamines are appreciably more active than primary amines or ammonia.

The chlorine atom is sterically similar to the methyl group but, in view of the −*I*-effect of the halogen, α-chloroacrylonitrile has a reactivity comparable with that of acrylonitrile[107,115]. If the chlorine atom is in the β-position, then in inert and even in proton-donor solvents, secondary amines are "cyanovinylated" according to the mechanism[116]:

$$ClCH{=}CHCN + RR'NH \rightarrow RR'NCH{=}CHCN$$

Similar substitution of functional groups has been noted for other classes of αβ-unsaturated compounds (β-chloroacrylates, β-halogeno- and β-alkoxy-vinyl ketones, β-chlorovinyl aryl sulphones). Nevertheless a mechanism involving initial nucleophilic addition with subsequent elimination of the hydrogen halide (or the alkoxy-group) is postulated for these reactions. In a kinetic study of the reaction of β-chloroacrylonitrile with piperidine (methanol, 0°C) appreciable differences between the rates for the *cis*- and *trans*-isomers were not observed (K_2 was respectively 2×10^{-2} and 2.67×10^{-2} litre mole^{-1} s^{-1}). Sterically homogeneous *trans*-2-piperidinoacrylonitrile was formed in both cases[116] (cf. ethyl β-chloroacrylate[117]). According to the authors[116], the intermediate dipolar ion has an appreciable lifetime, which permits isomerisation by rotation about the C–C bond. These views are indirectly confirmed by the formation of the bisadduct (VII) in the alkylation of aniline with β-chloroacrylonitrile:



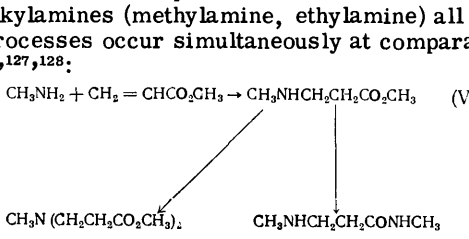
(VII)

5. ACRYLIC ACID ESTERS

Highly basic heterocyclic imines—ethyleneimine[107], pyrrolidine, piperidine[119,120], morpholine[16], and hexamethyleneimine[121]—readily add to the double bond ‡ of methyl and ethyl acrylates, sometimes with a slight temperature rise, giving high yields of the corresponding esters of *N*-substituted aminopropionic acids. The reaction of lower dialkylamines is slower[120,122]. Even the reaction of dibutylamine requires a long time[120,123], probably due to the high steric hindrance at the nitrogen atom.

Similarly, 2-methylaminobutane (with an imino-group at a secondary carbon atom) reacts with ethyl acrylate only when the mixture is refluxed, and di-isopropylamine and di-s-butylamine do not react even on prolonged refluxing with ethyl acrylate[119,124]. However, recently it proved possible to carry out the addition of di-isopropylamine and 2,6-dimethylpiperidine to methyl acrylate in methanol[121].

The interaction of ammonia and primary amines with acrylic acid esters both without solvent and in methanol can take place in three ways. The weakening of the basicity of the alkylamine caused by the introduction of the group $CH_2CH_2CO_2R$ is relatively slight (see, for example, Holley and Holley[125]), so that the initially formed monoadduct can combine with a second molecule of acrylate. Furthermore, the addition reaction may be accompanied by the conversion of the ester group into an amide group, at least at elevated temperatures. Thus in the case of lower alkylamines (methylamine, ethylamine) all the above processes occur simultaneously at comparable rates[122,127,128]:



(VIII)

The yield of the amide then increases in proportion to the duration of the experiment. The formation of the monoadduct (VIII) appears to be favoured by the replacement of

‡ The same applies also to butyl, allyl, and other alkyl esters of acrylic acid, which are much more rarely used in chemical practice. It has been established that the amine may attack the C–O bond in cyanomethyl and *p*-nitrophenyl esters of αβ-unsaturated acids with formation of acid amides[18].

methanol by ethanol. As might have been expected, the reaction does not occur when ethylamine is introduced as the hydrochloride [129].

For less basic amines (butylamine, cyclohexylamine, β-tetrahydronaphthylamine, benzylamine, α-methylphenylethylamine), the formation of mono-2-alkoxycarbonylethyl derivatives takes place fairly smoothly in the mixture with acrylate kept in methanol for a period ranging from one day to several weeks [129-134]. Primary amines with tertiary substituents (t-butylamine, t-octylamine, 2-amino-1-ethoxycarbonyl-2-methylpropane) add to acrylic acid esters only under very severe conditions [20,130]. To accelerate the process, the latter is carried out in aqueous solution in the presence of alcohol or dilute acid [22,25,131,135]. According to patent data [136], acetic acid effectively catalyses the reactions of acrylates also with other strongly sterically hindered amines such as di(2-ethylhexyl)amine §. It is suggested that certain alkaline reagents be used as catalysts for the reactions of polymethyleneimines [107,138], but these data require verification.

In contrast to the cyanoethylation reaction, when aliphatic and aliphatic-aromatic primary amines are simply refluxed with 2–3 moles of acrylate, high yields of bisalkoxycarbonylethylation products are obtained [124,135,139]. According to other data, the latter reactions take place satisfactorily at lower temperatures too in alcoholic media [130]. This also applies to the addition of methyl and ethyl acrylates to amino-esters with the general formulae (IX) [139,140] and (X) [123,141,142]:

$$C_6H_5(CH_2)_n NHCH_2CHRCO_2R' \qquad RNHCH_2CHR'CO_2R^2$$
(IX) (X)

It is interesting that the shift of the branching point of the alkyl chain towards the nitrogen atom, which hinders the usual addition of acrylates, stimulates the "symmetrisation" reaction [142-144]:

$$C_6H_5(CH_2)_2NHCHCH_3CH_2CO_2C_2H_5 \xrightarrow{\vee\,/\,\wedge} C_6H_5(CH_2)_3NCHCH_3CH_2CO_2C_2H_5$$
$$\rightarrow C_6H_5(CH_2)_2N(CH_2CH_2CO_2CH_3)_2 \qquad CH_2CH_2CO_2CH_3.$$

Methyl and ethyl acrylates can react, albeit with difficulty, with aniline in the presence of alkaline catalysts or methanol [145,146], but the yield of adducts is low. For preparative purposes, the 2-alkoxycarbonylethylation of aromatic amines is carried out with heating (8–15 h) in the presence of acetic acid [147]:

$$ArNH_2 + CH_2{=}CHCO_2R \xrightarrow{H^+} ArNHCH_2CH_2CO_2R$$

The reactions of methyl acrylate with aniline [38,148-150], toluidines [132-150], anisidines [148,149], halogenoanilines [132,148], *N*-alkylanilines, and α-naphthylamine and its analogues [150,151] have been achieved under these conditions. Amines of low basicity (diphenylamine, *o*-, *m*-, and *p*-aminobenzoic acids [151-153]) require more prolonged heating. Acetic acid can be replaced by acetic anhydride or an ammonium salt [120]. It has been stated that anhydrous stannous chloride has a catalytic effect [129,148].

A number of studies have been made on the kinetics of the reaction of amines with acrylic acid esters [48,77,101,145,154]. The reactions of morpholine and piperidine with acrylates in methanol are of second order, are not inhibited by alkalis, but are somewhat inhibited in the presence of acid reagents (acetic or perchloric acid). Replacement of part of the methanol by benzene greatly reduces the rate of the process, the rate decreasing faster than the dielectric constant of the mixture. The reactivity of methyl acrylate is higher than that of ethyl acrylate, but the latter scarcely differs from that of the butyl ester.

Table 1 lists the rate constants for the pseudounimolecular reaction of methyl acrylates with various amines in tetrahydrofuran (THF) [145].

It is striking that ethanolamine reacts 150 times faster than allylamine which has the same pK_a and ten times faster than the highly basic butylamine. A similar anomaly has been noted also for the diethanolamine–benzylamine pair. The reactivity of amino-alcohols $HO(CH_2)_nNH_2$ is almost independent of the number of methylene groups n, [154] and therefore in all cases it is necessary to assume an accelerating effect of the HO group, probably as a result of intermolecular interactions.

Table 1.

Amine	pK_a	K_1^{20}, min^{-1}
Ethanolamine	9.50	$2.4 \cdot 10^{-2}$
Butylamine	10.59	$2.1 \cdot 10^{-3}$
Allylamine	9.49	$1.6 \cdot 10^{-4}$
Diethanolamine	8.80	$9 \cdot 10^{-5}$
Benzylamine	9.34	$5 \cdot 10^{-5}$

Indeed when the reaction of ethanolamine with methyl acrylate is carried out at 20°C in dioxan, pyridine, dimethylformamide, and acetonitrile, a very slight increase of k_1 (from 2×10^{-2} to 4×10^{-2} min^{-1}), corresponding to the increase in the polarity of the medium, was observed [145]. However, in methanol, which has a smaller dielectric constant but is a potential proton donor, $k_1 = 9 \times 10^{-2}$ min^{-1}. (The high value $k_1 = 7 \times 10^{-2}$ min^{-1} quoted for the reaction in tetrahydrofuran may be due to the effect of peroxy-compounds [155]). Similarly it has been shown that the condensation of butyl-amine with ethyl acrylate in tetrahydrofuran [154] is very markedly accelerated (by a factor of 5–350) on introduction of alcohols, water, and butanethiol. These findings agree well with the hypothesis that the reactions of amines and activated olefins have the ionic mechanism discussed above for acrylonitrile [29].

A group of American workers [48,101] compared the reactivities of vinyl compounds of the acrylic series in reactions with 11 amino-acids. At pH 8.5 (30°C) methyl acrylate proved to be 3.6 times more reactive in relation to glycine than acrylonitrile. This is somewhat inconsistent with other observations [6,8] according to which the nitrile group has more pronounced electron-acceptor properties than the ester group. To account for this fact, it was suggested [101] that, in condensation with neutral nucleophilic reagents, one of the additional factors determining the reactivity of the olefins $CH_2{=}CHX$ is resonance stabilisation of the transition state by the functional group X. This is of course more likely for $COOCH_3$ than for CN.

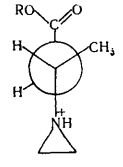
There are few data for the reactions of alkylacrylic acid esters with amines. The introduction of a methyl substituent at the double bond of methyl acrylate has little effect on the bond polarity, but, as in the case of acrylonitrile, it significantly reduces the steric accessibility of the reaction centre. The relative rates of reaction of methyl *trans*-crotonate and methyl methacrylate with glycine in aqueous buffer solutions are respectively 0.24 and 0.0116 of the rate of cyanoethylation of glycine [101].

§ In reactions with participation of acrylic and methacrylic esters in an aqueous medium, an anomalous reaction involving the migration of alkyl groups may take place to some extent as well as the addition of amines to the double bond [137].

CHEMICAL SOCIETY REFERENCE LIBRARY BURLINGTON HOUSE, W.1

It is interesting that crotonates exhibit more stringent steric requirements as regards the structure of the amine. Thus ethyl crotonate combines with piperidine [156], dimethylamine [157], propylamine [124], and methylamine [156,158] only on refluxing. In the last case variable amounts of the *N*-methylamide of 3-methylaminobutyric acid are also formed [158]. Diethylamine scarcely reacts with ethyl crotonate without heating, while at 200°C the main product is *N*-ethylcrotonamide. Normal, albeit slow, addition to the double bond occurs only in alcoholic solution [158]. On the other hand, the condensation of ethyl crotonate with butyl-, cyclohexyl-, benzyl-, and phenylethyl-amines takes place in alcohol even at room temperature [143,159,160], high yields of monoalkylation products being achieved.

Another unexpected observation of the steric inhibition of the reaction was made in a comparative study of the condensation of ethyleneimine with methyl and ethyl crotonates [107]. At 75°C methyl crotonate reacts completely, while its homologue gave only 2% of the adduct. Probably this is due to the mutual repulsion of the methyl and ester groups in the transition state (Newman's projection), which increases sharply with increasing size of the substituent R.



p-Anisidine and *p*-chloroaniline add to ethyl crotonate on refluxing in the presence of small amounts of acetic acid [161]. Ethyl and methyl ββ-dimethylacrylates combine slowly with methylamine [162] and very slowly with ammonia [156] in alcoholic solutions. On heating with anhydrous ethylamine, the main product is the *N*-methylamide; in the absence of additives, there is no reaction with piperidine [156]. Dimethylamine condenses with the β-dimethylaminoethyl ester of ββ-dimethylacrylic acid in the presence of acetic acid [163].

Methyl methacrylate readily reacts with piperidine [164], but the reaction with dimethyl- and diethyl-amines requires prolonged heating [44,124]. As already mentioned above, the ethyl ester proved to be even less reactive under comparable conditions [153,157]. Non-catalytic reactions of methacrylates with a number of aliphatic and aliphatic-aromatic amines have also been described [124,140,165]. However, the addition of methyl methacrylate, on refluxing the mixture, to dibutylamine [123], ethyl *N*-methylaminopropionate [123,141], and t-butylamine [166] could not be achieved. Aniline reacts with methyl methacrylate at 200°C to give a low yield of a mixture of three substances: the normal addition product, the anilide of 3-anilino-2-methylpropionic acid, and methacrylanilinide [120].

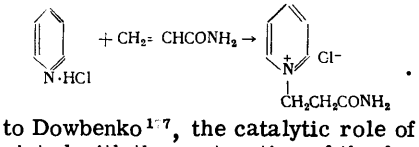
When alcohols are used as solvents, the reaction is either initiated or the temperature required is appreciably reduced. Thus in the presence of methanol the reactions of lower amines and dialkylamines (and also benzylamine) give, after a fairly long time, high yields of the corresponding monoadducts even at a low temperature [123,127,128,137,142,160,164]. With methylamine, a small amount of the double addition product is also obtained [123]. Hexamethyleneimine, β-tetrahydronaphthylamine, and cyclohexylamine react with methyl methacrylate on heating in the presence of added alcohol—the reaction takes place smoothly without the formation of side products [121,167]. For aniline, it is recommended that the synthesis be carried out in the presence of acetic acid [44,164], while methanol is inactive as a catalyst [120]. Acid catalysis can probably be used also in the reactions of other weakly basic amines, for example carboline derivatives [168].

The ethyl ester of α-ethylacrylic acid does not react with ammonia and dimethylamine on prolonged heating [156]. However, in an alcoholic medium it proved possible to add methyl-, butyl-, and benzyl-amines to a number of α-alkylacrylates with high yields [140,169].

6. ACRYLAMIDE

Diethylamine adds to acrylamide on refluxing (2–3 h), while without heating the reaction scarcely occurs [170]. It has been stated that with ammonia there is a possibility of the formation of a bis- or even a tris-adduct [171,172]. When acrylamide is added to an alcoholic solution of piperidine and morpholine, the process begins exothermically [121,170,173], although heat is required to complete the reaction. The method of 2-carbamoylethylation in alcoholic media has been successfully applied to dimethyl-, dipropyl-, and dibutyl-amines [173] and to a number of ring-substituted benzylamines [121,165,174]. For amines of low basicity (pyrazolines, pyrazoles, amino-acids), aqueous solutions are employed, sometimes with the addition of tertiary amines [108,121,172,175]. The effect of solvents on the addition of acrylamide to an amino-group proved to be more pronounced than in the case of acrylonitrile [29,121,165], but the overall nature of the catalysis by proton-donor solvents is probably the same. In particular 3-arylaminopropionamides may be obtained by condensing substituted anilines with acrylamides in the presence of both water and acetic acid in alcohol [147,176]. The kinetics of 3-carbamoylethylation of amino-acids have also been described [48,101].

Acrylamide can combine with the hydrochloride of pyridine (and a number of other heterocyclic bases) on refluxing in methanol [177]:



According to Dowbenko [177], the catalytic role of the acid is not associated with the protonation of the functional group of acrylamide.

N-Dodecylacrylamide (and dodecyl acrylate) reacts slowly by a similar mechanism with trimethylammonium and pyridinium salts [178]. Triethylamine proved to be inactive, probably for steric reasons or because of the impossibility of charge delocalisation of the type which occurs in pyridinium salts.

The substitution of hydrogen atoms in the amide group of acrylamide by alkyl groups alters the reactivity of the double bond but not always in the same way [8,107,179]. Thus *N*-benzylacrylamide reacts smoothly on heating with hydrazine hydrate in the presence of alcohol and dimethylformamide [180]:

$$N_2H_4 \cdot H_2O + CH_2{=}CHCONHCH_2C_6H_5 \rightarrow NH_2NHCH_2CH_2CONHCH_2C_6H_5 .$$

With phenoxycarbonylhydrazine, similar condensation takes place on refluxing with added acetic acid [181]. The reactions of *N*-methyl-, *N*-benzyl-, and *NN*-dimethylacrylamides with the most basic aromatic amines, which occur relatively readily in the presence of organic acids, have been described [182].

Diacrylamidomethane and 1,3,5-triacryloyl-1,3,5-triazine react similarly [183,184]. In the condensation of bisacrylamides (particularly 1,4-diacryloylpiperazine) with

primary and secondary amines in proton-donor media, polymers were obtained [185]. The reactions of α- and β-methyl-acrylamides have been described [172,186,187].

7. ACRYLIC ACID

Acrylic acid itself and its alkyl-substituted derivatives are the least reactive among acrylic olefins in condensations with amino-compounds. Thus aqueous ammonia (in a large excess) adds to crotonic and $\beta\beta$-dimethyl-acrylic acids after prolonged heating in an autoclave [188]. The same reaction involving crotonic acid takes place more readily on irradiation with ultraviolet light, the product being N-methyl-β-alanine and also its amide [189].

One of the factors inhibiting the reactions of acrylic acids with amines is undoubtedly salt formation and the consequent decrease of the activating effect of the carboxylate group on the adjacent double bond. Thus when crotonic acid is mixed in alcohol with 2-aminoethanol, 2-hydroxyethylammonium crotonate is precipitated [190]. After heating to 100°C, the latter is converted into β-(2-hydroxyethylamino)butyric acid.

Recently several ways have been suggested for overcoming these difficulties. For example, benzylamine, some of its substituted derivatives, isobutylamine, and hexylamine have been added to crotonic acid with high yields on heating an equimolar mixture of the reactants in pyridine solution [134,191,192]; when optically active α-phenylethylamine is introduced into this reaction, a mixture of diastereoisomers is formed, which can be separated [193]. The use of proton-donor solvents (water, lower alcohols, ethylene glycol) has been recommended in patents [194,195] for the synthesis of the adducts of unsaturated acids with higher aliphatic amines and polyamines. Nevertheless in a few cases the reaction in aqueous solution takes place in different ways and polymeric substances are formed together with alkylaminopropionic acids. Probably this can be explained by the addition of the monomer to the intermediate ion (XI) [192]:

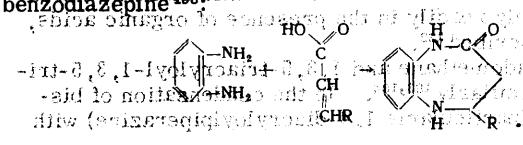
$$RNH_2 + CH_2=C(CH_3)CO_2H \rightarrow R\overset{+}{N}H_2CH_2\overset{-}{C}(CH_3)CO_2H\ .$$

Acrylic and methacrylic acids interact with an excess of aniline only at 180–190°C, the reaction involving both the double bond and the carboxy-group [196]:

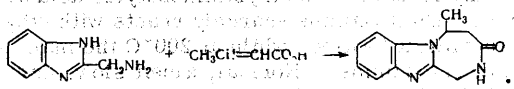
$$C_6H_5NH_2 + CH_2=CHCO_2H \rightarrow C_6H_5NHCH_2CH_2CONHC_6H_5\ .$$

Adducts of aromatic amines and $\alpha\beta$-unsaturated acids (1 : 1 composition) can be obtained in a low yield by exposing toluene solutions of the reactants to ultraviolet light [188]. Equivalent amounts of p-chloroaniline and crotonic acid were successfully condensed on refluxing in benzene [161]. According to the authors [161], in this case crotonic acid behaves at the same time as an acid catalyst. In a 1937 patent application by I.G. Farbenindustrie [197] the adducts of acrylic acid with a number of aromatic amines were described, but these data have not been reproduced so far.

The condensation of $\alpha\beta$-unsaturated acids and also their esters with difunctional amines leads to the formation of seven-membered heterocyclic compounds. For example, o-phenylenediamine is converted into the corresponding benzodiazepine [198]:



The structure of products of similar condensations is determined both by the reaction conditions and the relative nucleophilicity of the functional groups. When 2-aminomethylbenzimidazole is heated with crotonic acid, the double bond attacks a ring nitrogen atom [199]:



When the molecule contains a mercapto-group (o-aminothiophenol, β-aminoethanethiols), the reaction takes place with initial 2-carboxyethylation of the sulphur atom [200].

8. VINYL KETONES

Vinylketones (CH_2=CHCOR) have a highly activated double bond and their reactions with aliphatic dialkylamines and heterocyclic imines take place very vigorously [107,201–203]:

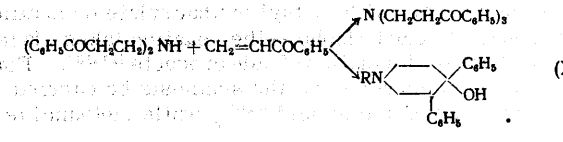
$$RR'NH + CH_2=CHCOR^3 \rightarrow RR'NCH_2CH_2COR^3\ .$$

Therefore the reaction is usually carried out either with cooling [204] or in ethereal and benzene solutions; in some cases alcohols have also been used as solvents [205].

When the rate of reaction is high, it is difficult to estimate qualitatively the effect of the basicity of the amino-component [204]; on the other hand, the effect of steric factors is very distinct. Thus a very bulky substituent in the 2-position of the piperidine ring (or two small substituents) greatly hinders the reactions with aryl vinyl ketones. Whereas dimethyl- and diethyl-amines react quantitatively with methyl vinyl ketone even at −5°C, the preparation of the corresponding adducts of methylcyclopentyl- and methylcyclohexyl-amines requires heating to 40°C [204]; the reaction of di-isopropylamine and dicyclohexylamine with methyl vinyl ketone would not proceed at all. The relative decrease of the rate of reaction is characteristic also of 2-alkylcarbonylethylation of amines with low basicity [206].

Primary aliphatic amines usually react with vinyl ketones without solvent, a complex mixture of products being formed (probably because of the simultaneous attack on the double bond and the carbonyl group). The process can be regulated by adding acetic or formic acid to the reaction mixture, so as to bind part of the amine [202]. Under these conditions, propylamine with ethyl vinyl ketone yields a mixture of mono- and di-adducts. Likewise, while aqueous ammonia and vinyl ketones form a mixture of di- and tri-alkylation products [207], with ammonium acetate it is possible to obtain a small amount of the monoadduct [201]. However, there are data [208,209] showing that ammonia and methylamine in the form of their hydrochlorides do not react with phenyl vinyl ketone even on heating in aqueous alcohol. In another method the monoadducts of primary amines and methyl vinyl ketone are synthesised at room temperature or with cooling in ethereal solution [210].

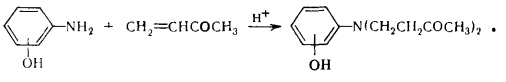
By heating an aqueous alcoholic solution of β-benzoylethylamine with phenyl vinyl ketone, the triadduct $N(CH_2CH_2COC_6H_5)_3$ was obtained, while the reaction of di(benzoylethyl)amine with the same unsaturated ketone yields a mixture of the same triadduct and a piperidinol (XII, R' = $C_6H_5COCH_2CH_2$) [208,209]:



On the other hand, the hydrochloride of *N*-benzoylethyl-*N*-methylamine and phenyl vinyl ketone form the adduct $(C_6H_5COCH_2CH_2)_2NCH_3$ or its mixture with a piperidinol of type (XII), with R = CH_3, depending on the medium (water or aqueous alcohol). Probably in both cases the reaction proceeds via a dipolar intermediate state, which is stabilised by the addition of a proton or by intramolecular aldol condensation[208].

Aromatic amines (aniline, *p*-toluidine, certain *N*-alkylanilines) add to methyl vinyl ketone[210,211], ethyl vinyl ketone[211,212], phenyl vinyl ketone[213-215] on slight heating or standing for a long time at room temperature. It has actually been stated that the addition of aniline to phenyl vinyl ketone causes an exothermic reaction[214], but the less basic anthranilic acid gives high yields only at 60°C[216]. The addition of an unsaturated ketone to an aromatic amine is the first stage in the synthesis of quinolines by the Döbner–Miller method[217]. In the presence of a proton-donor solvent (methanol, 50% ethanol) these processes appear to be accelerated[215,216]. When *N*-methylaniline and dimethylamine hydrochlorides are introduced into the reaction under these conditions, a mixture of Mannich bases is formed from both amines as a result of a mobile equilibrium[215]. The addition of an inert solvent appears to inhibit 2-carbonylalkylation of amines[216].

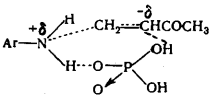
The products of the addition of methyl vinyl ketone to *p*-phenylenediamine and its analogues have been described[216]. In methanol in the presence of a slight excess of the unsaturated component, a bismonadduct is formed, while refluxing with an excess of methyl vinyl ketone leads to double alkylation of both amino-groups. When an acid catalyst (acetic acid) is used, it is also possible to obtain dialkylation products of other, somewhat less basic aromatic amines but there are few such examples yet[218]:



The study of the kinetics of the addition reactions has shown[101] that in aqueous solutions methyl vinyl ketone reacts with glycine eighty times faster than does acrylonitrile. Zuman and coworkers[219,220] determined polarographically the first-order rate constant for the reaction of phenyl vinyl ketone with a tenfold excess of morpholine and a number of primary amines in the presence of the corresponding hydrochlorides. The reaction with ethanolamine and cyclohexylamine goes almost to completion, while for other amines an equilibrium was observed after 37–60% conversion. Within the limits of experimental error, k_1 proved to be independent of ionic strength and pH. A direct correlation between the rate of 2-phenylcarbonylethylation and the basicity of the amine has not been found and therefore the different values of k_1 have been attributed mainly to the effect of steric factors[101]. This interesting result has not been adequately explained.

The reaction of methyl vinyl ketone with aromatic amines (in an acetate or phosphate buffer solution) up to a conversion in excess of 80% is satisfactorily described by a second-order equation[210]. The Hammett equation with $\rho = -1.60$ holds ($r = 0.998$; $s = 0.09$) for p-$RC_6H_4NH_2$ (R = CH_3O, CH_3, H, Cl, NO_2). The activation energy for the reaction in the temperature range 20–50°C is 5.2–6.1 kcal mole^{-1} and the entropy is between −48 and −50 e.u. By varying the composition of the buffer solution and its concentration, the authors established that the process is catalysed by both acids and bases (Table 2).

The activity of the $H_2PO_4^-$ ion is striking; it greatly exceeds the catalytic effect of acetic acid which has a much higher pK_a value. The phosphate ion may be involved in the transition state as a bifunctional catalyst:



If the reaction is carried out in dioxan–water mixtures, the catalytic effect of aniline itself (and similarly pyridine) is clearly shown. Evidently the amino-component in some form can participate in the formation of the transition complex, functioning, together with water, as a proton-transfer agent.

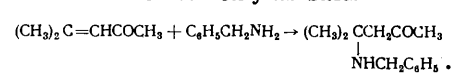
Table 2. Catalytic constants (k_1) for the reaction of methyl vinyl ketone with aniline at 31°C under different conditions.

Catalyst	Water	Solvent (40% aqueous dioxan)	Catalyst	Water	Solvent (40% aqueous dioxan)
CH_3COOH	0.02	—	H^+	10^3	
CH_3COO^-	0.26	—	Water	$5.5\cdot10^{-3}$	$1.6\cdot10^{-4}$
$H_2PO_4^-$	0.45	—	Aniline	—	$4.3\cdot10^{-3}$
HPO_4^{2-}	0.42		Pyridine	—	$7\cdot10^{-2}$

Alkyl substituents at the double bond of vinyl ketones (usually a methyl group) lower its reactivity only slightly. Thus the ketones RCOCH=$CHCH_3$, where R = methyl, phenyl, or alkoxyphenyl, combine with aliphatic amines, piperidines, and morpholine at room temperature[221,222]. High yields of monoalkylation products are attained after 1–4 h if the reaction is carried out in methanol or water.

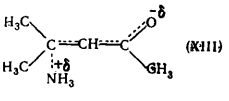
α-Benzylidene-ketones react with secondary amines somewhat more slowly[223] and the reaction depends more on steric factors than on the basicity of the amine. For example, diethylamine already adds with difficulty to methyl styryl ketone.

Among multiply substituted vinyl ketones, the condensations of amines with mesityl oxide has been most thoroughly investigated[224]. In the presence of water mesityl oxide combines with ammonia, methylamine, benzylamine, and hydroxylamine and its *N*-alkyl derivatives. However, the adducts formed are thermally unstable and can be isolated only as salts:



Diethylamine adds to mesityl oxide without solvent at 50°C[225]. Aromatic amines react with difficulty and do not give high yields. Mesityl oxide and other vinyl ketones react with diamines and amino-thiols forming seven-membered heterocyclic nitrogen-containing compounds[198].

On the basis of the study of the kinetics of the reaction of mesityl oxide with ammonia under pressure in aqueous solution or in methanol[226], the intermediate formation of the dipolar ion (XIII) has been suggested:



(XIII)

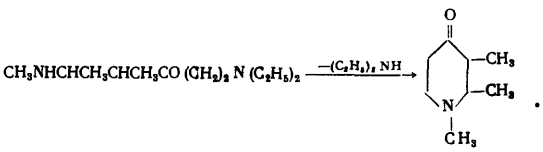
The rate of reaction in methanol increases with pressure appreciably faster [$\ln(k_p/k_1) = 1.224$] than in water (0.737) but nevertheless remains lower by a factor of 3–5. Calculation based on activation volumes shows a considerable

separation of charges in the transition state (0.42–0.65 of electron charge).

Compounds of the type $R_2C{=}CHCOCH{=}CH_2$, where one vinyl group is markedly screened, undergo smooth addition of aliphatic dialkylamines, piperidine, isopropylamine, and aniline to the sterically accessible double bond on brief heating to 60°C [207]. The yields fall somewhat with increasing length of the alkyl group R. The reaction with isopropylamine is accelerated by the addition of a few drops of water:

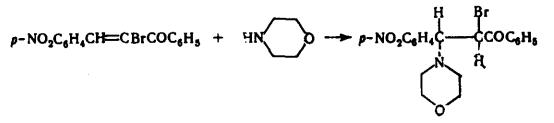
$$(CH_3)_2C{=}CHCOCH{=}CH_2 + (CH_3)_2CHNH_2 \rightarrow (CH_3)_2C{=}CHCO(CH_2)_2NHCH(CH_3)_2 .$$

In an alcoholic or aqueous medium it is possible to achieve a condensation involving the second double bond as well. Thus 1-diethylamino-4-methylhex-4-en-3-one combines with methylamine and certain other primary amines, forming a linear diadduct [228]. However, on heating these reactions lead to cyclisation with formation of γ-piperidones [228,229]:

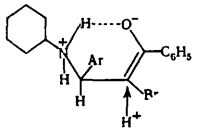


It is possible to use directly mixtures of a primary amine with divinyl ketones or β-methoxyalkyl vinyl ketones [230]. The cyclisation reaction, which consists essentially in a dialkylation process involving the amino-group, is of course controlled both by steric factors and by basicity [228,230,231]. A large number of γ-piperidones with various substituents in the ring and at the nitrogen atom have been obtained by this process.

A number of studies dealing with the stereochemistry of the addition of amines to the double bond of $\alpha\beta$-unsaturated ketones have been published. In the condensation of morpholine in benzene with *cis*- and *trans*-isomers of α-bromo-4-nitrochalcone, the same sterically homogeneous *threo*-adducts were obtained regardless of the configuration of the ketone, although the yield was somewhat higher when the *trans*-isomer was used [223]:



Primary amines (for example cyclohexylamine) react with α-bromochalcones forming diastereoisomeric β-amino-α-bromo-ketones, which cyclise spontaneously during the reaction, with retention of the configuration, to the corresponding *cis*- and *trans*-ethyleneimines [233,234]. It was found that the ratio of the isomers, as in the case of heterocyclic imines, is almost independent of the configuration of the initial $\alpha\beta$-unsaturated ketone, but may vary with the solvent. From these data, it was concluded [232,234] that the alkylation reaction proceeds via an intermediate complex incorporating the enolic form of the ketone:



The protonation of the α-carbon atom by the bulky cyclohexylammonium ion (in inert media) is responsible for the preferential formation of *trans*-adducts. Methanol probably attacks the complex less specifically, which results in an increase of the yield of products with a *cis*-configuration. These results have been analysed in greater detail by Hughes [23].

9. NITRO-OLEFINS

In a discussion of reactions involving a double bond activated by an adjacent nitro-group, it is necessary to take into account not only the polarity of the bond [5,6] but probably also the greater possibility of the delocalisation of a negative charge in the activated complex. On the other hand, the properties of nitro-compounds as carbon acids play a certain role, so that sometimes the process may occur autocatalytically. This is the reason for the exceptional ease of the reaction, of even highly substituted nitro-olefins, with nucleophilic reagents, including amines.

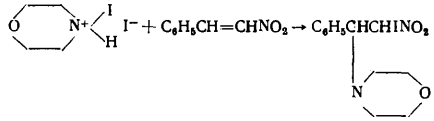
A typical example is provided by nitroethylene [236,237]. In an inert solvent (ether, dioxan, xylene, nitrobenzene) it combines with benzylamine, cyclohexylamine, and *N*-methylcyclohexylamine even at −20°C with formation of the corresponding 2-nitroalkylamines. Under the same conditions, benzylamine gives with an excess of the olefin the diadduct $C_6H_5CH_2N(CH_2CH_2NO_2)_2$. Two adducts (1 : 1 and 1 : 2) can also be obtained from aniline at 20° and 40°C respectively [236–238]. On slight heating, naphthylamines, *N*-alkylanilines, aminoanthraquinones, and aromatic diamines are 2-nitroethylated [227].

Homologues of nitroethylene combine with ammonia, diethylamine, and aromatic amines at room temperature without solvent or in ethereal solution [238]. Because of their instability, the acids are usually isolated as salts. The nitro-olefin $CH_3OCOCH_2[CH(OCOCH_3)]_3CH{=}CHNO_2$ has been successfully condensed (in the presence of methanol) with ammonia, benzylamine, cycloalkyleneimines, 2-aminoethanol, and isopropylamine. Under comparable conditions, aromatic amines give lower yields [239].

Under mild conditions, ω-nitrostyrene combines with piperidine, ammonia, semicarbazide, aniline, phenylhydrazine, benzidine, and a number of other amines [238,240]. Probably the yield of adducts is determined mainly by the isolation conditions and cannot be related to the basicity of the amine used. Thus with *p*-toluidine the reaction is completed after several minutes. Nevertheless aromatic amines of low basicity (for example, *p*-chloro- and *p*-nitro-anilines) do not react with ω-nitrostyrene at room temperature. Condensations of this kind are usually not carried out with heating to avoid secondary reactions. For example, it has been shown that certain 1-aryl-2-nitroethylation products are cleaved at elevated temperatures with formation of nitromethane [241]:

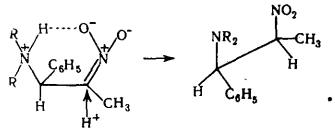
$$C_6H_5NHNH_2 + ArCH{=}CHNO_2 \rightarrow C_6H_5NHNHCHArCH_2NO_2 \rightarrow C_6H_5NHN{=}CHAr + CH_3NO_2 .$$

The addition of hydrazine and a number of acylhydrazines to ω-nitrostyrene has been achieved in absolute alcohol [242]. When the iodonium complex of morpholine is introduced into the condensation reaction in the presence of acetic acid, a positively charged iodine atom enters into the molecule of the alkylation product [243]:



The reactions of β-methyl-β-nitrostyrene with pyrrolidine, piperidine, morpholine, and certain aliphatic

amines have been investigated stereochemically[244]. In petroleum ether with equimolar proportions of the reactants, the *erythro*-isomers are formed preferentially while in the presence of an excess of the amine or in an alcoholic medium the main products are the corresponding *threo*-isomers. It was assumed[244] that the reaction takes place via an intermediate *aci*-compound, which exists as the inner complex (XIV):



(XIV)

The proton donor should attack it preferentially from the unhindered side, which leads to the *erythro*-disposition of the substituents. The gradual isomerisation of the *erythro*-isomers gives the more stable *threo*-adducts.

A number of studies have been made to elucidate the effect of substituents in the aromatic ring on the reactivity of arylnitro-alkenes. Methyl, methoxy-, or hydroxy-groups in the para-position of the benzene ring occasionally deactivate the double bond and the corresponding nitro-olefins cannot be condensed with *p*-toluidine and *p*-phenylenediamine (slight heating in the presence of alcohol)[245,246]. The introduction of an additional nitro-group or halogen atom leads, on the other hand, to an increase of the electrophilicity of the double bond[245-247]. Thus 2-chloro-4-nitro-ω-nitrostyrene readily reacts with many aromatic amines and hydrazines[247].

The nitro-group in the *ortho*- or *para*-position relative to the double bond of the styrene molecule activates the latter sufficiently for certain nucleophilic reactions[248]. On being refluxed in alcoholic solutions with an excess of secondary amines (pyrrolidine, piperidine, dimethylamine), *p*-nitrostyrene forms the corresponding adducts in yields in excess of 90%; the yield gradually falls on going to diethyl- and dipropyl-amines. When di-isopropylamine is used, only traces of the desired product are obtained, and di-isobutylamine does not react with *p*-nitrostyrene at all. In all cases *o*-nitrostyrene is less reactive. t-Butylamine reacts with difficulty with *p*-nitrostyrene and in particular with *o*-nitrostyrene (yields 45 and 7% respectively). It has been shown that these effects are not associated with the interaction between the amines and the nitro-group but are caused by direct frontal hindrance of the addition reaction.

Recently very interesting results were obtained in the study of the kinetics of the reaction of butylamine and benzylamine in dioxan with various nitrostyrenes, β-nitropropenylbenzenes and β-nitrobutenylbenzenes[249]. The pseudo-first-order constants obtained can be represented by the equation

$$K_{tot} = [RNH_2]^2/[A(RNH_2] + B)$$

where A and B are constants which can be roughly correlated with Hammett's σ coefficients. In other words, the authors believe that the transition state of the reaction includes, together with the αβ-unsaturated compound, two molecules of the amine. On the other hand, if the condensation (for example with aniline) is carried out in an alcoholic solution of a phosphate buffer, the reaction is of first order with respect to the amino-component. Consequently in such cases the protic solvent assumes the functions of the second amine molecule.

10. VINYL SULPHONES

The available information about the condensation of vinyl sulphones with nucleophilic reagents is insufficiently systematic[6]. For a long time the problem of the nature of the interaction between the double bond and the sulphonyl group also remained unresolved[250,251]; it is most reasonable to assume a purely inductive effect of the SO_2R group. This makes even more unexpected the appreciable reactivity of vinyl sulphones in reactions with amino-compounds[101].

Aryl vinyl sulphones have been thoroughly investigated in this respect, particularly the readily available p-$CH_3C_6H_4SO_2$-$CH{=}CH_2$ [252-255]. The latter sulphone gives quantitative yields of adducts with various amines in benzene solution at room temperature[256,257]. However, the addition of sterically hindered amines such as diazopropylamine could not be achieved[256]. In preparative experiments methanol as solvent has a favourable effect[254,255]. Condensations involving allyl aryl sulphones, which are evidently first isomerised to the αβ-unsaturated isomers, also take place comparatively readily at 50–70°C [255,258]:

$$ArSO_2CH_2CH{=}CH_2 + R_2NH \rightarrow ArSO_2CH_2CH(CH_3)NR_2 .$$

Table 3. First-order rate constants for the reaction of *p*-tolyl vinyl sulphone with amines in alcohol at 25°C.

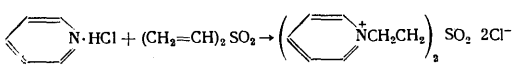
Amine	pK_a	$k_1 \cdot 10^3$	Amine	pK_a	$k_1 \cdot 10^3$
Piperidine	11.1	585	Hexylamine	10.6	10.6
Dimethylamine	10.8	451	Butylamine	10.6	8.0
Morpholine	8.4	33.8	Isopropylamine	10.6	4.32
Diethylamine	11.0	23.3	s-Butylamine	10.6	4.24
Dibutylamine	11.3	12.5	2-Ethylpiperidine	—	3.78
2-Methylpiperidine	11.0	10.9	t-Butylamine	10.7	0.86
Isobutylamine	10.7	10.8	2,6-Dimethylpiperidine	11.1	0.085

The addition of numerous amines of different classes to the double bond of aryl vinyl sulphones was recently investigated by kinetic methods[256,257,259]. It was found that, as in the case of vinyl ketones, the reactivity of the amines depends more on the steric environment of the nitrogen atom than on its basicity[256] (Table 3). In alcohol the reaction is definitely of first order with respect to each component; in benzene solution the rates of all the reactions are greatly reduced (approximately by a factor of 40) and the order with respect to the amine becomes non-integral, approaching two in the presence of an excess of the amino-component. Probably the second amine molecule enters into the transition state and evidently functions, instead of alcohol, as a proton transfer agent[256]. The rate of addition of t-butylamine to *meta*- and *para*-substituted aryl vinyl sulphones $RC_6H_4SO_2CH{=}CH_2$ (R = H, CH_3, CH_3O, Cl, NO_2, or CH_3SO_2) is satisfactorily correlated with the Hammett relation ($\rho = 1.59$)[257]. This also suggests that the reactions take place via a co-ordinated mechanism with very marked charge separation and a high degree of new bond formation in the transition state. According to kinetic data[259], the introduction of a methyl group in the β-position in the double bond of the *p*-tolyl vinyl sulphone molecule lowers the rate of addition of piperidine by a factor of 840 and in the case of α-substitution the rate falls by a factor as high as 6500. The explanation given for this behaviour is similar to that

discussed above for substituted acrylonitriles—destabilisation of the carbanionic centre in the transition state as a result of the donor properties of the methyl group[259].

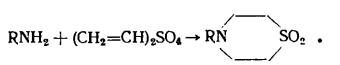
There are data (mainly in patents) on the addition of aromatic amines, but these probably require experimental verification: thus *N*-ethylaniline can add to *p*-tolyl vinyl sulphone on heating to 100°C[253], β-naphthylamine reacts satisfactorily on being refluxed in methanol, and *o*-aminobenzenesulphonic acid and amines of similar structure react in aqueous sodium carbonate solutions[252,253]. Data have also been published on the acceleration of the reaction in the presence of benzoyl peroxide or zinc acetate[253]. Weakly basic aromatic amines such as *p*-nitroaniline and diphenylamine apparently react only in the presence of alkaline additives (metallic potassium, sodium hydroxide)[253,254].

Divinyl sulphone, which can interact with secondary amines in proportions of 1:1 and 1:2, exhibits high chemical reactivity[260-263]. Most of the bis-addition reactions take place with high yields in the presence of an excess of the amino-component even at room temperature or with slight heating[260,262]. For this reason, the formation of monoadducts is favoured by dilution of the reactant mixture with a non-polar solvent and by cooling (for example in ether at a temperature between −1° and −3°C)[263]. The condensation of divinyl sulphone and pyridine hydrochloride and some of its substituted derivatives has been described[260,264]:



The reaction is reversible and takes place rapidly only in an almost neutral alcoholic medium (pH 6.5–7.5). An increase of acidity, which leads to binding of part of the tertiary amine, sharply inhibits addition processes.

On heating with divinyl sulphone, primary amines cyclise in most cases to 1,1-dihydroxy-1,4-thiazane derivatives[256,266]:



Diamines, aniline, hydroxylamine, phenylhydrazine, and amino-acids and their esters react by the same mechanism. The reactions are accelerated in the presence of alcohol. Somewhat longer heating and a somewhat greater amount of solvent are required for higher and especially aromatic amines[266].

Advances in the Synthesis of α-Ethynylcarbonyl Compounds

R.I.Katkevich and L.I.Vereshchagin

The methods of synthesis of α-ethynylcarbonyl compounds are discussed. Attention has been concentrated on the methods of synthesis of preparative value. Despite the practical approach employed, the review deals with a large number of studies devoted to methods of purely theoretical interest. The biliography includes 215 references.

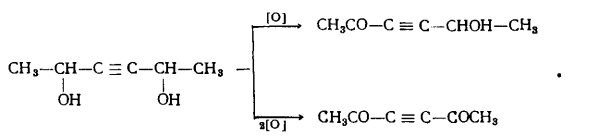
I. INTRODUCTION

In recent years there has been a considerable growth of interest in the chemistry of ethynylcarbonyl compounds for two reasons. Firstly, ethynyl ketones contain several reaction centres in the molecule and therefore can be legitimately included amongst synthetically promising substances, and, secondly, many ethynyl ketones isolated from plant raw material have shown antibiotic properties. This is particularly important because, despite the application of wide-spectrum antibiotics discovered recently, there is an urgent need in clinical chemotherapy for new antibacterial preparations and continuous and intensive research in this field is necessary. The chemistry of acetylene has been developing very rapidly. Whereas acetylene itself, ethynyl alcohols, and acetylenic acids have been extensively reviewed, no reviews are as yet available on the methods of synthesis and the chemistry of ethynylcarbonyl compounds. In this sense the present review is essentially the first attempt to set out the principal information available on this problem. The data on which the review is based were selected from the standpoint of their practical value. Attention has been concentrated on the methods of synthesis of α-ethynylcarbonyl compounds which, in the authors' view, are the most interesting representatives of this class of compounds, and also on the assessment of these methods and the elucidation of the limits of their applicability. It should, however, be noted that the generally known and widely used methods of preparation of aliphatic ketones and aldehydes in most cases cannot unfortunately be extended to ethynyl compounds. On the other hand, among synthetic methods for the latter, many are exceptionally specific and there is no prospect of their general employment.

II. OXIDATION OF ETHYNYL ALCOHOLS AND HYDROCARBONS

One of the most widely used synthetic methods for ethynylcarbonyl compounds is the oxidation of the corresponding primary and secondary carbinols and certain hydrocarbons. A wide variety of oxidising agents may be used for the oxidation of alcohols, but the presence in the ethynylcarbinol molecule of a group as reactive as the triple bond narrows considerably the range of acceptable oxidants. The application of vigorous oxidising agents such as, for example, potassium permanganate or nitric acid is undesirable because of the consequent disruption of the multiple bond by the agent.

Historically, the first oxidising agent employed was chromium trioxide CrO_3. Andre[1] was the first to employ chromium trioxide in acetic acid solution for the preparation of ethynyl ketones. Depending on the reactivity and the stability of the alcohol, this oxidising agent can be used in combination with various solvents at different temperatures. The nature of the solvent employed, the concentration of the reactants, and temperature have an appreciable effect on the reaction. Thus various aliphatic, aromatic, and heterocyclic ethynyl ketones have been obtained by the action of chromium trioxide in sulphuric acid[2-6]. Secondary diethynyl carbinols[7-12], vinylethynyl carbinols[6,13], acetylenic hydroxy-acids[14,15], and ethynyl glycols[2,16-18] are oxidised under similar conditions. It was noted that aliphatic glycols are oxidised with much greater difficulty than aromatic glycols[2]. Compared with diaroylacetylenes, the yields of the analogous aliphatic diketones are much lower, which is probably due to their low stability. Primary and secondary hydroxy-groups are oxidised. By selecting the reaction conditions and the starting material: : oxidant ratio, it is possible to achieve the oxidation of only one of the hydroxy-groups[2,19]:



Thus in the oxidation of hex-3-yne-2,5-diol by an equimolar amount of chromium trioxide in sulphuric acid at low temperatures the product was 2-hydroxyhex-3-yn-5-one. Using an excess of chromium trioxide, it is possible to convert the glycol into the corresponding diketone. To oxidise more unstable alcohols and glycols, less reactive solutions of chromium trioxide in acetone[20-22] or in acetic acid[23-26] are employed. Recently a chromium trioxide–pyridine complex was proposed for the oxidation of ethynyl

carbinols[27-29]. Owing to the mildness of the reaction conditions, the method gives good results; the replacement of pyridine by acetone as the solvent impairs the yields.

Very contradictory data have been published on the oxidation of primary ethynyl alcohol. Thus Jones and coworkers[30,31] showed that the oxidation of primary alcohols and glycols with chromium trioxide in acetone does not stop at the stage involving the formation of the carbonyl compound. The reaction takes place with formation of mono- and di-carboxylic acids, the yields of which vary from 20 to 40%.

At the same time Wille et al.[32], who oxidised propargyl alcohol by the same oxidising agent, and also Jacobs et al.[33], who oxidised 1-phenylpent-3-en-1-yn-5-ol, obtained the corresponding aldehydes in a yield of about 50%. These different results are associated with the different duration of contact between the reactants and their relative amounts.

The problem of the mechanism of the oxidation of various alcohols by chromium trioxide has been widely discussed. Two principal hypotheses concerning the oxidation mechanism have been put forward on the basis of numerous kinetic studies: Westheimer's so called "ether" mechanism[34] and the mechanism in which the dissociation of hydrogen as the hydride ion is postulated[35]. The above data clearly show the large scale of the application of chromium trioxide for synthetic purposes. However, a certain limitation of this method should also be noted: many highly unsaturated ketones, which are very sensitive to the acidity of the medium, cannot be obtained by this method. Potassium dichromate is less often used for the oxidation of alcohols[36].

In recent years new oxidising agents with a wide range of activity and high selectivity have been found. Among these, activated manganese dioxide obtained in 1948 and extensively used for the oxidation of a wide variety of different classes of compounds occupies a prominent place. Monoethynyl[37-39], vinylethynyl, and polyethynyl ketones[40-42], and ethynyl, vinylethynyl, and polyethynyl aldehydes[43-45] have been synthesised with the aid of activated manganese dioxide. Glycols[17,46] and esters of acetylenic hydroxy-acids[28] are oxidised less successfully. A characteristic feature of this reaction is the lack of sensitivity of the carbon framework, in particular the double and triple bonds, to the action of the oxidant. Because of the specificity of its action, activated manganese dioxide is justifiably regarded as the most convenient and almost irreplaceable dehydrogenating agent for the oxidation of highly unsaturated and extremely unstable hydroxy-compounds. The oxidation is carried out under a wide variety of conditions: with various solvents, in a fairly wide range of temperatures, and with different proportions of the components. It has been established empirically[47,48] that the polarity of the solvent has a very significant effect on the rate and mode of this reaction.

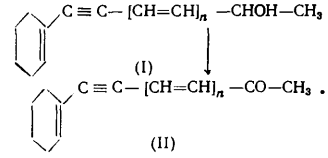
It is considered more desirable to employ chloroform, benzene, pentane, and ether than acetone, since the degree of deactivation of activated manganese dioxide is directly related to the polarity of the solvent employed. The most highly deactivating solvents are aliphatic alcohols, particularly tertiary alcohols; acetone and ethyl acetate also deactivate the oxidant, but much less. The duration and temperature of the reaction depend on the activity of the manganese dioxide, the substance to be oxidised, and the proportions of the components. To reduce its duration, the reaction is frequently carried out at an elevated temperature. The test substance : reactant weight ratio is usually varied in the range 1 : 5–1 : 20 and in some cases 1 : 50. According to many investigators, the ease of oxidation depends on the adsorbability of the given compound on the oxidant. Experimental confirmation has been obtained[40] for the earlier hypothesis of Ball et al.[50] that the more saturated compounds, which are less well adsorbed on the oxidant, should react at a lower rate. However, the degree of adsorption is scarcely the sole factor determining the rate of reaction.

Pratt proposed a free-radical mechanism for the oxidation by activated manganese dioxide[51,52]:

$$R_2CHOH + O{=}Mn{=}O \rightarrow R_2\dot{C}OH + HO{-}Mn{=}O \rightarrow$$
$$\rightarrow R_2\dot{C}{-}\dot{O} + HO{-}Mn{-}OH \rightarrow R_2CO + MnO + H_2O\,.$$

It must be particularly emphasised that the capacity for the selective oxidation of a hydroxyl activated by multiple bonds and an aromatic ring is one of the many specific features of manganese dioxide.

A less widely used synthetic method for ethynylcarbonyl compounds is based on the Oppenauer oxidation of ethynyl alcohols. On prolonged refluxing with aluminium t-butoxide in acetone–benzene solution, ehtynyl carbinols are converted into the corresponding ketones[53-56]:



(I) (II)

It has been noted that the ethynyl alcohols (I) with $n = 0$ react slowly with this oxidising agent. An increase in the number of double bonds has a favourable effect on the reaction and leads to an improvement of the yield of the ketones (II).

Nickel peroxide and manganese acetate are less widely used oxidising agents but give good results[57,58,59]. Nickel peroxide is more often used[57]; the reaction is carried out in a neutral medium, since in an alkaline medium primary alcohols are converted into acids. The yields of the desired products are fairly high.

A satisfactory result was obtained in the oxidation of ethynyl and vinyl alcohols by quinones[60]. Thus 1,5-diphenylpent-4-en-1-yn-3-ol mixed with *o*-chloranil in an alcoholic solution gives at room temperature the ethynyl vinyl ketone (III) in 91% yield:

$$Ph{-}C{\equiv}C{-}\underset{OH}{CH}{-}CH{=}CH{-}Ph \rightarrow Ph{-}C{\equiv}C{-}CO{-}CH{=}CH{-}Ph\,.$$
(III)

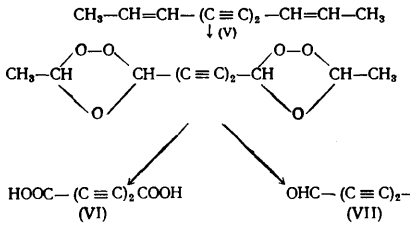
Together with the oxidation of the alcoholic group, ketones are also prepared by a method involving the dissociation of unsaturated compounds at the double bond. The double bond in vinylethynyl compounds is known to be oxidised by peracids much faster than the triple bond and the rate of oxidation increases with the number of substituents at the double bond. This feature was used to synthesise ethynyl ketones[61]. Acetylacetylene and vinylacetylacetylene have been synthesised by heating isopropenylacetylene and isopropenylvinylacetylene with hydrogen peroxide for 35–40 h at 35–45 °C in acetic acid and acetic anhydride. Sometimes monoacetates derived from the alcohols (IV) are formed together with the ketones:

$$R{-}C{\equiv}C{-}\overset{CH_3}{\underset{|}{C}}{=}CH_2 \xrightarrow{CH_3COOH} R{-}C{\equiv}C{-}CO{-}CH_3 + R{-}C{\equiv}C{-}\overset{OOCCH_3}{\underset{|}{C}}{-}CH_3\,,$$
(IV)

where R = H or $CH{=}CH_2$.

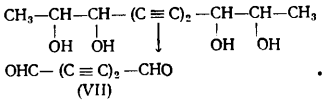
The double bond in enynes is also more sensitive than the triple bond to the action of ozone. This difference in the reactivities of the multiple bonds has been used for

preparative purposes [62]. It has been established that the reaction of dienediynes (V) with ozone takes place smoothly with formation of diozonides, the acid hydrolysis of which gives the acetylenic acids (VI) in 65% yield. At the same time the reductive dissociation of ozonides with zinc dust in water or dioxan makes it possible to obtain a good yield even of the highly unstable diethynyl dialdehyde (VII)

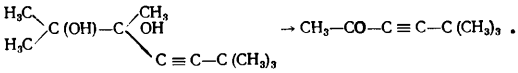


However, this method is more suitable for the synthesis of acetylenic acids than aldehydes.

One of the methods for the synthesis of aliphatic carbonyl compounds is the cleavage of the carbon chain of α-glycols between the hydroxylated carbon atoms with lead tetra-acetate, sodium periodate, and periodic acid. This method has also been successfully used in the acetylenic series. Bohlmann and coworkers employed sodium periodate and periodic acid for the dissociation of diols. Thienylpropiolic aldehyde [63], α-hexynal [64], and the diethynyl dialdehyde (VII) were obtained in this way [62]:

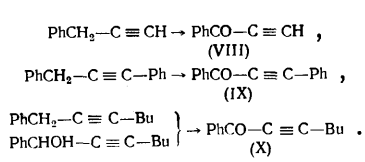


The oxidation of α-glycols with lead tetra-acetate also takes place relatively easily [65]. It is sufficient to heat the diol for 2–3 h to 60–65°C in glacial acetic acid with a 20% excess of the oxidising agent [66,67]:

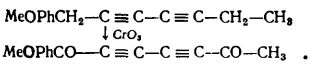


Depending on the structure of the initial glycol, it is possible to obtain by this method both aldehydes and ketones [68]. The method cannot be regarded as preparative, but it is very convenient for the identication and the demonstration of the structures of organic substances.

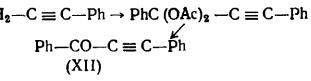
Iwai and Okajima [69-71] introduced the carbonyl group into acetylenic compounds by direct oxidation of the propargylmethylene group with selenium dioxide. Ethynyl ketones (VIII), (IX), and (X) were obtained by prolonged refluxing of the hydrocarbon with sublimed selenium dioxide in alcohol or in a 1 : 1 alcohol–dioxan mixture.



The reaction takes place more unambiguously and a smaller number of side products are formed when the propargylmethylene group is activated by other multiple bonds. By selecting the experimental conditions, the reaction can be stopped at the stage involving the formation of the carbinol [69,70]. On the other hand, there are indications in the literature that primary and secondary ethynyl alcohols can be oxidised to the corresponding ketones and aldehydes [71,72]. The yields of the required products vary in the range 5–27%. Despite its apparent simplicity, the method has not found wide application because of the toxicity of selenium dioxide and the difficulty of obtaining the initial acetylenic hydrocarbons. Together with selenium dioxide, chromium trioxide in acetic acid [73] and lead tetra-acetate [74] have been used to oxidise the propargylmethylene group:

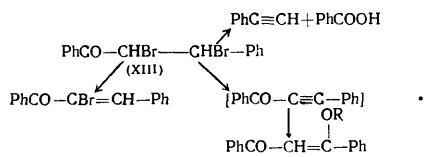


Benzylethynyl hydrocarbons exchange the hydrogen atom activated by the adjacent triple bond and the phenyl ring for the acetoxy-group on treatment with lead tetra-acetate. Thus the interaction of triphenylpropyne with lead tetra-acetate in acetic acid at 100°C gave the diacetate (XI), which was hydrolysed to diphenylpropynone (XII) by refluxing with a solution of sodium carbonate:

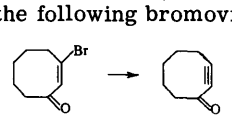


III. THE DEHYDROHALOGENATION REACTION

The most widely employed method of synthesis of ethynyl compounds is dehydrohalogenation of halogeno-derivatives. However, in the series of ethynylcarbonyl compounds the application of this method is very limited because of the exceptional reactivity of the α-ethynylcarbonyl group. The triple bond of α-ethynyl ketones is highly activated by the adjacent carbonyl group and readily undergoes various nucleophilic addition reactions [75,76]. The dehydrohalogenation of dihalogeno-derivatives is performed using alcoholic solutions of alkalis or sodamide in liquid ammonia. These methods, with few exceptions, are unsuitable for the synthesis of ethynyl ketones. In 1904 Watson [77] attempted to prepare phenylbenzoylacetylene from dibromobenzylideneacetophenone and α-bromobenzylideneacetophenone. He found that, when the halogeno-ketone (XIII) is treated with alcoholic alkali, the reaction takes place in different ways depending on the conditions:



Under mild conditions, the reaction does not go to completion. Only one molecule of hydrogen bromide is dissociated from dibromobenzylideneacetophenone. After prolonged refluxing, the alcohol addition product, β-ethoxybenzylideneacetophenone, was isolated. The reaction does not occur in water and, when attempts are made to split off hydrogen bromide with solid alkali, the molecule is cleaved into phenylacetylene and benzoic acid [78]. Under the action of potassium carbonate, it was possible to dehydrobrominate the following bromovinyl ketones [79]:



Dehydrohalogenation with pyridine and sodium acetate stops at the stage involving the formation of the monohalogeno-derivative [80]. When the monobromo-ketones are treated with ammonia and primary or secondary amines,

the halogen is usually substituted by an amino-group. On the other hand, after dehydrochlorination of the β-chlorovinyl ketone (XIV) with sodamide in liquid ammonia, the ethynyl ketone (XV) was isolated[81]:

$$\underset{\text{(XIV)}}{\text{R—CO—CH=CHCl}} \rightarrow \underset{\text{(XV)}}{\text{R—CO—C}\equiv\text{CH}} .$$

R= ferrocenyl

Reactions involving addition to the triple bond can be avoided in certain cases when the dehydrohalogenation is carried out with a base in solvents such as benzene or acetone[78,82]. The use of triethylamine in benzene or in acetone permits the synthesis of dibenzoylacetylene from the dibromide (XVI)[82] in 82–95% yield and also from the monochloride (XVII)[83]:

$$\left.\begin{array}{l}\text{ArCO—CHBr—CHBr—CO—Ar}\\ \text{(XVI)}\\ \text{Ar—CO—CCl=CH—CO—Ar}\\ \text{(XVII)}\end{array}\right\} \rightarrow \text{ArCO—C}\equiv\text{C—CO—Ar} .$$

It is noteworthy that Japanese chemists[84] succeeded in obtaining ethynyl phenyl ketone in the usual way by the dehydrochlorination of the dichloro-derivative with alcoholic alkali, the mixture being refluxed for 5 h. However, these results are somewhat doubtful.

Compounds with a protected carbonyl group are more successfully dehydrohalogenated. Claisen obtained the first ethynyl aldehyde as early as 1896 by the dehydrobromination of the dimethylacetal of dibromopropionaldehyde[85]:

$$\text{R—CHBr—CHBr—CH(OR')}_2 \xrightarrow[\text{ROH}]{\text{KOH}} \text{R—C}\equiv\text{C—CH(OR')}_2 \xrightarrow{\text{H}_3^+\text{O}} \text{R—C}\equiv\text{C—CHO} .$$

Subsequently this method became one of the principal procedures for the synthesis of α-ethynyl aldehydes[86–90]. The protective acetal group prevents side reactions and its removal by hydrolysis in an acid medium does not involve any special complications[91].

IV. INTERACTION OF METAL ACETYLIDES AND IOTSICH REAGENTS WITH ACID DERIVATIVES

1. Reaction of Metal Acetylides and Iotsich Reagents with Acid Halides

Until the 1940's ethynyl ketones were obtained mainly by the condensation of alkali metal acetylides and acid halides. Thus in 1899 Nef[92] was the first to obtain phenylacetylacetylene and phenylbenzoylacetylene by the action of sodium phenylacetylide in ether on acetyl and benzoyl chlorides respectively:

$$\text{R—COCl} + \text{NaC}\equiv\text{C—Ph} \rightarrow \text{R—CO—C}\equiv\text{C—Ph} ,$$

where R = methyl or phenyl.

Later this reaction was extended to other acetylenic hydrocarbons and acid halides[93–96]. Sodium, potassium, and lithium acetylides were employed. Sodium phenylacetylide proved to be convenient for preparative purposes. In some cases acid bromides react under milder conditions than the corresponding acid chlorides[2,96,97]. It has been shown[93] that the reaction of sodium phenylacetylide with benzoyl chloride is complicated by side reactions. The ethynyl ketone formed reacts readily with a second molecule of acetylide, yielding the corresponding tertiary carbinol. For this reason, the method gives unsatisfactory yields of the desired products, which are contaminated by carbinols and halogeno-compounds. Good results were achieved only in the synthesis of relatively unreactive nitroarylethynyl ketones and similar compounds[98,99]:

$$\text{m-NO}_2\text{C}_6\text{H}_4\text{COCl} + \text{NaC}\equiv\text{C—Ph} \rightarrow \text{m-NO}_2\text{C}_6\text{H}_4\text{CO—C}\equiv\text{C—Ph} ,$$

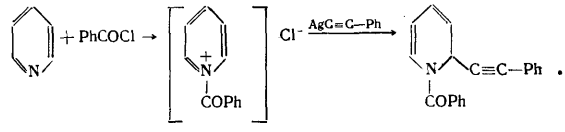
$$\text{m-NO}_2\text{C}_6\text{H}_4\text{C}\equiv\text{C—COCl} + \text{NaC}\equiv\text{C—Ph} \rightarrow \text{m-NO}_2\text{C}_6\text{H}_4\text{C}\equiv\text{C—CO—C}\equiv\text{C—Ph} .$$

The attempt to prepare the symmetrical ketone from sodium ethylacetylide and phenylpropiolic acid chloride was unsuccessful[100]. However, Chauvelier[24], who carried out this reaction with care, succeeded in synthesising 1,5-diphenylpenta-1,4-diyn-3-one, which was characterised as the hydrazone. In 1936 Kroeger and Nieuwland showed that the substitution of metal acetylides by the Iotsich reagent gives more satisfactory results[101]. It is best to employ ethynylmagnesium chloride derivatives; these are less reactive than the analogous bromides and iodides, which readily take part in secondary reactions[102–104]. The use of silver acetylides, which do not interact with the carbonyl group, excludes the possibility of the appearance of side products. By heating silver phenylacetylide with benzoyl chloride, Nef[92] obtained 1,3-diphenylprop-1-yn-3-one in a high yield. It is more convenient to carry out this reaction with silver derivatives soluble in carbon tetrachloride, chloroform, or benzene. In some cases the normal course of the reaction requires the addition of aluminium chloride[105]. The same paper describes the synthesis of halogenoethynyl ketones from silver acetylides and halogeno-carboxylic acid chlorides:

$$\text{X—CH}_2\text{COCl} + \text{AgC}\equiv\text{C—R} \rightarrow \text{X—CH}_2\text{CO—C}\equiv\text{C—R},$$

where X = Cl or Br and R = C_4H_9 or C_6H_{13}.

The synthesis of these ketones from sodium acetylides results in very low yields. Silver acetylides are much more soluble in pyridine[106] but the reaction in this solvent mainly gives rise to the formation of *N*-acyl-2-alkynyl-2-dihydropyridine:



The possibility of preparing α-ethynyl ketones by the reaction of copper acetylides with acid halides is of some interest[107]. The authors determined the conditions under which the desired products are formed with very satisfactory yields (up to 45%):

$$\text{PhCOCl} + \text{CuC}\equiv\text{C—Ph} \rightarrow \text{PhCOC}\equiv\text{C—Ph} .$$

Organozinc and organocadmium compounds, which have found wide application in the synthesis of saturated and vinyl ketones, are more promising in this type of process. The attempts to extend this method to ethynyl ketones proved to be unsuccessful[108] and only in recent years has it been established[109] that phenyl- and vinyl-acetylenes form ethynylzinc iodides by the reaction with solutions of alkylzinc iodides. The reaction of ethynylzinc iodides with aliphatic and aromatic acid chlorides gives rise to the corresponding ethynyl ketones. The reaction involves considerable charring, which is reduced when ethynylzinc chlorides are employed. The yields of ketones reach 40–70%. Similar results were obtained with ethynylcadmium halides[110]. The ethynylcadmium halide reagent was obtained by the action of cadmium chloride on the ethylnylmagnesium halide derivative. The reagent thus formed reacts with mono- and di-carboxylic acid chlorides, giving rise to the formation of ethynyl ketones in 40–70% yield. Ethynyl ketones were obtained similarly from an ethynyllead reagent[111].

Recently Gavrilenko et al.[112] suggested that complex aluminium acetylides, which can be readily obtained from lithium, potassium, or sodium aluminium hydrides and monosubstituted acetylenes in tetrahydrofuran, diglyme [2-methoxyethyl ether (Ed. of Translation)], or pyridine, be used for the synthesis of ethynyl ketones:

$$MAlH_4 + RC{\equiv}CH \rightarrow MAl(C{\equiv}C{-}R)_4 + 4H_2 \ .$$
(XVIII)

Under certain conditions, the complex acetylides (XVIII) are formed strictly selectively without the addition of lithium aluminium hydride to the triple bond. The interaction of complex aluminium acetylides with acid chlorides is carried out at 29–40°C and with acid anhydrides at 70°C:

$$MAl(C{\equiv}C{-}R)_4 \xrightarrow{R'COCl} R'CO{-}C{\equiv}C{-}R$$
$$MAl(C{\equiv}C{-}R)_4 \xrightarrow{(R''CO)_2O} R''CO{-}C{\equiv}C{-}R \ .$$

When the temperature is raised in excess of the above limits, charring becomes more extensive and the yields of ethynyl ketones, which even under optimum conditions are only 20–40%, are reduced. Thus this method is hardly likely to find wide application.

2. Interaction of Alkali Metal Acetylides and Iotsich Reagents with Acid Anhydrides

Although as early as 1899, Nef[92] indicated the possibility in principle of synthesising ethynyl ketones from sodium acetylides and acetic anhydride, it was not until 1936 that Kroeger and Nieuwland[101] made a detailed study of this reaction and demonstrated the advantage of anhydrides over acid chlorides. It was established that much better results are achieved, as with acid chlorides, when Iotsich reagents are employed instead of alkali metal acetylides. The relatively unreactive ethynylmagnesium chlorides are preferable to the bromides and iodides, which largely favour the occurrence of side reactions involving the formation of ethynyl carbinols:

$$(CH_3CO)_2O + R{-}C{\equiv}C{-}MgCl \rightarrow R{-}C{\equiv}C{-}CO{-}CH_3 \ .$$

The yields of ethynyl ketones in this reaction are in the range 40–80%. According to Nieuwland, more satisfactory results are obtained in reactions with alkylacetylenes when the anhydride is added to the Iotsich reagent at −25°C. When condensations of this kind are carried out in the range between −50° and −70°C, the yields of the desired products are improved[113–115]. When the reaction is carried out at room temperature, the reagents must be mixed in the reverse order (i.e. ethynylmagnesium halide must be added carefully to the anhydride) to prevent more completely the occurrence of side effects. This method was used successfully in the synthesis of ethynyl ketones with aliphatic substituents[113,114,116–118] and cycloalkyl-[119,120], silylethynyl-[115,121], and asymmetric vinylethynyl-carbonyl compounds[122].

The reaction of sodium acetylides with acid anhydrides yields the corresponding ketones, but there are many exceptions[123]. Symmetrical vinylethynyl ketones (XIX) were obtained in satisfactory yields from the anhydrides of cinnamic, crotonic, succinic, and maleic acids and sodium phenylacetylide[108,109]:

$$\begin{matrix} PhCH{=}CH{-}CO \\ \qquad\quad O + NaC{\equiv}C{-}Ph \rightarrow PhCH{=}CH{-}CO{-}C{\equiv}C{-}Ph \ . \\ PhCH{=}CH{-}CO \end{matrix}$$
(XIX)

The attempt to obtain the analogous ketones from the anhydride of acrylic acid and ethynylmagnesium chlorides or lithium acetylides was unsuccessful[124]. Either the starting materials were recovered unchanged or the yield of reaction products was unsatisfactory.

The use of lithium acetylides as the acetylenic component leads to the formation of tertiary ethynyl carbinols. The preferential formation of alcohols can be explained by the high solubility of the lithium complex in ether and its capacity for the ready formation of the ketone, the subsequent reaction of which with a second molecule of the acetylide no less readily gives rise to the ethynyl alcohol, which is undesirable in this case. However, in many studies it was noted that, when the condensation of lithium acetylides with acid anhydrides is carried out at temperatures of the order of −80°C, it is possible to stop the process at the stage where the carbonyl compound is formed[125]. The interaction of lithium acetylides with cyclic anhydrides of dicarboxylic aliphatic[126], alicyclic, and aromatic acids[127] leads to the formation of α-ethynyl keto-acids in high yields. The attempts to employ in this synthesis ethynylmagnesium bromides and the analogous ethynylmagnesium chlorides were unsuccessful.

In order to suppress the side reaction involving the formation of acetylenic hydroxy-acids, the condensation must be carried out at a temperature between −5° and 30°C.

3. Interaction of Nitriles, Amides, and Salts with Iotsich Reagents and Alkali Metal Acetylides

The method of preparation of saturated ketones from Grignard reagents and saturated nitriles is generally known. Ethynylmagnesium derivatives are much more reactive than the saturated and aromatic derivatives. However, even these yield the corresponding ethynyl ketones on reaction with aliphatic and aromatic acid nitriles and amides. Thus diphenylpropynone was obtained by the reaction of phenylethynylmagnesium bromide with benzonitrile[128]. On the other hand, Iotsich reagents do not react either with acetonitrile or acetamide[101]. The nitriles of substituted propiolic acid react fairly less readily with ethynylmagnesium compounds, giving high yields of diethynyl ketones[129]:

$$R{-}C{\equiv}C{-}CN + R'{-}C{\equiv}C{-}MgBr \rightarrow RC{\equiv}CC(=NMgBr)C{\equiv}CR' \xrightarrow{H_2O} RC{\equiv}CCOC{\equiv}CR' \ .$$

In a study of the reaction between a Grignard reagent and the nitrile of β-bromocrotonic acid, Boularand and coworkers showed that the reaction involves an elimination–addition mechanism[130]:

$$CH_3CBr{=}CH{-}CN \xrightarrow{RMgX} CH_3{-}C{\equiv}C{-}CN \xrightarrow{RMgX}$$
$$CH_3{-}C(R){=}CHCN + CH_3{-}C{\equiv}C{-}CO{-}R \ ,$$

where R = methyl or ethyl.

The use of aromatic organomagnesium compounds makes it possible to obtain as the sole reaction product arylated nitriles of the type $CH_3{-}C(Ar){=}CH{-}CN$. The reaction of β-mesityl-β-methoxyacrylonitrile with phenylmagnesium bromide involves a 1,2-addition mechanism with formation of benzoylmesitylacetylene[131].

In 1903 a method was proposed for the synthesis of saturated aldehydes from disubstituted formamides and Grignard reagents [132]. Later this method found fairly wide application for the syntheses of aldehydes of the ethynyl [63,133] and vinylethynyl series [134]:

$$R{-}C{\equiv}CMgBr + (CH_3)_2NCHO \rightarrow R{-}C{\equiv}C{-}CH\,N(CH_3)_2OMgBr \xrightarrow{H_2O+} R{-}C{\equiv}C{-}CHO\,.$$

The reaction of acetamides with ethynylmagnesium bromides yields the corresponding ethynyl ketones [135]. Anomalies were observed in this reaction. For example, Viguer [136], in his attempt to obtain tetrolic aldehyde from diethylformamide and propynylmagnesium bromide, obtained 4-diethylaminohepta-2,5-diyne by the reaction:

$$HCON(C_2H_5)_2 + CH_3C{\equiv}CMgBr \rightarrow CH_3C{\equiv}C{-}\underset{\displaystyle OMgBr}{\underset{|}{CH}}{-}N(C_2H_5)_2 \xrightarrow{CH_3C{\equiv}CMgBr} \rightarrow CH_3C{\equiv}C{-}\underset{\displaystyle N(C_2H_5)_2}{\underset{|}{CH}}{-}C{\equiv}C{-}CH_3\,.$$

As in the case where the Iotsich reagent is employed, the reaction of heptynyl-lithium bromide with acetamide does not yield ethynyl ketones, the acetylenic hydrocarbon being regenerated [101].

Vinylamino-ketones (XX) and vinylamino-aldehydes (XXI), which are vinylogues of carboxylic acid amides, react with Iotsich reagents via the following mechanism:

$$R{-}C{\equiv}CMgBr + \underset{R'}{\overset{R'}{>}}N{-}CH{=}CH{-}CO{-}R'' \rightarrow R{-}C{\equiv}C{-}CH{=}CH{-}CO{-}R'',$$

(XX)

$$R{-}C{\equiv}C{-}MgBr + \underset{Me}{\overset{Ph}{>}}N{-}CH{=}CH{-}CHO \rightarrow R{-}C{\equiv}C{-}CH{=}CH{-}CHO\,,$$

(XXI)

yielding vinylethynylcarbonyl compounds [137,138].

Salkind [139] established that aldehydes and ketones may be prepared by the reaction between Grignard reagents and anhydrous salts of formic and acetic acids. Later this reaction was used to synthesise ethynylcarbonyl compounds. Thus in the reaction with methylmagnesium iodide sodium phenylpropiolate is converted into phenylacetylacetylene [140]. A similar result was obtained in the reaction of an excess of methyl-lithium with free propiolic acid [141]. Phenylmagnesium bromide and phenyl-lithium do not enter into this reaction. In this case the yields of ketones are usually lower than when acid chlorides, amides, and nitriles are employed and therefore the reaction has not been used for preparative purposes.

4. Interaction of Iotsich Reagents and Ethynyl Derivatives of Alkali Metals with Esters

Usually the reaction of formic acid esters with Grignard reagents yields secondary alcohols. However, Gattermann [142], who used an excess of the ester, cooled the system intensively, and mixed the reagents in the reverse sequence, succeeded in driving the process towards the formation of aldehydes. Under similar experimental conditions, Iotsich reagents can be used successfully because of their relatively lower reactivity [143]. Formate esters react with equimolar amounts of alkali metal acetylides to form the corresponding aldehydes [144-146], but this synthesis is relatively inconvenient, since, even when the experimental conditions are rigorously maintained, ethynyl aldehydes are formed in a mixture with alcohols and the yield does not exceed 30%. Iotsich [146-149] made a fairly detailed study of the interaction between carboxylic acid esters and ethynylmagnesium derivatives:

$$CH_3COOC_2H_5 + R{-}C{\equiv}CMgBr \rightarrow R{-}C{\equiv}C{-}CO{-}CH_3 \xrightarrow{R{-}C{\equiv}CMgBr} \rightarrow (R{-}C{\equiv}C)_2C(OH){-}CH_3\,.$$

The primary reaction products are ketones. With ethyl acetate and higher carboxylic acid esters, ketones could not be isolated and therefore the sole reaction products were tertiary diethynyl alcohols [150-152]. Condensation of ethynylmagnesium compounds with ethyl benzoate also yields ethynyl carbinols [153]. Esters of acids with a triple bond, including the α-position, behave similarly. Ethyl phenylpropiolate reacts in this way with methylmagnesium iodide, phenylmagnesium bromide [140], and tolylmagnesium bromide [154]:

$$PhC{\equiv}C{-}COOC_2H_5 + 2\,CH_3MgI \rightarrow PhC{\equiv}C{-}\underset{\displaystyle OH}{\underset{|}{C}}(CH_3)_2\,.$$

On the other hand, Hurd [155], who started with ethyl phenylpropiolate and phenylmagnesium bromide, obtained 1,3-diphenylprop-1-yn-3-one in 85% yield. The interaction of ethyl cinnamate with sodium phenylacetylide gives rise to the ethynyl vinyl ketone (XXII) [156]:

$$PhCH{=}CH{-}COOC_2H_5 + PhC{\equiv}CNa \rightarrow \underset{(XXII)}{PhCH{=}CH{-}CO{-}C{\equiv}C{-}Ph}\,.$$

However, the formation of compound (XXII) has been inadequately demonstrated, since the analogous ketone obtained from cinnamic acid anhydride and sodium phenylacetylide differs sharply from it in its physical constants and chemical properties [109]. The reaction of oxalic esters with Iotsich reagents has been successfully used to synthesise the esters of ethynyl keto-acids [157]:

$$R{-}C{\equiv}C{-}MgBr + C_2H_5OOC{-}COOC_2H_5 \rightarrow R{-}C{\equiv}C{-}CO{-}COOC_2H_5\,.$$

The method of synthesis is simple and convenient, consisting in mixing the ethereal solutions of equimolar amounts of alkyl- or aryl-ethynylmagnesium bromides and oxalic acid esters at a temperature not exceeding 5°C. When the alkoxy-group in the ester becomes more complex, the yield of reaction products increases.

5. Synthesis of Ethynyl Ketals and Acetals and Their Hydrolysis to Ethynyl Ketones and Aldehydes

Chichibabin [158] and Bodroux [159] showed that the orthoformic ester reacts with organomagnesium derivatives to form acetals. This reaction is one of the best procedures for the preparation of aldehydes by the Grignard reaction and is superior as regards yields and the availability of the reactants to other methods of synthesis of aldehydes (from carboxylic acid esters, formic acid salts, amides, etc.). The orthoformic acid ester reacts smoothly with an equimolar amount of the Iotsich reagent, forming ethynyl acetals in yields of 75–80%: [143,160-162]

$$R{-}C{\equiv}CMgBr + HC(OR')_3 \rightarrow R{-}C{\equiv}C{-}CH(OR')_2 \xrightarrow{H_2O^+} R{-}C{\equiv}C{-}CHO\,.$$

In the decomposition of the organomagnesium complex either the acetal or the ethynyl aldehyde directly can be isolated, depending on the conditions. The reaction of

ethynylenedimagnesium dibromide with orthoformate constitutes a simple and convenient synthesis of the diacetal of butynedial[163]:

$$BrMgC{\equiv}C{-}MgBr + HC(OR)_3 \rightarrow \underset{(XXIII)}{(RO)_2HC{-}C{\equiv}C{-}CH(OR)_2} \xrightarrow{H^+} \underset{(XXIV)}{OHC{-}C{\equiv}C{-}CHO}.$$

Satisfactory results were obtained when the reaction was carried out in benzene. In ether the diacetal (XXIII) could be obtained only after refluxing for several days. The isolation of the acetylene–dialdehyde (XXIV) is difficult because of its low stability. Acetals of vinylethynyl aldehydes were synthesised by the same method[164]:

$$R{-}CH{=}CH{-}C{\equiv}CMgBr + HC(OR')_3 \rightarrow \underset{(XXV)}{R{-}CH{=}CH{-}C{\equiv}C{-}CH(OR')_2} \xrightarrow{H_2^+O} \rightarrow R{-}CH{=}CH{-}C{\equiv}C{-}CHO,$$

where R = H or alkyl.

In the hydrolysis of the acetals of vinylethynyl aldehydes (XXV) with 3% hydrochloric acid extensive charring is observed. Gusev and Kucherov showed[165,166] that the optimum conditions for the hydrolysis of the acetal (XXVI) of diacetylene-aldehyde are achieved by brief refluxing of compound (XXVI) with dilute hydrochloric acid in dioxan. The extreme lability of the aldehyde (XXVII) precludes its isolation in a pure form:

$$\begin{aligned} &H_3C\diagdown\ \ C(OH){-}C{\equiv}C{-}C{\equiv}CH + HC(OR_3) \rightarrow \ H_3C\diagdown\ \ C{-}C{\equiv}C{-}CH(OR)_2 \rightarrow \\ &H_3C\diagup\ H_3C\diagup OH \\ &\xrightarrow{KOH} \underset{(XXVI)}{HC{\equiv}C{-}C{\equiv}C{-}CH(OR)_2} \xrightarrow{H^+} \underset{(XXVII)}{HC{\equiv}C{-}C{\equiv}C{-}CHO}. \end{aligned}$$

When lithium or sodium phenylacetylide was allowed to react with the acetal of α-bromoacetaldehyde, the acetal of 4-phenylbut-3-ynal was obtained[167]:

$$PhC{\equiv}CLi + BrCH_2CH(OR)_2 \rightarrow PhC{\equiv}C{-}CH_2CH(OR)_2 \xrightarrow{H^+} PhC{\equiv}C{-}CH_2CHO.$$

Howk[168] proposed a single-stage catalytic synthesis of acetals and ketals from readily available starting materials—monosubstituted acetylenes and orthoformic esters:

$$R{-}C{\equiv}CH + HC(OR')_3 \xrightarrow{ZnX_2} R{-}C{\equiv}C{-}CH(OR')_2.$$

The suggested mechanism is as follows:

$$HC(OR)_3 + ZnX_2 \rightarrow [HC^+(OR)_2] + [ZnX_2OR^-]$$

$$HC{\equiv}CR'$$

$$\left[RO\diagdown\ \ C\diagup\ \ \overset{+}{C}H{\equiv}CR'\ \ \ H\ \ OR\right] + ZnX_2OR^- \rightarrow R'{-}C{\equiv}C{-}CH(OR)_2 + ZnX_2 + ROH.$$

The best catalysts proved to be zinc chloride, iodide, and nitrate, and also cadmium iodide. Orthoformate, orthoacetate, and orthovalerate were used as the ester components. The method of synthesis is simple, the yields of acetals and ketals varying in the range 15–80%.[169]

The acetal of tetrolic aldehyde can be obtained by treating diacetylene with ethanol and potassium hydroxide under the conditions of Favorskii's reaction[170]. When the reaction mixture is heated to 100°C, ethyl β-ethynylvinyl ether (XXVIII) is formed. The acetals are produced in appreciable amounts only at temperatures above 130°C and also when the amount of alcohol is increased. The acetal (XXIX) isomerises to the acetal of tetrolic aldehyde by the mechanism discovered by Favorskii for acetylenic hydrocarbons:

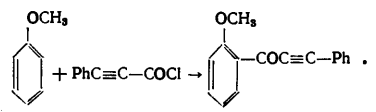
$$HC{\equiv}C{-}C{\equiv}CH{-} \begin{cases} \xrightarrow{100^\circ} \underset{(XXVIII)}{HC{\equiv}C{-}CH{=}CHOEt} \\ \xrightarrow{>130^\circ} HC{\equiv}C{-}CH_2{-}CH(OEt)_2 \xrightarrow{KOH} CH_3C{\equiv}C{-}CH(OR)_2. \end{cases}$$

(XXIX)

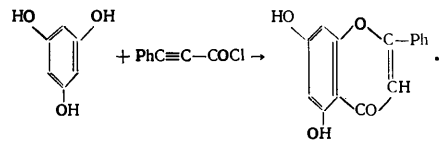
The hydrolysis of the acetals to aldehydes[91] by dilute inorganic acids causes extensive polymerisation. It has been found[171-173] that, when acetals of acetylenic aldehydes are heated with oxalic acid, it is possible to obtain aldehydes in yields of the order of 35%. Even better results are achieved when acetals are refluxed with aqueous tartaric acid with subsequent elimination using calcium chloride of the alcohol formed simultaneously. In this case the yield of tetrolic aldehyde rises to 55%.

V. ACYLATION OF AROMATIC COMPOUNDS BY ACETYLENECARBOXYLIC ACID CHLORIDES UNDER THE CONDITIONS OF THE FRIEDEL–CRAFTS REACTION

The Friedel–Crafts reaction, discovered as early as 1877, is in important method for the preparation of aromatic ketones. Its detailed and extensive study established that acylation with aliphatic carboxylic acids, their chlorides, and anhydrides is possible for a wide variety of aromatic compounds—benzene and its homologues, naphthalene and its derivatives, and also a number of heterocycles. The Friedel–Crafts reaction with the chlorides of $\alpha\beta$-unsaturated acids has been less well investigated. Experiments have shown that the acylation of aromatic compounds by the chlorides of acetylenecarboxylic acids has many limitations. The first such synthesis, carried out by Gatterman, was the acylation of anisole with the chloride of phenylpropiolic acid[174]:



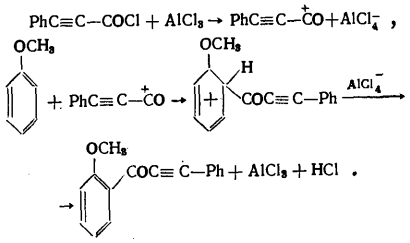
Seka and Prosche[175] also successfully employed the Friedel–Crafts condensation of phenylpropiolic acid and polyhydric phenols for the direct synthesis of hydroxyflavones:



The attempt to carry out this reaction with benzene did not result in the formation of ethynyl ketone[77]. The reported synthesis of tetradecylbenzoylacetylene under analogous conditions is doubtful[176].

The different behaviour of benzene, anisole, and phenols is probably associated with the electronic nature of the methoxy- and hydroxy-groups. If one remembers that the mechanism of this condensation includes a stage in which an acylcarbonium ion is formed with subsequent attack by the latter on the position in the benzene ring with the highest electron density then the promoting effect of HO and CH_3O groups on the acylation process becomes understandable. Other substituents with a $+I$ effect,

leading to an increase of electron density in *ortho*- and *para*-positions, should have a similar effect:



This hypothesis is confirmed by the exceptional ease of the acylation of *p*-methylanisole with the chloride of phenylpropiolic acid[177]. It is interesting that the reaction with an excess of aluminium chloride leads to the formation of chlorination products only.

The above methods of synthesis of ethynyl ketones have not found extensive application.

VI. HYDRATION OF POLYETHYNYL COMPOUNDS

The hydration of polyethynyl compounds has been investigated in fair detail. It is known[178,179] that in the presence of mercury(II) salts the addition of water to polyacetylenes takes place with participation of all the triple bonds and leads to the formation of a mixture of polyketones. However, as early as 1892, Griner[180] obtained by the hydration of hexa-2,4-diyne in the cold in the presence of aqueous sulphuric acid a substance to which he ascribed the structure of a β-ethynyl ketone (XXX):

$$CH_3C{\equiv}C{-}C{\equiv}C{-}CH_3 \rightarrow CH_3CO{-}CH_2C{\equiv}C{-}CH_3 .$$
(XXX)

Later Bohlmann et al.[181] established on the basis of the infrared spectra of the ketones and their hydrazones that the product of the addition of water to dimethyldiacetylene is an α-ethynyl ketone. Di-t-butylacetylene reacts with water slowly, probably due to steric hindrance. Under analogous conditions, the corresponding α-pentadiynyl ketone (XXXI) was obtained from octatriyne:

$$CH_3{-}C{\equiv}C{-}C{\equiv}C{-}C{\equiv}C{-}CH_3 \xrightarrow[H_2SO_4]{H_2O} CH_3C{\equiv}C{-}C{\equiv}C{-}CO{-}C_2H_5 .$$
(XXXI)

When an attempt is made to hydrate tetra-acetylene, the latter breaks down completely. By hydrating asymmetric triacetylenes (XXXII), it is possible to form isomeric ethynyl ketones [(XXXIII) and (XXXIV)]:

$$(CH_3)_2CH{-}C{\equiv}C{-}C{\equiv}C{-}C{\equiv}C{-}CH_3 \text{ (XXXII)} \rightarrow \begin{cases} (CH_3)_2CH{-}C{\equiv}C{-}CO{-}CH_2{-}CH_3 \text{ (XXXIII)} \\ (CH_3)_2CH{-}CH_2{-}CO{-}C{\equiv}C{-}CH_3 \text{ (XXXIV)} \end{cases} .$$

By analysing the NMR spectra of the hydration products of isopropylmethyldiacetylene, Petrov et al.[182] established that these are a mixture of compounds (XXXIII) and (XXXIV) with the latter predominating. It has been established chromatographically that the ketones (XXXIV) and (XXXIII) are formed in proportions of 9 : 1. Petrov et al. deduced a general rule governing the addition of water to asymmetric diacetylenes on the basis of the hyperconjugation effect of substituents, which varies in the series $CH_3 > CH(CH_3)_2 > C(CH_3)_3$.

The spreading of the hyperconjugation effect over a conjugated system, which determines the mode of addition, is respresented as follows:

$$CH_3{-}C{\equiv}C{-}C{\equiv}C{-}CH(CH_3)_2 .$$

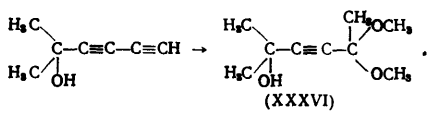
Consequently the hydration of isopropylmethyldiacetylene should involve preferentially the triple bond adjacent to the isopropyl group, since it is precisely this bond that has the highest electron density. Depending on the hydration conditions, diacetylenic hydrocarbons are capable of being converted into diketones and further into 2,5-disubstituted furans[183].

Gorn and Gorin investigated the hydration of diacetylene over a cadmium phosphate–calcium phosphate catalyst in the gas phase[184]. The liquid-phase hydration of diacetylene in an acid medium in the presence of mercury salts is known to result in the formation of diacetyl. German investigators[185] concluded that, together with diacetyl, another product is ethynyl methyl ketone (XXXV), which becomes wholly polymerised under the conditions of this reaction:

$$HC{\equiv}C{-}C{\equiv}CH \rightarrow [HC{\equiv}C{-}CO{-}CH_3] \rightarrow H_3C{-}CO{-}CO{-}CH_3 .$$
(XXXV)

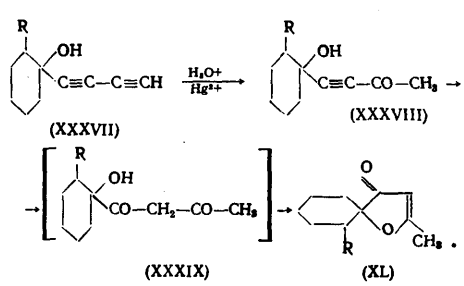
The vapour-phase hydration of diacetylene yields the same results. The authors propose a hydration mechanism similar to that described above. They infer indirectly the intermediate formation of ethynyl methyl ketone from an appreciable amount of a polymeric deposit on the catalyst.

Acid-catalysed hydration may be used to synthesise ethynyl ketones with a monosubstituted triple bond. Sokolov and Petrov[186] obtained propionyl- and butyryl-acetylenes from penta-1,3-diyne and hex-1,3-diyne respectively. Water then adds to the triple bond adjacent to the alkyl substituent. On the other hand, the reaction of 5-methylhexa-1,3-diyn-5-ol with methanol in the presence of mercury salts results in the formation of the dimethylketal of 5-hydroxy-5-methylhex-3-yn-2-one (XXXVI):[187]



(XXXVI)

Volkov et al.[188] and Gusev et al.[189] studied the hydration of tertiary diacetylenic alcohols (XXXVII) in alkaline and acid media and the choice of conditions for the selective involvement of the triple bond of the alcohols (XXXVII) under the conditions of this reaction:



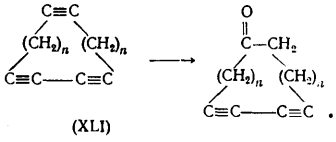
(XXXVII) (XXXVIII) (XXXIX) (XL)

Gusev et al.[189] found that the sole reaction products in an acid medium are the dihydrofuranones (XL) formed via the cyclisation of the intermediate β-diketones (XXXIX).

After a thorough study of the hydration of diacetylenic alcohols in an acid medium[188], it was concluded that the reaction takes place in stages. It is believed that the

principal primary products are ethynyl ketones (XXXVIII), which were isolated in good yields.

Under the conditions of Kucherov's reaction, macrocyclic triacetylenes (XLI) very readily combine with water at the isolated triple bond[190]; the hydration of the conjugated triple bonds requires more severe conditions:



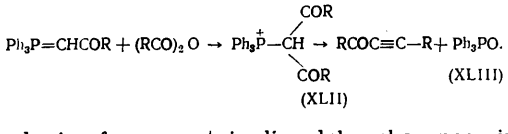
(XLI)

The hydration of acetylenes for preparative purposes is not particularly complicated and, if one remembers that at the present time there exist many methods for the synthesis of diacetylenic systems, one may hope that the above reaction will occupy an important place among the methods of synthesis of ethynyl ketones.

VII. OTHER SYNTHETIC METHODS

Apart from the general methods discussed in this review, there exist also many specific methods for the preparation of ethynyl ketones which are of value only in specific cases and have not found wide practical application.

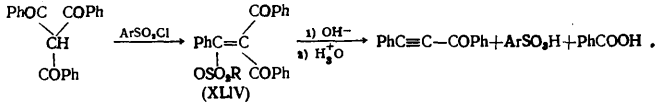
In recent years the intramolecular Wittig reaction has been widely used for the synthesis of various unsaturated compounds. Chopard et al.[191] used this method to prepare ethynyl ketones: on heating with acid anhydrides, stable phosphoranes with acyl substituents are acylated at the carbon atom adjacent to the phosphorus atom, forming diacylphosphoranes (XLII), the pyrolysis of which results in their conversion into ketones (XLIII) in high yields:



(XLII) (XLIII)

The pyrolysis of asymmetric diacylphosphoranes gives a mixture of ethynyl ketones. The yields of the desired products are 70–90%.

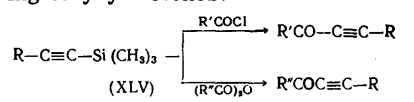
A novel method for the synthesis of ethynyl ketones was recently described by Brown and Harley-Mason[192]; under the action of an arenesulphonyl chloride, tribenzoylmethane is converted into the enolic ether (XLIV), which is converted by treatment with alkali in a dioxan–water mixture into phenylbenzoylacetylene and benzoic and arenesulphonic acids:



(XLIV)

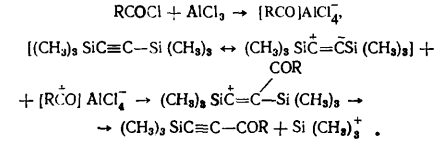
Bromobenzenesulphonyl and toluenesulphonyl chlorides may be used as the sulphonyl component.

We believe that the organosilicon synthesis of α-ethynylcarbonyl compounds by the method of Birkoffer[193] is promising. Bistrimethylsilylacetylene is known to be stable towards boiling water and alkali. Trimethylsilyl derivatives of hept-1-yne and hex-1-yne are also insensitive even to the action of inorganic acids. However, in the presence of aluminium chloride silylacetylenes (XLV) react with the chlorides and anhydrides of carboxylic acids, forming the corresponding ethynyl ketones:

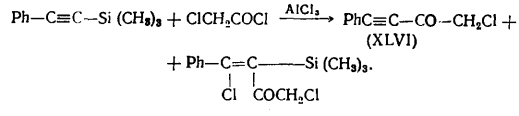


(XLV)

It is believed that the reaction has the following mechanism

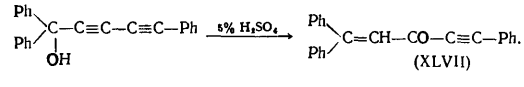


The synthesis is carried out at temperatures below 10°C in carbon disulphide or nitrobenzene. With the disilyl derivative of acetylene, only one trimethylsilyl group is replaced by an acyl residue. Usually the reaction takes place easily, ketones being formed in a yield of 40–90%. Only when chloroacetyl chloride is employed is the yield of the ketone (XLVI) reduced due to a side reaction involving its addition to the triple bond:



(XLVI)

Certain rearrangements of acetylenic carbinols leading to the formation of ketones undoubtedly merit attention. Thus, under the conditions of the Meyer–Schuster rearrangement, Cadiot and coworkers[194] obtained the ethynyl vinyl ketone (XLVII) from 1,1,5-triphenylpenta-1,3-diyn-5-ol:

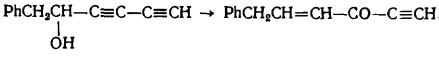


(XLVII)

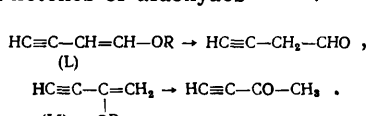
In the alkaline hydrolysis of the acetates of secondary diacetylenic carbinols (XLVIII), ethynyl vinyl ketones (XLIX) are formed instead of the respective alcohols[195]:

(XLVIII) (XLIX)

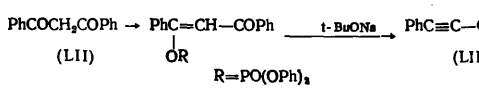
The authors believe that the diacetylenic carbinols formed are extremely stable in an alkaline medium and undergo a prototropic rearrangement. This hypothesis was confirmed by Kucherov[196]. On heating with a 3% alcoholic solution of potassium hydroxide, 6-phenylhexa-1,3-diyn-5-ol is readily converted into 6-phenylhex-3-en-1-yn-5-one:



The acid hydrolysis of alkoxyvinylacetylenes (L, LI) yields ethynyl ketones or aldehydes[197–200]:



Readily enolisable β-diketones (LII) can react smoothly with alcohols to form the corresponding enolic ethers[201], which are converted by alkaline hydrolysis into ethynyl ketones (LIII):[202]



(LII) (LIII)

Dibromotriphenylphosphorane is sometimes used as the esterifying agent[203] and the reaction is carried out in triethylamine:

$$PhCOCH_2COPh + Ph_3PBr_2 \rightarrow [PhC(OPPh_3)=CH-COPh]Br \rightarrow PhC\equiv C-COPh + Ph_3PO .$$

The interaction of diphenylketen with phenylethynylmagnesium bromide leads to the formation of ethynyl ketone (LIV):[204]

$$Ph_2C=C=O + PhC\equiv CMgBr \rightarrow Ph_2CH-CO-C\equiv C-Ph .$$

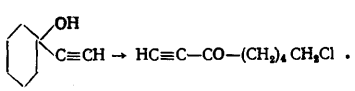
(LIV)

However, the reaction of diphenylketen with ethynylenedimagnesium dibromide led to a substance without the properties of ketones or the corresponding dienols[205].

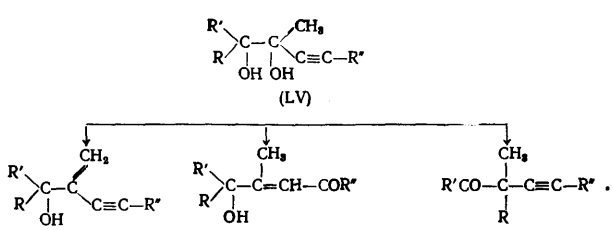
The method of synthesis of ethynyl ketones by the treatment of the sodium salt of acetylacetone with the chlorides of propiolic acids is noteworthy[206]:

$$PhC\equiv C-COCl + NaCH(COCH_3)_2 \rightarrow PhC\equiv C-CO-CH(COCH_3)_2 .$$

Good yields of monosubstituted ketones are quoted in a patent[207] where a method is proposed for the rupture of the cycloalkane ring in ethynyl alcohols with hypochlorous acid according to the following mechanism:



Recently a fairly detailed study was made of the isomerisation of various dihydroxyacetylenes to β-ethynyl ketones[208-215]. Numerous studies by Venus-Danilova and coworkers have been devoted to the elucidation of the reactions of acetylenic ditertiary α-glycols (LV) catalysed by sulphuric acid[210-214]. On heating with 20–40% sulphuric acid, these glycols are converted into compounds with the following structures:



(LV)

Usually the isomerisation takes place simultaneously via all three pathways. One of the reaction products is a β-ethynyl ketone. On the other hand, it has been stated that similar α-glycols (LVI) yield α-ethynyl ketones (LVII) after being passed over a dehydrating catalyst at 200–400 °C:[215]

The Chemistry of *O*-alkyl Derivatives of Lactams

R.G.Glushkov and V.G.Granik

The review gives a general account of the methods of synthesis and chemical properties of *O*-alkyl derivatives of lactams: lactim ethers, lactam acetals, and others. The reactions of *O*-alkyl derivatives of lactams with various nucleophilic and electrophilic reagents are described. Particular attention has been devoted to the possibility of using *O*-alkyl-lactams for the synthesis of various heterocyclic compounds which are of both chemical and biological interest. The bibliography includes 135 references.

I. INTRODUCTION

The chemistry of *O*-alkyl derivatives of lactams (lactim ethers and lactam acetals) constitutes one of the least investigated branches of the chemistry of lactams in general. The lactams themselves have already been the subject of many investigations in various branches of organic chemistry. In particular extensive and interesting studies have been made on the chemistry of β-lactams [1] (with the aim of investigating the structure and synthesis of penicillins), reactions involving the incorporation of hydroxy- and aminoacyl-groups into lactams with conversion of the latter into the corresponding cyclols, cyclodepsipeptides, or cyclopeptides [2,3], and particularly on the development of methods for the synthesis of lactams for the preparation of various polymeric materials.

An attempt has already been made to give a general account of the available data on the chemistry of lactams as a specific class of heterocyclic compounds [4].

One of the most promising pathways in the development of the chemistry of lactams is the synthesis of various classes of organic compounds on the basis of lactams, associated with the preliminary activation of their amide function [5]. Activation of this kind of functional groups in various organic compounds has already yielded extremely interesting results. It is sufficient to point out that the conversion of ketones into enamines [6] or of acid amides into imino-ethers [7] made it possible to employ these compounds in new, hitherto unknown ways. Similarly the conversion of lactams into lactim ethers and lactam acetals gives rise to new possibilities in the application of lactams in organic synthesis.

The chemical properties of lactim ethers have already been the subject of two short reviews [8,9] but the latter cannot be regarded as sufficiently complete. Lactam acetals have begun to be studied only in recent years and these investigations have not been reviewed at all.

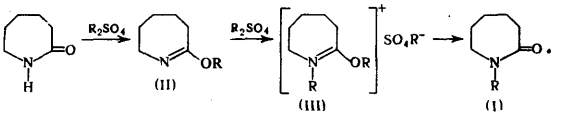
In the present review an attempt is made to give a general account of all the available data on the chemistry of *O*-alkyl derivatives of lactams in order to assess the advances in this field and the likely scope of the application of lactim ethers and lactam acetals in the synthesis of complex organic compounds.

One should also bear in mind that, apart from their use as starting materials for the synthesis of various organic compounds including dyes [10,11], lactim ethers are also of independent interest as biologically active materials [12] and also as accelerating agents in polymerisation processes [13].

II. METHODS OF SYNTHESIS OF LACTIM ETHERS

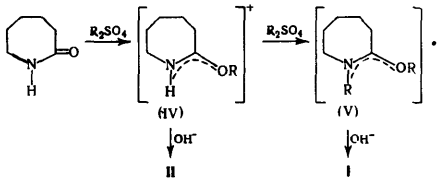
1. Direct Alkylation of Lactams

The methods for the preparation of lactim ethers by direct alkylation of lactams include the interaction of the latter with diazoalkanes [14] and also the alkylation of metal salts of lactams with alkyl halides [15]. Both methods are rarely used for the preparation of lactim ethers, since it is more convenient to use for this purpose the alkylation of lactams by dialkyl sulphates and trialkyloxonium fluoroborates. The alkylation of lactams by dialkyl sulphates was investigated in detail for caprolactam by Benson and Cairns [16], who established that this process depends to a considerable extent on the relative amounts of the components employed in the reaction. An excess of dialkyl sulphate leads, on the one hand, to a sharp reduction of the yield of lactim ethers due to the preferential formation of *N*-alkyl derivatives (I). On the other hand, the slow addition of an equimolar amount of an alkylating agent leads to an increase of the yield of *O*-alkylcaprolactim (II). The authors suggested that a considerable proportion of (I) is formed via compound (II) by the following hypothetical mechanism:



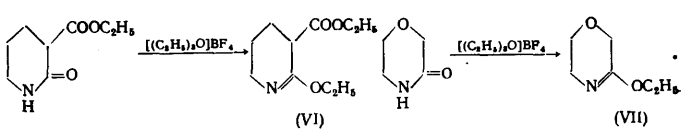
On the basis of the work of Bredereck and coworkers [17,18] on the reaction of acid amides with dimethyl sulphate, one may postulate that the ambidentate cation (IV) is formed

as an intermediate in this reaction and in the presence of an excess of dialkyl sulphate is alkylated further to the *NO*-dialkyl derivative (V). Under the influence of alkaline reagents, compounds (IV) and (V) are converted respectively into compounds (II) and (I). The conversion of compound (V) into (I) can also be achieved by heat treatment with elimination of dialkyl sulphate:

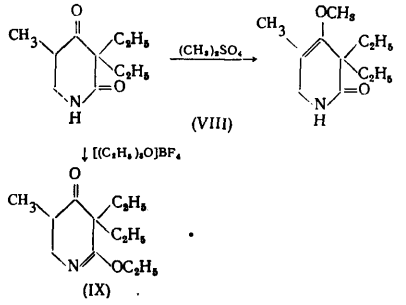


The method of Benson and Cairns is still used for the preparation of lactim ethers from the simplest lactams. However, recently another method of synthesis of lactim ethers has been acquiring increasing importance—alkylation of lactams by tertiary oxonium salts, in particular triethyloxonium fluoroborate [19,20]. This reaction involves the formation of an ambidentate cation, similar to the cation (IV), from which lactim ethers are also obtained by treatment with aqueous solutions of alkaline reagents. By virtue of their high electrophilicity, oxonium salts give better results than other alkylating agents [21].

It is noteworthy that in none of the numerous cases where equimolar amounts of trialkyloxonium fluoroborates were used to alkylate lactams [21-27] were *N*-alkyl derivatives isolated. This suggests the high selectivity of oxonium salts in such reactions. It is interesting that the high tendency towards *O*-alkylation under the action of triethyloxonium fluoroborate, compared with other alkylating agents, is shown also in the alkylation of keto-enols [28], the ambidentate ions of nitro-alkanes [29,30], and also potassium diethyl phosphorothioate [31]. Although special studies dealing with the comparison of the alkylating activities of dialkyl sulphates and trialkyloxonium fluoroborates have not as yet been published, nevertheless the available information suggests that tertiary oxonium salts provide a more univeral means for the synthesis of lactim ethers. Thus it has been noted that the attempts to alkylate 3-ethoxycarbonyl-2-piperidone [25] and 3-morpholinone [32] with dimethyl sulphate were unsuccessful, whereas the use of triethyloxonium fluoroborate resulted in high yields of 2-ethoxy-3-ethoxycarbonyl-3,4,5,6-tetrahydropyridine (VI) and 3-ethoxy-3,4-dehydromorpholine (VII):



The selective properties of triethyloxonium fluoroborate in the alkylation of lactams are shown particularly clearly in its interaction with 3,3-diethyl-5-methylpiperidine-2,4-dione (VIII) [25]. The interaction of compound (VIII) with an equimolar amount of dimethyl sulphate resulted in the alkylation of the carbonyl group in the 4-position, while in the reaction of compound (VIII) with triethyloxonium fluoroborate the corresponding lactim ether (IX) was obtained:



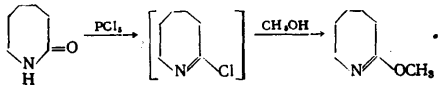
Recently a number of studies have been published on the alkylation of lactam with triethyloxonium fluoroborate when the ring contains, apart from the lactam group, also cyano-, ethoxycarbonyl, and acylated secondary amino-groups [25,33-41]. Selective alkylation of the lactam carbonyl was observed with formation of lactim ethers. In many cases when lactams were alkylated with triethyloxonium fluoroborate, the initial lactams were isolated as well as the lactim ethers, which is in all probability due to hydrolysis [analogous to the conversion of compound (V) into compound (I)] when the ambidentate cation, similar to the cation (IV), is attacked by the hydroxide ion during the isolation of the lactim ether.

Summarising, we may note that the use of triethyloxonium fluoroborate has real advantages over other alkylating agents both because of better yields of lactim ethers and because, when there is a choice between a possible attack on the lactam and other carbonyls, the former takes place preferentially (see above). This is also confirmed by the studies of Meerwein et al. [42], who classify carbonyl compounds in accordance with their capacity for alkylation by oxonium salts in the following series:

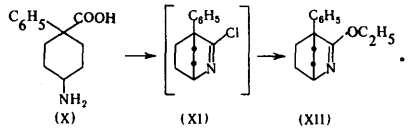
lactams > non-cyclic acid amides > lactones > carboxylic acid > esters > ketones > aldehydes.

2. Other Methods for the Synthesis of Lactim Ethers

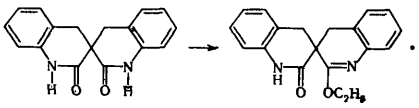
An important method for the preparation of lactim ethers consists in the conversion of lactams into the corresponding chlorinides followed by treatment with alcohols. Thus the interaction of caprolactam with phosphorus pentachloride and subsequent treatment of the reaction mixture with methanol led to the synthesis of *O*-methylcaprolactim [43]:



Similarly in the interaction of 4-amino-1-phenylcyclohexane-1-carbocyclic acid (X) with phosphorus pentachloride cyclisation takes place with formation of the chlorimide (XI), the alcoholysis of which yielded the lactim ether (XII) [44]:

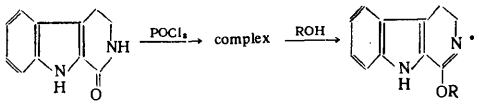


Similarly the interaction of the bishydrocarbostyryl-spirane (XIII) with phosphorus trichloride and phosphorus oxychloride followed by alcoholysis gave the corresponding lactim ether (XIV), which is also formed as a by-product in the reduction of di-(*o*-nitrobenzyl)malonic ester[45]:



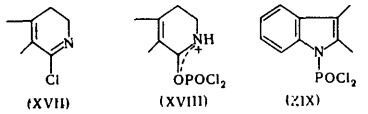
(XIII) (XIV)

Another example of the synthesis of lactim ethers from lactams and phosphorus oxychloride is the conversion of 3,4-dihydro-β-carbolin-1-one (XV) into 1-alkoxy-3,4-dihydro-β-carboline[46,47] (XVI):



(XV) (XVI)

Although the structure of the intermediate complex has not been accurately established, on the basis of the general properties of acid amides and lactams[48-52], one may suggest that, under the action of phosphorus oxychloride, the piperidone component of the molecule of compound (XV) is converted into compound (XVII) or (XVIII):

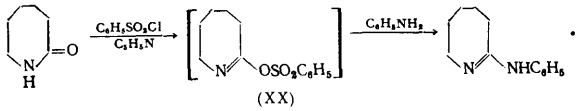


(XVII) (XVIII) (XIX)

However, one must remember that the indole component of the molecule is also capable of interacting with $POCl_3$ to form the phosphoramidic dichloride (XIX)[33].

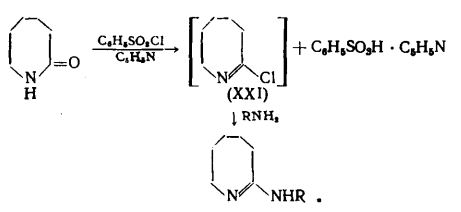
The reaction of the simplest lactams with benzenesulphonyl chloride probably takes place similarly as the reaction of β-carbolin-1-one (XV) with phosphorus oxychloride.

In their study of the synthesis of cyclic amidines from lactams, Oxley et al.[53] proposed a mechanism according to which, on treatment with benzenesulphonyl chloride in the presence of pyridine, caprolactam is converted into the intermediate *O*-benzenesulphonate of the caprolactim (XX), which readily reacts with amines, forming cyclic amidines:



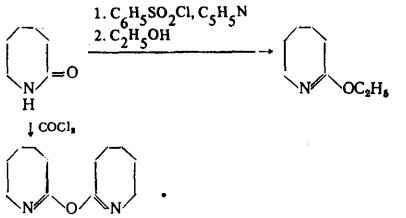
(XX)

However, later, in connection with the development of the synthesis of αβ-pentamethylenetetrazole[54], a detailed study of the first stage of this mechanism showed that this hypothesis is incorrect, since a high yield of the salt of benzenesulphonic acid and pyridine and not pyridinium chloride was isolated from the reaction mixture. Therefore a different mechanism was put forward, postulating the intermediate formation of the chlorimide of the caprolactam (XXI):



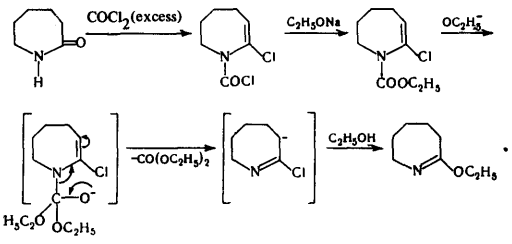
(XXI)

It is noteworthy that the intermediate chlorimide is extremely labile and is readily hydrolysed to caprolactam, all attempts to isolate it proving unsuccessful. This last study suggests that the syntheses of lactim ethers based on the interaction of lactams with reagents such as benzenesulphonyl chloride, chlorocarbonic ester, and phosgene[55-57] also probably takes place via the intermediate formation of chlorimides:

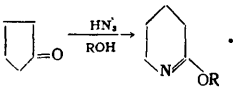


The interaction of sulphonyl chlorides with cycloalkanone oximes in pyridine probably also takes place similarly. In the first stage of this reaction the oxime evidently undergoes the Beckmann rearrangement and the lactam formed is converted into the chlorimide, from which the corresponding lactim ether is obtained by reaction with alcohol[58].

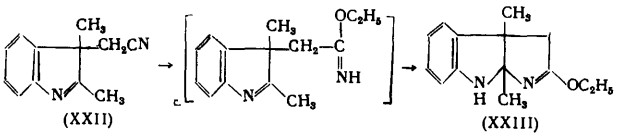
Tetenbaum's study[59] of the interaction of caprolactam with phosgene and the alcoholysis of 2-chloro-1-chlorocarbonyl-4,5,6,7-tetrahydro-1*H*-azepine also demonstrates the possibility of synthesising lactim ethers via the intermediate formation of compounds containing the chlorimide N=C–Cl group:



Among other methods of synthesis of lactim ethers, mention should be made of the procedure which consists in the interaction between cyclic ketones and hydrazoic acid in the presence of alcohol[60]:

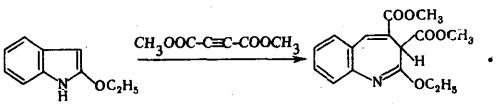


Apart from the general methods for the synthesis of lactim ethers described above, the ethers can also be obtained using the individual properties of particular organic compounds. An example is provided by the conversion of 3-cyanomethyl-2,3-dimethylindolenine (XXII) into the tricyclic lactim ether (XXIII)[61] under the influence of a solution of sodium ethoxide or hydrogen chloride in alcohol. In particular, in this case use was made of the capacity of indolenines to react with imines at the 2-position of the indolenine molecule:



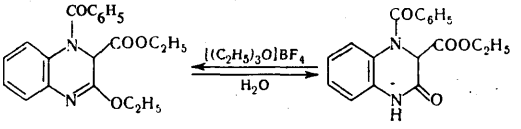
(XXII) (XXIII)

Mention can also be made of the synthesis of a lactim ether by the expansion of the indole ring to a benzazepine ring by the mechanism[62]:

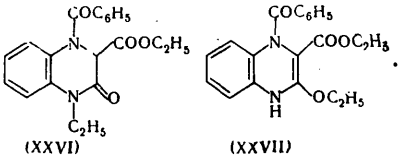


III. CHEMICAL PROPERTIES AND REACTIONS OF LACTIM ETHERS

Lactim ethers are extremely reactive towards nucleophilic agents, which readily distinguishes them from *N*-alkyl-lactams and other isomeric compounds. One may quote as an example the lactim ether derived from 4-benzoyl-3-ethoxycarbonyl-1, 2, 3, 4-tetrahydro-2-quinoxalinone (XXIV)[63]. The reaction of triethyloxonium fluoroborate with 4-benzoyl-3-ethoxycarbonyl-1, 2, 3, 4-tetrahydro-2-quinoxalinone (XXV) yielded a substance to which one of the following three isomeric structures (XXIV), (XXVI), or (XXVII) could be ascribed, bearing in mind the possibility to alkylation with transfer of the reaction centre:



(XXIV) (XXV)

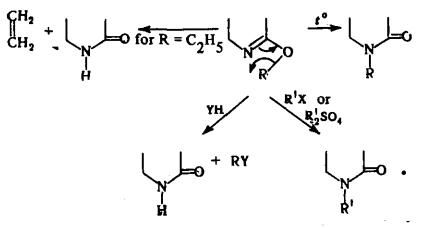


(XXVI) (XXVII)

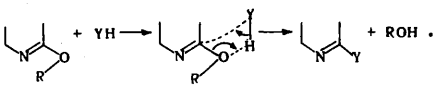
On the basis of infrared and NMR spectroscopic data, the structure (XXVII) was eliminated. However, the spectroscopic data did not allow an unambiguous choice between structures (XXIV) and (XXVI). Therefore the compound obtained was hydrolysed under exceptionally mild conditions (in water at 20°C) which gave an almost quantitative yield of the initial lactam (XXV). Such mild hydrolysis conditions undoubtedly indicate that the compound obtained is a lactim ether, this being confirmed subsequently also by its reactions (see below).

The reactions of lactim ethers with participation of the lactim ether group can be divided into two principal classes.

1. Reactions accompanied by the elimination of the *O*-alkyl residue and the formation of lactam derivatives:

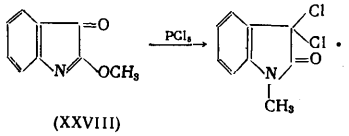


2. Reactions involving the lactim carbon atom with elimination of the alkoxy-group:



Reactions of the first type include the thermal rearrangement of lactim ethers into *N*-alkyl-lactams. In particular it was noted that 2-methoxy-3-oxoindolenine (XXVIII) undergoes on heating thermal isomerisation to *N*-methylisation[64]. In the paper by Benson and Cairns[16] mentioned above, a similar conversion of *O*-methyl(ethyl)caprolactim into the *N*-methyl(ethyl) derivative was described.

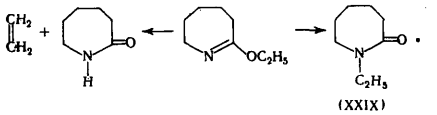
Another example of this type of rearrangement is the interaction of the lactim ether derived from isatin (XXVIII) with phosphorus pentachloride, which is also accompanied by the substitution of the oxo-group in the 3-position by two chlorine atoms[66]:



(XXVIII)

According to many investigators[16,65], this rearrangement is a common property of lactim ethers, similar to the analogous rearrangement of the simplest imino-ethers[7].

New data on this problem were obtained by Ralls and Eliger[67] in a study of the thermal isomerisation of *O*-ethylcaprolactim. In this investigation it was shown that the lactim ether remains unchanged at 193°C and only after prolonged heating (21 h at 237°C) is a small amount converted into *N*-ethylcaprolactam. The principal reaction product is caprolactam formed from the lactim ether on elimination of ethylene:

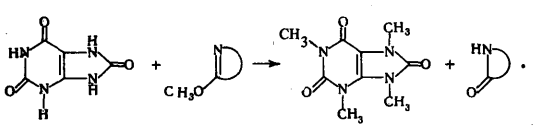


(XXIX)

The authors suggested that the rearrangement of the lactim ether into *N*-ethylcaprolactam (XXIX) is caused by traces of dialkyl sulphate and demonstrated this by the heat treatment of *O*-ethylcaprolactim in the presence of diethyl sulphate; the *N*-alkyl derivative (XXIX) was isolated as the main product. Similar behaviour was observed also with *O*-methylvalerolactim[67].

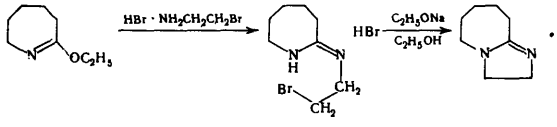
The need for the presence of dialkyl sulphate in the rearrangement of lactim ethers into *N*-alkyl-lactams is also consistent with the finding that similar isomerisation was achieved earlier in the interaction between *O*-methylcaprolactim and dimethyl sulphate[16]. The process probably involves the intermediate formation of compound (V) (see Russ. p. 914).

Reactions of the first type include also alkylation by lactim ethers of compounds with definite acid properties. Thus lactim ethers have been used as alkylating agents in reactions with compounds containing imino-groups[68], such as uric acid, xanthines, and hypoxanthines, and also for the esterification of organic acids[69]:

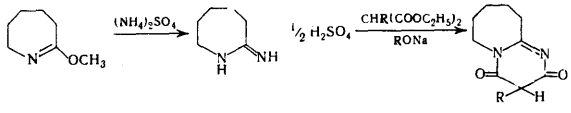


Among reactions of the second type the most common and probably the most promising for the synthesis of heterocyclic systems are reactions with various amino-derivatives and also with compounds having active methylene groups.

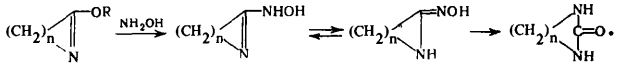
The synthesis of amidines from lactim ethers and amines takes place very readily and with high yields [8,9,16,21,70-76]. As an example, one may quote the synthesis of derivatives of imidazo[1,2-*a*]azepines carried out by Stolle et al.[77] by the reaction of *O*-ethylcaprolactim with β-bromoethylammonium bromide followed by cyclisation under the action of sodium ethoxide of the resulting β-bromoethylamidine derived from the caprolactim:



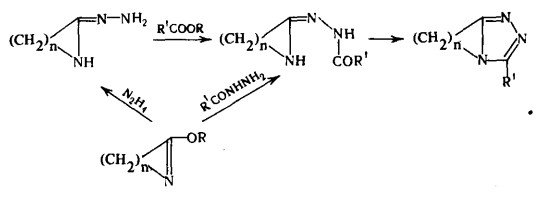
and also the synthesis of derivatives of pyrimidino[1,2-*a*]-azepines from *O*-methylcaprolactim[70]:



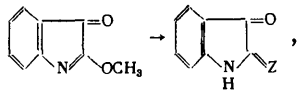
Lactam oximes have been synthesised by the interaction between lactim ethers and hydroxylamine [9,72,73,78]. This reaction became particularly important after it had been established that, under the influence of polyphosphoric acid, lactam oximes undergo the Beckmann rearrangement with formation of polymethyleneureas[79]:



The reaction of lactim ethers with hydrazine hydrate and substituted hydrazines [5,54,76,80-82] takes place even more readily because of the even more pronounced nucleophilic properties of the latter reagents. The "hydrazidines" formed in this process are extremely active and can take part in various cyclisations involving the amino-group of the side chain and the ring nitrogen. Thus, when the hydrazine of caprolactim was treated with nitrous acid, αβ-pentamethylenetetrazole (corazole) was synthesised [54,80,81], while the syntheses employing hydrazidines derived from other lactim ethers gave analogues of this compound [32,35]. It should also be mentioned that polymethylenetetrazoles may be synthesised by the action of an excess of hydrazoic acid on lactim ethers[83] as well as by the reaction of this acid with *O*-acyl-lactims (or lactam chlorimides) obtained from lactams and sulphonyl chlorides or phosphorus oxychloride[84]. Other possibilities which arise when similar "hydrazidines" are obtained may be demonstrated using as an example their conversion into polymethylenetriazoles [85-87]:



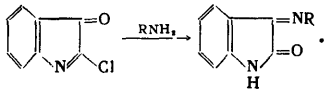
The reactions of the lactim ether of isatin (XXVIII) with amines, hydroxylamines, and substituted hydrazines [76,88] require special consideration. When compound (XXVIII) reacts with the above reagents, the condensation involves only the lactim ether group but not the oxo-group:



(XXVIII)

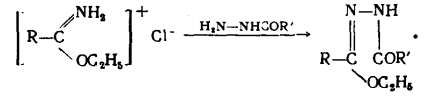
where Z = RN^-, $RNH-N^-$, or $-N-OH$.

From this, one may conclude that the lactim ether group in compound (XXVIII) is extremely reactive. We may also mention that the lactim ether group in this compound is probably even more reactive than the chlorimide group. Thus, it has been stated that, under the action of tosylhydrazine and aniline on isatin chlorimide, the oxo-group in the 3-position is attacked; the reaction is accompanied by the hydrolysis of the chlorimide to the lactam[89]:



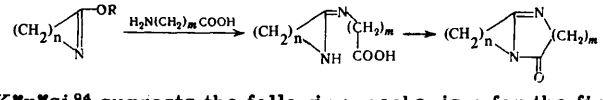
The reactions of lactim ethers with semicarbazides, thiosemicarbazides, and sulphonyl hydrazides as a rule stop at the amidrazone stage.

It is interesting that the reaction of aliphatic imino-ethers with the above components take place by a completely different mechanism: not with the elimination of alcohol and the formation of a C=N bond, but with the dissociation of the C=N bond and the elimination of ammonia [90-92]:

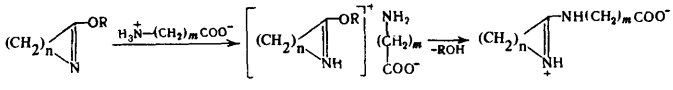


The reactions of lactim ethers with amino-acids have been investigated in fair detail [21,23,93]. It has been established that these reactions take place very readily, substituted amidino-acids, the cyclisation of which leads to various condensed dihydropyrimidines or imidazolines, being formed.

The cyclisation of aliphatic amino-acids requires fairly severe conditions, while with aromatic or heterocyclic amino-acids, where a fairly high degree of aromatisation of the diazine ring is attained, the process takes place readily so that the intermediate amidines cannot be isolated:



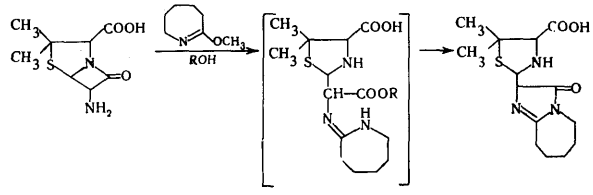
Körösi[94] suggests the following mechanism for the first stage of this process:



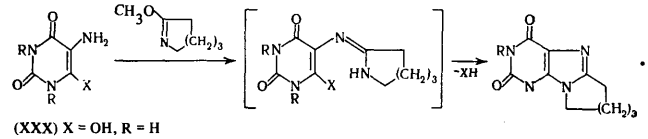
According to this mechanism, the reaction begins with the protonation of the lactim nitrogen, which is achieved more readily when the acid properties of the amino-acid carboxyl are enhanced (i.e. in the case of aromatic and heterocyclic amino-acids). The protonation of the lactim nitrogen increases the electrophilicity of the adjacent carbon atom and is responsible for the ease of the subsequent nucleophilic substitution of this atom. Consequently, when lactim ethers are condensed with amines, account must be taken not only of the basicity of the initial amines but also of the possibility of the formation of a salt by the lactim ether group.

The reactions of lactim ethers with amino-acid esters[95] lead to the corresponding amidino-acid esters. The principal factor which determines the course of this process is the basicity of the amino-group, which is clearly illustrated, for example, by the condensation of lactim ethers with the aminocrotonic ester, which either does not occur at all[21,95], or takes place with a relatively low yield[70].

The interaction of *O*-methylcaprolactim with 6-aminopenicillanic acid takes place with the opening of the β-lactam ring and subsequent cyclisation of the derivative of penicilloic acid involving the ester group and the endocyclic nitrogen of the azepine ring[96]:

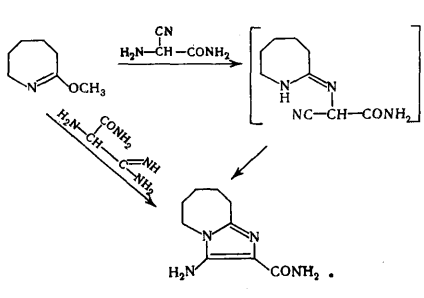


The ease of formation of amidines in the reactions of lactim ethers with amines was used in the synthesis of 8,9-polymethylenepurines. The attempts to condense *O*-methylcaprolactim with uramil (XXX) and 4,5-diamino-1,3-dimethyluracil (XXXI), undertaken to obtain 8,9-pentamethylenexanthine showed that lactim ethers do not react with 5-aminouracil derivatives, probably because of the low basicity of their amino-groups:



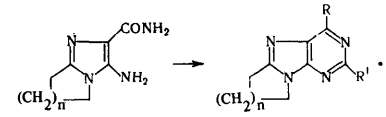
(XXX) X = OH, R = H
(XXXI) X = NH_2, R = CH_3

The synthesis of 1,2-polymethylene derivatives of 5-amino-4-carbamoylimidazoles, which are key compounds in the synthesis of 8,9-polymethylenepurines, was achieved by condensing lactim ethers with α-amino-α-cyanoacetamide. It was found that, despite the presence of an active methine unit in the latter compound, the reaction involves selectively the amino-group, as shown by the physicochemical properties of the products, further reactions, and, in the case of *O*-methylcaprolactim, also by synthesis—the condensation of the caprolactim with the dihydrochloride of α-amidino-α-aminomalonamide[97]:



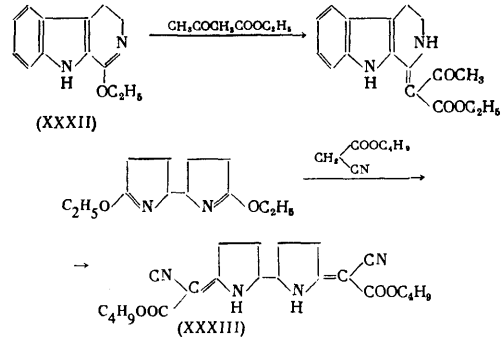
When this reaction was extended to butyro- and valerolactims, it was found[98] that an additional enhancement of the electrophilicity of the attacking carbon atom of the lactim group is necessary, and this was achieved by carrying out the reaction in alcohol containing catalytic amounts of hydrogen chloride.

The reaction of lactim ethers with α-amino-α-cyanoacetamide thus developed permitted the synthesis of a group of polymethyleneimidazoles and made it possible to convert the latter into 8,9-polymethylenepurines:



The general features of this reaction have also been compared using more complex examples such as 1-ethoxyisoindolenine[24] and also lactim ethers containing an additional hetero-atom in the lactam ring[32,35,99]. When α-amino-α-cyanoacetamide was condensed with lactim ethers derived from 3-morpholinone[32], 3-thiazanone[99], and 2-piperazinone[35], it was shown that the introduction of a second hetero-atom in the 4-position of the lactam ring does not alter significantly the reactivity of lactim ethers.

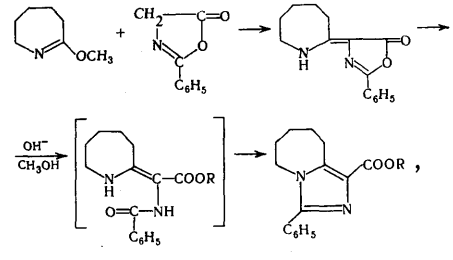
The high reactivity of lactim ethers is shown particularly clearly in their capacity to form a new carbon–carbon bond in the reaction with compounds containing active methylene groups, such as acetoacetic, cyanoacetic, and malonic esters and their derivatives, acetylacetone, barbituric acid, rhodanine, nitromethane, oxindole, and others[8,9,33,100–102]. One may quote as examples the condensation of the lactim ether derived from 3,4-dihydro-β-carbolin-1-one (XXXII) with acetoacetic ester[103] and also the condensation of the bislactim ether derived from 2,2′-di-5-pyrrolidone (XXXIII) with butyl cyanoacetate[26]:



(XXXII)

(XXXIII)

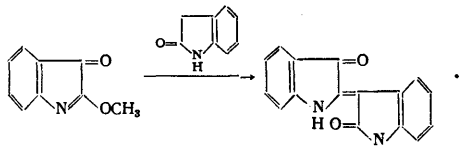
Another example of the reaction of lactim ethers with compounds having an active methylene group is the condensation of *O*-methylcaprolactim with 2-phenyl-5-oxazolone[104] which leads to the synthesis of 3,4-pentamethyleneimidazoles via the intramolecular rearrangement of the intermediate 2-phenyl-4-(2′-homopiperidylene)-5-oxazolone:



where R = H or CH_3.

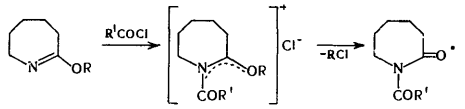
The condensation of the lactim ether derived from isatin (XXVIII) with oxindole in an anhydrous medium (benzene, acetic anhydride) in the presence of a catalytic

amount of concentrated sulphuric acid involves the active α-methylene unit with formation of indirubin (XXXIV)[102]:

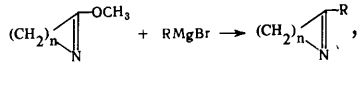


(XXVIII) (XXXIV)

In the literature there are contradictory data on the interaction between lactim ethers and acid chlorides. In 1956 a patent was published in which it is stated that this interaction leads to the corresponding *O*-acyl-lactams[105]. In another study on this problem[106] it was shown for a large number of examples, using spectroscopic methods, that the reaction products are *N*-acyl-lactams:

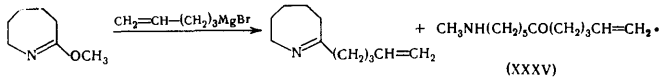


Numerous studies have been made on the interaction between lactim ethers and Grignard reagents[72,73,107-112]. It has been stated that this reaction depends on the size of the lactam ring. Thus, whereas *O*-methylbutyro- and *O*-methylvalero-lactims give bases of the same type:



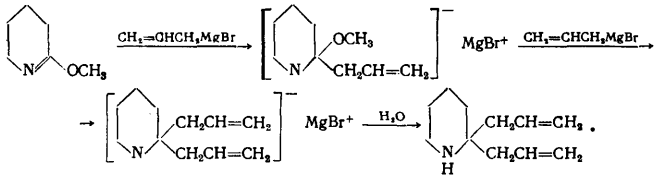
(*n* = 2,3)

in the case of *O*-methylcaprolactim, in addition to similar bases, *N*-methylaminoketones of type (XXXV) are sometimes formed, which can be explained by the conversion of *O*-methylcaprolactim into *N*-methylcaprolactam and subsequent interaction of the latter with a Grignard reagent[109]:

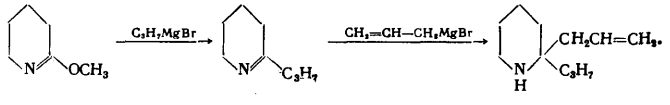


(XXXV)

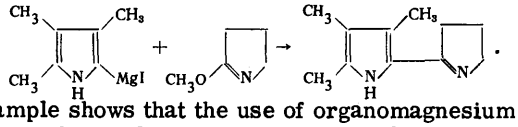
In the general case (where R in RMgX is a simple alkyl or aryl) it is suggested that the reaction does not take place via the addition of the Grignard reagent to the C=N bond but involves the direct substitution of the alkoxy-group of the lactim ether by the alkyl residue. In this connection, the reaction of *O*-methylvalerolactim with allylmagnesium bromide constitutes an unusual case[112]. This reaction yields only the gem-derivative, which is probably due to the addition of the Grignard reagent to the C=N bond:



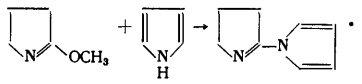
This mechanism is consistent with the capacity of allylmagnesium bromide to add to the double bond of 2-propyl-3,4,5,6-tetrahydropyridine:



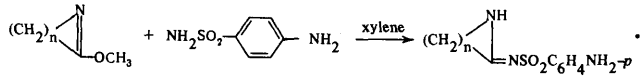
An interesting example of the reaction of lactim ethers with organomagnesium compounds is the synthesis of 2,2′-pyrrolylpyrrolines[108]:



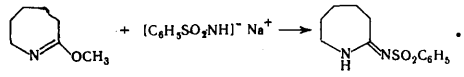
This example shows that the use of organomagnesium derivatives of pyrrole makes possible condensation involving the α-position of the pyrrole ring. When pyrrole itself reacts with the lactim ether, the condensation involves the pyrrole nitrogen with formation of a C–N bond[113]:



Sulphonamides enter into a similar condensation with lactim ethers and in the presence of an aromatic amino-group and a sulphonamide group the reaction of the lactim ether involves preferentially the sulphonamide group[114]:

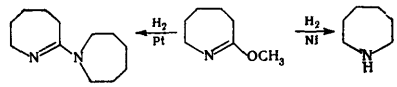


The interaction of lactim ethers with ammonium benzenesulphonate leads to the corresponding amidine salt and that with sodium benzenesulphonate yields the benzenesulphonyl derivative of amidinocaprolactim[71]:



An important property of lactim ethers is the relative (compared with lactams) ease of their reduction to cyclic imines. The reduction of lactams involves considerable difficulties and is as a rule carried out with lithium aluminium hydride. In this connection, the comparatively easy hydrogenation of lactim ethers is promising[16,72,109].

The studies of Benson and Cairns[16] showed that the hydrogenation of *O*-methyl and *O*-ethylcaprolactims over Raney nickel, ruthenium oxide, and the barium–copper–chromite catalyst give high yields of hexamethyleneimine. When platinum is used in this case, an amidine is formed by the mechanism:

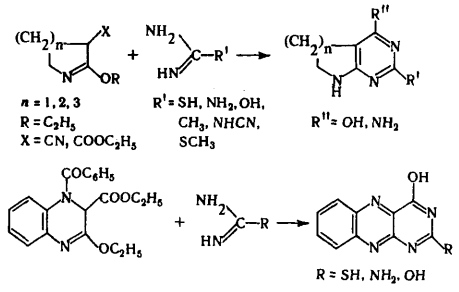


The catalytic hydrogenation of *O*-methylvalerolactim over platinum oxide yielded piperidine[109] and the hydrogenation of *O*-methylbutyrolactim over platinum in acetic acid resulted in the formation of pyrrolidine[72]. In addition, the reduction of lactim ethers with lithium aluminium hydride has also been described—cyclic imines were obtained in all cases[109].

So far we have considered the reactions of monofunctional lactim ethers involving mainly their imino-ether group. In such cases new heterocyclic rings are formed from the carbon and nitrogen of the lactim ether group.

Recently a number of studies have been published, in which di- (or tri-) functional lactim ethers were used for this purpose[25,38-41,115]. The first example of this type of synthesis was the interaction of the lactim ether derived from 3-ethoxycarbonyl-2-piperidone (XXXVI) with thiourea in the presence of an alcoholic solution of sodium ethoxide[25]. A detailed study of this reaction was carried out for

lactim ethers derived from 3-ethoxycarbonyl-2-piperidone (XXXVI), 3-cyanocaprolactam (XXXVII), 3-ethoxycarbonylcaprolactam (XXXVIII), 3-ethoxycarbonyl-2-pyrrolidone (XXXIX), and ethoxycarbonyl-4-benzoyl-1,2,3,4-tetrahydro-2-quinoxalinone (XL) [35-38,40,115].



It was shown that this reaction constitutes a general synthesis of condensed pyrimidines and that the pyrimidine cyclisation depends both on the structure of the lactim ethers and on the properties of the "amidine" component. The use of guanidine and thiourea as the "amidine" component gives the best results in all cases of the synthesis of the corresponding condensed pyrimidines. It is noteworthy that, whereas in the condensation of compounds (XXVIII)–(XL) with urea condensed uracils were obtained in a low yield, in a similar condensation of compound (XXXVI) hydrogenated 2,4-dihydroxypyrido[2,3-*d*]pyrimidine was obtained in a satisfactory yield, comparable to that of the product obtained in the reaction of compound (XXXVI) with acetamidine.

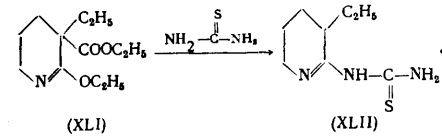
The reactivity of other "amidine" components is as a rule intermediate between the above extremes and the components can be arranged in the following sequence:

guanide ≃ thiourea > cyanoguanidine > acetamidine > *S*-methylisothiourea > urea.

If one disregards the anomalously low yields when *S*-methylisothiourea is used, then the relative reactivities of the amidine components in the above series are the same as in the usual pyrimidine cyclisations [116-119]. Furthermore the condensation of lactim ethers derived from 3-ethoxycarbonyl-lactams with amidine components greatly depends on the stability of the reactants, as in the analogous reaction of malonic esters [120].

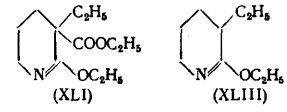
Like aliphatic imino-ethers, lactim ethers are very labile both in acid and alkaline media. Therefore the reaction depends in many respects on the relative rates of the main process (pyrimidine cyclisation) and the side reactions associated with the instability of the starting materials. When the "amidine" components are substances with high basicity and high capacity for enolisation under the process conditions, pyrimidine cyclisation predominates and the yields of the condensed pyrimidines are high. On the other hand, when the "amidine" components do not have these properties (or have them to a much smaller extent), the lactim ethers are probably alcoholysed to lactams with subsequent rupture of the lactam ring [121]. Comparison of the reactivities of the lactim ethers derived from 3-cyano- and -3-ethoxycarbonyl-caprolactams shows that, as in the usual pyrimidine cyclisations [120], the latter are more reactive. Whereas the condensation of the lactim ether derived from 3-cyanocaprolactam with urea does not occur at all, in the condensation of the 3-ethoxycarbonyl derivative condensed uracil was obtained, albeit in a low yield.

The use of bifunctional lactim ethers in the synthesis of condensed pyrimidines made it possible to achieve the synthesis of a new heterocyclic system—pyrimido[4,5-*b*]-tetrahydroazepine [36,37] and also to develop new methods for the synthesis of alloxazines [41], 7*H*,5,6-dehydropyrrolo[2,3-*d*]pyrimidines [38,39], and 8*H*,piperidino[2,3-*d*]pyrimidines [25,115]. A further development of these studies was the investigation of the condensation of the lactim ether derived from 3-ethoxycarbonyl-3-ethyl-2-piperidone (XLI) with thiourea, guanidine, and other amidine components [115]. The aim was to synthesise condensed piperidino[2,3-*d*]-pyrimidines with an angular ethyl group, which are cyclic analogues of the biologically active 5,5-disubstituted barbituric acids. The study of the interaction of compound (XLI) with thiourea showed that the condensation does not occur when an equimolar amount of sodium alkoxide is employed, while in the presence of an excess of this reagent *N*-(3-ethyl-3,4,5,6-tetrahydropyrid-2-yl)thiourea (XLII) was isolated:



(XLI) (XLII)

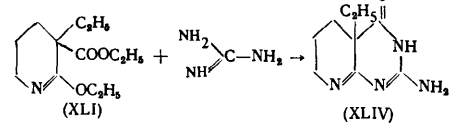
The above mechanism shows that in this reaction the ethoxycarbonyl group is eliminated, probably as a result of its alcoholysis with formation of diethyl carbonate, as was observed earlier for disubstituted cyanoacetic esters in the synthesis of iminobarbituric acids [122,123]. Comparison of the reactivities of the lactim ethers (XLI) and (XLIII) shows that the former should be more reactive in nucleophilic substitution reactions than compound (XLIII) because of the negative inductive effect of the ethoxycarbonyl group and the associated higher partial positive charge on the "lactim" carbon atom:



(XLI) (XLIII)

On this basis, one may suppose that the first stage in this process is attack by thiourea on the "lactim" carbon atom and consequently the lactim ether group is more reactive under the conditions of this reaction than the ethoxycarbonyl group. The need for an excess of sodium hydroxide in this reaction is probably due to the low dissociation constant of thiourea.

The interaction of compound (XLI) with guanidine, which is a stronger base, now leads to the product of cyclisation involving the ethoxycarbonyl group, 2-amino-4-hydroxy-10-ethyl-4,5,6,7,8,10-hexahydropyrido[2,3-*d*]pyrimidine (XLIV) with an angular alkyl group in the 10-position of the bicyclic compound being formed. In this case the yield is lower than in the condensation of compound (XXXVI) with guanidine, which can probably be accounted for by the incomplete aromatisation of the pyrimidine ring in compound (XLIV):



(XLI) (XLIV)

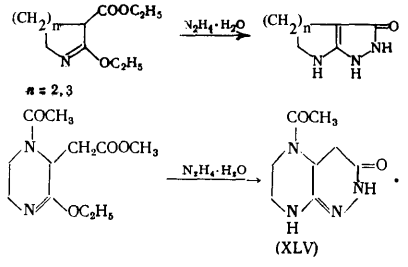
The last factor is evidently decisive in cyclisations of this type, involving the formation of a diazine ring. This is also confirmed by the fact that the attempts to condense

the lactim ether derived from 4-acetyl-3-methoxycarbonylmethyl-2-piperazinone with "amidine" components proved to be unsuccessful[40].

It is striking that the reaction of compound (XLI) with urea does not occur at all, probably because of the lower tendency of the latter to enolise under the reaction conditions compared with thiourea[113]. In all these cases one should also bear in mind the slightly reduced reactivity of the lactim ether group of compound (XLI) compared with compound (XXXVI) in consequence of the electron-donor effect of the alkyl group in the 3-position of the lactam ring.

In this connection it is also interesting to note that the reduced reactivity of compound (XLI) compared with compounds (XXXVI)–(XL) is confirmed by its higher stability to alcoholysis under the conditions of condensation with "amidine" compounds, since, in contrast to compounds (XXXVI)–(XL), compound (XLI) is partially regenerated in almost all cases.

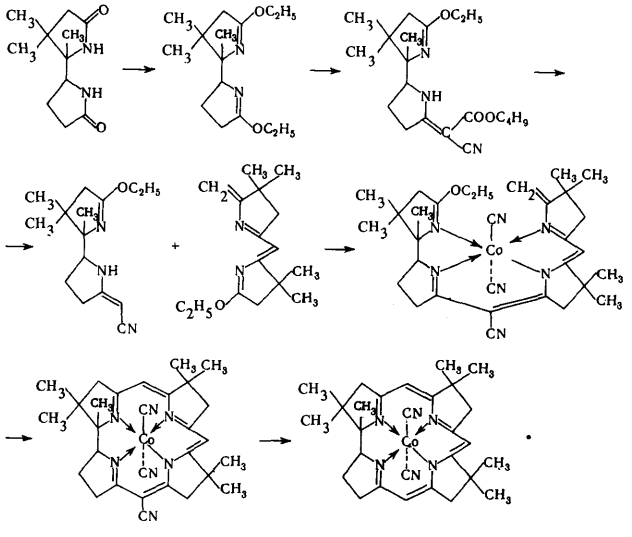
The condensation of bifunctional lactim ethers with "amidine" reagents does not exhaust the vast possibilities created by these compounds for the synthesis of various heterocycles. As an illustration, one may quote the condensations of certain lactim ethers with hydrazine hydrate, giving condensed pyrazoles[25,37] and pyridazines[40]:



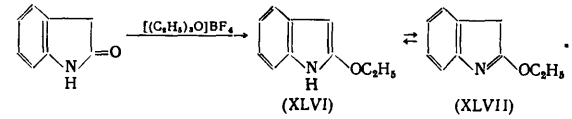
(XLV)

The "amidine" structure of compound (XLV) was demonstrated by infrared and NMR spectroscopy.

The high reactivity of lactim ethers made it possible to use these compounds in the study of the synthesis of complex organic compounds such as representatives of the corrin system[124-127]. As an example, one may quote the synthesis of racemic dicyano(1,2,2,7,7,12,12-heptamethylcorrin)cobalt (III)[125]:

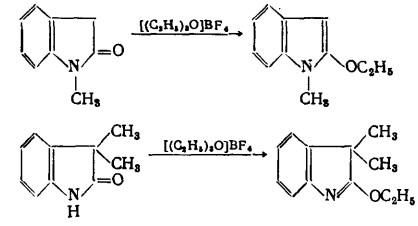


The ethylation of oxindole and its derivatives with triethyloxonium fluoroborate occupies a special place in the chemistry of lactim ethers. Harley-Mason and Leeney[22] established that the interaction of oxindole with triethyloxonium fluoroborate yields 2-ethoxyindole (XLVI) which isomerises on sublimation to the lactim ether (XLVII) derived from oxindole. When the latter is heated above the melting point, the reverse conversion of compound (XLVII) into compound (XLVI) can be achieved:



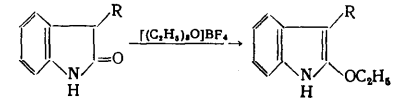
(XLVI) (XLVII)

2-Ethoxy-1-methylindole and 2-ethoxy-3,3-dimethylindolenine were prepared as models for the investigation of these reactions:



The study of the NMR and infrared spectra of the compounds obtained and their comparison with the spectra of the model compounds convincingly demonstrated the occurrence of the tautomerism (XLVI) ⇌ (XLVII).

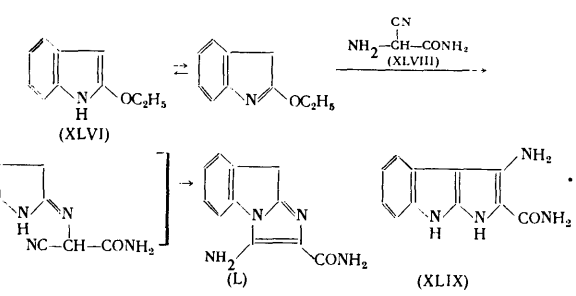
In another study an attempt was also made to obtain the lactim ether derived from oxindole (XLVII) and 3-ethoxycarbonylindole[33]. However, in both cases indole and not indolenine derivatives were isolated:



where R = H or $COOC_2H_5$.

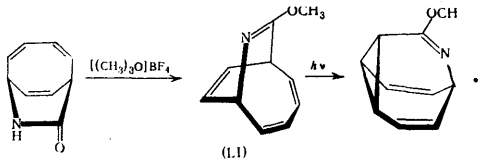
Bearing in mind the capacity of compound (XXXVI) for isomerisation to compound (XLVII), the capacity of lactim ethers to condense with α-amino-α-cyanoacetamide (XLVIII), and also the capacity of the α-alkoxy-derivatives of certain enamines for nucleophilic substitution of alkoxy-groups[128], an attempt was made in this investigation to condense compound (XLVI) with compound (XLVIII) in alcohol in the presence of catalytic amounts of hydrogen chloride.

A detailed study of the physicochemical properties of the product and in particular its NMR spectrum, showed that it is not 3-amino-2-carbamoyl-pyrrolo[2,3-*b*]indole (XLIX) but the "normal" product of the reaction of lactim ethers with compound (XLVIII)—3-amino-2-carbamoylimidazo[1,2-*a*]indoline (L). This process may be represented by the following mechanism:



(XLVI) (L) (XLIX)

Together with high reactivity in relation to nucleophilic reagents, the lactim ether group is sufficiently stable to achieve certain sometimes very complex reactions. As an illustration one may quote the isomerisation of the lactim ether (LI) in which the lactim ether group is preserved[27]:

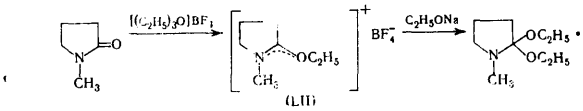


(LI)

IV. METHODS OF SYNTHESIS AND CHEMICAL PROPERTIES OF OTHER *O*-ALKYL DERIVATIVES OF LACTAMS

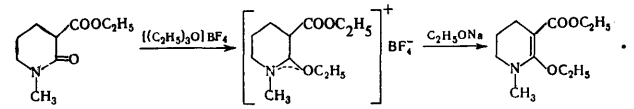
The activation of the amide group in lactams by their conversion into lactim ethers greatly extended the range of applications of lactams and made it possible to synthesise examples of various classes of organic compounds. However, the above reactions are always subject to a constant limitation in the choice of the lactam, since in the synthesis of lactim ethers only lactams unsubstituted at the nitrogen atom must be employed.

A further extension of the application of *O*-alkyl derivatives of lactams in organic chemistry was achieved in the study of a new branch of lactam chemistry—that of lactam acetals[50,129-132]. Lactam acetals were synthesised for the first time by Meerwein and coworkers[130,131] by the alkylation of *N*-substituted lactams with triethyloxonium fluoroborate, followed by the decomposition of the resulting fluoroborate complex (LII) with sodium ethoxide:

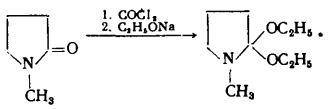


(LII)

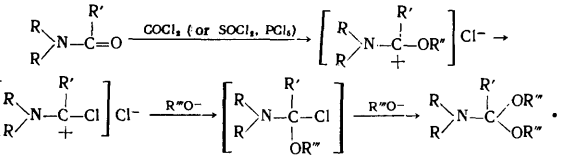
In the presence of an electron-acceptor substituent in the 3-position of the lactam ring, the decomposition of the intermediate fluoroborate complex by sodium ethoxide is accompanied by the elimination of a proton from the 3-position and the formation of a 2,3-dehydro-derivative, as happens, for example, in the case of 3-ethoxycarbonyl-*N*-methyl-2-piperidone[133]:



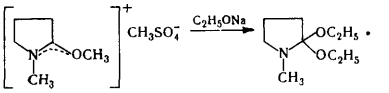
Another method for the synthesis of lactam acetals consists in the interaction of *N*-substituted lactams with phosgene, resulting in the formation of the corresponding amide-chlorides, from which the acetals are obtained by treatment with sodium ethoxide or triethylamine in alcohol[50,132]:



It has been stated that this reaction takes place by the following hypothetical mechanism[132]:

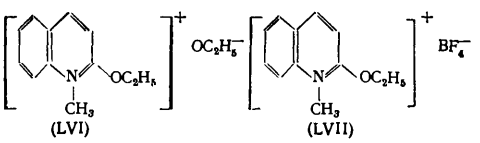


The preparation of lactam acetals by the interaction of the complex of *N*-methyl-2-pyrrolidone and dimethyl sulphate with sodium ethoxide, similar to the procedure where lactim ethers are obtained by treating lactams with triethyloxonium fluoroborate or dimethyl sulphate, has been also described[129]:



The chemical properties of lactam acetals have been inadequately investigated, although there is an indication[130] that these compounds are similar in their chemical behaviour to the acetals of non-cyclic acid amides, which have been investigated in greater detail[130,134,135]. Like lactim ethers, lactam acetals enter fairly readily into nucleophilic substitution reactions. In particular, on reaction with water, these compounds are hydrolysed relatively easily with formation of the corresponding lactams.

In this connection the comparative reactivities of the acetals of *N*-methyl-2-quinolone (LIII), *N*-methyl-2-benzothiazolone (LIV), and *N*-methyl-2-benzoxazolone (LV) should be mentioned[130]. It has been established that compound (LIII) hydrolyses so readily that it is difficult to isolate it in a pure form. In contrast to compound (LIII), compounds (LIV) and (LV) are relatively stable to hydrolysis. In order to account for this phenomenon, it has been suggested that the acetal (LIII) exists partially in the ionised form (LVI):

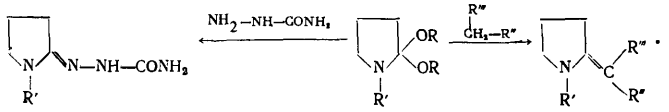


(LVI) (LVII)

The formation of compound (LVI) is facilitated in this case by the complete aromatisation of the quinoline ring and the presence of the above ionised species leads of course to an enhanced reactivity in relation to nucleophilic reagents [compared with compounds (LIV) and (LV)]. This hypothesis was confirmed by the relatively high electrical conductance of solutions of compound (LIII) in nitrobenzene and dimethylformamide and also by the fact that the fluoroborate complex (LVII) is much more stable to hydrolysis than the corresponding complex obtained from *N*-methyl-2-benzoxazolone and *N*-methyl-2-benzothiazolone. Similar relative reactivities of compounds (LIII), (LIV), and (LV) are observed also in other nucleophilic substitution reactions.

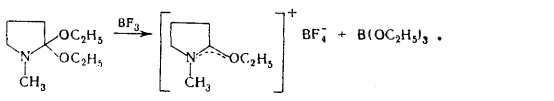
Among the reactions of lactam acetals with nucleophilic reagents, the interaction of the acetals of *N*-methyl-2-pyrrolidone with semicarbazide, with formation of the corresponding semicarbazone, as well as reactions with

compounds having active methyl or methylene groups have also been reported[130]:

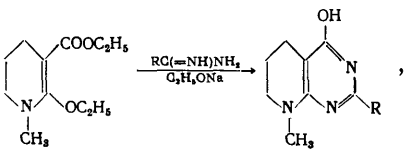


It is noteworthy that the last reaction takes place as a rule extremely readily, which suggests that the acetals are more reactive than lactim ethers.

The high reactivity of the acetals is also shown in the reaction of the diethylacetal of *N*-methyl-2-pyrrolidone with boron trifluoride accompanied by the elimination of one alkoxy-residue and the formation of the fluoroborate complex (LII)[131]:



In conclusion we may quote the condensation of 3-ethoxycarbonyl-2-ethoxy-*N*-methyltetrahydropyridine with guanidine and thiourea, resulting in the formation of 2-substituted 4-hydroxy-8-methyl-5,6,7,8-tetrahydropyrido[2,3-*d*]pyrimidines[133]:



where R = NH_2 or SH.

This reaction shows that the conversion of lactim ethers to *O*-alkyl derivatives of lactams with a substituent at the ring nitrogen atom gives rise to the possibility of the synthesis of condensed heterocyclic compounds with predetermined positions of the substituents.

The use of *O*-alkyl derivatives of lactams in organic synthesis has led to important results both as regards synthesis and theory. A large number of heterocyclic compounds, in particular examples of new heterocyclic systems which are of interest both biologically and chemically, have been synthesised on their basis. The wide choice of reagents and their relative availability combined with high reactivity give rise to a wide range of applications of *O*-alkyl derivatives of lactams as starting materials in the synthesis of a wide variety of organic compounds.

The Chemistry of Corrin Systems

T.A.Melent'eva, N.D.Pekel', and V.M.Berezovskii

The review deals with the modern state of the chemistry of corrin compounds. The principal methods of the synthesis of corroles, metal complexes of tetradehydrocorrins and corrins are discussed together with the mechanisms of the cyclisation of tetrapyrrole systems on irradiation or in the presence of metal salts, which leads either to corroles or tetradehydrocorrin complexes. The limits of the applicability of the methods for the synthesis of corrins via imino-ethers and by the reduction of tetradehydrocorrins are estimated. The results of studies on the stereospecific synthesis of cobyrinic acid are presented. The available literature data on the properties of synthetic corrinoid systems are considered as well as the properties of the metal complexes, deuterium exchange, protonation and alkylation of corroles and corrins and the rearrangements of tetradehydrocorrins. Much attention has been devoted to the spectroscopic characteristics of tetrapyrrole macrocyclic compounds, in particular their ultraviolet, infrared, and NMR spectra, which are widely used to establish the structure of corrin systems. The bibliography includes 82 references.

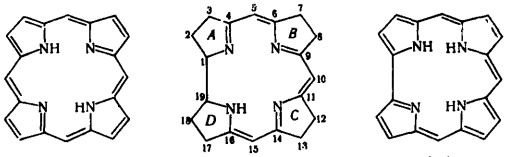
I. INTRODUCTION

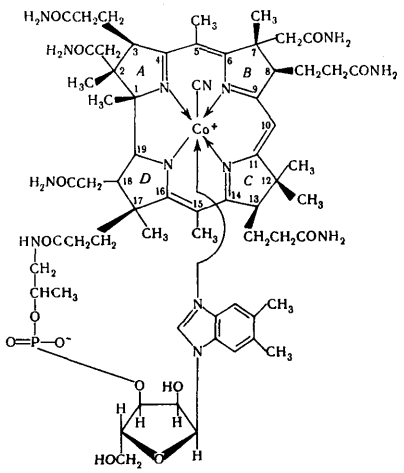
The attention of chemists is at present increasingly drawn to biologically active substances which play an important role in the living processes of organisms. Such substances are in particular the macrocyclic tetrapyrrole systems, two types of which are encountered in nature. The first type consists of porphyrins (I), for example haemin, which is the basis of the blood pigment (haemoglobin) and cytochrome coenzymes, and also dihydroporphyrins or chlorins, for example the pigment in plant leaves—chlorophyll. The second type consists of corrins (II)†, for example cobalamins, represented by vitamin B_{12} and its coenzyme:



(I) (II) (IV)

Both types include important natural compounds, characterised by a similar asymmetric distribution of β-substituents in the ring and the fact that they exist as metal complexes. The close relation between these two groups is demonstrated by the fact that the early stage of their biosyntheses includes porphobilinogen[2-4].

Vitamin B_{12} (cyanocobalamin) (III) counteracts pernicious anemia. As a coenzyme, vitamin B_{12} catalyses many enzymic reactions, in particular the conversion of glutamate into methylaspartate[5], succinyl-coenzyme A into methylmalonyl-coenzyme A,[6,7] and 1,2-diols into deoxyaldehydes[8-11] and the dissociation of lysine into aliphatic acids and ammonia[12]. The methyl analogue of the vitamin B_{12} coenzyme takes part in the synthesis of methionine[13] and the cobamide coenzyme serves also as a cofactor in the reduction of ribonucleosides[14] and in the synthesis of egg albumin[15].



(III)

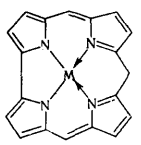
The chemical structure of vitamin B_{12} has been completely elucidated as a result of a brilliant application of X-ray diffraction analysis[16] and studies on chemical degradation[2]. The cobalamine molecule can be divided into two parts, known as the "planar" part and the "nucleotide"; the latter lies in a plane almost perpendicular to the planar component. In the planar part the central cobalt atom is linked to four reduced pyrrole rings, forming a macrocycle. Three of the four junctions are formed by the *meso*-carbon atoms and in the fourth position the junction is formed by a direct bond between two α-carbon atoms of the heterocyclic rings. The macrocycle contains six conjugated double bonds and nine asymmetric carbon atoms.

† The name "corrin" is given to the macrocyclic compound (II) which constitutes the basis of vitamin B_{12}; it was adopted in 1957 at the First International Symposium on Vitamin B_{12}.[1]

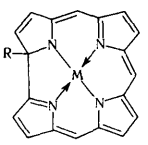
Several reviews have been written on the chemistry and biochemistry of vitamin B_{12} and its coenzyme[2,17-20].

The macrocyclic compound (IV), differing from corrin by four additional double bonds and constituting an 18π-electron aromatic system, was synthesised[21] in 1964. This compound was called "corrole"[22]. It is of independent interest as a new aromatic heterocyclic system.

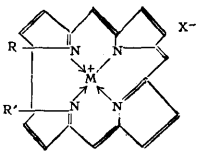
At present three types of new heterocyclic compounds[23] with two directly linked pyrrole rings and containing ten double bonds are known: corroles (IV) and their metal complexes (V), neutral nickel and cobalt complexes of 1-substituted tetradehydrocorrins (VI) and salts of the nickel and cobalt complexes of 1,19-disubstituted tetradehydrocorrins (VII). The last two macrocyclic compounds are not aromatic, and therefore they are referred to as tetradehydrocorrins and not substituted corroles.



(V)



(VI)



(VII)

The structure of tetradehydrocorrins includes, like that of corroles, a direct α-carbon–α-carbon bond between two pyrrole rings but differs from corrins by a higher degree of unsaturation. Possibly pyrroles and tetradehydrocorrins are intermediates in the biosynthesis of vitamin B_{12}. In the study of the biosynthesis of cobalamin[3,24] it was established that porphobilinogen is a precursor of both corrin and porphyrins. It is believed[20,25-27] that porphobilinogen condenses to a linear tetrapyrrole system and the latter cyclises either into porphyrin or into corrin, possibly via corrole.

The complete chemical synthesis of vitamin B_{12} has not as yet been achieved. The most difficult problem is the stereospecific synthesis of the central heterocyclic part of the molecule with the required substituents.

II. METHODS FOR THE SYNTHESIS OF CORRIN SYSTEMS

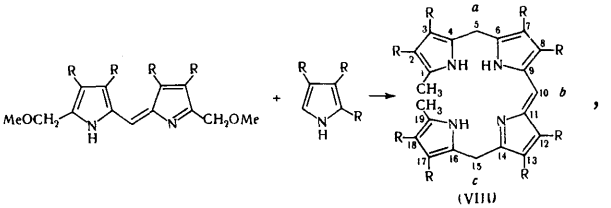
A. SYNTHESIS OF CORROLES AND TETRADEHYDROCORRINS

1. Synthesis of Corroles by Photocyclisation

Methods for the synthesis of corrole and tetradehydrocorrins were developed by Johnson and coworkers. Corroles are synthesised by the photocyclisation of linear tetrapyrrole systems, namely the dihydrobromides of 1,19-dideoxybiladienes-*ac*[28-31] and the hydrobromides of 1,19-dideoxybilenes *b*‡[28,32]. Special methods have been developed for the preparation of these tetrapyrrole systems.

‡ Since the bile pigments (bilirubin) are the most thoroughly investigated tetrapyrrole systems, the bile pigment nomenclature has been adopted for all the tetrapyrrole systems[33]. The prefix "deoxy" indicates the absence of two hydroxy-groups in positions 1 and 19.

Bilenes-*b* (VIII) were synthesised by the condensation[28,32] of 5,5′-di(methoxymethyl)dipyrromethene with two equivalents of 2,3,4-trialkylpyrrole:

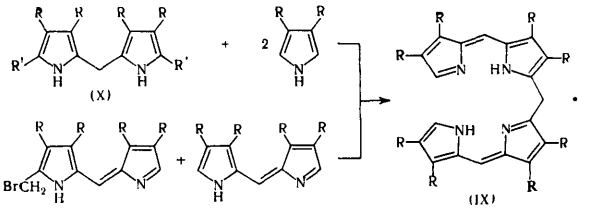


(VIII)

where R = H, CH_3, or C_2H_5.

Two methods have been developed for the synthesis of biladienes-*ac* (IX).

1. Condensation[28] of 5,5′-diformyldipyrromethane (X, R′ = CHO) with two equivalents of 3,4-dialkylpyrroles or condensation of dipyrromethane-5,5′-dicarboxylic acids (X, R′ = COOH) with two equivalents of 5-formyl- or 5-acetyl-pyrroles:

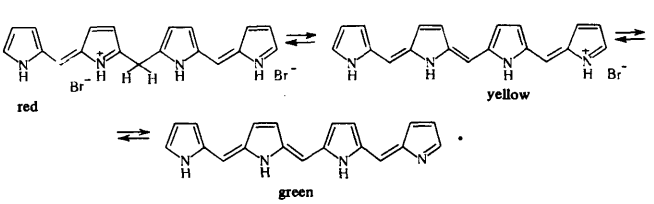


(X) (IX)

2. Condensation[29-31] of 5-bromomethyldipyrromethene with dipyrromethene having a free α-position in the presence of tin chloride.

Corrole was obtained for the first time[34] by irradiating with the light from a tungsten lamp a suspension of a biladiene-*ac* in boiling methanol in the presence of a base. This results in the formation of a solution, the colour of which rapidly changes from yellow to green and then to red; from the last solution, crystals of corrole (IV) precipitate on cooling[35]. Relatively stable nickel and copper complexes of corrole[35], which may be obtained by the addition of metal cations either to solutions of corroles or to a suspension of 1,19-dideoxybiladienes-*ac* before irradiation, have been isolated.

The exact mechanism of the photocyclisation of biladienes-*ac* to corroles has still not been established[36,37], but it is most probable that the reaction has a free-radical mechanism[23,37]. Protons in the 10-position are definitely involved in the cyclisation. Solutions of the dihydrobromides of 1,19-dideoxybiladienes in benzene are red, while those in alcohol and in dimethyl sulphoxide are yellow, becoming green on addition of a base, for example piperidine. The colour change is caused by the abstraction of a proton in the 10-position by polar solvents and the formation of the monohydrobromide of 1,19-dideoxybilatriene-*abc*, which is converted into a free base under the action of piperidine.



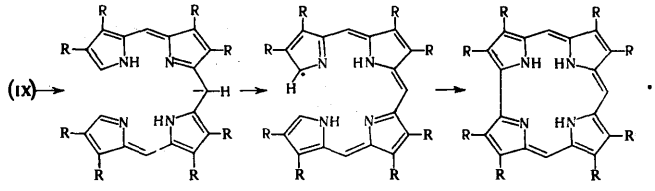
red yellow green

Photocyclisation of biladienes-*ac* is possible only in the presence of bases, which indicates the initial elimination of a proton from the central methylene group during the

photocyclisation process. This hypothesis is confirmed by the fact that 10,10-dimethylbiladienes are not cyclised to corroles[32].

Apart from the protons at the C_{10} atom, the photocyclisation is greatly affected by substituents in the 1- and 19-positions and also by the presence of metals. Corrole could not be obtained from 1,19-dimethylbiladiene by photocyclisation, while the cyclisation of biladienes unsubstituted in the 1- and 19-positions takes place readily. The reason for this is that the 1,19-dimethyl or 1,19-diethoxycarbonyl groups give rise to steric hindrance to cyclisation.

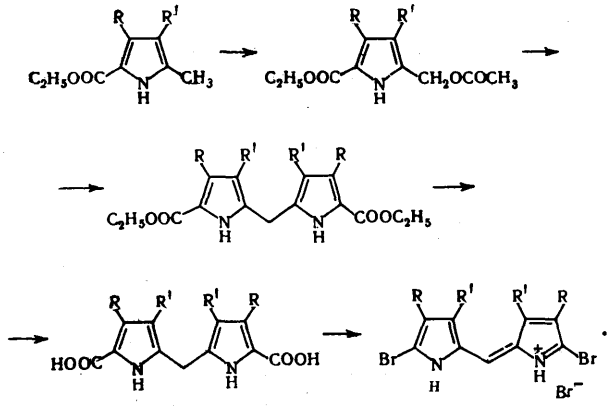
The mechanism proposed for the formation of corrole includes the formation of an intermediate radical:



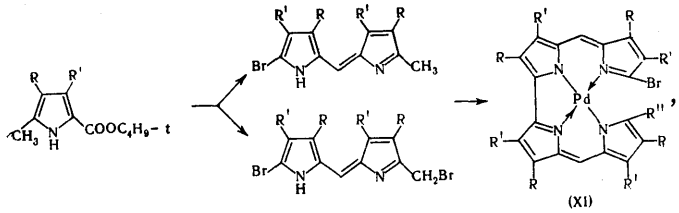
The effect of various free-radical initiators and one-electron oxidising agents on the cyclisation of 1,19-dideoxy-2,3,7,8,12,13,17,18-octa-alkylbiladienes-*ac* in the presence of ammonia has been examined[37]. When potassium hexacyanoferrate(III), ferric chloride, ceric sulphate, hydrogen peroxide, benzoyl peroxide, or t-butyl peroxide are added, cyclisation takes place readily and the replacement of atmospheric oxygen by nitrogen does not affect the rate of reaction and the yield of corroles; the corroles are formed in yields of 68–84%.

2. Attempts at Synthesis of Corrole by the Introduction from the Outside of a *meso*-Carbon Atom and Cyclisation of Tetrapyrrole Systems on Introduction of Hetero-Atoms

The cyclisation of various tetrapyrrole systems with introduction from the outside of a *meso*-carbon atom has been investigated as one of the possible ways of synthesising corrole[21,32,38]. The initial dipyrromethenes with symmetrical β-substituents were synthesised from substituted 5-ethoxycarbonyl-2-methylpyrroles[39], which, on oxidation with lead tetra-acetate, are converted into 2-acetoxymethylpyrroles and in an acid medium the latter are condensed into dipyrromethanes. After the hydrolysis of the ester groups, dipyrromethane-5,5′-dicarboxylic acid is treated with bromine in acetic acid and the hydrobromide of β-substituted 5,5′-dibromodipyrromethene is obtained[40]:



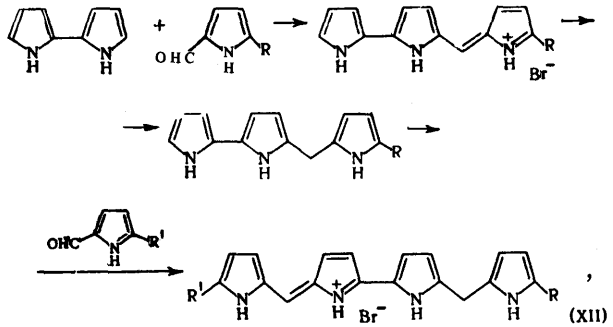
Dipyrromethenes with asymmetric β-substituents can be obtained by the action of bromine on the t-butyl ester of 5-methylpyrrole-2-carboxylic acid[41]; this results in the formation of a mixture of 5-bromo-5′-methyldipyrromethene and 5-bromo-5′-bromomethyldipyrromethene. The condensation of these pyrromethenes in the presence of palladium on strontium carbonate yields the chelate complex (XI, R″ = CH_3), which could not be cyclised. When two moles of 5,5′-dibromodipyrromethene were condensed in the presence of palladium on strontium carbonate or in the presence of copper and cobalt salts[22], the corresponding metal complexes (XI, R″ = Br) were obtained but these could not be cyclised either under the action of formaldehyde in an acid medium:



(XI)

where R = R′ = H, R = R′ = CH_3, or R = CH_3 and R′ = Br.

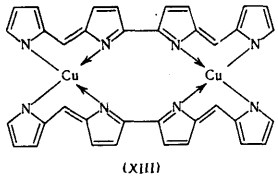
Tetrapyrrole systems (XII) containing a direct α-carbon–α-carbon bond between the two pyrrole rings have been used to synthesise corroles[38]. Two methods have been proposed for the preparation of compound (XII). When 2,2′-bipyrroles are condensed[28,42] with 2-formylpyrrole[43], one molecule of formylpyrrole adds on and 5-(pyrrol-2-yl)dipyrromethene is formed; hydrogenation of the latter yields pyrrolyldipyrromethane, the reaction of which with 2-formylpyrrole gives compound (XII):



(XII)

where R = R′ = H, R = R′ = CH_3, or R = CH_3 and R′ = Br.

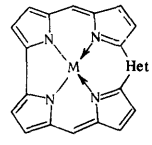
The second method of synthesising compound (XII) consists in the condensation[32] of 2-chloromethylpyrroles with 5-(pyrrol-2-yl)dipyrromethenes in the presence of tin chloride. In the cyclisation of the tetrapyrrole system (XII) in the presence of copper[32] or zinc[44] acetates, the corresponding chelate complexes of type (XI) and the copper complex (XIII) where isolated.



(XIII)

However, it it was not possible to introduce the *meso*-carbon atom into the tetrapyrrole system and cyclise the latter into corrole, a pseudocorrole system could be synthesised by the external introduction of a hetero-atom (O, N, or S).

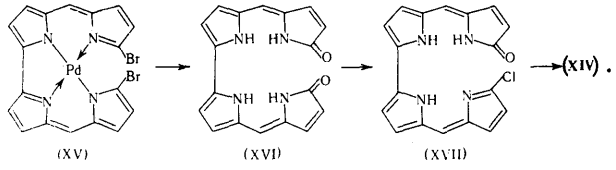
Oxa-, aza-, methylaza-, and thia-analogues of corrole (XIV) are planar compounds; each of the bridge atoms (Het = O, N, or S) contains at least one pair of free electrons which participate in the overall conjugated macrocyclic system:



(XIV)

In the condensation of two molecules of 5-bromodipyrromethenes in the presence of palladium on strontium carbonate a tetrapyrrole palladium complex (XV) [22] was obtained; when refluxed in the presence of hydrochloric acid it yielded a cyclic product to which the structure of a hydroxopalladium complex of corrole was initially ascribed [22]. Subsequent studies [45,46] showed that this compound is a derivative of the cyclic ether (XIV) (Het = O) in which the C_{10} carbon atom has been replaced by oxygen. Nickel and copper complexes of this ether have been synthesised.

The mechanism of the cyclisation of the free tetrapyrrole dibromide to the cyclic ether is probably as follows: in the course of the acid hydrolysis of the dibromide two products are formed—a dilactam (XVI) and a monolactam (XVII); the latter is produced as a result of the hydrolysis of one bromine atom and replacement of the second bromine atom by chlorine. Under the action of copper(II) acetate, nickel chloride, and palladium(II) chloride, the monolactam (XVII) is converted into complexes of the cyclic ether (XIV):



(XV) (XVI) (XVII)

Possibly the monolactam (XVII) isomerises initially to a lactim form, which in fact gives rise to the metal complexes.

The macrocyclic ether (XIV Het = O) can be obtained in a free form when copper is removed by treating the copper complex with concentrated sulphuric acid at 20°C. When the copper complex is treated with hot concentrated hydrochloric acid, the ring opens with formation of the monolactam (XVII). Under these conditions, nickel and palladium complexes are not converted into the dilactam (XVI), i.e. ring opening is facilitated by preliminary removal of the metal.

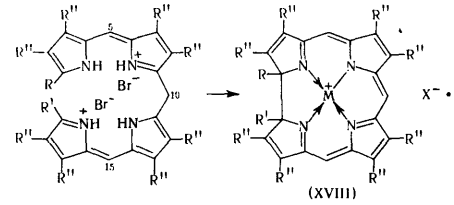
Treatment of the free cyclic ether with metal salts results in the formation of the corresponding metal complexes. The attempts to synthesise the macrocyclic ether (XIV) from the dibromides of the nickel and cobalt chelate complexes of type (XV) resulted in the formation of the dilactam (XVI) only.

The aza- and thia-derivatives (XIV, Het = NH, NCH_3, S) were synthesised by treating the palladium derivative (XV) in pyridine with ammonia, methylamine, or sodium sulphide respectively. The cyclic aza-derivatives were obtained in the form of both palladium and copper complexes as well as the free cyclic compounds.

3. Synthesis of Metal Complexes of Tetradehydrocorrins

Since in natural corrins the macro-ring has an angular 1-methyl group, the synthesis of various tetrahydrocorrins with angular substituents attracted much attention.

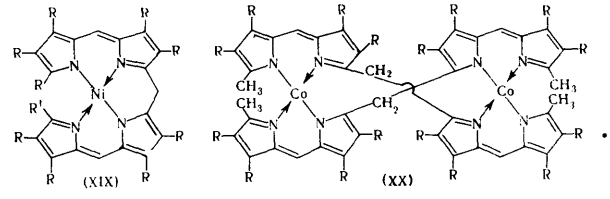
Aeration [47] of solutions of dihydrobromides of 1,19-dimethyl- or 1,19-diethoxycarbonyl-1,19-dideoxybiladienes-*ac* in the presence of bases and nickel or cobalt acetates yields salts of the nickel or cobalt complexes of 1,19-substituted tetradehydrocorrins (XVIII, M = Ni or Co, and R = R′ = CH_3 or $COOC_2H_5$): [48,49]



(XVIII)

Treatment of the methanol solutions of the dihydrobromides of 1,19-dimethyl-1,19-dideoxybiladienes-*ac* or the corresponding bilenes-*b* with copper salts results in the formation of porphyrin, the cyclisation of which takes place with the loss of one carbon atom [33].

When methanol solutions of 1,19-dimethyl-1,19-dideoxybiladiene-*ac* are heated with sodium and nickel acetates, a chelate nickel complex of biladiene (XIX) is formed initially and on further aeration and treatment with NO_3^-, Cl^-, or ClO_4^- ions cyclises into a complex of 1,19-dimethyltetradehydrocorrin (XVIII). In the reaction of 1,19-dimethyl-1,19-dideoxybiladienes-*ac* with cobalt acetate, the biladiene cobalt complex was not isolated; in this case the formation of the cobalt complex of 1,19-dimethyltetradehydrocorrin is accompanied by that of compound (XX), containing two tetrahedral cobalt atoms and two biladiene ligands [47]. Under the conditions of mass-spectrometric analysis, this dimer dissociates and cyclises with the elimination of hydrogen, being converted into the cobalt complex of 1,19-dimethyltetradehydrocorrin. The cyclisation of 1,19-disubstituted 1,19-dideoxybiladienes can be achieved only in the presence of a metal:

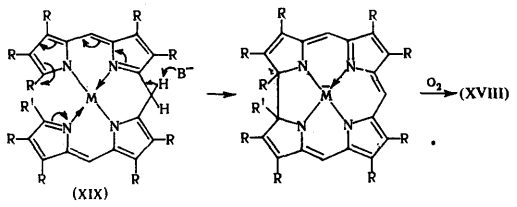


(XIX) (XX)

For a more detailed investigation of the cyclisation of biladienes, certain biladienes with substituents in the 5-, 10-, and 15-positions were synthesised [47]. It was found that the cyclisation of 10,10-dimethylbiladienes is impossible under any conditions. The cyclisation products of 5,10-dimethylbiladienes were not identified. The cyclisation of 5,15-dimethyl- and 10-methyl-biladienes yielded the salts of the nickel complexes of 5,15-dimethyl-10-methyl-tetradehydrocorrins, the cyclisation of 10-methylbiladienes being much slower than that of biladienes with a free 10-position.

The following mechanism was proposed for the cyclisation of 1,19-disubstituted 1,19-dideoxybiladienes-*ac* on the basis of these observations [36,47]. Initially a metal complex (XIX) is formed, the metal having a coordinating effect on the 1- and 19-positions, bringing them closer together and thereby facilitating the cyclisation. In the presence of

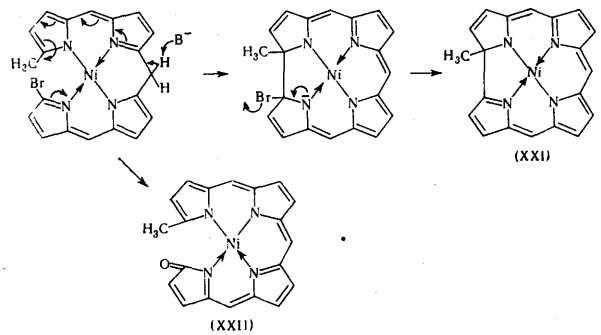
a base, the proton is eliminated from the C_{10} atom and an anion is formed, which on oxidation with atmospheric oxygen is converted into a complex of 1,19-disubstituted tetradehydrocorrin (XVIII):



(XIX) (XVIII)

To synthesise tetradehydrocorrins with an angular 1-methyl group, the dihydrobromides of 19-bromo-1-methyl-1,19-dideoxybiladienes-*ac* were cyclised. When methanol solutions of these compounds are heated with bases in the presence of nickel ions[50], nickel complexes of 1-methyltetradehydrocorrin (XXI) are readily formed in the absence of atmospheric oxygen[51]. The presence of air causes the formation of the nickel complex of the lactam (XXII); ordinary heat treatment of 19-bromo-1-methyl-1,19-dideoxybiladienes results in the formation of porphyrins[51].

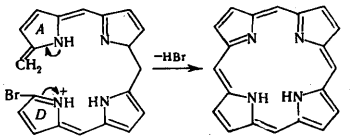
The mechanism of the formation of 1-methyltetrahydrocorrins can be represented as follows:



(XXI) (XXII)

In contrast to cyclisation which leads to complexes of 1,19-disubstituted tetradehydrocorrins, the formation of 1-methyltetradehydrocorrins includes the elimination of hydrogen bromide without an oxidation stage. The cyclisation is very rapid and the nickel complex of the biladiene was not isolated. In contrast to the alkaline cyclisation of 19-bromo-1-methyl-1,19-dideoxybiladienes, the formation of porphyrins[30,52] includes a stage involving the formation of an intermediate with an enamine structure of ring *A* followed by the attack of the enamine on the α-carbon atom of ring *D*.

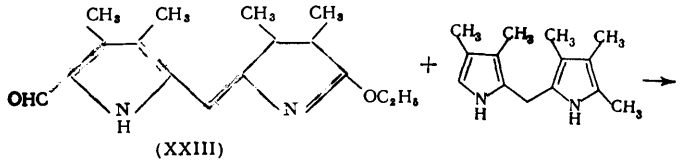
The cyclisation of 19-bromo-1-methyl-1,19-dideoxybiladienes was extended to 1-ethyl and 1-isopropyl-1,19-dideoxybiladienes, which were converted into the nickel complexes of the corresponding 1-alkyltetradehydrocorrins.



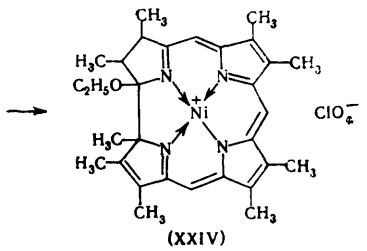
Attempts were made to activate the cyclisation of 19-bromo-1-methyl-1,19-dideoxybiladienes using copper acetate instead of nickel acetate, but the sole reaction product was then the copper complex of porphyrin. The cyclisation of 19-bromo-1-methyl-1,19-dideoxybiladienes in the presence of cobalt acetate in various solvents yielded a mixture of products. These results are inconsistent with the ease of isolation of the cobalt complexes of 1,19-disubstituted tetradehydrocorrins[47] and can be accounted for by the high reactivity of the cobalt complex of 1-methyltetradehydrocorrin. Hydrogenation of solutions obtained after treating 19-bromo-1-methyl-1,19-dideoxybiladienes with cobalt acetate over Raney nickel at 100°C under a pressure of 100 atm yields the cobalt complex of 1-methylcorrin[23].

The cyclisation of biladienes[53] containing the 19-alkoxy- instead of the 19-bromo-group has been described, but the use of such compounds proved to be less convenient. The cyclisation of the dihydrobromides of 19-ethoxycarbonyl-1-methyl-1,19-dideoxybiladienes-*ac*[47] yields the nickel complexes of 19-ethoxycarbonyl-1-methyltetradehydrocorrins; the ester group may be removed by hydrolysis followed by decarboxylation.

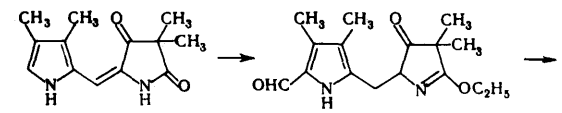
The cyclisation of certain reduced pyrrole derivatives constitutes a modification of the biladiene synthesis[53]. Condensation of the imino-ether (XXIII), obtained by the action of the Meerwein reagent[54,55] on the corresponding pyrrolidone, with 5-methyldipyrromethane yields a linear tetrapyrrole derivative, which is cyclised, without isolation, by aeration in the presence of nickel acetate into the complex (XXIV) containing 9 double bonds. The condensation of 3,3-dimethylpyrrole-2,4-dione with 2-formyl-3,4-dimethylpyrrole yields the dipyrromethene (XXV), which is hydrogenated, formylated, and converted into an imino-ether. The condensation of the latter with 5-ethoxycarbonyl-3,3′,4,4′-tetramethyldipyrromethane in the presence of nickel acetate yields the complex (XXVI) containing 8 double bonds:



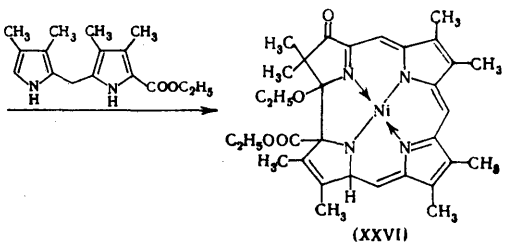
(XXIII)



(XXIV)



(XXV)



(XXVI)

B. SYNTHESIS OF CORRINS

There exist three approaches to the synthesis of the corrin ring—the central component of vitamin B_{12}. On the basis of the biosynthetic mechanism of the formation of corrin, Johnson[23] carried out the ring-closure of linear tetrapyrrole systems with subsequent reduction of the resulting macrocyclic compounds—metal complexes of tetrehydrocorrins.

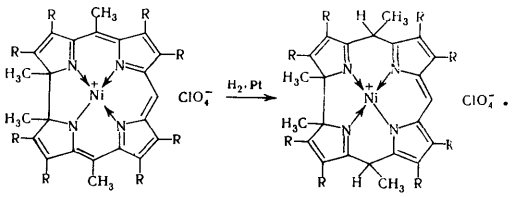
Eschenmoser and coworkers[56] achieved the synthesis of corrin from compounds oxidised to the same extent as the natural corrin compounds, using imino-ethers as the electrophilic components in the condensation reaction involving the formation of C–C bonds.

Neither of these methods permits the synthesis of corrins with a definite steric disposition of the β-substituents, analogous to their disposition in the corrin ring of vitamin B_{12}, where there are nine asymmetric centres. Woodward[57] is close to achieving the stereospecific synthesis of the corrin ring.

1. Synthesis of Corrins and Mono- and Di-dehydrocorrins by the Reduction of Tetradehydrocorrins

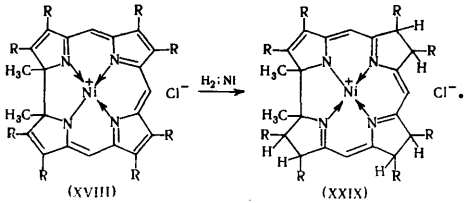
One of the methods for the synthesis of corrins is reduction of 1-methyltetradehydrocorrins. In the course of studies on the conditions governing the formation of corrins, a number of macrocyclic compounds intermediate between corrins and tetradehydrocorrins as regards degree of oxidation have been synthesised.

In the hydrogenation of corrole solutions[35] in the presence of platinum an extremely unstable unidentified product was isolated, which was rapidly oxidised in air and converted into the initial corrole. In the hydrogenation of the nickel complex of 1,5,15,19-tetramethyltetradehydrocorrin (XXVII)[47] in the presence of platinum the compound combines with one mole of the hydrogen and an amorphous very unstable orange perchlorate is formed, the ultraviolet spectrum of which resembles that of the nickel complex of dipyrromethene; the possible structure of the hydrogenated compound is represented by formula (XXVIII).



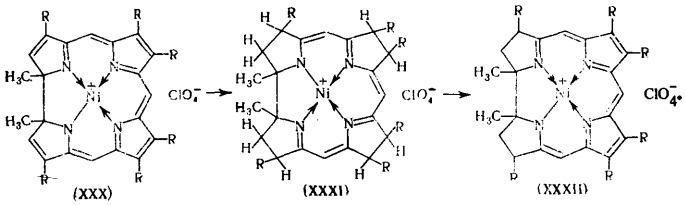
(XXVII) (XXVIII)

The salts of the nickel and cobalt complexes of 1,19-dimethyltetradehydrocorrins could not be reduced with zinc in acetic acid or sodium borohydride in methanol nor could they be hydrogenated over platinum[47]. The hydrogenation of the chloride and perchlorate of the nickel complex of 1,19-dimethyltetradehydrocorrin (XVIII) in the presence of Raney nickel at 100°C and a pressure of 100 atm proved to be more successful. Under these conditions, the product is the orange-yellow salt of the nickel complex of monodehydrocorrin (XXIX) containing seven double bonds. It is stable to oxidation and does not break down under the action of acids and alkalis:



(XVIII) (XXIX)

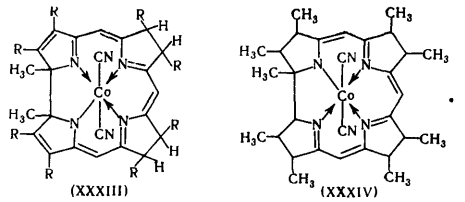
In all the corrins known at the present time[56] the directly linked pyrrole rings do not contain a ββ-double bond. Since the ββ-double bond of ring *A* in compound (XXIX) is sterically protected, a study was made of the hydrogenation of the perchlorate of the nickel complex of 1,19-dimethyltetradehydrocorrin (XXX) with free 2- and 18-positions[23], which results in the formation of the salt of the nickel complex of 1,19-dimethylcorrin (XXXI):



(XXX) (XXXI) (XXXII)

When compound (XXXI) is heated with alcoholic potassium hydroxide in air, a purple substance is rapidly formed, the ultraviolet and visible spectra of which are analogous to those of the tetradehydrocorrin complex but with an overall hypsochromic shift; the NMR spectrum corresponds to 7,12-didehydrocorrin (XXXII).[58] Similar dehydrogenation by bases in the presence of oxygen was observed previously[59].

The hydrogenation of the perchlorate of the cobalt complex of 1,19-dimethyltetradehydrocorrin (XVIII)[47] in the presence of Raney nickel at 100°C and a pressure of 100 atm leads to didehydrocorrin (XXXIII) after treatment with sodium cyanide, while hydrogenation of the cobalt complex of 1-methyltetradehydrocorrin of type (XXI)[23] under the same conditions gives 1-methylcorrin (XXXIV), isolated in the form of the cyanide. It is an amorphous product (probably a mixture of stereoisomers), its visible spectrum coincides with that of dicyanocobalamin, and the NMR spectrum indicates the presence of three *meso*-protons and the absence of olefinic substituents:



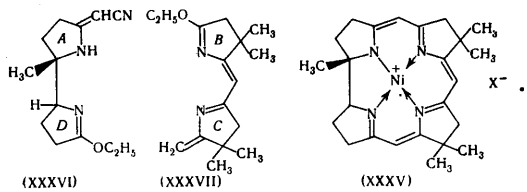
(XXXIII) (XXXIV)

Partial hydrogenation of substituted corrins and tetradehydrocorrins gives rise to asymmetric carbon atoms and the reaction products are mixtures of stereoisomers. Thus the reduction of tetradehydrocorrins cannot be used as a method for synthesising corrin systems analogous to natural corrins and by this method one cannot obtain compounds with a specified steric disposition of β-substituents.

2. Synthesis of Corrins via Imino-ethers

Corrins containing certain β-methyl substituents were synthesised for the first time by Eschenmoser and coworkers in 1964.[56] Imino-ethers[60] were used in this synthesis as the electrophilic components of the condensation in the formation of the nitrogen–carbon conjugated chain of the corrin chromophore[61,62]. These reactions were possible owing to the Meerwein reagent—triethyloxonium tetrafluoroborate[55].

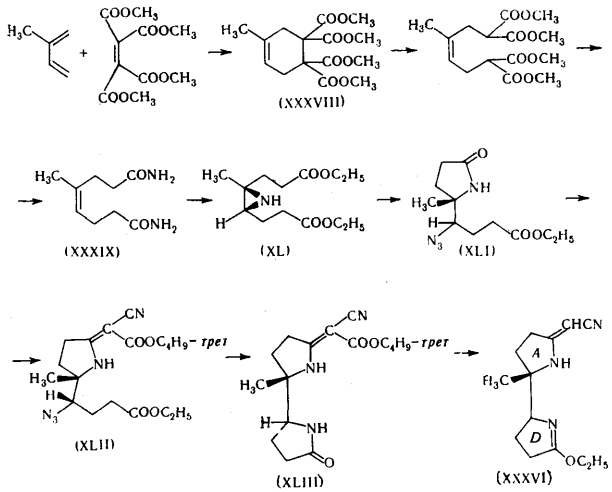
The synthesis of the corrin macrocyle (XXXV) consists of three principal stages: the formation of the *A*–*D* ring system (XXXVI), the formation of the *B*–*C* ring system (XXXVII), and finally the condensation of both systems with closure of the macroring (XXXV):[62]



(XXXVI) (XXXVII) (XXXV)

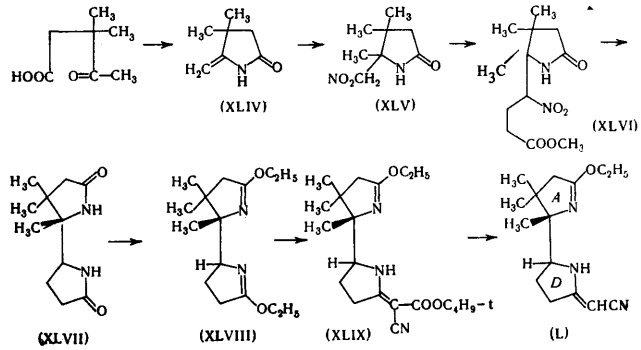
In the synthesis of the *A*–*D* ring system (XXXVI) the starting material is the tetraester (XXXVIII), which is obtained by the Diels–Alder reaction (see Scheme I).

Scheme 1



(XXXVIII) (XXXIX) (XL) (XLI) (XLII) (XLIII) (XXXVI)

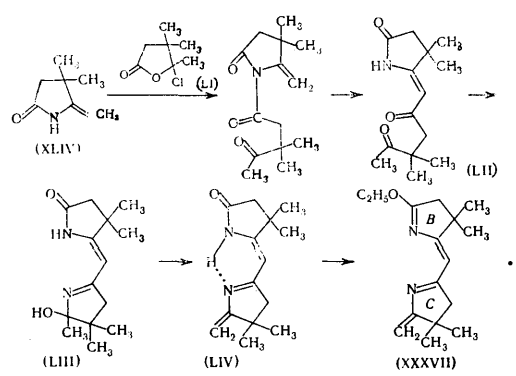
The opening of the ring (XXXVIII) leads to an aliphatic tetraester, which is converted under the action of sodium in liquid ammonia into the crystalline diamide (XXXIX). Stereospecific imination of the double bond in compound (XXXIX) followed by hydrolysis yields an aziridine derivative with the *cis*-configuration (XL). Under the action of the azide ion, a second nitrogen atom is introduced into the molecule with the opening of the aziridine ring and the formation of the butyrolactam ring (XLI). Condensation of the latter with butyl cyanoacetate leads to the ester (XLII). Selective catalytic hydrogenation of the azido-group in compound (XLII) results in the formation of the bicyclic monolactam (XLIII). Elimination of the butyl ester group by treatment with anhydrous trifluoroacetic acid and alkylation of the lactam group with an excess of triethyloxonium tetrafluoroborate yields the *A*–*D* ring system (XXXVI).



(XLIV) (XLV) (XLVI) (XLVII) (XLVIII) (XLIX) (L)

The cyclic enamide (XLIV) was used as the starting material in the synthesis of the *A*–*D* ring system. On nucleophilic addition of nitroethane to compound (XLIV) in the presence of potassium t-butoxide, the nitro-derivative (XLV) is formed. The Michael condensation of methyl acrylate with compound (XLV) yields a mixture of diastereoisomers (XLVI) which on reduction in the presence of Raney nickel is converted into a mixture of the diastereoisomeric dilactams (XLVII); the latter are readily separated by virtue of their different solubilities. The dilactam (XLVII) is converted[54,61] into the di-imino-ether (XLVIII), the treatment of which with butyl cyanoacetate gives compound (XLIX); the conversion of only one imino-group in compound (XLIX) is due to steric factors; compound (XLIX) is converted into compound (L).

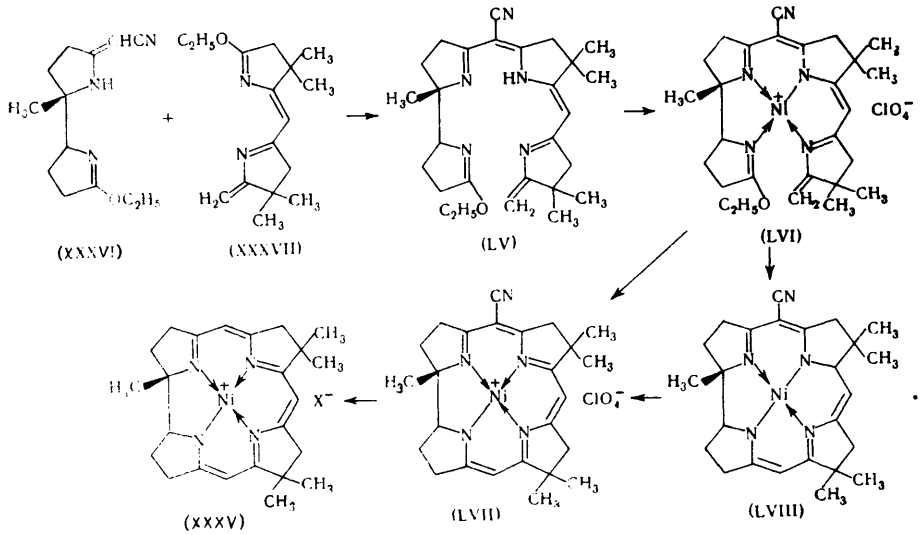
In the synthesis of the *B*–*C* ring system the starting material was also compound (XLIV). *N*-Acylation of the potassium salt of this enamide with a pseudo-acid chloride (LI) followed by photochemical rearrangement leads to compound (LII). The replacement of the carbonyl oxygen atom in compound (LII) by a nitrogen atom is achieved by the action of ammonia in methanol, which results in compound (LIII), the tertiary hydroxy-group of which is readily eliminated with formation of compound (LIV). Because of the intermolecular hydrogen bond in compound (LIV), when the latter is acted upon by triethyloxonium tetrafluoroborate, only *O*-alkylation takes place with formation of compound (XXXVII):



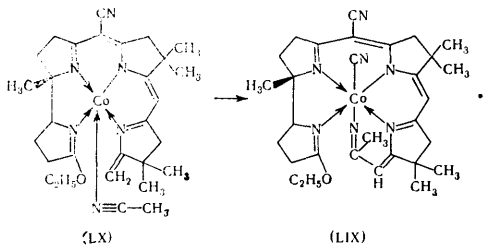
(XLIV) (LI) (LII) (LIII) (LIV) (XXXVII)

The main synthetic problem is the combination of both corrin components: the *A*–*D* (XXXVI) and *B*–*C* (XXXVII) ring systems[56]. It was solved using the specific C → C condensation of the β-iminocrotononitrile group of compound (XXXVI) with the imino-ether group of compound

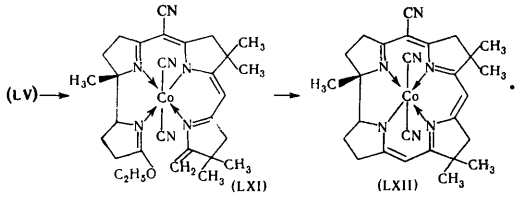
(XXXVII), leading to compound (LV), isolated as the sodium salt. The interaction of this salt with nickel perchlorate in acetonitrile yields the planar complex (LVI), where the imino-ether group and the exocyclic methylene group are sterically fixed, i.e. the geometrical conditions for the closure of the macroring have been created. When compound (LVI) is acted upon by potassium t-butoxide and then treated with perchloric or hydrochloric acid, compound (LVII) is formed. If an acid medium is avoided in the cyclisation reaction, the neutral deprotonated corrin complex (LVIII) is isolated, the protonation of which by acids leads to compound (LVII). When compound (LVII) is hydrolysed in an acid medium, the nitrile group is eliminated and compound (XXXV) is formed:



In the synthesis of the cobalt complex of corrin in the presence of acetonitrile, compound (LIX), called "pseudocorrin", was formed[63]. Initially a complex with acetonitrile attached to the cobalt atom (LX) is probably formed, whereby acetonitrile is activated and fulfils the role of the imino-ether group of ring *A*, which attacks the exocyclic methylene group:



In the absence of acetonitrile the reaction of the sodium salt (LV) with cobalt perchlorate leads, after treatment with cyanide ions and aeration, to the neutral complex (LXI), which cyclises to the dicyanide (LXII) under the action of potassium t-butoxide[64]:

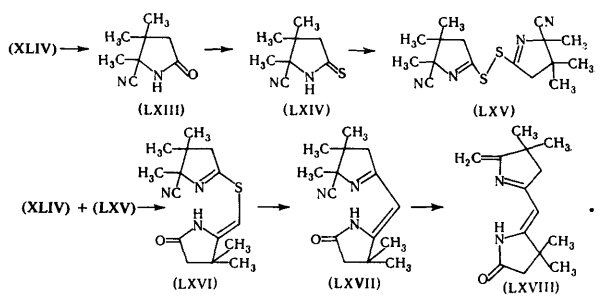


Analogous condensation of compound (L) with compound (XXXVII) results in the formation of the dicyanide of the cobalt complex of 1,2,2,7,7,12,12-heptamethylcorrin[65].

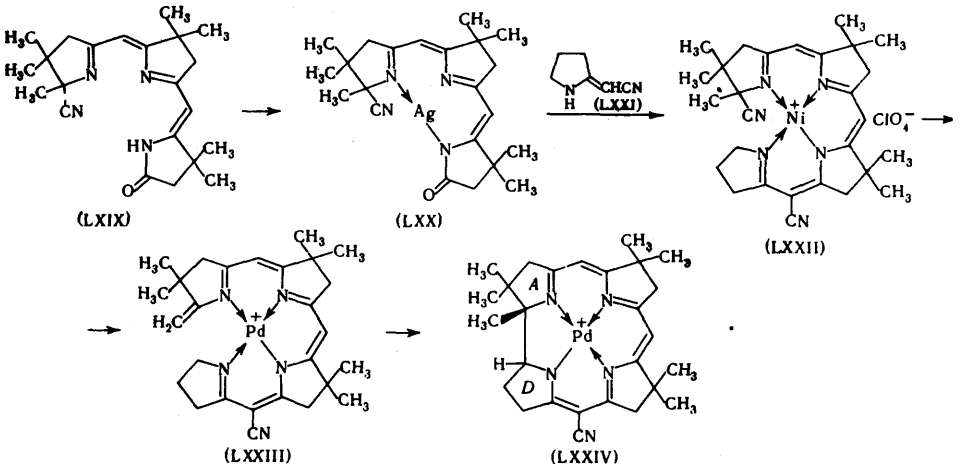
3. Synthesis of Corrins by the Introduction of a Sulphur Bridge Atom

Eschenmoser and coworkers[66] synthesised corrin also by another procedure, based on the formation of the corrin ring from monocyclic enamines and enamides by introducing a sulphur bridge atom; the final stage in this process is the photo-induced cycloisomerisation of the metal complexes of the tetracyclic system, proposed earlier by Johnson[37], and the formation of a bond between rings *A* and *D*.

Before introducing the enamide (XLIV) into the condensation reaction, the active C=C bond is protected by converting compound (LXIII) into the cyano-lactam (XLIV), the reaction of which with P_2S_5 yields the thiolactam (LXIV). The final oxidative formation of the sulphide bridge between the thiolactam (LXIV) and the enamide (XLIV) takes place under the action of benzoyl peroxide; this involves the intermediate formation of the di-imidazolinyl disulphide (LXV), which, under the action of an acid catalyst, undergoes an electrophilic substitution reaction with the CH_2 group of the enamide (XLIV) leading to the formation of compound (LXVI). Since the enamide (XLIV) is inert with respect to benzoyl peroxide, the formation of compound (LXVI) can be achieved in a single stage:



Scheme 2



When compound (LXVI) is heated with triphenylphosphine, compound (LXVII) is formed, which, after elimination of the CN group, is converted into the bicyclic lactam (LXVIII). Repetition of the process makes it possible to add to the lactam (LXVIII) a further molecule of compound (LXIV) and obtain the tricyclic lactam (LXIX). To introduce the fourth ring, the silver complex (LXX) is synthesised, in which the two nitrogen atoms are protected by being linked to silver. The reaction of the complex (LXX) with triethyloxonium tetrafluoroborate and subsequent condensation with pyrrolidine (LXXI) yields a tetracyclic compound, which is isolated as the perchlorate of the nickel complex (LXXII); under the action of palladium acetate in the presence of potassium cyanide, this compound is converted into the palladium complex and, after the elimination of the protective CN group, compound (LXXIII) is obtained, which cyclises quantitatively under the action of ultraviolet radiation or sunlight with formation of the palladium complex of 15-cyano-1,2,2,7,7,12,12-heptamethylcorrin (LXXIV) (see Scheme 2).

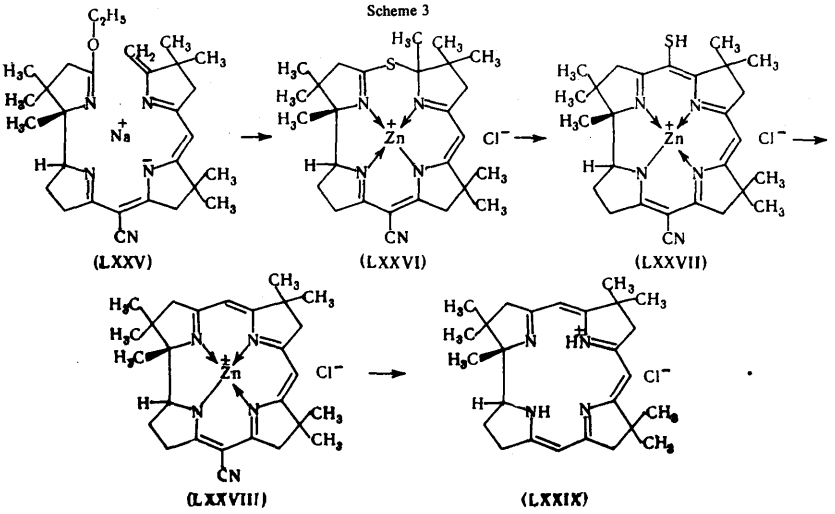
The structure of compound (LXXIV) was established on the basis of infrared, ultraviolet, NMR, and mass spectra and also by synthesis from compound (L) (*A*–*D* ring system) and compound (LXVIII) (*B*–*C* ring system). The nickel complex of compound (LXXII) could not be cyclised—probably the palladium(II) ion has a high tendency towards planar coordination.

A corrin system without cobalt was isolated[67] from the photosynthesing bacterium *Chromatium* strain D; this led to the syntheses of similar compounds. The synthesis is based on the formation of an amidine system with the intermediate introduction of a sulphur bridge atom[68].

In contrast to the imino-ether method for the synthesis of the corrin system, in the presence of a sulphur bridge atom it is not necessary to fix the ligand system into a rigid metal complex and it is possible to employ the labile zinc complex, from which the zinc ion can be readily removed in an acid medium.

Under the action of hydrogen sulphide in an acid medium, the tetracyclic compound (LXXV)[65] is converted into a thiolactam derivative, which is isolated as the zinc complex (LXXVI); without isolation of the intermediates, the latter is converted into the complex (LXXVII) by means of the following reactions: (a) oxidation with benzoyl peroxide in the presence of trifluoroacetic acid; (b) heating with trifluoroacetic acid in the presence of ethylenediaminetetra-acetic acid; (c) treatment with zinc perchlorate.

Scheme 3



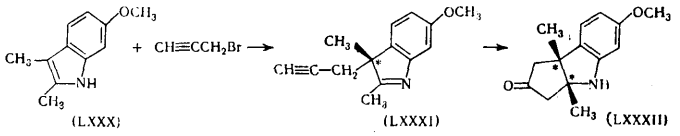
Probably trifluoroacetic acid converts compound (LXXVI) into an open-chain thiolactam which is oxidised by benzoyl peroxide, the sulphur atom being transferred to the methylene group of ring *B*; heating in the presence of ethylenediaminetetra-acetic acid results in the formation of the corrin chromophore; at the beginning of this process the intermediate breakdown of the complex ligand system probably takes place (Scheme 3).

Under the action of triphenylphosphine, the complex (LXXVII) is smoothly converted into compound (LXXVIII), the treatment of which with trifluoroacetic acid leads to the hydrochloride of the corrin base (LXXIX).[68]

4. Studies on the Stereospecific Synthesis of the Corrin Ring in Cobyrinic Acid

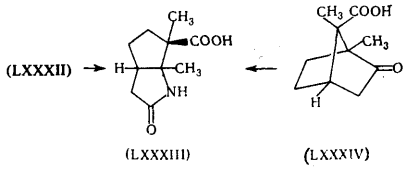
The corrin ring of vitamin B_{12} contains nine asymmetric centres, six of which are in the *A*–*D* ring system. To synthesise the corrin ring of vitamin B_{12} in which eight substituents have the correct absolute orientation, Woodward and Eschenmoser and coworkers obtained compounds which consist of rings *B* and *C* and the *A*–*D* ring system in an optically active form with the corresponding absolute specific configuration[57].

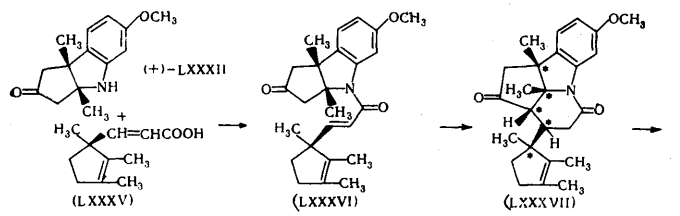
Rings *A*–*D* were obtained from methoxydimethylindole (LXXX).[69] The first asymmetric centre was produced by the reaction of the magnesium derivative of indole (LXXX) with propargyl bromide. Under the action of boron trifluoride and mercury(II) oxide in methanol, propargylindolenine (LXXXI) cyclises stereospecifically, yielding a tricyclic ketone (LXXXII) and forming the second asymmetric centre:

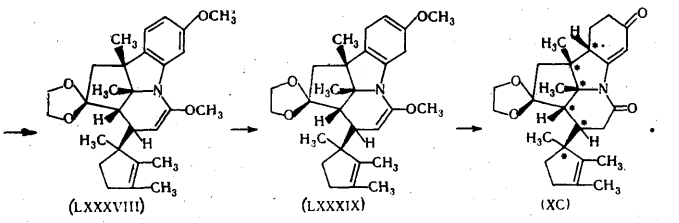


The tricyclic ketone (LXXXII) was separated into optical isomers by crystallising the diastereoisomeric ureas formed by the reaction of the racemic compound (LXXXII) with optically active α-phenylethyl isocyanate.

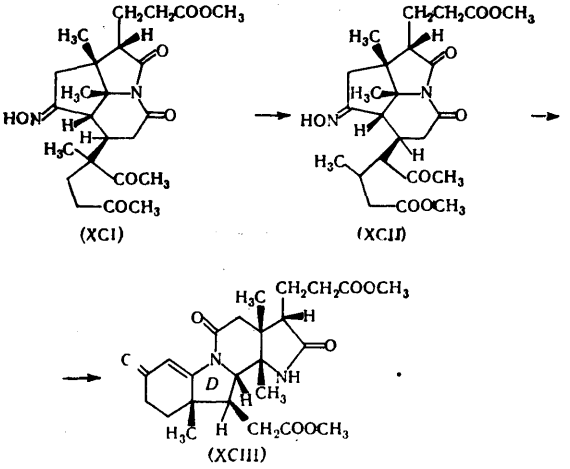
The absolute configurations[57] of the tricyclic ketones (LXXXII) were established by converting the laevorotatory isomer of compound (LXXXII) into the acid (LXXXIII) derived from the tricyclic lactam, which had been obtained from the keto-acid (LXXXIV) with known absolute configuration:



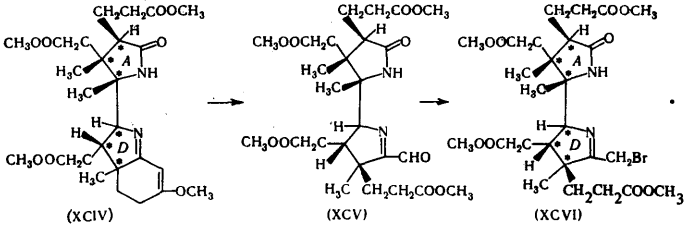




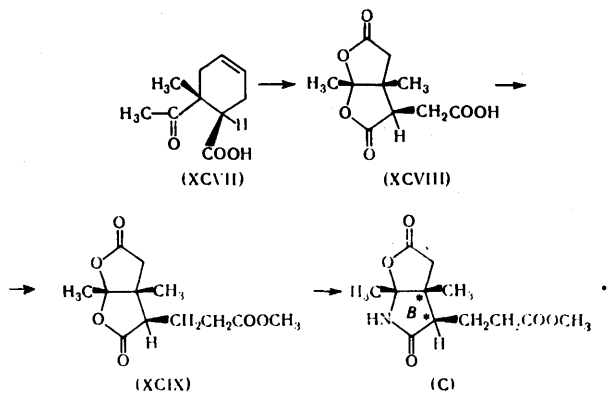
When the dextrorotatory tricyclic ketone (LXXXII) was condensed with the laevorotatory acid (LXXXV), the amide (LXXXVI) was formed, which, on treatment with potassium t-butoxide, gave the pentacyclic lactam (LXXXVII) containing two new asymmetric centres. To protect the active oxo- and carbamoyl groups, compound (LXXXVII) was converted into the ketal of the methoxyenamine (LXXXVIII), which was converted by treatment with lithium in liquid ammonia into the dihydro-derivative (LXXXIX). Acid treatment of compound (LXXXIX) yields the pentacyclenone (XC) with formation of the sixth and last asymmetric centre necessary for the synthesis of the *A*–*D* ring. To introduce a second nitrogen atom into the pentacyclenone (XC) molecule, the protecting ketal group is removed with formation of an oxime, the treatment of which with ozone and then iodic (HIO_3) acid and diazomethane converts it into compound (XCI). This substance is then converted into the keto-ester (XCII), the Beckmann rearrangement of which yields compound (XCIII) with two five-membered nitrogen-containing rings *A* and *D*:



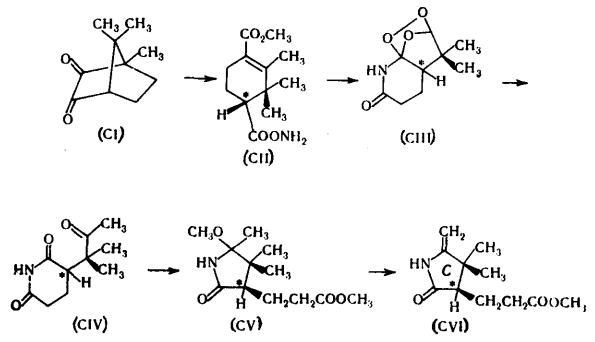
By heating compound (XCIII) with an excess of a base, acidifying, and treating with diazomethane, an isomer differing from compound (XCIII) by the orientation of the propionic acid chain was obtained. Its treatment with a methanol solution of hydrogen chloride leads to compound (XCIV), which, on reaction with ozone, subsequent acidification, and treatment with dimethyl sulphide gives rise to the aldehyde (XCV). The latter is converted into the bromide (XCVI), which constitutes the left-hand half of the vitamin B_{12} molecule:



The synthesis of ring *B* was begun with the condensation of β-acetyl-β-methylacrylic acid with butadiene leading to the cyclohexenecarboxylic acid (XCVII), which was separated into optical isomers by crystallising its salts with optically active α-phenylethylamine. Oxidation of the dextrorotatory acid (XCVII) gave the dilactone acid (XCVIII). By lengthening the acetate chain, the acid (XCIX) was obtained, which, after treatment with ammonia, was converted into the lactam (C), i.e. ring *B*. The absolute configuration of compound (C) was established by converting it into succinimide, the product of the ozonolysis of heptamethyl cobyrinate:

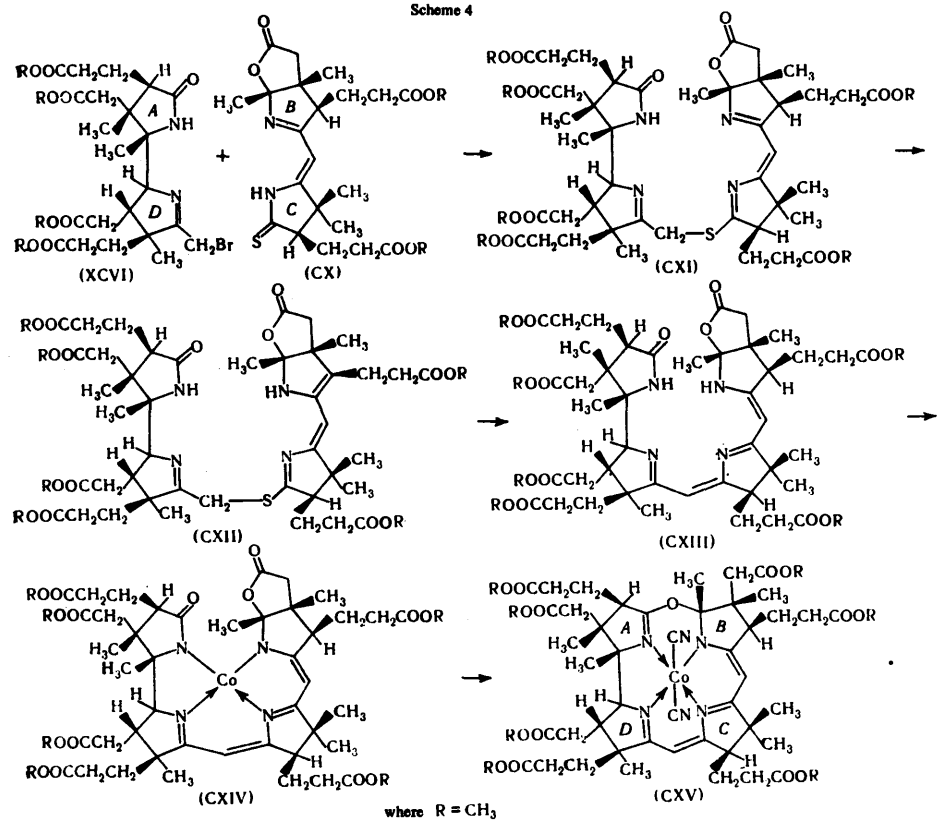


Ring *C* was synthesised from the dextrorotatory camphorquinone (CI), which was converted by a number of reactions into the amide (CII) with formation of the asymmetric centre of the required absolute configuration. Treatment of this amide with ozone leads after a number of reactions to the ozonide (CIII), the reduction of which yields compound (CIV) and the latter is converted in an acid medium into compound (CV). Finally pyrolysis of compound (CV) gives rise to the lactam (CVI), which constitutes ring *C*:

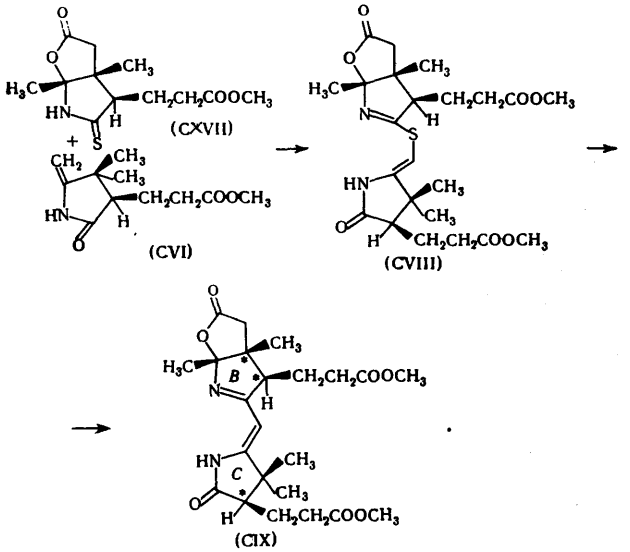


Rings *B* and *C* are joined by the introduced of a sulphur bridge atom [66] (see p. 933). The lactam (C) (ring *B*) is first converted into the thiolactam (CVII). Treatment of compound (CVII) and the enamide (CVI) (ring *C*) with benzoyl peroxide results in the formation of the S-bridge derivative (CVIII), which, on heating with $(C_2H_5O)_3P$, is converted into compound (CIX), constituting the *B*–*C* ring

Scheme 4



system with all the substituents having the correct absolute configuration:



For condensation into corrin, compound (CIX) was converted into the thiolactam (CX), which combines with the bromide (XCVI) in the presence of potassium t-butoxide with formation of the very labile sulphide (CXI). Under the action of aluminium oxide, compound (CXI) is converted into the isomer (CXII), which is desulphurated by treatment with diphenylphosphine, yielding compound (CXIII). The reaction of compound (CXIII) with cobalt perchlorate in acetonitrile in the presence of di-isopropylethylamine yields the cobalt derivative (CXIV). However, treatment of compound (CXIV) with triethyloxonium tetrafluoroborate gave the cyclic ether (CXV) instead of the expected corrin (see Scheme 4).

There is no doubt that cobyrinic acid will be synthesised in the near future.

III. PROPERTIES OF CORRIN SYSTEMS

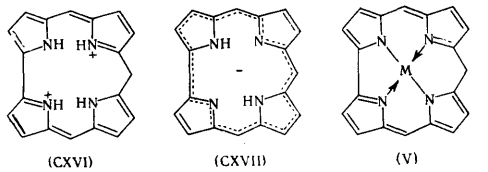
The chemical and physical properties of synthetic corrins, tetradehydrocorrins, and corroles have been little investigated§. Corrin compounds, both as free bases and metal complexes, are crystalline, intensely coloured, high-melting substances. They are sparingly soluble in water and organic solvents and readily soluble in chloroform.

The corrin ring without a metal is a base of moderate strength[68] with a pK of 8.6 (in the 4 : 1 dimethylcellosolve–water solvent).

A. CHEMICAL PROPERTIES

1. Formation and Properties of Metal Complexes

Free corrin systems (corroles and corrins) readily form metal complexes. Under the action of concentrated sulphuric or trifluoroacetic acid, the corrole (IV) [35] is converted into the non-aromatic dication (CXVI), from which the initial corrole is regenerated by treatment with alkali. The addition of dilute alkali to corrole solutions leads to the formation of the stable aromatic anion (CXVII). When corrole is treated with solutions of nickel or cobalt salts in the presence of ammonia, the corresponding metal complexes (V) are formed, the principal structural unit of which is a non-aromatic base corresponding to the dication (CXVI):



The reaction of corrin hydrochloride (LXXIX) with an excess of $Co[(CH_3)_2NCHO]_6[ClO_4]_2$ in acetonitrile yields, after oxidation with air and treatment with cyanide ions, the dicyanide of the cobalt complex 15-cyano-1,2,2,7,7,12,12-heptamethylcorrin[68].

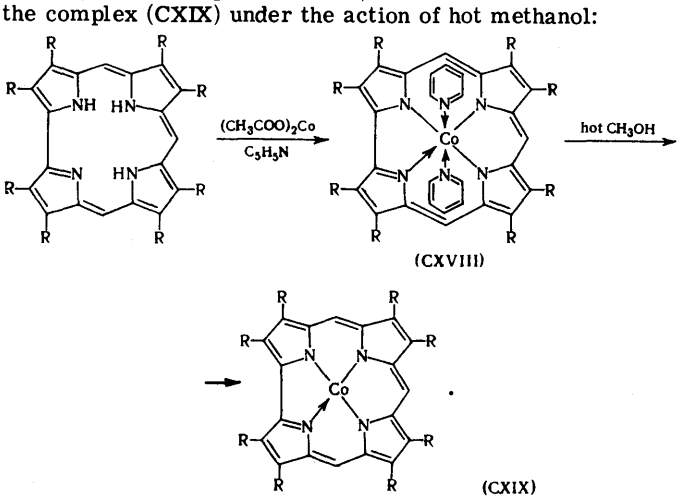
The cobalt and nickel complexes of corrins and 1,19-dimethyltetradehydrocorrins are extremely stable; the metal atom cannot be removed by treatment with strong acids and alkalis[21,47,56]. In this respect the complexes resemble natural cyanocobalamin[2].

Corrin systems are stable. Only two cases of the rupture of the tetracyclic macroring are known: the conversion of 1,19-dialkyltetradehydrocorrins on heating in *o*-dichlorobenzene into porphyrins[23,51] and the oxidation of the nickel complex of 1-methyltetradehydrocorrin to the lactam (XXII) by chromatography on alumina[51]. The mechanism of the oxidation was not established—possibly the 19-hydroxy-1-methyl derivative is formed initially and then converted into the lactam.

In contrast to the cobalt and nickel complexes, the zinc complex of corrin[68] is fairly labile, liberating the metal in an acid medium at room temperature and yielding the hydrochloride of the free base.

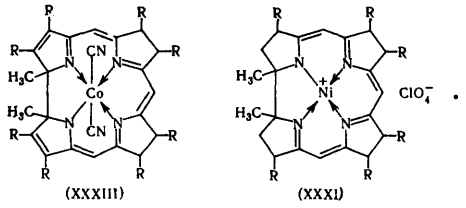
The nickel, cobalt, and copper complexes of corrole are relatively stable[35]. Their solutions are green, becoming red on treatment with alkali with the appearance of a Soret band in the ultraviolet spectra, which indicates the formation of an aromatic system.

The capacity of the cobalt atom to form octahedral complexes is responsible for the high reactivity of the cobalt complexes of corrin systems. The treatment of corrole with cobalt acetate in pyridine[36] results in the formation of the dipyridine complex (CXVIII), which is converted into the complex (CXIX) under the action of hot methanol:



§ The properties of synthetic corrin systems only are considered in the present review. The chemical and physical properties of cobalamins are deal with in other reviews[2,17].

When cobalt complexes of corrin[64] and 1,19-dimethyltetradehydrocorrins[47] are treated with cyanide ions, the corresponding dicyano-compounds are formed. The reduction of the dicyanide (XXXIII) with sodium borohydride followed by treatment with methyl iodide gives rise to spectroscopic changes corresponding to the formation of a derivative with a cobalt–methyl bond. This compound is readily photolysed and after treatment with sodium cyanide is reconverted into the initial complex (XXXIII):



(XXXIII) (XXXI)

The nickel complex (XXXI) is known to react with methyl iodide in an alkaline medium[63], but the structure of the product formed has not been established.

2. Deuterium Exchange

Deuteration of all types of corrinoid systems has been investigated—corrole[35], the nickel complex of 1-methyltetradehydrocorrin[51], and also the nickel and cobalt complexes of corrin[70].

All three *meso*-protons of corroles are rapidly exchanged for deuterium in deuterotrifluoroacetic acid[35], in contrast to porphyrins[71] where there is no exchange in the *meso*-positions under analogous conditions.

The *meso*-protons of the nickel complex of 1-methyltetradehydrocorrin are also exchanged in an acid medium. It was found that in a 0.25 M solution of the complex in deuterotrifluoroacetic acid at 35°C the period required for 50% exchange of the proton in the 10-position is 15 min and that for the protons in the 5- and 15-positions is 11 min[51].

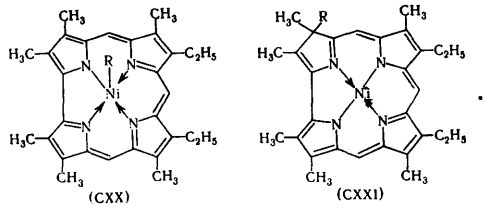
When the dicyanide of the cobalt complex of corrin is deuterated in an acid medium (pD 2, 5 days),[70] all three vinyl *meso*-protons are also exchanged but the allyl protons are not. When the duration of the deuteration process is reduced to 24 h, partial deuterium exchange takes place, preferentially in the 15-position.

The base-catalysed deuteration of the cobalt and nickel complexes of corrins[70] takes place selectively in the 8-position, i.e. the exchange takes place only in the allyl methylene group of ring *B*. The deuteration of the dicyanide of the cobalt complex of corrin under the action of the (1 : 1 t-C_4H_9OD–D_2O)–NaOD–KCN system (concentration of complex 0.071 M, pD 12, duration 7 h, temperature 31°C) is a first-order reaction with respect to corrin, the time required for 50% exchange being 99 ± 5 min. The exchange of protons in the 8-position of the nickel complex of corrin takes place even in the presence of a weak base (1 : 1 pyridine–D_2O, 15 h).

3. Some Reactions of the Corrin Ring

Of the electrophilic substitution reactions in corrin systems, only the cyanation of the nickel and cobalt complexes of corrins[70] and the alkylation of the nickel complexes of corroles[72] and 1-methyltetradehydrocorrins[73] have been investigated. The reaction of the dicyanide of the cobalt complex of corrin with three equivalents of chlorosulphonyl isocyanate followed by treatment with dimethylformamide leads to the 15-cyano-derivative. The cyanation of nickel complexes of corrin and 8,8-dideuteriocorrin[70] also takes place in the 15-position.

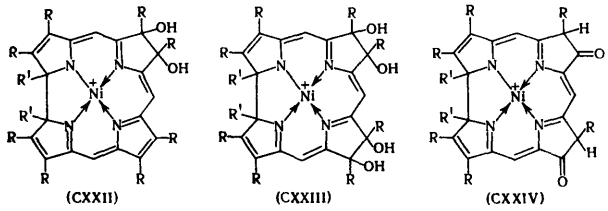
The alkylation of the nickel and cobalt complexes of 1-methyltetradehydrocorrins[73] with alkyl halides involves the 19-position, which results in the formation of salts of the complexes of 1,19-dialkyltetradehydrocorrins[23,51,73]. Methyl, ethyl, n-propyl, allyl, and benzyl groups were introduced in this way into the 19-position. The methylation of corrole[35] under the action of methyl iodide leads to the formation of a mixture of two *N*-methyl derivatives. The alkylation of the nickel complexes of corrole[72] involves the nickel atom with formation of an Ni–C bond, which yields Ni-alkyl derivatives (CXX). When compound (CXX) is heated in chlorobenzene in an atmosphere of nitrogen, a mixture of products is formed, containing the nickel complex of 3,3-dialkylcorrole (CXXI):



(CXX) (CXXI)

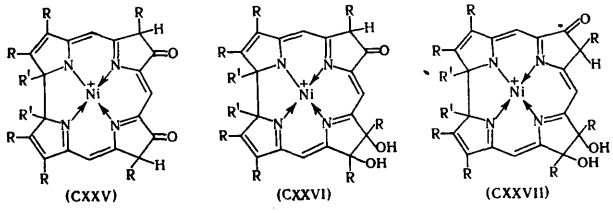
When allyl bromide is used as the alkylating agent[72], the nickel complex of *gem*-allylmethylcorrole (CXXI, R = $CH_2CH=CH_2$), which may be a product of the rearrangement of the Ni-allyl derivative, is isolated immediately.

The oxidation of the nickel complexes of tetradehydrocorrins with osmium tetroxide, leading to a mixture of 7,8-dihydroxytridehydrocorrins (CXXII) and 7,8,12,13-tetrahydroxydidehydrocorrins (CXXIII), has been investigated[74,75]:



(CXXII) (CXXIII) (CXXIV)

In the case of tetradehydrocorrins with free 2- and 18-positions, 2,3,7,8,12,13-hexahydroxydehydrocorrin and 2,3,7,8,12,13,17,18-octahydroxycorrin are formed in addition to compounds (CXXII) and (CXXIII). The pinacol rearrangement of compound (CXXIII) yields a mixture of diketones (CXXIV) and (CXXV):



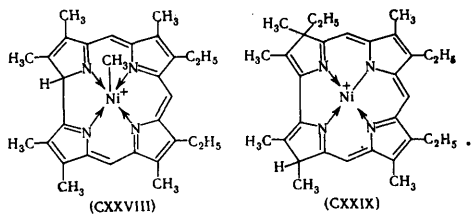
(CXXV) (CXXVI) (CXXVII)

The pinacol rearrangement of compound (CXXII) results in the formation of a mixture of monoketones, which, after treatment with OsO_4, are converted into dihydroxy-ketones (CXXVI) and (CXXVII), compound (CXXVI) being formed in

a greater amount. The structures of compounds (CXXVI) and (CXXVII) were confirmed by the products resulting from the pinacol rearrangement: compound (CXXVI) gives a mixture of compound (CXXIV) and compound (CXXV), while in the case of compound (CXXVII) only compound (CXXIV) is isolated.

Acids have different effects on the free bases of corroles and corrins and their metal complexes. The treatment of corrole with a dilute solution of hydrogen bromide in acetone leads to the formation of a monohydrobromide[34,35], in contrast to porphyrins which give rise to dihydrobromides under similar conditions. Similarly free corrin is isolated as the monohydrochloride[68].

The treatment of the nickel complex of 1-methyltetradehydrocorrin with strong acids, for example perchloric, results in the addition of a proton in the 19-position and the formation of a salt of the nickel complex[23,51]. The deprotonated complex of corrin (LVIII) is converted into the usual corrin complex under the action of hydrochloric or perchloric acid[65]. The nickel complex of the methyl derivative of corrole (CXX) is protonated by trifluoroacetic acid in the 19-position with formation of the complex (CXXVIII), which is converted by bases into the initial complex (CXX). When the nickel complex of *gem*-dialkylcorrole (CXXI) is treated with trifluoroacetic acid, a proton adds in the 17-position with formation of the complex (CXXIX):[72]



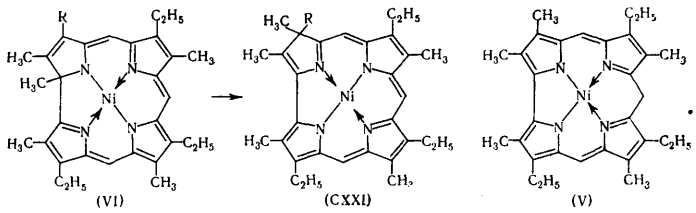
(CXXVIII) (CXXIX)

While alkylation of 1-methyltetradehydrocorrins leads to 1,19-dialkyl derivatives, there are reactions whereby 1,19-disubstituted tetradehydrocorrins are converted into corroles and 1-methyltetradehydrocorrins. The treatment of the perchlorate of the cobalt complex of 1,19-diethoxycarbonyltetradehydrocorrin with a methanol solution of sodium hydroxide at 20°C results in the hydrolysis and decarboxylation of both ethoxycarbonyl groups with formation of the cobalt complex of corrole. Similarly the nitrate of the nickel complex of 19-ethoxycarbonyl-1-methyltetradehydrocorrin is readily converted into the nickel complex of 1-methyltetradehydrocorrin[51].

In contrast to the ease of hydrolysis and decarboxylation of the 1- and 19-ethoxycarbonyl groups of tetradehydrocorrins, the hydrolysis of the 5-cyano-group of corrin complexes[56,64] with subsequent decarboxylation of the carboxylic acid formed takes place only after heating for many hours in an acid medium.

4. Rearrangements of Metal Complexes of Tetradehydrocorrins

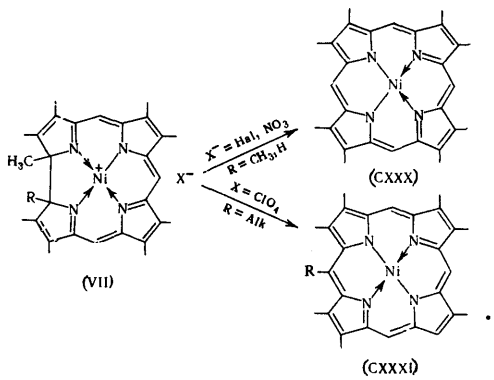
An interesting reaction of the nickel complexes of tetradehydrocorrins is their thermal rearrangement without expansion of the macroring. The nickel complexes of 1-methyltetradehydrocorrins (VI), which have a conjugated system of double bonds locked in the 1-position by an angular methyl group, are converted by refluxing in *o*-dichlorobenzene into nickel complexes of 3,3-dialkylcorrole (CXXI).[73,76] The migration of the angular methyl group from the 1- to the 3-position may be regarded as a sigmatropic shift[77]:



(VI) (CXXII) (V)

The thermal rearrangement of compound (VI) with R = H leads to the nickel complex of corrole of type (V) with formation of the acyclic lactam (XXII) as a side product. Another example of this kind of rearrangement is the formation of compound (CXXI, R = $COOC_2H_5$)[76] by heating the chloride of the nickel complex of 1,19-diethoxycarbonyltetradehydrocorrin in chlorobenzene with elimination of one ethoxycarbonyl group.

The salts of the nickel complexes of 19-alkyl-1-methyltetradehydrocorrins of type (VII) undergo the thermal corrin–porphyrin rearrangement[78] with expansion of the macroring, which leads to the formation of the nickel complexes of unsubstituted porphyrins (CXXX) or *meso*-substituted porphyrins (CXXXI):



(VII) (CXXX) (CXXXI)

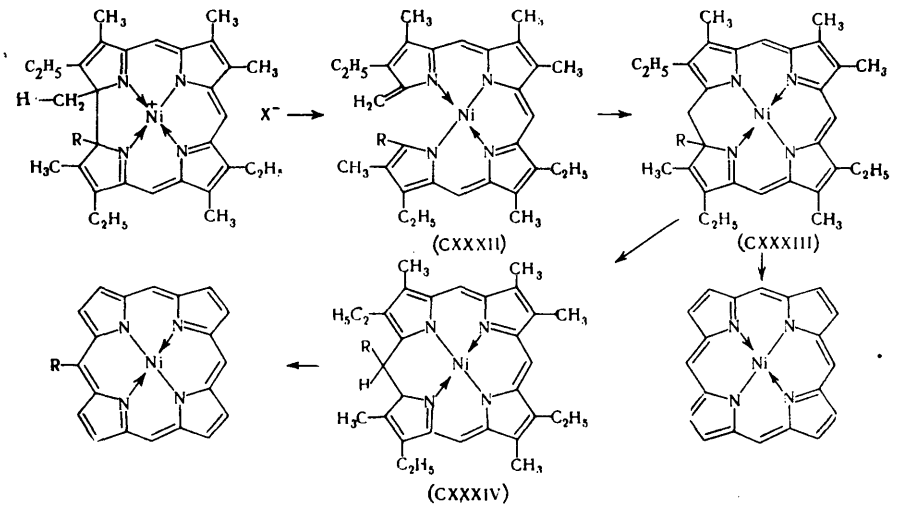
The formation of the nickel complexes of unsubstituted porphyrins takes place with elimination of an alkyl group in the rearrangement of the halides or nitrates of the nickel complexes of 19-alkyl-1-methyltetradehydrocorrins. The salts of the nickel complexes of 1,19-dimethyl- and 1-methyltetradehydrocorrins, containing any anion, give rise to the nickel complexes of substituted porphyrins, while the neutral nickel complex of 1-methyltetradehydrocorrin rearranges to 3,3-dialkylcorrole. This difference in thermal rearrangement is due to the presence of a positive charge in the macroring of salts of type (VII).

Perchlorates give rise mainly to *meso*-alkylporphyrins, formed by the migration of the alkyl group without isomerisation of its carbon framework; an exception is the 19-allyl derivative which is converted into *meso*-propenylporphyrin[78].

The first stage in the corrin–porphyrin rearrangement is the formation of an intermediate bilatriene complex (CXXXII) with elimination of a proton from the angular methyl group, the anion behaving as a base. The complex (CXXXII), containing a benzylidene instead of a methylene group, was isolated after the rearrangement of the bromide of the nickel complex of 19-benzyl-1-methyltetradehydrocorrin (see Scheme 5).

The cyclisation of compound (CXXXII)[78] leads to the complex (CXXXIII), which, after the migration or elimination of the alkyl group, is converted into a substituted or

Scheme 5



unsubstituted porphyrin. The type of porphyrin formed depends on the anion. The perchlorate ion, in the presence of which *meso*-substituted porphyrins are formed, has oxidising properties and the corrin–porphyrin rearrangement of perchlorates takes place via the cation (CXXIV).

The study of the rearrangement of the perchlorates of the nickel complexes of 1,19-dialkyltetradehydrocorrins with unsubstituted 2- and 18-positions showed that in this case the products are only *meso*-alkylporphyrins, i.e. there is no migration of the alkyl group to the adjacent free β-position.

The thermal corrin–porphyrin rearrangement of the chloride of the nickel complex of decamethyltetradehydrocorrin takes place anomalously, the product being the unsubstituted porphyrin and porphyrin oxide.

B. SPECTROSCOPIC PROPERTIES

One of the most important characteristics of tetrapyrrole macrocyclic systems is their absorption in the visible and ultraviolet regions. The electronic absorption spectra of the solutions of all corroles in chloroform have an intense absorption band at about 400 nm [30,34,35] (the Soret band) which indicates the aromaticity of the corrole ring. In concentrated sulphuric acid the Soret band disappears, i.e. corrole is converted into the non-aromatic dication (CXVI) (p. 937). The addition of dilute alkali to corrole solutions alters the spectrum, but the Soret band persists, which indicates that the anion (CXVII) is aromatic [35,36] (p. 937).

All corroles absorb at 396–399 nm (Soret band) and at 536–545, 550–553, and 592–594 nm. The Soret band persists in the spectrum of corrole hydrobromide [35] but there is additional absorption at 577 nm.

The spectra of the neutral complexes of corroles (V) (p. 937) do not contain the Soret band [35]; nickel complexes show a characteristic absorption at 360 and 659 nm, cobalt complexes absorb at 389, 499, and 528 nm, and finally copper complexes absorb at 397 and 548 nm. The salts of the nickel and cobalt complexes of 1,19-disubstituted tetradehydrocorrins (VII) (p. 927) have three characteristic absorption regions [47]: 273–278, 352–360, and 557–572 nm. The replacement of angular methyl groups by ethoxycarbonyl groups does not alter the spectrum [appreciably], the 557 nm band undergoing a bathochromic shift by 15 nm only, probably due to steric factors.

The presence of *meso*-methyl groups [47] has a considerable influence on the absorption of tetradehydrocorrins; when a *meso*-methyl group is introduced, the 557 nm band undergoes a bathochromic shift. The spectral shifts caused by the methyl group in the 10-position are equivalent to the overall effect of the methyl groups in the 5- and 15-positions; in both cases the 557 nm band is displaced by 45 nm and is located at 600 nm.

When the nickel complexes of 1-methyltetradehydrocorrins (XXI) (p. 930) are protonated by strong acids [23,47], the products are salts, the visible spectra of which are similar to those of the salts of the nickel complexes of 1,19-dimethyltetradehydrocorrins (XVIII) (p. 929). The spectra of the nickel and cobalt complexes of synthetic corrin [56,64] are typical for vitamin B_{12}. The visible spectrum of the dicyanide of the cobalt complex of 1-methylcorrin obtained by the reduction of the corresponding tetradehydrocorrin [23] coincides fully with the spectrum of cyanocobalamin [2].

Infrared spectroscopy has not been used quite as widely to characterise corrin systems. In the spectra of the nickel [56], cobalt [64], and zinc complexes of corrin and also in the spectrum of corrin hydrochloride [68] there are two intense bands in the region of the C=C and C=N absorption at 1592 and 1508 cm^{-1}, which are characteristic of the corrin chromophore and are present in the same region in the spectrum of cobyrinic acid [79].

The infrared spectra of the nitrates and perchlorates of the nickel and cobalt complexes of 1,19-disubstituted tetradehydrocorrins and also of the dicyanide of the cobalt complex of 1,19-dimethyltetradehydrocorrin [47] have been recorded; the spectra of the salts show absorption characteristic of the nitrate and perchlorate ions. In the spectra of compounds with angular ethoxycarbonyl groups there are bands at 1730–1740 cm^{-1} due to the ester carbonyl group, which is consistent with the presence in the tetradehydrocorrins of an ethoxycarbonyl group attached to an aliphatic carbon atom, while the ester carbonyl groups of biladienes, linked to unsaturated carbon atoms, absorb at 1695–1710 cm^{-1}.

Nuclear (proton) magnetic resonance spectra have been most widely used to establish the structures of tetrapyrrole macrocyclic compounds.

The NMR spectrum of 2,3,8,12,17,18-hexaethyl-7,13-dimethylcorrole[35], recorded in deuterochloroform using tetramethylsilane as standard contains a 0.88 τ singlet (5- and 15-*meso*-protons), a 1.18 τ singlet (10-*meso*-proton) a broad 13.48 τ singlet (the three protons of the NH groups), three partially overlapping quartets with the centre at 6.18 τ (the twelve protons of the methylene groups in the ethyl substituents), a 6.72 τ singlet (the six protons of the methyl groups), and three partially overlapping triplets with the centre at 8.30 τ (the 18 protons of the methyl groups in the ethyl substituents).

The NMR spectra of the chloride[36] and nitrate[47] of the nickel complex of 1,19-dimethyltetradehydrocorrin showed the following signals: a 9.34 τ singlet (the two angular methyl groups), a 2.41 τ singlet (the three *meso*-protons), a 7.30 τ singlet (the six methyl groups), and 8.54 τ triplet (the two methyl groups in the ethyl substituents), and a 6.83 τ quartet (the two methylene groups in the ethyl substituents).

The abnormally high signal due to the angular methyl groups (9.34 τ) is caused by the closeness of the $\beta\beta$-double bonds of the adjacent *A* and *D* rings, although it may be the result of the increasing drawing together of the cyclic system in consequence of the sp^3 hybridisation of both the 1- and 19-carbon atoms. The positive charge of the metal in the salts of 1,19-dimethyltetradehydrocorrins can lead to the de-screening of the protons of the 1- and 19-methyl groups, but this effect should be slight. In support of this hypothesis, one may say that neither vitamin B_{12} [80] nor synthetic corrin[56], which do not have a $\beta\beta$-double bond in rings *A* and *D*, give rise to signals in excess of 9 τ.

According to steric considerations the 1- and 19-substituents should be located on the opposite sides of the macroring.

The planar salts of the cobalt complexes of 1,19-dimethyltetradehydrocorrins are paramagnetic but the dicyanide octahedral complex[47] has a spectrum in which the angular methyl groups give rise to a signal of 9.26 τ.

The introduction of a 10-*meso*-methyl group results in a 6.83 τ singlet characterising this group, and reduces the intensity of the 2.55 τ singlet (two *meso*-protons), the remaining signals being unchanged. The spectrum of the nickel complex of 1,5,15,19-tetramethyltetradehydrocorrin reveals the presence of only one *meso*-proton (2.50 τ singlet), the 5- and 15-methyl groups giving rise to a 6.82 τ singlet and the two angular methyl groups to a 9.42 τ singlet[47].

The spectra of all the neutral nickel complexes of 1-methyltetradehydrocorrins[23,50,51] have an 8.5 τ singlet due to the three protons of the angular methyl group. The angular groups of the nickel complexes of 1-ethyl- and 1-isopropyl-tetradehydrocorrins[51] are characterised by 9.59 τ (ethyl) and 9.58 τ and 9.55 τ (isopropyl) singlets. The shielding of the angular alkyl groups can be accounted for by their closeness to the π-electron system of ring *A*, the degree of shielding depending strongly on the dimensions of the angular groups.

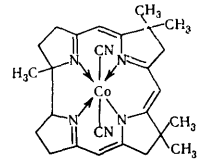
The protonation of the nickel complexes of 1-methyltetradehydrocorrins by strong acids results in the formation of salts the angular methyl groups of which are characterised by a 9.38 τ singlet[50] and the proton in the 19-position by a 6.73 τ singlet[51]; as for the metal complexes of 1,19-dimethyltetradehydrocorrins, the high signal due to the angular methyl group is caused by its interaction with the $\beta\beta$-double bond of the adjacent ring.

In the spectra of the nickel complexes of 1-methyltetradehydrocorrins[51] with several β-methyl substituents, the signal of one of them is at 8 τ, while those of the remaining methyl groups are at 7.6–7.8 τ. The study of the NMR spectra of many metal complexes of 1-methyltetradehydrocorrins with β-methyl substituents in various positions led to the conclusion that the shift of the signal to 8 τ is caused by the methyl group in the 3-position. Molecular models show that the substituents cluster together near the 1-, 2-, 18-, and 19-positions, i.e. the direct bond between rings *A* and *D* is protected.

The signals due to the *meso*-protons of the neutral nickel complexes of 1-methyltetradehydrocorrins[51] are at 2.8, 3.0, and 4.0 τ, while the analogous signals of the salts are at 2.4–2.5 τ (C_{10}) and 2.65–2.8 τ (C_5 and C_{15}). The lower chemical shift of the signals due to the *meso*-protons shows that the deshielding effect of the nickel cation is directed to the *meso*-positions. For example, the three *meso*-protons of the salts of the nickel complexes of 1,19-dimethyltetradehydrocorrins give rise to one or two singlets at 2.5 τ,[47] in contrast to porphyrin salts[81].

The signal due to the *meso*-proton of the nickel complex of 1-isopropyltetradehydrocorrin at 2.88 τ has the form of a sharp singlet, while the other two *meso*-protons give rise to very broad signals at 3.3 and 4.13 τ; the *meso*-protons of the nickel complex of 1-methyltetradehydrocorrin are characterised by three sharp singlets. Possibly in 1-isopropyltetradehydrocorrin the conformation equilibrium is established slowly along the axis passing through C_{10} and the C_1-C_{19} bond, similarly to the analogous effect in annulenes[82].

In the NMR spectra of the nickel and cobalt complexes of corrin[56,65] the positions, structures, and intensities of all the signals correspond to the following hypothetical molecular structure:



In the NMR spectrum of the dicyanide of the cobalt complex of corrin[70] in $CDCl_3$ there are signals due to five methyl groups, two non-allylic methylene groups, four allylic methylene groups, and three vinyl *meso*-protons, which are characterised by singlets at 4.60, 4.56, and 4.44 τ; the last refers to the proton in the 15-position and is very broad due to the spin–spin interaction with the protons of the allyl group of ring *C*, the signal of which is also a diffuse singlet at 7.16 τ. The methylene group in the 8-position is characterised by a singlet at 7.09–7.07 τ and the methylene groups in the 3- and 17-positions are characterised by a multiplet at 6.9 τ.

In the NMR spectrum of the nickel complex of corrin the *meso*-proton in the 15-position gives rise to a weak triplet; it has been established by the double resonance method that the triplet is due to the spin–spin interaction of the *meso*-proton with the methylene group of ring *C*.

The NMR spectra of the corrins (XXXI) and (XXXIV) [23] (p. 931), obtained by the hydrogenation of tetradehydrocorrins, show that none of the β-methyl groups is [part of] an olefinic substituent: the three *meso*-protons of corrin (XXXI) give rise to singlets at 3.93 and 4.04 τ and the *meso*-protons of compound (XXXIV) are characterised by a broad singlet at 4.5 τ.

As already noted, NMR spectroscopy is the principal method for the establishment of structures of tetrapyrrole macrocyclic compounds. This is particularly true as regards the determination of the structures of the reduction products of tetradehydrocorrins.

In the studies on the synthesis of corrins a number of tetrapyrrole macrocyclic compounds with different degrees of unsaturation were isolated. The metal complex (XXIV)[53] (p. 930), which has nine double bonds, is characterised by three singlets between 7.45 and 7.69 τ (aromatic methyl group), two doublets at 8.38 and 8.62 τ (aliphatic methyl group), and a singlet at 8.8 τ (angular methyl group).

The chelate complexes (XXVI),[53] (XXXII),[63] and (XXXIII)[47] (pp. 930 and 931) each contain eight eight double bonds. In the NMR spectra of these compounds there are signals due to the three *meso*-protons (singlets at 2.41–3.13 τ) [in the case of compound (XXVI) one *meso*-proton gives rise to a doublet] and signals arising from the methyl groups attached to the unsaturated carbon atoms (singlets at 7.55–7.75 τ). In the spectrum of compound (XXVI) there are singlets at 8.31 and 8.43 τ produced by the *gem*-methyl groups.

Compound (XXIX) contains seven double bonds[47] (p. 931). The spectrum of this compound is very complex, but certain assignments have been made: the *meso*-protons are characterised by three singlets near 4.4 τ, which coincide with the signals from the synthetic nickel complex of corrin[56]; the intensity ratios are not 1 : 1 : 1, probably because of the presence of several stereoisomers. The 7.97 τ singlet is due to the protons of the two olefinic methyl groups, which indicate the retention of the $\beta\beta$-double bond in ring *A* or *D*. The 9.22 τ singlet, corresponding to three protons, suggests the screening of one angular methyl group by the $\beta\beta$-double bond of an adjacent ring. Finally a complex series of peaks at 8.6–9.1 τ characterise the β-methyl groups attached to the aliphatic carbon atoms and the signals at 6.7–7.4 τ characterise the β-protons of the reduced rings.

In conclusion it should be noted that the development of the chemistry of corrin systems is still in the initial stage. Future studies will undoubtedly reveal many interesting and important facts in this field as well as theoretical generalisations, which will make it possible to synthesise natural biocatalytic systems and biologically active structures similar to them.

Catalytic Properties of Rhenium and Its Compounds

M.A.Ryashentseva and Kh.M.Minachev

The most promising applications of rhenium are in electronics, radio technology, electrical technology, and the vacuum electronics industry. The present review deals with the application of rhenium and its compounds as catalysts for various reactions in organic synthesis. 107 references.

IV. Mixed rhenium catalysts (liquid-phase hydrogenation, rearrangement of hydrocarbons, and reforming of light petroleum fractions) 952

I. INTRODUCTION

Since its discovery in 1925, rhenium has claimed a special place among the rare elements[1,2]. Its existence was predicted by Mendeleev, who called the element dvi-manganese. Rhenium belongs to Group VII of the Periodic Table, with atomic number 75, atomic weight 186.3, atomic radius 1.361 Å, and a hexagonal lattice with lattice parameters $a = 2.765$ Å, $c = 4.470$ Å, $c/a = 1.61$. Its melting point (3170°) is the third highest after diamond and tungsten, and its physical properties are similar to those of the refractory metals of Group VI. Due to the presence of five electrons in the 4*d* shell, which are available for covalent bond formation in addition to the two 6*s* electrons, rhenium is a fairly reactive element. The chemical properties of rhenium are similar to those of the Group VII metals (in particular, manganese). The metal is stable towards oxidation and shows remarkable corrosion resistance in moist and aggressive ambients. The most stable oxygen, sulphur, and selenium compounds of rhenium are those in which the element has a valence of four or seven (ReX_2 and Re_2X_7, where X = O, S, Se). Several reviews of the chemistry of rhenium and its compounds have appeared[3-19].

Rhenium is used at present as an electrical contact material, for metallic coatings, for alloys having special physical properties, as an additive in corrosion-resistant alloys, etc. The demand for rhenium and rhenium salts is increasing continuously in the USSR as well as in the USA, Germany, Britain, and France.

The production of rhenium in the USA had reached 1000 tons per annum in 1957[17], the main deposits of rhenium being found in that country. In countries where platinum resources are inadequate, the search for alternative catalysts is an urgent problem: rhenium offers attractive possibilities in this direction. The fact that rhenium lies close to the platinum group metals in the Periodic Table suggests comparable catalytic properties in the presence of hydrogen: in particular, the ability to catalyse hydrogenation and dehydrogenation reactions, activation of unsaturated bonds, promoting action, etc. The properties of rhenium supported on various carriers are being extensively studied. When producing a catalytically active surface it is important to choose a metal which will not suffer recrystallisation during the catalytic reaction. Hence, metals with a high melting point and resistant to ageing effects are particularly valuable. Rhenium is very promising in this respect because of its high melting point and its closely packed structure.

No systematic investigation of the catalytic properties of rhenium was published until the 1930's, the only information being found in the Patent literature. The recent discovery of the element, and the high cost of its production, may have been responsible for the lack of open publications.

Thus, the use of rhenium as a catalyst for the chlorination of methane to chloroform, and of rhenium sulphide on active carbon for the dehydrogenation of fuel oils under pressure and for the synthesis of ammonia, is disclosed in a number of Patents[20-28]. Deuterium can be obtained from D_2O by exchange with hydrogen in the presence of Re_2S_7. Rhenium oxide and rhenium salts have been proposed for the oxidation of sulphur dioxide to sulphur trioxide; colloidal rhenium (in large excess) has been used for the reduction of the double bonds in maleic and cinnamic acid. Fast isotope exchange between water and deuterium has been reported on a rhenium heptasulphide catalyst supported on carbon[29]. The replacement of deuterium by hydrogen in heavy water occurs also in the presence of metallic rhenium[30,31]. Rhenium is not normally used as an oxidation catalyst because its oxides are too volatile in an oxidising medium[32]. However, telluric oxide containing 5% of rhenium oxide[33] is used for the selective oxidation of methyl or methylene groups adjacent to a double or a triple bond by a phenyl radical or hydroxyl group. In the oxidation of propene by air to acrolein[34,35], the yield is ~16% on a catalyst containing rhenium oxide as compared with ~2% on a catalyst without rhenium oxide. Alloy catalysts have a high activity in the vapour-phase oxidation of sulphur dioxide to sulphur trioxide[36,37]. Small additions of rhenium to these catalysts increase their catalytic activity and improve their stability towards poisoning. Thus, tungsten is relatively inactive towards the oxidation of sulphur dioxide to sulphur trioxide, but it becomes active when alloyed with 10% of rhenium. In the presence of this alloy, supported on glass wool, the extent of reaction is 75%, whereas it is only 30% when the rhenium is omitted. In the oxidation of ammonia[34,35] a platinum–rhenium alloy gives a higher yield of product than does the simple platinum catalyst as

well as showing higher uniformity and resistance to poisoning. In aqueous solutions[33] rhenium oxide can be used for the oxidation of nitrites to nitrates and sulphites to sulphates.

Tropsch and Kassler[38,39], who studied the hydrogenation of ethylene to ethane and the production of methane from CO_2 and H_2, and demonstrated the large increase in activity resulting from the addition of rhenium to a copper catalyst, also published their work in the 1930's. These authors suggested the possibility of hydrogenating unsaturated hydrocarbons containing not less than three carbon atoms. Schmidt[40] pointed out that rhenium is inferior to platinum, palladium, and nickel in dehydrogenating power.

Evidently, only fragmentary knowledge of the catalytic properties of rhenium was available in the 1930's. During the 1940's, and particularly since 1960, intensive studies of the catalytic properties of rhenium began, both in the Soviet Union and abroad, concurrently with the greater availability of the element.

II. RHENIUM AND ITS OXYGEN, SULPHUR, AND SELENIUM COMPOUNDS (dehydrogenation of alcohols and reduction of various organic compounds)

Platonov and coworkers[41-49] showed that finely divided rhenium at room temperature is relatively inactive towards the hydrogenation of maleic acid and cyclohexene. On raising the temperature to 250° the element catalyses the hydrogenation of benzene, cyclohexene, nitrobenzene, and nitric oxide. Up to 22% of cyclohexane is formed from cyclohexene[41]. A simple method of preparing rhenium in a disperse and active form from ammonium perrhenate — the "nitric acid" method — has been described[41]. Acetone was obtained in 85% yield by dehydrogenation of isopropanol on a finely divided rhenium catalyst[42,43] at 400°; from n-propanol, propionaldehyde was obtained in 20.8% yield. Isopropanol is dehydrogenated much more readily than n-propanol on a rhenium catalyst[43], but not so readily as n-butanol[44]. The dehydrogenation of isopentanol has also been investigated[45]: no side-products (acids, esters, unsaturated compounds) are found in the catalysis product. Cyclohexanol at 450° gives[47] up to 25% of cyclohexanone, and small amounts of cyclohexene, benzene, and a trace of phenol. Known alcohol dehydrogenation catalysts, such as platinum, nickel, zinc, and copper, were shown to have a lower activity and selectivity.

The dehydrogenation properties of rhenium catalysts have been studied[45] by examining the decomposition of formic acid ($HCOOH \rightarrow CO_2 + H_2$). The activity of the rhenium catalyst was found to be comparable to (or higher than) the activity of spongy Pt, Pd, and Cu catalysts. The percentage decomposition to CO_2 and H_2 was 8.7, 57.5, 100, and 100% at 100, 175, 230, and 250° respectively.

Broadbent and coworkers[50-55] studied the catalytic activity of rhenium catalysts in the liquid-phase hydrogenation of over 100 organic compounds. The following rhenium compounds were used as catalysts: (A) rhenium black, prepared by reduction of Re_2O_7 *ex situ*; (B) rhenium black, prepared by reduction of Re_2O_7 *in situ*[50]; (C) Re_2O_3, reduced by sodium borohydride[51]; (D) the tetrahydropyran complex of Re_2O_7[52]; (E) $ReO_2 . 2.5H_2O$[53]; (F) ReO_3[54]; (G) $ReO.2H_2O$.[55] Optimum reduction conditions were identified (temperature, pressure, and time), and suitable solvents were chosen. The properties of these catalysts are compared in Table 1, which lists only cases in which the yield was practically quantitative.

It is evident from Table 1 that many of the rhenium catalysts have considerable activity. By choosing comparable hydrogenation conditions (temperature, reaction time, and pressure), the best catalysts can be identified. For example, the best catalyst for the reduction of hex-1-ene to hexane is *in situ* rhenium black (B); for the reduction of 2,4,4-trimethylpent-1-ene to 2,4,4-trimethylpentane, the tetrahydropyran complex of Re_2O_7 (D) and $ReO.2H_2O$ (G); for the reduction of maleic to succinic acid, *ex situ* rhenium black (A) and Re_2O_3 (C); for the reduction of the C=C double bond in the side chain of styrene to ethylbenzene, Re_2O_3 (C); for the reduction of cyclohexanone to cyclohexanol, $ReO.2H_2O$ (G); for the reduction of the N=N double bond in azobenzene to aniline, ReO_3 (F); for the reduction of the C=C double bond in cyclohexene to benzene and cyclohexane, ReO_3 (F); for the reduction of the C=C bond in the carbonyl group of crotonaldehyde to n-butanol, $ReO_2 . 2.5H_2O$ (E); for the reduction of butan-2-one to n-butanol, $ReO.2H_2O$ (G); for the reduction of ethyl benzoate to benzyl alcohol, *in situ* rhenium black (B); for the reduction of acetophenone to 1-phenylethanol, Re_2O_3 (C); for the reduction of ethyl acetate to ethanol, *in situ* rhenium black (B). The best catalyst for the reduction of the carbonyl group in acetic, octanoic, and dodecanoic acid to the corresponding alcohol is $ReO.2H_2O$ (G); for the reduction of hexanoic acid to n-decanol, *in situ* rhenium black (B); for the reduction of benzoic acid to toluene, $ReO.2H_2O$ (G); for the reduction of amino and nitro groups, and also hydrazobenzene to aniline, *ex situ* rhenium black (A). Conditions leading to the synthesis of various important alcohols from their corresponding acids have also been discovered[50] (see Table 1, No. 22-28).

From a comparison of the activity of rhenium catalysts with that of the conventional hydrogenation catalysts (Raney-Ni, PtO_2, and $CuCr_2O_4$), Broadbent concludes[50] that the rhenium catalysts are inferior to PtO_2 and Raney-Ni for the reduction of nitrobenzene to aniline, of styrene to ethylbenzene, and of cyclohexanone to cyclohexanol. However, the rhenium catalysts are unique in their ability to reduce acids to alcohols.

By using different catalysts based on rhenium oxide, other valuable products can be obtained. As Table 2 shows, Re_2O_3 reduced by sodium borohydride (C) can be used to reduce the C=C bond and the NO_2 group when chlorine or bromine atoms are present in the molecule (for example, *p*-chlorostyrene to *p*-chloroethylbenzene and *p*-bromonitrobenzene to *p*-bromoaniline); the tetrahydropyran complex of Re_2O_7, unlike other rhenium catalysts, allows the hydrogenation of the aromatic ring (see Table 2, compounds 6, 7, 9, 10). In the presence of $ReO_2 . 2.5H_2O$ (E) the olefin bond is reduced more rapidly than the carbonyl (14, 15) and the carboxyl group (16-18); ReO_3 (F) is an active catalyst for the reduction of various carboxylic acids (19-22) to the corresponding alcohols, and also of amides (28-30) to alkylamines. The ability of this catalyst selectively to reduce carboxyl groups without affecting the aromatic ring is also remarkable (26, 29, 30). It is evident from the examples given in Table 2 that the $ReO.2H_2O$ catalyst, prepared by reduction with alkali metals in ethylamine, is the most effective of the rhenium catalysts for the hydrogenation of carboxylic acids to alcohols (32-34), and for the reduction of nitro compounds to amines (39-42) and of ketones to alcohols (44-56).

Balandin and coworkers[56] obtained 100% yield in the hydrogenation of cyclohexene, octene, benzene, and acetone on a skeletal rhenium catalyst under a hydrogen

Table 1. Activity of rhenium catalysts towards the reduction of various organic compounds.

pressure of 100–130 atm and temperature in the range 160–180°C. With this catalyst, the reduction of dimethyl maleate goes to completion even at room temperature and atmospheric pressure.

Platonov[46] was the first to note the interesting fact that rhenium catalysts can be activated by controlled amounts of typical catalyst poisons such as H_2S and As_2O_3. This effect was investigated in the particular case of ethanol dehydrogenation. At 500°, 30.7% of acetaldehyde and 0.9% of ethylene are formed from ethanol in the presence of a rhenium catalyst. On adding H_2S or As_2O_3 at a concentration of 0.004 mole per mole of ethanol the yields became (under otherwise identical conditions) 47.8 and 6.1% (with H_2S) and 43 and 3.8% (with As_2O_3) of aldehyde and ethylene respectively. With a further increase in the concentration of the poison to 0.008 mole per mole of alcohol, the yield of aldehyde falls off. Whereas formaldehyde is fully decomposed on a rhenium catalyst, the decomposition is suppressed[57] in the presence of H_2S or As_2O_3 (41.7 and 30.2% respectively of CH_2O are detected at 400°). The catalytic conversion of cyclohexanol yields mainly phenol[47], whereas in the presence of finely divided rhenium the main product is cyclohexanone. These observations led to an intensive study of the catalytic properties of rhenium sulphide.

The dehydrogenation of alcohols to aldehydes and ketones in the presence of rhenium sulphide was investigated by Platonov[58]. The products obtained from methanol, ethanol, and isopropanol (at 400, 550, and 500° respectively) contained 53.2, 53.5, and 91.4% of the appropriate aldehyde or ketone; cyclohexanol at 500° gave 78.8% of phenol and 6.7% of cyclohexanone. The interesting catalytic properties of rhenium sulphide are ascribed[58] to the similarity of its crystal lattice to that of MoS_2, which is extensively used as a catalyst for various reactions. Thus, formaldehyde, acetaldehyde, and acetone can be obtained in high yields from the corresponding alcohols by using ReS_2 as a catalyst.

The rhenium sulphides (ReS_2 and Re_2S_7) have been investigated by Broadbent and coworkers[59] as liquid-phase hydrogenation catalysts. The hydrogenations were carried out in a bomb containing 0.5 mole of the compound, a solvent, and 2.5 g of the catalyst per mole of the compound to be hydrogenated, under a pressure of hydrogen between 56 and 300 atm. The reaction conditions and the results obtained in the presence of rhenium heptasulphide and disulphide are listed in Table 3. The reductions obtained on Re_2S_7 include styrene to ethylbenzene, 1,1-methylphenylethanol (2-phenylpropan-2-ol) to cumene, maleic to

* Reduced by lithium ethylamide
** Reduced by lithium in liquid ammonia
*** Reduced by sodium in liquid ammonia

succinic acid, nitrobenzene to aniline, *p*-bromonitrobenzene to *p*-bromoaniline, allyl phenyl sulphide to propyl phenyl sulphide, diphenyl disulphide to thiophenol. The carbonyl double bond (acetophenone) is reduced less readily than the carbon–carbon double bond (styrene). The C–S bond is not broken during the hydrogenation of organosulphur compounds. Thus, allyl phenyl sulphide gives only propyl phenyl sulphide, diphenyl disulphide gives only thiophenol, thiophen gives only thiophane. If the reaction is carried out under more drastic conditions, for example at 300°, cyclohexane and benzene are formed from the thiophenol, and benzene is formed from the diphenyl disulphide. The nitro group is readily reduced at or just above room temperature. Rhenium disulphide is less active than the heptasulphide. The activity of rhenium sulphide catalysts towards a number of reactions was compared with the activity of the existing catalysts molybdenum sulphide and cobalt sulphide[59]. The most active hydrogenation catalyst was found to be Re_2S_7, followed by ReS_2, MoS_2, and CoS_x (in that order). Cobalt polysulphide has a high activity (comparable to that of Re_2S_7) only in the reduction of nitrobenzene to aniline.

Thus, Re_2S_7 has been shown to be an active liquid-phase hydrogenation catalyst. It induces quantitative reduction of styrene, cyclohexene, maleic acid, nitrobenzene, *p*-bromonitrobenzene, and diphenyl sulphide.

Balandin and coworkers[60] studied the catalytic reduction of chloronitrobenzenes in the presence of Re_2S_7 (in amounts between 2 and 10% of the weight of chloronitrobenzene) at 100–123° and for reaction times of 40–60 h. *p*-Chloronitrobenzene, 3,4-dichloronitrobenzene, and 2,4,5-trichloronitrobenzene gave the corresponding chloroanilines in 100% yield (measured chromatographically).

The catalytic reduction of functional groups in sulphur compounds is difficult to realise, because all known catalysts are susceptible to catalytic poisoning (to a greater

or lesser extent) by sulphur in the bivalent state. However, Re_2S_7 proved to be very active even under these conditions[61].

Aretos and Viall[62] reduced 2-nitrothiophen to 2-acetylaminothiophen at 100° in the presence of acetic anhydride:

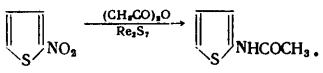

Table 3. Hydrogenation in the presence of sulphide catalysts.

Initial compound	Amount of catalyst, g/mole of initial cpd.	Solvent	Pressure, atm	Temperature, °C	Time, h	Reduction product	Yield, %
			Re_2S_7 catalyst				
Styrene	2.5	C_2H_5OH	120	100-135	1	Ethylbenzene	100

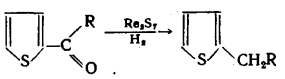
The thiophen ring was hydrogenated at 200°, giving thiophane and 2-methylthiophane. Various 1,2-dithiol-3-thionones have also been hydrogenated at 180-200°:

where R = 4-C_6H_5, 5-C_6H_5, and 5-*p*-$CH_3OC_6H_4$. In every case, ring opening was observed, with formation of benzene and a thiol.

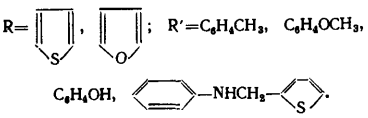
Ryashentseva and coworkers[63,64] achieved selective reduction of the carbonyl group in a series of thiophen compounds. In the presence of rhenium heptasulphide, they obtained 2-methylthiophen and 2-ethylthiophen (in 50 and 80% yield respectively) from 2-thiophenal and 2-acetothienone in dioxan under autoclave conditions (170-190°, 100-130 atm hydrogen pressure):



where R = H, CH_3.

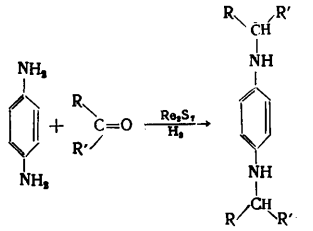
The same workers[65,66] also found conditions leading to the selective hydrogenation of the azomethine group (-C=N-) without attacking the thiophen or aromatic ring. Thus, they prepared the appropriate secondary amines from *N*-thienylidene-*p*-toluidine, *N*-thienylidene-*p*-anisidine, *N*-thienylidene-*p*-aminophenol, *N*-furfurylidene-*p*-toluidine, and *N,N'*-dithienylidene-*p*-phenylenediamine:

where

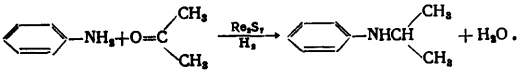


Conditions for the reduction of azomethines to secondary amines in the presence of 100 mg Re_2S_7 in dioxan, and under a hydrogen pressure of 130 atm, are summarised in Table 4. It is evident that the presence of *p*-toluidine, *p*-anisidine, or *p*-aminophenol groups has practically no effect on the selectivity of the hydrogenation of the azomethine group: reduction takes place at 150-170° in 3 h in the presence of 1.5-2 g Re_2S_7 per mole of the azomethine. If the thiophen residue is replaced by furan in the original azomethine, the hydrogenation (under otherwise comparable conditions) is hindered, and the yield of secondary amines drops to ~40%. It has been shown that the catalyst can be re-used a number of times.

Ryashentseva and coworkers[67,68] studied the alkylation of *p*-phenylenediamine and its hydroquinone complex by ketones (acetone, ethyl methyl ketone, and cyclohexanone) in the presence of Re_2S_7. Reaction took place, in a rotating autoclave, at 150-200° and under 100-130 atm hydrogen pressure, in 2.5-3 h. *N,N'*-di-isopropyl-, *N,N'*-di-isobutyl-, and *N,N'*-dicyclohexyl-*p*-phenylenediamine were obtained in 60-94% yield, as well as their hydroquinone complexes. The best results were obtained by using a three-fold excess of the ketone. Alkylation takes place by the scheme



Dovell and Greenfield[69] used rhenium heptasulphide for the reductive alkylation of aniline by acetone to give *N*-isopropylaniline:



The alkylation took place in an autoclave at 140° and 80-100 atm hydrogen pressure. After 4.4 h, *N*-isopropylaniline was obtained in 90% yield (measured by gas-liquid chromatography).

These results show that the reductive alkylation of aromatic amines in the presence of rhenium heptasulphide is not accompanied by hydrogenation of the benzene ring, cleavage of the C=N bond, or reduction of the ketone. Rhenium heptasulphide was the most active of all the sulphide catalysts examined[68,69] in this particular reaction.

Platonova and coworkers[70] were able to reduce the double bond in a series of steroid compounds in the presence of Re_2S_7. Thus, they isolated in ~15% yield the methyl ether of *d,l-D*-homo-$\Delta^{1,3,5,8(8)}$-oestrapentaene-one-17a (II), with a *cis* configuration of the *C* and *D* rings, from the methyl ether of *d,l-D*-homo-$\Delta^{1,3,5(10),8,14}$-oestrapentaenone-17a (I) in benzene and under hydrogen pressure.

Table 4.

Initial compound, g	Reaction temp., °C	Yield of products, %	
		secondary amine	primary amine
N-thienylidene-*p*-toluidine (Ref.10)	170[a]	55	10

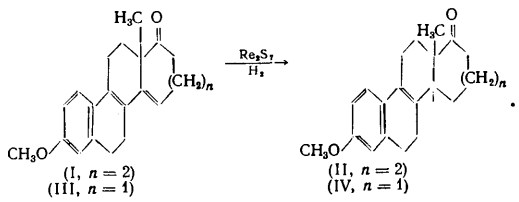
[a] Pressure 125 atm; [b] Pressure 170 atm; [c] Re_2S_7 150 mg; [d] Re_2S_7 200 mg; [e] in benzene; [f] in n-hexane.

In a similar way, the methyl ether of $\Delta^{1,3,5(10),8}$-oestratetraenone-17 (IV) was obtained in 40% yield from the methyl ether of $\Delta^{1,3,5(10),8,14}$-oestrapentaenone-17 (III). Products of the partial and the complete reduction of the keto group in position 17 were isolated and identified among the side-products:



(I, $n = 2$) (III, $n = 1$) (II, $n = 2$) (IV, $n = 1$)

Broadbent and Whittle[71] showed that Re_2Se_7 can also be a good hydrogenation catalyst at 100–240° and 200–300 atm pressure, with or without a solvent. Hydrogenation conditions and yields (which sometimes exceed 70%) are listed in Table 5.

It is evident from Table 5 that the C=O bond is saturated more readily than the C=C bond in the presence of Re_2Se_7, unless the latter is associated with other double bonds. Hydrogenation of the C=C bond in thiophen and in allyl phenyl sulphide proceeds without rupture of the C–S bond. By studying the reduction of *p*-bromonitrobenzene it was shown that the carbon–halogen bond is also unattacked whilst the nitro group is easily reduced. The benzene ring is fairly resistant to hydrogenation: only 4.5% of cyclohexane is formed from benzene.

Table 5. Hydrogenation in the presence of Re_2Se_7.

Comparing the activity of Re_2Se_7 towards hydrogenation reactions with the activity of rhenium, molybdenum, and cobalt sulphides we find[59] that Re_2Se_7 is second only to Re_2S_7, but is much more active than molybdenum and cobalt sulphides. In the reduction of nitrobenzene it was shown that the Re_2Se_7 catalyst is unaffected by nitrogen, phosphorus, sulphur, selenium, and tellurium compounds, but is sensitive to arsenic compounds.

III. SUPPORTED RHENIUM CATALYSTS (dehydrogenation of alcohols, rearrangement of hydrocarbons, and treatment of petroleum fractions)

Platonov and coworkers[41,48] prepared a rhenium catalyst on a ceramic carrier containing a large proportion of alumina by a modified "nitric acid" method. The catalyst was shown to have a high selectivity towards the dehydrogenation of ethanol to acetaldehyde. However, the yield of acetaldehyde was only 14% at 600°.

In Balandin's laboratory, rhenium catalysts were prepared[72] by impregnating the carrier (active carbon, alumina, asbestos, or quartz) with solutions of ammonium perrhenate or of the rhenium–dioxan complex ($Re_2O_7.C_4H_8O_2$).[73] The highest activity was found in the rhenium catalysts supported on carbon, prepared by the dioxan method[72,74]. Transformations of primary and secondary alcohols (ethanol, n-propanol, isopropanol, and s-butanol) were investigated. Isopropanol at 150–200° gave acetone with a yield approaching the maximum thermodynamically possible value. The dehydrogenation of primary alcohols is complicated by the formation of esters and by decarbonylation of the resulting aldehyde. The intermediate product in the formation of γ-butyrolactone from 1,4-butandiol is γ-hydroxyoleic aldehyde.

Balandin, on the basis of the structural correspondence principle of the multiplet theory of catalysis, was the first to suggest the possibility of dehydrogenation of six-membered rings by a sextet mechanism on rhenium, since the latter has hexagonal symmetry.

Balandin and coworkers[75] studied the dehydrogenation kinetics of cyclohexane, methylcyclohexane, and ethylcyclohexane on rhenium catalysts supported on carbon. The rate of dehydrogenation decreases with increase of molecular weight of the hydrocarbon. The same workers[75] investigated the dependence of catalyst activity and activation energy for the dehydrogenation of cyclohexane upon the rhenium content of the catalyst. An activation energy of 12.8 kcal mole^{-1} was found to correspond to a rhenium content of 30 wt.% in the catalyst. It was also shown that the relative benzene adsorption coefficient is independent of the reaction temperature. The dehydrogenation of cyclohexane on rhenium is a zero-order reaction. The carbon-supported rhenium catalyst develops its highest activity during the first few minutes of the reaction[76]. Thus, the yield of benzene from cyclohexane at 360–380° is 90–95% after the first 5–7 min. Subsequently, the activity falls to a constant value at some intermediate level. The catalyst is regenerated by hydrogen treatment at 500° for 1–1.5 h. The authors[76,77] offer an explanation of the effect of the carrier on the activity of the catalyst in this reaction. They suggest that rhenium on carbon is similar to platinum on carbon, and should be an active dehydrogenation catalyst for cyclohexane under conditions of energy correspondence: this prediction is confirmed by experiment. However, their explanation of the results obtained with rhenium–alumina catalysts is less convincing, and is inconsistent with other experimental results[78–81]. Thus, according to Balandin, the ratio of M–M to O–O interatomic distance is: for Pt, 2.77/2.64 = 1.05; for Re, 2.736/2.64 = 1.035; for Ni, 2.48/2.64 = 0.94. The corresponding deviations from the integral value of 1 are: +5% for Pt, +3.5% for Re, and –6.4% for Ni. They conclude that negative deviations are favourable, and therefore that Ni on Al_2O_3 should be the most active catalyst. With rhenium the correspondence between interatomic distances is fairly good, but the deviation (though small) is positive, and therefore the rhenium lattice is under compression and the catalytic activity is low (the yield of benzene from cyclohexane is 5–7% with a Re/Al_2O_3 catalyst). But according to this argument the activity of the platinum–alumina catalyst (the industrial platinum forming catalyst) should be negligible. The authors ascribe the activity of this catalyst to the state of the platinum. They postulate relatively large Pt crystals, insensitive to the influence of the carrier, even though platinum forming catalysts are known to contain only 0.3–0.5% of platinum on alumina.

Balandin and coworkers[76] also studied the dehydrocyclisation of n-heptane on a rhenium–carbon catalyst. At 468°, and with a flow of n-heptane of 0.173 ml min^{-1}, the product contains 14.0% of aromatic hydrocarbons and 9.4% of unsaturated compounds. Later they examined the properties of a rhenium–carbon catalyst made by the dioxan method[56] and containing 30% of rhenium. On this catalyst, complete reduction of cyclohexene to cyclohexane and of acetone to isopropanol was obtained in 1–2 h at 160–180° and 70–110 atm hydrogen pressure; cinnamic aldehyde was quantitatively reduced to hydrocinnamic alcohol at 250° and 110–130 atm pressure.

It was also shown[82] that the rate of dehydrogenation of cyclohexane on a rhenium–carbon catalyst is higher than the rate of dehydrogenation of cyclohexene, and therefore that cyclohexene cannot be an intermediate in the transformation of cyclohexane to benzene.

Isagulyants and coworkers[83] studied the mechanism of conversion of cyclohexane and of cyclohexene at 270–400° at atmospheric pressure in the presence of the same catalyst. They showed that cyclohexene is not a precursor in the formation of benzene from cyclohexane: benzene is formed directly from cyclohexane. This conclusion is consistent with the earlier observations[82] from the same laboratory.

Ryashentseva and Minachev[84–88] studied the properties of rhenium catalysts with special reference to the reactions of C_5–C_7 hydrocarbons under reforming conditions.

Metals in the neighbouring groups of the Periodic Table (VI and VIII) have been studied intensively from this point of view, and some of them have found application in various industrial processes (in particular, petroleum refining).

The reactions of hydrocarbons have been used to study the properties of rhenium catalysts as a function of metal content, nature of the carrier, specific surface area, catalyst treatment, and reaction conditions. The experiments were made in a flow reactor under pressure of hydrogen. The products of catalysis were analysed by gas–liquid chromatography. Ryashentseva and Afanas'eva[84] developed a procedure for extracting the rhenium from rhenium–alumina and rhenium sulphide–alumina catalysts, using 5% HNO_3 and HNO_3–H_2O_2 mixtures respectively, followed by a photometric determination.

Catalysts containing 20% of rhenium were found to be the most active of the rhenium–alumina catalysts[79]. At 380°, 5 atm hydrogen pressure, and a feed rate of 1.0 h^{-1} [litre h^{-1}? (Ed. of Translation)] (5 : 1 ratio of hydrogen to hydrocarbon), up to 80% of benzene was obtained from cyclohexane during the first few hours' operation, but the activity of the catalyst decreased with time, and after 21 h the product contained only 5% of benzene. Methylcyclopentane and n-hexane under the same conditions undergo mainly hydrogen cracking. Convincing results were obtained with a catalyst containing 5% of rhenium on zeolite. In this system, high selectivity for the cyclohexane dehydrogenation reaction is observed.

Treatment of the rhenium–alumina catalysts with hydrogen sulphide[85] increases their activity. As in the case of the rhenium–alumina catalysts themselves, the activity increases with rhenium content. For example, for catalysts treated with hydrogen sulphide and containing 1, 5, 10, 15, and 20% of rhenium the yield of benzene from cyclohexane is 2.9, 20, 31, 34, and 76% respectively. The catalyst containing 20% of rhenium is the most active. At 500°, 5 atm hydrogen pressure, and 5 : 1 hydrogen to hydrocarbon ratio, this catalyst gives up to 80% of benzene from cyclohexane, and 53% of benzene from methylcyclopentane. Under the same conditions, n-hexane suffers appreciable cracking, but the product contains 10% of aromatic hydrocarbons, indicating some measure of dehydrocyclisation.

Prinzler and Klotzsche[89] studied the dehydrogenation of cyclohexane to benzene, the dehydrocyclisation of n-heptane to toluene, the isomerisation of n-pentane to isopentane, and the demethylation of toluene to benzene on $Re–Al_2O_3$ and $Re–Al_2O_3.SiO_2$ catalysts at atmospheric pressure and 480–490°. They showed that in these reactions the rhenium catalysts are much less active than the platinum–alumina catalysts. At feed rates of 0.5–5.0 changes per hour, 5% of benzene is formed from cyclohexane and only 1.7% of toluene from n-heptane. Addition of ZnO_2 to these catalysts does not raise their activity.

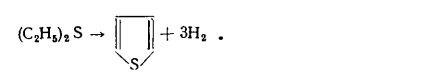
Müller and Wencke[90] studied the effect of different carriers on the catalytic properties of rhenium catalysts. They examined two modifications of alumina (α and γ) and beech charcoal. The chosen model reaction was the gas-phase dehydrogenation of cyclohexane between 250 and 420° at ~50% conversion. Rhenium on α-Al_2O_3 had the

highest catalytic activity. Rhenium deposited on γ-Al_2O_3 shows the same activity only at much higher concentrations of the metal. The authors conclude that α-Al_2O_3 is a better carrier than γ-Al_2O_3 at low concentrations of rhenium; beech charcoal occupies an intermediate position.

Müller and Wencke offer the following explanation of their findings. The pure carriers have different BET surfaces: 939, 143, and 8 $m^2 g^{-1}$ for beech charcoal, γ-Al_2O_3, and α-Al_2O_3 respectively. Since α-Al_2O_3 has the smallest surface, catalytically active groupings of atoms can form on it at quite low metal concentrations (~0.5%). γ-Al_2O_3 requires a higher metal concentration to achieve the same condition. Beech charcoal, which has the largest surface area, should become catalytically active at significantly higher concentrations of the metal than is found in practice. The discrepancy is ascribed to the possibility of epitaxial growth, on the assumption that surface formations on the charcoal can lead to dehydrogenation of cyclohexane as well as the octahedral surface of the rhenium lattice.

Blackham and coworkers[91] studied the properties of rhenium–alumina catalysts as a function of the method of preparation of the catalyst in the dehydrocyclisation of n-heptane at 550–600° under atmospheric pressure. Rhenium catalysts are inferior to platinum catalysts in this reaction. Thus, up to 80% of dehydrocyclisation products are obtained with a 1% Pt–Al_2O_3 catalyst under optimum conditions, as compared with ~60% on a 5% Re–Al_2O_3 catalyst. Rhenium–alumina catalysts prepared by different methods had comparable activities.

Rhenium catalysts have been investigated[92] in the dehydrocyclisation of diethyl sulphide to sulphide to thiophen under 3 atm hydrogen pressure, apparent contact time 0.6 s, catalyst particle size 1–1.5 mm, and 15 wt.% concentration of the sulphide in helium:



The activity of rhenium catalysts in this reaction was found to be similar to that of other dehydrocyclisation catalysts, such as chromium and molybdenum. In the presence of rhenium, the dehydrocyclisation reaction is complicated by decomposition of the sulphide at the C–S bond, and the yield of thiophen is no more than 13% of the initial diethyl sulphide.

Sokolova and coworkers[60] obtained the appropriate chloroanilines in 100% yield from *p*-dichlorobenzene and trichlorobenzene in the presence of a 5% Re_2S_7–SiO_2 catalyst at 120–140° and 40–65 h reaction time.

The use of rhenium catalysts in the treatment of petroleum fractions at high temperatures in the presence of a pressure of hydrogen has been investigated[80,81,93].

A Patent by Hummel[80] discloses that the fraction boiling at 100–180°, containing 14% of aromatic hydrocarbons and having an octane number of 53, can be dehydrogenated at 475–500° under 50 atm pressure to give a 49% content of aromatics and an octane number of 71. The catalyst was prepared from a rhenium salt solution containing 3 g $litre^{-1}$ of rhenium, deposited on activated alumina to which 0.3% of fluoride and 0.1% of MgO had been added. Before the reaction, the catalyst was activated by hydrogen reduction at 475°. The preparative details of the catalyst are not disclosed in the Patent. It is shown[80] that the rhenium catalyst leads to isomerisation as well as to the formation of aromatic hydrocarbons from n-alkanes, and is more effective than platinum catalysts in this respect.

The same author[81] subsequently proposed the rhenium–alumina–silica catalyst for the production of liquid fuels from high-boiling hydrocarbon oils, jellies, and petroleum products under 100–700 atm pressure and at temperatures between 300 and 450°.

Lüder and Drescher[93] studied the application of rhenium catalysts in hydrogenation and reforming processes. The experiments were made with a fraction containing 13.6% of aromatic hydrocarbons, 43.5% of naphthenes, and 42.9% of alkanes. Rhenium catalysts on alumina were inferior to the industrial molybdenum and platinum catalysts, which gave 54% of aromatic hydrocarbons from the experimental fraction as compared with only 22% using the rhenium–alumina catalyst. Replacement of the NH_4ReO_4 by $KReO_4$ did not improve the aromatising properties of the catalyst. The authors succeeded in raising the content of aromatics to 32–36% and the octane number to 72–74 by using much higher proportions of rhenium in the catalyst and by including small amounts of MgO and fluorides.

Additions of iron had no effect, even in the presence of large amounts of rhenium. By varying the preparative conditions of the catalyst, up to 50% of aromatic hydrocarbons can be obtained in the reforming products, but the overall yield of liquid products is significantly decreased by the formation of gaseous hydrocarbons. However, a rhenium dehydrogenation catalyst for hydrocarbons boiling in the benzine range could not be prepared. Good results were obtained by treating a middle prehydrogenation oil with a rhenium catalyst supported on Fuller's earth. The rhenium content was 3 g $litre^{-1}$, corresponding to 0.4–0.5 wt.% (as compared with 5–10 wt.% in the hydrogenation media used in industrial catalysts). The rhenium was used as the metal or the sulphide. The authors[93] observed extensive fission of the oils: the yield of the fraction boiling up to 200° was 82%. Better results were obtained with a catalyst of composition 3 g $litre^{-1}$ supported on Fuller's earth treated with fluorides. The octane number of the reforming products obtained with an industrial catalyst was 60.1, whereas the rhenium catalyst gave a higher value (74.8). The catalyst was tested during 1150 h. A Diesel fraction gave a reforming product with cetane rating 45 and 47. However, the high initial activity of the rhenium catalysts falls off quite rapidly. If this shortcoming could be overcome, the rhenium catalyst would offer interesting possibilities for the treatment of middle oil fractions. The authors believe that rhenium catalysts will find industrial applications, but that more research is needed into their regeneration and into more general applications.

Minachevich and Ryashentseva[87] showed that between 32 and 47% of aromatic hydrocarbons can be obtained from the direct-distillation benzine fraction of b.p. 38.5–196°, containing 10% of aromatic hydrocarbons, by reforming with a 20% Re–Al_2O_3 catalyst (treated with hydrogen sulphide) at 480–490°, 5 atm pressure, flow rate 1.0 changes per hour, and 5 : 1 ratio of H_2 to hydrocarbons. The octane number (without tetraethyllead) increases from 47.8 to 71 and 87.2. Reforming of the benzine fraction (b.p. 89.5–126°) from the Volga–Urals region[87] increased the content of aromatics from 6 to 20–60%, and lowered the content of sulphur compounds from 0.017 to 0.002–0.007%. This catalyst was studied during 500 h, including 5 regenerations. Although the aromatising power of the catalyst was effectively restored after each regeneration, the stability gradually deteriorated. The yield of aromatic hydrocarbons during the first 30 h was 55–60%; subsequently the activity began to fall off, and after 60 h operation the content of aromatics was only ~20%. This level

of activity was retained for approximately 100 h, but after this period the activity decreased and the content of aromatic hydrocarbons fell to 12%.

Hence, the rhenium catalysts cannot compete with the industrial platinum catalysts as regards stability. Furthermore, their rhenium content must be much higher than the platinum content of conventional platinum forming catalysts.

IV. MIXED RHENIUM CATALYSTS (liquid-phase hydrogenation, rearrangement of hydrocarbons, and reforming of light petroleum fractions)

Sokol'skii and coworkers[94-99] studied the effect of adding rhenium on the activity and selectivity of various nickel catalysts for liquid-phase hydrogenation.

They investigated the hydrogenation of unsaturated compounds containing ethylene, acetylene, and aldehyde bonds, on nickel–silica catalysts, and showed[94] that the rate of hydrogenation is increased by adding up to 5% of rhenium to the catalyst. Higher rhenium contents degrade the activity of the catalyst. Very small additions of rhenium (<0.5%) were also found to deactivate the catalyst. By adding an alcoholic solution of potassium perrhenate to a Raney nickel catalyst, they were able to hydrogenate tetramethylbutynediol, vinyl ether, cinnamaldehyde, and vinylethynyldimethyl carbinol (2-methylhex-3-yne-5-ene-2-ol) in the liquid phase and to demonstrate the promoting action of potassium perrhenate. Addition of rhenium to the catalyst not only increases the rate of hydrogenation of unsaturated compounds, but also extends the useful life of the catalyst. For example, a nickel catalyst without rhenium can be used three times for liquid-phase hydrogenation, but it remains active during five operations if promoted with rhenium.

Hydrogenation of cotton-seed oil[95] on a Raney nickel–rhenium catalyst in absolute ethanol is 1.5–1.7 times faster than on a straight Raney nickel catalyst.

It was also shown[96,97] that the addition of 1–3% of rhenium to a nickel–aluminium alloy increases its activity towards the hydrogenation of cinnamic alcohol to phenylpropanol. If the rhenium content is increased to 5–7% the catalytic activity decreases, but in every case the rhenium-containing catalysts were more active than the nickel–aluminium alloy. The hydrogenation rate constant on a catalyst made from a 3% Re, 47% Ni, and 50% Al alloy was higher by a factor of 1.6 at 40° and a factor of 2 at 20° than the rate constant found in the hydrogenation of cinnamic alcohol on Raney nickel.

Rhenium–palladium alloy catalysts[98] have been studied in the hydrogenation of dimethylethynyl carbinol in water, 96% ethanol, 0.1*N* KOH in water and in ethanol, at 10, 20, 30, and 40°. Hydrogenation in water is produced by adsorbed hydrogen, but in ethanol the reaction involves hydrogen supplied from the bulk of the catalyst. The catalysts are stable both in aqueous and in alcoholic media, and show some selectivity when 0.1*N* KOH in 96% ethanol is used as the solvent. The reaction stops at the stage of half-hydrogenation. However, the palladium–rhenium catalyst is less active than the palladium–iridium alloy catalyst. The state of the surface during the reaction was monitored by potential measurements[99].

The activity of skeletal nickel–rhenium catalysts prepared from Ni–Re–Al alloys has been studied[100] in the hydrogenation of potassium maleate, potassium *o*-nitrophenate, and dimethylethynyl carbinol in 0.1*N* KOH solution, and of nitrobenzene in 50% ethanol. At temperatures below 40°, the skeletal nickel catalyst is deactivated towards the hydrogenation of compounds with multiple carbon–carbon bonds. At higher temperatures the rate of hydrogenation goes through a maximum as a function of rhenium concentration in the alloy. When potassium *o*-nitrophenate is reduced in 0.1*N* KOH, the reaction is drastically retarded as the rhenium content is increased, particularly at high temperatures. The rhenium was shown to increase the lattice parameter of the Raney nickel catalyst. The authors consider that the promoting effect of rhenium at elevated temperatures resides in its favourable influence on the activation of the  and –C≡C– bonds, and they ascribe the poisoning of the catalyst during the reduction of nitro compounds in alkaline media to oxidation of the rhenium or its hydride.

Mashkina and Vakurova[92] also demonstrated the promoting effect of rhenium. By adding 2.5% of rhenium to an industrial nickel–chromium catalyst, they obtained a much higher rate of hydrogenation (at 20° and under atmospheric pressure) of sulpholene to sulpholane:

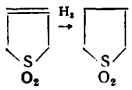


Table 6. Catalytic conversion of hydrocarbons on rhenium–palladium–alumina catalysts*.

Ryashentseva and coworkers[101-104] studied the properties of mixed rhenium–palladium–alumina–silica catalysts towards the transformations of cyclohexane, methylcyclohexane, methylcyclopentane, and n-hexane[101,102]. The rhenium–palladium–alumina catalyst containing 1% of rhenium and 1% of palladium on fluorinated (0.4% F) alumina, and treated with hydrogen sulphide[102], was found to be the most active and stable towards the dehydrogenation of cyclohexane and methylcyclohexane, the dehydroisomerisation of methylcyclopentane, and the isomerisation of n-hexane. The results are summarised in Table 6. This catalyst was also used under reforming conditions on Baku B-70 light

petroleum and on the light petroleum fraction from the Volga-Urals oilfields. The results of these tests are given in Table 7.

Table 7. Properties of initial light petroleum fractions and of reforming products (470°, 10 atm, $v = 1.0\ h^{-1}$, H_2 : hydrocarbon = 5 : 1).

Properties	Initial fraction		Properties of product after 25 h operation of the catalyst

Boiling ends	202.0	119.0	208.0	173.5	210.0

As Table 6 shows, the extent of dehydrogenation on a rhenium–palladium–alumina catalyst activated with hydrogen sulphide is 87% for cyclohexane and 90% for methylcyclohexane, and 61.2% of benzene can be obtained from methylcyclopentane. Catalysts consisting of rhenium (or palladium) alone on alumina gave much lower conversions of the hydrocarbons than the mixed catalyst. Reforming of Baku light petroleum and other fractions[75,102] on rhenium–palladium–alumina catalysts treated with hydrogen sulphide raised the aromatics content 7–10-fold, and lowered the concentration of sulphur compounds by a factor of 1.4. The addition of 1% of rhenium to a palladium–alumina catalyst treated with hydrogen sulphide increases the stability of the catalyst under reforming conditions by almost a factor of 4. As Table 6 shows, mixed rhenium–palladium–alumina are also active towards isomerisation reactions. Thus, the yield of hexane isomers on a rhenium–palladium–alumina catalyst is 32%, and 52% on a rhenium–palladium–alumina catalyst treated with hydrogen sulphide. Whereas a 1% rhenium–alumina gives only 7% isomerisation of n-hexane, the sulphided catalyst gives 14% isomerisation[101]. There was no indication of a decrease in the isomerisation activity of the mixed catalyst after prolonged operation (90 h). The activity of a catalyst containing 1% of palladium but no rhenium had fallen by a factor of 2 after 50 h. Hence, the addition of 1% of rhenium to a palladium–alumina catalyst increases the stability of the catalyst very significantly. All these findings point to the high efficiency of H_2S-treated rhenium–palladium–alumina catalysts for dehydrogenation, dehydroisomerisation, and isomerisation reactions.

This catalyst was tested under static and fluidised bed conditions for reforming the 72–102° fraction of Karadag light petroleum[104]. The results, set out in Table 8, show that the concentration of aromatic hydrocarbons in the reforming product is 36–42% after 25 h operation under static or fluidised bed conditions. The concentration of benzene increases 4-fold, that of toluene 5-fold. The concentration of C_5 and C_6 alkanes remains almost constant. In the initial light petroleum fraction, the hexane isomers account for ~50% of the total content of hexanes. Thus, the aromatic hydrocarbons are formed mainly by dehydrogenation of six-membered cyclanes, with a much smaller contribution from the dehydroisomerisation of alkylcyclopentanes. In subsequent studies of the stability of the catalyst it was shown that in a static layer the activity gradually decreases, and after 40 h the concentration of aromatic hydrocarbons in the reforming product has fallen to 20%, whereas under fluidised bed conditions the concentration of aromatics has barely decreased at all (36%) after 100 h operation. It follows that the stability of the catalyst is approximately 4 times higher for the fluidised bed than for the static catalyst. A likely explanation is that the macroscopic surface area of the catalyst is much higher in the fluidised bed than in the static layer, and also that isothermal conditions are more rigorously observed in the fluidised bed. After 100 h the catalyst was regenerated by air under atmospheric pressure at 400° (fluidised bed), and treated with hydrogen. The experiments were made under 10 atm pressure, at a flow rate of 1.5–2 changes per hour, and 10 : 1 ratio of H_2 to hydrocarbons. Under these conditions, the concentration of aromatics in the reforming product was increased 5-fold (as previously). Thus, we may conclude that the rhenium–palladium–alumina catalyst treated with hydrogen sulphide regains its full activity on being regenerated.

Table 8. Properties of initial 71–102° Karadag light petroleum and of reforming products under static and fluidised bed catalytic conditions (480°, flow rate 0.8–3.5 h^{-1}, 10 atm pressure, H_2 : hydrocarbon ratio 5–20).

Composition of petroleum and reforming products, wt.%	Initial 71–102° fraction	Static bed	Fluidised bed	
		Reforming products after operating catalyst for		
		25 h		100 h
Isopentane	1.4	1.2	1.1	0.9

This work on the reforming of hydrocarbon mixtures on catalysts containing rhenium justifies the conclusion that this element offers interesting possibilities as a component of dehydrogenation, isomerisation, and dehydroisomerisation catalysts, offering enhanced activity and stability.

Müller and Schnabel[105] studied rhenium–platinum catalysts on carbon in the dehydrogenation of cyclohexane and the "C_5-dehydrocyclisation" of iso-octane at 250–400° under atmospheric pressure. Koppers coke [a brown coat coke (Ed. of Translation)] was found to be a better carrier than birch charcoal. The activity of the carbon-supported platinum–rhenium catalyst showed a significant improvement only when 50% of platinum and 50% of rhenium was used, and the platinum was deposited first. Otherwise, the activity of the Pt–Re catalysts, though much

higher than that of rhenium catalysts, was somewhat lower than the activity of platinum catalysts. A maximum activity is found at Pt or Re concentrations between 0 and 1 wt.%, followed by a sharp fall in catalytic activity. An increase in activity occurs at 5% Re content (or 2.5% Re and 2.5% Pt in mixed catalysts). The activity of the catalysts towards the dehydrocyclisation of iso-octane is very sensitive to the preparative conditions. Thus, catalysts prepared by impregnating the carbon with a platinum solution, with subsequent hydrogen reduction, are less active than catalysts in which the platinum was reduced by the Zelinskii formalin–alkali method. The advantage of using Koppers coke lies in the constancy of its composition.

However, there is no prospect as yet of using these catalysts in industrial production because no suitable method of regeneration has yet been found. Hence, only oxide carriers such as alumina, silica, alumina–silica, zeolite, etc., are likely to be of importance in petroleum refining applications of rhenium catalysts.

---o0o---

We have shown that specific areas of application of rhenium in the field of catalysis can already be identified, despite the fact that the chemistry of the element began to be studied only recently (since the 1930's), and systematic studies of its catalytic properties are of even more recent date.

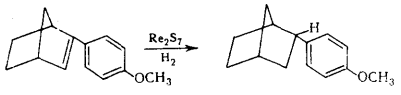
Rhenium catalysts can be of importance in the preparation of a number of rare organic compounds. For example, rhenium black[50] and $ReO.2H_2O$[55] are universal catalysts for the preparation of alcohols from ethanol to undecanol by reduction of the corresponding acids or ketones; the tetrahydropyran complex of Re_2O_7[52] and skeletal rhenium[56] are selective hydrogenation catalysts for the aromatic bond. The sulphides of rhenium have been found to have specific activity towards the dehydrogenation of alcohols to aldehydes and ketones[58,59], the reduction of the C=C double bond, the reduction of organosulphur compounds without cleavage of the C–S bond[59], of the azomethine group (C=N) without hydrogenation of the benzene or the thiophen ring[65,66], of carbonyl groups in aldehydes and ketones of the thiophen series[63,64], and the reductive alkylation of aromatic amines by ketones[67,69] without breaking the C–N bond or hydrogenating the ketone and the aromatic ring.

Lastly, addition of rhenium to hydrogenation catalysts[92,94-100] and reforming catalysts[101-104] produces a substantial improvement in the activity and stability of these catalysts. This observation may be important, and may lead to the practical use of rhenium catalysts in the chemical industry.

The recent paper by Davenport and coworkers[106], and our own very recent results, have had to be omitted from the present review.

Rhenium–alumina catalysts treated with hydrogen sulphide[107] are appreciably active in the dehydrocyclisation of diethyl sulphide to thiophen.

Rhenium heptasulphide reduces *p*-norbornenylanisole quantitatively to *endo*-norbornylanisole:



and also reduces the pyridine ring in substituted aryl-γ-pyridylmethanes and γ-arylpyridines.

Application of Mass-spectrometry to the Study of the Decomposition Kinetics and Mechanisms of Solids

O.P.Korobeinichev

The application of mass-spectrometry to the study of the decomposition kinetics and mechanisms of solids is discussed. Different designs of equipment and experimental procedures for studying the kinetics and the mechanism of the primary and the secondary processes in the decomposition of solids are described, and their relative advantages are analysed. Conditions likely to clarify specific aspects of universal importance to the decomposition of solids are formulated, and the advantages of dynamic mass-spectrometry in this type of study are stressed. The most important results of mass-spectrometric experiments on the kinetics and mechanism of the decomposition of solids are reviewed, including the thermal decomposition of inorganic solids, high-temperature reactions involved in the decomposition of solid propellants, the thermal and mechanical degradation of polymers, and other illustrations of the possibilities of the method.

I. INTRODUCTION

Mass-spectrometry offers valuable information on the composition of materials and on the structure and concentration of molecules, and has an important part to play in the study of complex reaction mechanisms, since it helps to identify unstable intermediates such as atoms and radicals. The application of mass spectrometry to the study of radicals and their reactions in the gas phase and to the study of gas-phase kinetics has been discussed in a number of review articles[1-3]. More recently, mass spectrometry has been extensively used to study the kinetics and mechanisms of the thermal decomposition and evaporation of solids, including ionic and molecular crystals, metals and oxides, and also the pyrolysis of polymers, coal, and explosives. Recent work on the kinetics and mechanism of decomposition of solid propellants at temperatures close the surface temperatures encountered in combustion has made an important contribution to our understanding of the combustion of these solids. Valuable work is also proceeding on the ignition and combustion of solid propellants.

II. GENERAL FEATURES OF THE MASS-SPECTROMETRIC STUDY OF THE KINETICS AND MECHANISM OF THERMAL DECOMPOSITION OF SOLIDS

Studies of the initial stages of the formation and growth of nuclei, in which the amount of material undergoing chemical change is of the order of 0.1–0.001%, are of

fundamental importance to an understanding of the kinetics and mechanism of thermal decomposition of solids. The scope of this work has been considerably extended by the use of mass spectrometers for measuring partial pressures: modern mass spectrometers have extremely high sensitivities (up to 10^{-11} mmHg for Ar). Processes in the condensed phase can be monitored by using a mass spectrometer to determine the composition of the gas phase. Because of the very high sensitivity of the mass spectrometer, decomposition can be studied in single crystals, thus avoiding the complications associated with intercrystalline boundaries and gas diffusion.

The decomposition of many solids (formates, perchlorates, nitrates) is known to occur in different stages, some of which involve only the solid surface, giving rise to primary decomposition products, whilst the subsequent (or secondary) processes involve the gas phase or the solid/gas interface. Hence it is most important to distinguish primary from secondary processes, so as to study them separately and to identify their individual role in the overall process. In order to study only the primary decomposition stages of solids, and to exclude secondary reactions in the gas phase, the pressure in the reaction vessel must be low enough (10^{-4}–10^{-5} mmHg) to ensure that the molecular mean free path is large compared with the dimensions of the vessel. This condition is satisfied when the ion source of a mass spectrometer is used as the reaction vessel. In order to detect unstable, short-lived species such as atoms, radicals, and also molecules of compounds which are involatile at room temperature, and corrosive gases, the sample must be located very close to the ionisation volume (within a few millimeters). This requirement has been observed in most of the published work on the decomposition mechanism of solids (polymers, coal, ionic crystals, solid propellants, oxides).

The method of heating the solid sample deserves special mention: the powerful sources used for flash heating include xenon lamps[4,5], optical arc furnaces[4,6-8], lasers[9], and electrically heated metal strips[10-12] and gauzes[13-14].

Heating by radiation has the advantage that contact between heater and sample is unnecessary, uniform temperature can be obtained throughout the sample (for transparent samples), and fast heating rates (up to 10^6 deg s^{-1}) and high temperatures (several thousands of degrees with laser beams) can be achieved. However, sample temperatures are difficult to measure with these methods of heating. We have used[10-12] a very small sample of the solid ($\sim 10^{-6}$ g) resting on a titanium strip which was heated electrically, other workers[13,14] have used a platinum strip. Fast heating (in 10^{-3} s) was obtained by discharging a capacitor through the strip whilst passing also a continuous electric current to compensate for thermal losses. Temperature constancy (to within 1–2°) could be achieved by suitable choice of the capacitor voltage and of the constant current: this is particularly important in studies of the decomposition kinetics of solids under isothermal conditions. By using small samples (crystallites, or layers a few microns thick in good thermal contact with the heater strip) the heating time can be kept small (of the order of milliseconds) and the temperature gradients can be reduced to a fraction of a degree when heat is absorbed or evolved as a result of decomposition. The temperature of the heater strip (approximately 100 μm thick) was measured by a thin (5 μm diameter) thermocouple spot-welded or stuck to the strip with a heat-resistant cement. Fig. 1 shows the design of an apparatus used[11] to study the kinetics of the isothermal decomposition of solids by a time-of-flight mass spectrometer method.

The decomposition of coals has been studied[13] also under non-isothermal conditions. Coal particles of 60 μm diameter were placed on a grid with holes 50 μm in diameter, and heated at a constant rate of 10^3 deg s^{-1}. In contrast to the previous work[11], the temperature of the sample was varied linearly with time. Assuming first-order kinetics, all the kinetic parameters (activation energy and pre-exponential factor) could be derived from the results of a single experiment. However, because of the need to assume the kinetic order of the reaction, the method is less accurate than the isothermal method, which directly gives the reaction rate as a function of time. This is particularly important in studies of the decomposition of solids, when the reaction can show diffusional limitation or autocatalytic phenomena, and the problem of identifying the kinetic order becomes complicated or even meaningless.

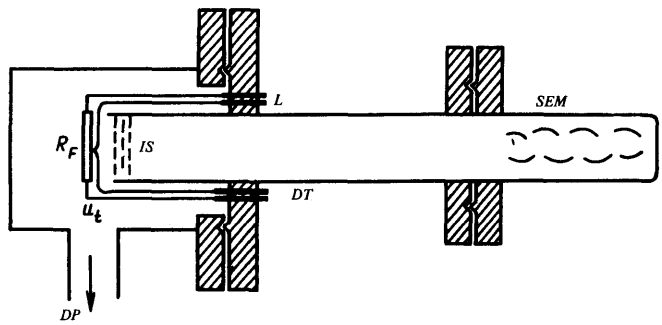

Figure 1. Location of the heater in the ion source of a time-of-flight mass spectrometer[11]: R_F, heater; u_t, thermocouple; *IS*, ion source; *DT*, drift tube; *SEM*, secondary electron multiplier; *L*, electrical leads; *DP*, diffusion pump.

The time constant of the mass spectrometer presents some problems in measurements of the kinetics of fast thermal decomposition reactions in solids. Thus, the most commonly used mass spectrometers, which rely on fixed magnets, can only be used for reactions extending over periods of hours, and their use at elevated temperatures is therefore severely limited. Therefore, dynamic mass spectrometers are far more useful in this type of work: they include time-of-flight mass spectrometers (which have no magnet, and a time constant of 10^{-5}–10^{-4} s), mass spectrometers with a permanent magnet and a variable accelerating potential ($\sim 10^{-2}$ s), quadrupole mass spectrometers, omegatrons, etc.

The design and the areas of application of time-of-flight mass spectrometers have already been discussed[15].

In kinetic studies of the decomposition of solids in the ion source of a mass spectrometer, the most important problem is to establish the relationship between the measured peak intensities and the rates of formation of the gases which contribute to these peaks (i.e. the reaction rates). When the reaction rate is comparable in magnitude to the pumping speed, the rate w_i of formation of the component i is related to the peak intensity I_i; this is proportional to the partial pressure of that component in

the ionisation volume if no other component contributes to the peak, according to the expression[16]:

$$w_i = A\left(\frac{dI_i}{dt} + KI_i\right)$$

where K is the pumping rate constant and A is a proportionality constant related to the sensitivity of the apparatus.

In the limit of a reaction rate much higher than the pumping speed this equation takes the form:

$$w_i = A\frac{dI_i}{dt}.$$

In the opposite limit, when the pumping speed is much higher than the reaction rate, the intensity of the appropriate peak is directly proportional to the latter:

$$w_i = AKI_i = BI_i.$$

In some recent studies[17,18] of the kinetics of polymer degradation using a time-of-flight mass spectrometer with stroboscopic presentation of the signal, which offers a substantially higher sensitivity[19], the constant B had the value $\sim 10^{11}$ molecules s^{-1}.

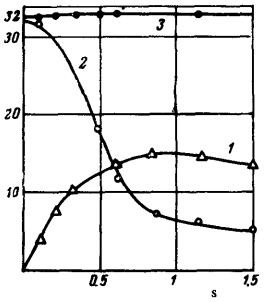

Figure 2. Time dependence at a constant temperature of 310° (see curve *3*) of the intensity of the mass 16 peak (curve *1*) and of the reaction rate (curve *2*), in relative units, during thermal decomposition of ammonium perchlorate in the ion source of a time-of-flight mass spectrometer[11].

Fig. 2, which was obtained in the writer's laboratory[11], shows the time dependence of temperature, intensity of the mass 16 peak, and reaction rate, all in relative units, measured in a study of the thermal decomposition of ammonium perchlorate in the ion source of a time-of-flight mass spectrometer under conditions of comparable pumping speed and reaction rate.

When the decomposition kinetics and mechanism of solids are studied at relatively high pressures (up to 1 atm), secondary reactions in the gas phase cannot be excluded. These add to the difficulty of quantitative mass spectroscopic analysis of gas mixtures (since the measured peak intensities are linearly related to partial pressures in the reactor irrespective of the composition of the gas only if the gas is mixed with a large proportion of an inert diluent) and to the other difficulties of studying gas kinetics a high pressures[1-3]. If the reaction is observed under static conditions, the diffusion time of the decomposition products to the sampling point (or orifice) must be much less than the reaction time. If the reverse is true, the measured rate will be the rate of diffusion of the products from the solid to the orifice rather than the reaction rate. The diffusion time can be significantly decreased by carrying out the reaction under flow conditions using an inert gas stream to carry the reaction products from the sample to the orifice.

Tauerman and coworkers[6-8] studied the volatile products evolved immediately before ignition of two-component solid propellants by a beam of radiation from an optical arc furnace. In this way, the distance between the fuel charge and the conical diaphragm was reduced to 5 mm, and the distance between the orifice and the ionisation volume was 19 mm. The vessel containing the charge was swept with helium at 10–200 mmHg pressure containing 1% of argon as an internal sensitivity standard. This precaution is essential, as the sensitivity decreases when the reaction rate is increased. The apparatus is shown in Fig. 3. The surface temperature of the charge was measured by a thin (50 μm) Chromel–Alumel thermocouple.

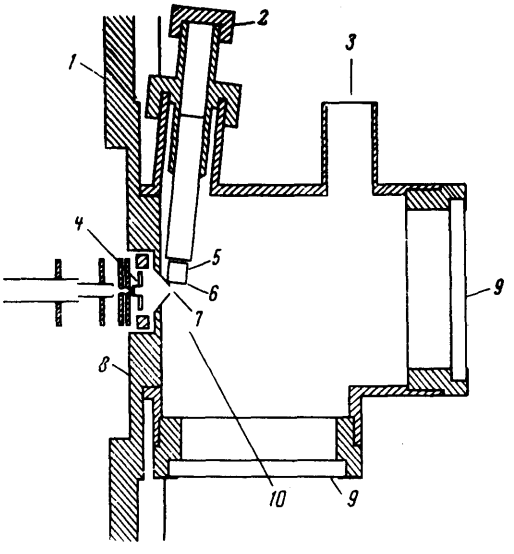

Figure 3. Combustion chamber combined with the ion source of a mass spectrometer[8]: *1*) upper flange of ion source; *2*) sample holder; *3*) to pump; *4*) electron beam; *5*) sample of propellant; *6*) thermocouple; *7*) orifice; *8*) ion source; *9*) quartz viewing port; *10*) radiation from optical arc furnace.

We shall now discuss the most important results obtained by the methods described, and consider concrete examples of the usefulness of the methods.

III. RESULTS OF MASS-SPECTROMETRIC STUDIES OF THE DECOMPOSITION KINETICS AND MECHANISMS OF SOLIDS

1. Decomposition of Inorganic Compounds

Many papers have been written on the thermal decomposition of ammonium perchlorate[10-12,20-24]. Heath and Majer[20], who were among the first to examine this system,

tried to identify the primary decomposition products of ammonium perchlorate in the ion source of a mass spectrometer at 100°. Unfortunately, they used large samples and were therefore unable to exclude secondary reactions in the pores of their sample, where the pressure was probably several order of magnitude higher than in the ion source. As a result, they detected several secondary products (H_2O, NO, NO_2, O_2, Cl_2) as well as the primary product (NH_3). Because of the large distance between the ion source and the sample, and of the modest pumping speed of their apparatus, the authors[20] failed to detect any perchloric acid in the mass spectrum. In order to analyse corrosive gases such as perchloric acid, chlorine, and hydrogen chloride, the time between their formation and detection must be much shorter than their lifetime. (These species disappear as a result of wall reactions.) This condition was evidently not fulfilled in Heath and Majer's work[20]. Since their mass spectrometer was of the static type, with a large time constant, the reproducibility of their results was also poor: the rate of change of the peak intensities was of the same order as the rate of scanning of the mass scale.

More reliable results were obtained in a later study[21] of the main products of the thermal decomposition of ammonium perchlorate at relatively low temperatures (230°). A time-of-flight mass spectrometer was used at pressure of the order of 10^{-3} mmHg. According to the authors[21], the ammonia and perchloric acid formed as primary products did not enter into secondary gas-phase reactions in the hot region of the reaction vessel, and they recombined in the cold regions with formation of NH_4ClO_4. This study included the decomposition of $^{15}NH_4ClO_4$ in order to distinguish the nitrous oxide peak from the background carbon dioxide. The main reaction products at 230° were found to be: water, nitrous oxide, chlorine, and oxygen, together with significant amounts of hydrogen chloride and nitrogen. Hence the equation suggested by Bircumshaw[25], giving H_2O, N_2O, Cl_2, and O_2 as the products, is not completely accurate. A later paper by the same authors[22], dealing with the decomposition kinetics of $^{14}NH_4ClO_4$, $^{15}NH_4ClO_4$, $NH_xD_{4-x}ClO_4$ at 160–230° and 10^{-4}–10^{-7} mmHg, gives the activation energy for the decomposition (28 kcal mole^{-1}) and the ratio of products ($O_2 : N_2O : Cl_2 = 3 : 3 : 2$).

The primary decomposition step of ammonium perchlorate and the decomposition kinetics in a vacuum have been studied in the writer's laboratory[10-12], using time-of-flight mass spectrometry and fast heating techniques. The primary decomposition products were found to be ammonia and perchloric acid. By using small samples (10^{-6}–10^{-5} g), the complicating effects of secondary reactions in the pores between crystallites of the sample were avoided, and the primary decomposition products were identified over the range 280–500°. This work showed that neither decomposition by electron transfer nor breaking of the Cl–O bond play a significant role, and that the main reaction is dissociation of ammonium perchlorate into ammonia and perchloric acid by the scheme

$$NH_4ClO_4(s) \rightarrow NH_3(g) + HClO_4(g), \quad (1)$$

followed by oxidation of the ammonia by the decomposition products of perchloric acid. The mass spectrum of the flash pyrolysis products of ammonium perchlorate is discussed by Boldyrev and coworkers[12]. The spectrum was recorded 1 ms after the onset of decomposition. The perchloric acid spectrum is practically indistinguishable from that obtained by Fisher[26] on an apparatus specially designed for the study of atoms and free radicals. Other papers also discuss the dissociation of ammonium perchlorate into ammonia and perchloric acid[11,27]. The experimental method of studying the kinetics of this reaction has already been described in the previous Section. Ammonium perchlorate crystallites of 10 μm diameter were deposited on the heater strip by evaporation of a droplet of an aqueous or alcoholic solution of ammonium perchlorate. The following relationship was found between the maximum decomposition rate $\left(\frac{d\alpha}{dt}\right)_{max}$ and temperature over the range 280–320°:

$$\left(\frac{d\alpha}{dt}\right)_{max} = 10^{9.09}\exp(-24\,000/RT)\ s^{-1}.$$

Combining this result with data[28] on the equilibrium pressure of ammonia and perchloric acid vapour we obtain a sublimation coefficient $\beta = 8 \times 10^{-2}$ for ammonium perchlorate, which is only a factor of 2 higher than the value reported[29] for the range 230–270° by a different method. The activation energy is lower than a previously published value[29] by 6 kcal mole^{-1}, but higher than another reported value[30] by 2.5 kcal mole^{-1}.

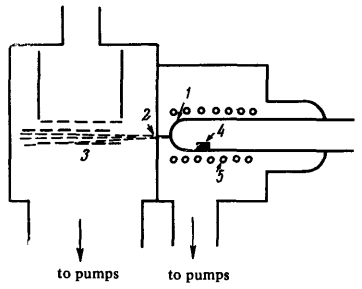

Figure 4. Mass spectrometric assembly for studying the decomposition of solids in the vicinity of the ion source at relatively high pressures[24]: *1*) orifice; *2*) diaphragm; *3*) ion source of time-of-flight mass spectrometer; *4*) sample; *5*) furnace winding.

The decomposition of ammonium perchlorate has been studied[24] at 400° and 20–100 mmHg pressure, i.e. under conditions which did not exclude secondary gas-phase reactions. The combined reaction vessel and effusion orifice used in this work was of molybdenum glass, previously heated to the required temperature. The distance between the orifice and the ionisation volume was a few millimeters, the pumping speed was ~ 100 litre s^{-1}. As a result, unstable particles and corrosive gases could be reliably monitored. The sample was inserted into the heated reaction vessel by magnetic "ram" (Fig. 4). It was located 10 mm from the orifice, and therefore the diffusion time of gas molecules from the sample to the orifice was as short as 0.05 s at 8 mmHg and 0.5 s at 80 mmHg. Because of the shortness of the diffusion path, the procedure allowed the primary decomposition products of ammonium perchlorate (ammonia and perchloric acid) to be detected as well as the secondary products (chlorine, oxygen, nitrous oxide, water, nitrogen, nitric oxide, hydrogen chloride). The measured concentrations of ammonia and perchloric acid were practically the same as the reported[28]

equilibrium pressures of ammonia and perchloric acid over solid ammonium perchlorate:

$$NH_4ClO_4(s) \rightleftharpoons NH_3(g) + HClO_4(g). \quad (2)$$

This confirms the decomposition scheme for ammonium perchlorate proposed by the writer[27] and the hypothesis that the equilibrium corresponding to reaction (2) is maintained during the decomposition. Changes in gas phase composition during the reaction were also observed in the absence and in the presence of iron oxide, and correlated with the catalytic effect of impurities on the dissociation of nitrous oxide.

The dissociation of perchlorates other than ammonium perchlorate has also been investigated. Thus, the kinetics of the thermal decomposition of nitronium perchlorate NO_2ClO_4 has been studied[31] at 100–160° at pressures high enough for the secondary reactions to be significant. The decomposition products are O_2, NO, and Cl_2, the activation energy 15 kcal mole^{-1}. The primary stages in the decomposition of guanidinium perchlorate have been investigated[32] in the ion source of a time-of-flight mass spectrometer. In addition to the reaction previously proposed[33],

$$CH_5N_3 \cdot HClO_4 \rightarrow CN \cdot NH_2 + HClO_4 + NH_3 \quad (3)$$

it was shown that guanidinium perchlorate dissociates by the reaction

$$CH_5N_3 \cdot HClO_4 \rightarrow CH_5N_3 + HClO_4. \quad (4)$$

One-third of the material dissociates by reaction (3), and two-thirds by reaction (4).

An omegatron has been used[34] to study the decomposition of ammonium polymolybdate and polytungstate; ammonia, and molybdenum and tungsten oxides, have been identified as the decomposition products. The accompanying hydrogen and nitrogen are assumed[34] to result from the catalytic decomposition of the ammonia pumped through a layer of molybdenum or tungsten oxide.

The products of the pyrolysis of nickel tetracarbonyl and iron pentacarbonyl have been investigated[35,36]. The mass spectrum of $Ni(CO)_4$ positive ions was established in the mass spectrometer by a method which allowed the molecular beam to be distinguished from the decomposition products formed in the ion source. The evidence for the existence of gas-phase intermediates such as $Ni(CO)_3$ could not be confirmed by sampling the gas from the low-pressure reactor. Appearance potentials and dissociation energies were obtained for the ions $Ni(CO)_x^{+q}$ ($q = 1.2$; $x = 1, 2, 3, 4$).

Bowden and coworkers[37] made a mass-spectrometric study of the kinetics of the thermal dissociation of sodium and thallium azide single crystals. They showed that in the initial stages of dissociation of small NaN_3 single crystals in a vacuum of 10^{-9} mmHg (i.e. close to the ion source of the mass spectrometer) various gases are evolved, such as Ne, Ar, He, and H_2, which are strongly held on the crystal surface by adsorption forces. Subsequently, when the nitrogen lines begin to appear in the mass spectrum, the residual OH^+ and CO_2^+ peaks disappear, obviously as a result of reactions between the background gases and the Na atoms formed by decomposition of the azide. The long induction periods frequently observed in the decomposition of solids can perhaps be ascribed to the disappearance of metal nuclei by reaction with the residual gases.

Many papers, only some of which are mentioned here[38–40], deal with the evaporation mechanism of solids and with the composition of their vapour. Thus, Shchukarev and coworkers[38] have studied the composition of the vapour over the oxides of gallium, thallium, and indium, Mostovskii and Sakseev[39] have examined the vapour over Sb_2S_3 and GeSe. Studies of the evaporation of GeSe have confirmed the view that this compound undergoes little dissociation in the vapour state. The vapours of many solids contain monomers, dimers, and trimers. Due to superposition of the lines, their ratio is often difficult to determine mass-spectrometrically.

Using a time-of-flight mass spectrometer[41,42], the following species have been detected by rapidly heating to 1400–3000° a tungsten wire which had been kept at room temperature in an oxygen atmosphere: O, WO, WO_2, WO_3, W_2O_6, and W_3O_9. These results indicate that only a few per cent of the surface tungsten atoms are oxidised at room temperature. The evaporation products include monomers, dimers, and trimers of WO_3. The activation energy for the evaporation of these oxides is ~ 100 kcal mole^{-1}.

2. Thermal and Mechanical Degradation of Polymers

The kinetics and mechanism of polymer degradation have attracted a great deal of study. Thermal degradation of polymers is known to give rise to a mixture of products of different volatilities[43]. Bradt and coworkers[44,45] published the first papers on the nature of the fractions which are involatile at room temperature but volatile at the temperature of the thermal degradation experiment. In this work, the polymers were decomposed in the immediate proximity of the ion source of a mass spectrometer. The thermal decomposition of polystyrene was shown[44] to produce dimeric and trimeric molecules in addition to the monomer. Analogous results were obtained in a study[46] of the decomposition of polyethylene at 200–330°. The mass spectrum consists of lines which can be assigned to C_nH_{2n+1} ions. The C_4H_9 peak is the strongest in the mass spectrum of the decomposition products of polyethylene at 200°. As the temperature is raised from 200 to 330°, the intensity maximum tends to flatten out and to shift from $n = 4$ to $n = 8$. The degradation is shown to proceed in two stages. In the first stage, mainly at the lower temperatures (~ 200°), the rate is limited by diffusion of light molecules through the polymer. In the second stage, at higher temperatures, the thermal degradation is rate-limiting. The decomposition products of poly(tetrafluoroethylene) and poly(fluoroethylpropylene) have been studied[47] at 350–875° with a time-of-flight mass spectrometer; the flash-pyrolysis products of various polymers have also been studied[16] using a fast pulse of energy from a high-power xenon flash tube. The experimental problems encountered in the study of polymer degradation by mass spectrometry have been discussed in a number of papers[48–50].

The time-of-flight mass spectrometer has been used[17,18,50–53] to study the kinetics and mechanism of the mechanical and thermal degradation of polymers. The polymer samples were fractured and heated close to the ion source of a mass spectrometer, as shown in Fig. 5.

The primary products of the thermal and the mechanical degradation of poly(methyl methacrylate) and polystyrene were shown[51] to have identical mass spectra. Hence it was concluded that the gas evolution accompanying mechanical degradation of these polymers has a thermal origin: the polymer suffers local heating during fracture, and gases are evolved as a result of the rise in temperature. Regel' and Muinov[18] showed that gases are evolved as soon as the load is applied, not only after fracture of the polymer sample. This suggests that decomposition of the polymer sets in as soon as the load is applied. Since the

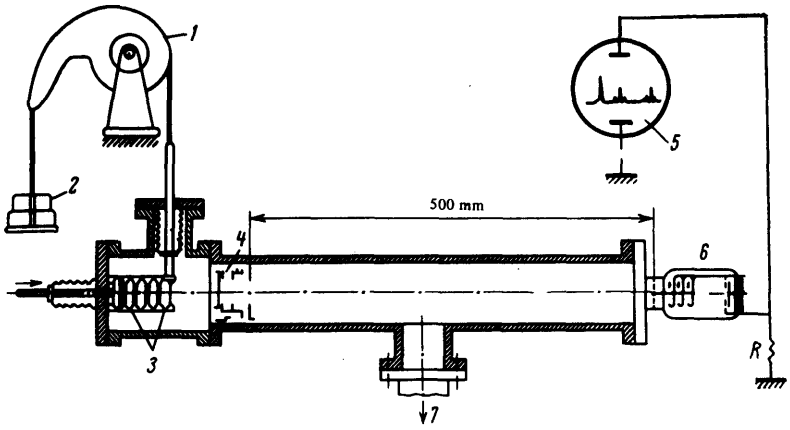

Figure 5. Apparatus for studying the kinetics and mechanism of mechanical degradation of polymers by a time-of-flight mass spectrometric method[52]: *1*) cam; *2*) load; *3*) sample magazine; *4*) source; *5*) mass spectrum; *6*) electron multiplier; *7*) to vacuum pump.

curves of elongation and gas evolution against time are identical, the degradation and deformation processes must be intimately related. The rate of gas evolution is an exponential function of the applied stress. Amelin and coworkers[53] have reported studies of the thermal and mechanical degradation of poly(methyl methacrylate), polystyrene, poly(vinyl chloride), polypropylene, and polyacrylonitrile. They show that the volatile products of thermal and mechanical degradation are identical if the decomposition of the polymer begins in the main chain. When thermal degradation of the polymer involves the removal of side chains, the volatile products are different from those of mechanical degradation. These findings confirm and extend the results of the kinetic theory of degradation, according to which the mechanical fracture processes are related to the thermal degradation of polymers. In a kinetic study[17] of the thermal degradation of poly(methyl methacrylate) and of the methyl methacrylate monomer, initially the activation energy is found to be 30 kcal mole^{-1}, but at a more advanced stage of degradation it becomes ~ 50 kcal mole^{-1}.

3. High-temperature Decomposition of Solid Propellants

Valuable information on the mechanism and the kinetics of the high-temperature decomposition of solid propellants, which play an important part in combustion, can be obtained by fast heating of solid samples to elevated temperatures, and by identifying the decomposition products (including unstable species) in a dynamic mass spectrometer such as a time-of-flight or other instrument with a short time constant. The kinetic parameters of the decomposition reaction can be obtained from a mass spectrometric study of the rate of formation of these products[23]. As a result of the recent developments in the relevant experimental techniques, this type of work has grown considerably in the last few years.

We shall take as our first example a study[4] of the pulsed pyrolysis of nitrocellulose. The source of heat was radiation from an optical arc furnace. Both the characteristics of the source of heat[4,54,55] and the unstable intermediates found in the pulsed pyrolysis of solid organic compounds[4,56,57] have already been described. However, unequivocal identification of these products is far from easy. One of the most important results of this work is the realisation that the composition of the pyrolysis products of cellulose is a function of the rate of heating: this is evident from the data summarised in the Table. For low heating rates up to 300°, using conventional resistance heating, the main decomposition products are water, solid carbonaceous deposits, and volatile organic compounds.

Pyrolysis products of cellulose[4].

Heat source	Electric furnace	Carbon arc	Carbon arc	Xenon flash tube
Thermal flux, cal cm^{-2} s^{-1}		1.5	11	3000 at peak of output

H_2O	19	32	16	28
CO	3	3	13	37
CO_2	?	9	11	4
Volatile organic compounds	51	3	6	30
Tar	2	19	51	none
Solid carbonaceous residue	25	33	3	1
CO/CO_2 ratio	—	0.33	1.2	9.2

With the higher heating rates obtainable from an optical arc furnace (heating time 4–10 s), a large amount of tar is formed and the yield of volatile organic compounds decreases. Under flash pyrolysis with a xenon lamp (heating time ~ 0.5 ms) the main products are volatile

organic compounds (mainly aldehydes and ketones), water, and carbon monoxide. As the heating rate is increased, the CO/CO_2 ratio increases and the molecular weight of the products decreases. Fast heating appears to subdivide the polymer chains into smaller segments. Evidently, pyrolysis in the condensed phase is accompanied by a whole spectrum of chemical reactions in series and in parallel whose probability depends on the heating rate. Useful products can be obtained by controlling the heating rate. Similar effects have been observed during the carbonisation of coal.

The use of a pulsed laser beam for heating coal particles is a new and interesting technique in this area of research[9]. Very small particles of coal (less than 10 μm in diameter, $\sim 10^{-6}$ g) were placed in a quartz tube within the ion source of a time-of-flight mass spectrometer about 10 mm from the ionisation volume, and heated by a pulse of radiation from a focussed laser beam. The energy of the pulse was 0.7 J, corresponding to an energy flux of $\sim$ 100 kW cm^{-2} for a spot diameter of 7 mm. The mass spectrum was recorded 0.2 ms after application of the pulse of radiation. In addition to the stable decomposition products, including polyacetylenes, free radicals (H, C, CH_3) and alkali metal ions (Na^+, K^+) were observed. The mass spectra obtained at low energies of the ionising electrons provide further evidence of the formation of radicals and ions. The temperature of the spot could not be estimated, but it must have reached several thousand degrees, since a considerable amount of atomic carbon was found in the gas phase. The techniques used in this work are suitable for the detection of atoms and radicals in other high-temperature decomposition reactions.

Methods for studying the decomposition of coal under non-isothermal conditions have been developed[13]. The heating rate must be constant, or a known function of time. The method was tested on simple decomposition reactions of solid organic acids, giving rise to water, carbon monoxide, and carbon dioxide, and satisfactory agreement between theory and experiment was obtained. A resistance furnace was used for low heating rates (0.5–0.3 deg min^{-1}), and the decomposition products were led to the detector (a conventional mass spectrometer) by a stream of inert gas. A platinum gauze heater was used for higher heating rates (10^3–10^5 deg min^{-1}), and temperatures were measured by a platinum/platinum–rhodium thermocouple. The decomposition was studied close to the ion source of a time-of-flight mass spectrometer. The highest temperature was 1000°. Assuming first-order kinetics for the formation of ethane by the decomposition of coal, an activation energy of 42.1 kcal mole^{-1} and a pre-exponential factor of 10^{11} min^{-1} were obtained. It was shown that the evolution of methane and hydrogen from coal during pyrolysis is not a first-order reaction, but follows more complex kinetics. The theoretically predicted shift of the maximum reaction rate towards higher temperatures at higher heating rates was confirmed experimentally. Perhaps as a result of the arbitrary assumption of first-order kinetics, the error in the determination of rate constants was as high as two orders of magnitude.

A more satisfactory method of studying the kinetics of fast reactions relies on isothermal conditions, combined with the use of a time-of-flight mass spectrometers[10,11]. The method was applied[58] to kinetic studies of the mechanism of high-temperature decomposition of nitrocellulose. The rates of formation of various decomposition products (NO_2, CH_2O, H_2O, CO, and CO_2) have been studied[58] as a function of reaction time at temperatures (220–280°) close to the surface temperature of pyroxylin guncotton. The reaction was shown to be autocatalytic. The maximum decomposition rate, measured from the rate of formation of the mass 30 peak, is described by the equation

$$W_{max} = 10^{14.4} \exp(-35000/RT)\ s^{-1}.$$

Extrapolation to 220° of the rate of decomposition of nitrocellulose measured[59] at 130–160° in a vacuum of $\sim 10^{-4}$ mmHg (i.e. close to the experimental conditions of the previous investigation[58]) gives a value about an order of magnitude lower than reported in that work[58]. This may be due to a difference in the thickness of the nitrocellulose samples used in the two investigations ($\sim$ 3 μm in Ref. 58, and very much thicker in Ref. 59). The activation energy given in Ref. 58 is lower than the value obtained by other methods[59–61]. The difference may be ascribed to the different methods used to measure the rate constant. In Ref. 58, NO_2, CH_2O, CO, CO_2, and H_2O are chosen as the primary decomposition products although their relative amounts vary during the course of the reaction. The mass spectra of the decomposition products suggest that other nitrogenous species are formed in addition to NO_2 (possibly NO_3).

A series of papers by Dauerman and coworkers[6–8,62] discusses the primary act in the decomposition of nitrocellulose, nitroglycerine, and propellants based on these compounds, under low-pressure combustion and ignition conditions. Their experimental procedure, using a mass spectrometer with a variable accelerating potential has already been discussed (see Fig. 3). Since these experiments were made at relatively high pressures (10–100 mmHg), i.e. under conditions which permit secondary reactions in the gas phase, these workers' claims to have investigated the primary decomposition and combustion products are, to say the least, suspect. Thus, mass spectrometric data on the composition of the high-temperature pyrolysis products of nitrocellulose are quoted[7] in the presence of 10–100 mmHg pressure of helium. Radiant energy from an optical arc furnace is used, and the products are monitored immediately before ignition, at ignition, and during combustion. From an analysis of the intensity ratios of the mass 30 and 46 peaks, they conclude that nitric oxide is predominant among the primary decomposition products, with the reservation that the NO in their experiments could have been formed by decomposition of NO_2. Comparing these results with others[58], obtained under conditions which precluded secondary gas-phase reactions, we conclude that the nitrogen dioxide in Dauerman's experiments[7] must have been converted into NO before reaching the detector. These experiments give no information on the rate of formation of the various components as a function of the extent of conversion of the condensed phase, and in this respect also they differ from our own[58], since they were carried out under non-isothermal conditions of continuously rising temperature. However, in spite of these shortcomings, Dauerman's results[6–8] are very interesting because they reveal the correspondence between the surface temperature of the propellant and the rate of decomposition, thus increasing our knowledge of the processes involved in the ignition and combustion of solid propellants. They lead to the conclusion[6,8,62], very important from the standpoint of the theory of combustion of two-component solid propellants (consisting mainly of nitroglycerine and nitrocellulose), that the main product of the ignition and combustion of these propellants is the NO_3 radical and not NO_2, as previously suggested. This conclusion is based on the fact that the intensity ratio of the mass 46 and mass 30 peaks for the ignition and combustion products at 10 mmHg pressure was well above unity, and that no peaks above mass 46 were found in the

mass spectrum. Fig. 6 shows the time dependence[8] of the intensity of the main ion peaks, which are proportional to the rate of formation of the corresponding gaseous components during ignition of the propellant. The singularities on these curves (points where the differential shows a break) correspond to the moment of ignition and onset of combustion.

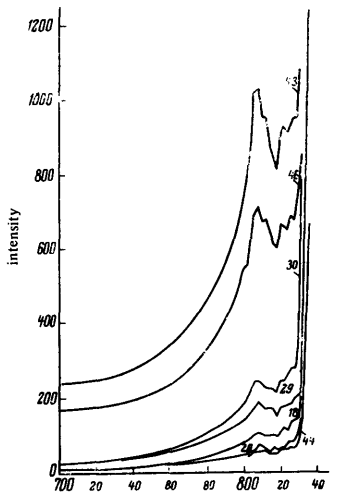

Figure 6. Intensity of various mass peaks as a function of time of irradiation during ignition of solid propellants by radiant energy[8]. The number of ciné-film frames, which is proportional to time, is plotted horizontally. The sample is an uncatalysed D-4 propellant.

Comparing Dauerman's mass spectrum[6,8] with published mass spectra of nitrate esters and other nitro compounds[63], including nitroglycerine, we conclude that it cannot be assigned to any known nitro ester. The mass spectrum was therefore assigned to the NO_3 radical, with the assumption that removal of this radical is the first step in the decomposition of two-component solid propellants (and also of nitroglycerine). However, this conclusion is also debatable, since the observed mass spectrum[6,8,62] could be due to a species (possibly even NO_3) resulting from secondary reactions in the gas phase, e.g. from the gas-phase decomposition of nitroglycerine, which is volatile under the experimental conditions used in that work[6,8,62]. The writer's mass-spectrometric study of the primary products of the decomposition of nitroglycerine compositions at 170–290° in a high vacuum, i.e. in the absence of gas-phase reactions, is also inconsistent with that conclusion[6,8,62]. The value of the mass spectroscopic method in studies of the decomposition of solid propellants is clearly shown in two papers by Dauerman and coworkers[8,64]. Lead stearate—an efficient catalyst for the combustion of two-component solid propellants—is shown[8] to catalyse other condensed-phase chemical reactions of these propellants. The role of the emulsifier in mixed solid propellants based on a butadiene–acrylic acid copolymer has been studied by a similar method[64].

Coats[65] also used the pulsed mass spectrometric method in his study of the thermal decomposition of mixed solid propellants based on ammonium perchlorate. In that work (quoted by Friedman[66]), a thin platinum wire coated with a film (5 μm thick) of the mixed solid propellant was heated to 500–600° in 50 ms by discharging a condenser, and the decomposition products were led to the ion source of a time-of-flight mass spectrometer. Peaks corresponding to hydrocarbon residues, NH_3, $HClO_4$, HCl, and ClO_2 were observed in the mass spectrum.

Recently published work[63,67–73] on the mass spectra of the molecules of individual explosives should prove very valuable in the interpretation of the mass spectra of the decomposition products of solid propellants.

Mass spectrometry has been widely used in recent years to study the kinetics and mechanism of the thermal decomposition of solids. Further developments are being constantly reported, and new fields of application in science and technology are being suggested. The method should prove valuable in areas such as cosmochemistry, the interaction of powerful light beams with matter, and also the study of the combustion mechanism of solid propellants and associated high-temperature, fast reactions. Many unsolved problems remain in all these fields.

Poly(arylenealkyls)

I.I.Yukel'son and V.S. Glukhovskoi

Information on the preparation of poly(arylenealkyls) by polycondensations and on their chemical reactions is surveyed. The chemical reactions of poly(arylenealkyls) can lead to the preparation of materials and products interesting in practical and theoretical respects. There are 75 references.

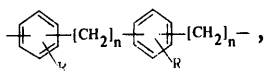
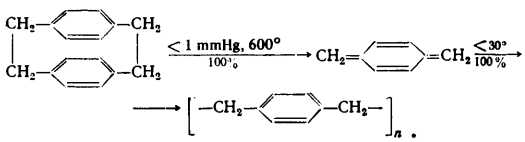
1. INTRODUCTION

It is now known that the methods, mechanism, and conditions of synthesis determine the significant features of the structure of a polymer chain, its structure and the properties of the polymer articles. This is well illustrated by the example of the poly(arylenealkyls)—polymers which contain benzene rings in a chain separated by methylene groups, of the general formula



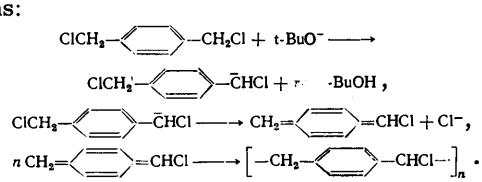
where $n \geqslant 1$ and R = H, CH_3, C_2H_5, C_3H_7, halogen, etc. Poly-(*p*-phenylene-ethylene) prepared by pyrolysis of *p*-xylene, was found to be less thermostable than the same polymer obtained by the reaction of phenyl-lithium with *p*-bisbromomethylbenzene[1]. A considerable number of methods for making such polymers is known and we will only point out some of them.

The preparation of poly-(*p*-xylylene) by the thermal decomposition of di-(*p*-xylylene) in vacuo at 600°C has been described[2]. First two molecules of the intermediate reactive *p*-xylylene are formed, which are spontaneously converted into linear poly-(*p*-xylylene) by the scheme:



Apart from di-(*p*-xylylene), dichloro-, dibromo-, dicyano-, dimethyl-, diethyl-, and tetrachloro-substituted di-(*p*-xylylene) can be used as the initial monomers. Linear, high-molecular-weight sparingly soluble polymers with good physico-mechanical and dielectric properties are formed[3]. Poly-(*p*-xylylene) can be obtained by heating $\alpha\alpha'$-dihalogeno-substituted *p*-xylene with nickel or cobalt powder in the presence of water[4].

A recent paper describes the synthesis of polymers of the poly-(*p*-xylylene) type by the polymerisation of halogenated *p*-xylenes in the presence of bases[5]. α-Chloro-*p*-xylene, by reacting with potassium t-butoxide (t-BuOK), gives poly-(α-chloro-*p*-xylylene) by the following series of reactions:



The polymers thus obtained exhibit considerable thermal stability and good physico-mechanical properties.

The preparation of poly-(*p*-xylylenes) by the electrolytic reduction of $\alpha\alpha'$-dihalogeno-*p*-xylenes has been proposed[6].

Several investigators[7] have prepared poly-*p*-xylylene with high thermal stability and chemical resistance by heating *m*-methylbenzyltrimethylammonium halides and metal hydroxides in alcohol medium then heating the product in hydrocarbons.

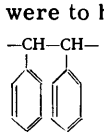
The simplest method for obtaining polymers containing a chain of benzene rings separated by methylene groups is the polycondensation of benzyl chloride and its derivatives, and also of dihalogenoalkanes with aromatic derivatives in the presence of Friedel–Crafts catalysts. However, the poly(arylenealkyls) thus obtained are strongly branched and have a comparatively low molecular weight and low physico-mechanical properties, unlike poly-(*p*-xylylenes).

2. SYNTHESIS OF POLY(ARYLENEALKYLS) BY THE FRIEDEL–CRAFTS REACTION

The preparation of polymers with a chain of benzene rings separated by methylene bridges, has been known for a long time. Perkin[8] reported that benzyl chloride reacts with aluminium chloride to form resins and hydrogen chloride. The polycondensation of benzyl chloride has been studied most fully not only in the presence of Friedel–Crafts catalysts, but also of strong acids[9], and even in the presence of such an inert substance as glass[10].

Many workers thought[10,11] that the polybenzyl formed should have a structure of the

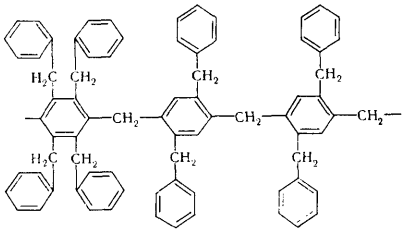
type, but did not give any proof in support of this. Mass-spectroscopic analysis of the pyrolysis products of polybenzyl showed that they consist of toluene, benzene, and xylene[12]. If polybenzyl were to have the structure



and not

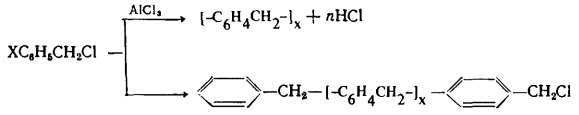
(both structures correspond to the same empirical formula $[-C_7H_6-]_n$) then one of the products of destruction should

be stable. The absence of stilbene shows that the linear structure is correct for polybenzene. The linearity of the polybenzyl structure is also shown by its high thermal stability. In this molecule where the phenyl groups do not enter into the composition of the main chain and there are substituents at each successive carbon atom, all the carbon–carbon bonds of the chain should be weakened by the presence of tertiary carbon atoms. The presence of benzene nuclei in the main chain of the polymer is responsible for its high stability because of the possibility of conjugation. The reason for the high thermal stability of polybenzyl could be a strongly branched structure, which was proposed because of the X-ray diffraction analysis and the infrared spectra:



In pyrolysis of polybenzyl the proportion of volatiles amounts to almost 100%, which shows the absence of a cross-linked polymer or at least of one strongly cross-linked.

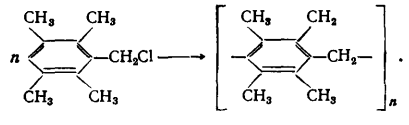
Korshak and coworkers [13] obtained polybenzyl by the polycondensation of benzyl chloride under the action of various Friedel–Crafts catalysts. It was found that in the presence of $AlCl_3$ a powdery product was formed, only partly soluble in benzene, with a softening point of 220–230°C and molecular weight 2000. In the presence of $ZnCl_2$ and $SnCl_4$ a powdery polymer soluble in benzene is formed. The polycondensation proceeds with the formation mainly of a linear polymer:



Owing to secondary alkylation of the same benzene ring the polymer can be branched and the formation of dihydroanthracene rings is possible.

By using the $AlCl_3$.nitrobenzene complex Moore [14] obtained polybenzyl and polyphenethyl with molecular weights not exceeding 1880 by the polycondensation of benzyl chloride and phenethyl chloride in nitrobenzene solution.

Haas [15] showed that the polymer obtained from chloromethyldurene is highly crystalline and has a completely linear structure, unlike the strongly branched and amorphous polybenzyl. The explanation for this difference in the properties of the polymers is that in the polymer based on chloromethyldurene all the positions of the benzene ring except *para*- are blocked:



Overhults and Ketley [16] investigated the effect of substituents in the benzene ring of a chloromethyl-substituted monomer on the formation of a linear polymer. Copolymers of dichloromethyldurene and aromatic compounds were obtained in solution in the presence of $TiCl_4$ catalyst. It was found that if the number of methyl groups present in the second monomer is reduced from 4 (durene) to 2 (*p*-xylene) and to zero ($\alpha\alpha'$-dichloro-*p*-xylene) but the number of methyl groups in the first monomer remains at 4 then the polymers formed are crystalline, insoluble in organic solvents, and have low molecular weights (the degree of polymerisation does not exceed 8). However, when the aromatic ring does not have a substituent, for example, in the copolymerisation of $\alpha\alpha'$-dichloro-*p*-xylene with *p*-xylene, an amorphous product is formed, insoluble in organic solvents and not melting above 500°C. The properties of the polymer show that branching followed by cross-linking occur during the reaction. The polymers obtained from dichloromethyldurene and aromatic compounds in which methyl groups are in positions ensuring *ortho*- and *meta*-addition of the copolymer (for example, a copolymer of dichloromethyldurene) have a small amount of a crystalline product insoluble in benzene and a large amount of amorphous, soluble, low-melting product with degree of polymerisation 4–5. The formation of a low-molecular-weight polymer is evidently due to steric hindrance. If the number of blocking groups is reduced sufficiently to remove the steric hindrance the chain growth prevents cross-linkage. The maximal molecular weight of the soluble polymer is reached immediately before the start of cross-linking. On carrying out the reaction to partial cross-linking, the molecular weight of the soluble part falls from 3800 to 2000 and less. This shows that the longer chains of the polymer are cross-linked first. Attempts to inhibit cross-linking in polycondensation for the preparation of a higher-molecular-weight polymer did not lead to the desired result since chain growth ceases during this.

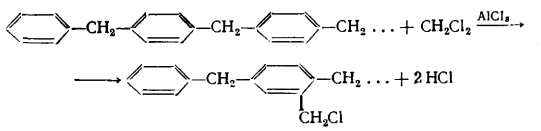
The polymer obtained from $\alpha\alpha'$-dichloro-*p*-xylene and *p*-xylene can, after separation and purification, be moulded at 120–140°C.

Crystalline polybenzyl, poly-(2,5-dimethylbenzyl), and poly-(α-methylbenzyl) were made by adding a solution of $AlCl_3$ in ethyl chloride to benzyl chloride or to 1-chloroethylbenzene respectively at ~ −130°C. [17] The X-ray powder diagrams of the polymers show their linear structure and high crystallinity. The linear structure is confirmed by an analysis of their infrared spectra (the absorption band of 1,4-disubstituted aromatic rings is at 805 cm^{-1}), and also of the NMR spectra, in which there are signals of aromatic protons with chemical shift 7.05 and methylene protons with 3.08, with relative intensity 2 : 1, which corresponds with the structure $H-[-C_6H_4CH_2-]_n$ for polybenzyl.

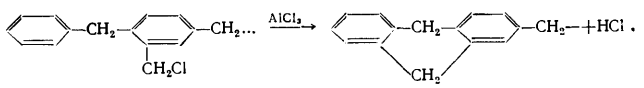
High-melting-point crystalline polybenzyls are obtained from benzyl chloride and its derivatives in the presence of $AlCl_3$ at −100°C. The best results in the low-temperature Friedel–Crafts reaction are also obtained with substituted benzyl chloride. Whereas polybenzyl has maximal m.p. 142°C, poly-(2,5-dimethylbenzyl) softens only at 190°C and melts above 300°C. [18] A polymer of the polybenzyl–poly(phenylenemethyl) (PPM) type can be obtained also by the polycondensation of benzene with methylene dichloride in the presence of $AlCl_3$: [19]

During the polycondensation cross-linked products are not formed at any ratio of the reactants. The reason for

the arrest of chain growth is the formation of dihydroanthracene terminal groups. It is thought that initially branched PPM molecules of the type:



are formed, although compounds with a terminal $-CH_2Cl$ group were not observed. The interaction of the chloromethyl group with a neighbouring aromatic nucleus leads to the formation of a dihydroanthracene ring:



The highest molecular weight of a polymer, 2970, was obtained at a methylene dichloride : benzene ratio of 3.12 : 1 and a catalyst concentration of 4.3 mole %. PPM is a viscous liquid and is soluble in halogenoalkanes and aromatic hydrocarbons.

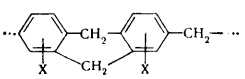
The possibility of the preparation of PPM [20] by the complete arylation of diphenylmethane under the action of $AlCl_3$ by the reaction:

has been shown[20]. The low-molecular-weight product of the complete arylation of diphenylmethane is benzene.

A polymer with the low molecular weight of 1350 is evidently obtained because of the formation of dihydroanthracene rings at the ends of the growing chains which leads to the arrest of chain growth.

The formation of a cross-linked product was observed only on raising the reaction temperature to 170 °C. Increasing the catalyst concentration also leads to an increase in the yield of PPM but an increase in the molecular weight is not observed.

Linear polymers with a molecular weight not exceeding 2500 were obtained by the polycondensation of fluorobenzene, chlorobenzene, and bromobenzene with methylene dichloride[21]. This shows that the activity of halogenobenzenes is less than that of benzene. It could be expected that the formation of dihydroanthracene rings at the ends of the growing polyhalogenophenylenemethyl chains leads to the breaking of the chain

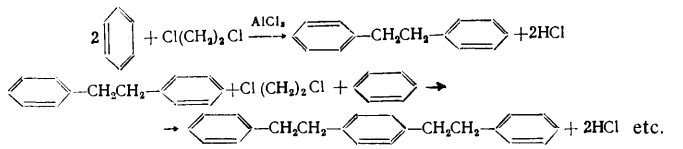


where X is a halogen atom.

A high-molecular-weight polymer is also not formed in the polycondensation of *p*-xylylene dichloride with various aromatic hydrocarbons in the presence of $SnCl_4$ in nitrobenzene at 60 °C. Only gelatinous polymers were obtained[22].

Polymers with benzene rings in a chain separated by $-CH_2-CH_2-$ groups are obtained by the polycondensation of 1,2-dichloroethane with benzene and its derivatives[23-25] in the presence of $AlCl_3$.

Polyphenylene-ethyl (PPE) is formed by polycondensation of 1,2-dichloroethane with benzene in the presence of $AlCl_3$. The molecular weight of PPE increases with decrease in the benzene: dichloroethane ratio and is maximal at the ratio 1.20 : 1,[26] but at 1.10 : 1 the only product of the reaction is insoluble PPE:



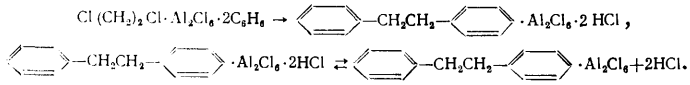
The first stage of the polycondensation of 1,2-dichloroethane with benzene in the presence of $AlCl_3$ is the formation of a complex of $AlCl_3$ with 1,2-dichloroethane[27]:

$$ClCH_2CH_2Cl + Al_2Cl_6 \rightleftarrows ClCH_2CH_2Cl \cdot Al_2Cl_6 .$$

The complex reacts further with benzene, forming a ternary complex:

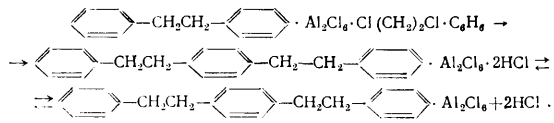
$$ClCH_2CH_2ClAl_2Cl_6 + 2C_6H_6 \rightleftarrows ClCH_2CH_2Cl \cdot Al_2Cl_6 \cdot 2C_6H_6 .$$

The reaction between 1,2-dichloroethane and benzene takes place inside this complex and leads to the formation of a diphenylethane–aluminium chloride–hydrogen chloride ternary complex.



The complex of diphenylethane and $AlCl_3$ reacts again with dichloroethane and benzene to form:

The reaction proceeds in the ternary complex and leads to the formation of a polymeric chain and the release of hydrogen chloride:



Further increase in the chain proceeds similarly. The yields of the reaction in the ternary complex were confirmed by Garmonov and coworkers[28] who isolated and determined the composition of this complex with the aid of labelled atoms. ^{14}C-Labelled benzene, toluene, ethylbenzene, propylbenzene, and 1,2-dibromoethane, were used.

The mixtures of the components deposited the complexes as dark red, heavy oily liquids. The change in the activity of ^{14}C-labelled radioactive specimens was measured with an end window Geiger counter. The results show that the ternary complexes have the composition:

$$HalCH_2CH_2Hal \cdot (5—7)\,ArR \cdot Al_2Cl_6 .$$

The composition of the complex is almost independent of the molar ratio of the components. Interestingly, with increase in the alkyl groups in the benzene ring the stability of the complex increases. A sufficient excess of one of the initial components is needed to shift the equilibrium

$$ClCH_2CH_2Cl \cdot Al_2Cl_6 + 2C_6H_6 \rightleftarrows ClCH_2CH_2Cl \cdot Al_2Cl_6 \cdot 2C_6H_6$$

to the right.

The polycondensation of aromatic hydrocarbons with dihalogenoalkanes in the presence of aluminium chloride is connected with their transfer from a hydrocarbon layer into a catalytic complex and back again. With this there is

a change in the value of the distribution of the hydrocarbons between the catalytic and hydrocarbon layers, just as in the alkylation of aromatic compounds[29].

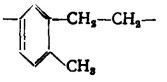
The reaction mass is a heterophase system consisting of a liquid catalytic complex of aluminium chloride with aromatic compounds, halogenoalkanes, and a hydrocarbon layer insoluble in the complex.

Poly(phenylene-ethyl) with a high molecular weight, 60 000, can be obtained by the polycondensation of diphenylethane[30,31]. To obtain a soluble polymer as well as increasing the temperature the reaction time must be shortened, otherwise a three-dimensional product is formed. To produce a high molecular weight the reaction must be stopped before the formation of a cross-linked polymer. An analysis of the infrared spectra of PPE obtained from dibenzyl and dichloroethane gives a basis for considering that a strongly cross-linked product is formed.

Poly(toluylene-ethyl) (PTE) is formed in the polycondensation of toluene with 1,2-dichloroethane[32]:

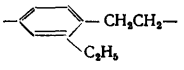
$$(n+1)\,C_6H_5CH_3 + n\,Cl\,[CH_2]_2Cl \xrightarrow{AlCl_3} CH_3C_6H_4\,[-CH_2CH_2C_6H_3(CH_3)-]_nH + 2HCl$$

The maximal molecular weight of PTE (4280) is reached when there is a slight excess of 1,2-dichloroethane and a cross-linked polymer is formed only when there is an excess of the latter. Steric hindrance is responsible for the difficulty in forming a cross-linked polymer. Destructive oxidation of the reaction products offers the possibility of suggesting the structure of the PTE chain:



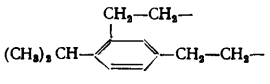
The infrared spectrum of the polymer also shows the presence of a 1,3,4-substituted nucleus in PTE.[33]

Yukel'son and coworkers[34] obtained poly(ethylphenylene-ethyl) (PEPE) by the polycondensation of ethylbenzene with 1,2-dichloroethane in the presence of $AlCl_3$. The highest molecular weight of PEPE is obtained at ethylbenzene : dichloroethane ratios close to 1. An analysis of the infrared spectra of the polymer shows that the benzene ring has predominantly 1,2,4-substitution:



The reaction of cumene with dichloroethane under the action of $AlCl_3$ gives poly(cumylene-ethyl) (PCE) with a low molecular weight even at a cumene : dichloroethane molar ratio[35].

An analysis of the infrared spectrum of PCE shows that the main type of substitution of the benzene ring should be 1,2,4-substitution:



In polycondensation the isopropyl group is completely retained and n-propylbenzene is not formed under the action of $AlCl_3$. This is shown by an analysis of the NMR spectrum.

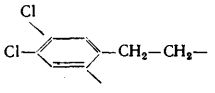
Shegoev[36] showed that the polycondensation of xylene with 1,2-dichloroethane proceeds smoothly and with a good yield of poly(dimethylphenylene-ethyl) (PDMPE), but in the polycondensation of di-isopropylbenzene with dichloroethane the process stops at the dimer stage owing to the large size of the alkyl substituents. However, the condensation of trialkylbenzene containing an alkyl with 1–3 carbon atoms and a dihalogenoalkane with 2–4 carbon atoms in the alkylene in the presence of $AlCl_3$ leads to the formation of a polymer with a molecular weight of 8000–9000.[37] The reaction of chlorobenzene with 1,2-dichloroethane gave poly(chlorophenylene-ethyl) (PCPE).[38] The greatest increase in the molecular weight to 4250 is observed in approaching an equimolecular ratio of the reactants and the formation of three-dimensional products at the equimolecular ratio. A 1% excess of chlorobenzene gives a mixture of a linear and a cross-linked product.

The study of the structure of PCPE by the method of destructive oxidation and an analysis of the infrared spectrum[39] suggests that the benzene ring of the chain is predominantly 1,2,4-substituted:

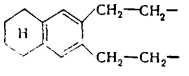
The formation of poly(fluorophenylene-ethyl) (PFPE)[40] proceeds similarly with the only difference that with a 5 mole % excess of fluorobenzene an exclusively three-dimensional infusible and insoluble polymer is formed. The molecular weight of the polymer reaches a maximum at a catalyst concentration of 6 mole % on the fluorobenzene and at a fluorobenzene : dichloroethane ratio of 1 : 1.19.

The PFPE unit cell has the same structure as PCPE.

Korshak and Kolesnikov[41] showed that increasing the substituents in the benzene ring still further hinders the formation of a cross-linked product. Thus in the polycondensation of 1,2-dichloroethane with *o*-dichlorobenzene in the presence of $AlCl_3$ (up to 6 mole %) insoluble products are not formed even when there is a considerable excess of dichloroethane. Poly(dichlorophenylene-ethyl) (PDCPE) of the highest molecular weight (~ 3920) is formed at the equimolecular ratio of the reactants. The polymer is a solid of low melting point (50 °C). Simultaneously with the polycondensation there is a redistribution of the halogen, leading to a decrease in the chlorine content of the reaction product. PDCPE consists mainly of monomeric units of the structure:



Insoluble products are also not formed during polycondensation of tetralin with 1,2-dichloroethane even with an excess of the latter[42]. Tetralin, like *o*-dichlorobenzene, can be regarded as a dialkyl derivative of benzene in which the substituents are in the *ortho*-position. The experimental results showed that the molecular weight of poly-tetralylene-ethyl (PTTE), which is a solid, rises to a maximum (6400) at the dichloroethane : tetraline ratio of 1 : 1.10. It is thought that in PTTE the tetralin residues are linked by $-CH_2-CH_2-$ groups, which occupy both β-positions in the aromatic ring of tetralin:

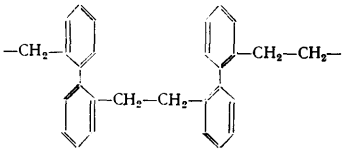


It is interesting to note that the molecular weight of PTTE remains constant in the range of catalyst concentrations 3–12 mole % of the tetralin.

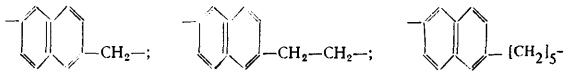
Poly(diphenylene-ethyl) (PDE) isobtained as a result of the reaction of biphenyl with dichloroethane[43,44].

A polymer with a molecular weight of 5120 is formed at a dichloroethane : biphenyl molar ratio of 1 and a catalyst concentration of 10 mole % of the biphenyl. At dichloroethane : biphenyl ratios > 1 and a catalyst concentration of

23 mole %, insoluble PDE is formed. Conclusions about the structure of the polymer are drawn on the basis of an analysis of the infrared spectra of PDE:



Polymers containing naphthalene rings in chains are also obtained under the same conditions:



Kolesnikov and coworkers[45] made copolymers in the dichloroethane–benzene–fluorobenzene and dichloroethane–chlorine–benzene–fluorobenzene systems. The ratio of the units $(-C_6H_4CH_2CH_2-):(-C_6H_3HalCH_2CH_2-)$ in the polymer obtained by common polycondensation of dichloroethane with benzene and fluorobenzene is less than in the copolymer obtained by the polycondensation of the dichloroethane–chlorobenzene–fluorobenzene system. This shows that the relative activity of fluorobenzene is less than the relative activity of chlorobenzene. The highest molecular weight of a copolymer of dichloroethane with benzene and fluorobenzene is 2610 and that of the copolymer of dichloroethane, benzene, and fluorobenzene is 2120. The rate of the polycondensation process in the dichloroethane–fluorobenzene–chlorobenzene system is appreciably greater than that in the dichloroethane–benzene–chlorobenzene system. The possibility of the synthesis of a ternary copolymer of dichloroethane with cumene and bibenzyl by polycondensation in the presence of $AlCl_3$ was shown by Kolesnikov and coworkers[46]. As expected, the molecular weight increases with the bibenzyl : cumene ratio.

It was found by turbidimetric titration that the polycondensation product is a copolymer and not a mixture of homopolymers. The infrared spectrum of the product of the common polycondensation of cumene and bibenzyl with dichloroethane is similar to that of PCE.

Hence from what has been stated above the following conclusions can be drawn:

1. In the polycondensation of either benzyl chloride or of aromatic hydrocarbons with halogenoalkanes in the presence of a Friedel–Crafts catalyst low-molecular-weight polymers are formed.

2. The highest molecular weight of polyarylenealkyls is reached on approaching the equimolecular dihalogenoalkyl : aromatic compound ratio, which agrees with the polycondensation theory.

3. Since the Friedel–Crafts catalyst is not stereospecific, the polyarylenealkyls obtained are branched and are a mixture of polymeric chains in which the benzene rings have different substitution.

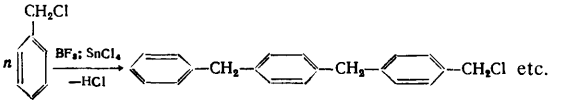
3. CHEMICAL REACTIONS OF POLY(ARYLENEALKYLS)

As a result of polycondensation polymers of low molecular weight and poor mechanical properties are formed. The polymers are either viscous liquids or solids difficult to reprocess. The polyarylenealkyls do not contain functional groups with the aid of which they could be subjected to chemical changes, whereas polyarylenealkyls such as PPM are thermally stable products and withstand heating in the absence of air to 380–400°C without undergoing significant changes[12].

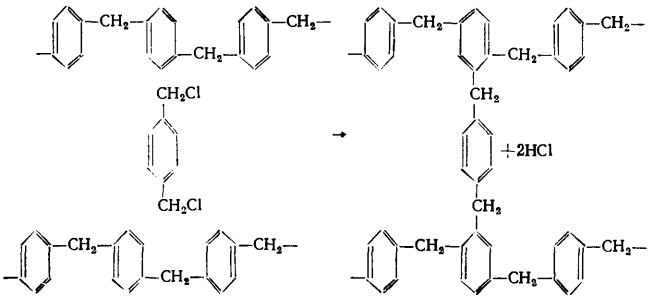
Polyarylenealkyls also exhibit increased resistance to radiation[47]. Thus the viscosity of lubricating oils of polymers obtained by the polycondensation of aromatic hydrocarbons $C_6H_{6-n}R_n$ (where R = alkyl C_1-C_5, $n = 1-5$) with alkylene dihalides C_1-C_4 (for example, $ClCH_2Cl$ or CH_2BrCH_2Br) in the presence of $AlCl_3$, $ZnCl_2$, or BF_3 after the action of a 2×10^9 rad dose of β-radiation increased by 150%, whereas ordinary mineral oil of the same viscosity showed an increase in viscosity of 500%.

A search is now being made for means of the chemical modification of polyarylenealkyls to obtain commercially usable products based on them.

Phillips[48] effected the cross-linking of polybenzyl with a Friedel–Crafts reaction. First the polycondensation of benzyl chloride in the presence of mild catalytic agents (BF_3 or $SnCl_4$) was brought about and fusible and soluble polybenzyl was obtained:



Cross-linking took place when this polymer reacted with *p*-dichloroxylene in the presence of a mild catalyst:



The products were named Friedel–Crafts polymers.

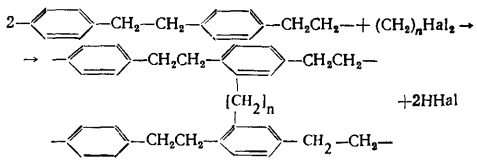
This method of cross-linking, proposed for strengthening polybenzyl and terphenyl, can also be used for other polymers which contain aromatic or heterocyclic rings.

Glass fibre, organic fibre, and siliconorganic fibres are readily impregnated by Friedel–Crafts polymers. The strengthening of these plastics is longer-lasting than, for example, with phenolic resins but the stability of these polymers to the action of chemical reagents is sufficiently high. Thus they do not have the drawback characteristic of phenolic resins—instability towards alkalis, since they do not contain hydroxyl groups arranged in series with methylene bridges. They are also stable to the action of radiation.

A little Friedel–Crafts catalyst is added to the polymer obtained from $\alpha\alpha'$-dichloro-*p*-xylene before moulding and during the moulding at 120–140°C a thermoreactive material which exhibits high thermal stability is formed[16].

The polymers which contain benzene rings in a chain separated by methylene groups, can be cross-linked also by dihalogenoalkanes in the presence of Friedel–Crafts catalysts. PPE with a molecular weight of 5900 was cross-linked with dihalogenoalkanes : methylene dibromide, 1,2-dibromoethane, 1-bromo-3-chloropropane, 1,4-dibromobutane, and 1,6-dibromohexane[49]. The dihalogenoalkanes can be arranged in the following series according

to the rate of formation of the trimer: 1,4-dibromobutane > 1-bromo-3-chloropropane > 1,6-dibromohexane > methylene dibromide > 1,2-dibromoethane. The cross-linking takes place in two stages. Initially a strongly branched polymer is formed, soluble up to a certain stage, and subsequently the branched molecules are converted into cross-linked ones and lose the ability to dissolve:



The higher the molecular weight of the initial polymer the less the need for a cross-linking agent. Initially the longer chains of the polymer molecules are cross-linked, which is shown by the drop in the molecular weight of the soluble part of the polymer.

Another method found for strengthening poly(arylenealkyls) is with the aid of sulphur[50]. In the reaction of poly(arylenealkyls) with sulphur at 200–250°C the sulphur is added to the polymer, hydrogen sulphide is eliminated, the viscosity increases, and double bonds are formed[51]. Most of the polymer becomes insoluble. The vulcanising of PPE, PTE, PEPE, PCE, PCPE, and PDE has been studied[52].

The controlling stage of the vulcanising of poly(arylenealkyls) is the breakdown of inactive sulphur particles into active ones.

The activation energy of the –S–S– bonds in the polysulphide chain of sulphur is 33.4 kcal mole^{-1} and the energy of the fission of $^{\bullet}S_2^{\bullet}$ to the monoradical is 63 kcal mole^{-1}.[53] The activation energy of the vulcanising of polyarylenealkyls lies in the range 37–41 kcal mole^{-1} [52] but the activation energy of the thermal destruction of poly(arylenealkyls)—for example, poly-(*p*-phenyleneethylene) has a value of not less than 58 kcal mole^{-1}.[54] On comparing the values given it can be assumed that the initial active species under the conditions of the reaction is $^{\bullet}S_2^{\bullet}$.

Owing to the formation of new chemical bonds between the poly(arylenealkyl) molecules structuring of the polymer takes place[55]. An analysis of the infrared spectra of vulcanised PPE, PTE, PEPE, and PCE prepolymers in the range of planar deformation vibrations (1225–960 cm^{-1}), of out-of-plane deformation vibrations (below 900 cm^{-1}), and also in the range of the overtones and constituent frequencies (2600–1650 cm^{-1}) shows the absence of changes in the substitution of the benzene ring of the chain[56].

On the basis of the above it has been suggested that in the thermal vulcanising of poly(arylenealkyls) cross-linking takes place by the loss of a hydrogen atom from the methylene groups of the bridge and the alkyl substituents. In the vulcanising of poly(arylenealkyls) owing to the dehydrogenating action of sulphur double bonds are formed conjugated with the benzene ring[57]. The electronic spectra of the vulcanised polymers show that sulphide bridges have the $-S_x-$ structure, where $x \geqslant 2$, and not of type =S= as suggested[58].

The vulcanising proceeds by a radical mechanism[57]:

$$S_8 \xrightarrow{>200^\circ} {}^{\bullet}S_y^{\bullet} + {}^{\bullet}S_z^{\bullet},$$

$$PH + {}^{\bullet}S_z^{\bullet} \rightarrow P^{\bullet} + HS_z^{\bullet},$$

$$HS_z^{\bullet} + HS_z^{\bullet} \rightarrow H_2S + {}^{\bullet}S_z^{\bullet},$$

$$P^{\bullet} + HS_z^{\bullet} \rightarrow PSSH,$$

$$PS_z^{\bullet} + PH \rightarrow PSSH + P^{\bullet},$$

$$P^{\bullet} + {}^{\bullet}S_z^{\bullet} \rightarrow PS_z^{\bullet},$$

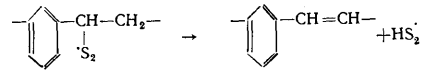
$$PSSH + PH \rightarrow PSP + H_2S,$$

$$PS_z^{\bullet} + PS_z^{\bullet} \rightarrow PS_4P,$$

$$P^{\bullet} + P^{\bullet} \rightarrow P-P,$$

where PH = poly(arenylalkyl).

The formation of double bonds evidently proceeds thus:



The appearance of absorption bands in the 970–960 cm^{-1} range in the infrared spectra shows the presence of double bonds. After bromination of the poly(alkylenealkyl) this absorption band is not present in the infrared spectrum.

The radical nature of the interaction of sulphur with poly(arylenealkyls) is confirmed by the fact that the products of the thermal vulcanising, subjected to EPR analysis, show a narrow absorption line (~ 10.0e) without signs of hyperfine structure with a *g*-factor of the free electron[59]. The concentration of the paramagnetic species for the vulcanised prepolymers of PPE, PTE, PEPE, PCPE, and PCE falls within the range $(0.12-0.5) \times 10^{20}$ g^{-1}. The EPR signal is unchanged after the products have been stored for several months, but in dissolution in toluene it disappears and does not reappear after removal of the solvent. The intensity of the EPR signal is also reduced on irradiation of the specimens with X-rays. The existence of an EPR signal in vulcanised poly(arylenealkyls) is due to the formation of radicals of the type $R_{arom}-CH_2-\dot{C}H-R_{arom}$ and $R_{arom}-\dot{C}H_2$ produced according to the scheme given above.

Poly(arylenealkyls) react with sulphur at different rates[60]. They are arranged according to hydrogen sulphide liberation in the order PDE > PCE > PTE > PEPE > PCPE and according to the rate of formation of a cross-linked polymer in the order PEPE > PPE > PTE > PCE > PCPE > PDE. Such a difference in the rate of liberation of hydrogen sulphide and the formation of a cross-linked polymer depend on the structure of the initial poly(arylenealkyl). The activating action of the benzene ring on the methylene groups of the bridge ensures that PDE has a high rate of reaction with sulphur. The presence in the benzene ring of the electronegative substituent chlorine reduces the lability of the hydrogen atoms of the methylene groups in the *o*-position to chlorine. Therefore the vulcanisation of PCPE takes place under more severe conditions.

The high rate of gelatinisation for PEPE ensures the presence of a methylene group at the substituent $-CH_2CH_2-$ which should react just like the bridge methylene groups.

The vulcanised poly(arylenealkyls), prepolymers, are solids soluble in aromatic hydrocarbons and halogenoalkanes. Subsequent heating of the prepolymers at temperatures not less than 200°C leads to the formation of cross-linked products.

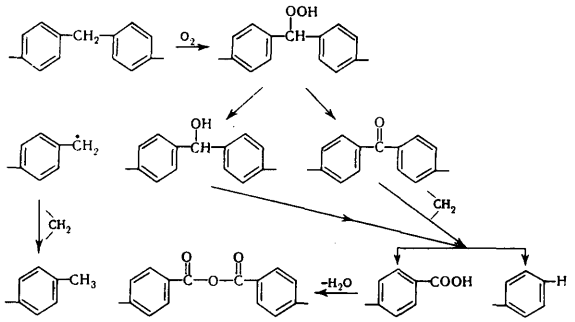
Vulcanised poly(arylenealkyls) can be used as thermoreactive paint constituents[57]. Coatings based on such polymers exhibit good dielectric properties, high chemical stability, and good adhesion to metals.

The prepolymers can be used also as binding agents for plastics, for which purpose glass fibre is impregnated with the prepolymer, pressed and hardened at 220°C or above. The specimens exhibit good thermal stability and chemical resistance and have physico-mechanical indices higher than for plastics based on phenol–formaldehyde resins.

Vulcanised poly(arylenealkyls) have a stabilising effect, like low-molecular-weight antioxidants of the R–S–S–R type[61].

To reduce the temperature of structuring of the poly-(alkylenealkyls) with sulphur, vulcanising under the action of aluminium chloride was studied[62]. The reaction takes place at 80–90°C. Unlike thermal vulcanising, the formation of new chemical bonds in the polymer evidently occurs at the benzene ring. The structured polymer formed in the catalytic vulcanising is a powdery product but the cross-linked polymer after thermal vulcanising is a tough material, ground into powder with difficulty.

Conley[63] studied the thermal oxidation of polybenzyl in air and in oxygen in the temperature range 140–220°C and proposed a mechanism for the oxidation:

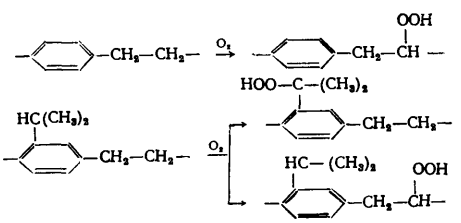


The oxidation, like the vulcanising, takes place at the methylene bridges with the formation of ketonic and carbonyl groups. On the basis of the results on the rate of formation of carbonyl compounds, the initial activation energy of the oxidation was found to be 14.5 ± 3.5 kcal. A vapour-phase chromatographic analysis of the volatile products shows that the main products of the oxidation are benzoic acid and benzophenone; small amounts of toluene, water, and CO_2 are formed. The secondary reactions of the decomposition, which lead to breaking of the chain are considered to be further oxidation of the benzhydrilic and benzophenone bonds.

The thermal oxidation of several polymers containing a chain of benzene rings separated by two methylene groups has been studied. It was found that unlike polybenzyl and poly-(*p*,*p*'-diphenylenemethylene) appreciable decomposition of most of the polymers with a $-CH_2-CH_2-$ bond in oxygen is observed in the temperature range 340–410°C.[1] These polymers can be arranged in the following order of thermal oxidation resistance: poly-(2,6-naphthylene-ethylene) > poly-(*p*-phenylene-ethylene) > poly-(9,10-anthrylene-ethylene).

The mechanism given for the oxidation of polybenzyl is evidently correct for the thermal decomposition of these polymers.

Kolesnikov and Chuchin[64,65] oxidised several poly-(arylenealkyls) both in the melt and in solution. The oxidation as far as hydroperoxides proceeds according to the scheme:



An analysis of the infrared spectra showed that the oxidation of poly(arylenealkyls) in the melt goes further than in solution. The spectrum of poly(cumylene-ethyl) oxidised in the melt gave absorption bands characteristic for aromatic acids (1270 cm^{-1}), aldehydes (1715 cm^{-1}), and other oxygen-containing groups. In the oxidation of poly-(arylenealkyls) in cumene the decomposition products of the hydroperoxides do not contain tertiary alcoholic groups. In thermal decomposition poly(phenylene-ethyl) hydroperoxide gives the same products as poly(cumulene-ethyl) hydroperoxide, obtained by oxidation in cumene. Judging by the infrared spectra, the hydroperoxides have the same structure, that is, the oxidation takes place at the methylene groups just as in the thermal oxidation of polybenzyl[63] and the thermal destruction of poly-(*p*-xylylene).[66] The decomposition follows the reaction:

The oxidation of PPE in cumene and tetralin solutions was studied and it was found that the oxidation in cumene is much faster than that in tetralin[67]. Analysis of the infrared spectra showed that oxidation of PPE by atmospheric oxygen at elevated temperatures proceeds like oxidation by oxygen at 80°C, mainly to the hydroperoxide.

Poly(cumylene-ethyl) (M = 1100) oxidised by oxygen in the presence of benzoyl peroxide gave a polymeric hydroperoxide containing 2.4% hydroperoxide groups.

The decomposition of the hydroperoxides is a first-order reaction with an activation energy of 3.5 kcal $mole^{-1}$.

The product of the common polycondensation of cumene and dibenzyl was oxidised[69] and it was found that with increase in the fraction of cumene in this reaction mixture the concentration of peroxide groups in the oxidised poly-(arylene-ethyl) increases, reaching a maximal value in PCE. The reverse picture was observed in the oxidation of poly(arylenealkyls) in cumene solution, when the maximal concentration of hydroperoxide groups was observed in the oxidation of PPE. This difference has been explained[69] by the presence of an alkyl substituent in the benzene ring, which weakens the induction effect, in connection with which there is a decrease in the mobility of the hydrogen atom of the methylene group. Therefore in the common presence in the benzene ring of methylene groups and of groups with α-carbon tertiary atoms a decrease in the rate of autoxidation of dialkylbenzenes and a decrease in the maximal concentration of hydroperoxide was observed. This evidently also explains the increase in the concentration of hydroperoxide groups in poly-(arylene-ethyl) with decrease in the proportion of isopropyl groups in the polymeric chain.

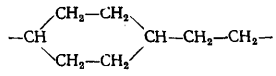
The polymeric hydroperoxides synthesised were used for the production of ion-exchange resins.

Granular sulphonic cation-exchange resins were obtained on the basis of spatially cross-linked copolymers, by the adding on of styrene to polymeric hydroperoxides[70]. For the chain carrier and polymeric initiator respectively the polyarylenealkyl (a product of the common polymerisation of cumene and bibenzyl with dichloroethane) and its hydroperoxide were used; divinylbenzene was the cross-linking agent.

The capacity of the ion-exchange resins, determined by the degree of vulcanising of the specimens, increases with increase in the proportion of poly(arylenealkyl) in the original mixture and of hydroperoxide groups in the polymeric hydroperoxide.

The sulphonic cation-exchange resins obtained are capable of sorbing large organic ions[71].

Poly(arylenealkyls) were subjected to hydrogenation[72], as a result of which poly(cycloalkylenealkyls) of the general formula

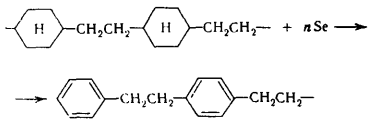


were obtained. The hydrogenation was carried out in the presence of a solvent and in a melt on Raney nickel, according to the reaction:

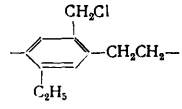
$$[-CH_2-CH_2C_6H_4-]_n + 3n\,H_2 \xrightarrow{Ni} [CH_2-CH_2-C_6H_{10}-]_n$$

The hydrogenation products of the poly(arylenealkyls) retain their initial appearance but their colour is appreciably paler than that of the original polymers. The molecular weight of the hydrogenated poly(arylenealkyls) is almost the same as that of the original polymer.

Dehydrogenation of the hydrogenated PPE with selenium led to the initial poly(phenylethyl):



Polyarylenealkyls are readily chloromethylated. The chloromethylation of PEPE[71,73] gave the polymer



containing up to 19% chlorine.

Water-soluble polyelectrolytes were obtained by the same method. To do this, first the PPE was chloromethylated, then the product was aminated, or vulcanised, or phosphorylated; this was followed by hydrolysis and oxidation[74].

Yukel'son and coworkers[75] nitrated poly(arylenealkyls) and obtained nitro-products with up to 6% free nitrogen. The use of nitropolymers as plasticizers and antioxidants in rubber mixtures based on SKS-30 ARKM rubbers increases the strength properties of the vulcanised products.

Hence the following conclusions can now be drawn:

1. For the improvement of the physicomechanical properties of poly(arylenealkyls) obtainable by polycondensation, several methods for strengthening them have been found.

2. The low melting point and good solubility of the polymers isolated at intermediate stages of the process enables these polymers to be treated rather simply.

3. The introduction of functional groups in poly(arylenealkyls) opens paths for their use for practical purposes.

Biologically Active Compounds of Silicon

M.G.Voronkov and E.Lukevics

The literature data and the studies by the authors of the review on biologically active organosilicon compounds are reviewed. The role of silicon in living organisms, the toxicity and biological activity of its organic derivatives, and the therapeutic applications of its compounds are discussed.
The bibliography includes 358 references.

CONTENTS

1. Introduction 975

3. Therapeutic applications of silicon compounds 976
4. Toxicity of organosilicon compounds 977
5. Biological activity of organosilicon compounds 977

1. INTRODUCTION

The unusually wide practical applications of inorganic and organic compounds of silicon resulting in daily and frequently direct contact with the human organism, the increasing use of organosilicon polymers in medicine, cosmetics, and the food industry, and also the continued contact of all living terrestial organisms with natural silicon compounds led to the widely held view that this element is biologically inert. Silicon does not belong either to macro- or oligo-biogenic elements [1] and it is usually believed that it does not play an appreciable role in the vital processes of higher animals and man. However, in reality this is not the case.

Silicon compounds play a significant role in vital processes and many of them (particularly organic derivatives) have specific effects on living organisms.

The present paper, which is based on the plenary report by one of the authors (L. G. Voronkov) at the Second International Symposium on the Chemistry of Organic Silicon Compounds in Bordeaux (July, 1968), is a brief review of studies devoted to the elucidation of the role of silicon in living organisms and in particular the biological activity of organosilicon compounds. Its aim is to draw the attention of specialists in the field of organosilicon chemistry, biochemists, biologists, pharmacologists, and physicians to a new and extremely interesting and important branch of the chemistry of silicon.

2. THE ROLE OF SILICON IN LIVING ORGANISMS

The scientific data accumulated so far leave no room for doubt that silicon is one of the principal elements and not only in non-living nature. About 10 000 million tons of silicon are involved in the life cycle of living matter on our planet [2]! This element is included (albeit in slight amounts) in the composition of all plant and animal organisms and their existence without it is impossible [2-23].

Silicon compounds play a particularly important role for many living entities at a lower stage of evolutionary development (silicate bacteria, the simplest algae, spore plants, etc.) in whose organisms it is present in very large amounts [23-54]. Silicon is also important for many higher plants, which have come to be called "siliceous" because of their high silicon content. Silicon compounds play extremely important functions also in the organisms of higher animals and man, despite the fact that in the majority of their organs the content of this element is relatively small. In the tissues of human and animal organisms silicon compounds are present in three principal forms [14,55-76].

1. Water-soluble inorganic compounds capable of passing through cell walls which can be readily eliminated from the organism. These include orthosilic acid and ortho- and oligo-silicate ions.

2. Organosilicon compounds and complexes soluble in organic solvents and containing Si–O–C groups. These include ortho- and oligo-silicate ethers derived from carbohydrates, proteins, cholesterol and other steroids, choline, lipids, and phospholipids. Compounds containing Si–N–C bonds may also be present. Organosilicon compounds containing Si–C bonds have not been detected in higher animal and human organisms but they have been found in the bacteria *Proteus Mirabilis* [29,31].

3. Insoluble silico-polymers. These include polysilicic acid, amorphous silica, and insoluble silicates and quartz. In the organism the surface of these polymers is always covered by a chemisorbed layer of organic compounds containing hydroxy- or amino-groups.

It has now been firmly established that silicon compounds are essential for epithelial and connective tissues to which they impart, in particular, strength, elasticity, and impermeability. It is also suggested that silicon compounds play an important role in all metabolic processes in living matter, in particular in the metabolism of lipids. They probably participate in the dynamics of living plasma, their role consisting in altering the surface potential of cells. It is suggested that silicon compounds also participate in oxidation processes and enter into the composition of diastases as a coenzyme.

Thus the presence of silicon compounds in organisms is not only normal but necessary. Furthermore, living tissues exhibit a definite affinity for silic acid ("silicotropism"). The metabolism of silicon compounds in the cells of the organisms is evidently determined by the activity of special enzymes.

Numerous pathological processes, including cancer, atherosclerosis, tuberculosis, and diabetes, goitre, certain types of dermatitis, stone formation in the urethra, etc., are associated with the breakdown of the metabolism of silicon compounds. The latter play an important protective role in the organism, improving its self-protective functions and the capacity for detoxication. Partly this is due to the fact that silicon compounds facilitate the removal with urine of metabolites and extraneous and toxic substances, serve as a barrier preventing the propagation of degenerative processes [13], and intensify the biosynthesis of collagen [77].

3. THERAPEUTIC APPLICATIONS OF SILICON COMPOUNDS

Bearing in mind the important role of silicon in the normal activity of the organism, one may hope that the regulation of its metabolism by the introduction into or the removal from the organism of definite compounds of this element will lead to considerable advances in the treatment of many diseases and in the fight against old age. The first attempts on these lines were made long ago although they were not always entirely successful. Their inadequate effectiveness can be explained by the extremely narrow range and lack of variety of the silicon compounds used in the attempt at therapy (silic acid, silicates of sodium, potassium, cobalt, magnesium, iron, and copper, kaolin, and talc) [78-109]. All these inorganic compounds are insoluble or give rise to the insoluble silic acid on contact with gastric juices and therefore they are assimilated by the organism with difficulty.

At the same time mineral waters rich in soluble compounds (containing 20–80 mg litre^{-1} of silica) are distinguished by high physiological activity and have been used for a long time in treatment at spas [110]. They exhibit sympathomimetic activity, have a favourable effect on cardiac muscle, sharply intensify cardiac activity and heart rhythm, inhibit the motor function of the small intestine, intensify the capacity for work of skeletal muscle, greatly intensify the activity of the ciliary epithelium of the alimentary canal, etc. Mineral waters rich in silicon content not only improve the positive silicon balance in the organism but also significantly alter the functional state of the liver, the stomach, and the kidneys. They intensify the activity of the oxidative enzymes in the liver, increase the content of adrenaline in the adrenal glands and the content of noradrenaline and the oxidation products of aminocatechols in cardiac muscle, and have a favourable effect on the autonomic nervous system. Silicate mineral waters are widely used in the therapy of uric acid diathesis, inflammatory diseases of the urinogenital system, etc.

In the first half of the present century tuberculosis and certain other diseases began to be treated by various orthosilicate esters. These include, in particular, the preparation "Silistren" produced by the Bayer company, which consists of the tetraglycol ester of orthosilic acid [111-117]. Orthosilicate esters of hydroxycarboxylic acids and their esters and salts have also been used [118-123]. Other organic derivatives of orthosilicic [84,124-129] and even fluorosilic acid [130,131] have been proposed for use in therapy. Inorganic silicon compounds were not forgotten either. Quite recently the resistance of guinea pigs to tubercular infection was found to increase after peroral introduction of sodium silicate [132-134].

Using these and similar preparations, specialists in therapy assumed that the therapeutic effect of silicon compounds in tuberculosis consists in the stabilisation of lung tissue and in the formation of a protective coating in the affected region [78,85,89].

One of the rational approaches to the problem of "silicon therapy" consists in the use for therapeutic purposes of "plant silicon" present in plants, for example in the horse-tail [13,94,135-141]. In these plants silicon is present to a large extent as organic compounds [142] already incorporated in cellular protoplasm. Silicon compounds of precisely this type are in fact assimilated by man together with food, but, according to Monceaux [13], the human organism cannot assimilate inorganic silicon compounds in the way that autotrophic plants can.

Complexes of potassium methylsilicate [Me Si(OH)(OK)$_2$ (Ed. of Translation)] with salicylic, citric, ascorbic, heparinic, penicillic, or deoxyribonucleic acids have been proposed for the treatment of acute and chronic diseases of the joints, supercutaneous staphylococcal diseases, hypertension, sclerosis, various types of arteritis of the lower limbs, diseases of the capillaries, atrophic phenomena, the breakdown of cellular mitosis, and a number of other affections [143]. The use of silicon compounds in the treatment of atherosclerosis proved to be particularly successful. In this disease the silicon content in the tissues of the arteries is known to decrease sharply [144-150]. The introduction of sodium silicate [148], phenylpolysiloxane [151], and the complexes of potassium or sodium methylsiliconate with salicylic [150] or citric acids [143,152] not only prevents the occurrence of experimental atherosclerosis but also has a therapeutic effect.

In view of the particular ease of penetration of the complexes of potassium methylsilicate with organic acids into the organism via the skin [153], their anti-inflammatory and antisclerotic activity, and also the stimulating effect of silicon on the synthesis of connective and elastic tissues [149], an effective method has been developed for the treatment of coronary affections based on the use of controlled ionophoresis [154,155]. Ionotherapy using complexes of potassium methylsilicate with citric or heparinic acids is used at present in the treatment of chronic heart disease (including treatment after 1–2 myocardial infarctions), arterial hypertension, and obliterative arteriopathy of the lower limbs. A seven year clinical experiment with 500 patients resulted in 80% of complete cures [154,155].

Complexes of potassium methylsilicate with organic acids have also been used in the treatment of cancer: cancer of the bone (osteosarcoma), the lungs, and the prostate gland. According to Janet [156], in many cases, in particular in the treatment of rapidly evolving tumours, satisfactory results have been achieved.

The complex of potassium methylsilicate with penicillin G proved to be effective in the treatment of myxomatosis, a virus disease which is not affected either by potassium methylsilicate or penicillin G used separately [157]. Thus the use of the complex with potassium methylsiliconate extended the spectrum of activity of penicillin. This could also prove true of other antibiotics.

A special application of organosilicon compounds in medicine [158-168] consists in the increasing use of polyorganosiloxane liquids, resins, and rubbers in the therapy of the diseases of the stomach, eyes, and the respiratory tract, in surgery, haemotology, dermatology, dentistry, and vetinary practice. However, in this case their application is based mainly on the specific physical properties of the organosilicon polymers (hydrophobic, antiadhesive, and antifoaming effects, etc.), their high chemical stability, and high physiological inertness.

4. TOXICITY OF ORGANOSILICON COMPOUNDS

The vigorous development of the organic chemistry of silicon after the Second World War led to the creation of a wide range of organosilicon polymers and materials based on them. At present the number of known individual organic silicon compounds exceeds 15 000. The outstanding practical importance acquired by organosilicon polymeric compounds made it necessary, of course, to investigate their physiological activity and in the first place toxicity. However, the range of compounds investigated in this respect remained very narrow until recently, being largely restricted to products of industrial synthesis (alkoxysilanes [189-224], chlorosilanes, [12,23,192,195-199,202,204,206,207,212,216,221,222,225-253] and polyorganosiloxanes [174-177,200,205,254-286]). The toxicity of other classes of organosilicon compounds, in particular nitrogen-containing compounds, has been investigated very little [191,194,198,203,209,213-215,217,223,224,287-304].

No organosilicon compound with a particularly distinct or specific physiological activity closely related to the presence of a silicon atom in the molecule had been found until the beginning of systematic studies by the present authors (1962), although fairly toxic (lethal dose LD_{50} = 1–50 mg kg^{-1}) compounds with $Si-OCH_2CH_2$, [305] Si–F, [306-310] and Si–NC [254] bonds have been synthesised. However, the effect of such compounds with silicon-containing functional groups on the organism is largely due to the toxicity of their hydrolysis products ($HOCH_2CH_2F$, HF, HCN).

Table 1. Toxicity of $(CH_3)_{4-n}SiX_n$.

X	References	Test animals	Method of administration	Characteristics of toxicity	h = 1	2	3	4
Cl	222	white mice	by inhalation	LC^*_{100}	0.1	0.4	0.4	15
OC_2H_5	199	rats	oral	LD_{100}	2	10	10	5
$OCH_2CH_2NH_2$	295	white mice	intraperitoneal	LD_{50}	0.32	0.57	0.40	—
$OCH_2CH_2N(C_2H_5)_2$	295	white mice	intraperitoneal	LD_{50}	0.50	0.72	0.60	0.23

*LC = absolute lethal concentration (mg litre^{-1}); LD = lethal dose (g kg^{-1}).

Nevertheless it can be asserted that the specific effect of the silicon atoms in the molecule of more or less readily hydrolysable compounds with silicon-containing functional groups in the series $R_{4-n}SiX_n$ does affect their toxicity. Firstly, the toxicity of such substances often proves to be appreciably higher or lower than that of their hydrolysis products used separately. This is clearly seen, in particular, for tetramethoxysilane [193-194], which is more poisonous and dangerous than methyl alcohol and colloidal silicic acid. Secondly it would appear that the toxicity of compounds of this type should increase with the number n of functional groups at the silicon atom, since this involves an increase in the amount of toxic agent formed in the organism on hydrolysis:

$$R_{4-n}SiX_n + n\,H_2O \rightarrow R_{4-n}Si(OH)_n + n\,HX \quad (n = 1-4).$$

However, silicon compounds with $n = 1$, i.e. the least hydrolysable compounds forming on hydrolysis a minimal amount of HX, proved unexpectedly to be the most toxic (Table 1).

In this connection it should be noted that in the series of organotin compounds $R_{4-n}SnX_n$ the monofunctional compounds ($n = 1$) are also the most toxic [311].

5. BIOLOGICAL ACTIVITY OF ORGANOSILICON COMPOUNDS

The aim of the first attempts to prepare physiologically active organic compounds of silicon was the synthesis of silicon analogues or organosilicon derivatives of organic substances known to have a pronounced and definite effect on the organism. In the course of studies of this kind the biological activity of a fairly large range of organosilicon compounds, described in Table 2, was investigated.

Table 2. Compilation of studies on biologically active organosilicon compounds.

Type of Effect	Compounds investigated
1	2
Effect on respiratory activity	*N*-trimethylsilylpyrrolidone [312], triethylisocyanatosilane [313], silatranes [22, 287-293], 2-aminoethoxysilanes [293, 295], 3-aminopropylsilanes [293,294,298], organosilicon arylalkylamines [301, 314], barbiturates [302, 315], carbamates [23, 300, 303, 304], aromatic acid amides [316]
Anabolic, androgenic, and oestrogenic activity	Organosilicon derivatives of steroids [317-319]
Allergic reactions	Dis(hydroxyphenyl)dialkylsilanes [320]
Inhibition of dihydronicotinamide adenine dinucleotide ($NADH_2$)-oxidase	Organosilicon carbamates [23]
Cholinergic and anticholinergic activity	2-(trimethylsilyl)ethyl acetate [321], 2-(dialkylamino)ethyl esters of trialkylsilylphenyl-β-hydroxypropionic acids [322], organosilicon carbamates [323], organosilicon derivates of choline [299]
Insecticidal activity	Organoisothiocyanatosilanes [324], polyorganosilthianes [325], organosilicon derivatives and analogues of pyrrolidone [312], sulphonamides [326], carbamates [327], salts of dithiocarbamic acids [328], unsaturated diols [329], and DDT [330], trialkylsilylalkyl phosphonic acid esters [331], organosilicon derivatives acetylene [332], trialkyl(trialkylsiloxy)stannanes [333]
Insect repellent activity	Methyl (*NN*-dialkylaminomethyl)dialkoxysilanes [334, 335], *N*-(trialkylsilylmethyl)-ethylamides of carboxylic acids [336]
Fungistatic activity	Organosilicon amines [293, 314, 337], organoisothiocyanatosilanes [324], polyorganosilthianes [325], organosilicon derivatives of mercury [338, 339], copper salts of dithiocarbamic acids [328], sulphonamides [326], and isothiocynates [340]
Bacteriostatic activity	3-Aminopropylsilanes and other organosilicon amines [293, 314, 337, 341], bis(hydroxyphenyl)-dialkylsilanes [342], trimethylsilylmethanol [343], mercury-containing polyorganosiloxanes [338], organosilicon derivatives of penicillin [344, 345], alkyl esters of aziridinecarboxylic acids [346]; and 2-(dialkylamino)ethyl esters of aromatic acids [347], organoethynylsilanes [348]
Regulation of plant growth	Chloroalkylsilanes [349, 350], ethynylsilanes [351]

Of the pharmocologically investigated [299] organosilicon derivatives of physiologically active organic compounds synthesised in our laboratory [352], mention should be made of the previously unknown *C*- and *O*-trialkylsilyl derivatives

of choline—$[R_3SiCH_2NR'R''CH_2CH_2X]Y$ and correspondingly $[(CH_3)_3NCH_2CH_2OSiR_3]Y$ (Table 3).

All compounds of this type exhibit *N*-cholinolytic activity. In this respect the most active compounds exhibit also ganglion-blocking activity on the parasympathetic ganglia of the heart. The hypotensive effect of organosilicon derivatives of choline is particularly pronounced for *C*-silyl substituted derivatives with R = R′ = R″ = CH_3 and Y = I in which the substituent X is the $OCOCH_3$ group (70–90 mmHg at a dose of 1 mg kg^{-1}) or an iodine atom (50–60 mmHg). Apart from the depressor response, these compounds cause intensified respiration in cats.

Table 3. Biological activity of organosilicon derivatives of choline.

Compound	Cholinolytic activity (straight muscle of frog stomach) EC_{50}^{*}	Ganglion-blocking activity (in cats) ED_{30} mg kg^{-1}	Hypotensive activity (in cats) ED_{30} mg kg^{-1}	Median lethal dose (for white mice with intraperitoneal administration) LD_{50}, mg kg^{-1}
$[(CH_3)_3SiCH_2N(CH_3)_2CH_2CH_2OH]I$	$8.0\cdot10^{-4}$	0.56	2.5	266
$[(C_2H_5)_3SiCH_2N(CH_3)_2CH_2CH_2OH]I$	$4.9\cdot10^{-4}$	0.85	3.6	53
$[(CH_3)_3SiCH_2N(CH_3)_2CH_2CH_2Cl]I$	$9.1\cdot10^{-5}$	0.50	0.86	124
$[CH_3(C_2H_5)_2SiCH_2N(CH_3)_2CH_2CH_2Cl]I$	$3.2\cdot10^{-4}$	0.35	1.69	71
$[(CH_3)_3SiCH_2N(CH_3)_2CH_2CH_2I]I$	$2.5\cdot10^{-5}$	0.69	0.25	40
$[(CH_3)_3SiCH_2N(CH_3)_2CH_2CH_2OCOCH_3]I$	$2.4\cdot10^{-4}$	0.62	0.7	328
$[(CH_3)_3SiCH_2N(CH_3)_2CH_2CH_2OCOC_6H_5]I$	$2.3\cdot10^{-5}$	1.26	3.1	465
$[(CH_3)_3SiOCH_2CH_2N(CH_3)_2]I$	$4.5\cdot10^{-4}$	—	—	238
$[(CH_3)_3SiCH_2NH(CH_3)CH_2CH_2Cl]Cl$	$1.3\cdot10^{-5}$	—	—	137

*Concentration expressed in fractional units.

The trimethylsilyl ester of choline has virtually no ganglion-blocking activity. When administered to cats in doses of 2–10 mg kg^{-1} the depressor phase is replaced by a pronounced increase in the level of blood pressure. The persistence of the pressor effect in experiments on spinal cats after the vagus nerves have been severed, the exclusion of the adrenal glands from blood circulation, and the prevention of this effect by hexamethonium salts indicate a stimulating effect of the trimethylsilyl ester of choline on the autonomic vegetative ganglia, particularly the sympathetic ganglia.

The physiological activity of organosilicon derivatives or analogues of known organic medicinal preparations and other substances with a distinct biological activity is not by itself in any way surprising. Although among all the compounds of this type investigated none has found wide practical application, investigations in this field are nevertheless very interesting and promising. This claim is based on studies of the "bioisosteric" organosilicon compounds carried out in recent years in the USA by Fessenden [23,300–304,353]. The idea underlying them may be regarded as the pharmacochemical development of the once very popular "analogue hypothesis" of Wöhler, Ladenburg, and Friedel, according to which the replacement in any organic compound of one or several carbon atoms by silicon (i.e. the formation of a "sila-derivative") does not alter appreciably the physical and chemical properties. Although this hypothesis has now been disproved, it nevertheless remains to a certain degree valid when applied to organosilicon compounds which do not contain functional groups attached to the silicon atom, at any rate functional groups which are readily hydrolysed.

As an example of the validity of the analogue hypothesis for carbon and silicon compounds in its pharmocological aspect, several pairs of isostructural substances are quoted below:

$(4\text{-}HOC_6H_4)_3M(CH_3)_3$ (I) $\quad C_6H_5(CH_3)_2MCH(CH_3)NH_2\cdot HCl$ (II)

$R(CH_3)_2M(CH_2)_nOCONH_2$ (III) $\quad R(CH_3)M[(CH_2)_nOCONH_2]CH_2OCONH_2$, (IV)

where M = C (a) or Si (b).

Thus compounds (Ia) and (Ib) exhibit the same allergic activity [320]. The organosilicon analogue (IIb) of the familiar adrenergic medicinal preparation (IIa) resembles it in both its overall biological activity and in its toxicity [301]. The toxicity of organic carbamates (IIIa, IVa) and the organosilicon carbamates having an analogous structure (IIIb, IVb) is of the same order of magnitude [303].

The similarity of the biological activities of isostructural organic and organosilicon compounds is of undoubted interest for the creation of new medicinal preparations, pesticides, and other types of biologically active substances if only because the corresponding silicon compounds are in many cases easier to synthesise and are cheaper. Nevertheless sometimes the sila-analogues of the physiologically active organic substances may differ from the latter to a greater or smaller extent in their effect on the organism. In turn this difference may be successfully used in the synthesis of new medicinal preparations and pesticides.

For example the familiar tranquiliser meprobamate (Va) and its sila-derivative (Vb), [303]

$CH_3CH_2CH_2(CH_3)M(CH_2OCONH_2)_2$ (V)

where M = C (a) or Si (b), has similar effects on the motor activity of animals and inhibits NAD-H_2 oxidase. However, their physiological activity is otherwise not the same. The effect of compound (Va) is four times more prolonged than that of (Vb). When administered orally, compound (Vb), in contrast to compound (Va), is inactive despite the fact that it is absorbed and then eliminated from the organism in urine. This suggests that the metabolic fate of both analogues (V) in the organism is different. Indeed, while compound (Va) is oxidised in the organism and eliminated as the hydroxy-derivative (VIa), compound (Vb), apart from being oxidised by an analogous process to compound (VIb), is converted into the disiloxane (VII) with elimination of an n-propyl group [23,353]:

$CH_3CH(OH)CH_2(CH_3)M(CH_2OCONH_2)_2$ [VI; M = C (a); Si (б)] $\quad [CH_3(H_2NCOOCH_2)_2Si]_2O$ (VII)

The only metabolic product of $CH_3CH_2CH_2(CH_3)_2SiCH_2OCONH_2$ is the corresponding dealkylation product $[H_2NCOOCH_2(CH_3)_2Si]_2O$†. [353] Thus the different metabolic fate of the sila-analogues of physiologically active substances may have a significant effect on the nature and duration of their action.

The carbon and silicon structural analogues of type (VIII) show particularly marked differences in their biological activity, which can probably be attributed to the β-effect of the silicon atom:

$(CH_3)_3MCH_2CH_2OCONH_2$ (VIII)

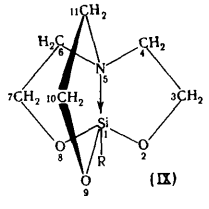
where M = C (a) or Si (b).

†Until Fesenden's investigation [353], the metabolism of organosilicon compounds in the organism was hardly studied. It was only known that $(CH_3)_3Si(CH_2)_{15}CH_3$ and $(CH_3)_3Si(CH_2)_{11}COOCH_3$ are absorbed via the gastrointestinal tract [354] and that [^{14}C] polydimethylsiloxane is not eliminated from the organism in the form of $^{14}CO_2$. [355]

Compound (VIIIa) is ten times more toxic than its sila-analogue (VIIIb). The latter is a rapid-acting muscle relaxant which does not give rise to side effects. On the other hand, compound (VIIIa) does not exhibit this type of activity, causing convulsions instead [303]. At the same time both compounds (VIII) give rise to a prolonged cholinergic response when introduced into the lateral hypothalamic region of the brain [356].

The last few examples clearly demonstrate that in physiological activity too the "analogue hypothesis" is not always justified even when compounds with silicon-containing functional groups are excluded from consideration. This is not in fact surprising because the much lower electronegativity, the higher covalent radius of the atom (by a factor of 1.5), and the presence of vacant 3*d* orbitals constitute appreciable differences between silicon and carbon. This difference does actually lead to the expectation in a number of cases that the sila-analogues of physiologically active organic compounds will have a quite specific effect on living organisms. This makes further investigations in this field undoubtedly promising.

We believe that even more interesting and promising is the study of the physiological activity of organosilicon compounds which have no organic analogues at all or which exhibit an activity which is closely related to the presence in their molecule of a silicon atom (or atoms). Compounds of this type, investigated up to the present time, are also listed in Table 2. These include in the first place silatranes (IX), the wide employment of which in our laboratory began in 1962. We have shown that certain silatranes, namely 1-arylsilatranes exhibit high and specific physiological activity [22,287-293,357].



(IX)

For example, 1-phenylsilatrane (IX, R = C_6H_5) and even more so 1-*p*-tolylsilatrane (R = *p*-$CH_3C_6H_4$) are unusually toxic for warm-blooded animals. Their lethal dose (LD_{50}) for white mice is only 0.33 and 0.20 mg kg^{-1}. Both compounds are several times more toxic than the widely known poisons such as hydrocyanic acid or strychnine. At the same time 1-arylsilatranes are almost harmless for cold-blooded animals (frogs, etc.), plants, and micro-organisms. Below the lethal dose (0.2–0.25 mg kg^{-1}), 1-phenylsilatrane is a powerful analeptic, i.e. it gives rise to motor excitation and intensifies the respiration of animals. It is interesting that for animals under narcosis 1-phenylsilatrane proves to be much less toxic. A dose ten times greater than the lethal dose causes only an excitation of respiration and convulsive movements of skeletal muscles. In animals with damaged central nervous systems 1-phenylsilatrane does not cause muscular convulsions even in doses of 1.5 mg kg^{-1} (introduced intravenously).

A wide variety of numerous experiments showed that 1-arylsilatranes do not affect the peripheral neuromuscular apparatus. The physiological activity of 1-arylsilatranes is due to their effect on a hitherto unknown enzyme system which is important for the function of the central nervous apparatus in warm blooded animals and which is absent or is less important for the activity of the central nervous system of cold blooded animals. For this reason, 1-arylsilatranes have no toxic effect on all living organisms at a lower level of evolutionary development.

The difference between 1-arylsilatranes and many of the familiar poisons is also indicated by the fact that enzymes such as cholinesterase and acetylcholinesterase are not inhibited by them.

The physiological activity and in particular the toxicity of silatranes vary within extremely wide limits, being determined mainly by the nature of the substituent R attached to the silicon atom itself (Table 4). The wide range of variation of this activity is indicated, for example, by the complete harmlessness of alkyl- and alkoxysilatranes (R = $CH_3C_2H_5O$ etc.).

Table 4. Toxicity of silatranes $RSi(OCH_2CH_2)_3N$ for white mice with intraperitoneal administration*.

R	LD_{50}, mg kg^{-1}	R	LD_{50}, mg kg^{-1}
p-$CH_3C_6H_4$	0.20	*p*-$CH_3C_6H_4O$	1270
C_6H_5	0.33	$C_6H_5CH_2$	1115
m-ClC_6H_4	4.4	CH_3O	2100
H	100	C_2H_5O	>5000
$CH_2(CH_2)_4CH$	150	CH_3	>5000
C_6H_5O	200	C_2H_5	>5000
p-$O_2NC_6H_4O$	700	$(CH_3)_2CH$	>5000
p-ClC_6H_4O	1050	$CH_2{=}CH$	>5000

*For 3,5-dimethyl-1-phenylsilatrane and 1-phenyl-2-carboxysilatrane, LD_{50} = 14.7 and 8.1 mg kg^{-1} respectively.

The introduction of methyl radicals into the silatrane system of 1-phenylsilatrane or the replacement of one of the oxygen atoms by a CH_2 group (1-phenyl-2-carbasilatrane) greatly reduces the toxicity of the compound. When the aromatic ring in 1-arylsilatranes is separated from the silatrane system by a methylene group (1-benzylsilatrane), the compound virtually loses its toxicity and the introduction of an oxygen atom into the Si–C_6H_5 bond (1-aryloxysilatranes) lowers the toxicity by several powers of ten. It is interesting that the hydrogenated analogue of 1-phenylsilatrane, i.e. 1-cyclohexylsilatrane, and also silatrane itself (1-hydrosilatrane) exhibit some, albeit low, toxicity.

In order to establish whether the structure of 1-arylsilatranes is specific for high physiological activity, we investigated the toxicity of open-chain silatrane analogues —a wide variety of 2-aminoethoxysilanes containing the Si–O–C–C–N group (derivatives of tri-, di-, and monoethanolamine) and also the initial amino-alcohols (Table 5). [295] It was found that all the organosilicon ethers of monoethanolamine in the series $R_{4-n}Si(OCH_2CH_2NH_2)_n$ with n = 1–3 are 2–9 times more toxic than $HOCH_2CH_2NH_2$ itself. At the same time the analogous derivatives of *NN*-dialkylaminoethanols usually prove less toxic than the corresponding amino-alcohol $HOCH_2CH_2NR_2$ (particularly for R = CH_3 or C_4H_9), or their toxicity is of the same order of magnitude (for R = C_2H_5).

Trialkylsilyl derivatives of triethanolamine are less toxic than triethanomaline itself, while the analogous diethanolamine derivatives are somewhat more toxic than diethanolamine itself. The toxicity of compounds in the

series $H_{3-n}N(CH_2CH_2OSiR_3)_n$, where R = CH_3 or C_2H_5 and n = 1–3, decreases appreciably as n increases. A change in the nature of the hydrocarbon substituent of the silicon atom in all types of the compounds investigated has little effect on the toxicity. On the whole, the toxicity,of organosilicon ethers of amino-alcohols is low and varies in the range from 120 mg kg^{-1} for $(C_2H_5)_2Si(OCH_2CH_2NH_2)_2$ to 4000 mg kg^{-1} for $N[CH_2CH_2OSi(C_2H_5)_3]_3$.

Table 5. Acute toxicity (LD_{50}) of 2-aminoethoxysilanes and 2-aminoethanols and dose which impairs the co-ordination of movement (ED_{50}) on intraperitoneal administration to white mice.

$[(CH_3)_3SiOCH_2CH_2]_3N$	3500	1400
$[(C_2H_5)_3SiOCH_2CH_2]_3N$	4000	—
$(CH_3)_3SiOCH_2CH_2NC_5H_{10}$	400	—
$(C_2H_5)_3SiOCH_2CH_2NC_5H_{10}$	280	180
$(C_2H_5)_3SiOCH_2CH_2NHC_4H_9$	360	240
$(CH_3)_3SiOSi(CH_3)_3$	4500	

In the study of the effect of all the above aminoalkoxysilanes on the co-ordination of movement it was found that compounds of the type $(CH_3)_{4-n}Si[OCH_2CH_2N(C_2H_5)_2]_n$ with n = 1 and 2 are active at a dose smaller by a factor of 11–13 than the median lethal dose.

The data obtained convincingly demonstrate that the toxicity of 2-aminoethoxysilanes is scarcely due to the toxic effect of their hydrolysis products (one of these, hexamethyldisiloxane, for example, has LD_{50} = 4.5 g kg^{-1}) but is caused by the molecular structure as a whole. They also show that the high toxicity and physiological activity of 1-arylsilatranes cannot be attributed solely to the simultaneous presence in their molecule of the Si–aryl and Si–O–C–C–N bonds. Nor is it possible to explain the activity of 1-arylsilatranes by the presence in their molecules of the silatrane group $Si(OCH_2CH_2)_3N$, because 1-alkyl- and 1-alkoxy-silatranes are almost non-toxic. It might have been supposed that the physiological activity of 1-arylsilatranes is associated with the effect on the aromatic ring of the transannular co-ordinate bond Si ← N, which leads to an enhancement of its π-electron density and consequently its electron donor properties. However, the toxicity of 1-phenylgermatrane (smaller by a factor of 100 than that of 1-phenylsilatrane), which has a similar structure and dipole moment [358], suggests that the problem of the high physiological activity of 1-arylsilatrane still remains open, although it may be supposed that the much lower toxicity of 1-phenylgermatrane is due to its lower chemical stability.

The high physiological activity of 1-arylsilatranes suggested to us that other organosilicon compounds containing a nitrogen atom in the γ- or δ-position in relation to the silicon atom might be of definite interest in this respect. This was also indicated by a brief communication concerning the fairly high toxicity of compound (X):

$$(C_2H_5O)_2Si(CH_3)CH_2CH_2CH_2CH_2NH_2$$
(X)

(0.045 ml kg^{-1} when absorbed through the skin of the rabbit). [198,254]

Table 6. Acute toxicity (LD_{50}) of 3-aminopropylsilanes and dose which impairs the co-ordination of movements (ED_{50}) in white mice after intraperitoneal administration.

Compound	Formula	LD_{50}, mg kg^{-1}	ED_{50}, mg kg^{-1}

XXIX	$O[Si(CH_3)_2CH_2CH_2CH_2NH_2]_2$	80	60

To confirm this hypothesis, we investigated the toxicity and the effect on the co-ordination of movement of γ-aminopropyl substituted silanes and their unsaturated analogues. The data obtained (Table 6) show that, among compounds of this type, there are some fairly toxic [compound(XI) with LD_{50} = 6 mg kg^{-1}] and also compounds which fairly effectively reduce the motor activity and impair the co-ordination of movement [compounds (XXVI) and (XXVIII)] [294,298].

Among γ-aminopropylsilane derivatives, derivatives of bis-(3-aminopropylsilyl)benzene are of particular interest. For example, one of these [compound (XXVIII)] impairs the co-ordination of movement at a dose as low as 10 mg kg^{-1}, while at a dose of 4.8 mg kg^{-1} it reduces the body temperature by 3 deg.

It should be pointed out that the toxicity of the hydrochlorides of γ-aminopropylsilanes is reduced [compounds (XIV) and (XIVa)]. In the series of the hydrochlorides $[(C_2H_5)_3Si(CH_2)_nNH(CH_2)_4CH_2]Cl$ the toxicity decreases with increasing n. Thus for $n = 1$, 2, and 3, LD_{50} is respectively 60, 88, and 120 mg kg^{-1}.

We investigated the fungistatic and bacteriostatic activities of several dozen of nitrogen-containing organosilicon compounds of a wide variety of types [293,337]. Among these substances with a comparatively high activity were detected (Table 7).

Table 7. Minimum concentration (C) of nitrogen-containing organosilicon compounds suppressing the growth of micro-organisms.

Compound	Formula	Test microbe	C, mg ml^{-1}
XII	$CH_3(C_2H_5O)_2SiCH_2CH_2CH_2NH_2$	*Escherichia coli* 675	10.4
XV	$(n\text{-}C_3H_7)_3SiCH_2CH_2CH_2NH_2$	*Candida albicans* 67/846	41.7
		Epidermophyton Kaufmann Wolf 41	13.8
		Trichophyton gypseum 4/3	13.8
		Bac. mycoides 675	14.0
XXI	$(C_2H_5)_3SiCH_2CH_2CH_2NH$—	*Staphylococcus aureus haemolyticus* 209	10.4
		Bac. mycoides 675	10.4
XXX	$(CH_3)_2Si(CH_2Cl)CH_2CH(CH_3)CONH_2$	*Epidermophyton Kaufmann Wolf* 41	6.9
		Trichophyton gypseum 4/3	13.8

Although nitrogen-containing organosilicon compounds of a wide variety of structures have been investigated, only substances with the nitrogen atom in the γ-position in relation to the silicon atom proved to be active. Two of the compounds, listed in Table 7 [compounds (XV) and (XXX)], are only slightly inferior (by a factor of 1.8) in their fungistatic activity on *Trichophyton gypseum* to the fungicidal preparation nystatin widely used in clinical practice. Two other compounds effectively suppress gram-positive [compound (XXI)] and gram-negative [compound (XII)] bacteria.

There is no doubt that continued studies in this field will lead to the discovery of even more active organosilicon fungistatic and bacteriostatic substances which may find practical application, in particular for the formation of stable fungicidal and antibacterial coatings.

Thus we have shown that a wide variety of classes of nitrogen-containing organosilicon compounds containing both nitrogen and silicon atoms, separated from one another by three other atoms, exhibit useful and varied effects on the living organism. These are the most promising possible new silicon-containing medicinal preparations and pesticides. Nevertheless we discovered substances with a high physiological activity also among other classes of nitrogen-containing organosilicon compounds. For example, we found (together with D. P. Dremova) that compounds of the series $R_2NCH_2(CH_3)Si(OR')_2$ are insect repellents [335]. Some data on the activity of the compounds of this type are presented in Table 8.

We hope that further study of organosilicon insect repellents will make it possible to produce stable coatings with a similar property.

---o0o---

The findings described above urgently necessitate development of a new branch of silicon chemistry—the chemistry, biochemistry, and pharmacology of biologically active organosilicon compounds, i.e. "bio-organosilicon chemistry". This should include a detailed study of the role of silicon in living organisms and the physiological processes and pathological and gerontological changes occurring in them, the search for compounds of this element with high and specific biological activity, and the study of the possible practical application of such compounds in medicine, veterinary practice, agriculture, and other branches of human activity.

Table 8. Repellent activity of $R_2NCH_2(CH_3)Si(OR')_2$ in relation to a culture of fleas *X. Cheopis* at a concentration of 20 g m^{-2}.

R	R'	Coefficient of repellent activity (after 24 h)
$n\text{-}C_4H_9$	$n\text{-}C_4H_9$	73.9
$n\text{-}C_4H_9$	$iso\text{-}C_4H_9$	80.7
C_2H_5	$n\text{-}C_6H_{13}$	70.0
C_2H_5	$CH_2(CH_2)_4CH$	79.9
C_2H_5	$n\text{-}C_8H_{17}$	77.9

In this connection we cannot fail to quote the prophetic lines written as early as 1878 by the French genius Louis Pasteur: "There is a great future for the therapeutic applications of silicon".

It is to be hoped that the time is near when, as a result of the combined efforts of chemists, biochemists, pharmacologists, physicians, biologists, and agronomists, a multiplicity of new synthetic and natural physiologically active organic compounds of silicon, which will prove as useful to man as silicates and silicones, will begin to be produced industrially.

Degree of Branching in Polymeric Chains

V.A.Grechanovskii

CONTENTS

I.	Introduction	987
II.	Fundamental concepts	987
III.	Unperturbed dimensions of branched macromolecules	988
IV.	Hydrodynamic properties of branched macromolecules	989
V.	Degree of branching in polydisperse polymers	991
VI.	Synthesis and investigation of model branched polymers	994
VII.	Variation of the hydrodynamic parameters of branched polymers with molecular weight	996
VIII.	Treatment of the experimental data in studying branching	997
IX.	Other methods of determining degree of branching	998

The degree of branching of polymeric chains is one of the most important molecular parameters which determine the physicomechanical and technological properties of the polymers.
The results of theoretical calculations of the influence of the degree of branching on the dimensions and nydrodynamic properties of the macromolecules are surveyed. The experimental results from the study of the properties and methods of synthesis of various model branched polymers are systematised. The problem of the molecular weight distribution of branched polymers and also experimental methods of determining the degree of branching of mono- and polydisperse polymers are considered briefly.

I. INTRODUCTION

The presence of branching in molecular chains leads to extensive changes in the physico-mechanical and technological properties of various polymers in comparison to the corresponding linear polymers. For example, branched divinylstyrene rubbers, polybutadienes, and other branched elastomers have less elasticity, lower breaking stress, etc.[1-4]; the decrease in the strength properties and the change in dynamical mechanical characteristics with increase in the degree of branching are characteristic also with such thermoplastic polymers as polystyrene, polyethylene, poly(vinyl chloride), etc.[5-7]. There are also significant differences in the rheological properties of linear and branched polymers. Thus at low loads (shear stresses) linear polymers and their melts flow like newtonian liquids and exhibit a viscosity lower than that of the branched polymers but under higher loads the flow departs from newtonian so that the viscosity of a branched polymer is less (or almost equal) to that of the linear[8,9]. Similar rules also hold for concentrated solutions. Hence like the regularity of the structure of the polymeric chains, the molecular weight, and the molecular weight distribution (MWD), the degree of branching is a most important molecular parameter of polymers.
Branching arises during polymerisation mainly as a result of reactions in which active centres are transferred to the polymer chain; during this either the loss (abstraction) of a hydrogen atom in one of the monomeric units or the interaction of active centres with double bonds of the polymer chain is possible. In radical polymerisation these reactions take place in the following way:

1. Loss of a proton, H:

$$\sim M_n^{\cdot} + P_m \rightarrow M_nH + P_{m(-H)}^{\cdot};$$

$$\sim M_n^{\cdot} + \sim CH_2{-}CHR{-}CH_2 \sim \rightarrow M_nH + \sim CH_2{-}\dot{C}R{-}CH_2\sim$$

2. Interaction with the double bond:

$$\sim M_n^{\cdot} + P_m \rightarrow \sim M_{n+m}^{\cdot};$$

$$\sim M_n^{\cdot} + \sim CH=CH\sim \rightarrow \sim \overset{M_n}{\overset{|}{\dot{C}H}}{-}CH\sim.$$

Here $\sim M_n^{\cdot}$ and P_m denote the "live" and "dead" polymeric links of degree of polymerisation n and m respectively. (Two "live" polymeric chains can take part in the interaction but usually this is less probable.) In the first instance so-called trifunctional branching nodes are formed, in the second, tetrafunctional nodes (the branches leave from two points separated by a C–C bond and the distance between them can be neglected).

Similar changes also take place in catalytic polymerisation by the formation of branched molecules of different functionality. Clearly, not one but several branching nodes can be formed in a single macromolecule (but usually with fixed functionality).

Branched polymers with f-functional nodes are also formed in widely employed syntheses for the common polycondensation of bi- and f-functional monomeric units and in the irradiation of polymers.

II. FUNDAMENTAL CONCEPTS

In dependence on length, long-chain and short-chain branches are distinguished. Branches of a length commensurate with that of the main chain are termed long-chain, and the present article will mainly consider long-chain branching. By the length of a branch we understand the distance between the two nearest nodes of the branching or the distance between the nearest pair of nodes of the branching the end of the chain. Examples are distinguished when all the branches have the same length

(branching with a fixed chain length) and when there is a random distribution of branch lengths. This shows that if the structure of a branched molecule is determined by the molecular weight of each branch then any structures with a specified total number of nodes and molecular weight for the macromolecule are equally probable. Depending upon the nature of the attachment of the branches, branched molecules can be divided into: (1) comblike (graft branching), where the branches are attached to a main chain (Fig. 1*a*) and (2) statistical, where the polymer does not have a main chain (Fig. 1*b*); such structures can arise because of secondary branching†.

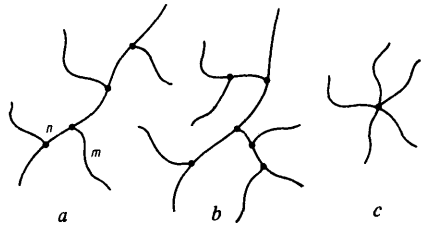

Figure 1. Models of branched macromolecules: *a*) comblike branched; *b*) statistically branched; *c*) starlike branched.

Whatever the nature of the branching the number of branches p is connected with the number of nodes b and the functionality of the branching by the relation:

$$p=(f-1)b+1. \quad (1)$$

A measure of the quantitative characteristic of branching is the branching density ρ, equal to the fraction of "cross-linked" (that is, having branching nodes) monomeric units in relation to their total number in the macromolecule:

$$\rho=\alpha\frac{b}{x} \quad (2)$$

where x is the degree of polymerisation, and α a constant depending on the functionality of the branching.

When during polymerisation the branching density exceeds some critical value ρ_c, which depends on molecular weight, an insoluble polymer starts to form, a gel which is a single space lattice [10,11]. Sometimes reference is made to the "degree of cross-linking" of polymeric molecules, characterised by the cross-linking (branching) parameter γ, where

$$\gamma=\rho/\rho_c \quad (3)$$

$\gamma = 1$ corresponds to the moment of gel formation.

III. UNPERTURBED DIMENSIONS OF BRANCHED MACROMOLECULES

In view of the small number of nodes in long-chain branching spectroscopic methods are used for identifying branched polymers. Therefore branching is investigated in dilute solutions, because the introduction of even one or two long-chain branching nodes leads to an appreciable decrease in the mean square dimensions of the macromolecules in comparison with linear ones of the same molecular weight.

The calculation of the undisturbed dimensions (that is, the dimensions in a θ-solvent) of branched macromolecules of various types has been carried out by various authors, who usually calculated the ratio of the mean square radii of inertia of branched $\overline{R}_b^2$ and linear $\overline{R}_l^2$ molecules of the same molecular weight; the g-factor is:

$$g=\overline{R}_b^2/\overline{R}_l^2. \quad (4)$$

For a small number of branching nodes this calculation can be made from purely geometric considerations. With a significant increase in the number of nodes statistical methods are employed. For example, for a branched macromolecule with one branching node a geometrical consideration gives [12]:

$$g=\sum_\lambda\left(\frac{3n_\lambda^2}{n^2}-\frac{2n_\lambda^3}{n^3}\right) \quad (5)$$

where n is the total number of segments (kinetically independent units) in the macromolecule), and n_λ the number of segments in the λ branch.

If a node has functionality f and the branch has a fixed length, that is, $n_\lambda = n/f$, then for such a star-shaped molecule we obtain from Eqn. (5):

$$g=\frac{3}{f}-\frac{2}{f^2} \quad (6)$$

in the particular example of trifunctional branching $g = 7/9$ and for tetrafunctional $g = 5/8$. For arbitrary branching the general equation for the g-factor has the form [13,14]:

$$g=\frac{6}{p(p+1)(p+2)}\left\{p^2+\sum_{\lambda,\mu}\nu_{\lambda\mu}\right\}. \quad (7)$$

Here $\nu_{\lambda\mu}$ is the number of branches between any two isolated branches λ and μ and the summation is over all the possible subdivisions of p branches of the macromolecule into different pairs (subsystems). Depending on the nature of the attachment of the branches and their distribution in lengths (at a given molecular weight and number of branching nodes) the sum will be somewhat different and the value of the g-factor will change correspondingly. From physical considerations it is evident that comblike branched macromolecules possess a large number of different subsystems compared with the statistically branched ones; fixing the branch lengths also leads to a decrease in the number of possible subsystems. Hence statistically branched macromolecules with a fixed branch length exhibit the least number of subsystems. The values of the g-factor should decrease in the same order. Accurate calculations have been made by Zimm and Stockmayer [12], Ptitsyn [15], and Kurata and Fukatsu [16].

In these studies values of the g-factor for various models of branching were calculated assuming that the branches are sufficiently long, that is, the distribution of the distances between the segments in the branches is a gaussian function. Table 1 gives the results of calculations [12,15,16] for various models of the branching. We note that the value of the g-factor for a given type of branching depends only on the number of branching nodes.

Tsvetkov developed an approximate method for calculating the dimensions of a branched chain in which the length of a side branch equals the length of the main chain; the

†Sometimes macromolecules in which f branches are attached to a single "point" (Fig. 1*c*) are regarded as a separate class of starlike macromolecules.

variation of the g-factor with the number of branches p for trifunctional nodes is of the form [17]:

$$g_3(p) = \frac{1}{p^2}\left\{25 + 6(p+3)\left[\frac{\ln(p+3)}{\ln 2} - 3\right]\right\} , \quad (8)$$

and that for the tetrafunctional is:

$$g_4(p) = \frac{1}{p^2}\left\{10 + 3(p+2)\left[\frac{2\ln(p+2)}{\ln 3} - 3\right]\right\}. \quad (9)$$

Table 1. Numerical values of the g-factor.

Note: g_1 random distribution of branch lengths; g_2 fixed branch lengths.

The results given in Table 1 relate to an idealised example in which monodisperse linear and branched polymers are compared and all the branched molecules have the same number of branching nodes. In practice, however, there is always a definite scatter both in the molecular weight and in the number of branching nodes for different macromolecules. Leaving aside the problem of the breadth of the molecular weight distribution, we will point out that for homogeneous polymers the molecules of which have a different number of branching nodes, Zimm and Stockmayer [12] obtained an equation relating the averaged mean square dimensions of molecules of such a polymer to the mean number of branching nodes b_n per molecule. For trifunctional branching nodes the mean value of the g-factor equals‡:

$$\langle g_3(b)\rangle = \left(\sqrt{1 + \frac{b_n}{7}} + \frac{4b_n}{9\pi}\right)^{-1/2} \quad (10)$$

and that for the tetrafunctional nodes is:

$$\langle g_4(b)\rangle = \left(\sqrt{1 + \frac{b_n}{6}} + \frac{4b_n}{3\pi}\right)^{1/2} . \quad (11)$$

The values of $< g(b) >$ are characteristic for fractions of the branched polymer if the fractionation proceeds only according to the molecular weights. These values are given in Table 1.

‡The sign $<>$ denotes the mean of the quantity considered.

It is noteworthy that not only do long-chain branchings lead to an appreciable decrease in the dimensions of the macromolecules; it is known that for comblike molecules with a large number of short side-chain attachments of the same length, the value of the g-factor is given by [18]:

$$g = \frac{n - \sum_\lambda n_\lambda}{n} = \frac{n_x}{n} \quad (12)$$

where n is the total number of segments in the macromolecule, n_λ the number of segments in the λ side chain, and n_X the number of segments in the "spine" of the macromolecule. Ptitsyn [15] obtained a similar relation:

$$g = \frac{m}{m+n} \quad (12a)$$

(see Fig. 1).

By short side branches is understood those branches with a length comparable with the distance between them ($m \simeq n$). Hence when there is a large number of short side attachments ($n_\lambda/n \ll 1$) the value of the g-factor can also differ considerably from unity. However, unlike the long-chain branching in this instance the dimensions of the macromolecules are determined mainly by the length of the spine; it is then possible in principle for 99% of the mass of the macromolecule to be centred in the side-chains of the branches. Such macromolecules can have anomalously small dimensions for a large molecular weight. As Eqns. (12) and (12a) show, the value of the g-factor depends not only on the number but also on the lengths of the side-chains, therefore the determination of the number of nodes solely from the g-factor cannot be considered reliable for short-chain branching.

Direct measurements of the mean sizes of the macromolecules can be made using a light scattering method but this method is as yet little used in analysing branching. The theory of the scattering of light by branched macromolecules has been developed only for certain particular instances [19-21], therefore these problems will not be discussed here. The present investigation of branching is now mainly on the basis of a study of the hydrodynamic behaviour of macromolecules in solutions (characteristic viscosity and sedimentation).

IV. HYDRODYNAMIC PROPERTIES OF BRANCHED MACROMOLECULES

Branched polymers in which the branching density does not exceed the critical value dissolve in the same solvents as do the linear polymers. However, in several studies it was noted that the solubility of branched polymers is less than that of linear, since the critical temperature of mixing of a polymer with a solvent for branched polymers is higher than for linear polymers of equal molecular weight [22,23].

In thermodynamically ideal solvents linear macromolecules can be regarded as unflowing coils with a gaussian distribution of the segments around the centre of gravity. The appearance of branching leads to a concentration of the segments and their more uniform distribution in the volume of the macromolecule, therefore the statistics of a branched macromolecule in solution are gaussian [25,26]. In this sense the effect of branching is opposite to the influence of phenomena of the volume effects (well studied theoretically) [10,24] in "good" solvents, where the "dilution" of the segments in the bulk of the macromolecule is observed.

1. Sedimentation and Diffusion of Branched Macromolecules

The sedimentation constant S and diffusion constant D of the macromolecules are connected with their dimensions by the coefficient of translational friction F_{tr} (here and subsequently reference is made to the sedimentation and diffusion constants extrapolated to infinite dilution):

$$S = \frac{M(1-\bar{v}\rho_0)}{NF_{tr}} \quad (13)$$

$$D = \frac{kT}{F_{tr}} \quad (14)$$

$$F_{tr} = P(\overline{R^2})^{1/2}\eta_0 = B\eta_0 \quad (15)$$

where M is the molecular weight, $\bar{v}$ the specific partial volume of the polymer, η_0 and ρ_0 are the viscosity and density of the solvent, N is Avogadro's number, k the Boltzman constant, and P the Flory constant, which characterises the hydrodynamic interaction of the macromolecules with the solvent in translational motion for linear polymers in a θ-solvent, $P = 5.11 \times \sqrt{6}$. The sedimentation and diffusion constants are determined by the first power of the hydrodynamically effective dimensions of B. Application of Eqns. (13)–(15) to linear and branched macromolecules gives:

$$\frac{S_b}{S_l} = \frac{D_b}{D_l} = \frac{P_l(\overline{R_l^2})^{1/2}}{P_b(\overline{R_b^2})^{1/2}} = \frac{P_l}{P_b}g^{-1/2}; \quad (16)$$

$$\frac{P_l(\overline{R_l^2})^{1/2}}{P_b(\overline{R_b^2})^{1/2}} = \frac{B_l}{B_b} = h; \quad (17)$$

$$\frac{S_b}{S_l} = \frac{D_b}{D_l} = \frac{F_{tr,b}}{F_{tr,l}}, \quad (18)$$

where h is the ratio of the dimensions hydrodynamically effective in forward motion; the subscripts b and l refer to branched and linear macromolecules.

On the basis of the Kirkwood and Riseman theory of the hydrodynamic properties of macromolecules [28,29], Stockmayer and Fixman [27], Ptitsyn [15], and Kurata and Fukatsu [16] made direct calculations of the ratio of the coefficients of friction and of the sedimentation and diffusion constants of branched and linear macromolecules of the same molecular weight. For starlike molecules with a fixed branch length the following relation was found [27] between the ratio of the hydrodynamic dimensions h and the branching functionality f:

$$h = \frac{f^{1/2}}{2 - f + \sqrt{2}(f-1)} \quad (19)$$

The values of h for comblike and statistically branched macromolecules were calculated by Ptitsyn [15] and by Kurata and Fukatsu [16]; the corresponding analytical expressions are extremely large and will not be given here; calculated values for the various types of branching are given in Table 2. It is noteworthy that concordant results were obtained in these studies [15,16].

Kurata and Fukatsu [16] showed that for statistically branched macromolecules the ratio P_b/P_l increases monotonically with increase in the branching density, tending to the asymptotic value of 1.34. As the branching density is increased, for graft branched macromolecules the value of the ratio P_b/P_l first rises then passes through a maximum and decreases, tending to 1.00 independent of the functionality of the branching. These results show that the hydrodynamically effective dimensions in translational motion of the macromolecules depend not only on the density but also the type of branching. In principle the relation $h = f(p)$ could be used for finding the branching type but in practice this is made difficult, since significant differences in the behaviour of the function $h = f(p)$ start only when the number of branching nodes reaches 30–40§.

Table 2. Numerical values of h.

							3	0.68	0.62	—	—

Note: h_1 random distribution of branch lengths; h_2 fixed branch lengths.

2. Characteristic Viscosity of Branched Monodisperse Polymers

The characteristic viscosity, $[\eta]$, in a θ-solvent is connected with the unperturbed mean square dimensions of the test macromolecules by the following relation:

$$[\eta] = \Phi\frac{(\overline{R^2})^{3/2}}{M}; \quad (20)$$

where Φ is Flory's constant, characterising the hydrodynamic interaction of macromolecules with the solvent in rotational motion; for linear polymers in a θ-solvent $\Phi = 6^{3/2} \times 2.86 \times 10^{21}$. Evidently the characteristic viscosity depends not only on the dimensions of the macromolecules but also on the nature of their hydrodynamic interaction with the solvent. When allowance is made for this the characteristic viscosity is determined by the cube of the hydrodynamically effective dimensions A:

$$[\eta] = \frac{A^3}{M}. \quad (20a)$$

From Eqn. (20) the characteristic viscosity of the branched macromolecules should be less than that for linear polymers of the same molecular weight. The use of Eqns. (20) and (20a) for linear and branched polymers leads to the following relations:

$$\frac{[\eta]_b}{[\eta]_l} = \frac{\Phi_b}{\Phi_l}\left(\frac{\overline{R_b^2}}{\overline{R_l^2}}\right)^{3/2} = \frac{\Phi_b}{\Phi_l}\cdot g^{3/2}, \quad (21)$$

$$\frac{[\eta]_b}{[\eta]_l} = \frac{A_b^3}{A_l^3}. \quad (22)$$

§While this paper was in the press a paper by Berry [82] dealing with the calculation of the coefficient of translational friction of statistically branched macromolecules of comblike structure appeared.

The value of the ratio of the hydrodynamic interaction constants Φ_b/Φ_1 of branched and linear polymers is determined by the statistics of the macromolecular coil in the solution. Many calculations [15,16,27,30] have shown that the effect of branching on the geometric dimensions is more pronounced than on the hydrodynamic parameters, in other words, the hydrodynamic interaction of branched macromolecules with a solvent is stronger than that of linear, that is, $\Phi_b/\Phi_1 > 1$. Assuming that hydrodynamically effective dimensions in translational and rotational motion of macromolecules are the same, $A = B$, Stockmayer and Fixman [27] obtain for models of star-shaped branched molecules the following relation (in this instance the functionality agrees with the number of branches):

$$\frac{[\eta]_b}{[\eta]_1} = h^3 = \frac{f^{3/2}}{\{2 - f + \sqrt{2}(f-1)\}^{3/2}}. \quad (23)$$

On the other hand, for the model under consideration

$$g = \frac{3f-2}{f^2}. \quad (24)$$

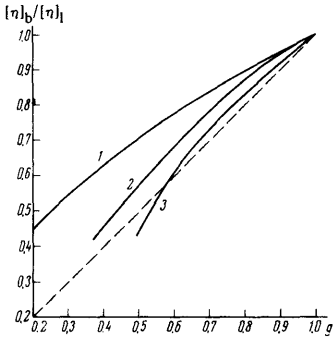

Figure 2. Variation of the characteristic viscosity with the g-factor: *1*) Zimm–Kilb theory; *2*) and *3*) calculated by Eqn. (25); *2*) Stockmayer and Fixman's results; *3*) Kurata and Fukatsu's results ($f = 3$, statistically branched); broken line, the relation $[\eta]_b/[\eta]_1 = g$.

On eliminating f from Eqns. (23) and (24), the variation of the ratio of the hydrodynamic dimensions, that is, the ratio of the characteristic viscosities (sedimentation constant) of branched and linear macromolecules with the g-factor can be found (Fig. 2, curve *1*). In practice, however, examples are seldom encountered in which the functionality of the branching exceeds 8. On also allowing for the fact that in this instance the presence of only one branching node is assumed it is evident that the use of Eqns. (23) and (24) is extremely limited in principle. Therefore Stockmayer and Fixman assume that the relation $h^3 = f(g)$ remains valid for any model of branching and propose to use it for finding not only the functionality but also the number of branching nodes if the relation $[\eta]_b/[\eta]_1$ is known.

Zimm and Kilb [30] attempted to find whether there is actually any general connection between the ratio of the characteristic viscosities of branched and linear macromolecules and the value of the g-factor beyond the dependence on the nature of the branching. On the basis of the Kirkwood–Riseman theory [28,29] of hydrodynamic properties of macromolecules, within the framework of the "pearl necklace" model, Zimm and Kilb directly calculated the value of the characteristic viscosity for two models of starlike branching of macromolecules: (1) one branching node with four branches of equal length; (2) one branching node with two long and eight short branches. The results of these calculations lead to the conclusion that for both branching models examined the following approximate relation is valid:

$$[\eta]_b/[\eta]_1 \cong g^{1/2}; \quad (25)$$

Zimm and Kilb also suggest that this equation can be applied with good approximation to any type of branched macromolecules.

It is noteworthy that the Stockmayer–Fixman and the Zimm–Kilb calculations were carried out for starlike macromolecules and *a priori* extension of results to comb-like macromolecules give rise to objections. We think that the more accurate relation $[\eta]_b/[\eta]_1 = f(g)$ for comb-like and statistically branched polymers can be obtained on the basis of calculations of hydrodynamically effective dimensions of macromolecules made by Kurata and Fukatsu [16] (Table 2). Here again it is suggested that the relation

$$[\eta]_b/[\eta]_1 = h^3 \quad (26)$$

is valid.

Fig. 2 gives the results of calculations of the relation $[\eta]_b/[\eta]_1 = f(g)$, which we made with allowance for Eqn. (26), according to Stockmayer and Fixman's and to Kurata and Fukatsu's results and according to Zimm and Kilb's theory. It should be noted that Eqn. (26) evidently over-rates the influence of branching on the value of the characteristic viscosity, especially in the range of high branching densities, where the hydrodynamic interaction increases considerably, therefore the true $[\eta]_b/[\eta]_1 = f(g)$ curves for models considered by Stockmayer and Fixman, and by Kurata and Fukatsu rule out some of the above references.

The existence of the relation $h = f(g)$ allows the degree of branching of a polymer with a narrow MWD to be evaluated on the basis of measurements of the characteristic viscosity or sedimentation (diffusion). Knowing the ratio of the hydrodynamic dimensions (that is, the ratio of the characteristic viscosities or sedimentation constants) of branched and linear macromolecules of equal molecular weight and of equal branching type, the corresponding ratio of geometric dimensions (the g-factor) and then from tables the number of nodes (branches) in a macromolecule can be found.

V. DEGREE OF BRANCHING IN POLYDISPERSE POLYMERS

Most of the synthetic polymers which are dealt with in practice are polydisperse. The degree of branching of polydisperse polymers is estimated by averaging the corresponding characteristics of monodisperse branched polymers. The concept of mean density of branching is introduced as a quantitative characteristic of branched polydisperse polymers. The number average branching density b_n is determined by the expression:

$$b_n = \frac{\sum_{x=1}^{\infty}\sum_{b=0}^{\infty} bP_{b,x}}{\sum_{x=1}^{\infty}\sum_{b=0}^{\infty} P_{b,x}}, \quad (27)$$

where $P_{b,x}$ is the number of molecules of degree of polymerisation x, having b branching nodes, and b_n the mean number of branching nodes for a single polymeric molecule. The weight average branching density b_w is determined similarly:

$$b_w = \frac{\sum_{x=1}^{\infty}\sum_{b=0}^{\infty} b_x P_{b,x}}{\sum_{x=1}^{\infty}\sum_{b=0}^{\infty} x P_{b,x}}. \quad (28)$$

Before analysing the value of the characteristic viscosity of polydisperse branched polymers we will examine the principal functions of MWD of branched polymers.

1. MWD of Branched Polymers

Branched polymers are usually characterised by wider molecular weight distribution functions than for linear ones, a polydispersity index determined as the ratio of the mean weight index of polymerisation x_w to the numerical mean x_n for branched polymers is usually greater than two, $x_w/x_n > 2$. Here we will consider some MWD functions typical for branched polymers.

The MWD of a polymer formed in the common statistical polycondensation of bi- and tetra-functional monomeric units is described by the distribution function given by Stockmayer [31], which can be represented as a system of equations:

$$P_{0,x} = x/y_n^2 \exp\{(x/y_n)(1+\gamma/2)\},$$
$$P_{b,x} = \frac{\gamma (x/y_n)^2}{2b(2b+1)(2b+2)} P_{b-1,x}, \quad (29)$$

where γ is the branching index—see Eqn. (3), y_n the number average degree of polymerisation of the corresponding linear polymer, which would be obtained were the tetrafunctional units replaced by the stoichiometric amount of bifunctional units, and a polymer with "most probable" MWD is formed. The mean degrees of polymerisation of the branched x and linear y polymers thus obtained are connected by the relations [31]:

$$x_w = \frac{y_w}{1-\gamma}; \quad (30)$$
$$x_n = \frac{y_n}{1-\gamma/4}; \quad (31)$$
$$y_w = 2y_n. \quad (32)$$

The branching parameter γ is connected with the number average b_n and the weight average b_w by the number of branching nodes by the following equations:

$$b_w = \frac{\gamma}{1-\gamma}; \quad (33)$$
$$b_n = \frac{\gamma}{4-\gamma}. \quad (34)$$

A variant of the Stockmayer function for polymers with trifunctional branching nodes (common polycondensation of bi- and tri-functional units) was obtained by Schultz [32]:

$$P_{0,x} = x/y_n^2 \exp\{-x/y_n(\gamma+1)\}; \quad P_{b,x} = \frac{\gamma (x/y_n)^2}{b(b+2)} P_{b-1,x}. \quad (35)$$

Fig. 3*a* shows a Stockmayer-type MWD for polymers with trifunctional and tetrafunctional branching nodes and various γ, the "most probable" distribution being given. Clearly the increase in the degree of branching leads to the appearance of high-molecular-weight "tails" and the MWD maximum is shifted to lower molecular weights; such regularities are actually observed in the synthesis of branched polystyrenes [33] and polybutadienes [34]. For a MWD describable by the system of equations (35), the following relations are obeyed:

$$x_w = \frac{y_w}{1-\gamma}; \quad (36)$$
$$x_n = \frac{y_n}{1-\gamma/3}; \quad (37)$$
$$b_w = \frac{2\gamma}{1-\gamma}; \quad (38)$$
$$b_n = \frac{{}^2/_3\gamma}{1-\gamma/3}. \quad (39)$$

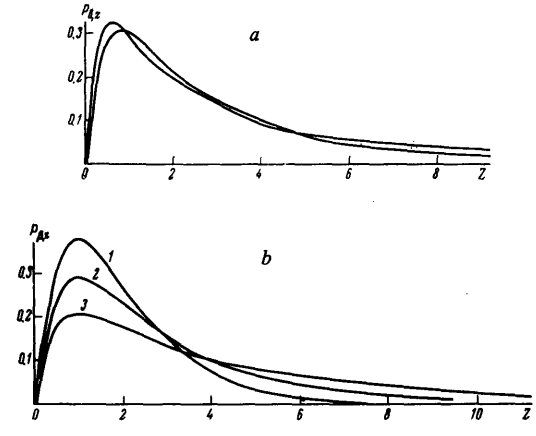

Figure 3. MWD of branched polymers, $Z = x/y_n$: *a*) MWD of the Stockmayer type, $f = 3:1$; *1*) $\gamma = 0.96$; *2*) $\gamma = 0.40$; *b*) MWD of the Beasley type, β: *1*) 0; *2*) 0.2; *3*) 0.499.

Another important distribution function was given by Beasley [35] for the MWD of polymers in the preparation of which the termination of the growing chains is brought about by disproportionation, conversion to the monomer, and conversion to a polymer (trifunctional branching), analytically the Beasley function is expressed by Eqn. (40) (Fig. 3*b*):

$$P_{\beta,x} = \frac{x/y_n^2}{(1+\beta x/y_n)^{1+1/\beta}} \quad (\beta < {}^1/_2), \quad (40)$$

where β is a long-chain branching parameter, equal to the ratio of the number of units in the side-branches and their total number in the macromolecule, with [35,36]:

$$x_n = \frac{y_n}{1-\beta}; \quad (41)$$
$$x_w = \frac{y_w}{1-2\beta}; \quad (42)$$
$$b_n = \frac{\beta}{1-\beta}; \quad (43)$$
$$b_w = \frac{1}{(1-\beta)(1-2\beta)} - 1. \quad (44)$$

Under comparable conditions the Beasley distribution is wider than the Stockmayer distribution. From Eqns. (30)–(34), (36)–(39), and (41)–(44) we obtain the frequently

used relations connecting the polydispersion of the polymer with the mean number of branching nodes:

$$\left.\begin{aligned}\frac{x_w}{x_n}&=\frac{2}{3}\frac{b_w}{b_n};\\ \frac{x_w}{x_n}&=\frac{2}{1-b_n};\end{aligned}\right\}\quad\begin{aligned}&\text{Stockmayer distribution}\\&\text{trifunctional nodes}\end{aligned}\qquad(45),\ (46)$$

$$\left.\begin{aligned}\frac{x_w}{x_n}&=\frac{1}{2}\frac{b_w}{b_n};\\ \frac{x_w}{x_n}&=\frac{2}{1-3b_n};\end{aligned}\right\}\quad\begin{aligned}&\text{Stockmayer distribution}\\&\text{(tetrafunctional nodes)}\end{aligned}\qquad(47),\ (47a)$$

$$\left.\begin{aligned}\frac{x_w}{x_n}&=\frac{1}{2}\left(\frac{b_w}{b_n}-1\right);\\ \frac{x_w}{x_n}&=\frac{2}{1-b_n}\end{aligned}\right\}\quad\text{Beasley distribution}\qquad(48),\ (48a)$$

Certain parameters of the branched polydisperse polymers with the Beasley-type and Stockmayer-type MWD are also shown in Table 3. Other MWD functions for branched polymers obtained in various polymerisation processes and also for the cross-linking and destruction were given detailed consideration by Bamford and Tompa [37], Katsura [38], Spiro [39], etc.

2. Characteristic Viscosity of Branched Polymers

We will assume that for monodisperse polymers the following relations are true:

$$[\eta]_b = g^{1/2}[\eta]_l, \qquad (49)$$

$$[\eta]_l = K_\eta x^a, \qquad (50)$$

where x is the degree of polymerisation, K_η and a are constants for the given series of polymer homologues.

Furthermore let $f(x)$ and $f(\gamma, x)$ be the weight functions of the distribution according to the degree of polymerisation for a linear and a diluted polymers, and γ a branching parameter determinable so that

$$f(\gamma, x)|_{\gamma\to 0} = f(x). \qquad (51)$$

On averaging in accordance with Eqns. (49) and (50) we obtain the following equation for the ratio of the characteristic viscosities of the branched and linear polydisperse polymers:

$$\langle[\eta]_b\rangle/\langle[\eta]_e\rangle = \frac{\int_0^\infty K_\eta g_x^{1/2} x^a f(x,\gamma)\,dx}{\int_0^\infty K_\eta x^a f(x)\,dx}. \qquad (52)$$

By using Eqns. (30) and (36) and taking into account that linear and branched polymers with the same mean weight are being compared, Eqn. (52) can be converted into [40]:

$$\langle[\eta]_b\rangle/[\eta]_e\rangle = (1-\gamma)^a \frac{\int_0^\infty g_x^{1/2} x^a f(\gamma, x)\,dx}{\int_0^\infty x^a f(x)\,dx}. \qquad (53)$$

The calculation of $<[\eta]_b>/<[\eta]_l>$ with the aid of Eqn. (53) is carried out as follows:

1. By using the MWD functions (29), (35), and (40), the number average values of the branching nodes b_n for various x are determined.

2. From the values for b_n, the corresponding values of $g_x^{1/2}$ are found on the basis of Stockmayer's equations (10) and (11).

3. By using the values found for x, $g_x^{1/2}$, and $f(\gamma, x)$ and replacing integration by summation the value of the numerator in Eqn. (53) is calculated.

4. The value of the denominator is expressed by elementary functions. A complete calculation of the ratio $<[\eta]_b>/<[\eta]_l>$ for polydisperse polymers with a Stockmayer-type MWD (with γ variable) was made on an electronic computer by Klib [40] for the tetrafunctional nodes and by Shultz [32] for trifunctional branching nodes (Table 3) and by Myers and Dagon [41] for a Beasley-type MWD.

Table 3. Ratio of the characteristic viscosities of branched and linear polymers of the same mean molecular weight (MWD of the Stockmayer type).

0.7	0.722	0.709	0.744	—	—
0.8	0.633	0.614	0.654	0.61	0.58
0.9	0.490	0.462	0.501	0.47	0.43
0.92	0.450	0.421	0.463	—	—
0.94	0.402	0.371	0.415	—	—
0.96	0.342	0.308	0.364	—	—

The results of Table 3 can be used in evaluating the branching of polydisperse polymers on the basis of measurements of characteristic viscosity. For this a knowledge of the characteristic viscosity of the linear polymer with the "most probable" distribution and the same weight mean molecular weight is necessary. If the value of x_w is known the corresponding value of $<[\eta]_l>$ can be determined by using the equation for the dependence of characteristic viscosity on molecular weight for linear monodisperse polymers

$$[\eta]_l = K_\eta x^a, \qquad (50a)$$

which are usually found in investigating hydrodynamic characteristics; the corresponding equation for the weight mean degree of polymerisation in a θ-solvent has the form [42]:

$$\langle[\eta]_l\rangle = \frac{K_\eta}{1.14} x_w^a. \qquad (54)$$

In principle the ratio $<[\eta]_b>/<[\eta]_l>$ can be compared at the same values of number mean molecular weight, but this method appears less sensitive to branching than that described above [40].

It is noteworthy that estimation of branching of polydisperse polymers with the aid of the $<[\eta]_b>/<[\eta]_l>$ dependence, strictly speaking, is valid only in those instances when the branching reaction leads to the departure of the MWD of polymers from the most probable.

The influence of the form of the MWD functions on the value of $<[\eta]_b>/<[\eta]_l>$ is clear from Table 4, which gives values calculated on the basis of Beasley-type [41] and Stockmayer-type [32] MWD (trifunctional nodes) at equal values

of x_w/x_n (the MWD of a linear specimen is considered "most probable"), with

$$\gamma = \frac{3\beta}{2-\beta}. \quad (55)$$

At equal values of x_w/x_n the Beasley distribution is wider than the Stockmayer distribution; as Table 4 shows, this leads to some decrease (by 6–14%) in the values of $\langle[\eta]_b\rangle/\langle[\eta]_l\rangle$. The Beasley distribution is known to somewhat overestimate the breadth of the experimentally observable curves[41,42] of branched polymers, therefore the use of results obtained with the aid of the Stockmayer equation is evidently more correct.

Table 4. Ratio of the characteristic viscosities of branched and linear polymers depending on the MWD of the branched polymer ($f = 3$).

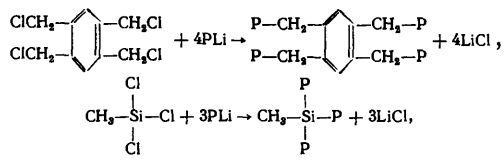
β	x_w/x_n	γ	$\langle[\eta]_b\rangle/\langle[\eta]_l\rangle$	
			Beasley distribution	Stockmayer distribution
0.05	2.11	0.077	0.922	0.981
0.10	2.25	0.158	0.901	0.960
0.15	2.43	0.243	0.876	0.935
0.20	2.67	0.333	0.847	0.906
0.25	3.00	0.429	0.809	0.869
0.30	3.50	0.529	0.763	0.826
0.35	4.33	0.636	0.700	0.766
0.40	6.00	0.750	0.612	0.680
0.45	11.0	0.871	0.465	0.542

In concluding this section it must be emphasised that all the calculated values of $\langle[\eta]_b\rangle/\langle[\eta]_l\rangle$ obtained under the condition that Eqn. (49) is valid are derived, strictly speaking, for the polymer solvent θ-system ($\alpha = 0.5$), therefore the problem of measurements in "good" solvents for the purpose of evaluating the branching still remains open, and corresponding experimental results will be considered below.

VI. SYNTHESIS AND INVESTIGATION OF MODEL BRANCHED POLYMERS

In most polymerisation processes it was previously impossible to predict the number of nodes associated with a single polymeric molecule, the lengths of the branches, the nature of their distribution, or even the functionality of the branching. Therefore it is very difficult to make a strict comparison between the values calculated theoretically under definite conditions and the same quantities observable experimentally. With the aim of surmounting this difficulty attempts were made to synthesise model branched polymers with a geometry known beforehand.

Starlike macromolecules can serve as the simplest models. This type of model polymer is synthesised with the aid of "living" polymeric chains and bonding agents such as 1,2,4,5-tetrachlorobenzene, silicon tetrachloride, methyltrichlorosilane, etc. Several papers[44–48] describe methods of production and give structural characteristics for tri- and tetra-functional starlike polymers of styrene and butadiene; the synthesis proceeds as follows:



where PLi denotes a "live" polymeric chain.

Ideally all the chlorine atoms are replaced by a polymer anion; hence if the initial polymer molecules have a narrow MWD, as a result almost monodisperse branched polymers with a tripled or quadrupled molecular weight are formed. In practice, as a result of incomplete replacement and of side-reactions a mixture of molecules of different molecular weight and functionality is obtained, however, the choice of appropriate conditions gives an overwhelming yield of molecules of the specified structure.

*Zimm–Kilb theory.
**Stockmayer–Fixman theory.

Furthermore, to obtain polymers with high homogeneity both in respect of molecular weights and of the functionality of branching further fractionation is employed, which in this instance is especially effective owing to the great difference in the molecular weights. Sufficiently homogeneous, but low-molecular-weight, branched polymers are evidently formed in the synthesis of polyamides of star structure[49], and also of polyhedra from monodisperse blocks of polyethylene glycols with the aid of the trichloride of trimesic acid and other compounds[50]. Some experimental results for model branched (starlike structure) polymers of styrene are given in Table 5, where p is the value found experimentally for the mean number of branches attached to one molecule.

A method of controlled synthesis making use of the chain transfer reaction to a polymer (with narrow MWD) introduced earlier into the reaction zone has been used[51] for obtaining comblike trifunctional poly(vinyl acetates) with a fixed side-chain length, and with random distribution of the branches along the main "spine". Homogeneous branched polymers with short side-chains of known number and length were thus obtained; statistically branched poly(vinyl acetates) have been synthesised[52]. Fig. 4 and Table 6 give some results from published studies[52,53].

From Tables 5 and 6 and Fig. 4 and also from other experimental results[30,49,50], the appearance of branching actually leads to a decrease in the characteristic viscosity of the corresponding polymers in comparison with the linear ones of equal molecular weight, and the viscosity of the statistically branched polymers is less than that of the comblike ones. The variation predicted theoretically for a θ-solvent of the ratio of the characteristic viscosities of branched and linear polymers at a fixed molecular weight[30], see Eqn. (25), is obeyed satisfactorily for star-like polymers of various chemical structures.

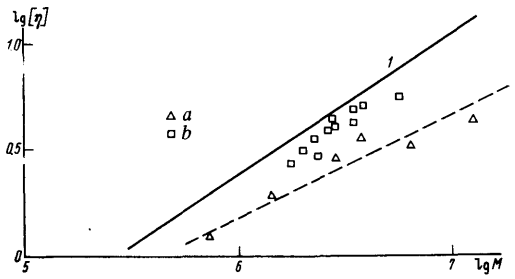

Figure 4. Variation of the characteristic viscosity of poly(vinyl acetates) in benzene at 35°C: *1*) linear structure, $[\eta] \simeq M^{0}$;[68] *a*) statistical branching, $[\eta] \simeq M^{0.47}$; *b*) comblike branching.

It is noticeable, however, that most of the model polymers contained only one branching node, therefore it is evidently still early to extend rule (25) to the region of high branching densities. Furthermore in some instances, for example, for polyethylenes[43] of the high pressure type, poly(vinyl acetates)[53], and other polymers, appreciable departures from the rule are observed, namely, the number of nodes calculated with the aid of Eqn. (25) is greater than expected and for these polymers the relation

$$[\eta]_b/[\eta]_l = g^{\epsilon}, \qquad (56)$$

where $\epsilon > \frac{1}{2}$, holds, that is, Eqn. (25) underestimates the effect of branching.

From Table 6 it is evident that the value of $g^{1/2}$ systematically exceeds the ratio $[\eta]_b/[\eta]_l$ even in a good solvent; from this it follows that when there are a large number of short-chain branches Eqn. (25) also underestimates the effect of branching on the hydrodynamic properties.

Such anomalies are not remarkable, they must be expected at high branching densities, owing to the change in Φ_p (by analogy with P_p). Results on the model branched polymers with a considerable number of branching nodes are still extremely few and relate to polymers with short side-chains[51,53,54].

From the example of poly(vinyl acetate) (Table 6) clearly the ratio $[\eta]_b/[\eta]_l$ in a good solvent is usually greater than that in a θ-solvent and the value of the g-factor characterising the ratio of the dimensions in a θ-solvent is less than the directly measured ratio of the dimensions. This regularity agrees with a stated[55,56] viewpoint that volume effects should be stronger for branched polymers than for linear ones, therefore the characteristic viscosity of branched polymers should increase with improvement in the quality of the solvent more rapidly than the viscosity of the linear ones. However, on assuming that the Flory swelling coefficients α of linear and branched macromolecules are connected by the relation[53]:

$$\frac{\alpha_b^5 - \alpha_b^3}{\alpha_l^5 - \alpha_l^3} = \frac{C_b}{C_l} g^{-1/2}, \qquad (57)$$

where C_b and C_l are constants, which depend on statistics of branched and linear macromolecular coils in the solution, then the difference in the values of the ratios $([\eta_b]/[\eta]_l)_0$ and $([\eta]_b/[\eta]_l)$, should become appreciable only when the molecular weight becomes sufficiently high (~ 500 000). This can explain the fact that this regularity, observable for very high-molecular-weight polymers of vinyl acetate, was not observed for different model structures (Table 5) and the statistically branched polymers of lesser molecular weight[22,36,57,58].

Table 6. Characteristics of branched poly(vinyl acetates)[51-53].

The synthesis of model branched polydisperse polymers with the aim of verifying the corresponding theoretical relations is a much more complex task. Nevertheless, attempts were made to synthesise polymers of vinyl acetate with a known degree of branching (that is, with b_n and b_w) and known MWD, using the method of controllable polymerisation with transfer of chains to the polymer. It has been found[36] that the value of the ratio $\langle[\eta]_b\rangle/\langle[\eta]_l\rangle$ is almost independent of the quality of the solvent, as for monodisperse polymers. Furthermore it has been shown that for the vinyl acetate polymers investigated the relation between the value of $\langle[\eta]_b\rangle/\langle[\eta]_l\rangle$ and the weight mean number of branches b_w there is just the same correlation as between $\langle g^{1/2}\rangle$ and b_w for polymers with a Stockmayer distribution[31]:

$$\langle g^{1/2}\rangle = \left(\frac{6}{b_w}\right)^{1/2}\left\{\frac{1}{2}\frac{2+b_w^{1/2}}{b_w}\ln\frac{(2+b_w)^{1/2}+b_w^{1/2}}{(2+b_w)^{1/2}-b_w^{1/2}} - 1\right\}^{1/2}. \qquad (58)$$

From this there must be a relation of type (25) in this instance:

$$\frac{\langle[\eta]_b\rangle}{\langle[\eta]_l\rangle} = \langle g^{1/2}\rangle. \quad (25a)$$

However, it was shown that this agreement can be accidental and can vary with the nature of the reactions which lead to the branching of the polymeric chains.

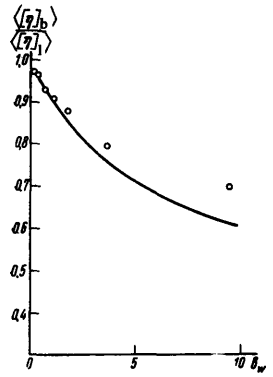

Figure 5. Variation of $[\eta]_b/[\eta]_l$ with the branching density for polymers with a Stockmayer-type MWD, with experimental points plotted from published results [36].

The decrease in the ratio $\langle[\eta]_b\rangle/\langle[\eta]_l\rangle$, expressed directly as a function of the number of branching nodes b_w, does not agree quite so well with the corresponding calculated relation obtained for trifunctional branched polymers with a Stockmayer-type MWD—calculated from the results of Table 4 and Eqn. (38), —see Fig. 5.

VII. VARIATION OF THE HYDRODYNAMIC PARAMETERS OF BRANCHED POLYMERS WITH MOLECULAR WEIGHT

The relations

$$[\eta]_l = K_{\eta l} M^{0.5}, \quad (59)$$

$$S_l = K_{Sl} M^{0.5}, \quad (60)$$

where $K_{\eta l}$ and K_{Sl} are coefficients which remain constant for a given series of polymer homologues, hold for linear monodisperse polymers in a solvent. In good solvents the value of the exponent in Eqns. (59) and (60) differs from 0.5. Most experimental studies on the investigation of branching have been carried out in good solvents and the dependence of the characteristic viscosity of branched polymers on molecular weight in logarithmic coordinates is usually bent towards the abscissa axis [22,33,59-62]. The explanation for this is that with increase in the molecular weight there is usually an increase in the branching density, therefore the dependence of the characteristic viscosity on molecular weight will be weakened, and the corresponding dependence of the sedimentation constant will be intensified; Eqns. (59) and (60) will become:

$$[\eta]_b = K_{\eta b} M^{0.5-\delta}, \quad (61)$$

$$S_b = K_{Sb} M^{0.5+\varphi}. \quad (62)$$

We will first examine the change in characteristic viscosity; from (59) and (61) we obtain:

$$[\eta]_b/[\eta]_l = K_1 M^{-\delta}. \quad (63)$$

In practice the greatest interest is in statistical and comblike branched macromolecules; it will be assumed that the increase in their molecular weight takes place by successive addition of branches of equal length with retention of the functionality of the branching. On assuming the correctness of the relation:

$$\langle[\eta]_b\rangle/\langle[\eta]_l\rangle = h^3,$$

we have:

$$h^3 = K' M^{-\delta}. \quad (64)$$

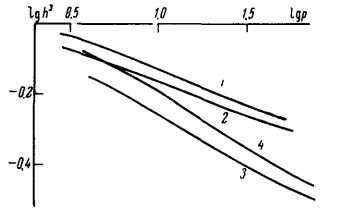

Figure 6. Variation of the ratio of the hydrodynamic dimensions of comblike branched and linear macromolecules with the number of branches: *1*) random distribution of branches with lengths $f = 3$; *2*) branches of equal length, $f = 3$; *3*) branches of equal length, $f = 4$; *4*) random distribution of branch lengths, $f = 4$.

Fig. 6 shows the relation:

$$\lg h^3 = f(\lg M)$$

for comblike branched macromolecules, $f = 3$ or 4, at a fixed branch length, calculated from Kurata and Fukatsu's results, where the number of branches is taken as a measure of the molecular weight; Fig. 6 also gives curves for the random distribution of the branches in length. Treatment of the results in Fig. 6 leads to the following results:

$f = 3$ { $\delta = 0.19$ branches of fixed length, $\delta = 0.20$ random distribution of branch lengths;

$f = 4$ { $\delta = 0.29$ branches of fixed length, $\delta = 0.31$ random distribution of branch lengths.

The values of δ are approximate (they were calculated by neglecting the low curvature of the curves discussed) and correct when the branching nodes lie between 3 and 20.

Earlier [58] for polymers with 1–4 trifunctional branching nodes and fixed branch lengths the value $\delta = 0.09$ was obtained by the relation

$$[\eta]_b/[\eta]_l = g^{1/2}$$

and $\delta = 0.12$ by calculation from Kurata and Fukatsu's results for the initial form of $h^3 = f(g)$ (1–4 nodes). Experimental results for dextranes [64] poly(vinyl acetates) [53], and polysiloxanes [65,66] with a large number of trifunctional

branching nodes, and for polybutadienes with a small number of nodes [47,63] agree satisfactorily with these calculations; for poly(vinyl acetates) $\delta = 20$, for polybutadienes $\delta = 0.09$, and for polysiloxanes $\delta = 0.22$ and 0.30.

Examples where the increase in molecular weight occurs only as a result of an increase in the functionality of the branches (a tenfold change in molecular weight produces a change in functionality from 3 to 30) will not be considered here because of their low practical importance. The value of δ differs from zero only if the increase in molecular weight is accompanied by an increase in the number of branching nodes because of their functionality; when the increase in molecular weight is due solely to the lengthening of the branches at $f = \text{const}$, $p = \text{const}$, then $\delta = 0$. Since

$$S_b / S_l = h^{-1},$$

it is evident that $\varphi = \delta/3$. Hence whereas the absolute value of the ratio of characteristic viscosities or sedimentation constants of the branched and linear macromolecules determine the length of the side-chains their dependence on molecular weight (especially in the range $b > 3$) can serve as an indicator of the functionality.

VIII. TREATMENT OF THE EXPERIMENTAL DATA IN STUDYING BRANCHING

As what has been said above shows, for a definite degree of branching of any polymer its hydrodynamic parameters must be compared with the parameters of the corresponding linear polymer of equal molecular weight, in other words, it is necessary to know the constants in the relation

$$[\eta]_l = K_l M^a \qquad (65)$$

for the linear polymer. However, this relation is not always known previously, and sometimes even the synthesis of the linear polymers presents difficulties. There are two main methods of studying branching in those instances when relation (65) is unknown. In both instances preliminary separation of the test polymer into a series of homogeneous fractions is necessary. The first method, based on the determination of the molecular weights of the fractions and working in a θ-solvent, was first used in studying branching in polymers of butadiene and isoprene [22,59,63].

Extension of the Flory theory of polymer solutions to branched molecules leads to the following relation [59]:

$$[\eta]^{2/3}/M^{1/3} = K_l^{2/3} g_{[\eta]} + 2C_M \psi K_l \frac{M}{[\eta]} g_{[\eta]}^{1/2}\left(1 - \frac{\theta}{t}\right); \qquad (66)$$

where ψ and C_M are constants for a given polymer–solvent system and

$$g_{[\eta]} = ([\eta]_b / [\eta]_l)^{2/3}.$$

From this equation, clearly whereas for linear polymers the relation at the temperature $T = \theta$ (in a θ-solvent) is expressed by a straight line parallel to the abscissa axis, for branched macromolecules this relation should have the form of a curve with negative slope, since $g_{[\eta]}$ in a disordered distribution of branching nodes decreases with rise in molecular weight. However, since as $M \to 0$ the number of branching nodes in the macromolecule also tends to zero and consequently $g \to 0$, the limiting value of $[\eta]^{2/3}/M^{1/3}$ remains as before equal to $K_l^{2/3}$. Hence by constructing this relation for branched polymers it is possible to determine the value of K_l and then by using the ratio $[\eta]_b/[\eta]_l$ to find the number of branches in the macromolecules of any molecular weight. Typical examples of the relation

$$[\eta]^{2/3}/M^{1/3} = f(M/[\eta])$$

for K-polybutadiene polymers obtained at various temperatures [22] are given in Fig. 7.

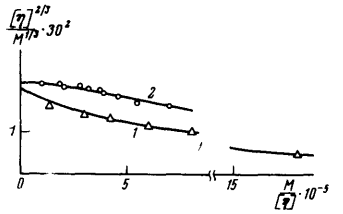

Figure 7. Variation of $[\eta]^{2/3}/M^{1/3}$ with $M/[\eta]$ in a solvent for polybutadienes of various structures: *1*) strongly branched; *2*) weakly branched.

Branching affects the hydrodynamic properties and dimensions, therefore there is a possibility in principle of obtaining information about the branching of macromolecules by direct measurement of any pair of hydrodynamic parameters connected with the coefficients of translational (diffusion, sedimentation) and rotational (characteristic viscosity) friction. This was first discussed by Tsvetkov [67].

This method of evaluating branching, based on combined measurements of sedimentation and characteristic viscosity, was proposed by Blachford and Robertson [68]; it is not necessary to know the molecular weight. It is known that

$$[\eta]_l = K_l M^a; \qquad (67)$$

$$S_l = K_s M^{\frac{1-a}{3}}. \qquad (68)$$

From Eqns. (67) and (68) we obtain

$$S_l = A[\eta]_l^{\gamma}; \qquad (69)$$

where A is a constant and

$$\gamma = \frac{2-a}{3a}. \qquad (70)$$

Applying the Flory theory to linear and branched polymers and assuming that

$$\Phi_l^{2/3} P_l^{-1} \cong \Phi_b^{2/3} P_b^{-1}, \qquad (71)$$

Blachford and Robertson [68] obtain

$$S_l [\eta]_l^{1/3} = S_b [\eta]_b^{1/3}. \qquad (72)$$

On substituting Eqn. (69) in (72) we have

$$A[\eta]_l^{\frac{3\gamma+1}{3}} = S_b [\eta]_b^{1/3}. \qquad (73)$$

Eqn. (73) is the principal one in this method; if γ, A, S_b, and $[\eta]_b$ are known, then the quantity $[\eta]_l$ can be obtained from Eqn. (73) and then the number of nodes in the macromolecules can be found in the usual way through the g-factor. A and γ are determined from the graph of $\lg S$ against $\lg[\eta]$ for fractions of the polymer being investigated, part of which is usually linear. An example of

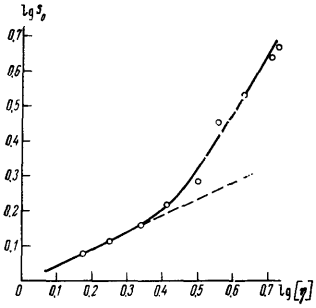

Figure 8. Variation of the sedimentation constants with the characteristic viscosity in benzene for fractions of butadienestyrene copolymer. The broken line corresponds with polymers of linear structure.

such a relation for fractions of emulsion butadienestyrene rubber are given in Fig. 8, and from the initial slope of the graph $A = 0.944$ and $\gamma = 0.61$. This method was used also for studying branching in polyurethanes [69]. The use of θ-solvents increases the accuracy of the method and its resolving power.

IX. OTHER METHODS OF DETERMINING DEGREE OF BRANCHING

The second virial coefficient A_2 is a measure of the interaction of polymer segments with one another in dilute solutions. The value of A_2 depends on the form of the intersegmental interaction potential and the statistics of the macromolecular coil in solution, approximate calculations of A_2 for certain models of starlike branched macromolecules have been given [70,71]. However, at present there is no complete and rigorous theory connecting the value of the second virial coefficient with the structure of branched macromolecules. The virial coefficient can be determined from osmometric and light scattering measurements¶:

$$\pi/c = \frac{RT}{M_n}(1 + A_2c + \ldots), \tag{74}$$

$$Kc/R_0 = \frac{1}{M_w}(1 + 2A_2c + \ldots), \tag{75}$$

where π is the osmotic pressure, R_0 the relative intensity of scattered light, c the concentration, and K a constant.

Extension of the theory of solutions of linear polymers to branched ones leads to the following approximate equation [44]:

$$(A_2)_b/(A_2)_l \cong g^{1/2}\left(\frac{\alpha_b}{\alpha_l}\right)^3, \tag{76}$$

where α_b and α_l are the swelling coefficients of linear and branched macromolecules respectively. Eqn. (76) is further simplified in the limiting case of large volume effects (high-molecular-weight polymer in a good solvent) [53]:

$$(A_2)_b/(A_2)_l = g^{1/2}. \tag{77}$$

¶Calculations of the value of the second virial coefficient for comblike branched polymers of various structures have recently appeared [80,81].

This result, allowing for Zimm–Klib calculations, agrees with the results of Krigbaum and Trementozzi [56], who suggested that for polymers of equal molecular weight the relation

$$(A_2)_b/(A_2)_l \cong \frac{[\eta]_b}{[\eta]_l} \tag{78}$$

is valid.

The experimental results [44,56] show that this relation is well confirmed for polymers with a narrow MWD. Hence the second virial coefficient is also somewhat sensitive to branching, like the value of the characteristic viscosity, but a more reliable theoretical basis and accuracy of measurements makes a study of the hydrodynamic parameters preferable.

A qualitative index of the presence of long-chain branching is the increased value of the Huggins constant K' in the equation for the concentration dependence of viscosity:

$$\eta_{sp}/c = [\eta] + K'[\eta]^2c. \tag{79}$$

For linear monodisperse polymers in a θ-solvent $K' = 0.5$; an improvement in the solvent leads to a decrease in K' and branching to an increase [72]. Therefore the presence of branching at a given K' is best judged by using a θ-solvent. For branched polymers of polystyrene [44,45], poly(vinyl chloride) [73], polybutadiene [74], polyacrylonitrile [75], poly(vinyl acetate) [76], etc. in corresponding "poor" and especially in θ-solvents systematic increasing in the values of K' are observed, whereas in "good" solvents this regularity does not always appear [77,78] and evidently is masked by the effect of polydispersity and volume effects. The relation between K' and branching has not been studied much theoretically, therefore this method remains purely qualitative.

It has similarly been shown [68,79] that the concentration dependence of the sedimentation constant of branched macromolecules is weaker than that of linear ones. An attempt has also been made to qualitatively characterise branching with the aid of the dynamo-optical constants of flow birefringence [59].

Determination of the polydispersity index M_w/M_n can also serve as a criterion of branching. However, the use of the value of M_w/M_n for a quantitative characteristic of branching is justified only in those instances where the branching reaction leads to the production of polymers with a given type of MWD, as for example, in the processes considered by Beasley [35], Stockmayer [31], or Bamford [37]. In the remaining instances when polymers are formed with $M_w/M_n > 2$ and it is known earlier that reaction take place leading to the formation of branched chains, use of the polydispersity index is possible only for qualitative and comparative estimates.

---o0o---

The theoretical principles and experimental methods at present available permit in several instances a qualitative characterisation of the branching of various polymers. However, several problems need further attention. The principal ones are as follows: (1) the development of the theory of characteristic viscosity and of the coefficient of translational friction for branched polymers having an appreciable long-chain branching density; (2) the development of methods allowing long-chain and short-chain branching to be differentiated; (3) the synthesis and investigation of comblike branched polymers of known structure with long side-chains; and (4) a deeper study of polydisperse branched polymers.

Acylation of Hydrazine and Its Substituted Derivatives with Derivatives of αβ-unsaturated Monobasic Acids

T.A.Sokolova and N.P.Zapevalova

The literature on the formation of hydrazides of αβ-unsaturated acids and also five-membered heterocyclic compounds in the interaction of hydrazine and its mono- and di-alkyl-substituted hydrazines with derivatives of saturated monobasic acids is reviewed. The properties and applications of these compounds are described.
The bibliography includes 97 references.

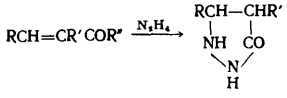
CONTENTS

1. Acylation of hydrazine and monosubstituted hydrazines with αβ-unsaturated acids and their derivatives 1001
2. Interaction of αβ-unsaturated acid derivatives with asymmetrically disubstituted hydrazines 1003

1. ACYLATION OF HYDRAZINE AND MONOSUBSTITUTED HYDRAZINES WITH αβ-UNSATURATED ACIDS AND THEIR DERIVATIVES

Alkylhydrazines $RNHNH_2$ are known to be acylated at the NH_2 or NH group depending on the reagent used and the reaction conditions [1]. As a rule, when mild acylating agents (for example esters) are used and the system is cooled, monoacyl derivatives substituted at the NH_2 groups are formed [2-6]. Under more severe conditions, products of acylation at the NH group are obtained [3]. When monoalkylhydrazines are acylated with acid anhydrides [7,8], the products are acyl derivatives substituted at the NH group, while reaction with acid chlorides or heating with an excess of the anhydride yield *NN'*-diacylalkylhydrazines [9-11].

On the other hand, the interaction of hydrazine with derivatives of αβ-unsaturated acids usually leads to pyrazolidinones (I):[12]

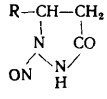


For this reason, the monomeric hydrazides of the majority of αβ-unsaturated acids have not been obtained until quite recently [13,14] and there are numerous contradictory literature data concerning the formation in this reaction of pyrazolidinones or hydrazides. For example, it has been stated [15] that phenylhydrazides of α-methyl and α-butylacrylic acids have been synthesised from their chlorides and phenylhydrazine. On the other hand, when the acids themselves were heated with phenylhydrazine, the products were 4-alkyl(ethyl or butyl)-2-phenyl-3-pyrazolidinones.

In the attempt to synthesise the hydrazides of other αβ-unsaturated acids pyrazolidinone derivatives were obtained†. Thus in the reaction of hydrazine hydrate with acrylic acid unsubstituted 3-pyrazolidinone is formed [15,17] while in the reaction of phenylhydrazine the product is 2-phenyl-3-pyrazolidinone [15,17,19]. Phenylhydrazine reacts with crotonic acid to form 5-methyl-2-phenyl-3-pyrazolidinone [18,20], while the reaction with ββ-dimethylacrylic acid gives 5,5-dimethyl-2-phenyl-3-pyrazolidinone [21,22].

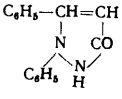
In 1963 Shvaika and Makarenko [23] described the preparation of the hydrazide of methacrylic acid by heating methyl methacrylate with hydrazine hydrate. However, it was found that in reality this results in the formation of 4-methyl-3-pyrazolidinone [24-28]. The infrared spectrum of this compound does not contain an absorption band corresponding to C=C stretching vibrations. Under the action of nitrous acid, the compound is converted [24,26] into 4-methyl-1-nitroso-3-pyrazolidinone and not into the azide of methacrylic acid. The formation of a coloured complex by the acyl derivative of this compound and a trivalent iron ion, recommended as a test for the hydrazide of methacrylic acid [23,29], is also a qualitative test for 3-pyrazolidinones [17,30]. The preparation of the hydrazide of acrylic acid by the reaction of methyl acrylate with anhydrous hydrazine has been reported [31]. However, on treatment with hydrochloric acid this substance too is converted into the hydrochloride of 3-pyrazolidinone, which suggests that it is not a hydrazide but a cyclic isomer.

Muckermann [32] described the preparation of hydrazides by heating crotonic and cinnamic acids with hydrazine hydrate. The products formed hydrochlorides and their reaction with benzaldehyde gave crystalline compounds to which the author [32] attributed to the structure of hydrazones. However, the reaction with nitrous acid gave *N*-nitrosopyrazolidinones (II) instead of the expected azides, which was accounted for by the cyclisation of the unsaturated hydrazides on treatment with nitrous acid [29,32-35]:



(II)

1,5-Diphenyl-Δ^4-3-pyrazolone (III) was obtained by heating cinnamic acid with phenylhydrazine [36]. The author suggested that the phenylhydrazide is formed initially and then cyclises and is oxidised by atmospheric oxygen:

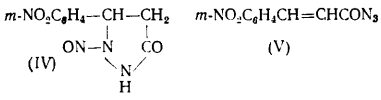


(III)

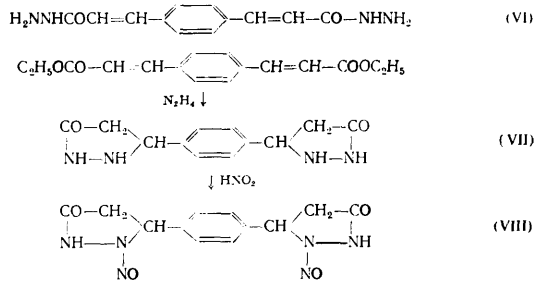
Two compounds were obtained on treating ethyl *m*-nitrocinnamite with hydrazine hydrate [37,38]. Both substances interacted with aldehydes and ketones and on this basis the author regarded them as different forms of hydrazides. However, one of these compounds, formed as the main product, is converted under the action of nitrous acid [38] into *N*-nitrosopyrazolidinone (IV) and the other (the side

†In the presence of oxygen, hydrazine can reduce the double bond of unsaturated acids [16].

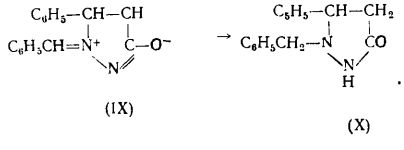
product) is converted into the azide (V), i.e. it is the acid hydrazide:



By allowing diethyl p-phenylenediacrylate to react with hydrazine hydrate in alcohol, Ruggli and Theilheimer [39] obtained a substance which was erroneously regarded as the dihydrazide (VI), although the structure of the bis-pyrazolidinone derivative (VII) was also considered for it. On treatment with nitrous acid, the substance is converted into the N-nitroso-derivative (VIII):

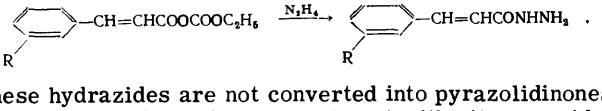


The formation of nitroso-derivatives under the action of nitrous acid demonstrates that the products of the reaction of $\alpha\beta$-unsaturated acids with hydrazine hydrate have the structure of pyrazolidinones [25-27,31]. However, a serious objection against this structure is the capacity of these compounds to condense with aldehydes and ketones. This contradiction was resolved by Godfredsen and Vangedal [40], who proposed the betaine structure (IX) for the product of the condensation of 5-phenyl-3-pyrazolidinone with benzaldehyde. On catalytic hydrogenation of this compound, one mole of hydrogen is absorbed and 1-benzyl-5-phenyl-3-pyrazolidinone (X) is obtained [40], which confirms the structure of compound (IX):



Later products of the interaction of 5-phenyl-3-pyrazolidinone with other aldehydes were also obtained [28,41].

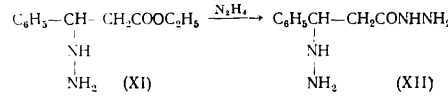
The hydrazides of cinnamic, m-nitrocinnamic, and p-nitrocinnamic acids have been obtained by the action of hydrazine hydrate on the mixed anhydrides of the corresponding acids with a carbonic ester:



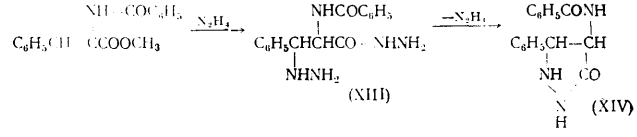
These hydrazides are not converted into pyrazolidinones on heating and yield azides on treatment with nitrous acid. It has been suggested [40] that the first stage in the formation of pyrazolidinone is the addition of hydrazine to the double carbon–carbon bond, which is followed by cyclisation to 3-pyrazolidinone.

The addition of monosubstituted hydrazine involves either the free or the alkylated amino-group of the hydrazine depending on the reaction conditions which results in the formation of 3-pyrazolidinone with substituents at the N_1 [24,31,40-43] or N_2 [15,18-22] nitrogen atoms.

The cyclisation is fairly slow and the hydrazine-ester formed initially, for example (XI), yields the hydrazide (XII) in the presence of an excess of hydrazine:



In the attempt to synthesise the hydrazides of α-benzoylaminocinnamic acid by the reaction of the methyl ester of this acid with an excess of hydrazine hydrate, Stodola [44] obtained the hydrazide (XIII) which on heating *in vacuo* was converted into 4-benzamido-5-phenyl-3-pyrazolidinone (XIV) with elimination of hydrazine. The benzamido-group was unaffected:



Hydrazides of unsaturated β-hydrazino-acids have also been obtained by treating esters of cinnamic and m- and p-nitrocinnamic acids with an excess of hydrazine hydrate [11,40,45].

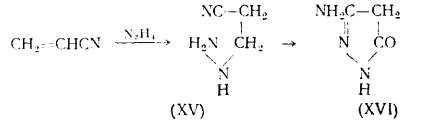
In a series of studies Deles and Polackowa [46-49] investigated the effect of the substituent on the rate of reaction and the yield of the product of the interaction of hydrazine with esters of ring-substituted cinnamic acids. When esters of cinnamic, m- and p-bromocinnamic, m- and p-nitrocinnamic, and p-methoxycinnamic acids were treated with hydrazine hydrate, a mixture of the β-hydrazino-ester, the hydrazides of the unsaturated and β-hydrazinodihydrocinnamic acids, and the corresponding pyrazolidinone was obtained. The authors established that the pyrazolidinones are formed by the cyclisation of the hydrazino-esters, but in the presence of an excess of hydrazine hydrate they are in turn capable of being converted with ring opening into the hydrazides of the β-hydrazino-acids.

Thus the first step in the formation of pyrazolidinone is the addition of hydrazine to the double bond of the $\alpha\beta$-unsaturated acid. Probably pyrazolone derivatives are formed similarly from esters of $\alpha\beta$-acetylenic acids [29,50,51]. This mechanism appears to be very probable [52], since the double bond in derivatives of $\alpha\beta$-unsaturated acids readily combines with nucleophilic reagents, including hydrazines [7,15-20,42,43,50-64].

The main chemical evidence in the determination of the structure of the products of these acylation reactions comes from their interaction with nitrous acid. Pyrazolidinones then yield N-nitroso-derivatives and hydrazides give the azides. In the hydrogenation of hydrazides over metallic catalysts one mole of hydrogen is absorbed with formation of saturated acids, while pyrazolidinones are not hydrogenated.

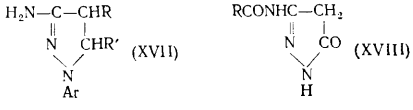
The most thoroughly investigated addition to an activated double bond is the interaction of nucleophilic agents (including hydrazines) with acrylonitrile. Several reviews have been published on the cyanoethylation reaction [52,54-57]. Hydrazine readily reacts with acrylonitrile yielding mono-, di-, tri-, and tetra-cyanoethylation products depending on the reaction conditions [7,57]. In the

presence of basic catalysts the β-cyanoethylhydrazine (XV) obtained cyclises to 3-aminopyrazoline (XVI):[7]



(XV) (XVI)

Substituted aminopyrazolines (XVII) were obtained by the cyanoethylation of phenylhydrazine in an alkaline medium and also by the reaction of phenylhydrazine with the nitriles of methacrylic, crotonic, or cinnamic acids[60,61]:



(XVII) (XVIII)

Acylhydrazines are also cyanoethylated at the amino-group both without catalysts and in the presence of acids[62,63]. In an alkaline medium the imino-group is probably cyanoethylated with subsequent cyclisation to the acylaminopyrazoline (XVIII). Monoalkylhydrazines react with the nitriles of αβ-unsaturated acids, forming derivatives substituted at the NH_2 or NH group[7,63] depending on the reaction conditions.

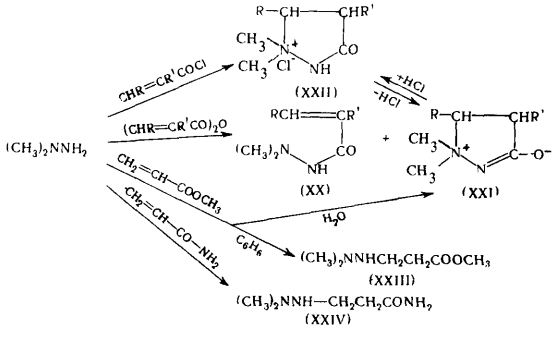
The interaction of derivatives of αβ-unsaturated acids with hydrazine and substituted hydrazines is nowadays widely used for the synthesis of pyrazolidinones[26-28,43,64-69]. It is also used for the identification of the products obtained in studies on other reactions.

2. INTERACTION OF αβ-UNSATURATED ACID DERIVATIVES WITH ASYMMETRICALLY DISUBSTITUTED HYDRAZINES

Derivatives of αβ-unsaturated acids react with asymmetrically disubstituted hydrazines in different ways depending on the reagent and the reaction conditions. For example, dimethylhydrazine adds to the double bond of acrylonitrile[59] with formation of a monocyanoethylation product (XIX):

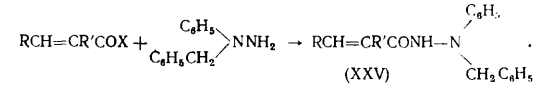
(XIX)

The action of the chlorides, anhydrides, and esters of αβ-unsaturated acids on asymmetric dimethyl- and benzylphenyl-hydrazines was investigated by Sokolova and co-workers[25,26,70-76]. The reactions of dimethylhydrazine with derivatives of αβ-unsaturated acids are represented by the following general scheme[26]:



where (a) R = R′ = H, (b) R = H and R′ = CH_3, and (c) R = CH_3 and R′ = H.

The products of the acylation of dimethylhydrazine with the anhydrides of acrylic, methacrylic, and crotonic acids are the dimethylhydrazides of these acids (XX) together with isomeric compounds (XXI) which the authors call 1,1-dimethylpyrazolinium 3-oxides[25,26,70,71]. When the chlorides of αβ-unsaturated acids are used, the salts (XXII), i.e. the hydrochlorides (XXII) of compounds (XXI), are formed[26,71]. The interaction of aqueous solutions of the salts (XXII) with anion-exchange resins yields the bases (XXI). The mode of the reactions of the esters of the same acids with dimethylhydrazine and the yields depend on the structure of the ester and the nature of the solvent. In polar solvents (water, alcohol) 1,1-dimethylpyrazolinium 3-oxide (XXI, a) is formed in almost quantitative yield from methyl acrylate and dimethylhydrazine, while the reaction with methyl methacrylate under the same conditions results in the formation of compound (XXI, b) in a much lower yield, which agrees with the lower activity of the C=C bond in the methacrylic acid ester[26,73]. In a non-polar medium or without a solvent dimethylhydrazine reacts with methyl acrylate, the product of addition to the double bond (XXIII) being formed. When an even weaker acylating agent (acrylamide) is used, the reaction with dimethylhydrazine yields only the product of addition to the double carbon–carbon bond (XXIV) regardless of the polarity of the medium[26]. On the other hand, in the reaction of the chlorides and anhydrides of αβ-unsaturated acids with asymmetric benzylphenylhydrazine cyclic compounds were not obtained. High yields of the benzylphenylhydrazides of the corresponding acids (XXV) were produced[26,72]:

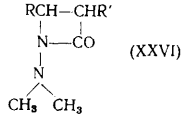


(XXV)

It is suggested[26,71,72] that cyclic compounds are not formed due to the screening effect of the bulky substituents at the nitrogen atom and the lower basicity of benzylphenylhydrazine compared with dimethylhydrazine, which hinders the nucleophilic addition of hydrazine to the double carbon–carbon bond[26].

The Structure and Properties of Hydrazine Alkylation Products

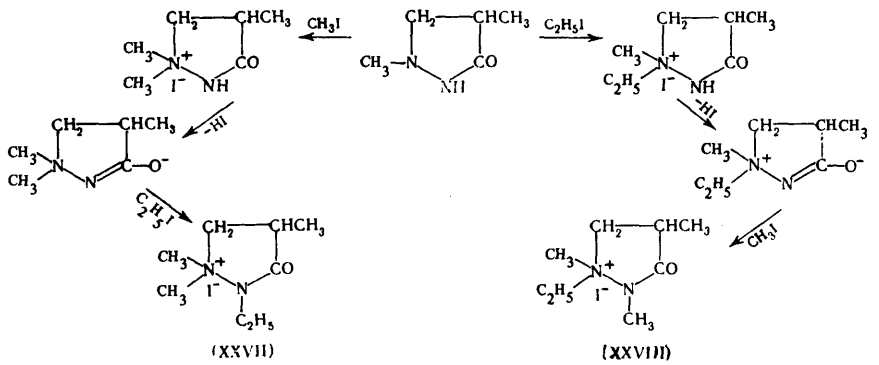
The interaction of dimethylhydrazine with derivatives of αβ-unsaturated acids is a method for the synthesis of the asymmetrically disubstituted hydrazides of these acids and also of a new class of heterocyclic compounds with a dipolar structure. On the basis of PMR spectra and studies of the hydrogenation products, the structure of *N*-dimethylamino-2-azetidinones (XXVI) was attributed initially to the cyclic isomers of the dimethylhydrazides[74,76]:



(XXVI)

However, it was subsequently shown by synthesis of pyrazolidinones of known structure[28] and also by the synthesis of various alkiodides and the study of their PMR spectra[26,74,75] that these compounds have the structure of compound (XXI).

Isomeric alkiodides (XXVII) and (XXVIII), which differ in the disposition of the methyl and ethyl groups at the nitrogen atom, were obtained by altering the order in which the initial 1,4-dimethyl-3-pyrazolidinone was methylated and ethylated [25,26]:



(XXVII) (XXVIII)

The crystalline alkiodides (XXVII) and (XXVIII), which have the same composition, exhibit different properties. With the β-lactam structure (XXVI) the same substance having all three alkyl groups at one nitrogen atom should be obtained regardless of the order of methylation and ethylation. However, the study of the PMR spectra of the alkiodides obtained showed [75] that two alkyl groups are located at one nitrogen atom while the third is at the second nitrogen atom.

The infrared spectra of compounds (XXI) show intense absorption bands in the region of 1580 cm^{-1}, which the authors assigned to absorption by the oxide group $-N=C-O^-$. [25,26,71] Such bands are also observed in the spectra of dipolar compounds with the linear structure (XXIX)‡ containing the group $N=C-O^-$: [77-80]

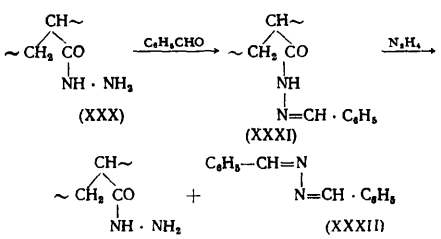
$$RCO\bar{N}-\overset{+}{N}(CH_3)_3 \leftrightarrow R\overset{O^-}{\overset{|}{C}}=N-\overset{+}{N}(CH_3)_3 \quad (XXIX)$$

In 1966 Wadsworth [65] synthesised several derivatives of pyrazolinium 3-oxides and called them, by analogy with Hinmann's compounds [77], cyclic amine-imides [65]. The pyrolysis of these cyclic compounds gave good yields of the dimethylhydrazides of methacrylic and crotonic acids [65]. Sokolova et al. [80] obtained by this procedure from 1,1-dimethylpyrazolinium 3-oxides the dimethylhydrazide of acrylic acid (XX, a), which is difficult to synthesise. Dimethylhydrazides of αβ-unsaturated acids are bases, like pyrazolinium 3-oxides, capable of combining with hydrogen halides and alkyl iodides [25,26,71]. The interaction of the methiodides of the dimethylhydrazides with bases (anion exchangers) results in the formation of the trimethylamine-imides of the corresponding unsaturated acids (XXIX). [78,80] The dimethylhydrazides of acrylic and methacrylic acids, their hydrochlorides, methiodides, and the trimethylamine-imides obtained from them are capable of polymerising in the presence of free-radical initiators with formation of high-molecular polyelectrolytes [81].

---o0o---

The interaction of arylhydrazines with derivatives of αβ-unsaturated acids [42,43,62,66-69,82-86] is one of the methods of synthesising "phenidones", i.e. 1-aryl-3-pyrazolidinones, which are important in photographic and cinematographic practice. They exhibit the properties of "superadditivity", increasing sharply the activity of hydroquinones in developing solutions [87-94]. 1-Phenyl-3-pyrazolidinone is used as a reducing agent in the determination of phosphorus in proteins [95].

Since the acylation of hydrazine is accompanied by cyclisation to pyrazolidinones, the preparation of unsaturated acid hydrazides is difficult and therefore Kern and coworkers [13,14] employed polymer-analogue reactions to prepare the polyhydrazides of acrylic and methacrylic acids. For this purpose, polyacrylic and polymethacrylic acid esters were treated with hydrazine hydrate. The polymeric hydrazides obtained in this way (XXX) are converted by treatment with aldehydes into polymeric hydrazones (XXXI) and can be used as "aldehyde-exchange" resins [14]. After the decomposition of the polymeric hydrazone (XXXI) with dilute sulphuric acid, the aldehyde may be re-isolated by steam distillation and the polymeric hydrazide is at the same time hydrolysed to polyacrylic acid. The polymeric hydrazone may be decomposed with hydrazine hydrate. Then the polymer is re-isolated as the hydrazide (XXX) and the aldehyde as the aldazine (XXXII): [14]



(XXX) (XXXI) (XXXII)

Polymeric hydrazones obtained by the interaction of polymeric acrylic hydrazide with aromatic hydroxyaldehydes may couple with diazo-compounds, forming polymeric azo-dyes with colours ranging from yellow to brown and brownish-black [14].

Polyhydrazides obtained by treating with hydrazine the copolymer of styrene and methyl acrylate have been proposed for the investigation of chain reactions and for use as polymeric soaps [29,96].

Polymeric hydrazides of methacrylic acid have been proposed as metal extractants. They form chelate complexes with nickel, cadmium, zinc, copper, and cobalt ions [97].

‡Hinmann [77] called such compounds trimethylamine-imides. This name cannot be regarded as sufficiently exact. Possibly these substances could be called *NNN*-trimethylhydrazinium *N'*-alkylidene-α-oxides.

Disperse Condensates of Metal Vapour

M.Ya.Gen and Yu.I.Petrov

This review deals with the role of associated complexes in the condensation and crystallisation of metals from their vapours. The presence in the metal vapour of polyatomic complexes (whether originally present or formed above the evaporation surface) is shown to have a significant influence on the initial condensation step on a solid surface or in an inert carrier gas. The mechanism of formation of highly disperse aerosol metal particles is discussed in detail. Some aspects of crystal and film growth from the vapour are briefly mentioned. 288 references.

1. INTRODUCTION

Metal vapours are usually treated as monatomic ideal gases in studies of elementary crystallisation processes from the gas phase (preparation of aerosol particles, and growth of single crystals, whiskers, and films).

The possibility of formation of polyatomic complexes in the gas phase is often ignored. Yet, complexes of this type can be evolved during evaporation of a metal, or alternatively they can be formed by atomic collisions if conditions are favourable to the removal of the heat of condensation.

Since the condensation of a metallic vapour is essentially a non-equilibrium process, it is important to define the kinetic aspects of the irreversible dissipation of the energy of the colliding atoms. In principle, this energy can be dissipated by ternary collisions of the metal atoms close to the evaporation surface, or by ternary collisions involving atoms of the carrier gas, the excess of energy being eventually transferred to the walls of the vessel.

In an analysis of the elementary processes involved in the crystallisation of a metal from its vapour, it is important to include the irreversible dissipation of the energy of the condensing atoms and the subsequent growth and coagulation of the polyatomic complexes. This approach is gaining wide acceptance.

2. POLYATOMIC COMPLEXES IN REAL GASES

Many scientists (Boltzmann, Clausius, van der Waals, and others) have ascribed departures from ideal gas behaviour to the formation of associated complexes in real gases[1].

Much experimental evidence (both direct and indirect) is now available on the existence of these associated species in the vapour of practically all substances. Most of the work has concentrated on measurements of the partial pressure and dissociation energy of dimers. The results have been summarised in a number of reviews[2-6].

The analytical methods most commonly used to study the composition of the gas phase are the spectroscopic[2,3] and the mass spectrometric method[4], but other methods also have been applied: measurements of molecular velocities, measurements of the displacement of a molecular beam in a magnetic field, the magnetic resonance method, the torsional variant of the effusion method, and the beam density method.[5]

The dissociation energy of the dimer is usually referred to a temperature of 0°K, and is denoted by D_0.

D_0 values for approximately 40 elements up to Rn ($Z = 86$) are known at present. However, among the 23 transition metals the bond energy of the dimer is known only for nickel ($D_0 = 3.36 \pm 0.217$ eV).[7]

Drowart and Honig[4] showed that D_0 varies periodically with the atomic number Z. Verhaegen and coworkers[6] established a periodic dependence upon the atomic number Z of the ratio of the heat of evaporation of an atom at 0°K (ΔH_0) to the dissociation energy of the dimer D_0. All the existing data fall into three distinct classes, depending on the electronic structure of the element.

The relative equilibrium vapour pressure of the dimer (P_2) is given by the expression[6]

$$\frac{P_2}{P} = \text{const}\, e^{\frac{\Delta H_0}{RT}\left(\frac{1-\alpha}{\alpha}\right)},$$

where P is the vapour pressure of the monomer, R is the gas constant, T is the absolute temperature, and $\alpha = \Delta H_0/D_0$. If $\alpha < 1$, the concentration of the dimer decreases with increase of temperature. This is the case with molecules which are known to be stable at low temperatures (N_2, I_2, etc). For Bi_2, $\alpha \simeq 1$, and we can expect the relative amount of the dimer to be insensitive to temperature. Experimentally, the proportion of Bi_2 in the vapour shows a fast initial increase with temperature, reaches a maximum of ~45% in the region of 500°, and then begins to decrease slowly.[8] More recent measurements, however, suggest that the concentration of dimers may remain constant in the region 500–900°, since a vapour composition of 43% Bi + 57% Bi_2 has been reported[9] for 900°.

When $\alpha > 1$, as in the case of carbon and the metals, the proportion of dimers in the saturated vapour increases with temperature. Thus, for sodium vapour $P_2/P = 8.61 \times 10^{-4}$ at 127° and 0.25 at 727°; similar (though numerically smaller) values are obtained for Li and K vapours[5].

For Cu, Ag, and Au, $\alpha = 1.8 \pm 0.1$,[6] and the relative concentration of dimers in the temperature region 1300–1500°K is $(4-10) \times 10^{-4}$.[10] Other examples can be found in Nesmeyanov's monograph[5].

The vapours of some alloys (Ag–Au, Ag–Cu, Au–Cu,[11] and Ag–Sn, Au–Sn, Cu–Sn[12]) contain, in addition to atoms of the components, also symmetrical (Cu_2, Ag_2, Au_2, Sn_2)

and unsymmetrical dimers (AgAu, AgCu, AgSn, AuSn, AuCu, CuSn). The bond energies of these dimers are listed in Table 1.

These values are comparable to the dissociation energies of molecules such as Cl_2, Br_2, I_2.

Table 1. Bond energies of some metal dimers

Dimer	T, °K	D, eV	Literature reference	Dimer	T, °K	D, eV	Literature reference
Ag_2	1260—1360	1.63±0.03	10	AgAu	0	2.06±0.096	11

					0	1.97±0.096	11

The bond energy D of the dimer can be simply related, in the case of hydrogen-like atoms, to the ratio of the ionisation potentials[14] of the given atom and of the hydrogen atom:

$$D = \frac{e^2}{4r_0}\left(\frac{I_X}{I_H}\right)^{1/2},$$

where e is the electronic charge (c.g.s.) and r_0 is the equilibrium separation of the atoms in the dimer. The extent to which this formula applies in practice is evident from Table 2.

Polyatomic complexes have been found to exist in many vapours. Thus, Miescher and Metzger[15-17] made the following observations in their study of the molecular complexity of vapours. Tellurium evaporates as Te_2 at 320°, selenium evaporates as 90% Se_6 and 10% Se_2 at 180°; arsenic evaporates as As_4 at low temperatures, as 70% As_2 + 30% As at 260°, and the vapour consists almost exclusively of As_4 molecules up to 530°.

According to Niwa and Yosiyama[18], selenium evaporates as an equilibrium mixture of Se_6 and Se_2, the proportion of Se_2 increasing from 12% at 185° to 25% at the boiling point. The presence of Se_2, Se_6, and Se_8 in selenium vapour near the boiling point has been inferred from measurements of the vapour density[19,20].

Early measurements[5] indicated that the vapour over liquid antimony consists of molecules containing 1, 2, and 4 atoms, whereas on approaching the boiling point the vapour consists mostly of dimers.

These results have been confirmed more recently by a mass spectrometric method[21], and some interesting features of the evaporation of antimony (both pure and from Au–Sb alloys) have been pointed out. Antimony vapour at ~550° consists entirely of Sb_4, whereas the vapour over an Sb–Au alloy contains Sb_2 and Sb in addition to Sb_4; at 950° the vapour contains 10% Sb and 25% Sb_2. On increasing the temperature from 800 to 1100° the concentration of Sb_2 and Sb increases by a few per cent because the concentration of Sb_4 decreases. The composition of the vapour is independent of the concentration of antimony in the alloy between 15 and 60%.

Searcy and coworkers[22], using the torsional variant of the effusion method, detected a large concentration of polyatomic molecules in silver vapour at pressures of 10^{-6}–10^{-4} atm. In the temperature range 1310–1420°K the effective molecular weight of the vapour was $M = 278 \pm 90$, corresponding to a molecular complexity of 2.56. The lack of agreement with Drowart and Honig's mass spectroscopic results[10] is probably due to a significant concentration of polyatomic complexes which escaped detection by the mass spectrometer. Korniev and Vintaikin[23] studied the sublimation of silver by combined radiochemical and mass spectrometric methods, and showed that (in contrast to evaporation from the melt[22]) evaporation from the solid involves exclusively monatomic species. Positive and negative polyatomic ions were detected in the mass spectra of Se, Te, Sb, and Bi vapours[24]. Mass spectrometric studies[25] of Ge, Sn, and Pb vapours revealed polyatomic complexes up to mass number ~400 at pressures of 5×10^{-6}–5×10^{-4} mmHg. The published plots make it clear that the predominant polymeric species in Ge vapour consists of 4-atomic groupings, whose proportion at 1300 and 1370° is 7×10^{-3} and 2×10^{-2} respectively of the number of single atoms.

Table 2. Dissociation energies of the dimers of some elements[14]

Dimer	$(I_X/I_H)^{1/2}$	r_0, Å	D, eV (observed)	D, eV (calc.)	Dimer	$(I_X/I_H)^{1/2}$	r_0, Å	D, eV (observed)	D, eV (calc.)

In tin vapour the ions Sn_2^+ and Sn_4^+ were detected at < 1% concentration at 1200°; the ratio of ion currents for the evaporation of lead (~800°K) was $Pb_2^+/Pb^+ = 3 \times 10^{-5}$. Schissel[13] found a significant concentration of trimers and tetramers in Cu, Ag, and Au vapours.

Carbon vapour gives a large number of peaks in the mass spectrum[4,26,27], from which the partial pressures of C, C_2, C_3, ..., C_7 molecules have been computed up to 4000°K.[28] A large number of polymeric molecules was found in the mass spectra of C, Be, Mg, Ti, Fe, and Cu vapours generated in a high-frequency discharge[29]. Under these conditions, molecular ions up to C_{31}^+, Be_{25}^+, Al_{14}^+, Mg_5^+, Ti_5^+, Fe_6^+, and Cu_5^+ can be detected.

The dissociation energy of the complexes Bi_2, Bi_3, Bi_4, and BiPb has recently been determined mass spectrometrically[30].

Most workers are of the opinion that the polyatomic complexes appear in the mass spectrum as a result of the evaporation of organised groupings from the liquid metal. This opinion is based on the low probability of binary and ternary atomic collisions at low pressures of metal vapour (10^{-4}–10^{-5} mmHg) over a crucible or in a beam emerging from a Knudsen cell, and also on the pressure independence of the various ion current ratios[24,25]. Martynkevich[31,32] has stressed the correlation between the complexity of the vapour and the structure of the liquid metal. These views are confirmed by the effect of irradiation with thermal neutrons on the composition of indium vapour[33]: after

irradiation, the ratio of ion currents for dimers and monomers in the temperature range 773–1373°K increases by a factor of 15–50. The effect of irradiation persists for a long time (up to one year), but falls off rapidly if the sample is heated 50–100° above the working temperature.

Studies[34-40] of the mass spectra of gases escaping at supersonic speeds into a vacuum from an orifice are very relevant to the mechanism of formation of polyatomic complexes. Associations of ten or more molecules have been detected in molecular beams of many gases (Ne, Ar, N_2, O_2, CO_2, H_2O, NH_3, N_2O, C_2H_6, C_3H_6), and the complexes $ArCO_2$, Ar_2CO_2, $Ar(CO_2)_2$, etc. have been identified in molecular beams of CO_2–Ar mixtures. It is assumed that these associations must be present at equilibrium in the reservoir[34], or alternatively they must be formed during the adiabatic expansion of the gas[35,37-39]. On changing the pressure in the reservoir from 100 to 700 mmHg the mean number of molecules in N_2 associations increases from 160 to 6500, and the proportion of free molecules in the beam falls from 30 to 0.15%.[40]

These experimental findings indicate the presence of large numbers of polyatomic complexes in real gases. As a rule, these complexes do not generate a large partial pressure, they cannot contribute significantly to the observed pressure dependence of the low-temperature thermal conductivity and viscosity coefficients[41], and they have no effect on the formation of films on solid surfaces. The presence of molecular associations in moist air manifests itself in the absorption of ultrasonic energy[42]. Hence, no theory of gases can be satisfactory unless it makes allowance for the presence of associated complexes.

Mayer's group theory[43,44] was the first step towards a solution of this problem. This theory, based on the approximate evaluation of the partition function, treated a real gas as a rapidly changing assembly of non-interacting groups of 1, 2, 3... molecules.

Band[45], Frenkel'[46,47], and Vukalovich and Novikov[48,49] produced independently—and almost simultaneously—an approximate formulation of the complete functional dependence of the molecular weight distribution of the complexes upon pressure and temperature. Their theories rely on similar physical assumptions, which were most clearly stated by Vukalovich and Novikov as follows:

1. Molecular association is a basic process common to all states of a gas.

2. Association is caused by the van der Waals interactions between gas molecules. Because these forces are weaker than the chemical bonds holding simple molecules together, the latter retain their structure and their properties in the complex.

3. Complex formation occurs by the collision of at least three molecules; some of the colliding molecules combine into relatively stable aggregates, whilst the remainder take away the heat of condensation in the form of translational kinetic energy.

4. The associated complexes are assumed to be in thermodynamic equilibrium with the single molecules and to have the same translational energy. The average life-time of the complex is much greater than the duration of a simple molecular collision. Below the critical temperature of the liquid–vapour phase transformation the bond energy of the association is higher than the thermal energy, and the dimers are stable. As the size of the complex increases, the bond energy of each molecule within the complex also increases. As Tables 1 and 2 show, the bond energy of the dimers can be much higher than the thermal energy.

5. A real gas is treated as a mixture of simple gases, consisting of single molecules, dimers, trimers, etc. When the system is in equilibrium, the dissociation of the complexes in any of these gases is exactly compensated by the formation of the same complexes from the simpler species present in the other gases. These processes are entirely analogous to reversible chemical reactions.

Frenkel'[46,47] developed the theory of hetero-phase fluctuations, according to which the distribution of associated complexes is described by the general formula of fluctuation probabilities:

$$N_r \sim \text{const}\, e^{-\Delta\Phi(r)/kT},$$

where N_r is the number of complexes having radius r, and $\Delta\Phi(r)$ is the fluctuation in the thermodynamic potential of the gas resulting from the appearance of a complex with radius r. The calculation predicts a substantial proportion of aggregates containing upwards of 1000 molecules in the saturated vapour.

Ginnel[50] developed a theory of association from the concepts of chemical kinetics. Taking account of topological differences between complexes (linear and closed chains) he deduced a system of equations from which equilibrium constants for the growth and decomposition of the aggregates could be obtained by the matrix method.

Chakraverty[51] discussed the formation kinetics and the steady-state distribution of complexes over molecular weight by solving the stochastic problem.

The concentration of dimers in Ar, Kr, etc. at ordinary temperatures and pressures was found[52] to be approximately 0.1% by an approximate evaluation of the statistical integral.

Since the presence of associated complexes in any real gas is now experimentally established, it becomes imperative to re-examine the problem of liquid–vapour phase transformations.

We are not concerned here with a discussion of the classical theory of the condensation of a supersaturated vapour developed by Volmer and Weber[53] and by Becker and Döring[54] (VWBD), based on the concept of a critical nucleus arising in an ideal monoatomic vapour at some well defined critical supersaturation as a result of fluctuations. The many theoretical and experimental studies of this problem have been adequately summarised in review articles and monographs[55-60]. We shall confine ourselves to a few remarks.

The VWBD theory is unsatisfactory in that it attempts to apply Kelvin's equation to very small aggregates: the concept of surface free energy becomes meaningless when most of the atoms lie on the surface[61-63]. Studies of the thermodynamics of very small systems are continuing to attract attention[64-71].

Attempts have been made[72,73] to deal with polyatomic complexes within the framework of the VWBD theory. The kinetic equations[54] were generalised by including the attachment or removal of complexes as well as single atoms. Frisch and Willis[72] found that the probability of formation of critical nuclei in the vapour is increased by the presence of dimers. However, Katz and coworkers[73] reached the opposite conclusion. Dunning[74] found an analogy between Mayer's and VWBD's theories under certain conditions.

In any nucleation theory based on Mayer's approach, the Mayer groups must be indistinguishable from the real polyatomic complexes found in the supersaturated vapour. If the Brownian motion (both rotational and translational) of the droplets is ignored, this approach leads to an equation for the equilibrium concentration of critical nuclei which is identical to the corresponding equation in the VWBD theory[75].

According to Lothe and Pound[76], allowance for the translational and rotational motion of the polyatomic complexes increases the classical rate of homogeneous nucleation by a factor of 10^{17} (!). A lively polemic on this topic is in progress[77-83].

The VWBD theory fails to take account of the influence of an inert carrier gas. As Bradley points out[84], the theory is not applicable at high pressures, because the diffusion parameters (which play an essential role under these conditions) do not appear in the formula for the rate of formation of critical nuclei. Bradley shows by a thermodynamic argument that on increasing the pressure of inert gas the supersaturated vapour becomes undersaturated, and the rate of formation of critical nuclei falls to zero.

In the presence of equilibrium polyatomic complexes in the vapour phase we are compelled to re-examine critically both the concept of a vapour phase and the familiar concept of "supersaturation", which has hitherto been applied exclusively to a non-associated vapour. The problem is to define the maximum size of a complex which can be treated as part of the gas phase from the point of view of partial pressure, density, and therefore also degree of supersaturation.

On the other hand, it is not easy to define the size of complexes beyond which one must treat the phase as condensed.

On changing the pressure or the temperature of a vapour, the complexes adopt a new size distribution, and a macroscopic liquid is simply the largest drop within the given distribution of complexes. From this point of view, the concept of supersaturation has no clear meaning, since a pressure in excess of the equilibrium pressure of non-associated vapour does not give rise to a distinct new phase but simply alters the size distribution of complexes in the vapour.

It is important to stress the fact that all the statistical and thermodynamic theories of vapour condensation discussed above rely on equilibrium (reversible) models. Yet, the condensation of a vapour is essentially a non-equilibrium, irreversible process, governed largely by the problem of dissipating the energy of the colliding atoms.

In the presence of an inert gas or of solid surfaces, which can disperse the heat of formation of the polyatomic complexes, both the steady-state size distribution of the complexes and the overall process of homogeneous condensation may be profoundly affected.

The problems arising from the irreversibility of the condensation of metal vapour are further complicated by diffusion and convective currents in the carrier gas, and by the relatively large temperature gradients in the vicinity of the evaporation surface.

3. CONDENSATION OF METAL VAPOURS IN AN INERT GAS

Many experimental studies of the formation of aerosol particles from metal vapours in the presence of an inert gas have been published. The earliest attempt to formulate the quantitative aspects of the problem was made in 1912 by Kohlschütter and coworkers[85,86]. Volatile metals (Zn, Cd, Se, As) were slowly distilled in a vacuum or under various pressures of different gases (H_2, N_2, CO_2). The size and density of condensate particles formed on a known area of glass or quartz were studied under an optical microscope (56–300 × magnification). No significant differences were observed on varying the rate of evaporation or the position of the substrate. All the particles were approximately spherical; spherulites and dendritic crystals were occasionally found in the selenium condensates. The main conclusions of this work were:

1. As the gas pressure increases from 55 to 850 mmHg, the particle size decreases from ~0.1 to ~0.001 mm.

2. For equal pressures, the size of the particles and the density of the deposit depend on the nature of the gas. The average particle diameter decreases from H_2 to N_2 to CO_2.

3. In hydrogen the deposits are denser than in CO_2; mirror-like deposits are obtained in a vacuum and at very low gas pressures, and at atmospheric pressure the deposits are powdery, with large inter-particle separations.

These results have been treated in various monographs[87-89] as giving a true picture of the formation of aerosol particles. However, it is now obvious that only the large secondary conglomerations were detected in Kohlschütter's experiments. More recent (see below) electron-microscopic work reveals an entirely different picture of the relationship between the pressure and nature of the background gas and the disperseness of the primary aerosol particles.

Gen and coworkers[90] studied the condensation of sodium vapour in the presence of xylene and butadiene vapours. They developed an industrial method of production of organosols by high-frequency heating of the sodium directly within the liquid. The preparation of metallic sols by striking an electric arc in a liquid (proposed by Tikhomirov and Lidov[91] and realised by Bredig[92] and Svedberg[87]) is obviously another instance of the condensation of a metal vapour in the presence of the vapour of a liquid.

Aerosol particles of metals and oxides have been studied in the electron microscope for many years[93,94], and the first attempt to correlate the size of particles with the conditions under which the particles had been formed was made in 1948.[95] Gold was evaporated from a heated tungsten wire, in a nitrogen atmosphere, and the deposits were studied on a collodion film. For a constant rate of evaporation (3 mg s^{-1}), the smallest spherical particles (15–100 Å, average diameter ~40 Å) were obtained at a pressure of 0.3 mmHg, whereas at 1–3 mmHg pressure the particle size was 125–200 Å. On increasing the rate of evaporation from 0.5 to 15 mg s^{-1} (N_2 pressure 0.5 mmHg) the amount of material deposited increased very considerably but the mean particle diameter was unaffected. Small additions of oxygen to the nitrogen (1.32 mmHg N_2 + 0.08 mmHg O_2) had no effect on the electron diffraction patterns. However, the topographic structure of the deposit was altered, and the transmission of infrared radiation increased. This effect is ascribed[95] to condensation of the volatile tungsten oxide WO_3. A highly disperse gold deposit has been shown[96] to be an efficient absorber of infrared radiation, with very little reflection.

During the 1930's, Pfund had reported[97-99] that black condensates of Bi and Zn are obtained in an inert gas atmosphere or in a moderate vacuum. Levinstein[100] showed that the phenomenon is a universal one, and ascribed it to the formation of aerosol particles during condensation of a metal vapour in the presence of background gases. He showed that the appearance of the metal condensate on a collodion film under the electron microscope undergoes profound changes as the residual gas pressure is increased from 10^{-5} to 0.1 mmHg during evaporation. The deposits obtained under high vacuum conditions (~10^{-5} mmHg) consist of separate crystallites with a well defined shape (in the case of Zn, hexagonal platelets ~10^{-5} cm in

diameter), but on raising the pressure to 0.1 mmHg most metal condensates present a uniform appearance (a black film consisting of a large number of particles ~10^{-6} cm in diameter). The most unexpected result was obtained in the evaporation of Zn and Cd at the relatively high pressure of 0.01 mmHg: the resulting condensates had a surprisingly uniform structure and a specular surface. Levinstein explains these phenomena by pointing out that the metal vapour in the presence of residual gas is not atomic, but consists of a cloud of particles which are probably formed near the evaporation surface. When these particles land on the target they remain indefinitely on their adsorption sites and act as condensation centres. On the other hand, the adsorbed atoms can re-evaporate from the surface until they are eventually captured. Metal deposits (Au, Ag, Cu, Ni, Fe, Co, Cr, Mn, Ti, Be, Pb, Sn, Pd, Pt) give sharp electron diffraction lines when condensed in a high vacuum. On the other hand, condensates of those same metals obtained at a pressure of 0.1 mmHg give diffuse rings. The electron diffraction patterns of W, Ta, Ir, Nb, Rh, Ge, and Si show diffuse rings irrespectively of vacuum conditions during depositions. Levinstein concludes that the particles formed near the evaporation surface are essentially indistinguishable from the crystallites obtained on the surface of the substrate when a high-melting metal is evaporated (W, etc.), but the crystallinity of the former is less developed than that of the latter when the metal is low-melting (Au, etc.).

Bagguley[101] prepared aerosol particles of Ni, Co, and Fe, and of Fe–Si, Fe–Cr, and Fe–Ni alloys by striking a high-frequency arc between electrodes of the experimental material in a hydrogen atmosphere. Suspensions of these particles in paraffin oil were used in studies of ferromagnetic resonance.

Sheftal' and coworkers[102,103] showed that the films of Ge and Si deposited on single crystals of the same materials in a hydrogen atmosphere (760 mmHg) had better structural and electrical properties than the films obtained in a vacuum. This phenomenon, analogous to the formation of mirror-like deposits of Cd and Zn in Levinstein's experiments[100], is explained by postulating the deposition of Ge and Si aggregates from the hydrogen gas phase. Well formed and outwardly uniform silicon crystallites of 150–200 μm dimensions were shown by electron microscopy to result from particles ~300 Å in diameter.

Reshetnikov[104] studied the structure of thin films of Sb_2S_3 prepared by sublimation in a nitrogen atmosphere at pressures below 4 mmHg. He ascribes the highly disperse structure of the condensate to the formation of aerosol particles from vapour molecules which had lost their excess kinetic energy by collisions with nitrogen molecules.

Gen and coworkers[105] have examined the disperseness of aluminium aerosols as a function of formation conditions. A sample of aluminium was evaporated from a heated tungsten wire at the centre of a water-cooled glass bulb 8 cm in diameter. The bulb was filled with hydrogen, helium, or argon at 1–36 mmHg pressure. The deposits on the wall of the bulb were examined by electron microscopy: as the gas pressure was increased, the average size of the spherical particles increased gradually at first, but remained constant after reaching a critical value. The limiting particle diameter depends on the nature of the gas (~500 Å for He, ~700 Å for H_2, ~1500 Å for Ar). Depending on the disperseness, the colour of the films varied from black (for the finest particles, ~200 Å) to light grey (for condensates consisting of particles ~1500 Å in diameter).

Additional evidence has been published[106,107] in support of the view that the black deposits obtained by the evaporation of various metals (Au, Ag, Bi, Pb, Cd, Zn, Sb, Sn) in various gases (air, nitrogen, argon) at pressures < 0.5 mmHg consist of aerosol particles.

Rosinski and Snow[108] developed a model of the combustion of meteorites in the earth's atmosphere with formation of secondary aerosol particles by evaporating iron (using the exploding wire method) in argon, oxygen, and argon–oxygen atmospheres at pressures of $(1-4.1) \times 10^{-3}$ mmHg. The grid supporting the collodion film for electron microscopy was located in a side arm, where it was accessible to atomic aggregates only by diffusion. Aerosol particles ≤ 300 Å in diameter were formed at a pressure of 4.1×10^{-3} mmHg. Particles of iron oxide were obtained in an oxygen atmosphere. These workers used Smolukhovskii's coagulation theory to derive a system of differential equations describing the change in concentration of the various aggregates, and computed the size distribution of secondary particles as a function of time after the instantaneous evaporation of a meteor in the earth's atmosphere.

Karioris and coworkers[109-111] also described an aerosol generator based on an exploding wire, and prepared aerosols of various metals. Particles ~ 1000 Å in diameter were obtained in a nitrogen atmosphere. An X-ray diffractometer was used to show that under these conditions nitrides are obtained from Al, Fe, In, Ta, Th, V, W, and Zr. The Au, Ag, and Mo condensates contain practically pure metal. It was shown that explosion of Ag, Au, and Pt wires in air, and of Cu and Al wires in argon, gives aerosols of the pure metal, whereas explosion of base metal wires in air gives aerosols of the oxides. In addition to the fine particles (0.1–0.01 μm), relatively coarse particles resulting from the splash of the molten metal were detected.

Kimoto and coworkers[112] made an electron microscopic and electron diffraction study of the condensates of many metals (Mg, Al, Cr, Mn, Co, Ni, Fe, Cu, Zn, Cd, Ag, Au, Sn, Pb, Bi) obtained in the presence of various pressures of argon on a collodion film. They observed separate particles, both faceted and spherical, of size increasing from hundreds to thousands of Ångstroms as the argon pressure was increased from 1 to 35 mmHg. The aerosol particles in these experiments are assumed to be formed by condensation of the vapour on impurities. This view is hard to accept. If the impurities can act as condensation nuclei in the vapour more readily than the metals themselves, the mechanism is far from self-evident, particularly since the concentration of impurities in most of the metals was low, and yet aerosol particles were obtained in all cases.

Gen and coworkers[113] obtained spherical aerosol particles of Ag–Cu alloy, in which the solubility limits of the macroscopic alloys were largely exceeded, by the simultaneous condensation of the metal vapours in a gaseous carrier (Ar, He). The conditions for the formation of highly disperse alloys, and methods of determining their composition, are also discussed in that paper.

The problem of the origin of the atomic aggregates (whether emitted by the evaporation surface or formed above the evaporation surface) must be solved in each individual case. In 1914, Swann[114] had suggested that polyatomic complexes can evaporate from a metal in order to account for the electrical conductivity of thin metallic films. The assumption is to some extent confirmed by mass-spectroscopic measurements. Petrov and Rusin[115] obtained additional information in their study of the condensation of aluminium vapour on glass at ~ 10^{-3} mmHg

pressure. They inserted a copper screen with a circular orifice in front of their glass plate, and obtained a narrow concentric ring surrounding the central spot which could only be explained by postulating a double reflection of the particles from the plate and from the screen. The particles travel in straight lines, conserving the momentum acquired during evaporation. Electron microscopy showed that both the central spot and the thin surrounding ring consisted of particles ~ 30 Å in diameter. Evidently, evaporation of aluminium gives rise to polyatomic complexes as well as to single atoms, and the complexes add on further atoms during their flight. (This conclusion is consistent with the mass spectrometric measurements[29].) On raising the residual gas pressure from ~ 10^{-3} to 5 × 10^{-2} mmHg a highly disperse black powder appears on the screen but the deposit on the glass plate remains specular. This observation confirms Levinstein's observation that a mirror-like condensate can be formed from aerosol particles at a particular pressure of residual gas[100].

Palatnik and coworkers[116-118] studied the effect of temperature of the inert gas (argon) on the size and shape of the condensate particles of various metals (Pb, Sb, Cd, Zn, Mg) and their alloys. They evaporated the metals from an alundum crucible within an aluminium cylinder which could be heated to < 350°. The Mg, Cd, and Zn could be evaporated by an electric arc. The argon pressure was varied from 3 to 90 mmHg. The deposits were studied by electron microscopy and X-ray diffraction, and the results were treated by assuming two separate condensation mechanisms (vapour → crystal and vapour → liquid → crystal). The predominance of either mechanism is critically dependent on the temperature of the gas, controlled by the cylinder walls. However, the authors ignore the fact that at these pressures of argon the aerosol particles are formed near the evaporation surface, where the temperature is determined mainly by the crucible rather than by the cylinder walls. Hence, the published electron micrographs[116-118] are more characteristic of the coagulation and sintering processes of the particles on the heated walls of the apparatus than of homogeneous condensation.

Condensates from alloys[116-118] showed the following behaviour. Alloys of the eutectic type (Pb–Sb, Bi–Zn) gave a mechanical mixture of aerosol particles of the components. Condensates from solid solution showing continuous solid solubility (Bi–Sb, Cd–Mg) consist of particles covering a wide range of concentrations. In the remaining cases (Pb–Bi, Cd–Sb, Mg–Sb, Mg–Bi) the diffraction patterns suggest simultaneous condensation of the components on nuclei of definite compounds. At high enough crucible temperatures and for short evaporation times the composition of the condensate is exactly the same as that of the initial alloy. For example, with Pb–Sb and Pb–Bi alloys evaporated in 20 s the composition of the deposit becomes the same as that of the initial alloy when the temperature is raised to 1200°, and remains unchanged at still higher temperatures. This result would appear to need confirmation, in view of the large difference between the vapour pressures of the components of these alloys, and of the fact that the rate of arrival of atoms of the more volatile component from the bulk of the melt is not constant.

Gen and coworkers[119] prepared highly disperse Fe–Co alloys containing between 0 and 100% of Co by the aerosol method. The particles prepared in argon and helium at atmospheric pressure (~ 500 and ~ 160 Å in diameter respectively) were spherical. As the Co content was increased, the alloys gradually passed through a one-phase region (α-Fe structure), a two-phase region (α-Fe and γ-Fe), and a one-phase region (γ-Fe), finally adopting the Co face-centred cubic structure. The lattice parameters of the aerosol alloys are different from those of bulk alloys with the same composition. The lattice parameters of Fe–Co aerosol alloys and of Fe and Co particles were shown to be smaller than those of the corresponding bulk phases, and to be a function of particle size.

A study of the coagulation of silver aerosol particles of ~ 30–50 Å primary diameter has been published[120]. The metal vapour issuing from an induction furnace was allowed to mix with a stream of cold air at 23–68 mmHg pressure. The aerosol was led along a tube and electrostatically precipitated at various distances from the furnace. The extent of coagulation was obtained from the number of particles found in the deposit. The absolute concentrations were measured by a radioactive silver isotope.

Palatnik and coworkers[121] studied the size and shape of Mg, Cu, and Al particles deposited in an argon atmosphere on rods variously oriented with respect to the evaporation source. As the authors themselves point out, the interpretation of the results is complicated by secondary growth and sintering processes on the rods.

Japanese physicists[122-125] studied the crystal structure and geometrical form of the aerosol particles of various metals prepared in argon. Again it was shown that as the pressure is increased the particle size increases from ~ 100 Å (at 1 mmHg pressure) to several tenths of a micron (at 30 mmHg). Particles less than 300 Å in diameter were spherical, whereas the larger particles had a normal outline. Addition of 0.1 mmHg of air to 6 mmHg of argon produced particles with a rounded (Au, Ag, Fe, Pb) or abnormal (Zn, Cd, Mg, Be) outline. No oxides were detected on the surface of the particles. Surprisingly, it was found that chromium particles prepared in pure argon had an unusual structure (lattice constant of unit cube a_0 = 4.588 ± 0.001 Å), whereas chromium evaporated in an argon–air mixture (6 mmHg + 0.1 mmHg respectively) gave well formed particles with a normal body-centred cubic lattice (a_0 = 2.88 Å).[124]

The formation of aerosol particles with a pentagonal or, less frequently, hexagonal profile by the evaporation of gold and silver in argon (12 mmHg) is extremely interesting[126]. Particles of this shape had previously been observed in gold and silver condensed in a high vacuum[127,128]. Electron diffraction showed that the decahedral particles (giving a pentagonal profile) consist of tetrahedra bounded by {111} planes in mutually twinned positions. The expected small angle of misfit in the combination of five tetrahedra was not observed. The hexagonal outline is produced by icosahedral particles composed of tetrahedra.

The most detailed study of gold "compound particles" is due to Komoda[129]: some of his electron micrographs (obtained in a high-resolution microscope) are shown in Fig. 1. It is interesting to note that the decahedral and icosahedral shapes are found in particles ~ 20 Å in diameter, and are retained up to 150–200 Å particle size. Coarser particles have a more complex structure, but they are free from dislocations.

Wada made a comparative study[130] of the formation of Mg, Zn, Cd, Al, Fe, Cu, and Ag aerosol particles in helium and argon at pressures between 1 and 600 mmHg. His results are in qualitative agreement with the conclusions of Gen and coworkers[105]: particles are formed in a condensation zone whose width increases as the gas pressure is decreased; the particle size increases with gas pressure; for equal pressures, the particles are smaller and the condensation zone is larger in helium than in argon.

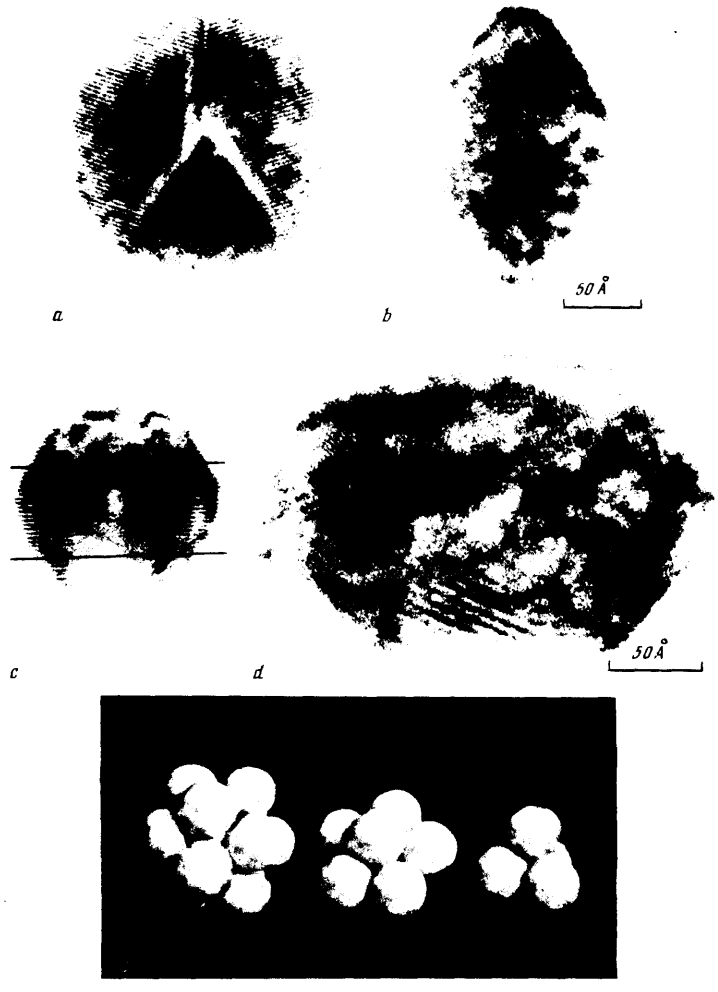

Figure 1. High-resolution electron micrographs of gold particles. The {111} planes are clearly visible. *a*) and *b*) show a small decahedral particle from above and laterally; *c*) is a small icosahedral particle with a hexagonal outline, the parallel straight lines are drawn to show the divergence of the lattice planes near the surface of the particle; *d*) is a larger particle of irregular shape, showing a complex internal structure; *e*) are models of the building of decahedral and icosahedral particles from the elementary tetrahedron

Particles of Fe–Co alloy of 100–700 Å diameter, prepared by evaporation in a low pressure of argon, are joined into long chains by magnetic forces[131].

Fukano and Kimoto[132] studied the structure of aerosol particles formed by evaporation of Ni–Pd, Fe–Ni, Au–Ni, and Ag–Pd alloys in argon. The particles had the same composition as the source alloy, and the composition dependence of their lattice parameter (face-centred cubic structure) was the same as for the bulk material within 2%. The aerosol particles of the Au–Ni alloy consisted of a solid solution which is normally stable only at high temperatures.

Highly disperse silver aerosols have recently been produced by evaporating the metal in argon and injecting the stream into cold air.[133]

The presence of an inert gas atmosphere enables new nuclei to be formed, and assists the coagulation of existing atomic complexes. On raising the gas pressure the average size of the metal aerosol particles initially increases to a limiting value, which is retained up to atmospheric pressure. This behaviour has an easy phenomenological explanation based on observations of fog formation. It is visually obvious that at high inert gas pressures the metal fog forms in a narrow region close to the vapour source: convective gas flow merely removes the particles from this "aggregation region", without appreciably affecting their size. When the gas pressure is lowered, the aggregation region widens, its inner boundary moves away from the evaporator, and its outer boundary moves closer to the

walls of the vessel. At the same time, the role of convective flow decreases and the role of diffusion increases. The mean particle size is affected by the gas pressure only when the outer boundary of the aggregation region reaches the wall of the apparatus. In this case the wall hinders the coagulation process which normally occurs in the bulk of the vapour–gas mixture.

No satisfactory explanation has yet been given of the limiting average particle size at high gas pressures or of the dependence of the limiting particle size on the nature of the gas [105,130].

The evaporated atoms come to thermal equilibrium with the gas very rapidly. According to Cravath's formula [134], the mean fractional loss of energy attending collisions between the atoms and the gas molecules is

$$f = \frac{8}{3}\frac{mM}{(m+M)^2}\left(1-\frac{T}{T_m}\right),$$

where m and M are the masses of the vapour atom and of the gas molecule respectively, T_m is the evaporation temperature of the atoms, and T is the gas temperature.

For example, in the evaporation of aluminium in argon $T_m \simeq 1800°K$, $T \simeq 300°K$, and therefore $f \simeq 0.53$, i.e. the energy of the atoms decreases by about a factor of two at each collision.

Rosin and Rabi [135] measured the mean free path of the evaporated atoms of alkali metals in various gases. From their results, summarised in Table 3, it is evident that the mean free path λ of the atoms is of the order of 1 mm at a gas pressure $P \simeq 10^{-2}$ mmHg. Hence, the atoms must come into thermal equilibrium with the ambient gas within a short distance from the evaporation source. Under these conditions, polyatomic complexes can be formed.

The effect of the complexes on the rate of evaporation of the metal has been studied [136]. The theoretical conclusion is that the diffusion layer of complexes which exists close to the evaporation surface in an inert gas atmosphere has no effect on the mass transport: hence, if the evaporation is limited by mass transport, the rate of evaporation is the same as for an atomic vapour.

Mizushima [107] tried to obtain a criterion for the formation of aerosol particles from the familiar expression for the number of atomic three-body collisions. Assuming that the higher complexes are formed by successive increments of single atoms, he obtained the approximate expression

$$\frac{Z_{n+1}}{Z_n} \approx \tau_n \frac{u}{\lambda},$$

where Z_{n+1} and Z_n are the numbers of collisions per second between atoms and complexes of $(n+1)$ and n atoms respectively; τ_n is the life time of the n-atom complex; u is the mean velocity and λ is the mean free path of the atoms.

Mizushima proposes the following inequality as the condition for the growth of particles:

$$\frac{Z_{n+1}}{Z_n} \geqslant 1, \quad \text{i.e.} \quad \tau_n \geqslant \frac{\lambda}{u}.$$

Taking $\lambda = 10^{-3}$–10^{-2} cm and $u = 10^4$–10^5 cm s^{-1} at $T \simeq 1000°K$, he obtains $\tau_n \simeq 10^{-7}$ s.

However, a growing particle must pass through the stage of association corresponding to a low value of n, for which $Z_{n+1}/Z_n \ll 1$. Hence, Mizushima's criterion is not realistic.

The most fruitful collisions are those between two atoms of the metal and a polymeric complex of the gas. Under these conditions the energy of combination of the atoms to give a dimer is transferred to internal degrees of freedom of the complex, which may undergo dissociation. Thus, the heat of condensation of the atoms can be dissipated without heating the gas. Dimers, trimers, etc. can then unite to give larger particles.

Table 3. Values of $P\cdot\lambda$ in units of 10^{-4} (P is the gas pressure in mmHg, λ is the mean free path of the metal atoms in cm)

Gas	Li, 860 °K	Na 700 °K	K 620 °K	Rb 590 °K	Cs 560 °K
H_2	16.2	8.30	5.44	4.24	3.20
D_2	18.6	8.74	5.85	4.65	3.65
He	22.6	12.52	8.32	6.50	4.89
Ne	22.5	10.94	7.77	6.65	5.41
Ar	11.4	5.90	4.22	3.75	3.34

Other conditions being equal, the size of the particles is practically independent of the rate of evaporation. This result suggests a relationship between the number of condensation centres and the rate of evaporation. The primary condensate particles (subcrystallites) can be bounded by close-packed crystal planes. For example, the smallest subcrystallite of a face-centred cubic metal is a tetrahedron consisting of four atoms and bounded by a family of {111} planes. Since the formation of a new layer on close-packed faces requires a high supersaturation [54,137], most of the atoms will be simply reflected from the close-packed faces of the subcrystallite. Hence, the formation of new subcrystallites (which can aggregate into aerosol particles by collision) becomes more favourable than the growth of existing subcrystallites at some stage in the dynamic condensation process. This seems to be the most likely explanation of the relative insensitivity of the aerosol particle size to the rate of evaporation. Strictly regular packing of the subcrystallites in the particle cannot be expected: some randomness in the mutual orientation of the subcrystallites is unavoidable. The molecular force field will have almost spherical symmetry, and the subsequent growth of the particle (by adding on more subcrystallites) will bear a similarity to the growth of a snow-ball. In practice, nearly all the metal aerosol particles examined in the writer's laboratory were found to be approximately spherical. Fig. 2 shows a crystalline particle of cobalt $\sim 10^{-5}$ cm in diameter photographed at high magnification ($\sim \times 300\,000$) in an electron microscope with ~ 10 Å resolution. The total absence of facets is obvious. Examples of the ordered grouping of tetrahedral subcrystallites in small gold particles (20–50 Å), and of the disordered grouping in larger particles ($\geqslant 150$ Å), are shown in Fig. 1.

The important role of subcrystallite coagulation in the formation of spherical aerosol primary particles, and in determining the size distribution in a given range of vapour concentrations, is stressed in a recent review by Fuks and Sutugin [138], and also by other workers [120,133,139].

In what follows we shall use the term subcrystallite to denote structural groupings of atoms ranging in size from the smallest possible unit cell to 20–30 Å, and bounded mainly by close-packed planes. X-Ray studies of phase transformations in aerosol particles have confirmed that their structure is subcrystalline [140,141]. Observations of ferromagnetic resonance in nickel, cobalt, and iron particles [142,143], and of plasma resonance in silver and copper

particles[144], and also of the temperature dependence of X-ray scattering[145,146], are consistent with this point of view.

Only a fraction of the subcrystallites, determined by the inert gas pressure, is able to coagulate in the gas volume: the remainder reaches the walls of the vessel. When these migrate over the surface of a solid, and experience the orienting effect of the substrate, they can give rise to well formed crystallites. The speed and direction of migration of the subcrystallites depends on their size, on the temperature and topography of the surface, on the presence of adsorbed impurities and external fields, etc.

Figure 2. Aerosol cobalt particle. Facets are completely absent though the particle has a crystalline structure

Most of the platelet-like crystallites so far obtained (Mg, Cd[112], and Zn[100,112]) by evaporating a metal in an inert gas atmosphere originated almost certainly at the surface. The grids and films used by Kimoto and coworkers[112,122] may have been heated quite significantly by radiation from the evaporation source, and this will have assisted the surface migration of subcrystallites. It has been shown[144] that silver condenses on a glass substrate 7 cm from the evaporator under 0.15 mmHg argon pressure in the form of islets consisting of a large number of sintered particles ~ 20 Å in diameter, whereas on removing the substrate to a distance of 15 cm coarser, isolated aerosol particles are obtained. The former deposits have a specular reflection, the latter are black. The black deposits exhibit plasma resonance under normal light incidence; the specular deposits do not, indicating a difference in electronic conductivity between the isolated and the sintered particles.

By suitable choice of evaporation conditions (gas pressure, position, and temperature of substrate), metal deposits of mixed origin can be obtained. An example is shown in Fig. 3, where a long chain of spherical particles held together by magnetic forces appears side by side with faceted particles of iron[112]. These chains are similar in size to the ferromagnetic particles of iron, nickel, and cobalt which are typical of condensates from the gas phase[119]. In a large enough vessel ($\geq$ 25 cm in diameter), and with an argon pressure of ~ 0.1 mmHg, spherical particles of most metals are usually obtained on the cold walls as condensates formed in the gas. These particles are sometimes amorphous (for example, aluminium[147] and bismuth[140]). However, larger particles ($\geq 10^{-5}$ cm) of low-melting metals can develop facets if their residence time in the hot gas is long enough. Kimoto and coworkers point out[112] that the lack of facets in particles less than a few hundred Ångstroms in diameter should not be dismissed as insufficient resolution in the electron microscope: it is an important aspect of the growth mechanism of the crystal. Under comparable preparative conditions, different metals give deposits with a narrow particle size distribution and approximately the same disperseness, but the higher-melting metals produce significantly smaller particles. Fig. 4 shows the integral and the differential size distribution of Bi, Pb, Sb, and Ag particles prepared by evaporating the metals from a hot tungsten wire in argon at 0.1 mmHg pressure in a glass bell-jar 25 cm in diameter.

Figure 3. Iron condensate on a collodion film, prepared in a magnetic field of ~ 1000 Oe under an argon pressure of 35 mmHg.[112] The faceted particles have grown on the surface of the substrate, whilst the chain of spherical particles must have been deposited from the gas phase

The actual colour of the macroscopic metal deposit gradually darkens as the particle size decreases. This trend is particularly noticeable with non-ferrous metals such as gold, silver, and copper. Complete oxidation of the particles produces a colour change. Thus, black powders of iron and lead develop the characteristic colour of the oxides (dark red and white, respectively) after being heated in air. The importance of the correct gas pressure during the preparation of the blackened sensitive areas of radiation detectors has been pointed out[148]: it is shown that a layer of black having reproducible optical characteristics can be prepared by evaporating Bi or Sb at 0.1–0.4 mmHg pressure.

The physicochemical properties of aerosol particles have been discussed in a number of papers, which we shall briefly mention below.

Harris and coworkers[149] discuss the sintering of gold aerosol particles. Gen and coworkers[147] studied the crystallisation of amorphous aluminium particles prepared under controlled conditions. Exposure of a photographic emulsion by the oxidation of aluminium particles (the Colson–Russell effect) has been observed by Petrov and coworkers[150–152]. The oxidation process, and the structural changes in the oxide skin surrounding aluminium particles, have been examined by Petrov and Bibilashvili[152]. Petrov made a detailed investigation of the thermal expansion, phase transformations, melt structure, and temperature dependence of X-ray scattering in aerosol particles of aluminium[146,151,153], lead[140,146,154], bismuth[140,146], antimony[140,146], nickel[145], cobalt[155], tin[141,146], silver[156], iron[157], and cadmium[158].

The optical properties of Al, Ag, Cu, and Se particles were investigated by Petrov[144]. Plasma resonance in Al particles, excited by fast electrons, has been discussed by Fujimoto and coworkers[159,160].

Gen and Petinov[161] studied electron paramagnetic resonance in lithium particles. Nuclear gamma-resonance was observed in particles of tin[162] and of an Fe–Ni alloy[163].

Petrov and coworkers measured the ferromagnetic resonance of nickel, cobalt, and iron particles[142], and also the magnetic and dielectric permeability of nickel suspensions in paraffin oil at a frequency of 9320 MHz.[143]

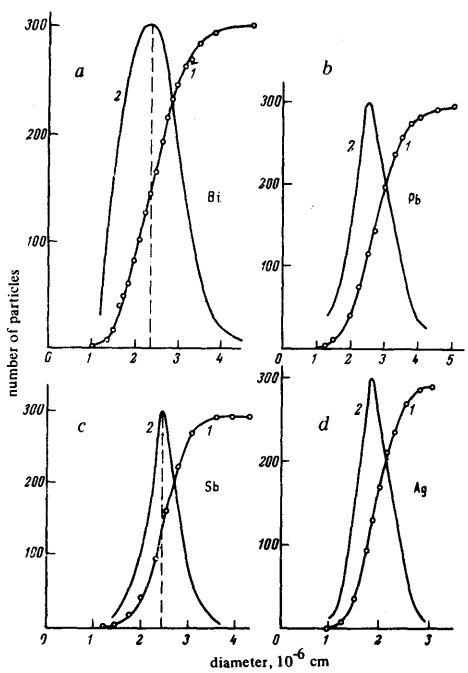

Figure 4. Size distribution of bismuth, lead, antimony, and silver aerosol particles prepared in a glass bulb 25 cm in diameter under ~ 0.1 mmHg argon pressure: *1*) integral distribution; *2*) differential distribution

The magnetic properties of Fe, Co, and Ni aerosol particles and of some of their alloys have been studied by several workers[131,164,165].

The hypothesis of a highly disperse structure of matter in the liquid and the solid state has been repeatedly proposed[166–183]. Experiments with aerosol particles are consistent with this hypothesis. Isolated subcrystallites, regularly assembled into a massive crystal, are assumed to be surrounded by a structureless (amorphous) layer of atoms which acts as an "inner lubricant". The thickness of the amorphous layers increases with temperature as a result of the "evaporation" of atoms from the surface of the subcrystallites, and this produces an increase in the rotational amplitude of the subcrystallites. At the melting point the subcrystallites enter a state of free random rotation: this is consistent with the appearance of an amorphous halo in the diffraction pattern of the liquid and with the vestigial structure of the original crystal found in the melt. The frequently reported "pre-fusion" of metals and associated specific heat anomalies[182–186], the increase in self-diffusion[187–189], and other phenomena[182] all point to a "loosening" of the bonds between subcrystallites[174] and to an increase in the thickness of the intervening amorphous layer. Lead particles ~ 200 Å in diameter close to the melting point have been shown to consist of approximately 115 face-centred cubic subcrystallites giving approximately 7 unit cells on each edge. On raising the temperature of the melt by 300° the size of the subcrystallites decrease only by a factor of 1.5.[154] It appears that the subcrystallites disappear completely only on approaching the critical temperature of the liquid–vapour transformation, when the melt adopts the uniform structure of a dense gas with the equilibrium distribution of polyatomic complexes. On cooling the melt, subcrystallites reform and gradually grow in size. Finally, the subcrystallites begin to touch one another, and an ordered array becomes energetically more favourable: in other words, the melt solidifies. The phase transformation is an avalanche-like cooperative process. The most convincing proof of the subcrystallite structure of aerosol particles is obtained by direct electron microscopy[126,129] (Fig. 1), and also by observing the anomalies in the coefficient of expansion of Al, Pb, Ag, and Cd particles close to the melting point.[158]

This secondary, disperse structure of matter in all three states of aggregation is due to kinetic processes on an atomic scale which are almost impossible to avoid in practice. Even carefully grown crystals exhibit a secondary structure in spite of the fact that an ideal single crystal of unlimited size is thermodynamically favoured. Thus, Delisle and Davis[190] observed a fine structure of particles ~ 1000 Å in diameter in copper crystals grown from the melt within the familiar mosaic blocks.

In some cases, crystals grown from the vapour in an inert gas atmosphere develop as a regular array of aerosol particles, especially when the latter show a narrow size distribution. Layer growth and dendritic growth of crystals can be explained by this mechanism.

It was pointed out long ago[191,192] that the thickness of layers at crystal faces is comparable to the size of the elementary cell (i.e. is larger than atomic dimensions, in contrast to the requirements of the dislocation theory). Growth steps up to ~ 1000 Å high[192] present insurmountable difficulties to the dislocation theory. Frank[193] was forced to postulate an empty channel at the centre of a dislocation with such a large Burgers vector: the function of this channel is to relieve the concentration of elastic energy which would otherwise exceed the mechanical strength of the material. No experimental evidence of the existence of this channel has yet been produced.

Spiral steps 0.1–1 μm high have been observed on the surface of various crystals (copper[194,195], lead[196], cadmium[197], germanium[198], silicon[199]). These are clearly associated with atomic groupings rather than with single atoms.

Sears[200] ascribes the formation of screw dislocations with a large Burgers vector to the collision of a growing ideal crystal platelet with an obstacle in the form of a colloidal particle. Lang[201] showed that random growth "faults" in the early stages of the formation of a step must result in a continuous spiral step of indeterminate height rather than in a circular step.

Evidently, subcrystallites or small aerosol particles of approximately uniform size can be packed as parallel layers on a growing solid surface, whereas the larger

particles or surface defects can provide the obstacles postulated by Sears and Lang to explain the large growth spirals found in crystals.

Straumanis[202] made the first experiments on the growth of Mg, Zn, and Cd crystals from the vapour in an inert gas (hydrogen) atmosphere. The metals were evaporated within a glass tube along which a temperature gradient was imposed. Well faceted crystallites up to a fraction of a millimetre in size were obtained under suitable conditions of hydrogen pressure and evaporation temperature. For hydrogen pressures above some well defined limit (~ 4 mmHg for Zn), platelet-like Zn and Cd crystals were grown. Mg gave loosely adherent thick layers when the pressure was raised to 0.5 atm. Thin layered Cd crystals were formed at hydrogen pressures of the order of 1 atm. The growth of metal crystals from the vapour in an inert gas atmosphere is discussed in a number of papers[203-208]. Keepin[203] studied the growth of Cd and Zn crystals from the vapour as a function of the evaporator temperature (molybdenum crucible), substrate temperature (Ag for Cd, Cu or Ni for Zn), and pressure of purified nitrogen (between 10^{-5} and 760 mmHg). Large but imperfect crystallites were obtained at nitrogen pressures > 0.5 mmHg. Dendritic crystals were predominant in the pressure range 10^{-2}–10^{-1} mmHg and substrate temperatures 250–350° (for Cd) and 200–350° (for Zn). Under the conditions listed in Table 4, large and well developed hexagonal crystals were grown. Under still lower pressures, and substrate temperatures close to room temperature, a few dendritic crystals were obtained but the deposits were predominantly amorphous (particle size ~ 100 Å, estimated from the X-ray line widths).

Table 4. Optimum conditions for the growth of Cd and Zn single crystals from the vapour in a nitrogen atmosphere[203]

Metal	Evaporator temp., °C	Partial vapour pressure, mmHg	Substrate temp., °C	Nitrogen pressure, mmHg
Cd	310–321	$\sim 10^{-1}$	305±3°	10^{-2}–$5\cdot10^{-2}$
Zn	409–419	$\sim 2\cdot10^{-1}$	410±3	10^{-2}–$3\cdot10^{-2}$

Keepin suggests that the removal of the heat of crystallisation is affected by the pressure dependence of the convective flow of inert gas: as a result, the shape and size of the crystals growing on the substrate by the addition of single atoms show a considerable variation. Coleman and Sears[204] studied the influence of inert gases on the growth of Zn, Cd, and Ag from the vapour. Filamentary growth ("whiskers") was observed in the presence of hydrogen or helium at 10–600 mmHg pressure. The whiskers were formed both on the growing Zn crystals and on the glass or quartz substrates. Some individual whiskers were up to ~ 17 mm long and 1–3 μm in diameter. The diameter of the whiskers decreased with increase of gas pressure, reaching a few tenths of a micron at 600 mmHg hydrogen pressure. Coleman and Cabrera[205] observed Zn and Cd whiskers 1–2 mm long and 1–10 μm in diameter, grown from the vapour in an inert gas at atmospheric pressure.

Price[206] grew Cd crystals from the vapour on a quartz fibre in an argon atmosphere. The temperature T and degree of supersaturation η were calculated at all points along the fibre, and a critical value ($\eta \simeq 0.4$) was noted below which no crystals grew. For $\eta \leqslant 2$, thin platelets and whiskers grew together on the filament irrespective of T and η; for $2 \leqslant \eta \leqslant 10^2$ thick hexagonal platelets were obtained; branching dendrites appeared and grew to a large size for $\eta \geqslant 10^2$ and $T \leqslant 250°$. Cd and Zn crystals have been grown[207,208] from the vapour in 10–600 mmHg of argon on the wall of a glass tube. Both platelet-like microcrystals and whiskers (up to 10 mm long and 1–5 μm in diameter) were obtained.

In all the work mentioned above[202-208] the rate of growth is assumed to be determined by the diffusion of atoms in the inert gas, and controlled by the degree of supersaturation of the vapour. The formation of aerosol particles, and their combination to give microcrystals, are ignored in spite of the fact that most of the evaporated material must have passed through the stage of aerosol condensates at the inert gas pressures used in this work. Aerosol particles are formed in all systems where crystallisation from the vapour phase is assisted by chemical reactions such as transport reactions and vapour-phase reactions[209,210]. This factor must be considered when analysing the mechanism of the process.

4. MECHANISM OF CONDENSATION OF A METALLIC VAPOUR ON A SOLID SURFACE

The primary stage in the formation of a metallic condensate on a solid surface is a very complex problem with many controversial aspects. Most workers (see previous reviews[57,211-213] and some more recent papers[214-221]) correlate the structure of condensed metal films exclusively with atomic processes at the substrate surface. The role of polyatomic vapour complexes is completely ignored.

Two different explanations have been put forward for the formation of small particles in the early stages of film deposition: they can be termed the "gradual" and the "spontaneous" nucleation mechanism respectively[222]. During "gradual" nucleation of particles the atoms of the deposit move over the substrate until they have lost their thermal energy and become attached at random or at preferred surface sites. "Spontaneous" nucleation of particles occurs in the amorphous or quasi-gaseous state at some critical concentration of deposited material.

According to Semenov[223], adsorbed atoms can be treated as a "two-dimensional" vapour which condenses on reaching some critical supersaturation.

Some of the earliest workers[224-230] had noted the existence of a critical surface temperature T_{cr} above which the metal vapour will not condense. T_{cr} was shown to be a function of the density of the molecular beam. Frenkel[231] put forward an explanation, involving the adsorption of all the impinging atoms, by further developing Langmuir's ideas[232]. If two atoms combine into a dimer during their life time in the adsorbed state, the latter can act as a centre for further condensation of atoms because the probability of secondary evaporation is lower for polyatomic surface species. However, at low beam densities the dimer can dissociate before the attachment of a third atom: obviously, in this case no film is formed. Because of the clear physical picture offered by Frenkel's theory, various modified theories were subsequently based on it.[57,212] On the other hand, the experimental fact that T_{cr} varies with time[233,234] lies outside the scope of this theory. Furthermore, theoretical calculations[235-237] suggest that metal atoms should always be adsorbed on a solid surface at all

experimentally accessible evaporation temperatures. Yet, supersaturations of $\sim 10^{15}$ or more are often needed in molecular beam experiments to induce significant condensation. Sears and Cahn[242] tried to resolve this drastic shortcoming of the theory of surface film nucleation by postulating a slow transfer of energy for atoms in the adsorption layer. According to these workers, the temperature of the layer must be intermediate between those of the substrate and of the evaporator. By modifying Frenkel's theory they concluded that for a constant beam intensity and a fixed substrate temperature there must be a critical evaporation temperature above which no nuclei are formed on the substrate.

Hudson[243-245] studied the formation of Zn, Cd, and Se crystal nuclei on glass and noted large discrepancies between the observed rates of condensation and those predicted by the classical theory. His explanation is analogous to that of Sears and Cahn[242], since he assumes a temperature of the adsorbed layer of condensate intermediate between the substrate temperature and the evaporator temperature.

However, Shade's experiments[241] with a cadmium molecular beam condensing on polyethylene films have shown convincingly that the results are independent of evaporator temperature, and hence that the theory of Sears and Cahn is incapable of explaining the enormous supersaturations ($\sim 10^{17}$–10^{20}) needed to initiate condensation.

Evseev and Ozhegov[246] have recently shown that for a fixed density of the molecular beam T_{cr} increases with beam temperature, whereas for a fixed substrate temperature the critical beam density decreases with increase of beam temperature. These results are not inconsistent with Shade's conclusions, since (as the authors themselves point out) the antimony vapour in their experiments probably consisted of 4-atomic complexes which could have dissociated on collision with the substrate. Gretz[217,220] tried to explain Hudson's experiments[243] on the condensation of Zn vapour on glass by refining the classical fluctuation theory of heterogeneous nucleation[76,247]. He introduced into the expression for the free energy of formation of a cap-shaped nucleus a term for the linear tension along the interface with the substrate. However, the theory of Gretz, like other variants of the classical theory based on the Gibbs–Kelvin equation, is not applicable to very small nuclei.

The very low observed rates of formation of Zn nuclei on glass and on mica[243] can be ascribed to a low thermal accommodation coefficient $\alpha_T = (T_0 - T_a)/(T_0 - T_S)$, where T_0, T_a, and T_S are the temperatures of the beam, the adsorbed atoms, and the substrate respectively.

If full thermal accommodation of the atoms is not achieved (i.e. $\alpha_T < 1$), the adsorbed layer will be at a higher temperature than the substrate, and the real supersaturation (η_a) will be correspondingly lower. Gretz attempted[219] to evaluate α_T from experimental data for η_a without resorting to the detailed equations of the theory of nucleation. He started from an empirically established linear relationship[57] between $\ln \eta_c$ and $(1/T_S)$, where η_c is the apparent critical supersaturation defined as the ratio of the effective vapour pressure in the beam to the vapour pressure corresponding to T_S. Assuming α_T independent of temperature, he postulated that $\ln \eta_a$ must also be linear in $(1/T_S)$, i.e. that the condition $\partial^2 \ln \eta_a / \partial (1/T_S)^2 = 0$ must obtain. In spite of these arbitrary assumptions, he obtained the reasonable values $\alpha_T = 0.993$ and $\alpha_T = 0.998$ for the condensation of Zn on glass[243] and on mica[248] respectively.

Hirth and coworkers[249] explain the discrepancy between Hudson's results[243] and the theory by pointing out that at low supersaturations stable nuclei are more likely to be formed by collisions between nuclei of subcritical size than by the addition of single atoms to critical nuclei.

Moore[250] has reviewed recent work on the condensation of metals on solid substrates using emission and electron microscopy. He also concluded that small atomic groupings have a high mobility which allows them to coalesce like liquid drops. Gretz observed[218] the sudden formation and the rapid growth of a silver nucleus in the emission microscope. Curzon and Kimoto[251] studied the condensation of lead vapour on molybdenite in an electron microscope, and observed an ordered deposition of small drops on surface microdefects of the substrate, which was heated to 350°. Ciné-photography was used to demonstrate the high mobility and the coalescence of the drops. The Brownian motion of 20–30 Å gold crystallites prepared by condensing the vapour on a KCl slip in a vacuum of 8×10^{-9} mmHg has recently been demonstrated experimentally[252].

Walton tried to resolve the uncertainties which arise when the concept of surface energy is applied to very small particles. He derived[253,254] a formula for the frequency of formation of nuclei in terms of the density of adsorbed atoms, the heat of adsorption of an atom, the dissociation energy of the critical nucleus, and the activation energy for surface diffusion. According to his model, configurations of two, three, etc. atoms on the substrate remain in stable equilibrium with the vapour phase until the critical supersaturation characteristic of each configuration is reached, when the shape of the nucleus suddenly changes. This theory was applied to the growth of oriented layers[255,256]. The possible orientation and the shape of the atomic groupings formed on a crystalline substrate by vapour condensation have been discussed theoretically by Halpern[216].

The growth of single-crystal films is a very complicated problem. The quality of the film depends on many factors, often inadequately controlled (e.g. the background pressure of residual gases). Background gases can affect the kinetics of the process both in the gas phase and at the surface of the substrate. For example, changes in structure and texture formation are observed on changing from a low vacuum ($\sim 10^{-2}$ mmHg) to an ultra-high vacuum ($\sim 10^{-9}$ mmHg) in the condensation of Au, Ag, Ni, and Al films[257]. There have also been reports of residual gas effects on the properties of condensed films of tin[258,259] and indium[260].

Palatnik and Komnik studied the structure of condensates (Bi, Sb, Pb, Sn, and other metals) on a glass plate which was heated non-uniformly[213,261-263]. They noted a sharp discontinuity in the optical transmission of the deposits at a substrate temperature (T_n) approximately 2/3 of the melting point of the metal, which they ascribed to a difference in the size and number of particles on either side of this transparency boundary. This difference in the structure of the condensate is explained by different condensation mechanisms, assuming that the supersaturated "two-dimensional" metal vapour condenses by a vapour → liquid → crystal mechanism on the hot side of the substrate and by a vapour → crystal mechanism on the cold side.

Fisher and Anderson[264], in a recent study of the condensation of lead, showed that T_n can change from 189 ± 2° to ~ 245° whilst the residual gas pressure remains below 10^{-5} mmHg. They also showed that the difference in structure of the deposit on either side of the transparency boundary lies mainly in the development of facets and not (as had been assumed by Palatnik and Komnik[261-263]) in the

size and number of the particles. At substrate temperatures above T_n the particles of the deposit are almost spherical, with rudimentary facets, whereas at substrate temperatures below T_n the particles are elongated with well developed facets. Fisher and Anderson were critical of Palatnik and Komnik's double condensation mechanism, and they proposed their own explanation of the difference in structure shown by lead condensates. Quoting some calculations by Burton and coworkers[137], they assume that different facets of the lead crystallites melt at slightly different temperatures: in this way, the crystal habit of the particles becomes a function of the substrate temperature. Fisher and Anderson's arguments also explain the experimental fact that T_n is independent of film thickness[261-264].

Many of the problems raised by the initial stage of formation of metallic condensates become clearer when allowance is made for the possible adsorption of polyatomic aggregates from the vapour. These have a longer life time in the adsorbed state than single atoms, and hence they can act as primary condensation centres. It can be assumed that at high substrate temperatures only the larger complexes are retained on the surface, whereas single atoms and small associations are either reflected or rapidly re-emitted from the surface. On this model, it is not difficult to explain the existence of a critical temperature for the condensation of a vapour on a solid surface, its dependence on time and on the density of the molecular beam, and also the structural differences observed when the substrate temperature is non-uniform.

Many experimental observations provide direct evidence for the deposition of quite large particles (although rapid growth of the primary adsorbed polyatomic complexes cannot be entirely dismissed).

Thus, when the condensation of Cd and Zn molecular beams on a Formvar substrate is observed directly in the electron microscope[265], primary particles up to ~ 200 Å in size appear quite suddenly. Newman and Pashley[266] made an electron diffraction study of the condensation of copper vapour on silver, and detected the sudden appearance and subsequent rapid growth of oriented primary crystallites ~ 60 Å wide and ~ 12 Å thick. Particles ~ 100 Å in size, mostly concentrated along step edges, are observed when defects in freshly cleaved NaCl and KCl surfaces are decorated by vacuum sublimation of Au, Pd, Pt, and Ge on the heated substrate surface. In spite of the large difference in the numbers of particles found on the smooth areas and on the step edges of the surface, the particle size is approximately constant. Furthermore, gold particles deposited on glass and on small NaCl crystallites previously sublimed on the same glass surface are of practically uniform size, despite the fact that the concentration of particles is approximately 10 times higher in the former case[268]. These results are not easy to explain in terms of the growth of particles by surface migration of adsorbed atoms, since that mechanism predicts an inverse relationship between the size of the particles and their concentration (assuming a uniform density of the molecular beam).

The finely grained films obtained at low substrate temperatures are particularly interesting. During the 1930's, Kramer[271-273] prepared thin (~ 10^{-4} cm) amorphous films of a large group of metals (Fe, Ni, Pt, Zn, Sn, Cd, Sb, Ir, Al, Pb, Hg, Mo) by condensing their vapour on a glass surface cooled in liquid air using thermal evaporation or cathodic sputtering in a low pressure of hydrogen. When the deposits were heated above some well defined critical temperature their electrical properties showed a sudden, irreversible change, approaching the properties of the bulk metal. Kramer suggested that the metal atoms lose their kinetic energy by collisions with gas molecules, and are therefore unable to combine with the crystal lattice when first adsorbed on the surface. However, polyatomic complexes and subcrystallites must have been present in his experiments. At low substrate temperatures, these are not mobile enough to combine into ordered single-crystal blocks.

Gen and coworkers[274] studied the electron diffraction patterns of Fe, Ni, Cd, and Hg deposits (and also the electrical conductivity of Cd deposits[88]) prepared in a high vacuum on a glass surface at liquid-nitrogen temperature, and found a crystalline structure with a crystallite size of ~ 10^{-7} cm. These layers underwent recrystallisation on being heated, as shown by the sharpening of the diffraction lines and by the irreversible decrease (by a factor of 2–2.5) in electrical resistance[88].

Later work confirmed the conclusion of Gen and coworkers[274] that low-temperature condensates are apparently amorphous only because of the small size of the primary crystallites of which the film is composed.

More recent electron-diffraction studies[275] of Bi, Ga, Be, Fe, Cr, and the Pb–(12% Bi) alloy, condensed at 4.2°K, has revealed a similarity in radial distribution function between atoms in the films and atoms in the corresponding bulk melts. The size of the primary subcrystallites is estimated to be only a few Ångstroms. On raising the temperature to 77°K the films are converted from an amorphous into a crystalline structure, with a crystallite size of the order of tens of Ångstroms. The same author[276] demonstrated the amorphous structure (subcrystallite size of the order of Ångstroms) of Ti, Mn, Co, Pd, Y, and Fe–Ni, Ag–Cu alloy films condensed in a high vacuum on a cooled substrate (77°K).

Grigson and Barton[277] have reviewed existing electron diffraction calculations for very small crystallites, and have developed a method of evaluating the Debye interference function for an assembly of identical, randomly oriented face-centred cubic subcrystallites containing from 2 to 9 atoms on an edge. By comparing the calculated diffraction patterns of liquid lead and of thin films of Pb, Ag, and Fe, it was shown[278] that the aggregates form an amorphous structure similar to that of a monoatomic liquid during the early stages of film growth (up to 10 Å).

Measurements of the line width in electron diffraction patterns of Cu, Al, Ti, Pb, Sn, Zn, In, Tl, and Hg condensates on a collodion substrate at 20 and 4.2°K indicate a primary crystallite size of ~ 30–100 Å.[279,280] When the films are annealed at a higher temperature their grain size increases and their electrical resistance decreases irreversibly.

During evaporation from the metal, single atoms are emitted together with polyatomic complexes, which become overgrown with atoms in the region of high vapour density close to the evaporator.

The structure and properties of the films are also determined by the angle of incidence of the molecular beam[281]. This effect is most probably due to the fact that the atomic complexes present in the vapour retain some directional motion along the surface when the incidence of the beam is not normal, whereas the single atoms are quickly scattered by the microscopic roughness of the surface. Furthermore, the larger aggregates are more readily oriented in the plane of the surface and are less easily influenced by the microscopic profile. This is consistent with the fact that oriented films on amorphous substrates are obtained much more easily by evaporating the metal in an inert gas

atmosphere than in a vacuum[282]. Thus, fully oriented Ni films with a {110} plane parallel to the substrate are formed on glass in the presence of a 1 mmHg background pressure of argon. These films had a BET surface area and a catalytic activity greater than those of films prepared in a high vacuum by a factor of 2 and 3–5 respectively[283]. Evidently, the vacuum condensates had been formed on smaller aggregates than the deposits obtained in an argon atmosphere.

---o0o---

Several interesting papers on the preparation and properties of metal aerosol particles have appeared while the manuscript was in press.

Wada[284] has developed a method of volatilisation in a mixed hydrogen–helium plasma, aimed at improving the efficiency of the aerosol method. He obtained 100 Å particles of an Fe–Co–Ni alloy at a gas pressure of 250 mmHg.

Chopra and coworkers[285] prepared very thin films of W, Ta, Mo, Re, Hf, and Zr by evaporating the metal in an argon plasma; there can be no doubt that these films consist of very small aerosol particles. Very interesting structural modifications of the particles are observed at substrate temperatures of 200–400°. Wada has shown[286] that evaporation of many metals in a xenon atmosphere gives particles 3–4 times larger than the particles obtained under the same pressure of argon.

The critical temperature of the transition to the superconducting state has been shown to be abnormally high in granular films consisting of aluminium aerosol particles[287].

Nishida[288] made a detailed study of the shape and structure of manganese particles obtained by evaporating the metal in argon or xenon at low pressures. He observed particles of the high-temperature β-Mn modification as well as α-Mn.

Thin-layer Chromatography of Biopolymers and Their Derivatives

S.A.Kibardin and V.B.Lazurkina

The modern state of thin-layer chromatography in its application to proteins, nucleic acids, and their derivatives is discussed. Thin-layer chromatography is a new technique in chromatographic analysis which has vigorously developed in recent years. In the review the inadequate development of the thin-layer chromatography of proteins compared, for example, with that of low-molecular-weight compounds is noted and the causes of this situation are analysed. Thin-layer chromatography is compared with other chromatographic methods and the studies on the thin-layer chromatography of biopolymers and their derivatives published up to the present time are critically assessed. New techniques in the thin-layer chromatography of proteins published recently are described.
The bibliography includes 97 references.

I. INTRODUCTION

At the present time chromatographic methods are used on an extremely large scale in a wide variety of branches of science and engineering. These methods have acquired particular importance in biochemistry, molecular biology, and related disciplines. In recent years a new technique—chromatography in thin layers—has been developing rapidly.

Thin-layer chromatography has proved an extremely effective means for the separation and analysis of mixtures of a wide variety of compounds. This method is of interest for chemists, biologists, and medical practitioners working with complex mixtures of natural substances.

The method arose initially as a procedure for the separation of extracts from medicinal plants[1], developing considerably in the period that followed. At the present time several hundred papers in this field are published every year. However, it should be noted that thin-layer chromatography is still used mainly for the analysis of various low-molecular-weight compounds. Studies on the use of thin-layer chromatography for the separation of high-molecular-weight compounds of biological origin, such as proteins and their derivatives, have begun to be published only in recent years, starting with 1962.[2,3]

The application of the thin-layer chromatographic method to proteins and nucleic acids has been developing much more slowly than in the case of low-molecular-weight compounds; thus the total number of studies on the thin-layer chromatography of low-molecular-weight compounds quoted in the bibliography of the Journal of Chromatography for the last two years reaches approximately 1700. On the other hand, the number of studies devoted to the thin-layer chromatography of proteins, nucleic acids, and their derivatives does not exceed 80. This imbalance in the development of the method is particularly notable compared with, for example, the column chromatography of proteins, which has been widely developed and used. Probably the reason for this is partly that until recently thin-layer chromatography as applied to proteins was used mainly as a method for the approximate estimation of the possibility of the separation of protein mixtures, the aim being to achieve the actual separation of the mixture under conditions of column experiments. Thin-layer chromatography then of course plays a subsidiary or auxiliary role. As a method of preparative isolation of proteins, thin-layer chromatography could not compete with the column technique either.

The inadequate theoretical and technical elaboration of the thin-layer chromatography of proteins has also probably retarded the development of this method. However, in recent years it has been shown that the thin-layer chromatography of proteins is by no means merely an auxiliary method and that it can also be of independent value. For example, thin-layer chromatography on different types of Sephadex may be used for the estimation of the molecular weights of the proteins investigated. It is very significant that only 0.1–0.2 mg of the protein is required for such determination[4]. It has also been shown that with the aid of thin-layer chromatography the presence of various groups of proteins can be determined in human blood serum. This requires only 1–2 ml of serum. The method can probably also be of diagnostic value[5,6].

Data indicating the possibility of using thin-layer chromatography for the estimation of various changes due to denaturation of protein molecules caused by external factors is of definite interest too. All these findings show that further development of the thin-layer chromatography of proteins as an independent research technique is promising.

The aim of the present article is to examine the modern state of the thin-layer chromatography of proteins, nucleic acids, and their derivatives, and to indicate new pathways in the development of this field of research, taking into account as far as possible all the experimental studies published in recent years.

II. DEVELOPMENT OF THIN-LAYER CHROMATOGRAPHY AND ITS COMPARISON WITH OTHER CHROMATOGRAPHIC TECHNIQUES

The first studies on thin-layer chromatography were made by the Soviet Scientists Izmailov and Shraiber, who in 1938 used thin layers of alumina to separate the alkaloids of medicinal plants[1]. However, 20 years elapsed before the method received general recognition. In 1958 a new stage in the development of thin-layer chromatography began, mainly in connection with the work of Stahl[7-13]. In these investigations Stahl used thin-layer chromatography for the separation of a wide variety of groups of organic compounds using various adsorbents. The rapid increase of publications on the use of thin-layer chromatography for the separation and identification of various, mainly low-molecular-weight, compounds of biological origin began only after these investigations had been published, approximately in 1960–1961.

Up to the present the thin-layer chromatographic method has been applied to almost all classes of compounds of biological importance. Historically thin-layer chromatography began to develop after techniques such as chromatography of proteins on columns and paper chromatography of amino-acids had been elaborated and received wide recognition.

Compared with column chromatography, thin-layer chromatography has its characteristic features. The entire process is carried out in an open layer and not in a closed column. A significant difference between thin-layer chromatography and column chromatography is also the fact that in the first case the layer of adsorbent is dry (ascending chromatography is most often used). As a result of this, the relative rates of migration of both the eluting buffer and the substance chromatographed are inconstant and R_f varies during chromatography on plates[14].

Compared with thin-layer chromatography, the results obtained in the paper chromatographic method depend very strongly on the properties and structure of the paper sheet itself; furthermore, paper chromatography requires much longer times than thin-layer chromatography. It should also be noted that paper chromatography is nowadays widely used for the separation of low-molecular-weight compounds such as amino-acids but the method has not been developed for the separation of proteins.

Thin-layer chromatography is free of the disadvantages characteristic of paper chromatography. Combining high sensitivity of paper chromatograms and the possibility of using a very small amount of the test substance, thin-layer chromatography has a higher resolving power because of the possibility of using ultrafine adsorbents. Thin-layer chromatography is also characterised by only very slight broadening of the spots of the test compounds and high concentration of the substance in the centre of the spot[15]. The entire chromatographic process requires a very short time and the apparatus and techniques of thin-layer chromatography are distinguished by extreme simplicity and ready availability and can be used in practically any laboratory.

In this respect thin-layer chromatography has advantages over many other methods for the analysis of proteins, which frequently require complex and expensive apparatus. It is interesting that in general advances in chromatography as a whole have been achieved using a very simple technology[16].

In many recently published monographs and reviews dealing with thin-layer chromatography problems concerning technique and partly theoretical problems associated with the application of this new method are discussed quite widely[14,15,17-22], but until recently thin-layer chromatography has been used predominantly for the separation of various low-molecular-weight compounds, mainly of biological origin. The extension of this method to the analysis and investigation of compounds with a high molecular weight, such as proteins, has proved particularly important.

The main principles and technical procedures in thin-layer chromatography are essentially the same for both proteins and compounds of comparatively low molecular weight. The significant difference consists in the fact that other adsorbents and other eluting systems are used in protein chromatography compared with the chromatography of low-molecular-weight compounds. In many reviews and monographs on thin-layer chromatography exhaustive compilations of the adsorbents used in this method as well as the eluting systems and buffer solutions are quoted[14-19,22] and therefore there is no need to consider them in detail. However, it should be noted that all the data quoted in the publications refer almost exclusively to the thin-layer chromatography of low-molecular-weight compounds.

The technical procedures used in the thin-layer chromatography of proteins, nucleic acids, and their derivatives are described below.

III. THE TECHNIQUE OF THE THIN-LAYER CHROMATOGRAPHY OF PROTEINS

1. Adsorbents

In contrast to the thin-layer chromatography of low-molecular-weight compounds, where adsorbents such as silica gel, kieselguhr, alumina, etc. are used, various types of Sephadex (mainly G-75, G-100, G-200, ultrafine varieties), ion-exchange celluloses (DEAE- and TEAE-cellulose, ecteola-cellulose, phosphocellulose) and, among inorganic adsorbents, mainly hydroxyapatite are used for the chromatography of proteins in thin layers.

2. Deposition of the Adsorbent on Plates

Manual method. Different procedures are used: (a) a suspension of the adsorbent is poured on to a plate mounted horizontally; (b) the plate is immersed in the suspension of the adsorbent; (c) the plate is sprayed with a dilute suspension of the adsorbent.

Apparatus of various designs is used in the mechanical method. The apparatus developed by Stahl is most frequently used for the deposition of thin layers[9,22].

3. Procedures Used in the Thin-Layer Chromatography of Proteins

Depending on the direction of movement of the eluting solution, ascending and descending varieties of chromatography are distinguished.

Ascending chromatography. In ascending chromatography the solvent moves up the plate as a result of capillary forces[14]. The chamber for ascending chromatography consists of a vessel with the eluting solution poured on to its bottom in an amount such that a plate with the adsorbent mounted vertically in it is immersed

approximately to a depth of 5 mm. The vessel is tightly closed on top with a lid. The rate of migration of the eluent along the plate is not constant in this case, depending on the path which must be traversed by the solvent, since the capillary forces are balanced by hydrostatic pressure as the liquid rises.

Descending chromatography. In descending chromatography the movement of the eluting solution down the layer of adsorbent is due to hydrostatic forces[15]. Descending chromatography requires a somewhat more complex technique than the ascending procedure. In its simplest version it requires a chromatographic boat (a tube sealed at either end and provided with a slit) into which the eluent is poured and a filter paper bridge is lowered to make contact between the buffer and the upper edge of the plate mounted at a certain angle. Descending chromatography is usually characterised by a constant linear velocity of the eluent. A number of investigators have used descending chromatography on Sephadex[23-25]. Descending countercurrent chromatography, based on a continuous supply of fresh eluting buffer on to the plate (the solution moves to the end of the plate and freely flows away) has been used for proteins[3].

Apart from descending and ascending chromatography there exist also other techniques of thin-layer chromatography: horizontal and circular[14]. These methods have not so far been used for proteins.

4. Eluting Systems for the Thin-Layer Chromatography of Proteins

Phosphate buffer solutions of different concentrations and at different pH are most often used for the thin-layer chromatography of proteins[3,9,23-27]. Depending on whether the concentration of the eluting buffer changes in the chromatographic process, thin-layer chromatography may be regarded as chromatography with constant or variable compositions of the buffer. Usually, for the separation of proteins, the eluting solution is passed once along the plates. However, there also exist methods of repeated chromatography with the same or different eluting buffers. Repeated chromatography in the same eluting system is used to achieve a greater migration of substances with a low R_f value. Before repeating the chromatographic process, the plate is dried.

In stepwise chromatography the eluting buffer is passed repeatedly with increase of its molar concentration.

Gradient chromatography in thin layers. In this case the elution is carried out under the conditions of a concentration gradient, i.e. the concentration of the eluting buffer is altered, usually increased, during chromatography on plates.

Determann[28] developed an apparatus for this type of gradient elution suitable for thin-layer chromatography. The apparatus consists of a glass cylinder mounted on a magnetic stirrer. At a height of 1 cm it is divided by a porous plate into two parts. In the lower part a magnetic stirrer is placed. The capillary tube for the supply of buffer is sealed into the wall of the cylinder. At a distance of 1 cm above the porous plate a tube is sealed into the cylinder for the outflow of the excess liquid. The plate with the adsorbent and the sample deposited on it are put on the porous plate and immersed in the buffer to a depth of 1 cm.

5. Detection of Protein Spots on Plates After Chromatography

Whereas in the thin-layer chromatography of low-molecular-weight compounds, the spots can be identified by a wide variety of reactions, depending on the type of compounds, in experiments with proteins and amino-acids the spots on the plates are usually detected by spraying with ninhydrin[2,26]. Sometimes the plates are covered with filter paper to obtain prints of the protein spots and the paper is then dyed[3,23,29]. The use of fluorescent labels for the detection of proteins in thin layers has also been suggested. For this purpose, the test protein is first treated with a fluorochrome and the distribution of the spots after chromatography is followed using their fluorescence in ultraviolet light[23].

Fluorescent supports with a layer of adsorbent deposited on them can also be employed[30]. Sometimes the fluorescent dyes are first mixed with the adsorbent before its deposition on the plates[14]. The chromatogram can also be sprayed after separation of the mixture of test substances with solutions of fluorescent dyes[22]. In all these cases the test compounds are detected as dark spots against a fluorescent background.

An interesting method for the identification of the test substances was proposed by Heyns and Grutzmacher[31]. They employed a combination of thin-layer chromatography and mass spectrometry for the determination of the derivatives of amino-acids and certain other low-molecular-weight compounds. After being scraped off from the chromatograms, the contents of the spots were introduced directly into a mass-spectrometer for the measurements.

Quantitative methods in thin-layer chromatography usually involve the elution of the substance on the plate followed by the determination of its concentration; or they are based on the determination of the size and colour intensities of the spots formed by the test compound on the plate with the adsorbent[14,15,22]. For example, a quantitative determination of the protein fractions of blood serum after chromatography on Sephadex plates (ultrafine G-100 and G-200) has been demonstrated by Japanese workers[6]. However, it should be noted that quantitative methods in thin-layer chromatography have been used on an inadequate scale compared with, for example, the determination of low-molecular-weight compounds.

IV. THIN-LAYER CHROMATOGRAPHY OF PROTEINS, AMINO-ACIDS, AND THEIR DERIVATIVES

1. Thin-Layer Chromatography of Amino-Acids and Their Derivatives

Mainly silica gel is used as an adsorbent in the thin-layer chromatography of amino-acids; ion-exchange celluloses or cellulose powders have been used to a lesser extent.

In one of the first studies of this kind a mixture of 24 amino-acids was successfully separated on silica gel plates using several solvents[32]. The best results are obtained with the n-butyl alcohol–acetic acid–water mixture and also mixtures of phenol and water. Very good results were achieved when amino-acids were separated on silica gel by two-dimensional chromatography using the chloroform–methanol–ammonia system in one direction and the phenol–water system in another[33]. By this procedure, it proved possible to separate 14 different amino-acids, while paper chromatography under the same conditions revealed

only ten amino-acids. The separation of amino-acids on silica gel with the aid of two-dimensional chromatography has also been achieved in other investigations[34,35]. These workers successfully separated 15 amino-acids on thin cellulose layers in the solvent systems n-butyl alcohol–acetic acid–water, methyl alcohol–water–pyridine, and certain others[36]. Amino-acids have also been satisfactorily separated on thin layers of ion-exchange DEAE-cellulose[37] and also by two-dimensional chromatography on cellulose[38]. Thus the thin-layer chromatography of amino-acids, particularly when the two-dimensional technique was used, proved to be much more effective (approximately by a factor of ten)[30] than the separation of amino-acids by paper chromatography.

Apparently the method of "finger prints" can be successfully used in thin-layer chromatography. Enzymic hydrolysates of human gamma-globulin, horse heart cytochrome, and certain other proteins were treated[39] with dimethylaminonapthalenesulphonyl chloride (fluorochrome). After the removal of the excess of the reagent, the hydrolysis products were separated by two-dimensional chromatography on thin layers of silica gel. It was shown that the results thus obtained agree with those from other methods. The amount of protein required for analysis is then smaller by a factor of ten (about 20 μg). Peptide maps have also been investigated with the aid of thin-layer chromatography[40,41].

The application of thin-layer chromatography to the separation and identification of dinitrophenyl and phenylthiohydantoin derivatives of amino-acids proved to be very promising. Silica gel is most frequently used in such cases. Thus it has been shown that almost all dinitrophenyl derivatives of amino-acids can be successfully separated in a thin layer of silica gel with the aid of both ascending and two-dimensional chromatography in various solvent systems[42–44].

Thin-layer chromatography of dinitrophenyl derivatives of amino-acids has also been used by other investigators[45,46] and Figge[47] and Burgi[48]. These workers used thin-layer chromatography to study urine and other physiological liquids. The thin-layer chromatography of ^{14}C-labelled dinitrophenyl-amino-acids on thin layers of silica gel has been used to study processes occurring in the pyruvic acid cycle[49].

A combination of thin-layer chromatography and quantitative ultramicro analysis of amino-acids in the form [^{14}C]-methyl esters and their dinitrophenyl derivatives were successfully employed in a recent study[50].

Deyl and Rosmus[51] described an interesting application of thin-layer chromatography in which they identified *N*-terminal amino-acids using their sulphonaphthyl derivatives. Fluorescent amino-acid spots can be determined at concentrations of 10^{-10} M. Recently *N*-terminal amino-acids have been determined as their dinitrophenyl derivatives on thin layers of silica gel[52].

Thin-layer chromatography has also been employed for the separation of phenylthiohydantoin derivatives of amino-acids. Thus a mixture of phenylthiohydantoin derivatives of 19 amino-acids has been successfully separated[42] by two- and one-dimensional chromatography on silica gel layers using various solvent systems. In another study[53] a combination of thin-layer chromatography and electrophoresis was employed to separate mixtures of phenylthiohydantoin derivatives of amino-acids, also on silica gel layers.

In a recently published study the thin-layer chromatography of phenylthiohydantoin derivatives of amino-acids was successfully achieved on silica gel[54].

In a number of investigations[55–57] the thin-layer chromatography of phenylthiohydantoin derivatives of amino-acids was used for the analysis of peptides. It should be noted that thin-layer chromatography of dinitrophenyl and thiohydantoin derivatives of amino-acids has certain advantages over paper chromatography. Firstly, in experiments in thin layers there is a considerable economy of time expended on the chromatographic process. Secondly, thin-layer chromatography exhibits high sensitivity, approximately ten times higher than that of paper chromatography. Recently data have been published[58] showing that the use of the optimum silica gel grain size (in the range 2–5 μm) and restriction of the path traversed by the solvent to 4–5 cm permits a sharp improvement (by a factor of 5–10 compared with the usual technique) of the sensitivity of the thin-layer chromatography of dinitrophenyl and phenylthiohydantoin derivatives of amino-acids and also a reduction of the duration of analysis.

This finding unquestionably demonstrates the promise of the thin-layer chromatographic technique for the identification and analysis of amino-acids and their derivatives and also for the separation of protein hydrolysis products and the investigation of complex mixtures of peptides and polypeptides.

2. Thin-Layer Chromatography of Proteins

Three groups of adsorbents are at present used for the thin-layer chromatography of proteins. These are different brands of Sephadex, ion-exchange celluloses, and also hydroxyapatites. Thin-layer chromatography on different types of Sephadex has been most widely used.

The first publications on the thin-layer chromatography of proteins appeared in 1962. These were the studies of Johansson and Rymo[3], who used thin layers of Sephadex, and of Hofmann[2,59], who used hydroxyapatite. Johansson and Rymo were two of the first investigators who used different types of Sephadex for the separation of a number of proteins in thin layers[3,23]. These workers employed G-50, G-75, G-100, and G-200 Sephadex for thin-layer gel filtration. For proteins with relatively low–molecular–weights, the adsorbents used were G-50 and G-75 Sephadex, while for proteins with molecular weights of 100 000 and above the less strongly cross-linked G-100 Sephadex and G-200 Sephadex were employed. The mobility of ceruloplasmin from human serum mixed with various peptides and amino-acids was estimated on G-25 Sephadex. In layers of G-25 Sephadex this protein can be readily separated from amino-acids the mobility of which is much lower. On G-75 Sephadex plates, it proved possible to separate mixtures of oxserum albumin and β- and α-lactoglobulines with molecular weights of 69 000, 35 000, and 15 000 respectively.

A satisfactory separation of tryptic hydrolysate of gamma-globulin from human serum has been achieved on G-75 Sephadex plates. The relevant papers give a detailed description of the conditions used in the preparation of the Sephadex plates.

The use of different types of thin-layers of Sephadex for the estimation of the molecular weights of various proteins is also of interest. It has been shown[4,28] that the molecular weights of the test proteins can be estimated approximately using G-75 and G-200 Sephadex. The following proteins have been employed for this purpose: lysozyme, haemoglobin, gamma-globulin, etc. This application has been developed further by Determann[27], who showed that the volume of the eluting buffer solution is linearly related

to the logarithm of the molecular weight of the test protein. The molecular weights of ribonuclease, chymotryptsin, trypsin, cytochrome *c*, and certain other proteins have also been estimated. Ultrafine G-200 Sephadex was used as adsorbent.

Various types of Sephadex have been used for the thin-layer gel filtration of proteins and mucopolysaccharides by Roberts[60], who described a technique for the preparation of the plates and the procedures employed to identify proteins on Sephadex plates.

Thus the thin-layer chromatography of proteins on different types of Sephadex can probably be used successfully as a simple method for the comparative estimation of the molecular weights of the test proteins. Although the method yields only approximate molecular weights, nevertheless in many cases it is preferable (large saving of time) to determinations by other procedures, requiring a complex apparatus.

A number of studies dealing with the separation of blood serum proteins by thin-layer chromatography have been published recently. Thus in the separation of human blood serum proteins on layers of G-75 Sephadex only one extended protein zone was observed, while on G-100 Sephadex the serum proteins are usually divided into three fractions[23]. It is interesting that the column chromatography of serum proteins on Sephadex also yields three fractions[61]. It has been shown[26] that a mixture of albumin and gamma-globulin from human serum can be successfully separated on phosphocellulose plates. The optimum conditions for the separation of these proteins are achieved with a definite water content in the thin layer of adsorbent, i.e. 70–75%. A decrease or increase of the concentration of water in the adsorbent plates greatly impairs the separation. This investigation showed that for optimum results it is necessary to control the moisture content of the adsorbent used in thin-layer chromatography.

An interesting application of the thin-layer gel filtration of blood serum proteins on Sephadex (ultrafine G-200) was found by Bergström[5], who employed gel filtration for the analysis of pathological human serum proteins under clinical conditions. He discovered that proteins from normal human serum yielded three zones when separated on plates corresponding to the sedimentation constants 4.5 S, 7.0 S, and 19.0 S. The contents of these three groups of proteins in normal serum were respectively 69.7, 24.6, and 5.7%, while pathological serum proteins yielded on gel filtration different percentages, depending on the illness. Analogous results were also obtained by Migita[6] in the thin-layer gel filtration of human blood serum proteins on different types of Sephadex. He employed Sephadex plates (G-100 and ultrafine G-200) on which proteins of normal serum were separated into three zones corresponding to the sedimentation constants 4.0 S, 7.0 S, and 19.0 S. The data on the gel filtration of the proteins from five pathological human blood sera are also quoted.

Italian workers[62] suggested that the thin-layer chromatography on G-200 Sephadex be used to investigate the serum from patients ill with paraproteinemia.

The above data show that thin-layer gel filtration on different types of Sephadex can yield over a comparatively short time (5–6 h) information about the changes in the protein composition of the blood, which should be of undoubted interest for clinicians.

The thin-layer chromatography of certain individual blood serum proteins (haemoglobin, albumin, etc.) has been carried out to estimate their mobility on Sephadex plates (G-100 and G-200)[24,25]. In a recent investigation[63] the authors were able to separate the proteins from normal human blood serum into ten fractions by the combination of thin-layer gel filtration (ultrafine G-200 Sephadex) and electrophoresis, while normal paper electrophoresis shows only five protein components.

The successful separation of haemoglobin and myoglobin on ultrafine Sephadex layers has been recently demonstrated[64,65].

Proteins with enzymic activity have also been subjected to thin-layer chromatography. Willand and Determann[66] used DEAE-Sephadex as an adsorbent for the separation of lactate dehydrogenases.

In other studies[23,29] ribonuclease, lysozyme, chymotrypsin, trypsin, pepsin, alkaline liver phosphatase, and certain other enzymic proteins were chromatographed on different types of Sephadex. In a recent investigation purified preparations of individual proteins were used for preparative estimates of their behaviour on Sephadex plates. It was shown that appropriate types of Sephadex can serve as suitable materials for the preparation of various enzyme proteins.

The use of hydroxyapatite as an adsorbent for the thin-layer chromatography of enzymes has been demonstrated by Kibardin and Lazurkina[67,68], who employed trypsin obtained from various sources, ribonuclease, and certain other enzymes. It was shown that thin layers of hydroxyapatite can be successfully used to estimate the possibility of the separation of protein mixtures and also to characterise the homogeneity and mobility of various enzyme proteins.

Recently thin-layer chromatography on ecteola-MN-300 was used[69] to separate certain coenzymes. The R_f values for eleven coenzymes are quoted. It was shown that some of them are grouped in a single spot. The compositions of the eluting mixtures most suitable for the clear separation of the individual coenzymes are given.

V. THIN-LAYER CHROMATOGRAPHY OF NUCLEIC ACIDS AND THEIR DERIVATIVES

Only comparatively recently thin-layer chromatography began to be applied for the separation of nucleic bases, nucleotides, and nucleosides. Different types of cellulose and to a certain extent silica gels have been mainly used as adsorbents. Other adsorbents have been employed for this purpose much more rarely[70–74].

Randerath[70,71] was the first to use thin-layer chromatography for the analysis of nucleic bases, nucleotides, and nucleosides. The thin-layer chromatography of these compounds has advantages compared with paper chromatography. The boundaries of the spots on the thin layers of adsorbents are much less diffuse than in paper chromatography[73]. Another advantage of thin-layer chromatography is the shorter time required for the separation of the test compounds than in paper chromatography.

The high sensitivity of the thin-layer chromatographic method has also been noted[75]. Ecteola-cellulose has been most frequently used for the separation and analysis of nucleotides and nucleosides. Using this adsorbent, it has proved possible to separate successfully 16 nucleotides in short periods ranging from 4 to 60 min[76]. Ecteola-cellulose has also been used by other investigators[70,71,77,78]. Recently ecteola-cellulose was employed for the thin-layer chromatography of DNA.[79]

A number of studies have dealt with the thin-layer chromatography of nucleic acid derivatives on DEAE-cellulose[77–81]. In one of these[81] a method was proposed

for two-dimensional thin-layer chromatography whereby it is possible to separate a mixture of mono-, di-, and triphosphates of adenosine, cytidine, guanosine, and uridine.

Thin layers of PEI-cellulose have been used for the ascending chromatography of deoxyribo-oligonucleotides [82,83]. Layers of MN-300-cellulose have been employed for the separation of nucleic bases and nucleosides [72,73,82].

DEAE-Sephadex A-25 has also been used as adsorbent in the separation of nucleotides by thin-layer chromatography.

The number of studies published on the application of silica gels for the thin-layer chromatography of nucleic bases and nucleic acid derivatives is much smaller [71,85].

Among inorganic adsorbents, alumina has also been employed for the thin-layer chromatography of nucleic acid derivatives [86]. Thus a comparatively small number of adsorbents have been used for the separation and analysis of nucleic acids and their derivatives by thin-layer chromatography.

Mangold [75] notes that the chromatography of nucleotides and nucleic acids in thin layers of ion-exchange celluloses is superior to all analytical methods for separation employed hitherto. In particular, the considerable saving in time when this method is employed must be pointed out. The high capacity of ion-exchange adsorbents makes it possible to use micro-amounts of the test substance. It is noteworthy that until now thin-layer chromatography has been used largely for the separation of purine and pyrimidine bases of nucleotides and mononucleotides. So far the method has not been applied to the analysis of the hydrolysis products of nucleic acids.

In a comparative assessment of various adsorbents employed in thin-layer chromatography published data show that nucleic bases are better separated from the corresponding nucleotides on layers of eteola-cellulose and other celluloses than on silica gel. On the other hand, the inorganic adsorbent gives better results in the separation of the bases themselves.

The efficiency of the adsorbents is approximately the same in the separation of nucleosides [75]. However, it should be noted that, despite its positive aspects, the thin-layer chromatography of nucleotides and other nucleic acid derivatives is at present essentially in its initial stage of development and has been only weakly developed so far compared with, for example, the column chromatography of nucleic acid. Up to the present time, there have been virtually no studies of the thin-layer chromatography of nucleic acids themselves and their hydrolysis products. Nor have there been any studies on the separation of the carbohydrate components of nucleic acids by thin-layer chromatography although this method might well prove to be quite suitable for the analysis of such compounds.

VI. NEW TECHNIQUES IN THE THIN-LAYER CHROMATOGRAPHY OF PROTEINS

In recent years certain new possibilities of the thin-layer chromatography of proteins and their derivatives have been demonstrated. Thus it has been shown [87] that enzymic reactions can be followed directly on plates. PEI-Celluloses served as the adsorbent.

As already mentioned, thin-layer chromatography has been successfully employed also for the analysis of the "peptide maps" of protein hydrolysates. Thus the possibility of the separation of the hydrolysis products of proteins by thin-layer chromatography on silica has been demonstrated [88] for myosine and protamine as examples.

Usually the complex mixture of hydrolysis products is separated by paper chromatography. A definite advantage of thin-layer chromatography over paper chromatography consists in much greater sensitivity [41] (approximately by a factor of ten).

The combination of thin-layer chromatography with electrophoresis in thin layers has proved very promising [63,89-91]. It has been shown in one of these investigations [89] that blood serum proteins can be separated into twelve components with the aid of chromatography and electrophoresis on G-100 and ultrafine G-200 Sephadex plates.

By combining electrophoresis and chromatography, Glaesner et al. [91] succeeded in separating the mixture of the hydrolysis products of haemoglobin into 28 peptides on silica gel plates.

In studies combining thin-layer electrophoresis and chromatography different types of Sephadex have been used as adsorbents for proteins and silica gel has been used for the separation of peptides.

The number of such studies is so far small. Nevertheless further developments of this technique are likely to be very promising. Bearing in mind the technical simplicity of thin-layer chromatography, this method can probably be successfully used also in clinical laboratories [62,92]. The investigations in this field are still very few.

Studies in which a combination of thin-layer chromatography and immunodiffusion are combined merit attention [93,94]. They demonstrated the possibility of thin-layer immunochromatography using as example serologically active proteins. The adsorbents were different types of DEAE-Sephadex. However, it should be noted that thin-layer immunochromatography has not so far been developed any further. The scope of this method appears at the present time to be more limited than that of Grabar's immunoelectrophoresis [75].

An interesting application of thin-layer chromatography under the conditions of the so called "barrier" method has been demonstrated [96]. Here the separation of oligonucleotides as a function of chain length and composition and chromatographic temperature can be achieved on cellulose plates. The same investigation demonstrated the possibility of detecting by thin-layer chromatography specific molecular complexes formed between poly- and oligonucleotides.

The possibility of estimating by thin-layer chromatography various changes due to modification and denaturation in proteins occurring under the action of external agents has been demonstrated recently. Immune human gamma-globulins treated with urea solutions at different concentrations show a reduced mobility in chromatography on hydroxyapatite plates. The decrease of the mobility of the proteins on plates takes place in parallel with the degree of the denaturing effect of urea on the gamma-globulin molecule. The biological activity of these proteins changed correspondingly. It is also interesting that the renaturation of immune globulins is likewise accompanied by the recovery of their mobility on adsorbent plates up to the normal level [97].

In another investigation it was shown that the treatment of human serum gamma-globulin with heavy metal salt solutions leads to a change in the mobility of this protein in chromatography on thin layers of hydroxyapatite compared with control experiments [68].

The above studies show that thin-layer chromatography can probably also serve for the assessment of the changes in proteins which are reflected in their surface and adsorption properties.

---o0o---

The data presented above show quite convincingly the wide use of thin-layer chromatography in protein chemistry. In conclusion we must briefly consider the principal factors determining the further development of the thin-layer chromatography of proteins.

At present we are in the initial stage of the development of this method as applied to proteins and nucleic acids. Its advantages—rapidity, high sensitivity, and the possibility of its application in mass analyses—are unquestionable. All these factors make the development of the thin-layer chromatography of proteins very promising. The problems next to be resolved in this field involve the necessity of further theoretical and practical development of the method, the elaboration of the technique, the selection of new adsorbents, and the widening of the range of proteins investigated. The development of new techniques in the thin-layer chromatography of proteins, particularly those involving the combination of different methods, are also extremely important: for example, thin-layer electrophoresis–chromatography, thin-layer immunochromatography, etc. The thin-layer chromatography of fluorescent protein complexes and new technical methods should be more widely used. These new developments will ensure the final promotion of thin-layer chromatography from a subsidiary method to one of independent importance in the study of biopolymers.
